Preface to the second edition

The first edition of "Drug Discovery and Evaluation – Pharmacological Assays" has been well accepted by a broad readership ranging from experienced pharmacologists to students of pharmacology. Therefore, already after a short period of time the question for a second edition arose.

The first edition was mainly centered around the personal laboratory experience of the editors and the contributors. The second edition tries to close evident gaps.

The input of biochemistry to pharmacology has grown. Molecular pharmacology puts more emphasis on the mode of action of drugs, albeit it becomes clear that the activities of most drugs are not confined to one single mode of action. Studies in single cells become more and more popular, however, they do not cover the complexity of a whole organism. Possible side effects of drugs can be better detected in whole animals than in single cells. Therefore, the new requirements of the health authorities on safety pharmacology put emphasis on experiments not only in whole anesthetized animals but in conscious ones. The second edition of this book takes note of these requirements and devotes special chapters for each indication to safety pharmacology.

Molecular biology also introduced new methods to pharmacology, such as the polymerase chain reaction (PCR), reverse PCR, Northern, Western and Southern blotting. Very recently, microarray technology, proteomics, and mass spectroscopy were added as novel *in vitro* methods. Furthermore, genetically modified animals have been created which resemble human diseases. Pharmacogenomics has already begun to influence pharmacology and even will have greater input in the future. Special attention is given to these new achievements in various chapters of the book.

The editor and the co-editors are well aware that the rapid progress in biology during the next decades will change the methodological approach. Electronic media will help the researcher for continuous information. However, it becomes more and more evident, that young pharmacologists have only insufficient training in the classical pharmacological methodology. Searching for these methods, e.g., for safety pharmacology, the researchers cannot find sufficient information on the methodological details in the electronic data bases currently available. This book covering the pharmacological methods of more than hundred years may be of help.

The guidelines concerning the care and use of laboratory animals have been updated.

A change in paradigm of pharmacological research has been claimed but superiorities of these new approaches compared to the old ones have still to be proven. To address this, an introductory chapter on new strategies in drug discovery and evaluation has been added, including combinatorial chemistry; high throughput screening, ultra high throughput screening and high content screening; pharmacogenomics, proteomics and array technology. Some critical thoughts on errors in screening procedures have been added.

At this place, we would like to express our sincere thanks to all colleagues who contributed to the new and to the first edition of this book. Their names and their positions are given alphabetically.

March 2002

Also in the name of the co-editors

Preface to the first edition

This book is intended to be an aid for experienced pharmacologists as well as for newcomers in the field of experimental pharmacology. The student in pharmacology, the pharmacist and the medicinal chemist will find a survey of pharmacological assays that can be used for a given indication and for which methods have demonstrated their relevance. The researchers working in special fields of pharmacology will find assays in other, unfamiliar areas which might help to expand their own research.

Certain therapeutic domains, such as cardiovascular, respiratory and renal disorders, psychiatry and neurology, peripheral nerve function, pain and rheumatic diseases, metabolic and endocrine diseases including diseases of the gastrointestinal tract, are discussed in this book.

Each chapter is divided into pharmacological classes, e.g., anxiolytics, anti-epileptics, neuroleptics, antidepressants, or anti-Parkinson drugs. For each class, in vitro methods, tests on isolated organs and in vivo methods are described.

For each method the purpose and rationale are given first, followed by a description of the procedure, evaluation of the data, modifications of the method described in the literature, and the relevant references. If possible, a critical assessment of the method based on personal experience is added. The hints for modifications of the method and the extended reference list will be of value for the experienced pharmacologist.

A few words for the justification for a book of this kind:

In 1959, A. J. Lehman, Director of the Division of Pharmacology at the Food and Drug Administration, USA, wrote:

> … Pharmacologists are individualists. Like most scientists they are seldom willing to copy each other's techniques in detail, and so their methods vary from one to the other. Nevertheless, there are basic principles and techniques which must be applied to establish the safety of a new drug.

Visitors could also read a sticker in his office:

> You too can learn pharmacology, in only three lessons: each of them lasting ten years.

Pharmacologists have always used methods from neighboring disciplines; in the past, e.g. from anatomy, pathology, surgery, zoology and predominantly physiology. Useful methods also came from electrophysiology and the behavioral sciences. Earlier drug discovery was almost exclusively based on animal experiments, clinical observations and serendipity.

In recent years, a major input has come from biochemistry. The effect of many drugs in human therapy could be explained biochemicaly as effects on specific enzymes or receptors. With the detection of more and more receptor subtypes, the activity spectrum of a single compound became more and more complicated. At present, molecular biology provides pharmacologists with human receptors and ion channels expressed in mammalian cells in culture. This avoids the apparently existing species differences, but the multitude of natural and perhaps artificial subtypes raises the question of physiological and pathological relevance.

The challenge for the pharmacologist always will be to correlate in vitro data with in vivo findings, bearing in mind the old saying: "*In vitro simplicitas, in vivo veritas*". The effects found in tissue cultures are quite often not typical for an intact organism.

Pharmacologists, especially in industry, have the task to find new drugs for human therapy by using appropriate models. Pharmacological models have to be relevant, that means they should predict the intended therapeutic indications. A pharmacological model can be considered relevant or correlational, if the effects obtained correlate with results observed in human therapy.

To be relevant or "correlational", a model has to fulfill some basic criteria:

- First, the model must be sensitive in a dose-dependent fashion to standard compounds that are known to possess the desired therapeutic property.
- Second, the relative potency of known active agents in the model should be comparable to their relative potency in clinical use.
- Third, the model should be selective, i.e. the effects of known agents in this therapeutic indication should be distinguishable from effects of drugs for other indications. Positive data with a new compound allow the prediction of a therapeutic effect in patients.

If new assays are applied to indications for which no effective drug is known, there must be sufficient evidence that this model is relevant for the pathological status in this indication.

The methods presented in this book have been selected according to these criteria.

Considerable discussion is going on about the necessity of animal experiments. One has to accept that only the whole animal can reflect the complexity of a human being. Even an experiment with human volunteers is only a model, albeit a highly relevant one, to investigate therapeutic effects in patients. The degree of relevance increases from isolated molecules (e.g. receptors or enzymes) to organelles, to organs up to conscious animals and human volunteers.

Without any doubt, animal experiments are necessary for the discovery and evaluation of drugs. However, they should be performed only if they are necessary and well conceived.

In Chapter N, regulations existing in various countries concerning the care and use of laboratory animals are listed. Furthermore, guidelines for anesthesia, blood collection and euthanasia in laboratory animals are given. In carrying out animal experiments, one must adhere strictly to these guidelines. Following these rules and planing the experiments well, will eliminate or minimize pain and discomfort to the animal. The methods described in this book had the welfare of the animals as well as the benefit of the procedure for the well-being of mankind in mind.

Here, we would like to express our sincere thanks to all colleagues who contributed to this book. Their names and positions are given alphabetically below.

Introduction
Strategies in drug discovery and evaluation[1]

0.1 Historical approaches in drug discovery

Today's medicine is based on traditional medicine. Traditional medicines exist in every continent of the globe and in every cultural area of the world. The most famous ones are traditional Chinese medicine in East Asia, Ayurvedic medicine in India, and formerly Galenic medicine in Europe, having same resemblance to each other (Vogel 1991).

Each of these traditional medicines has its own origin and an individual basic philosophy. The art of practicing **Chinese medicine** stretches back over several thousand years. The legendary culture hero, Shen-nong, is said to have tested many herbs for their medical properties. *Pen-ts'ao*, the first compilation of herbal medicines, is connected with his name (Unschuld 1973, 1986). Since ancient times, the Chinese have divided the world into five symbolic elements: Wood, Fire, Earth, Metal and Water. Everything in the world is dominated by one of these elements, and their constant interplay, combined with those of yin and yang, explain all change and activity in nature. The positive, generative cycle proceeds as follows: Wood burns to generate Fire. Fire produces ashes which generates Earth. Earth generates Metal which can be mined from the ground. When heated Metal becomes molten like Water, Water promotes growth of plants, thereby generating Wood. The negative subjugative cycle is complementary to the positive, generative one. Chinese medical views regarding the vital internal organs are based on the theories of *yin* and *yang*, the five elements which are each related to body organs and colors, and the meridians. With medicines consisting mainly of herbal drugs and minerals, Chinese doctors manipulate these natural relationships to adjust energy imbalances caused by the excess or deficiency of these forces in the body. Chinese physicians and philosophers developed a special system of physiology describing vital organs as storage houses and vital connections as meridians that became the basis of acupuncture (Porkert 1973).

In India *Ayurveda*, *Siddha* and *Unani* systems of medicine provide health care for a large part of the population. The word **Ayurveda** is composed of two parts: Ayu (= life) and Veda (= knowledge). The origins of this science of life had been placed by scholars of Ayurveda at somewhere around 6000 BC. They were orally transmitted by successive generations. The principles were recorded in great detail in compendia which are called *Samhitas* (Dash and Junius 1987; Dahanukar and Thatte 1989; Mazars 1990). Compared with modern anatomy and physiology Ayurveda is based on certain fundamental doctrines, known as the *Darshanas*, such as the seven *Dhatus*. They can be described not exactly as organs but as body constituents. The three *Doshas: vata*, *pitta* and *kapha* are regulators of cell function in various ways. A balance of the three doshas is essential for maintaining health. Imbalance of the doshas creates disease. Drug therapy in Ayurveda is highly individualized. The choice of drugs as well as the dose is not only influenced by the disease process, but also by the constitution of individuals and environmental conditions which affect the balance of the doshas and therefore the response to drugs.

Both traditional Chinese and Ayurvedic medicine developed further in terms of formulations. There is

[1] With contributions by G. Rieß and W. F. Vogel.

also the tendency to adopt the modern forms of clinical trials. But there has never been a change in paradigm as far as the basic philosophy is concerned.

Traditional European medicine goes back to the time of Egyptian and Babylonian-Assyrian culture. About 3 000 years BC the Sumerians developed a system of cuneiform writing that enabled them to write on clay tablets. At the time of King Assurbanipal 2 000 years BC a first comprehensive Materia Medica was written containing approximately 250 vegetable drugs and 120 mineral drugs (Koecher 1963). Around 1500 BC, the famous Egyptian papyrus *Ebers* was written, describing more than 700 drugs drawn from plants, animals and minerals. Some are still used in our time, such as garlic and poppy seeds.

Greek philosophers such as Empedocles, Aristoteles and Pythagoras, all from around 500 BC, influenced European medicine to a great deal. They created the theory of the Four Elements which were proposed to be the components of all matter, including animal and man. These Four Elements were Water, Air, Fire and Earth (Schöner 1964). The most famous physicians were Hippocrates (around 400 BC) and Galenus, living in the 2nd century after Christ. In medieval time the system of pathology and therapy, originating from Galenus, dominated Western medicine. The fundamental principle in the so-called Galenism was the transformation of humoral pathology into a rigid dogma (Siegel 1968). Already the school of Hippocrates had formulated the theory of the Four Humours (paralleling the Four Elements), the correct balance of which meant health, while every disturbance of this balance caused disease. There were Four Humours: Blood (coming from the heart), Phlegm (supposed to come from the brain), Yellow Bile (supposed to be secreted from the liver), and Black Bile (supposed to come from the spleen and the stomach). Each of these humours had definite qualities. Blood was moist and warm; Phlegm moist and cold; Yellow Bile warm and dry; Black Bile cold and dry. Furthermore, there was a definite connection between predominance of one humour in the metabolic system and an individual's temperament such as sanguine, phlegmatic, choleric, and melancholic.

European medicine has been influenced by Arabian medicine, mainly by the physician Ali Ibn Sina, who was known in Europe under the name Avicenna. His books were translated into Latin and his *Canon medicinae* has influenced European medicine for centuries (Gruner 1930).

Saint Hildegard of Bingen, the abbess of a monastery, was one of the most famous physicians and pharmacists in the 12th century (Müller 1982). She wrote many books on human nature and the use of herbal drugs. Theophrastus Bombastus von Hohenheim, called Paracelsus, who lived in the 15th century, was a reformer of European medicine (Temkin 1941). One of his ideas was that in nature a remedy could always be found against every disease. The Latin sentence "*Ubi malum, ibi remedium*" was the core idea of the signature theory that the shape or the color of a plant indicates against which disease the herbal drug can be used.

European medicine has undergone a great change in paradigm. In contrast to traditional Chinese medicine and Ayurveda, traditional European medicine does not exist any more and is only a matter of history of medicine. Even the self-understanding of modern phytotherapy in Europe is completely based on allopathy that means modern Western medicine.

0.2 Pharmacological approaches of modern medicine

The most important achievements of **modern Western medicine** were made in several areas such as diagnosis, infectious diseases, endocrinology and medicinal chemistry. Cellular pathology was founded by Virchow in the 19th century (Pagel 1906). The inten-

sive use of the microscope in medicine with histological comparison of diseased and normal organs allowed the change from humoral to **cellular pathology**.

Medicinal chemistry as an important science started less than 100 years ago. The active principles of plants, mostly alkaloids, were isolated and were the starting point for syntheses, such as:

Morphine and papaverine from *Papaver somniferum* for synthetic analgesics and spasmolytics; atropine from *Atropa belladonna* for synthetic spasmolytics; cocaine from *Erythroxylon coca* for synthetic local anaesthetics; quinine and quinidine from *Cinchona succirubra* for synthetic anti-malaria drugs and antiarrhythmics; ephedrine from *Ephedra sinica* for synthetic sysmpathicomimetics and sysmpathicolytics including β-blockers, xanthines like coffeine; theobromine and theophylline from *Coffea arabica*, *Theobroma cacao*, *Camellia sinensis* for vasotherapeutics such as pentoxyphylline; ergot alkaloids from *Claviceps purpurea* for semisynthetic ergot derivatives; reserpine and ajmaline from *Rauwolfia serpentina* for synthetic antihypertensives and antiarrhythmics; physostigmine from *Physostigma venenosum* for potential antidementic drugs; glycosides from *Digitalis lanata* and *Digitalis purpurea* for semisynthetic cardiac glycosides; anthraquinones from *Senna angustifolia* or *Rhamnus frangula* or *Rheum officinale* for synthetic laxatives.

Pharmacological research started in Europe in the second half of the 19th century when their founders, e.g., Rudolf Buchheim and Oswald Schmiedeberg, investigated the action of existing drugs in animal experiments (Kochweser and Schechter 1978).

With the emergence of synthetic chemistry the pharmacological evaluation of these products for therapeutic indications became necessary. Many new drugs were discovered by this classical approach during the 20th century.

The **classical way of pharmacological screening** involves sequential testing of new chemical entities or extracts from biological material in **isolated organs** followed by **tests in whole animals**, mostly rats and mice but also higher animals if indicated. Most drugs in use nowadays in therapy have been found and evaluated with these methods.

The chemistry and pharmacology of drugs, which have been found and used in therapy until 1970, are described in the 5 volumes of the book: Ehrhart G, Ruschig H (eds) Arzneimittel. Entwicklung, Wirkung Darstellung (1972).

In the mid-1970s **receptor binding assays** were introduced as an approach for compound evaluation by the development of radioligand binding assays, based on evaluation procedures and mathematical calculations provided by Schild (1947), Scatchard (1949), Stephenson (1956), Ariëns and van Rossum (1957), Arunlakshana and Schild (1959), Furchgott (1966), Cheng and Prusoff (1973), Rodbard and Frazier (1975), Bennett (1978), Creese (1978), Munson and Rodbard (1980), McPherson (1985a,b), Tallarida and Murray (1987), Greenstein (1991). Receptor binding assays were described for various transmitters as well as assays for ion channels and neurotransmitter reporters (e.g., by Snyder et al. 1975; Bylund and Snyder 1976; Enna 1978; U'Prichard et al. 1978, 1979; Bruns et al. 1980; Starke 1987; Dohlman et al. 1991; Krogsgaard-Larsen et al. 1991; Snider et al. 1991; Betz 1992; Wisden and Seeburg 1992; Amara and Arriza 1993; Bowery 1993; Wess 1993; Isom et al. 1994; Köhr et al. 1994; Goto and Yamada 1998; Chittajallu et al. 1999; Bormann 2000).

Characterization and classification of receptors is a continuous procedure (William 1991; Kebabian and Neumeyer 1994; Angeli and Guilini 1996; Trist et al. 1997; Godfraind and Vanhoutte 1998; Watling 1998; Alexander et al. 2001).

The use of radioligand binding assays has facilitated the design of new chemical entities, especially as the information obtained has been used in deriving molecular models for the structure-activity relationship. The receptor technology provides a rapid means to evaluate small amounts of compound (5–10 mg) directly for their ability to interact with a receptor or enzyme, independent of its efficacy. But as new assays were developed, it also provides a means to profile the activity of compounds against a battery of binding sites, thereby yielding an *in vitro* radioligand binding profile (Shaw 1992). Receptors have been divided in more and more subclasses (Vanhoutte et al. 1996) so that full characterization of a new chemical entity by receptor pharmacology also needs time and material.

Many receptors have been identified by DNA sequencing technology, mostly belonging to the G-protein coupled receptor superfamily, for which ligands have not yet been identified. Reverse molecular pharmacology and functional genomic strategies are recommended to identify the activating ligands of these receptors (Wilson et al. 1998). The reverse molecular pharmacological methodology includes cloning and expression of G-protein coupled receptors in mammalian cells and screening these cells for a functional response to cognate or surrogate agonists present in biological extract preparations, peptide libraries, and complex compound preparations.

The ligand binding assay is a powerful tool in the search for agonists and antagonists for novel receptors, and for identification of novel classes of agonists and antagonists for known receptors. However, it does not

differentiate between agonist and antagonist. Ligand binding mass screening can be adapted for very high throughput. However, well-defined criteria have to be fulfilled to avoid blind alleys (Burch 1991).

Pharmacological methods, including receptor pharmacology which led to the discovery and evaluation of drugs used in therapy until 2000, are described in the following chapters:

Chapter A Cardiovascular activity
Chapter B Activity on blood constituents
Chapter C Activity on urinary tract
Chapter D Respiratory activity
Chapter E Psychotropic and neurotropic activity
Chapter F Drug effects on learning and memory
Chapter G Effects on peripheral nerve function
Chapter H Analgesic, anti-inflammatory, and anti-pyretic activity
Chapter I Antiarthrotic and immunmodulatory activity
Chapter J Activity on the gastrointestinal tract
Chapter K Antidiabetic activity
Chapter L Anti-obesity activity
Chapter M Anti-atherosclerotic activity
Chapter N Endocrinology
Chapter O Ophthalmologic activity

The **classical approach** has the advantage of relatively high relevance. If a compound has blood pressure lowering activity in hypertensive rats after oral dosage, the chances of activity in humans are high. Measurement of dose-response-curves, effects over a given period of time and comparison of the effects after intravenous and oral administration already give hints for pharmacokinetic data. This approach has the disadvantage that it is time consuming and requires relatively large amounts of the new compound (usually about 5 g). Furthermore, this approach provides little information about the molecular mechanisms involved in the observed effects. On the other hand, one has to keep in mind that millions of diabetics were treated successfully with sulfonylureas over decades whereby only the release of insulin from the pancreatic β-cell, but not the molecular mechanism, was known (Bänder et al. 1969).

One has to admit that not all breakthroughs were achieved by the classical way of drug research. Several drugs have been identified by **serendipity** in the clinic, such as the diuretic action of sulfanilamide and acetazolamide as inhibitors of carbonahydrase (Schwartz 1949; Maren 1960, 1967), the blood sugar-lowering activity of sulfonylureas designed as antibacterial agents (Loubatières 1946; Franke and Fuchs 1955; Achelis and Hardebeck 1955), the antipsychotic of phenothiazines (Delay and Deniker 1952; Laborit et al. 1952; Courvoisier 1956), the antidepressant action of isoniazid (Kline 1958) and of imipramine (Kuhn 1958), the anticonvulsant effects of sodium valproate, or the effect of sildenafil, originally designed as a therapy for angina (Enna 2000).

0.3 New approaches in drug discovery

0.3.1 Combinatorial chemistry

It was always due to the ingenuity of the chemist that new chemical entities in pharmaceutical research were created (Schapira et al. 2000; Schreiber 2000). For some period of time, computer-based molecular modeling was thought to be the most effective approach. With the increasing characterization of the three-dimensional structures of receptors and enzymes, the design of molecules that interact with these biological targets was thought to be an intellectual approach using modern computer technology (Stigers et al. 1999).

This attitude to the development of **combinatorial chemistry** has changed. It has been defined as the systematic and repetitive covalent connection of a set of different 'building blocks' of varying structures to each other to yield a large array of diverse molecular entities (Gallop et al. 1994; Gordon et al. 1994; Fecik et al. 1998). As chemists gained experience in this technique, it has become possible to use solid- or solution-phase syntheses with different chemistries and scaffolds to produce libraries tailor-made for finding or optimizing a lead directed at almost any class of target (Hogan 1996; Maclean et al. 1997; Appleton 1999; Dooley and Houghten 1999; Lukas et al. 1999; Houghten 2000; Lazo and Wipf 2000; Rademann and Jung 2000). New tools, such as molecular docking algorithms (Burkhard et al. 1999), mapping of protein binding sites by nuclear magnetic resonance (Shuker et al. 1996), preparation of highly enantioselective selectors for chiral HPLC (Lewandowski et al. 1999), light-directed synthesis (LeProust et al. 2000), and homology modelling of proteins (Kiyama et al. 1999), allow an unprecedented level of rational design to guide the synthesis of prospective drugs. Spectroscopic methods, including especially mass spectrometry and to a lesser extend infrared and nuclear magnetic resonance, have been applied at different levels of combinatorial library synthesis: in the rehearsal phase to optimize the chemistry prior to library generation, to confirm library composition, and to characterize after screening each structure that exhibits positive response (Dancík et al. 1999; Hajduk et al. 1999; Loo et al. 1999; Scherer et al. 1999; Cancilla et al. 2000; Enjalbal et al. 2000; Kyranos et al. 2001).

0.3.2
High throughput screening, ultra high throughput screening, and high content screening

The logic development of receptor technology was high throughput screening. This evolution was closely connected with the changes in strategy of chemical synthesis. The vast number of compounds produced by combinatorial chemistry and the possibility to test many compounds, including natural products (Harvey 2000), in a short period of time by high throughput screening stimulated each other.

With the introduction of robotics, automation and miniaturization techniques, it became feasible to screen 50 000 compounds a day with complex workstations. Full automation of all assay steps, from compound addition to data collection, ultimately allows screens to be run continuously – 24 hours a day, 7 days a week. Another progress is the development of 1 536 well microtiter plate formats (Berg et al. 2000; Dunn et al. 2000). Multiple types of formats are emerging, besides 96-, 384-, and 1 536-, even 3 456- and 9 600-well plates (Sills 1998).

Harding et al. (1997) described the development of an automated high-throughput screening system involving two systems, the first handling isotopic assay ('hot' system), the second non-isotopic assays ('cold' system).

High-content screening (HCS) was proposed as a new approach to easing key bottlenecks in the drug discovery process by Giuliano et al. (1997). HCS defines the role of targets in cell function by combining fluorescence-based reagents with the ArrayScan™ to automatically extract temporal and spatial information about target activities within cells. High content screening integrates cell based assays, high resolution fluorescence microscopy, and proprietary image processing algorithms for the automated analysis of cellular and subcellular events. HCS delivers the potential to screen using targets that were minimally used or avoided due to a lack of a robust way to measure them, such as morphology changes, cellular differentiation and cytoskeletal changes; cell to cell interactions, chemotaxis and motility, spatial distribution changes like receptor trafficking or complex formation.

Clark and Pickett (2000) underlined the importance of computational methods for the prediction of 'drug-likeness', in particular for the prediction of intestinal absorption and blood-brain barrier penetration.

Several authors expressed their thoughts on the future of high throughput screening (Stahl 1999; Divers 1999; Eglen 1999; Fox et al. 1999, 2001; Mander 2000). Valler and Green (2000) expressed some doubts on diversity screening in drug discovery and proposed focussed screening using three-dimensional information of the target which may improve the hit rate 10–100 fold over random screening.

Nevertheless, this technical progress has led to a new concept in drug discovery: "a change in paradigm". Large numbers of hypothetical targets are incorporated into *in vitro* or cell-based assays and are exposed to large numbers of compounds of natural or synthetic origin.

This change in paradigm created new areas, such as bioinformatics, cheminformatics, and functional genomics (Ohlstein et al. 2000; Ryu and Nam 2000).

Many compounds can elicit a positive response in a particular assay, which are called hits. In this new terminology **"Hit"** is a molecule with confirmed activity from the primary high throughput-screening assay, a good profile in secondary assays and a confirmed structure.

The hits have to be structurally defined and may give rise to leads (Lahana 1999). **"Lead"** is a hit series for which the structure-activity relationship is shown and activity demonstrated both *in vitro* and *in vivo*.

The implementation of these methods is being complemented by an increase in the use of automation and robotics. Automation may be defined as the use of stand-alone instrumentation (work stations) that perform a given task whereas robotics use a robot arm or track systems to move microplates between these instruments. These technologies are continuously improved (Brown and Proulx 1997; Lightbody and Alderman 2001; Ruch 2001).

High throughput screening methods are also used to characterize metabolic and pharmacokinetic data of new drugs (Watt et al. 2000; White 2000).

A large pharmaceutical company has the potential to screen up to 100 000 000 compounds per year (Drews 2000). In any case, the leads or the derivatives from them have to be tested in more complex models, isolated organs or animals. Only compounds active in classical pharmacological tests can be taken into preclinical and clinical development.

With the completion of the human genome sequencing, bioinformatics will be an essential tool in target discovery and the *in silico* analysis of gene expression and gene function will be an integral part of it, facilitating the selection of the most important targets for a disease under study (Terstappen and Reggiani 2001).

Some doubts were expressed on the philosophy of research management in pharmaceutical industry neglecting the influence of creative scientists, failure to understand biological complexity and overestimating the outcome of the "change in paradigm" (Horrobin 2000). Nevertheless, the race to test more and more compounds in a shorter time in ultra high throughput screening with more automation is continuing.

0.3.3 Technologies for high throughput screening

Fundamental changes in assay technologies have facilitated the development of high throughput screening (Major 1995; Pazhanisamy et al. 1995; Devlin 1997; Harding et al. 1997; Houston and Banks 1997; Sittampalam et al. 1997; Su et al. 1997; Fernandes 1998; Gonzalez and Negulescu 1998; Kenny et al. 1998; Pasini et al. 1998; Silverman et al. 1998; Zysk and Baumbach 1998; Brandt 1998; Sills 1998; Wingfield 1998; Bolger 1999; Labute 1999; Winkler et al. 1999; Bosse et al. 2000; Cox et al. 2000; Feiglin et al. 2000; Gauglitz 2000; Landro et al. 2000; Meza 2000; Parker et al. 2000; Schuster et al. 2000; Sundberg 2000).

Dispensing technologies

Several systems for fluid dispensing are in use: The piezo- and inkjet, the "air displacement", and the "pintool" systems (Vollert et al. 2000). Piezoelectric and inkjet systems were the first introduced to the market (Lemmo et al. 1998; Rose 1999). There are three types of inkjet dispensers: thermal, solenoid and piezoelectric. All of these use some means of compressing a liquid against a small orifice to create sufficient linear velocity to eject the fluid in the form of a drop.

The "pintool" systems use pins (needles) to transfer liquid. Up to 1 536 needles are immersed into the fluid and withdrawn, taking up a few nanoliter and transferring the fluid into the wells of a microtiter plate.

Utilization of syringes and syringe needles as a contact tool enables multiple dispensing from a single fill. Generally, syringe dispensing has a higher degree of accuracy and repeatability compared with pin dispensing tools (Vollert 1998; Dunn and Feygin 2000).

Microfluidic arrays for high throughput submicroliter assays using capillary electrophoresis were described by Gibbons (2000). Capillary electrophoresis is an analytical technique that can achieve rapid high-resolution separation of water-soluble components present in small sample volumes. Separations are based on the electrically driven movement of ions. In high throughput screening, analytes are separated according to differences in electrophoretic mobility, depending on the charge-to-size ratio.

Cell-based assays

Cell-based assays are increasingly attractive alternatives to *in vitro* biochemical assays for HTS (Wallace and Goldman 1997; Silverman et al. 1998). They fall into three broad categories: second messenger assays that monitor signal transduction following activation of cell-surface receptors; reporter gene assays that monitor cellular responses at the transcription/translation level; and cell proliferation assays to monitor the overall growth/no growth response of cells to external stimuli (Sundberg 2000).

Cell-based reporter assays are used where human receptors are transfected into null cell lines either alone, or as part of receptor systems constructed to show alterations in light production (luciferin-luciferase) or light transmission (melanophore), that can be measured independently of radioactivity within minutes (Broach and Thorner 1996).

Pathirna et al. (1995) developed a transient transfection HTS assay to identify nonsteroidal human progesterone receptor modulators using luciferase expression (see also N.3.2.1.2).

Another reporter gene, green fluorescent protein, can be measured by fluorescence techniques in real time so that kinetic parameters can be determined from a single well of a microtiter plate (Chalfie et al. 1994; Chalfie 1995; Kain 1999; Meng et al. 2000).

Scheirer (1997) reviewed the various reporter genes and their applications.

González and Negulescu (1998) described intracellular detection assays for high throughput screening which employ either fluorescent or luminescent readouts. The method is particularly suitable to measure calcium mobilization (Akong et al. 1955; Burbaum and Sigal 1997).

Using receptor selection and amplification technology (R-SAT), it is possible to rapidly quantify specific pharmacological responses as a function of changes in cell proliferation rates (Messier et al. 1995). NIH3T3 cells (or other cell lines) are transfected with the plasmid coding for the receptor of interest and pSV-β-Gal. Cells are then transferred to 96-well microtiter plates and test compounds are added. Several days later, β-Gal activity is measured via a simple, inexpensive colorimetric assay. As a result of compound treatment, the changes in enzyme activity are a function of the proliferative activity of the cells. This functional assay can quantitatively differentiate full agonists, partial agonists, neutral antagonists, and negative antagonists (inverse agonists). An interesting aspect of this technology is that many genes in a related family can be combined in the same cell population for convenient assay.

Detection methods

Fluorescence-based assay technologies play an increasing role in high throughput screening. When compared to other biochemical and cell-based techniques, fluorescence has a significant advantage over such methods as isotopic labeling, colorimetry, and chemoluminiscence.

Sensitivity. It is relatively simple for modern instrumentation to reliably detect a signal being emitted from a single fluorescent molecule. In biological applications, this level of sensitivity means molecules that may be present only in very small numbers can be easily detected. In the case of imaging application, such as High Content Screening, their intracellular location can be determined. This high level of sensitivity also means that transient biological events can be detected very quickly, hence enabling the measurement and understanding of events that occur very rapidly inside living cells. The inherent sensitivity of fluorescence technology also permits the use of very low concentrations of fluorescent label.

Specificity. Fluorescent probes are readily available for labeling virtually any biomolecule, structure, or cell type. Immunofluorescent probes can be directed to bind not only to specific proteins but also to specific conformations, cleavage products, or site modifications like phosphorylation. Individual peptides and proteins can be engineered to autofluorescence by expressing them as AFP chimeras inside cells. Such high levels of specificity enable the use of several different fluorescent labels – each emitting at a unique color – and the subsequent understanding of the complex interactions that occur among and between subcellular constituents.

Accuracy. Reagents used for fluorescence labeling are well understood and their performance has been characterized under a wide variety of biological environments.

Flexibility. Fluorescence technologies have matured to the point where an abundance of useful dyes are now commercially available. Many dyes have been developed and optimized for labeling specific cell compartments and components, as well as for labeling proteins (antibodies, ligands, toxins, etc.) which can be used as probes. Other fluorescent sensors have been designed to report on biological activities or environmental changes (pH, calcium concentration, electrical potential, proximity to other probes etc.). Multiple fluorescent labels can be used on the same sample and individually detected quantitatively, permitting measurement of multiple cellular responses simultaneously. Many quantitative techniques have been developed to harness unique properties of fluorescence, including:

- Fluorescence resonance energy transfer (FRET),
- Fluorescence polarization or anisotropy (FP),
- Time resolved fluorescence (TRF),
- Fluorescence lifetime measurements (FLM),
- Fluorescence correlation spectroscopy (FCS),
- Fluorescence photobleaching recovery (FPR).

Mere et al. (1999) reported miniaturized **fluorescence resonance energy transfer (FRET)** assays and micro-fluidics as key components for ultra-high-throughput screening. An ultra-high throughput screening system (UHTSS™) platform integrates several microfluidic dispensing devices, which have been developed to deliver nanoliter to microliter volumes at high speed into the appropriate wells of 384-well NanoWell™ assay plates. The activity of the compounds dispensed into the assay wells is quantified via a highly sensitive dual-wavelength emission fluorescence detector.

Pope et al. (1999) discussed the advantages and disadvantages/limitations of fluorescence techniques for the establishment of miniaturized homogeneous screening assays, including prompt intensity assay (FLINT), anisotropy assay (FA), prompt energy transfer assay (FRET), fluorescence correlation spectroscopy (mass-dependent FCS), and fluorescent correlation spectroscopy (mass-independent FCS).

Auer et al. (1999) recommended fluorescence correlation spectroscopy for lead discovery by miniaturized HTS. By monitoring interactions of single molecules in fentoliter volumes, fluorescence correlation spectroscopy offers the highest potential as the detection technique in the nanoscale.

Haupts et al. (2000) compared macroscopic versus microscopic fluorescence techniques in (ultra)-high throughput screening.

Sportsman and Leytes (2000) discussed miniaturization of homogenous assays using **fluorescence polarization (FP)**. Fluorescence polarization can detect changes in molecule size as well as quantify the binding of small molecules to larger molecules. Polarization of fluorescence occurs when a fluorescent molecule is illuminated with plane-polarized light, provided that the molecule does not move during the course of fluorescent lifetime. For typical fluorescent molecules such as fluorescein, the polarization is not observed if the molecule is rotating rapidly in solution under condition typically used in biological assays. Thus, if the polarization of fluorescence of a fluorescein-labeled ligand is measured, a low polarization will be observed when the ligand is free in solution, and a high polarization will be observed when the ligand is bound to a macromolecule such as a specific receptor or antibody.

Banks et al. (2000) described fluorescence polarization assays for high throughput screening of G protein-coupled receptors in 384-well microtiter plates.

Parker et al. (2000) used fluorescence polarization to develop high throughput screening assays for nuclear receptor-displacement and kinase inhibition. This method is a solution-based, homogeneous technique, requiring no immobilization or separation of reaction components. As an example, the authors described the fluorescence polarization-based estrogen receptor assay based on the competition of fluorescein-labeled estradiol and estrogen-like compounds for binding to the estrogen receptor.

Li et al. (2000) developed an assay for measuring the activity of an enzyme that transfers multiple adenine-containing groups to an acceptor protein, based on fluorescence polarization technology in a 1 536-well plate format. Texas red (rhodamine) was covalently conjugated to adenine of the donor substrate through a C_6 spacer arm. As a result of the transfer of the adenine-containing moieties to the acceptor protein substrate, the rotational correlation time of the Texas red conjugate increased, hence increasing the degree of fluorescence polarization.

Kolb et al. (1997), Grepin and Pernelle (2000) described evolution of **homogeneous time resolved fluorescence (HTRF)** technology for HTS. HTRF uses Eu^{3+} ion caged into a polycyclic cryptate (Eu-cryptate) as donor. Laser excitation at 337 nm transfers the energy from the Eu-cryptate complex to an allophycocyanin acceptor molecule (XL665), the APC. This results in the emission of light at 665 nm over a prolonged time (milliseconds). Uncoupled or free XL665 emits at 665 nm, but with a short decay. The light emission is recorded in a time-resolved fashion over a 400 µs period, starting 50 µs after the excitation pulse, so that the autofluorescence from the media and the

short-lived fluorescence of the free APC are not recorded. Eu-cryptate emits at 620 nm and is discriminated from XL665 by wavelength.

The labeling of macromolecules for HTRF assay can be done in a number of ways, depending on the type of screen, using direct, indirect or semi-direct types of labeling. Direct labeling is characterized by having the (Eu)K and XL665 covalently bound to the molecule or molecules of interest. Indirect labeling is when the (Eu)K and XL665 are bound to macromolecules through secondary interactions, such as biotin-streptavidin interaction or antibody binding. Other indirect methods, such as (Eu)K or XL665 labeled lectin, can be used for binding to membranes. The semi-direct method is a combination of direct and indirect and is frequently used in HTRF.

HTRF immunoassays generally use a direct labeling strategy in which two antibodies against different antigenic sites are used. One antibody is labeled with (Eu)K and another is labeled with XL665. When both bind to the antigen, energy transfer occurs and the long-lived XL665 signal is generated.

To study the interaction of two proteins, the JUN FOS dimerization was used as a model assay. The JUN protein was biotinylated. Streptavidin:(Eu)K was used to bind that label to the JUN-biotin protein via the SA-biotin binding. The FOS peptide was directly labeled with XL665. Signal is only generated when JUN-biotin:SA-(Eu)K and FOS-XL665 dimerize to form the activated AP1 transcription complex.

The binding of ligands to membrane receptors and the competitive displacement by unknown molecules is one of the most common screening assays in drug discovery. To test the applicability of HTRF for receptor binding, the interaction of epidermal growth factor (EGF) with its receptor (EGFR) was studied (Mathis et al. 1994). To generate a HTRF signal, a semidirect labeling method was developed. EGF was labeled directly with (Eu)K, and a monoclonal antibody against a non-binding portion of the EGF receptor was used. The anti-EGRF antibody was labeled with XL665. The IC_{50} of displacement could be determined.

The phosphorylation of enzymes, proteins and receptors is a major mechanism of cell regulatory pathways and is therefore a frequent target for drug discovery. The epidermal growth factor receptor-intrinsic tyrosine kinase activity was used to develop an HTRF assay. Biotin labeled $(glutamine\text{-}alanine\text{-}tyrosine)_n$ (Poly GAT) was used as a substrate. The EGF receptor was isolated from A431 cells after partial purification of a cell homogenate. After the phosphorylation reaction, the HTRF signal was generated by adding streptavidin-XL665 and (Eu)-K-antiphosphotyrosine antibody. To establish the biological function of HTRF in this assay, inhibition of tryphostin-47 was assayed.

The **acumenexplorer** is a laser-scanning system that measures fluorescence and luminescence, combining the ability to detect sub-micron events and features with ultra-fast acquisition and data management. Different parts of the cell can be localized by labeling with Hoechst 33342, Alexa™ 488, Alexa™ 546, Alexa™ 594, or Cys™ 5. Many different colors (readouts) can be used simultaneously.

The **fluorometric imaging plate reader (FLIPR™)** permits rapid, kinetic measurements of intracellular fluorescence. Simultaneous measurements in 96 wells and in real time can be made every second: before, during and after the addition of test compounds. The detection optics of FLIPR are based on cooled charge-coupled device (CCD) technology. With each kinetic update, the system takes a picture of the bottom of a microplate, recording a signal for all the individual cells simultaneously. Enhanced sensitivity for cell-based assays is accomplished via an optical detection scheme, which allows for signal isolation on a cell monolayer. The system is ideal for monitoring intracellular calcium fluxes that occur within seconds of activation of G-coupled receptors. Using calcium sensitive dyes such as Fluo-3 and this permits the derivation of full dose response (or inhibition) curves in a matter of minutes (Kuntzweiler et al. 1998; Coward et al. 1999; Miller et al. 1999; Milligan and Rees 1999; Sullivan et al. 1999).

Swartzman et al. (1999) developed a simple, homogeneous bead-based immunoassay for use with **fluorometric microvolume assay technology (FMAT)**.

Koltermann et al. (1998) proposed rapid assay processing by integration of **dual-color fluorescence cross-correlation spectroscopy (RAPID FCS)** as an ideal tool for ultra high throughput screening when combined with nanotechnology, which can probe up to 10^5 samples per day. Auer et al. (1999) used fluorescence correlation spectroscopy for lead discovery by miniaturized HTS.

Winkler et al. (1999) presented **confocal fluorescence coincidence analysis** as an alternative for high throughput screening. Confocal fluorescence coincidence analysis extracts fluorescence fluctuations that occur coincidentally in two different spectral ranges from a tiny observation volume of below 1 fl. This procedure makes it possible to monitor whether an association between molecular fragments that are labeled with different fluorophores is established or broken, providing access to the characterization of a variety of cleavage and ligation reactions in biochemistry.

For high throughput screening, Schmid et al. (1998) proposed a method to reversibly attach receptor proteins via an affinity tag to a quartz surface and subsequently detect with high sensitivity the real-time binding of ligands by **total internal reflection fluorescence**.

The **CytoFluor® Fluorescence Multi-Well Plate Reader** is a versatile fluorescence intensity measurement instrument that detects and quantifies fluorescent molecules over a five-log dynamic range. The system has a sensitivity better than 8 femtomoles/well for fluorescein.

Ramm (1999) described the technique of **image-based screening in the LEADseeker™ system**, which contains a cooled charge-coupled device (CCD) camera and a telecentric lens with integral epifluorescence illumination.

Laser scanning imaging systems have been developed to measure cellular and subcellular quantitation of fluorescence in whole cells (Conway et al. 1999; Zuck et al. 1999; Hertzberg and Pope 2000).

Chemiluminescence is a photometric technique that is applicable to HTS. Detection of chemiluminescence is a convenient adjunct to fluorescence, since most plate readers capable of measuring fluorescence will measure luminescence as well. This technique has been used predominantly with luciferase reporter genes in cell-based assays and in high sensitivity enzyme-linked immunosorbent assays (ELISA), employing chemolumogenic substrates for alkaline phosphatase and horseradish peroxidase (Bronstein et al. 1994, 1996). The Luc-Screen® assay system with extended-glow light emission was designed for sensitive detection of firefly luciferase reporter enzyme. Liochev and Fridovich (1997) recommended lucigenin luminescence as a measure of intracellular superoxide dismutase activity in *Escherichia coli*.

The NorthStar™ HTS workstation has been developed as a chemiluminescence analyzer for the high throughput screening laboratory. Featuring online injection, a broad dynamic range, and an extremely low crosstalk, the NorthStar™ HTS workstation allows the routine analysis of more than 500 000 samples a day.

Grépin et al. (2001) presented an assay for precise and direct quantification of specific endogenous mRNAs in cell lysates. The technology is based on the bioluminescence detection of multiple biotinylated ssDNA probe/endogenous mRNA hybrids, which are captured onto a streptavidine coated multi-well plate. Using the Xpress-Screen™ technology, an assay was developed aimed to monitor the induction of endogenous cFos mRNA expression in NGF-treated PC12 cells and the miniaturization of the assay in 384 well format, which is adapted to high throughput screening.

The introduction of the **scintillation proximity assay (SPA)** obviated the need to separate bound from free radioactivity in the conventional radioligand-binding assay (Bosworth and Towers 1989; Picardo and Hughes 1997; Game et al. 1998). One version of the scintillation proximity assay utilized polyvinyltoluene microspheres or beads into which a scillitant has been incorporated. When a radiolabeled ligand is captured on the surface of the bead, the radioactive decay occurs in close proximity to the bead, and effectively transfers energy to the scillitant, which results in light emission (Sittampalam et al. 1997).

FlashPlate™ technology has been described by Brown et al. (1997). FlashPlates are white 96-well polystyrene microplates coated on the inside with solid scillitant in a polystyrene polymer. The polystyrene surface provides a hydrophobic surface for absorption of proteins, such as antibodies and receptors. When the binder molecule is coated on the FlashPlate, the reaction of the mixture of radiolabeled tracer and unlabeled ligand of interest with the binder molecule, and detection of the bound radioactivity can be done in one step. Due to the microplate surface scintillation effect, only the bound radioactivity will be detected by a scintillation counter.

The use of **high-performance microphysiometry** in drug discovery has been discussed by Alajoki et al. (1997). Microphysiometry measures the extracellular acidification rate. It is governed by catabolism, via the excretion of acidic end-products, such as carbon dioxide and lactic acid. In addition, it is substantially influenced in a complementary fashion by the regulation of intracellular pH, a process sensitive to physiological changes such as receptor activation (see also A.1.1.7 and E.5.1.2). The Light-Addressable Potentiometric Sensor (LAPS) uses a light-generated alternating current to probe the electrical potential at the interface between an electrolyte and the insulated surface of an appropriately biased silicon chip; the surface potential depends on pH in a Nernstian fashion. This system has been optimized for high throughput screening.

0.3.4 Pharmacogenomics

The concept of an altered response based on genetic background is not new. In 510 BC, Pythagoras recognized that some individuals developed hemolytic anemia with fava bean consumption (Nebert 1999). In 1914, Garrod expanded this observation, stating that enzymes detoxified foreign agents so that they were excreted harmlessly. However, some people lack these enzymes and experience adverse effects (Weber 1999). Hemolytic anemia due to fava bean consumption was later determined to occur in glucose-6-phosphate deficient individuals (Mager et al. 1965; Podda et al. 1969).

The term pharmacogenetics was first used by Friedrich Vogel in 1959. The dawn of pharmacogenetics continued by combining Mendellian genetics with observed phenotypes. In 1932, Snyder performed the first global study of ethnic variation and deduced that taste deficiency was inherited. He proposed that the phenylthiourea non-taster phenotype was an inherited

recessive trait and that the frequency of occurrence differed between races (Snyder 1932). Other genetic differences, such as aldehyde dehydrogenase and alcohol dehydrogenase, were discovered. These deficiencies are common in Asians and cause them to have less alcohol tolerance (Goedde et al. 1983; Inoue et al. 1984). Similarly, polymorphisms in the *N*-acetyl transferase enzyme are also segregated by ethnicity and correlate to the latitude of the country (Weber 1999).

These genetic differences were originally thought to be caused by genetic variance, but it was not until the advent of molecular biology that disease states could be carefully analyzed. The following dogma:

gene → protein → biochemical process → disease state

became the model for examining human diseases. Following this scheme, sickle cell anemia was the first trait to reveal that a single point mutation can change protein structure and lead to a disease phenotype (Murayama 1966; Bookchin et al. 1970). Single nucleotide polymorphisms (SNPs) are responsible for many diseases (Kleyn and Vesell 1998; Vesell 2000; Weaver 2001; Wieczorek and Tsongalis 2001). SNPs can change receptors, transport proteins, and drug metabolizing enzymes. The advances in genetic technology to detect polymorphisms have caused an explosion in pharmacogenetic research and many of these discoveries have been employed into clinical practice.

Many thousands of polymorphisms can be determined simultaneously in a patient. These single nucleotide polymorphisms are selected as markers evenly distributed to the genome, in the hope that functionally relevant polymorphisms can be associated with specific markers by virtue of their proximity to the chromosome. Such genome-wide association studies are used in the discovery of susceptibility genes for diseases, such as asthma and prostate cancer, but they are equally suitable for determining the genes in drug response (Sadée 1999).

Disorders like Huntington's disease or cystic fibrosis are associated with defects in a single gene product identified by positional cloning. This involves the isolation of a gene with the information on its subchromosomal localization and the phenotypic expression of a mutation of this gene that results in a particular disease state. Positional cloning is based on the unique, inheritable DNA fingerprint associated with each individual, from which the inheritance of identified polymorphisms can be tracked, along with the inheritance of the disease. While this approach has been more or less successful in diseases involving a single gene defect, more complex diseases, like Alzheimer's disease, cancer, asthma or cardiovascular diseases, appear to result from the influence of multiple gene defects.

The next step is to identify the function of the protein expressed by the DNA using functional genomics. This technique involves the use of sequence comparisons with known proteins, using computer databases, transgenic expression or expression in surrogate systems; gene knockouts in mice (Rudolph and Möhler 1999; West et al. 2000), or simpler organisms like *Drosophila melanogaster*, *Caenorhabditis elegans* (Link et al. 2000) or *Saccharomyces cerevisiae*. A two-hybrid system to identify molecular binding partners can be used to identify proteins that are associated with the gene product of interest.

Progress in genomics technology, especially the elucidation of the human genome (International Genome Sequencing Consortium 2001; Venter et al. 2001), has created an unique opportunity to significantly impact the pharmaceutical drug development processes (Carulli et al. 1998; van Oosterhout 1998; Debouck and Goodfellow 1999; Farber 1999; Vidal and Endoh 1999; Wilson et al. 1998; Jones and Fitzpatrick 1999; Zweiger 1999; Beeley et al. 2000; Bentley 2000; Broder and Venter 2000; Debouck and Metcalf 2000; Harris 2000; Marshall 2000; Meldrum 2000a,b; Rockett and Dix 2000; Schuster et al. 2000; Steiner and Anderson 2000; Peet and Bey 2001; Winkelmann 2001).

Genetic polymorphism in drug-metabolizing enzymes, transporters, receptors, and other drug targets are linked to individual differences in the efficacy and toxicity of many medications. Pharmacogenomic studies can elucidate the inherited nature of these differences, thereby enhancing the possibilities of drug discovery and providing a stronger scientific basis for optimizing drug therapy on the basis of each patient's genetic constitution (Evans and Relling 1999; Grant 2001).

Receptor polymorphism is also the reason for differences in drug effects among patients. Two genetic variants of the angiotensin-converting enzyme are described, depending on an insertion (I-form) or deletion (D-form) of a base pair at position 287 in the gene, which are equally distributed in the Caucasian population. Individuals with the D/D-form express ACE levels much higher than I/I individuals. They have an increased risk for myocardial infarction and may respond better to therapy with ACE inhibitors (Samani et al. 1996; Danser and Schunkert 2000). Another example is the association between β_2-adrenergic receptor polymorphisms and asthma (Liggett 1997). There are three polymorphisms that alter receptor function, which may influence the therapeutic success.

Genomics will introduce a new dimension in drug research. The number of molecular targets that are modified by the complete armamentarium of modern drugs is not greater than 500. The number of genes that contribute to multifactorial diseases might not be very high; the numbers reported for different forms of

diabetes and hypertension are 5–10 per disease (Guillausseau et al. 1997; Shimkets and Lifton 1996). There are 100–150 disease entities that present an epidemiological and economical problem to industrialized societies. If one assumes 10 contributing genes for 100 multifactorial diseases (including different forms of cancer, asthma, diabetes, hypertension, atherosclerosis and osteoporosis), one arrives at 1 000 'disease genes' that dispose patients to the most important multigenetic conditions (Drews 2000, 2001). It appears reasonable to assume that each of these disease genes, or rather proteins that are specified by the disease genes, connects with at least 5–10 proteins that are feasible levels for drug intervention. On the basis of these calculations, one can assume that 5 000 to 10 000 can be used as targets for drug interventions.

Lennon (2000) discussed the methods for high throughput gene expression analysis applicable for drug discovery, including differential display of eukaryotic mRNA, the modification thereof, called Restriction Enzyme Analysis of Differentially Expressed Sequences (READS), expression sequence tags (EST) methodology, serial analysis of gene expression, filter arrays, and DNA microarrays.

Celis et al. (2000) gave an excellent survey on microarray technology.

Gene expression analyses and genetic polymorphisms are not only important for determining predisposition to disease and for drug discovery, but also for predicting the incidence of adverse drug reactions (Meyer 2000). In the past, several drugs had to be withdrawn from the market due to rare, but severe, adverse events. Some drug metabolic enzyme variants have been found to cause severe adverse events. They form qualitatively or quantitatively different metabolites with toxicological implications (Bullingham 2001).

Most of the enzymes involved in drug metabolism and the elimination of many therapeutic agents are members of the cytochrome P450 (CYP) family which includes more than 30 isoforms (Gonzales 1990). One drug metabolizing enzyme, resulting in numerous drugs being withdrawn from the market, is CYP3A, which is involved in the oxidative biotransformation of up to 50% of clinically important therapeutic agents. The expression of CYP3A is regulated by genetic and non-genetic factors that can result in a 5–20-fold interindividual variability in metabolic clearance. Another enzyme, CYP2D6 (debrisoquine hydroxylase), metabolizes one quarter of all prescribed drugs and is inactive in 6% of the Caucasian population (Wolf and Smith 1999). A principal molecular defect in poor metabolizers is a single base pair mutation in exon 5 of CYP2C19 (De Morais et al. 1994; Sadée 1999). These enzymes are being screened at the earliest stages of the drug development process. The single nucleotide point mutation profile of an individual can indicate a predisposition for adverse side effects. Furthermore, drug transport protein polymorphisms and their drug interactions may provide another valuable tool in screening for potential toxic effects of drugs. The pharmacogenomic approach should reduce the number of compounds failing during late clinical development (Adam et al. 2000).

A detailed knowledge of the genetic basis of individual drug response is of major clinical and economic importance and can provide the basis for a rational approach to drug prescription. In the sense of a 'personalized medicine', prospective genotyping will lead to patients being prescribed drugs which are both safer and more effective (Sadée 1999; March 2000; Murphy 2000; Spear et al. 2001).

Winkelmann et al. (2001) initiated the Ludwigshafen Risk and Cardiovascular Health (LURIC) study, which aims to provide a resource for the study of environmental and genetic risk factors and their interactions, and of functional relationship between gene variation and biochemical phenotype (functional genomics), or response to medication (pharmacogenomics) and long-term prognosis of cardiovascular disease.

0.3.5 Proteomics

The term "proteome" was coined by Wilkins et al. (1995) to describe the protein complement of the genome. The term proteomics was first used to describe the two-dimensional gel electrophoresis (2-DE) and quantitative image analysis. 2-DE remains the highest resolution protein separation method available, but the ability to identify the observed proteins was always an extremely difficult problem. Mass spectrometry (MS) has been an integral part to solving this problem (Fields 2001; Mann et al. 2001). Although improvements in 2-D gel technology had been realized since its introduction, three enabling technological advances have provided the basis for the foundation of the field of proteomics (Patterson 2000). The first advance was the introduction of large-scale nucleotide sequencing of both expressed sequence tags (ESTs) and genomic DNA. The second was the development of mass spectrometers able to ionize and mass-analyze biological molecules and the widespread introduction of mass spectrometers, capable of data-dependent ion selection for fragmentation (MS/MS) (i.e., without the need for user intervention). The third was the development of computer algorithms able to match uninterpreted (or partially interpreted) MS/MS spectra with translations of the nucleotide sequence databases, thereby tying together the first technological advances. The mass spectrometer instruments are named for their type of ionization source and mass analyzer (Patterson and Abersold 1995; Carr and Annan 1997; Patterson 1998). To measure the mass of molecules, the test material must be charged (ionized) and desolvated. The two most successful mechanisms of ionization of peptides and proteins are matrix-assisted laser desorption ionization (MALDI) and electrospray ionization (ESI). In MALDI the analyte of interest is embedded in a matrix that is dried and then volatilized in a vacuum under ultraviolet laser irradiation. This is a relatively efficient process that ablates only a small portion of the analyte with each laser shot. Typically, the mass analyzer coupled with MALDI is a time-of-flight (TOF) mass analyzer, that measures the elapsed time from acceleration of the charged (ionized) molecules through a field-free drift region (Kowalski and Stoerker 2000). The other common ionization source is ESI, in which the analyte is sprayed from a fine needle at high voltage toward the inlet of the mass spectrometer (which is under vacuum) at a lower voltage. The spray is typically either from a reversed-phase HPLC column or a nanospray device (Wilm and Mann 1994), similar to a microinjection needle. The ions formed during this process are directed into the mass analyzer, which could be a triple-quadrupole, an ion trap, a Fourier-transform ion cyclotron resonance (FT-ICR), or a hybrid quadrupole TOF (Qp-TOF) type (Morris et al. 1996). Although unambiguous identification of a protein cannot always be derived from the masses of a few of its peptides in the tandem mass spectrometer, peptide ions from the first mass spectrometer run are fragmented and identified in a second run to yield a more valuable commodity of a peptide sequence.

The goal of proteomics is a comprehensive, quantitative description of protein expression and its change under the influence of biological perturbations, such as disease and drug treatment (Anderson and Anderson 1998; Müllner et al. 1998; Blackstock and Weir 1999; Dove 1999; Hatzimanikatis et al. 1999; Jungblut et al. 1999; Williams 1999). A combination of mRNA and protein expression patterns has to be simultaneously considered to develop a conceptual understanding of the functional architecture of genomes and gene networks (Kreider 2000). New methods are created like automated proteomics platforms (Quadroni and James 1999; Nielsen et al. 1999), combining two-dimensional electrophoresis, automated spot picking and mass spectrometry (Binz et al. 1999; Dancik et al. 1999; Loo et al. 1999; Dutt and Lee 2000; Feng 2000; Patterson et al. 2000; Ryu and Nam 2000; Service 2000; Yates 2000; James 2001; Jain 2001; Rabilloud 2001).

Improvements in quality, ability and utility of large-scale tertiary and quartery protein structural information are enabling a revolution in rational design, having a particular impact on drug discovery and optimization (Maggio and Ramnarayan 2001).

One may expect that with the new approach of drug research, including combinatorial chemistry, genomics, pharmacogenomics, proteomics, and bioinformatics, unprecedented results will be generated (Burley et al. 1999; Debouck and Metcalf 2000; Drews 2000; Haystead 2001).

0.3.6 Array technology

Array technology is based on the RNA and DNA hybridization reaction previously used in Northern and Southern expression analysis. However, these traditional approaches allowed only detection of one single gene. In contrast, gene arrays and microarrays allow the analysis of hundreds or thousands of genes simultaneously (DeRisi and Iyer 1999; Diehn et al. 2000; Epstein and Butow 2000; Rockett and Dix 2000; Deyholos et al. 2001; Jordan 2001; Taniguchi et al. 2001). Gene chips can be global, containing the entire genome of one species on the slide. Besides the miniaturization, the greatest leap of technology was the development of fluorescent-labeled nucleotides, which can be detected by laser scanning. They have replaced the more cumbersome and hazardous use of radioactive-labeled DNA.

Two different methods are used in array production: chips are either loaded with synthetic oligonucleotides or with a DNA fragment isolated directly from the respective gene. A specific process allows the synthesis of oligonucleotides directly onto the glass surface. Normally, every gene is represented by about 20 oligonucleotides from different regions of the gene. Each oligonucleotide is 25–30 base pairs in length and

is synthesized next to a control oligonucleotide with a mismatch. The development of DNA chips has been pioneered by researchers at Stanford University (Brown and Botstein 1999). The Stanford Microarray Database has been made widely available (Sherlock et al. 2001) and can be accessed at *http://genome-www.stanford.edu/microarray*.

DNA fragments of 200–400 base pair length are amplified from the gene of interest by PCR and spotted onto poly-lysine or otherwise coated slides (Nature Office 2000). Femto gram amounts of DNA are loaded per spot, which can be less than 50 µm apart from each other.

Regardless of using oligonucleotides or DNA arrays, one always needs two RNA samples for chip analysis. The RNA can be isolated from treated versus untreated cell lines, from the serum of an animal before or after drug administration, or from tumor versus normal tissue. Standard protocols require about 100 µg total RNA, from which poly A^+ RNA is extracted. Next, the RNA is converted by reverse transcription into cDNA in the presence of fluorescent-labeled dyes. Commonly, the sample is labeled with Cy-5 and the control with Cy-3. Both cDNAs are combined and hybridized against the array (Rautenstrauß and Liehr 2001). Since DNA-DNA binding reactions are thermodynamically slow, the chip is incubated overnight at temperature above 60 °C. Chip analysis is performed by scanning with two lasers at 562 nm (Cy-3) and 644 nm (Cy-5). The overlay of both scans shows genes that are deregulated. By convention, overexpressed genes are shown in green, repressed genes in red and unchanged expression in yellow. Data are evaluated by scatter blot analysis, where relative expression of each gene is indicated by logarithmic axes. Sophisticated bioinformatic protocols are used for further annotation and data comparison (Zhang 1999; Gaasterland and Berikanow 2000).

The best approach to microarray analysis is to begin with a small number of the elements in the microarray known to be a pattern and ask questions of the other elements in the microarray; i.e., perform instantaneous scientific experiments regarding whether each of the other elements in the microarray are related to the known pattern (Burke 2000).

Ge (2000) described the development of a universal protein array (UPA) system that provides a sensitive, quantitative, multi-purpose, effective and easy technology to determine not only specific protein-protein interactions, but also specific interactions of proteins with DNA, RNA, ligands and other small chemicals.

The application of biochip and microarray systems in pharmacogenomics has been discussed by Jain (2000).

0.4 Errors in screening procedures

Any screening procedure has a characteristic error rate. This is inevitable because in high throughput screening, it is especially necessary to sacrifice some accuracy or precision to achieve the requisite speed. Thus when a large number of compounds are carried through a particular screen, some of the compounds will be classified incorrectly. A screen may be used in an absolute sense, so that compounds that pass a certain criterion are termed positives, whereas those that fail to meet the criterion are termed negatives. Compounds that pass, but should have failed, are false positives. In general, false positives are tolerable, if they are not too numerous, because they will be rectified later. Compounds that fail, but should have passed, are false negatives.

False negatives are lost forever, if the failure eliminates them from further testing.

All screening procedures are based on assumptions of analogy. They have different degrees on relevance or predictability. Studies in phase II of clinical trials will predict with high probability the results in large clinical trails. But even there is the possibility of false positive or false negative results. The relevance of a test is much lower in the early pharmacological tests, such as used in high throughput screening. Generally, the relevance is inversely proportional to the simplicity of the test.

In any case, one is confronted with the problem of false positive results (first type error) and false negative results (second type error).

In each step two sources of error for **false positive results** have to be taken in account:

1. a = error of the first type due to the model
2. α = error of the first type due to statistics.

For definition: In the error of the first type a compound is considered to be active, but is actually ineffective. This type of error will be clarified during further development, after negative clinical trials at the latest.

However, there are also two sources of error for **false negative results**:

1. b = error of the second type due to the model
2. β = error of the second type due to statistics.

In the error of the second type a compound is considered to be ineffective, but is actually effective.

This type of error will never be clarified; an effective drug has just been missed. Perhaps another investigator will test this compound under different aspects.

The statistical errors derive from the fact that a pharmacological test is performed only several times or in a limited number of animals. One can specify the probability that a decision made is incorrect, i.e. a drug candidate is erroneously identified as effective, although it is actually ineffective. Usually this risk is set to 5% ($P < 0.05$) and is called the statistical error of the first type or type-I error. The error of the second type or type-II error is connected to the type-I error by statistical rules.

Usually, screening is performed sequentially. Tests in high throughput screening are followed by tests in isolated organs, then in small animals, and special tests in higher animals, until the compound is recommended for further development and for studies in human beings. From each step errors of type I, but also from type II, arise. As a consequence, many effective compounds will be lost.

There are two ways to circumvent this obstacle: Either to increase the number of compounds entering the screening procedure dramatically, and hoping for a reasonable number of true positives and accepting a high rate of false negative results (White 2000) as followed in the ultra high throughput screening, or to perform tests with high relevance, meaning tests with high predictive value in whole animals at an early stage (Vogel and Vanderbeeke 1990).

Zhang et al. (2000) studied the role of false negative results in high throughput screening procedures. They presented a statistical model system that predicts the reliability of hits from a primary test as affected by the error in the assay and the choice of the hit threshold. The hit confirmation rate, as well as false positive (representing substances that initially falls above the hit limit but whose true activity are below the hit limit) and false negative (representing substances that initially fall below the hit limit but whose true activity are in fact greater than the hit limit) rates have been analyzed by computational simulation.

The problem of type-II errors, i.e. false negative results, also exists in many other physiological and pharmacological studies (Martorana et al. 1982; Barros et al. 1991; Sandkühler et al. 1991; Waldeck 1996; Williams et al. 1997). Pollard and Howard (1986) re-investigated the staircase test, a well-accepted primary screening method for anxiolytics, and found several false negative results for clinically active anxiolytics.

Chapter A
Cardiovascular activity[1]

[1] With contributions to this and the first edition by B. A. Schölkens, H. Gögelein, F. P. Huger, W. Linz, K. A. Rudolphi, K. Wirth.

A.1 Cardiovascular analysis

A.1.1 *In vitro* methods

A.1.1.1 α_1-adrenoreceptor binding

PURPOSE AND RATIONALE

α_1-adrenoceptors are widely distributed and are activated either by norepinephrine released from sympathetic nerve terminals or by epinephrine released from the adrenal medulla. Receptor activation mediates a variety of functions, including contraction of smooth muscle, cardiac stimulation, cellular proliferation and activation of hepatic gluconeogenesis and glycolysis. In the CNS, the activation of α_1-adrenoceptors results in depolarization and increased neuronal firing rate.

The α-adrenoreceptor population of plasma membranes from rat heart ventricles consists only of the α_1-adrenoreceptor subtype. A constant concentration of the radioligand ^{3}H-prazosin (0.2–0.3 nM) is incubated with increasing concentrations of a non-labeled test drug (0.1 nM–1 mM) in the presence of plasma membranes from rat heart ventricles. If the test drug exhibits any affinity to α-adrenoceptors, it is able to compete with the radioligand for receptor binding sites. Thus, the lower the concentration range of the test drug, in which the competition reaction occurs, the more potent is the test drug. The assay is used to evaluate the binding characteristics of drugs at the α_1-adrenoceptor.

PROCEDURE

Solutions

preparation buffer A:		
Tris-HCl	5	mM
$MgCl_2 \times 6\,H_2O$	1	mM
D(+)-sucrose	250	mM
pH 7.4		
preparation buffer B (= rinse buffer):		
Tris-HCl	50	mM
$MgCl_2 \times 6\,H_2O$	10	mM
pH 7.4		
incubation buffer:		
Tris-HCl	50	mM
$MgCl_2 \times 6\,H_2O$	10	mM
ascorbic acid	1.6	mM
catechol	0.3	mM
pH 7.4		

radioligand:
^{3}H-prazosin × HCl
specific activity
0.37–1.11 TBq/mmol
(10–30 Ci/mmol) (NEN)

Tissue preparation
Male Sprague-Dawley rats (200–300 g) are sacrificed by decapitation and the dissected hearts are placed in ice-cold preparation buffer A. After removal of the atria, ventricles (approx. 30 g from 40 rats) are minced with a scalpel into 2–3 mm pieces.

Membrane preparation
Ventricles are homogenized by Ultra-Turrax (1 g tissue/20 ml preparation buffer A), the homogenate is filtered through gauze, and centrifuged at 2 000 *g* (4 °C) for 10 min. The pellets are discarded, the supernatant is collected, and centrifuged again at 40 000 *g* for 20 min. The resulting pellets are resuspended in approx. 300 ml preparation buffer B, homogenized by Ultra-Turrax and centrifuged as before. The final pellets are dissolved (by Ultra-Turrax) in preparation buffer B, corresponding to 1 g ventricle wet weight/4 ml buffer. The membrane suspension is immediately stored in aliquots of 5–20 ml at –77 °C. Protein content of the membrane suspension is determined according to the method of Lowry et al. with bovine serum albumin as a standard.

At the day of the experiment the required volume of the membrane suspension is slowly thawed and centrifuged at 40 000 *g* (4 °C) for 20 min. The pellets are resuspended in a volume of ice-cold rinse buffer, yielding a membrane suspension with a protein content of 1.0–1.5 mg/ml. After homogenization by Ultra-Turrax, the membrane suspension is stirred under cooling for 20–30 min until the start of the experiment.

Experimental course
For each concentration samples are prepared in triplicate.

The total volume of each incubation sample is 200 µl (microtiter plates).

Saturation experiments
total binding:
- 50 µl ^{3}H-prazosin
  (12 concentrations, 5×10^{-11}–5×10^{-9} M)
- 50 µl incubation buffer

non-specific-binding:
- 50 µl ^{3}H-prazosin
  (4 concentrations, 5×10^{-11}–5×10^{-9} M)
- 50 µl phentolamine (10^{-5} M)

Competition experiments
- 50 µl ^{3}H-prazosin
  (1 constant concentration, $2–3 \times 10^{-10}$ M)
- 50 µl incubation buffer without or with non-labeled test drug (15 concentrations, 10^{-10}–10^{-3} M)

The binding reaction is started by adding 100 µl membrane suspension per incubation sample (1.0–1.5 mg protein/ml). The samples are incubated for 30 min in a shaking bath at 25 °C. The reaction is stopped by withdrawing the total incubation volume by rapid vacuum filtration over glass fiber filters. Thereby the membrane-bound radioactivity is separated from the free activity. Filters are washed immediately with approx. 20 ml ice-cold rinse buffer per sample. The retained membrane-bound radioactivity on the filter is measured after addition of 2 ml liquid scintillation cocktail per sample in a liquid scintillation counter.

EVALUATION
The following parameters are calculated:

- total binding
- non-specific binding
- specific binding = total binding – non-specific binding

The dissociation constant (K_i) of the test drug is determined from the competition experiment of ^{3}H-prazosin versus non-labeled drug by a computer-supported analysis of the binding data.

$$K_i = \frac{K_D\,{}^3\mathrm{H} \times IC_{50}}{K_D\,{}^3\mathrm{H} + [{}^3\mathrm{H}]}$$

IC_{50} = concentration of the test drug, which competes 50% of specifically bound ^{3}H-prazosin in the competition experiment
$[^3\mathrm{H}]$ = concentration of ^{3}H-prazosin in the competition experiment.
$K_D\,{}^3\mathrm{H}$ = dissociation constant of ^{3}H-prazosin, determined from the saturation experiment.

The K_i-value of the test drug is the concentration, at which 50% of the receptors are occupied by the test drug. The affinity constant K_i [mol/l] is recorded and serves as a parameter to assess the efficacy of the test drug.

Standard data: phentolamine $K_i = 2–4 \times 10^{-8}$ mol/l

MODIFICATION OF THE METHOD
Binding of ^{3}H-WB 4101 to α_1-adrenergic receptors in brain is used to test hypotensive activity as possible side effect of neuroleptic drugs. The test E.5.1.6 is described in the chapter on neuroleptic activity.

SUBTYPES OF THE α_1-ADRENOCEPTOR

Several subtypes of the α_1-adrenoceptor have been identified by pharmacological means (α_{1A} and α_{1B}, α_{1C}, α_{1D}; α_{1H}, α_{1L} and α_{1N} adrenoceptors; Endoh et al. 1992; García-Sáinz et al. 1992, 1993; Ohmura et al. 1992; Regan and Cotecchia 1992; Satoh et al. 1992; Schwinn and Lomasney 1992; Veenstra et al. 1992; Aboud et al. 1993; Oshita et al. 1993; Vargas et al. 1993; Ruffolo et al. 1994; Minneman and Esbenshade 1994; Alexander et al. 2001) or by recombinant technology ($\alpha_{1a/d}$, α_{1b}, α_{1c} adrenoceptors). They correspond to the pharmacologically defined α_{1A}, α_{1B},and α_{1D} adrenoceptors in native tissues (Bylund et al. 1994, 1998; Hieble et al. 1995; Graham et al. 1996; Hieble and Ruffolo 1996; Alexander et al. 2001).

Binding of the radioligand [^{3}H]-prazosin to the α_{1A}-adrenoceptor subtype can be measured in membranes prepared from male Wistar rat submaxillary glands (Michel et al. 1989).

Binding of the radioligand [^{3}H]-prazosin to the α_{1B}-adrenoceptor subtype can be measured in membranes prepared from male Wistar rat livers (Adolfo et al. 1989).

Decreased blood pressure response in mice deficient of the α_{1b}-adrenergic receptor was found by Cavalli et al. (1997).

A.1.1.2 α_2-adrenoreceptor binding

PURPOSE AND RATIONALE

α_2-adrenoceptors are widely distributed and are activated by norepinephrine released from sympathetic nerve terminals or by epinephrine released from the adrenal medulla or from some neurons in the CNS. The most extensively characterized action is the prejunctionally mediated inhibition of the release of neurotransmitters from many peripheral and central neurons. α_2-adrenoceptors are also present at postjunctional sites, where they mediate actions such as smooth muscle contraction, platelet aggregation and inhibition of insulin secretion. Activation of postsynaptic α_2-adrenoceptors in the brainstem results in an inhibition of sympathetic outflow in the periphery.

Clonidine is a centrally-acting antihypertensive agent, which lowers blood pressure mostly through reducing sympathetic tone by acting at the nucleus tractus solitarius in the brain stem (Kobinger and Walland 1967). Clonidine can, however, act at both peripheral and central α_2-receptors. Peripherally administered clonidine causes a brief increase in blood pressure followed by a prolonged decrease (Rand and Wilson 1968). Functional studies (^{3}H-NE release) indicate a presynaptic mechanism for clonidine (Langer 1977, 1981; Starke 1977). However, lesioning studies fail to confirm a presynaptic location for clonidine receptors in either the CNS or periphery (U'Prichard et al. 1979; Bylund and Martinez 1981; U'Prichard et al. 1980). No change in clonidine receptor sites was seen after 6-hydroxydopamine lesions in cerebral cortex. This may be due to the fact that α_2-receptors are both pre- and postsynaptic (Hieble et al. 1988).

Alpha-adrenergic agonists most potently displace ^{3}H-clonidine. Ergot compounds, dopamine agonists and mianserin are also fairly potent (U'Prichard et al. 1977). A survey on functions mediated by alpha-2 adrenergic receptors was given by Ruffolo et al. (1988) and on the role of neurotransmitters in the central regulation of the cardiovascular system by McCall (1990). Although clonidine relieves the autonomic symptoms of morphine withdrawal (Gold et al. 1978), there is no evidence for a direct α_2/opiate-receptor interaction.

The purpose of this assay is to assess the interaction of hypotensive agents with central α_2-receptors and determine possible clonidine-like mechanisms of action. Clonidine binding may also be relevant to the activity of other classes of drugs such as antidepressants that interact with α_2-receptors.

PROCEDURE

Reagents

1. Tris buffer pH 7.7
   a) 57.2 g Tris HCl q.s. to 1 liter
      (0.5 M Tris buffer, pH 7.7)
      16.2 g Tris base
   b) make a 1:10 dilution in distilled H_2O
      (0.05 M Tris buffer, pH 7.7)
2. Tris buffer containing physiological ions
   a) Stock buffer

NaCl	7.014 g
KCl	0.372 g
$CaCl_2$	0.222 g
$MgCl_2$	0.204 g

   q.s to 100 ml in 0.5 M Tris buffer
   b) Dilute 1:10 in distilled H_2O.
      This yields 0.05 M Tris HCl, pH 7.7; containing NaCl (120 mM), KCl (5 mM), $CaCl_2$ (2 mM) and $MgCl_2$ (1 mM)
3. [4-^{3}H]-Clonidine hydrochloride (20–30 Ci/mmol) is obtained from New England Nuclear.
   For IC_{50} determinations: ^{3}H-Clonidine is made up to a concentration of 120 nM and 50 µl are added to each tube (yielding a final concentration of 3 nM in the 2 ml volume assay).
4. Clonidine-HCl is obtained from Boehringer Ingelheim.
   A stock solution of 0.1 mM clonidine is made up to determine non-specific binding. This yields a final concentration of 1 µM in the assay (20 µl to 2 ml).
5. Test compounds:
   For most assays, a 1 mM stock solution is made up in a suitable solvent and serially diluted, so that the final concentrations in the assay range from 10^{-5} to 10^{-8} M. Seven concentrations are used for each assay and higher or lower concentrations can be used, depending on the potency of the drug.

Tissue preparation

Male Wistar rats are sacrificed by decapitation and the cortical tissue is rapidly dissected. The tissue is homogenized in 50 volumes of 0.05 M Tris buffer pH 7.7 (buffer 1b) with the Brinkman Polytron, and centrifuged at 40 000 *g* for 15 min. The supernatant is discarded and the final pellet rehomogenized in 50 vol-

umes of buffer 2b. This tissue suspension is then stored on ice. The final tissue concentration is 10 mg/ml. Specific binding is 1% of the total added ligand and 80% of total bound ligand.

Assay

100 µl	0.5 M Tris – physiological salts pH 7.7 (buffer 2a)
830 µl	H_2O
20 µl	Vehicle (for total binding) or 0.1 mM clonidine (for nonspecific binding) or appropriate drug concentration.
50 µl	^{3}H-clonidine stock solution
1 000 µl	tissue suspension.

Tissue homogenates are incubated for 20 min at 25 °C with 3 nM ^{3}H-clonidine and varying drug concentrations, and immediately filtered under reduced pressure on Whatman GF-B filters. The filters are washed with 3 five ml volumes of 0.05 M Tris buffer pH 7.7, and transferred to scintillation vials. Specific clonidine binding is defined as the difference between total bound radioactivity and that bound in the presence of 1 µM clonidine.

EVALUATION

IC_{50} calculations are performed using log-probit analysis. The percent inhibition at each drug concentration is the mean of triplicate determinations.

MODIFICATIONS OF THE METHOD

Perry and U'Prichard (1981) described [^{3}H]rauwolscine (α-yohimbine) as a specific radioligand for brain α_2-adrenergic receptors.

Goldberg and Robertson (1983) reviewed yohimbine as a pharmacological probe for the study of the α_2-adrenoreceptor.

Pimoule et al. (1983) characterized [^{3}H]RX 781094 [(imidazolinyl-2)-2 benzodioxane-1,4] as a specific α_2-adrenoceptor antagonist radioligand.

Murphy and Bylund (1988) characterized alpha-2 adrenergic receptors in the OK cell, an opossum kidney cell line.

Binding of the radioligand [^{3}H]-rauwolscine to the α_{2A}-adrenoceptor subtype can be measured in membranes prepared from rabbit spleens (Michel et al. 1989).

Binding of the radioligand [^{3}H]-yohimbine to the α_{2B}-adrenoceptor subtype can be measured in membranes prepared from male Wistar rat kidney cortices (Connaughton and Docherty 1989).

SUBTYPES OF THE α_2-ADRENOCEPTOR

Using ^{3}H-rauwolscine as ligand Broadhurst et al. (1988) studied the existence of two alpha$_2$-adrenoreceptor subtypes.

Bylund et al. (1988) used [^{3}H]-yohimbine and [^{3}H]-rauwolscine to study alpha-2A and alpha-2B adrenergic subtypes in tissues and cell lines containing only one subtype.

Brown et al. (1990) found that [^{3}H]-yohimbine labels at α_{2A}- and α_{2B}-adrenoceptors whereas [^{3}H]-idazoxan labels the α_{2A}-adrenoceptor and, in addition, an imidazoline binding site.

Several subtypes of the α_2-adrenoceptor have been identified by pharmacological means (α_{2A}-, α_{2B}-, α_{2C}-, and α_{2D}-adrenoceptors; Ruffulo 1990; Uhlén and Wikberg 1990; Gleason and Hieble 1992; Satoh and Takayanagi 1992; Takano et al. 1992; Ruffolo et al. 1993) or by recombinant technology as α_{2a}-, α_{2b}-, α_{2c}-adrenoceptors (Bylund et al. 1994; Hieble et al. 1995; Hieble and Ruffolo 1996; Alexander et al. 2001).

Gleason and Hieble (1992) reported that the α_2-adrenoreceptors of the human retinoblastoma cell line (Y79) may represent an additional example of the α_{2C}-adrenoceptor.

Marjamäki et al. (1993) recommended the use of recombinant human α_2-adrenoceptors to characterize subtype selectivity of antagonist binding.

A.1.1.3 Electrically stimulated release of [^{3}H]norepinephrine from brain slices

PURPOSE AND RATIONALE

The existence of presynaptic receptors which regulate the evoked release of neurotransmitters has been functionally demonstrated in both peripheral and central nervous system (Langer 1981; Starke 1981; Raiteri et al. 1984). Presynaptic adrenergic α_2-receptors regulate the evoked release of norepinephrine, comprising a short negative feedback loop. Alpha-2 agonists, such as clonidine and guanabenz, inhibit evoked release and alpha-2 antagonists, such as yohimbine and idazoxan, enhance evoked release.

The assay is used as a biochemical screen for agents which enhance or inhibit release of [^{3}H]norepinephrine (^{3}H-NE) and is particularly useful for testing receptor function of α_2-adrenergic agonists and antagonists.

The procedures used emphasize delicate care of slices. By treating slices with great care, one is able to incubate at low tracer concentrations of ^{3}H-NE (25 nM), thus minimizing nonspecific labeling of releasable pools other than those in noradrenergic nerve terminals. It also permits the use of low (and more physiological) stimulation parameters, which allow the neurons to recover easily between stimulations and do not flood the synaptic cleft with released NE, which would compete with any applied drug thus decreasing sensitivity.

PROCEDURE

This assay is based on the method described by Zahniser et al. (1986).

A Reagents

1. Krebs-Henseleit bicarbonate buffer, pH 7.4 (KHBB):

NaCl	118.4 mM
KCl	4.7 mM
$MgSO_4 \times 7\ H_2O$	1.2 mM
KH_2PO_4	2.2 mM
$NaHCO_3$	24.9 mM
$CaCl_2$	1.3 mM
dextrose (added prior to use)	11.1 mM

   The buffer is aerated for 60 min with 95% O_2, 5% CO_2 on ice and pH is checked.

2. Levo-[Ring-2,5,6-^{3}H]-norepinephrine (specific activity 40–50 Ci/mmol) is obtained from New England Nuclear.

   The final desired concentration of ^{3}H-NE is 25 nM. 0.125 nmol is added to 5 ml KHBB.

3. Test compounds

   For most assays, a 1 mM stock solution of the test compound is made up in a suitable solvent and diluted such that the final concentration in the assay is 1 µM. Higher or lower concentrations may be used depending on the potency of the drug.

B Instrumentation

Neurotransmitter release apparatus consisting of:

- oscilloscope B8K, Precision Model 1420, dual-trace microscope (Dynascan Corp.)
- constant current unit, Grass model CCU1 (Grass Instr. Co.)
- stimulator, model S44, solid state square wave stimulator (Grass Instr. Co.)
- pump, Watson-Marlow, model 502 SHR, standard drive module; model 501 M multichannel pumphead (Bacon Technical Instr.)
- circulator, Haake D8 immersion circulator (Haake Buchler Instr. Inc.)
- fraction collector, Isco Retriever IV fraction collector (Isco Inc.)

C Tissue Preparation

Male Wistar rats (100–150 g) are decapitated, cortical tissue removed on ice and 0.4 mm slices are prepared with a McIlwain tissue chopper. The slices are made individually and removed from the razor blade by twirling an artist's paint brush underneath the slice. Care should be taken not to compress the slice or impale it on the bristles. The slices are placed in cold, oxygenated buffer (10–20 ml) and incubated at 35 °C for 30 min under oxygen. After this incubation, the buffer is decanted, leaving the slices behind. Then 5 ml of cold oxygenated buffer is added, and enough [^{3}H]NE to bring the final concentration to 25 nM. This is then incubated and shaken for 30 min at 35 °C under oxygen. After this step, the buffer is decanted and the "loaded" slices are rapidly placed on the nylon mesh in the stimulation chambers using a cut-off pipetman tip.

D Assay

To establish a stable baseline, control buffer is pumped through the chamber for 1 h at a flow rate of 0.7 ml/min before the first stimulation. One hour is allowed to pass before the second stimulation. When drugs are used, each concentration is prepared in a separate flask in control buffer and allowed to equilibrate with the tissue slice 20 min before the second stimulation. The experiment is stopped 40 min after the second stimulation.

Stimulation parameters are set at 5 Hz (2 ms duration) for 60 s, with 1 ms delay and voltage setting of 440 SIU (250 Ω).

After the experiment is completed, the chambers are washed with distilled water for at least 20 min, then 200 ml of 20% methanol in distilled water, then distilled water again for at least 20 min.

EVALUATION

After conversion of dpm, percent fractional release is calculated for each fraction, using the spreadsheet program.

Percent fractional release is defined as the amount of radiolabeled compound released divided by the amount present in the tissue at that moment in time. "Spontaneous release" (SP) values are the average of the two fractions preceding and the first fraction in that range after the stimulation period. "Stimulated" (S) are the summed differences between the percent fractional release during stimulation and the appropriate SP value.

The effects of drugs can be reported as S_2/S_1 ratios. To normalize the data, drug effects can be estimated by first calculating S_2/S_1 values for control and drug-treated slices and then expressing the S_2/S_1 value for the drug-treated slices as a percentage of the S_2/S_1 value for the control slices for each experiment. Each condition should be tested in slices from each animal.

A.1.1.4 Imidazoline receptor binding

PURPOSE AND RATIONALE

Imidazoline receptors constitute a family of nonadrenergic high-affinity binding sites for clonidine, idazoxan, and allied drugs. Drugs selectively binding to imidazoline receptors are expected to have less side effects than clonidine (Ernsberger et al. 1992, 1997; Molderings et al. 1992; Limon et al. 1992). One major subclass, the I_1 receptors, being mainly distributed in the brain and brain stem, partly mediates the central hypotensive action of clonidine-like drugs. The I_2 receptors, an other subclass, are mitochondrial, not G protein coupled, and have diversified functions. They may be involved in neuroprotection for cerebral ischemia. Two binding sites of [^{3}H]p-aminoclonidine, α_2-adrenoceptors and imidazoline binding sites, could be separated (Ernsberger et al. 1987; Bricca et al. 1988; Kamisaki et al. 1990). At least 3 subtypes of imidazoline/guanidinium-receptive sites have been found by photoaffinity labeling (Lanier et al. 1993).

Several endogenous ligands for imidazoline receptors, collectively termed clonidine displacing substances (CDSs), have been detected in tissues and serum (Reis et al. 1995; Chan et al. 1997).

An endogenous substance with clonidine-like properties originally isolated from brain which binds selectively to imidazoline receptors was described by Atlas and Burstein (1984), Ernsberger et al. (1988), Atlas (1991), Meeley et al. (1992), Dontenwill et al. (1992, Ragunathan and Reis 1996). The endogenous substance agmatine, a decarboxylated arginine, may be the physiological agonist at imidazoline receptors acting as neurotransmitter (Li et al. 1994; Gonzales et al. 1996; Head et al. 1997; Herman 1997; Reis and Regunathan 2000). Further candidates of endogenous ligands are discussed (Reis and Ragunathan 1998).

A critical review on imidazoline binding sites is given by Eglen et al. (1998).

PROCEDURE

Tissue preparation

Whole bovine brains and adrenal glands are obtained from a local slaughterhouse. The lateral medulla oblongata is isolated by a sagittal section through the lateral margin of the pyramids and then bisected. The ventral half is defined as the ventrolateral medulla.

Fresh bovine adrenal glands are perfused retrogradely through the adrenal vein twice with 25 ml ice-cold Krebs-Henseleit bicarbonate buffer. The glands are perfused again with 25 ml ice-cold Krebs-Henseleit buffer containing 0.025% collagenase (type I, Sigma Chemical), incubated at room temperature for 1 h, then perfused with 25 ml fresh buffer containing collagenase and incubated for 30 min at 35 °C. The digested glands are split, and the medulla is removed from the cortex. Adrenal medullae are minced and incubated while being stirred for 30 min at 37 °C. The digest is filtered and centrifuged at 200 *g* for 30 min at 20 °C. The cell pellet is resuspended in 30 ml Krebs' solution without collagenase, recentrifuged, flash-frozen, and stored at –70 °C.

Membrane preparation

Fresh bovine ventrolateral medulla and collagenase-digested rat renal medulla are homogenized with a Polytron (Tekmar Tissumizer; setting 80 for 15 s twice) in 20 vol of ice-chilled HEPES-buffered isotonic sucrose (pH 7.4) containing the protease inhibitors 1,10-phenanthroline (100 µM) and phenylmethyl-sulfonyl fluoride (50 µM). Bovine adrenomedullary chromaffin cells are homogenized in 15 ml HEPES-buffered isotonic sucrose by 10 strokes in a glass/glass handhold homogenizer. The homogenates are centrifuged at 1 000 *g* for 5 min at 4 °C to remove nuclei and debris. The pellets (P1) are resuspended in 20 ml of homogenization buffer and centrifuged again at 1 000 *g* for 5 min. The supernatants are centrifuged at 48 000 *g* for 18 min at 4 °C, and the resulting pellet (P2) is re-suspended in 10–25 vol 50 mM Tris-HCl buffer (pH 7.7) containing 5 mM EDTA. After recentrifugation at 48 000 *g* for 18 min, the resulting membrane pellet is resuspended in Tris-HCl containing 25 mM NaCl, preincubated for 30 min at 25 °C, chilled on ice, centrifuged again, resuspended a final time in Tris-HCl alone, centrifuged, flash-frozen, and stored at –70 °C.

Binding assays

For determination of specific binding to I_1-imidazoline sites and α_2-adrenergic receptors radioligand binding assays are performed with [^{3}H]clonidine, [^{3}H]*p*-iodoclonidine, or [^{3}H]moxonidine. Membranes are slowly thawed and resuspended in Tris-HCl or Tris-HEPES buffer (pH 7.7, 25 °C). Assays are conducted in a total volume of 250 µl in polypropylene 96 well plates (Beckman Macrowell). Each well contains 125 µl membrane suspension, 25 µl radioligand, and 100 µl drug or vehicle. Incubations are initiated by the addition of membrane suspension and carried out for 40 min at 25 °C. Nonspecific binding is defined in the presence of either piperoxan or phentolamine (0.1 mM), which are imidazoline-adrenergic agents. Specific α_2-adrenergic binding is defined by epinephrine (0.1 mM). In experiments with catecholamines, all samples contain ascorbic acid in a final concentration of 0.001%. Incubations are terminated by vacuum filtration over Reeves-Angel or Whatman GF/C fiberglass filters us-

ing a cell harvester (Brandel). The filters are washed four times with 5 ml ice-cold Tris-HCl, placed in scintillation vials, covered with 4 ml scintillation cocktail and counted at 50% efficiency. Protein is assayed by a modified Lowry et al. method (Peterson 1977) using a deoxycholate-trichloroacetic acid protein precipitation technique which provides a rapid quantitative recovery of soluble and membrane proteins from interfering substances even in very dilute solutions. Sodium dodecyl sulfate is added to alleviate possible nonionic and cationic detergent and lipid interferences, and to provide mild conditions for rapid denaturation of membrane and proteolipid proteins.

EVALUATION

Data are obtained as disintegrations per min and transferred to the Equilibrium Binding Data Analysis program (McPherson 1985). Then, several experiments are analyzed simultaneously with the LIGAND program for non-linear curve fitting (Munson and Rodbard 1980). IC_{50} values are estimated from inhibition curves by non-linear curve fitting (Mutolsky and Ransnas 1987). Protein assay data are also analyzed by non-linear curve-fitting (McPherson 1985).

MODIFICATIONS OF THE METHOD

Tesson et al. (1991) defined the subcellular localization of imidazoline-guanidinium-receptive sites by performing binding studies with the radioligand [^{3}H]idazoxan.

Lanier et al. (1993) visualized multiple imidazoline/guanidinium-receptive sites with the photoaffinity adduct 2-[3-azido-4-[^{125}I]iodo-phenoxy]methyl imidazoline.

Molderings et al. (1991) characterized imidazoline receptors involved in the modulation of noradrenaline release in the rabbit pulmonary artery pre-incubated with [^{3}H]noradrenaline.

Molderings and Göthert (1995) determined electrically or K^+-evoked tritium overflow from superfused rabbit aortic strips pre-incubated with [^{3}H]noradrenaline in order to characterize presynaptic imidazoline receptors which mediate noradrenaline release and compared them with I_1- and I_2-imidazoline radioligand binding sites.

Ernsberger et al. (1995) described optimization of radioligand binding assays for I_1 imidazoline sites.

Munk et al. (1996) reported the synthesis and pharmacological evaluation of a potent imidazoline-1 receptor specific agent.

Piletz et al. (1996) compared the affinities of several ligands for [^{125}I]p-iodoclonidine binding at human platelet I_1 imidazole binding sites.

Several selective ligands for imidazoline I_2 receptors have been identified, such as:

- LSL 60101 (Alemany et al. 1995; Menargues et al. 1995),
- RS-45041-190 (MacKinnon et al. 1995; Brown et al. 1995),
- RX801077 (= 2-BFI = 2-(2-benzofuranoyl)-2-imidazoline and analogues (Jordan et al. 1996; Lione et al. 1996; Alemany et al. 1997; Hosseini et al. 1997; Wiest and Steinberg 1997; Hudson et al. 1997).

A.1.1.5 β-adrenoreceptor binding

PURPOSE AND RATIONALE

β-adrenoceptors are widely distributed, found at both central and peripheral sites, and are activated either via norepinephrine released from sympathetic nerve terminals or via epinephrine released from the adrenal medulla. Important physiological consequences of β-adrenoceptor activation include stimulation of cardiac rate and force, relaxation of vascular, urogenital and bronchial smooth muscle, stimulation of renin secretion from the juxta-glomerular apparatus, stimulation of insulin and glucagon secretion from the endocrine pancreas, stimulation of glycogenolysis in liver and skeletal muscle and stimulation of lipolysis in the adipocyte.

Three β-adrenoceptor proteins have been cloned, and the characteristics of these recombinant receptors correspond with those of the three well characterized β-adrenoceptors on native tissue, designated as β_1, β_2 and β_3. The possible roles of β_3-adrenoceptors in the cardiovascular system were discussed by Gauthier et al. (2000). An additional β-adrenoceptor modulatingcardiac contractility has been designated as the β_4-adrenoceptor (Kaumann et al. 1998).

The β-adrenoceptor population of plasma membranes from bovine heart ventricles consists of 75–80% β_1- and 20–25% β_2-adrenoceptors. The use of this tissue allows a parallel investigation of the binding characteristics of drugs at both the β_1- and β_2-adrenoceptors. Both, the β_1- and β_2-adrenoceptors coexist in rat ventricular myocytes, but stimulation of these receptor subtypes elicits qualitatively different cell responses at the levels of ionic channels, the myofilaments, and sarcoplasmic reticulum (Xiao and Lakatta 1993).

A constant concentration of the radioligand ^{3}H-dihydroalprenolol (^{3}H-DHA) (4–6 nM) is incubated with increasing concentrations of a non-labeled test drug (0.1 nM–1 mM) in the presence of plasma membranes from bovine heart ventricles. If the test drug exhibits any affinity to ß-adrenoceptors, it is able to compete with the radioligand for receptor binding sites. Thus, the lower the concentration range of the test drug, in which the competition reaction occurs, the more effective is the test drug.

PROCEDURE

Materials and solutions

preparation buffer:

Tris-HCl	5	mM
$MgCl_2 \times 6\ H_2O$	1	mM
D(+)-sucrose	250	mM
pH 7.4		

310 mOsm sodium phosphate buffer:
pH 7.4

rinse buffer:

Tris-HCl	50	mM
$MgCl_2 \times 6\ H_2O$	10	mM
pH 7.4		

incubation buffer:

Tris-HCl	50	mM
$MgCl_2 \times 6\ H_2O$	10	mM
ascorbic acid	1.6	mM
catechol	0.3	mM
pH 7.4		

radioligand:
(–)^{3}H-dihydroalprenolol × HCl
(^{3}H-DHA) specific activity 1.48–2.59 TBq/mmol (40–70 Ci/mmol) (NEN)
for inhibition of ^{3}H-dihydroalprenolol binding in non-specific binding experiments:
(–)isoprenaline(+)-bitartrate salt (Sigma)

Bovine hearts are obtained freshly from the local slaughter house. The lower part of the left ventricle from 5 hearts is separated and kept in ice-cold preparation buffer. In the laboratory, approx. 60 g wet weight from the five ventricle pieces are minced with a scalpel into 2–3 mm pieces.

Membrane preparation

Ventricles are homogenized by Ultra-Turrax (1 g tissue/10 ml buffer), the homogenate is filtered through gauze and centrifuged at 500 *g* (4 °C) for 10 min. The pellets are discarded, the supernatant is collected, and centrifuged at 40 000 *g* for 20 min. The resulting pellets are resuspended in approx. 300 ml 310 mOsm sodium phosphate buffer, homogenized by Ultra-Turrax, and centrifuged as before. The final pellets are dissolved (by Ultra-Turrax) in sodium phosphate buffer corresponding to 1 g ventricle wet weight/2 ml buffer.

The membrane suspension is immediately stored in aliquots of 5–20 ml at –77 °C. Protein concentration of the membrane suspension is determined according to the method of Lowry et al. with bovine serum albumin as a standard.

At the day of the experiment, the required volume of the membrane suspension is slowly thawed and centrifuged at 40 000 *g* (4 °C) for 20 min. The pellets are resuspended in a volume of ice-cold rinse buffer, yielding a membrane suspension with a protein content of approx. 2.0 mg/ml. After homogenizing by Ultra-Turrax, the membrane suspension is stirred under cooling for 20–30 min until the start of the experiment.

Experimental course

All incubation samples are performed in triplicate.

The total volume of each incubation sample is 200 µl (microtiter plates).

Saturation experiments

total binding:

- 50 µl ^{3}H-DHA
  (12 concentrations, 3×10^{-10}–4×10^{-8} M)
- 50 µl incubation buffer

non-specific-binding:

- 50 µl ^{3}H-DHA
  (4 concentrations, 3×10^{-10}–4×10^{-8} M)
- 50 µl (–)isoprenaline (10^{-5} M)

Competition experiments

- 50 µl ^{3}H-DHA
  (1 constant concentration, $4–6 \times 10^{-9}$ M)
- 50 µl incubation buffer without or with non-labeled test drug
  (15 concentrations 10^{-10}–10^{-3} M)

The binding reaction is started by adding 100 µl membrane suspension per incubation sample (approx. 2 mg protein/ml). The samples are incubated for 60 min in a shaking water bath at 25 °C. The reaction is stopped by rapid vacuum filtration of the total incubation volume over glass fiber filters. Thereby the membrane-bound radioactivity is separated from the free activity. Filters are washed immediately with approx. 20 ml ice-cold rinse buffer per sample. The retained membrane-bound radioactivity on the filter is measured after addition of 2 ml liquid scintillation cocktail per sample in a Packard liquid scintillation counter.

EVALUATION

The following parameters are calculated:

- total binding
- non-specific binding
- specific binding = total binding – non-specific binding

The dissociation constant (K_i) of the test drug is determined from the competition experiment of ^{3}H-DHA versus non-labeled drug by a computer-supported analysis of the binding data.

$$K_i = \frac{K_D\ ^3\mathrm{H} \times IC_{50}}{K_D\ ^3\mathrm{H} + [^3\mathrm{H}]}$$

IC_{50} = concentration of the test drug, which competes with 50% of specifically bound ^{3}H-DHA in the competition experiment

$[^3\mathrm{H}]$ = concentration of ^{3}H-DHA in the competition experiment.

$K_D\ ^3\mathrm{H}$ = dissociation constant of ^{3}H-DHA, determined from the saturation experiment.

The K_i-value of the test drug is the concentration, at which 50% of the receptors are occupied by the test drug.

The affinity constant K_i [mol/l] is recorded and serves as a parameter to assess the efficacy of the test drug.

Standard data

propranolol hydrochloride $K_i = 6–8 \times 10^{-9}$ mol/l

MODIFICATIONS OF THE METHOD

Abrahamsson et al. (1988) performed a receptor binding study on the β_1- and β_2-adrenoceptor affinity of atenolol and metoprolol in tissues from the rat, the guinea pig and man with various radioligands, such as $[^{125}\mathrm{I}](\pm)$hydroxybenzylpindolol, $[^{125}\mathrm{I}](-)$pindolol, $[^3\mathrm{H}](-)$-dihydroalprenolol, and $[^3\mathrm{H}](-)$CGP 12177.

Fleisher and Pinnas (1985) used specific binding of $(-)[^3\mathrm{H}]$dihydroalprenolol to rat lung membranes for *in vitro* studies on the relative potency of bronchodilator agents.

A.1.1.6 β_1-adrenoreceptor binding

PURPOSE AND RATIONALE

β-adrenergic receptors were differentiated from α-receptors (Ahlquist 1948) and subsequently divided into 2 distinct subtypes, β_1 and β_2 (Lands et al. 1967) based on differing pharmacology in different tissues. β-receptors have been labelled in a number of tissues including heart, lung, erythrocytes and brain using the β-agonists [^{3}H]-epinephrine (U'Prichard et al. 1978), or [^{3}H]-hydroxybenzylisoproterenol (Lefkowitz and Williams 1977) or the β-receptor antagonists [^{3}H]-alprenolol (Mukherjee et al. 1975), [^{3}H]-dihydroalprenolol (DHA) (U'Prichard et al. 1978; Bylund and Snyder 1976) and (^{125}I)-iodohydroxypindolol (Weiland et al. 1980). DHA is a potent β-antagonist (Mukherjee et al. 1975), which labels both β_1 and β_2 adrenergic receptors. The binding characteristics of this ligand in brain were described by Bylund and Snyder (1976), who showed that antagonists competed potently and agonists less potently although stereospecificity was maintained. The pharmacology of binding was consistent with β_1-receptor occupancy. Lesioning studies (Wolfe et al. 1982), combined with non-linear regression analysis of data have shown that while β-receptors in rat cerebellum are primarily of the β_2 sub-type, the β_1 occurring in rat cerebral cortex are physiologically more significant. The assay can be used to evaluate the direct interaction of drugs with β-receptors labelled by [^{3}H]-dihydroalprenolol.

PROCEDURE

Reagents

Tris buffer, pH 8.0
- a) 44.4 g Tris HCl q.s. to 1 liter (0.5 M Tris, pH 8.0) 26.5 g Tris base
- b) Dilute 1:10 in distilled water. (0.05 M Tris, pH 8.0)

2. (–)-[propyl-1,2,3-^{3}H] Dihydroalprenolol hydrochloride (45–52 Ci/mmol) is obtained from New England Nuclear.

   For IC_{50} determinations: A stock solution of 20 nM ^{3}H-DHA is made up in distilled H_2O and 50 µl is added to each tube (this yields a final concentration of 1 nM in the 1 ml assay).
3. (±)-propranolol HCl is obtained from Ayerst.

   A 1 mM propranolol stock solution is made up in distilled water and further diluted 1:20 in distilled water to give 50 µM propranolol solution. Twenty µl of dilute stock solution is added to 3 tubes to determine nonspecific binding (yields a final concentration of 1 µM in a 1 ml assay).
4. Test compounds:

   For most assays, a 1 mM stock solution is made up in a suitable solvent and serially diluted, such that the final concentration in the assay ranges from 10^{-5} to 10^{-8} M. Seven concentrations are used for each assay. Higher or lower concentrations may be used depending on the potency of the compound.

Tissue preparation

Male rats are decapitated and the brains rapidly removed. The cerebral cortices are dissected free, weighed and homogenized in 50 ml of ice-cold 0.05 Tris buffer, pH 8.0. This homogenate is centrifuged at 40 000 *g*, the supernatant decanted and the pellet resuspended and recentrifuged at 40 000 *g*. The final pellet is resuspended in the initial volume of fresh 0.05 Tris buffer, pH 8.0. This tissue suspension is then stored on ice. The final tissue concentration in the assay is 10 mg/ml. Specific binding is about 3% of the total added ligand and 80% of the total bound ligand.

Assay

380 µl	H_2O
50 µl	0.5 Tris buffer, pH 8.0
20 µl	Vehicle (for total binding) or 50 µM (±) propranolol (for nonspecific binding) or appropriate drug concentration
50 µl	^{3}H-DHA stock solution
500 µl	tissue suspension.

The tissue homogenates are incubated for 15 min at 25 °C with 1 nM ^{3}H-DHA and varying drug concentrations. With each binding assay, triplicate samples are incubated with 1 µM (±)-propranolol under identical conditions to determine nonspecific binding. The assay is stopped by vacuum filtration through Whatman GF/B filters which are washed 3 times with 5 ml of ice-cold 0.05 Tris buffer, pH 8.0. The filters are counted in 10 ml of Liquiscint scintillation cocktail.

EVALUATION

The percent inhibition of each drug concentration is the mean of triplicate determinations. IC_{50} values are obtained by computer-derived log-probit analysis.

MODIFICATIONS OF THE METHOD

Dooley et al. (1986) recommended CGP 20712 A as a useful tool for quantitating β_1 and β_2 adrenoceptors.

A.1.1.7 β_2-adrenoreceptor binding

PURPOSE AND RATIONALE

Lands et al. (1967) classified β-receptors into β_1 and β_2 subtypes according to differences in the action of various catecholamines. Synthesis of more selective β-antagonists has helped to confirm the existence of receptor subtypes. Based on catecholamine pharmacology and differences in the tissue distribution, it has been suggested that the β_1-receptor serves as the receptor for norepinephrine acting as a neurotransmitter and the β_2-receptor serves as a receptor for epinephrine acting as a hormone. (Nahorski 1981; Ariens and Simonis 1983; Lefkowitz et al. 1983; Minneman 1983). Since [^{3}H]-dihydroalprenolol is a nonspecific ligand, it is necessary to select a tissue which is enriched in β_2-receptors in order to convey specificity to this assay. Tissues with predominantly β_2-receptors include lung (U'Prichard et al. 1978; Ariens and Simonis 1983; Lefkowitz et al. 1983), cerebellum (Lefkowitz et al. 1983; Minneman et al. 1983), rat and frog erythrocytes (Mukherjee et al. 1975; Lefkowitz et al. 1983) and ciliary process (Nathanson 1985) whereas, forebrain, heart and avian erythrocytes are relatively enriched in the β_1-subtype (Lefkowitz et al. 1983). Due to poor binding characteristics in cerebellum, rat lung is chosen as the tissue for β_2-adrenergic receptors.

A compound with β_2-selectivity would be less likely to produce cardiac effects but more likely to produce bronchiolar constriction. The test is used to determine the affinity of compounds for the β_2-adrenergic receptor subtype. A measure of receptor subtype selectivity can be determined when data are compared with those obtained in the β_1-adrenergic assay in rat cerebral cortex.

The present nomenclature of β_1, β_2, and β_3 receptors was reviewed by Alexander et al. (2001).

PROCEDURE

Reagents

1. Tris buffers, pH 8.0
   a) 44.4 g Tris HCl q.s. to 1 liter (0.5 M Tris, pH 8.0) 26.5 g Tris base
   b) Dilute 1:10 in distilled water (0.05 M Tris, pH 8.0)
2. (–)-[propyl-1,2,3-^{3}H] Dihydroalprenolol hydrochloride (45–52 Ci/mmol) is obtained from New England Nuclear.
   For IC_{50} determinations: A stock solution of 20 nM ^{3}H-DHA is made up in distilled water and 50 µl is added to each tube (this yields a final concentration of 1 nM in the assay)
3. (±)-propranolol HCl is obtained from Ayerst.
   A 1 mM propranolol stock solution is made up in distilled water and further diluted 1:20 in distilled water to give 50 µM propranolol solution. Twenty µl of dilute stock solution are added to 3 tubes to determine nonspecific binding (yielding a final concentration of 1 µM in a 1 ml assay).
4. Test compounds:
   For most assays, a 1 mM stock solution is made up in a suitable solvent and serially diluted, such that the final concentrations in the assay range from 10^{-5} to 10^{-8} M. Seven concentrations are used for each assay. Higher or lower concentrations may be used depending on the potency of the compound to be tested.

Tissue preparation

Male Wistar rats are sacrificed by decapitation and the lungs removed, weighed and homogenized in 50 volumes of ice-cold 0.05 M Tris buffer, pH 8.0 using a Tekmar homogenizer. The homogenate is passed through a cheese cloth and centrifuged at 40 000 *g* for 15 min. The final membrane pellet is resuspended in the original volume of Tris buffer, pH 8.0, and used in the assay.

Assay

380 µl H_2O
50 µl 0.5 Tris buffer, pH 8.0
20 µl Vehicle (for total binding) or 50 µM (±)-propranolol (for nonspecific binding) or appropriate drug concentration
50 µl ^{3}H-DHA stock solution
500 µl tissue suspension.

The tissue homogenates are incubated for 15 min at 25 °C with 1 nM ^{3}H-DHA and varying drug concentrations. In each binding assay, triplicate samples are incubated with 1 µM (±)-propranolol under identical conditions to determine nonspecific binding. The assay is stopped by vacuum filtration through Whatman GF/B filters which are washed 3 times with 5 ml of ice-cold 0.05 Tris buffer, pH 8.0. The filters are counted in 10 ml of Liquiscint scintillation cocktail.

EVALUATION

The percent inhibition of each drug concentration is the mean of triplicate determinations. IC_{50} values are obtained by computer-derived log-probit analysis.

MODIFICATIONS OF THE METHOD

Dooley et al. (1986) recommended CGP 20712 as a useful tool for quantitating β_1- and β_2-adrenoceptors.

Sarsero et al. (1998) recommended (–)[^{3}H]-CGP 12177A as radioligand for the putative β_4-adrenoceptor.

McConnell et al. (1991, 1992; Owicki and Parce 1992) used a special apparatus, the 'cytosensor microphysiometer' which measures the rate of proton excretion from cultured cells. Chinese hamster ovary cells were transfected with human β_2-adrenergic receptors. The β_2-adrenergic receptor activates adenylate cyclase resulting in an increase in the cyclic AMP concentration within the cell which can be measured as acidification. Addition of 10 µM isoproterenol, 500 µM 8-bromo cyclic AMP, or 10 µg/ml forskolin induced a reversible acidification.

A.1.1.8 Adenosine A_1 receptor binding

GENERAL CONSIDERATIONS

Adenosine receptors belong to the class of purinoceptors (Burnstock 1972, 1981; Olsson and Pearson 1990). Purinoceptors are divided into two general types on the basis of recognized natural ligands:

P_1 receptors recognize adenosine and AMP and P_2 receptors recognize ATP and AMP. Fredholm et al. (1994), Abbracchio and Burnstock (1994, Jacobson et al. 2000) proposed a nomenclature system which is now widely accepted: two families of P2 purinoceptors, P2X ionotropic ligand-gated ion channel receptors and P2Y metabotropic G-protein-coupled receptors. The nomenclature of seven subtypes of P2X receptors and six subtypes of P2Y receptors has been agreed by the NC-IUPHAR Subcommittee (Burnstock 2001; Alexander et al. 2001).

The effects of adenosine are mediated effects through cAMP (Sattin and Rall 1970; VanCalker et al. 1978). It was discovered that adenosine could either inhibit or stimulate the formation of cAMP. The discovery of dual effects on adenylate cyclase led to the proposal of two distinct adenosine receptors referred to as the A_1 and A_2 receptors. The A_1 subtype of adenosine receptor mediates the inhibition of adenylate cyclase; whereas, the A_2 subtype mediates stimulation of adenylate cyclase. The methylxanthines are relatively nonselective inhibitors of adenosine receptor subtypes and their pharmacological properties are thought to be mostly due to antagonism of these receptors.

Comparison of adenosine receptors with other G-protein linked receptors indicates that they comprise a family of G protein coupled receptors that can be grouped by subtypes or by species. Thus, in addition to A_1 and A_2, several authors described A_{1a}, A_{1b}, A_{2a}, A_{2b}, A_3, and A_4 receptors with species dependent differences (Jacobson et al. 1992 1996; Zhou et al. 1992; Linden et al. 1993; Salvatore et al. 1993; Linden et al. 1994; Fredholm et al. 1994; Alexander et al. 2001).

PURPOSE AND RATIONALE

The purpose of this assay is to measure the affinity of test compounds for adenosine (A_1) receptors. Evidence for an A_1 adenosine receptor in the guinea pig atrium was given by Collis (1983). Adenosine plays a physiological role in many systems, including platelet aggregation, lipolysis, steroidogenesis and smooth muscle tone (Daly 1982).The vasodilatory and cardiac depressant effects of adenosine are well known. In addition to cardiovascular effects, adenosine has marked effects in the CNS including depression of electrophysiological activity (Siggins and Schubert 1981), anticonvulsant activity, analgesic properties (Ahlijanian and Takemori 1985) and inhibition of neurotransmitter release (Harms et al. 1979).

The agonist, [^{3}H]cyclohexyladenosine (CHA), has affinity for the A_1 receptor in the nanomolar concentration range and has proven to be a suitable ligand for A_1 receptor assays (Bruns et al. 1980; Bruns et al. 1986). Selective A_1 (Schingnitz et al. 1991) and A_2 antagonists (Shimada et al. 1992; Jacobson et al. 1993) have been described. Adenosine and its nucleotides have not only a cardiovascular but predominantly a cerebral activity (Phillis and Wu 1981; Daly 1982; Fredholm et al. 1982).

PROCEDURE

Reagents

1. a) 0.5 M Tris buffer, pH 7.7
   b) 0.05 M Tris buffer, pH 7.7
2. Adenosine deaminase is obtained from Sigma Chemical Co.

   Adenosine deaminase is added to 0.05 M Tris-HCl buffer, pH 7.7 for final resuspension of the membrane pellet, such that the concentration in the assay is 0.1 U/ml of tissue.
3. Cyclohexyladenosine, N^6-[Adenine-2,8-^{3}H] (specific activity 34 mCi/mmol) is obtained from New England Nuclear.

   For IC_{50} determinations: [^{3}H]CHA is made up to a concentration of 40 nM and 50 µl are added to each tube. This yields a final concentration of 1 nM in the assay.
4. Theophylline is obtained from Regis Chemical Co.

   A 100 mM stock solution is made up in deionized water. 20 µl are added to each of 3 tubes for the determination of nonspecific binding, yielding a 1 mM final concentration in the assay.
5. Test compounds

   For most assays, a 1 mM stock solution is prepared in DMSO and serially diluted, such that the final concentrations in the assay range from 10^{-5} to 10^{-8} M. Seven concentrations are used for each assay. Higher or lower concentrations may be used depending on the potency of the drug.

Tissue preparation

Male Wistar rats are sacrificed by decapitation. Whole brains minus cerebellum are removed, weighed and homogenized in 10 volumes of ice-cold 0.05 M Tris buffer, pH 7.7. The homogenate is centrifuged at 48 000 *g* for 10 min, the supernatant decanted, the pellet resuspended in the same volume of buffer and centrifuged again as before. The final pellet is resuspended in 0.05 M Tris buffer containing 0.1 U/ml of adenosine deaminase.

Assay

1 000 µl	tissue suspension
930 µl	H_2O
20 µl	vehicle or theophylline or appropriate concentration of test compound
50 µl	^{3}H-CHA

The tubes are incubated for 2 hours at 25 °C. The assay is stopped by vacuum filtration through Whatman GF/B filters which are then washed 3 times with 5 ml of 0.05 M Tris buffer. The filters are then placed into scintillation vials with 10 ml liquiscintillation cocktail, left to soak overnight and counted.

EVALUATION

Specific binding is defined as the difference between total binding and binding in the presence of 1 mM theophylline. IC_{50} values are calculated from the percent specific binding at each drug concentration.

The complexity of interaction of adenosine ligands with receptors (Bruns et al. 1986) precludes the simple calculation of K_i values by the Cheng-Prusoff equation.

MODIFICATIONS OF THE METHOD

Stiles et al. (1985) used ^{125}I-labeled N^6-2-(4-aminophenyl)ethyladenosine as a selective ligand to probe the structure of A_1 receptors.

Lohse et al. (1987) described 8-cyclopentyl-1,3-dipropylxanthine (DPCPX) as a high affinity antagonist radioligand for A_1 adenosine receptors.

Klotz et al. (1989) described 2-chloro-N^6-[^{3}H]cyclopentyladenosine ([^{3}H]CCPA) as a high affinity agonist radioligand for A_1 adenosine receptors.

Von Lubitz et al. (1995) studied the therapeutic implications of chronic NMDA receptor stimulation on adenosine A_1 receptors.

The partial agonism of theophylline-7-riboside on the adenosine A_1 receptor has been reported by Ijzerman et al. (1994).

A.1.1.9 Adenosine A_2 receptor binding

PURPOSE AND RATIONALE

The A_2 receptor is a low-affinity binding site for adenosine (Daly et al. 1981). Activation of the A_2 receptor subtype by agonists mediates an increase in adenylate cyclase activity, while the A_1 receptor has the opposite effect. Although many of the physiological effects of adenosine seem to correlate with activity at the A_1 receptor, the effect on coronary blood flow correlates with activation of A_2 receptors (Hamilton et al. 1987).

This assay uses ^{3}H-NECA (5'-N-ethylcarboxamido [8-^{3}H]adenosine) to label A_2 receptors in rat striatum by the method described by Bruns et al. (1986). Comparison of data from this assay and the A_1 receptor assay provides a measure of selectivity for these two receptors.

PROCEDURE

Reagents

1. a) 0.5 M Tris buffer, pH 7.7
   b) 0.05 M Tris buffer, pH 7.7
   c) 0.05 M Tris buffer, pH 7.7, containing 12 mM $CaCl_2$ (final assay concentration: 10 mM)
2. Adenosine deaminase is obtained from Sigma Chemical Co.

   Adenosine deaminase is added to 0.05 M Tris-HCl buffer, pH 7.7, containing 12 mM $CaCl_2$ for final resuspension of the membrane pellet, such that the concentration in the assay is 0.1 U/ml of tissue.
3. 5'-N-Ethylcarboxamido[8-^{3}H]adenosine (specific activity 23–40 mCi/mmol) is obtained from Amersham.

   For IC_{50} determinations: ^{3}H-NECA is made up to a concentration of 80 nM and 50 µl is added to each tube. This yields a final concentration of 4 nM in the assay.
4. Cyclopentyladenosine (CPA) is obtained from Research Biochemicals Inc.

   A 5 mM stock solution is made up in DMSO. 20 µl are added to each of 3 tubes for the determination of nonspecific binding, yielding a 100 µM final concentration in the assay.

   Since [^{3}H]NECA is not a specific ligand for A_2 receptors, CPA is added to all other tubes to mask the A_1 receptors at a final concentration of 50 nM.
5. Test compounds

   For most assays, a 1 mM stock solution is made up in a suitable solvent and serially diluted, such that the final concentration in the assay ranges from 2×10^{-5} to 2×10^{-8} M. Seven concentrations are used for each assay. Higher or lower concentrations may be used depending on the potency of the drug.

Tissue preparation

Male Wistar rats are sacrificed by decapitation. Striata are removed, weighed and homogenized in 10 volumes of ice-cold 0.05 M Tris buffer, pH 7.7. The homogenate is centrifuged at 48 000 *g* for 10 min, the supernatant decanted, the pellet resuspended in the same volume of buffer and centrifuged again as before. The final pellet is resuspended in 100 volumes of 0.05 M Tris buffer containing 10 mM $CaCl_2$ and 0.1 U/ml of adenosine deaminase.

Assay

830 µl	tissue suspension
100 µl	CPA
20 µl	vehicle or CPA or appropriate concentration of test compound
50 µl	^{3}H-NECA

The tubes are incubated at 25 °C for 2 hours. The assay is stopped by vacuum filtration through Whatman GF/B filters which are then washed 3 times with 5 ml of 0.05 M Tris buffer. The filters are then placed into scintillation vials with 10 ml Liquiscint scintillation cocktail, left to soak overnight and counted.

EVALUATION

Specific binding is defined as the difference between total binding and binding in the presence of 100 µM CPA. IC_{50} values are calculated from the percent specific binding at each drug concentration.

The complexity of interaction of adenosine ligands with receptors precludes the simple calculation of K_i values by the Cheng-Prusoff equation.

MODIFICATIONS OF THE METHOD

Jarvis et al. (1989) reported on [^{3}H]CGS 21 680, a selective A_2 adenosine receptor agonist which directly labels A_2 receptors in rat brain. [^{3}H]CGS 21 680 binding was greatest in striatal membranes with negligible specific binding obtained in rat cortical membranes.

Gurden et al. (1993) described the functional characterization of three adenosine receptor types.

Hutchinson et al. (1990) described 2-(arylalkylamino)adenosin-5'-uronamides as a new class of highly selective adenosine A_2 receptor ligands.

A_{2A} Adenosine receptors from rat striatum and rat pheochromocytoma PC12 cells have been characterized with radioligand binding and by activation of adenylate cyclase (Hide et al1992).

Nonaka et al. (1994) reported on KF17837 ((E)-8-(3,4-dimethoxystyryl)-1,3-dipropyl-7-methylxantine), a potent and selective adenosine A_2 receptor antagonist.

The *in vitro* pharmacology of ZM 241385, a potent, non-xanthine, A_{2a} selective adenosine receptor antagonist has been reported by Poucher et al. (1955).

Monopoli et al. (1994) described the pharmacology of the selective $A_{2\alpha}$ adenosine receptor agonist 2-hexynyl-5'-N-ethylcarboxamidoadenosine.

Jacobson et al. (1993) described structure-activity relationships of 8-styrylxanthines as A_2-selective adenosine antagonists.

A.1.1.10 Adenosine A_3 receptor binding

PURPOSE AND RATIONALE

The A_3 adenosine receptor has been cloned and characterized by Zhou et al. (1992). A possible role in reproduction has been discussed. The role of central A_3 adenosine receptors may be the mediation of behavioral depressant effects (Jacobson et al. 1993). The design of selective ligands of A_3 adenosine receptors and the therapeutic concepts including effects on locomotor activity, cardiovascular effects, effects in cerebral ischemia (von Lubitz et al. 1994), in cardiac preconditioning and as antagonists in inflammation and asthma has been discussed by Jacobson et al. (1995). Von Lubitz et al. (1995) noticed some anticonvulsive activity of the adenosine A_3 receptor selective agonist IB-MECA (N^6-(3-iodobenzyl) adenosine-5'-N-methyl-carboxamide). Stimulation of the A_3 adenosine receptor facilitates release of allergic mediators in mast cells (Ramkumar et al. 1993) inducing hypotension in the rat (Hannon et al. 1995). A binding site model and structure-activity relationships for the rat A_3 adenosine receptor are described by van Galen et al. (1994).

PROCEDURE

Cell culture and membrane preparation

Chinese hamster ovary (CHO) cells stably expressing the rat A_3 adenosine receptor are grown in F-12 medium containing 10% fetal bovine serum and penicillin/streptomycin (100 units/ml and 100 µg/ml, respectively) at 37° in a 5% CO_2 atmosphere. When cells reach confluency, they are washed twice with 10 ml of ice-cold lysis buffer (10 mM EDTA, pH 7.4). After addition of 5 ml of lysis buffer, cells are mechanically scraped and homogenized in an ice-cold Dounce homogenizer. The suspension is centrifuged at 43 000 *g* for 10 min. The pellet is suspended in the minimum volume of ice-cold 50 mM Tris/10 mM $MgCl_2$/1 mM EDTA (pH 8.26 at 5 °C) buffer required for the bind-

ing assay and homogenized in a Dounce homogenizer. Aminodeaminase (ADA, Boehringer Mannheim) is added to a final concentration of 3 units/ml and the suspension is incubated at 37 °C for 15 min; the membrane suspension is subsequently kept on ice until use.

Radioligand binding assay

Binding of [^{125}I]APNEA (N^6-2-(4-aminophenyl)ethyladenosine) to CHO cells stably transfected with the rat A_3 adenosine receptor clone is performed according to Stiles et al. (1985). Assays are performed in 50/10/1 buffer in glass tubes and contain 100 µl of the membrane suspension, 50 µl of inhibitor. Incubations are carried out in duplicate for 1 h at 37 °C and are terminated by rapid filtration over Whatman GF/B filters, using a Brandell cell harvester. Tubes are washed three times with 3 ml of buffer. Radioactivity is determined in a Beckman γ-counter. Non-specific binding is determined in the presence of 40 µM R-PIA=N^6-[(R)]-1-methyl-2-phenylethyl]adenosine.

EVALUATION

K_i values are calculated according to Cheng and Prusoff (1973), assuming a K_d for [^{125}I]APNEA of 17 nM.

MODIFICATIONS OF THE METHOD

^{125}I-4-aminobenzyl-5'-N-methylcarboxamidoadenosine has been recommended as a high affinity radio-ligand for the rat A_3 adenosine receptor (Olah et al. 1994).

Molecular cloning and functional expression of a sheep A_3 adenosine receptor has been reported by Linden et al. (1993).

G protein-dependent activation of phospholipase C by adenosine A_3 receptors in rat brain was reported by Abbracchio et al. (1995).

Molecular cloning and characterization of the human A_3 adenosine receptor was reported by Salvatore et al. (1993).

The differential interaction of the rat A_3 adenosine receptor with multiple G-proteins has been described by Palmer et al. (1995).

Baraldi and Borea (2000) described new potent and selective human adenosine A_3 receptor antagonists using radioligand binding studies to the human A_3 receptor.

A.1.1.11 Inhibition of adenosine uptake in human erythrocytes

PURPOSE AND RATIONALE

Adenosine regulates multiple physiological functions in animals and humans. It plays a potent neuromodulatory role mainly by inhibiting the presynaptic transmitter release, e.g. of glutamate and aspartate. It is released by synaptic stimulation and during hypoxia in the central and peripheral nervous system. Adenosine

plays a neuroprotective role in hypoxia and ischemia since it reduces the excessive stimulation of the NMDA receptors. The use of adenosine uptake inhibitors has been proposed as a new therapeutic strategy for hypoxic/ischemic disease. Due to its vasodilatory action adenosine plays a key role in the regulation of coronary and cerebral blood flow. The rapid cellular uptake of adenosine by erythrocytes is a reason for the short duration of action of adenosine.

Human erythrocytes are used as a cellular model to detect adenosine uptake inhibitors. Erythrocytes are treated with test compound and thereafter incubated with ^{3}H-adenosine. The uptake of ^{3}H-adenosine is evaluated in relation to the untreated control group.

Dipyridamole is a potent inhibitor of adenosine uptake (IC_{50} of 3×10^{-7} M).

Standard compounds:
- theophylline
- dipyridamole (Persantin®)
- propentofylline (HWA 285)

PROCEDURE

Materials and solutions

isotonic glycyl-glycine buffer, pH 7.4

KCl	5.0 mM
NaCl	119.5 mM
$MgCl_2$	2.0 mM
glycyl-glycine	50 mM
Na_2HPO_4	2.0 mM
2-[^{3}H]-adenosine (specific activity 0.2 µCi/µmol)	5 µM

Buffer-washed fresh human erythrocytes are depleted of ATP by incubation in an isotonic glycyl-glycine buffer at 37 °C. Aliquots of the erythrocyte suspensions are incubated for 2 min in fresh glycyl-glycine buffer solution containing additional 10 mM glucose and test- or standard compound. In screening assays, test compounds are added at a concentration of 5×10^{-4} M. Drugs showing an effect in this assays, are further tested at a concentration range of 10^{-5}–5×10^{-4} M to determine IC_{50} values (triplicate samples for each concentration).

The suspension is then incubated with 5 µM radioactively labelled 2-[^{3}H]-adenosine for 30 s. The adenosine uptake is stopped by adding cold buffer (4 °C) containing 5 µM adenosine, 10 µM glucose and 7.4 µM dipyridamole. After centrifugation, the tritium radioactivity is determined in the supernatant.

EVALUATION

The percent change of ^{3}H-adenosine uptake relative to the vehicle control group is determined. The ^{3}H-adenosine uptake of the control group is taken as 100%; subsequent results are expressed as percentages of this.

IC_{50} values are determined by plotting the percent inhibition against test compound concentration; IC_{50} is defined as the dose of drug leading to a 50% inhibition of adenosine uptake.

Statistical evaluation is performed by means of the Student's *t*-test.

Standard data:
- IC_{50} of dipyridamole 3×10^{-7} M

MODIFICATIONS OF THE METHOD

Marangos et al. (1982), Verma and Marangos (1985) recommended [^{3}H]nitrobenzylthioinosine binding as a probe for the study of adenosine uptake sites in brain of various species. The highest density of binding sites were found in the caudate and hypothalamus of human and rat brain.

A.1.1.12 Inhibition of the angiotensin-converting enzyme *in vitro*

GENERAL CONSIDERATIONS

Vasopeptidase inhibitors (VPIs) inhibit both angiotensinconverting enzyme (ACE) and neprilysin (NEP) and can thus reduce the activity of the renin-angiotensin system and potentiate the vasodilatory, natriuretic and antiproliferative effects of bradykinin and natriuretic peptides (Burnett 1999; Bralet and Schwartz 2001). Combined inhibition of neutral endopeptidase 24.11 (NEP) and angiotensin converting enzyme is a candidate therapy for hypertension and cardiac failure (Duncan et al. 1999).

PURPOSE AND RATIONALE

An *in vitro* system can be used to screen potential angiotensin-converting-enzyme inhibitors. Fluorescence generated by an artificial substrate in presence or absence of the inhibitor is measured to detect inhibitory activity.

PROCEDURE

Reagents

1. 50 mM Tris-HCl buffer, pH 8.0 + 100 mM NaCl
2. 10 mM potassium phosphate buffer, pH 8.3
3. Substrate: O-aminobenzoylglycyl-p-nitro-L-phenylalanyl-L-proline (molecular weight 482) (Bachem Gentec. Inc., Torrance, California, USA)
   a) stock solution: 10 mg substrate in 10 ml 50 mM Tris-HCl buffer, pH 8.0 + 100 mM NaCl
   b) working solution: 2 ml stock solution is added to 18 ml 50 mM Tris-HCl buffer, pH 8.0 + 100 mM NaCl; final concentration in the assay is 170.2 µM.
4. Test compounds

   Compounds are made up to a concentration of 1 mM in 50 mM Tris-HCl buffer, pH 8.0 + 100 mM NaCl or 10% methanol in Tris/NaCl if insoluble in aqueous buffer alone. This will give a final concentration in the assay of 0.1 mM. If inhibition is seen, further dilution in Tris/NaCl should be made.

Enzyme preparation

Lung tissue from 10 rats is diced and homogenized in a blender with 3 pulses of 15 s each. The homogenate is centrifuged at 5 000 *g* for 10 min. The pellet is discarded, the supernatant is dialyzed against three 1 liter changes of 10 mM potassium phosphate buffer, pH 8.3 overnight in the cold and then centrifuged at 40 000 *g* for 20 min. The pellet is discarded, 390 mg $(NH_4)_2SO_4$ is added for each ml of supernatant. This will give 60% saturation. The solution is stirred on ice for 15 min. The pellet formed is dissolved in 15 ml potassium phosphate buffer, pH 8.3 and dialyzed against the same buffer overnight in the cold with three 1 liter changes. Some protein will precipitate during dialysis. The suspension is centrifuged at 40 000 *g* for 20 min and the supernatant is discarded. The final solubilized enzyme preparation can be aliquoted and stored at –20 °C at least 6 months.

Enzyme inhibition studies

1. Enzyme activity is measured with a Perkin Elmer LS-5 Fluorescence Spectrophotometer or equivalent at an excitation wavelength of 357 nm and an emission wavelength of 424 nm.
2. Enzyme assay

   50 µl vehicle or inhibitor solution and 40 µl enzyme are preincubated for 5 min, then 410 µl substrate working solution is added.

   Samples are mixed by drawing fluid back up into the pipette and by pipetting into the cuvette. For the initial control run of the day, the auto zero is pushed immediately after placing the sample in the cuvette.

EVALUATION

The individual fluorescence slope is measured and % inhibition is calculated as follows:

$$\%\ \text{inhibition} = 100 - \frac{\text{slope in presence of inhibitor}}{\text{control slope}} \times 100$$

Inhibitor concentrations on either side of the IC_{50} should be tested to generate a dose-response curve. The IC_{50} is calculated using Litchfield-Wilcoxon log-probit analysis.

Standard data:

- IC_{50} values for inhibition of angiotensin I-converting enzyme

– Compound	IC_{50} [M]
– Captopril	6.9×10^{-9}

MODIFICATIONS OF THE METHOD

Other assays use the cleavage of hippuric acid from tripeptides (Hip-Gly-Gly or Hip-His-Leu) whereby hippuric acid is either tritium labelled or determined spectrophotometrically (Cushman and Cheung 1969, 1971; Friedland and Silverstein 1976; Santos et al. 1985; Hecker et al. 1994).

Bünning (1984) studied the binding and inhibition kinetics of ramipril and ramiprilate (Hoe 498 diacid) with highly purified angiotensin converting enzyme using furanacryloyl-Phe-Gly-Gly as substrate.

The importance of tissue converting enzyme inhibition in addition to inhibition in plasma has been verified in several studies (Unger et al. 1984, 1985; Linz and Schölkens 1987).

A.1.1.13 Quantitative autoradiographic localization of angiotensin-converting enzyme

PURPOSE AND RATIONALE

Cardiac angiotensin converting enzyme can be quantified in tissue, such as in rat hearts with chronic infarction after left coronary ligation, by computerized *in vitro* autoradiography (Kohzuki et al. 1996)

PROCEDURE

Myocardial infarction is induced in Wistar rats by left coronary artery ligation (see A.3.2.2). After various time intervals (1–8 months) the animals are decapitated, the hearts rapidly removed, and snap-frozen in isopentane at –40 °C. Frozen section (20 µm) are cut in a cryostat at –20 °C. The sections are thaw-mounted onto gelatin-coated slides, dried in a desiccator for 2 h at 4 °C and then stored at –80 °C.

Quantitative autoradiography

Radioligand: MK351A is a tyrosyl derivative of lisinopril, a potent competitive inhibitor of ACE. MK351A is iodinated by the chloramine T method and separated free from ^{125}I by SP Sephadex C25 column chromatography.

^{125}I-MK351A binding: The sections are preincubated in 10 mmol/L sodium phosphate buffer, pH 7.4, containing 150 mmol/L NaCl and 2% bovine serum albumin for 15 min at 20 °C. The sections are then incubated with 11.1 KBq/ml ^{125}I-MK351A in the same buffer for 60 min at 20 °C. Nonspecific binding is determined in the presence of 10^{-6} mol/L MK351A or lisinopril. Binding isotherms are determined using a set of serial sections incubated with 10^{-12}–10^{-6} mol/L lisinopril for 60 min.

After incubation, the sections are rapidly dried under a stream of cold air, placed in X-ray cassettes, and exposed to Agfa Scopix CR3 X-ray film for 12–72 h at room temperature. After exposure, the sections are fixed in formaldehyde and stained with haematoxylin and eosin. The optical density of the X-ray films is quantified using an imaging device controlled by a personal computer.

EVALUATION

The optical density of the autoradiographs is calibrated in terms of the radioactivity density in dpm/mm^2 with reference standards maintained through the procedure. The apparent binding site concentration (B_{max}) and binding affinity constant (K_A) in all the areas (excluding coronary arteries) of the right ventricle, intraventricular septum, the infarcted area in the left ventricle and the non-infarcted area in the left ventricle are estimated by an iterative non-linear model-fitting computer program LIGAND (Munson and Rodbard 1980).

A.1.1.14 Angiotensin antagonism

The renin-angiotensin-aldosterone hormonal axis is the major long-term control for regulation of both arterial blood pressure and sodium balance. It supports normotension or hypertension via angiotensin vasoconstriction and angiotensin plus aldosterone-induced renal sodium retention (Laragh 1993).

Volpe et al. (1995) Wagner et al. (1996) showed that regulation of aldosterone biosynthesis by adrenal renin is mediated through AT_1 receptors in renin transgenic rats.

A.1.1.14.1 Angiotensin II receptor binding

PURPOSE AND RATIONALE

Angiotensin II receptor subtypes, AT_1 and AT_2, have been identified by structurally dissimilar antagonists, by different distribution in organs of various species and with specific radioligands (Chiu et al. 1989, 1990, 1992, 1993; Chang and Lotti 1991; Gibson et al. 1991; Chansel et al. 1992; Steckelings et al. 1992; Aiyar et al. 1993; Barnes et al. 1993; Bossé et al. 1993; Bottari et al. 1993; Dzau et al. 1993; Feuillan et al. 1993; van Meel et al. 1993; Alexander et al. 2001). These two types of receptors have been cloned (Sasaki et al. 1991; Murphy et al. 1991; Mukoyama et al. 1993; Kambayashi et al. 1993). Two other mammalian receptors named AT_3 and AT_4 have been described (de Gasparo et al. 1998).

The functional correlates of angiotensin II receptors have been discussed by Timmermans et al. (1992, 1993; Bernstein and Berk 1993). Most effects of angiotensin are mediated via the AT_1 receptors, but a possible role of angiotensin II subtype AT_2 receptors in endothelial cells and isolated ischemic rat hearts has been suggested (Wiemer et al. 1993a,b). Clearance studies in dogs indicated that the angiotensin type 2 receptor may be related to water handling in the kidney (Keiser et al. 1992).

Evidence for AT_1 receptor subtypes (AT_{1A} and AT_{1B}) has been reported (Iwai and Inagami 1992; Kakar et al. 1992; Balmforth et al. 1994; Matsubara et al. 1994; Bauer and Reams 1995; de Gasparo et al. 1998).

The assay described below is used to determine the affinity of test compounds to the angiotensin II receptor by measuring their inhibitory activity on the binding of ^{3}H-angiotensin II to a plasma membrane preparation from rat or bovine adrenal cortex.

PROCEDURE

Fresh bovine adrenal glands are obtained from the local slaughter house. For rat adrenal glands, male Sprague-Dawley rats weighing 250–300 g are sacrificed. The adrenals are separated from fat tissue and the medullae removed. The cortices are minced and homogenized in 5 mM Tris buffer containing 1 mM $MgCl_2$ and 250 mM sucrose, pH 7.4, using a chilled Potter homogenizer. The homogenate is centrifuged at 3 000 *g* and 4 °C for 10 min. The supernatant is recentrifuged at 39 000 *g* and 4 °C for 10 min. The pellets are resuspended in 75 mM Tris buffer containing 25 mM $MgCl_2$, pH 7.4, and recentrifuged twice at 39 000 *g* and 4 °C for 10 min. After the last centrifugation, the pellets are suspended in 75 mM Tris buffer containing 25 mM $MgCl_2$ and 250 mM sucrose, pH 7.4. Samples of 0.5 ml are frozen in liquid nitrogen and stored at –70 °C.

In the competition experiment, 50 µl ^{3}H-angiotensin II (one constant concentration of $0.5–1\times10^{-9}$ M), and 50 µl test compound (6 concentrations, $10^{-5}–10^{-10}$ M) and 100 µl membrane suspension from rat or bovine adrenal cortex (approx. 250 mg wet weight/ml) per sample are incubated in a bath shaker at 25 °C for 60 min. The incubation buffer contains 50 mM HEPES, 0.1 mM EDTA, 100 mM NaCl, 5 mM $MgCl_2$ and 0.2% bovine serum albumin, pH 7.4.

Saturation experiments are performed with 12 concentrations of ^{3}H-angiotensin II ($15–0.007\times10^{-9}$ M). Total binding is determined in the presence of incubation buffer, non-specific binding is determined in the presence of non-labeled angiotensin II (10^{-6} M).

The reaction is stopped by rapid vacuum filtration through glass fiber filters. Thereby the membrane-bound radioactivity is separated from the free one. The retained membrane-bound radioactivity on the filter is measured after addition of 3 ml liquid scintillation cocktail per sample in a liquid scintillation counter.

EVALUATION OF RESULTS

The following parameters are calculated:

- total binding of ^{3}H-angiotensin II
- non-specific binding: binding of ^{3}H-angiotensin II in the presence of mepyramine or doxepine
- specific binding = total binding – non-specific binding
- % inhibition of ^{3}H-angiotensin II binding: 100 – specific binding as percentage of control value

The dissociation constant (K_i) and the IC_{50} value of the test drug are determined from the competition experiment of ^{3}H-angiotensin II versus non-labeled drug by a computer-supported analysis of the binding data (McPherson 1985).

MODIFICATIONS OF THE METHOD

Olins et al. (1993) performed competition studies in rat uterine smooth muscle membranes and rat adrenal cortex membranes using [^{125}I] labeled angiotensin II.

Membranes from cultured rat aortic smooth muscle cells and from human myometrium were used for binding studies with [^{125}I] labeled angiotensin II by Criscone et al. (1993).

Wiener et al. (1993) used membrane preparations from rat lung and adrenal medulla for binding studies with [^{125}I] labeled angiotensin II.

Bradbury et al. (1993) used a guinea pig adrenal membrane preparation to study nonpeptide angiotensin II receptor antagonists.

Cazaubon et al. (1993) prepared purified plasma membranes from rat livers for [^{125}I] AII binding assays.

Kushida et al. (1995) tested AT II receptor binding in particulate fractions of rat mesenteric artery and rat adrenal cortex and medulla with ^{125}I-AT II.

Chang et al. (1995) used rabbit aorta, rat adrenal and human AT_1 receptors in CHO cells and AT_2 receptors from rat adrenal and brain to characterize a nonpeptide angiotensin antagonist.

Aiyar et al. (1995) tested inhibition of [^{125}I]angiotensin II or [^{125}I]angiotensin II (Sar^1,Ile^8) binding in various membrane and cell preparations, such as rat mesenteric artery, rat adrenal cortex, rat aortic smooth muscle cell, human liver, recombinant human AT_1 receptor, bovine cerebellum, and bovine ovary.

Caussade et al. (1995) tested [^{125}I]Sar^1,Ile^8-angiotensin II binding to rat adrenal membranes and rat aortic smooth muscle cells.

Using [^{125}I]Sar^1,Ile^8-angiotensin II as radioligand, de Gasparo and Whitebread (1995) compared the affinity constants of valsartan and losartan in liver and adrenal of rat and marmoset, human adrenal and in rat aortic smooth muscle cells.

Kiyama et al. (1995) used COS cells transfected with a cDNA encoding a human AT_1 angiotensin II receptor to evaluate nonpeptide angiotensin II receptor antagonists.

Mizuno et al. (1995) used bovine adrenal cortical membranes, Nozawa et al. (1997) membrane fractions from rat aorta, bovine cerebellum and human myocardium and [^{125}I]angiotensin II as radioligand.

Renzetti et al. (1995a,b) used membranes from rat adrenal cortex and bovine cerebellum for binding assays with [^{3}H]angiotensin II as radioligand.

Inter-species differences in angiotensin AT_1 receptors were investigated by Kawano et al. (1998).

The angiotensin II receptor subtype having a high affinity for lorsatan has been designated angiotensin AT_1 receptor and the receptor having a high affinity for PD123177 (1-(3-methyl-4-aminophenyl) methyl-5-diphenylacetyl-4,5,6,7-tetrahydro-1H-imidazo[3,5-c]pyridine-6-carboxylic acid) as angiotensin AT_2 receptor (Bumpus et al. 1991; Nozawa et al. 1994; Chang et al. 1995).

In order to determine affinity for the angiotensin AT_1 subtype in a radioligand binding assay with ^{125}I-sarcosine^1, isoleucine^8 angiotensin°II, Chang and Lotti (1991), Chang et al. 1995), Wong et al. (1995) incubated membranes of tissues with both AT_1 and AT_2 receptors in the presence of 1 µM PD121981 (which occupied all the AT_2 binding sites) and for the angiotensin AT_2 subtype in the presence of 1 µM lorsatan (which occupied all the AT_1 binding sites).

Hilditch et al. (1995) used membranes from rat livers and [^{3}H]-AT II for the determination of binding affinity at AT_1 receptors, or membranes from bovine cerebellum and [^{125}I]-Tyr^4-AT II for AT_2 receptors.

Lu et al. (1995) studied the influence of freezing on the binding of ^{125}I-sarcosine^1, isoleucine^8 angiotensin°II to angiotensin°II receptor subtypes in the rat. The results suggested that studies of AII receptor subtypes that involve freezing of the tissue underestimate the density and affinity of the AT_1 receptor subtype.

A.1.1.14.2 Angiotensin II induced contraction in isolated rabbit aorta

PURPOSE AND RATIONALE

The isolated rabbit aorta has been used to evaluate angiotensin II agonists (Liu 1993) and angiotensin II antagonists (Chang et al. 1992, 1994; Noda et al. 1993; Aiyar et al. 1995; Cirillo et al. 1995; Kushida et al. 1995; Mochizuki et al. 1995; Renzetti et al. 1995; Wong et al. 1995; Hong et al. 1998; Kawano et al. 1998).

PROCEDURE

New Zealand White male rabbits weighing 2–3 kg are sacrificed and exsanguinated. The thoracic aorta is removed and cleaned from adherent fat and connective tissue. The vascular endothelium is removed by gently rubbing the intimal surface of the vessel. Spiral aortic strips (2–3 mm wide and 30 mm long) are prepared and mounted in 5 ml organ baths containing Krebs-Henseleit solution (120 mM NaCl, 4.7 mM KCl, 4.7 mM $MgSO_4$, 1.2 mM KH_2PO_4, 2.5 mM $CaCl_2$, 25 mM $NaHCO_3$, glucose 10 mM, pH 7.4). The organ baths are kept at 37 °C and gassed continuously with 95% O_2 / 5% CO_2. Strips are attached to isometric transducers connected to a polygraph and a resting tension of 1 g is applied to each strip. Changes in contraction are analyzed with a digital computer. Aortic strips are allowed to equilibrate for 1 h and washed every 15 min. Two consecutive contractile-response curves to cumulative addition of ATII (0.1–300 mM) are constructed. After each curve the strips are washed 4 times and allowed to relax to the baseline tension. Afterward, each strip is incubated for 30 min with the vehicle or with a single concentration of the antagonist (1 – 10 – 100 – 1 000 mM) before a third concentration-response curve to angiotensin II is obtained.

EVALUATION

The result of each concentration is expressed as a percentage of maximum response to AII. The pA_2 and pD'_2 values are calculated (van Rossum 1963).

MODIFICATIONS OF THE METHOD

Isolated guinea pig aortas were used by Mizuno et al. (1995).

Cirillo et al. (1995) evaluated the antagonism against AII-induced vasoconstriction in rat isolated perfused kidney.

Chang et al. (1992, 1994) determined AII-induced aldosterone release in rat adrenal cells and AII-induced [^{3}H]inositol phosphate accumulation in cultured rat aorta smooth muscle cells.

J Cardiovasc Pharmacol 26:354–362

A.1.1.14.3 Angiotensin II antagonism *in vivo*

PURPOSE AND RATIONALE

The effect of ATII antagonists on blood pressure has been measured in anesthetized (Olins et al. 1993; Beauchamp et al. 1995; Kawano et al. 1998), in pithed (Cazes et al. 1995; Christophe et al. 1995; Cirillo et al. 1995; Deprez et al. 1995; Häuser et al. 1998) and in conscious (Junggren et al. 1996; Nozawa et al. 1997; Shibasaki et al. 1997; Hashimoto et al. 1998) normotensive and hypertensive rats.

PROCEDURE

Male Sprague-Dawley rats are anesthetized with 100 mg/kg i.p. Inactin® and placed on servo-controlled heating pads to maintain body temperature between 37 °C and 38 °C. PE50 catheters are implanted in the femoral artery and vein to measure arterial blood pressure and administer compounds, respectively. A catheter is placed in the trachea to ensure airway patency. Arterial pressure is measured continuously by connecting the arterial catheter to transducer coupled to a Gould pressure transducer. The output is recorded on a polygraph. Mean arterial pressure is derived electronically. After a 30–45 min stabilization period, autonomic transmission is blocked by treatment with mecamylamine (3 mg/kg i.v.) and atropine (0.4 mg/kg i.v.). After arterial pressure has stabilized, angiotensin is infused i.v. in isotonic saline with a syringe pump. When the pressure response to angiotensin has stabilized, angiotensin II antagonists are given in increasing doses. The doses are given intravenously in a cumulative fashion, i.e., the next highest dose is given at the time of maximum response to the prior dose.

EVALUATION

Data are presented as percent inhibition of the angiotensin pressor response to each dose of the antagonists and plotted against the log of the cumulative doses of antagonist. Linear regression is used to calculate the dose at which the response to angiotensin is inhibited 50% (ID_{50}) for each rat. Means ±SEM are calculated.

MODIFICATIONS OF THE METHOD

Olins et al. (1993), Cirillo et al. (1995) determined also the antihypertensive effects in conscious spontaneously hypertensive rats and in conscious sodium-deficient dogs.

Stasch et al. (1997) studied the long-term blockade of the angiotensin II receptor in renin trangenic rats, salt-loaded Dahl rats, and stroke-prone spontaneously hypertensive rats.

Nishioka et al. (1998), Richter et al. (1998) used the (mRen-2)27 transgenic (Tg^+) rat, a hypertensive model dependent on increased expression of the renin angiotensin system, to explore the role of angiotensin AT_2 receptors in the control of cardiovascular and renal excretory function.

Simoes e Silva et al. (1998) evaluated the effects of chronic administration of an angiotensin antagonist on diuresis and natriuresis in normotensive and spontaneously hypertensive rats.

Kai et al. (1998) examined the effects of an angiotensin II type 1 antagonist on cardiac hypertrophy and nephropathy using Tsukuba hypertensive mice (THM) carrying both human renin and angiotensinogen genes.

Kivlighn et al. (1995a,b), Gabel et al. (1995), studied angiotensin II antagonists in conscious rats, dogs, rhesus monkeys and chimpancees.

Keiser et al. (1995) studied arterial blood pressure in conscious renal hypertensive rats, conscious sodium-depleted dogs, conscious sodium-depleted monkeys and conscious renal hypertensive monkeys.

Kim et al. (1997) examined the effects of an angiotensin AT_1 receptor antagonist on volume overload-induced cardiac gene expression in rats. Cardiac volume overload was prepared by abdominal aortocaval shunt. Cardiac tissue mRNA was measured by Northern blot analysis with specific probes.

Yamamoto et al. (1997), Ogilvie et al. (1998), studied angiotensin II receptor antagonists in acute heart failure induced by coronary artery ligation in anesthetized dogs and in chronic heart failure induced by left ventricular rapid-pacing in conscious dogs.

Massart et al. (1998) evaluated the cumulative hypotensive effects of angiotensin II- and endothelin-1-receptor antagonists in a model renovascular hypertension in dogs.

Hayashi et al. (1997) examined the hemodynamic effects of an angiotensin II type 1 receptor antagonist in rats with myocardial infarction induced by coronary ligation.

Kivlighn et al. (1995c) studied the effects of a nonpeptide that mimics the biological actions of angiotensin II in anesthetized rats.

Huckle et al. (1996) evaluated angiotensin II receptor antagonists for their ability to inhibit vascular intimal thickening in a porcine coronary artery model of vascular injury.

A.1.1.15
Renin-inhibitory activity using human kidney renin and a synthetic substrate

PURPOSE AND RATIONALE

In contrast to other enzymes, renin shows a rather high species specificity. To be relevant for humans human renin has to be used. One of the reasons that human renin is specific for human angiotensinogen lies in the sequence of human angiotensinogen itself. Inhibition of renin is measured by angiotensinogen formed in the presence of angiotensinase inhibitors. The following procedure is used to determine the effect of potential renin inhibitors on purified human kidney renin without interference from plasma proteins or lipids.

PROCEDURE

The synthetic substrate represents the first fourteen amino acids of the N-terminus of human angiotensinogen: Asp-Arg-Val-Tyr-Ile-His-Pro-Phe-His-Leu-Val-Ile-His-Asn. The assay mixture is composed of phosphate buffer (pH 7.5), bovine serum albumin, 3 mM EDTA, 0.01 mM phenylmethyl-sulfonyl fluoride (PMSF), 0.002% Genapol PF 10®, test compound (dissolved in DMSO), substrate (3 µM) and purified human kidney renin (Calbiochem GmbH, Frankfurt/M., Germany; cat. no. 553861). The mixture is incubated for two hours at 37 °C. Then the reaction is stopped by transfer of 450 µl into preheated (95 °C) Eppendorf® tubes. The amount of angiotensin I liberated is measured by RIA (Renin MAIA® kit, Serono Diagnostika GmbH, Freiburg, Germany).

Human angiotensinogen (0.2 µM) may be used as a substrate instead of the tetradekapeptide. The pH value of the incubation mixture may be lowered to 6.0 by using a maleic acid buffer; this results in higher renin activity. HEPES (N-2-hydroxyethylpiperazine-N'-2-ethane sulfonic acid) may be substituted for phosphate in the pH 7.5 buffer.

EVALUATION

Renin activity, i.e. angiotensin I production (ng/ml × 2 h), is corrected for an angiotensin I – like immunoreactivity which can be measured in the assay samples even in the absence of added renin. IC_{50} values are determined from a plot of renin activity (as per cent of control) vs. molar concentration of the test compound.

MODIFICATIONS OF THE METHOD

Wang et al. (1993) described a continuous fluorescence assay of renin activity employing a new fluorigenic peptide substrate.

Inhibition of plasma renin activity in blood samples from various species can be determined in order to evaluate the species specificity of a renin inhibitor (Linz et al. 1994)

Blood samples are obtained from dogs, sheep and rhesus monkeys by venipuncture. Wistar rats and guinea pigs are anesthetized with Nembutal® (60 mg/kg intraperitoneally) and the blood is collected by puncture of the abdominal aorta. Human blood is collected from volunteers (Donafix blood collecting set, Braun Melsungen AG, Melsungen, FR Germany) in cooled bottles. All blood samples are anticoagulated with Na-EDTA (final concentration 10–15 mM). The renin is dissolved in DMSO as 10^{-2} M stock solution and diluted before each experiment in DMSO. The endogenous formation of ANG I in plasma during incubation at 37 °C is determined as the measure of renin activity. Generation and quantitation of ANG I are performed using a commercial radio immunoassay kit (Renin-MAIA®, Serono Diagnostika GmbH, Freiburg, FR Germany). Plasma samples are thawed on ice and centrifuged after addition of 100 µl PMSF solution (kit) per 10 ml. The assay mixture contains 450 µl plasma plus 1% (v/v) PMSF solution, 45 µl buffer (phosphate buffer, pH = 7.4, + 10^{-5} M ramiprilate) and 5 µl renin inhibitor solution (diluted in DMSO as required) or pure DMSO for controls. The assay is incubated for an appropriate time (2–3 hours) at 37 °C. ANG I is measured in 100 µl samples (triplicate determinations). Basal ANG I immunoreactivity of the plasma is determined from an unincubated control assay (0 °C). This pre-incubation value is subtracted from all measurements. The renin activity in the presence of the renin inhibitor is calculated as percent activity in relation to control samples containing only DMSO. The IC_{50} value is determined from a semilogarithmic plot of percent renin activity versus concentration of the renin inhibitor.

Wood et al. (1990) determined the activity of a synthetic renin inhibitor against rat, mouse, dog, guinea pig, rabbit, cat, marmoset and human renin using plasma pools from these species. Plasma from each species was collected using EDTA as an anticoagulant. Samples of plasma were incubated at 37 °C in the presence or absence of varying concentrations of test compound. The ANG I formed was measured by radioimmunoassay.

Shibasaki et al. (1991) used squirrel monkeys to study the *in vivo* activity of a specific renin inhibitor after intravenous and oral application.

Bohlender et al. (1996) reconstructed the human renin-angiotensin system in transgenic rats overexpressing the human angiotensin gene TGR(hOGEN) 1623 by chronically injecting human recombinant renin intravenously using Alzet pumps.

Salimbeni et al. (1996) tested the *in vitro* inhibition of human plasma renin activity by two synthetic angiotensinogen transition state analogues.

A.1.1.16 PAF binding assay

PRINCIPLE AND RATIONALE

Injection of platelet activating (PAF) factor induces a wide range of potent and specific effects on target cells, including aggregation of platelets and shock symptoms like systemic hypotension, pulmonary hypertension, increased vascular permeability, neutropenia and thrombocytopenia. Inhalation of PAF causes immediate bronchoconstriction followed by inflammation of the airways (further information see Sect. B.1.9).

The PAF receptor belongs to the superfamily of G protein-coupled receptors (Chao and Olson 1993, Izumi and Shimizu 1995). Cloning studies have indicated a single human PAF receptor gene containing an intron at the 5' flanking region, providing alternative sequences (Ishi and Shimizu 2000).

The following procedure is used to detect compounds that inhibit binding of ^{3}H-PAF (platelet activating factor) in rabbit platelets (PAF receptor).

PROCEDURE

Crude rabbit platelets are incubated in plastic tubes for 15 min at 25 °C in a buffer solution (0.54 g/l KH_2PO_4, 0.6 g/l Na_2HPO_4, 5.8 g/l NaCl, 1.0 g/l BSA, pH 7.1) with 1 nM synthetic ^{3}H-labeled PAF (1-*O*-[1,2-$^3H_2$]alkyl-2-*O*-acetyl-*sn*-glycero-3-phosphocholine) and various concentrations of test compound. Non-specific binding is determined in the presence of 10 µM CV 3988. Bound ligand is separated from the incubation medium by rapid filtration through Whatman GF/C glass fibre filters. Following rinsing with ice-cold buffer (3 × 5 ml), the filters are placed in 10 ml scintillation cocktail for radioactivity determination.

EVALUATION

The following parameters are calculated:

- total binding of ^{3}H-PAF
- non-specific binding in the presence of 10 µM CV 3988
- specific binding = total binding – non-specific binding
- % inhibition: 100 – specific binding as percentage of the control value

Compounds are first tested at a single high concentration (5 000 nM) in triplicate. For those showing more than 50% inhibition a displacement curve is constructed using 7 different concentrations of test compound. Binding potency of compounds is expressed either as a "relative binding affinity" (RBA) with respect to the standard compound (CV 3988) which is tested in parallel or as an IC_{50}.

$$RBA = \frac{IC_{50}\ \text{standard compound}}{IC_{50}\ \text{compound}} \times 100\%$$

Standard data:

- CV 3988 IC_{50}: 276 nM ±24 ($n = 20$)

MODIFICATIONS OF THE METHOD

Several authors (Casals-Stenzel et al. 1987; Dent et al. 1989a,b; Ring et al. 1992; Ukena et al. 1988) used the specific platelet activating factor receptor antagonist [^{3}H]WEB-2086 or [^{3}H]Apafant to identify and characterize the PAF-receptors expressed on the cell surface of platelets, macrophages, and eosinophils.

Balsa et al. (1996) characterized [^{3}H]Apafant binding to the PAF receptor on rabbit platelet membranes and compared a microplate filtration system with the standard method.

A.1.1.17 Endothelin

A.1.1.17.1 General considerations

Endothelin is a endothelium-derived peptide family consisting of three peptides (ET-1, ET-2, and ET-3) with very potent and long-lasting vasoconstrictive activity (Yanagisawa et al. 1988a,b; King et al. 1989; Miller et al. 1989; Yanagisawa and Masaki 1989; Inoue et al. 1989; Shinmi et al. 1989; Vanhoutte et al. 1992).

ET-1 is processed from prepro ET-1, pro-ET-1 to big ET-1, which is converted to ET-1 by the endothelin-converting-enzyme (ECE).

Subtypes of endothelin receptors have been described (Takayanagi et al. 1991; Miyazaki et al. 1992).

Molecular characterization of the ET_A and ET_B receptors was reported by Miyazaki et al. (1992), Sakuarai et al. (1992).

In addition, the existence of a third type, ET_C, was found in *Xenopus laevis* (Karne et al. 1993).

The comparison of recombinant endothelin receptors shows different affinity rank orders to the three endothelins (Masaki et al. 1994).

Grant et al. (1997) reported the *in vitro* expression of endothelin-1 (ET-1) and the ET_A and ET_B ET receptors by prostatic epithelium and stroma.

The ET peptides not only elicit potent and long-lasting contractions of isolated strips of various blood vessels *in vitro* but also increase blood pressure *in vivo* suggesting that this peptide family may be involved in the pathogenesis of cardiovascular diseases (Simonson and Dunn 1990; Masaki 1991; Doherty 1992; Goto et al. 1996; Gray and Webb 1996; Douglas and Ohlstein 1997).

A.1.1.17.2 Evaluation of endothelin activity

PURPOSE AND RATIONALE

Most investigators used isolated arteries to evaluate the activity of endothelins and derivatives. Rodman et al. (1989) compared the potency and efficacy of porcine and rat endothelin in rat aortic and pulmonary rings.

PROCEDURE

Arterial rings are obtained from male Sprague Dawley rats weighing from 300–400 g. Rats are anesthetized with 50 mg/kg i.p. pentobarbital, the chest is opened, 100 units heparin sulfate are injected into the right ventricle, and the rats are exsanguinated. Rings are then isolated from either the descending thoracic aorta or the right main pulmonary artery, cleaned of adventitia, and suspended from Grass FT03 force-displacement transducers in muscle baths containing 10 ml of physiologic salt solution of the following composition ($\times 10^{-3}$ M): $CaCl_2$ 1.80, $MgSO_4$ 0.83, KCl 5.3.6, NaCl 116.34, NaH_2PO_4 0.40, D-glucose 5.50, and $NaHCO_3$ 10.04. The solution is maintained at 37 °C and bubbled with 21% O_2 and 5% CO_2. Endothelium-denuded rings are prepared by gently rubbing the intima with a roughened steel rod. Denudation is confirmed by the absence of relaxation to 10^{-5} M acetylcholine in rings precontracted with 10^{-7} M norepinephrine. Resting force is adjusted to the optimum resting tension of 0.75 g for pulmonary artery rings and 1.0 g for aortic rings. Maximum contraction to 8×10^{-2} M KCl is determined and subsequent responses to endothelin are expressed as a percentage of maximum KCl contraction for determination of maximum effectiveness or as a percentage of maximum endothelin contraction for determination of potency.

EVALUATION

Concentration-response curves are compared using the method of Carpenter (1986). Data are expressed as means ±SEM and statistical comparisons are performed using Student's *t*-test, with $P < 0.05$ considered significant.

MODIFICATIONS OF THE METHOD

Lembeck et al. (1989) studied the effects of endothelin on the cardiovascular system and on smooth muscle preparations in different species.

Reynolds and Mok (1990) studied the role of thromboxane A_2/prostaglandin H_2 receptor in the vasoconstrictor response of **rat aorta** to endothelin.

Pang et al. (1990) studied the cellular mechanisms of action of endothelin in **isolated canine coronary arteries**.

Lüscher et al. (1992) used **perfused and pressurized mesenteric resistance arteries of rats** and **human internal mammary arteries** to study the interaction between endothelin and endothelium-derived relaxing factors.

Advenier et al. (1990) studied the contractile activity of three endothelins (ET-1, ET-2 and ET-3) on the **human isolated bronchus**.

Wallace et al. (1989) compared the effects of endothelin-1 and endothelin-3 on the **rat stomach**.

Aldosterone secretion in cultured calf zona glomerulosa cells was stimulated by ET-1 and sarafotoxin S6b to a similar degree, but less than by angiotensin II (Gomez-Sanchez 1990).

Brock and Danthuluri (1992) used **cultured vascular smooth muscle cells** to study the cellular actions of endothelin.

Pigment dispersion in cultured dermal melanophores from *Xenopus laevis* was used as indicator of ET_C receptor mediated responses (Karne et al. 1993).

A.1.1.17.3 Endothelin receptor antagonism *in vitro*

PURPOSE AND RATIONALE

Competitive endothelin antagonists are of therapeutic interest (Ihara et al. 1991; Fujimoto et al. 1992; Fukuroda et al. 1992; Urade et al. 1992; Breu et al. 1993; Mihara and Fujimoto 1993; Sogabe et al. 1993; Warner 1994; Opgenorth 1995; Brunner 1998).

A sensitive sandwich-enzyme immunoassay for human endothelin has been established by Suzuki et al. (1989).

PROCEDURE

The ventricles of rat hearts are minced with scissors and homogenized in 7 vol of ice-cold 20 mM $NaHCO_3$ containing 0.1 mM PMSF (Phenylmethylsulfonyl fluoride), pH 7.4, with a Polytron homogenizer (Brinkman Instruments Inc., Westberg, NY). The homogenates are centrifuged at 1 000 *g* for 10 min, and then the pellet discarded. The supernatant is centrifuged at 30 000 *g* for 30 min. The pellet is washed once and resuspended in Tris buffer (50 mM, pH 7.4 at 25 °C) containing 0.1 mM PMSF, and stored at –80 °C until use.

For binding studies (Gu et al. 1989) cardiac membranes (0.21 mg/ml as protein) are incubated with 25 pM [^{125}I]ET-1 or [^{125}I]ET-3 (New England Nuclear) in a final assay volume of 0.1 ml in borosilicated glass tubes, containing 50 mM Tris-HCl, 0.1 mM PMSF, 10 µg/ml aprotinin, 10 µg/ml leupeptin, 10 µg/ml pepstatin A, 250 µg/ml bacitracin, and 10 µg/ml soybean trypsin inhibitor (pH 7.4). Binding is performed for 60 min at 37 °C. The binding reaction is terminated by the addition of 2.5 ml of ice-cold 50 mM Tris-HCl (pH 7.4), followed by a rapid filtration through a Whatman GF/C glass fibre filter (pre-soaked in 1% polyethylene-imine) under reduced pressure. The filters are then quickly washed 4 times with 2.5 ml of the buffer. Radioactivity retained on the filter is counted.

EVALUATION

Non-specific binding is defined in the presence of ET-1. Specific binding is the difference between total and non-specific binding. K_i-values and Scatchard plots are calculated.

MODIFICATIONS OF THE METHOD

The nomenclature of endothelin receptors has been reviewed by Alexander et al. (2001).

Functional endothelin/sarafotoxin receptors were described in rat heart myocytes (Galron et al. 1989) and in the rat uterus (Bousso-Mittler 1989).

Mihara and Fujimoto (1993) cultured rat aortic smooth muscle A7r5 cells expressing ET_A receptors (Takuwa et al. 1990) and human Girardi heart cells ex-pressing ET_B receptors (Mihara and Fujimoto 1992). Receptor specificity could be demonstrated.

Aramori et al. (1993) studied the receptor-binding properties and the antagonistic activities of an endothelin antagonist in transfected Chinese ovary hamster cells permanently expressing the two ET receptor subtypes (ET_A and ET_B).

De Juan et al. (1993) characterized an endothelin receptor subtype B in the retina of rats.

Clozel et al. (1994) performed binding assay on cells or membranes from baculovirus infected insect cells that expressed recombinant ET_A or ET_B receptor, CHO cells that expressed recombinant ET_A or ET_B receptor, cultured human vascular smooth muscle cells from umbilical veins, rat mesangial cells (for ET_A), microsomal membranes from human placenta and from porcine cerebellum (for ET_{B1}) and from porcine trachea (for ET_{B2}, using BQ-3020 or sarafotoxin S6C as ligand).

Williams et al. (1995) used CHO cells expressing cloned ET_A or ET_B receptors directly in binding and functional assays without preparing membranes from them.

Reynolds et al. (1995) used CHO-K1 cells expressing recombinant human ET_B receptor, Ltk^- cells expressing human ET_A receptor and rabbit renal artery vascular smooth muscle cells expressing rabbit ET_A receptor for evaluation of an ET_A receptor antagonist.

Rat or bovine cerebella were used for differentiation of receptor subtypes (Williams et al. 1991).

Peter and Davenport (1995) proposed a selective ligand for ET_A receptors.

Ihara et al. (1992), Watakabe et al. (1992) described radioligands for endothelin (ET_B) receptors.

Vigne et al. (1996) described the properties of an endothelin-3-sensitive eta-like endothelin receptor in brain capillary endothelial cells.

Stables et al. (1997) described a bioluminescent assay for agonist activity at G-protein-coupled receptors, such as the endothelin ET_A receptor. Transient expression of apoaequorin in CHO cells and reconstitution with the cofactor coelenterazine resulted in a large, concentration dependent agonist-mediated luminescent response following cotransfection with the endothelin ET_A, angiotensin AT_{II}, TRH and neurokinin NK_1 receptors, all of which interact predominantly with the $G\alpha_q$-like phosphoinositidase-linked G-proteins.

A.1.1.17.4 Endothelin receptor antagonism *in vivo*

PURPOSE AND RATIONALE

Various pharmacological models have been used for the characterization of endothelins and endothelin antagonists, such as the isolated porcine coronary artery. (Hickey et al. 1985; Yanagisawa et al. 1988, 1989; Inoue et al. 1989; Kimura et al. 1989; Ihara et al. 1991; Fukuroda et al. 1991).

Since the smooth musculature is considered to contain mainly ET_A receptors the preparation is used to test ET_A antagonists.

PROCEDURE

Left anterior descending coronary arteries are isolated from fresh porcine hearts. Connective tissues and adherent fat are removed. For removal of vascular endothelium, the intimal surface of spiral strips is rubbed gently with filter paper. The endothelium-denuded arteries are

cut into spiral strips about 10 mm long and 1 mm wide. Each strip is suspended in an organ bath containing Krebs-Henseleit solution bubbled with 95% O_2 / 5% CO_2 at 37 °C. After equilibration, reference contraction is isometrically obtained with 50 mM KCl. Concentration-response curves for ET-1 are obtained by cumulative additions of ET-1. Antagonists are added 20 min before the cumulative additions of ET-1.

EVALUATION

The pA_2 values and slopes are obtained by analysis of Schild plots.

MODIFICATIONS OF THE METHOD

Calo et al. (1996) investigated three **rabbit vessels, the carotid, the pulmonary artery, and the jugular vein** to identify vascular monoreceptor systems, either ET(A) or ET(B), for structure-activity studies of endothelins and their antagonists.

Vedernikov et al. (1993) used **rings of the left circumflex coronary artery** from **dogs** which were denuded of endothelium and exposed to anoxic periods, Urade et al. (1992) **rat aortic smooth muscle denuded of the epithelium** and Sogabe et al. (1993) **spirally cut strips of rabbit aorta**.

Williams et al. (1995) used **rat aorta, rabbit iliac and pulmonary artery** for contractile assays, and **anesthetized ferrets and conscious normotensive dogs** as *in vivo* models to characterize a nonpeptidyl endothelin antagonist.

Itoh et al. (1993) studied the preventive effect of an ET_A receptor antagonist on **experimental cerebral vasospasm in dogs** using a two-hemorrhage model of subarachnoid hemorrhage. Clozel et al. (1993) performed similar experiments in rats.

The **vasodilating** effect in the **isolated perfused rat mesentery** which is found after infusion of rat endothelin (Warner et al. 1989) and after the selective ET_B receptor agonist sarafotoxin S6c (Williams et al. 1991) can be antagonized by an endothelin receptor antagonist (Clozel et al. 1993).

Ercan et al. (1996) found an increase of digoxin-induced ectopic ventricular complexes by endothelin peptides in **isolated guinea pig hearts**, which could be antagonized by an endothelin-A receptor antagonist.

The **endothelin-induced sustained increase of blood pressure** in anesthetized rats was studied by Yanagisawa et al. (1988), Inoue et al. (1989), Ihara et al. (1991). Intravenous bolus injection of endothelin causes a bi-phasic blood pressure response: a transient decrease, probably mediated from the release of vasodilator mediators (prostacyclin and EDRF), and a sustained increase (Rubanyi and Bothelho 1991).

Nishikibe et al. (1993) examined the **antihypertensive effect** of an endothelin antagonist in a genetic hypertensive model (**stroke-prone spontaneously hypertensive rats**).

Watanabe et al. (1995) characterized the pharmacological profile of a non-selective endothelin receptor antagonist and studied the **inhibition of myocardial infarct size** in rats.

The contractile activity of the **isolated guinea pig trachea without epithelium** and of the guinea pig longi-tudinal muscle was used by Urade et al. (1992) for determination of **ET_B receptor** mediated responses.

Spinella et al. (1991) assessed bioactivity of a specific endothelin-1 antagonist in an **isolated perfused guinea pig lung** preparation in which pulmonary artery pressure was monitored.

A.1.1.17.5 Quantitative autoradiographic localization of endothelin-1 receptor

PURPOSE AND RATIONALE

The endothelin-1 (ET-1) receptor can be quantified in tissue, such as in rat hearts with chronic infarction after left coronary ligation, by computerized *in vitro* autoradiography (Kohzuki et al. 1996)

PROCEDURE

Myocardial infarction is induced in Wistar rats by left coronary artery ligation (see A.3.2.2). After various time intervals (1–8 months) the animals are decapitated, the hearts rapidly removed, and snap-frozen in isopentane at –40 °C. Frozen section (20 µm) are cut in a cryostat at –20 °C. The sections are thaw-mounted onto gelatin-coated slides, dried in a desiccator for 2 h at 4 °C and then stored at –80 °C.

Quantitative autoradiography

Radioligand: Endothelin-1 is iodinated with ^{125}Iodine using Iodogen (Pierce Chemical Co, IL, USA)

^{125}I-ET-1 binding: The sections are preincubated for 15 min at 20 °C in 20 mmol/L Hepes buffer, pH 7.4, containing 135 mmol/L NaCl, 2 mmol/L $CaCl_2$, 0.2% BSA, and 0.01% bacitracin. The sections are then incubated with 11.1 KBq/ml ^{125}I-ET-1 in the same buffer for 60 min at 20 °C. Nonspecific binding is determined in the presence of 10^{-6} mol/L ET-1. Binding isotherms are determined using a set of serial sections incubated with 10^{-12} to 10^{-6} mol/L unlabelled ET-1 for 60 min.

After incubation, the sections are rapidly dried under a stream of cold air, placed in X-ray cassettes, and exposed to Agfa Scopix CR3 X-ray film for 12–72 h at room temperature. After exposure, the sections are fixed in formaldehyde and stained with hematoxylin and eosin. The optical density of the X-ray films is quantified using an imaging device controlled by a personal computer.

EVALUATION

The optical density of the autoradiographs is calibrated in terms of the radioactivity density in dpm/mm^2 with reference standards maintained through the procedure. The apparent binding site concentration (B_{max}) and binding affinity constant (K_A) in all the areas (excluding coronary arteries) of the right ventricle, intraventricular septum, the infarcted area in the left ventricle and the non-infarcted area in the left ventricle are estimated by an iterative non-linear model-fitting computer program LIGAND (Munson and Rodbard 1980).

A.1.1.17.6 Inhibition of endothelin converting enzyme

PURPOSE AND RATIONALE

Endothelin converting enzyme inhibitors suppress the biosynthesis of endothelin are therefore potential an-

tihypertensive drugs (De Lombaert et al. 1994; Trapani et al. 1995; Morita et al. 1994; Bihovsky et al. 1995; Claing et al. 1995; Descombes et al. 1995; Chackalamannil et al. 1996; Jeng 1997; Jeng and De Lombaert 1997; Brunner 1998).

Purification of rat and porcine endothelin converting enzyme (ECE) was reported by Ohmaka et al. (1993), Takahashi et al. 1993). Molecular cloning and characterization of the enzyme ECE-1 was performed from rat (Shimada et al. 1994), bovine (Ikura et al. 1994; Schmidt et al. 1994; Xu et al. 1994), and human tissue (Schmidt et al. 1994; Shimada et al. 1995; Yorimitsu et al. 1995).

A second enzyme, termed ECE-2, was cloned (Emoto and Yanagisawa 1995).

Walkden and Turner (1995) described the expression of endothelin converting enzyme and related membrane peptidases, e.g., the endopeptidase E-24.11, in the human endothelial cell line EA.hy926.

IN VITRO ASSAY

A rapid and selective *in vitro* assay for endothelin-converting enzyme was described by Fawzi et al. (1994). The assay is based on the quantitative determination of [^{125}I]endothelin-1 released from (3-[^{125}I]iodotyrosyl^{13})big endothelin-1 by binding to the membrane bound endothelin receptor.

PROCEDURE

For the **preparation of lung membranes**, frozen guinea pig lungs are weighed and homogenized in 10 times gram tissue weight of solution A (50 mM Tris-HCl, pH 7.4, 025 M sucrose, and 2 mM EDTA) using a Polytron tissue homogenizer. Homogenization is repeated 4 times with 5- to 8-min intervals between homogenization. Homogenates are spun for 30 min at 2000 *g*. Supernatants containing membranes are carefully decanted and saved. Pellets are rehomogenized in solution A and homogenates are spun at 2000 *g* for 30 min. Supernatants are removed, mixed with supernatants from the first spin and spun at 100 000 *g* for 60 min. Pellets containing membranes are suspended in solution B (10 mM Tris-HCl, pH 7.4, and 0.125 M sucrose) using a Dounce homogenizer. Samples are divided into 1-ml fractions, rapidly frozen in a dry ice-methanol bath, and stored at −80 °C.

Rat liver membranes are prepared with the same method and further purified over a sucrose step gradient. The membranes are suspended in solution C (10 mM Tris-HCl, pH 7.4) containing 44% sucrose at a protein concentration of 2 mg/ml. Samples of 25 ml are placed in ultraclear centrifuge tubes for the Beckman SW 28 rotor, overlaid with 10 ml solution C containing 42.3% sucrose, and spun for 2 h at 27 000 rpm (100 000 *g*). Top layers containing membrane are collected and diluted with solution C to obtain an 8% sucrose concentration. Samples are spun in a 45 Ti rotor (100 000 *g*) for 1 h. Supernatants are discarded. Pellets containing membrane are suspended in solution B, divided into 1-ml samples, rapidly frozen in dry ice-methanol bath, and stored at −80 °C.

For the **endothelin (ET) binding assay**, membrane preparations are incubated with selected concentrations of [^{125}I]endothelin-1 (final reaction volume = 500 µl) in a solution D containing 60 mM Tris-HCl, pH 7.4, 150 mM NaCl and 6 mg/ml BSA for 90 min at 37 °C. Reactions are terminated by the addition of 4 ml of solution E containing 10 mM Tris-HCl, pH 7.4, and 150 mM NaCl at 4 °C followed by rapid filtration on Whatman GF/B glass microfiber filters. Filters are presoaked for 1 h at 4 °C in a solution containing 50 mM Tris-HCl, pH 7.4, 10 mg/ml BSA and 0.1% sodium azide. Test tubes and filters are washed four times with 4 ml of solution E at 4 °C, and radioactivity retained on the filters is counted in a gamma counter. Nonspecific binding is determined in the presence of 1 µM unlabeled ET-1 in the reaction mixture.

For the **endothelin converting enzyme assay**, samples containing 10 µg of protein are incubated in a solution containing 50 mM Tris-HCl, pH 7.0, 100 mM NaCl and 5 mg/ml BSA in a final volume of 100 µl. Conversion reactions are initiated by addition of [^{125}I]big endothelin-1 to obtain a final concentration of 500 pM. Samples are incubated for 2 h at 37 °C. To measure [^{125}I]endothelin-1 released from [^{125}I]big endothelin-1 conversion, 50 µg of purified rat liver membranes (as a source of ET receptors) is added to the reaction mixture, and reaction volume is adjusted to 500 µl and solution composition is adjusted to that of solution D of the endothelin binding assay. Following a 90-min incubation at 37 °C to reach equilibrium in binding, reactions are terminated by addition of a solution E at 4 °C followed by rapid filtration on Whatman GF/B glass microfiber filters. Nonspecific binding is determined in the presence of 1 µM unlabeled ET-1 in the reaction mixture. Specific ET-1 binding is used as an index of endothelin converting enzyme activity.

To test the effect of endothelin converting enzyme inhibitors, endothelin converting enzyme assays are carried out in the presence of desired concentrations of the compounds.

EVALUATION

Endothelin converting enzyme activity in the presence of compounds is expressed as a percentage of control endothelin converting enzyme activity in the membrane preparation which is determined simultaneously. The concentration of compounds producing a 50% inhibi-

tion of endothelin converting enzyme activity (IC_{50} values) is determined from a plot of the percentage of control endothelin converting enzyme activity versus log concentration of compounds.

IN VIVO ASSAY

PROCEDURE

Male Sprague Dawley rats weighing 300–400 g are anesthetized with ether, spinalized and placed under artificial respiration. The vagus nerves are cut and the carotid arteries ligated. A catheter is placed in one of the carotid arteries to allow measurement of arterial blood pressure. The second catheter in placed into the penile vein to allow infusion or injection of drugs. After stabilization, the animals receive a first injection of either ET-1, big ET-1, norepinephrine, angiotensin I or AT II, The pressor responses are recorded and after return to the baseline, a second injection of the agonist is given either in the presence or the absence of the inhibitor.

EVALUATION

Data are calculated as mean ±SEM. Student's *t*-test for paired and unpaired observations is used to analyze the results.

MODIFICATIONS OF THE METHOD

Little et al. (1994) developed a two-step protocol for high-throughput assays of endothelin converting enzyme activity. Human umbilical vein and human aorta endothelial cells were found to preferentially convert the big endothelin-1 isopeptide through a membrane-bound, thiorphan-insensitive, and phophoramidon-sensitive zinc metalloendopeptidase. Endothelins are quantified by a separate step using either enzyme immunoassays or radioceptor assays in 96-well formats. The method can be used to either characterize ECE from different tissues or screen for inhibitors of a specific ECE activity.

McMahon et al. (1993) tested the effects of endothelin converting enzyme inhibitors and endothelin receptor subtype A antagonists on blood pressure in spontaneously and renal hypertensive rats.

Changes of vascular resistance in isolated perfused kidneys were used by Descombes et al. (1995) to characterize a selective inhibitor of big ET-1 responses. The studies were performed on kidneys taken from adult male Wistar rats (300–400 g). The rats were anesthetized with sodium pentobarbital (50 mg/kg i.p.) and the left kidney was prepared for infusion with Tyrode solution. The changes in renal vascular resistance were recorded as changes in perfusion pressure monitored at constant flow (6 ml/min). After stabilization, a bolus injection of ET-1 or big ET-1 was administered and the resulting pressure responses were recorded. On return to baseline levels, a second injection of the endothelins was given either under control conditions or in presence of the putative enzyme inhibitor.

Because increasing evidence implicates that endothelin plays a role in the pathophysiology of cerebral insults, Kwan et al. (1997) studied the prevention and reversal of cerebral vasospasm in an experimental model of subarachnoid hemorrhage. Three ml of arterial blood was withdrawn from the ear artery of rabbits and injected into the cisterna magna under anesthesia. Drugs were administered either before or 24 h after this procedure. Forty-eight hours later, the animals were anesthetized again and perfusion fixation was performed with Hank's balanced salt solution followed by a mixture with 2% paraformaldehyde and 2.5% glutaraldehyde. Cross sections of the basilar arteries were analyzed by computer-assisted morphometry.

A review on the knowledge of molecular pharmacology of endothelin converting enzymes was given by Turner and Murphy (1996).

A.1.1.18
Nitric oxide

A.1.1.18.1
General considerations on nitric oxide

PURPOSE AND RATIONALE

The endothelium releases a labile, diffusable vasorelaxing substance that has been termed endothelium-derived relaxing factor = EDRF. (Furchgott and Zawadszki 1980). Nitric oxide release accounts for the biological activity of endothelium-derived relaxing factor (Palmer et al. 1987).

Nitric oxide plays a role in a wide range of physiological processes including regulation of blood flow and arterial pressure via endothelium-dependent relaxation of blood vessels (Rees et al. 1989; Moncada et al. 1991; Umans and Levi 1995), peripheral nitregric transmission at smooth muscle (Rand and Li 1995), intracellular communication in the CNS with activation of guanylyl cyclase in target neurons (Southam and Garthwaite 1993), in neurogenic inflammation (Kajekar et al. 1995), and macrophage defense mechanisms following exposure to bacterial products (Förstermann et al. 1992; Förstermann and Kleinert 1995; Knowles and Moncada 1994). NO-donor drugs, such as sodium nitrite, sodium nitroprusside, S-nitroso-N-acetyl-D,L-penicillamine (SNAP), 3-morpholinosydnonimine (SIN-1) are used as vasodilators (Schör et al. 1989). N^G-Nitro-L-arginine was described as an antagonist of endothelium-dependent dilator responses by inhibiting endothelium-derived relaxing factor release (Moore et al. 1990; Lamontagne et al. 1991). Ribero et al. (1992) proposed inhibition of nitric oxide synthesis by long-term treatment of rats with nitro-L-arginine as a new model of arterial hypertension.

Excessive production of NO damages DNA and activates poly(ADP-ribose)polymerase (PARP) (Pieper et al. 1999). In cases of massive NO production, neurons enter the PARP-suicide pathway. NO damages DNA via to major pathways: the first involves nitrosation of primary or secondary amines and nucleic acid bases, whereas the second involves the combination of NO with superoxide to from peroxinitrite (Szabó et al. 1996, 1997). The most likely reactive oxidant intermediate responsible for DNA breakage is peroxynitrous acid which rapidly oxidizes sulphydryl groups, and also nitrates and hydroxylates aromatic compounds including tyrosine, tryptophan, and guanosine (Halliwell 1997). Downstream DNA damage that follows excessive NO production results in significant activation of poly(ADP-ribose)polymerase which leads to rapid energy depletion and cell death.

A.1.1.18.2 Bioassay of EDRF release

PURPOSE AND RATIONALE

EDRF release from arterial endothelium can be studied by a sandwich technique using donor tissue with intact endothelium facing with its intimal side the intimal side of a detector tissue.

PROCEDURE

Rabbits are subjected to various kinds of treatment, e.g., atherogenic diet or drug treatment for prevention of arteriosclerosis. Aorta segments, about 2 cm in length, are prepared, cut open along their longitudinal axis and pinned to a tissue suspender without damaging the endothelium. These segments serve as donor tissue for EDRF. Circumferential aorta strips from the abdominal aorta of untreated control rabbits are de-endothelialized by gently blotting their luminal surfaces on wet filter paper. These denuded abdominal aorta strips are pinned opposite the donor segments (intimal surface facing intimal surface) and function as detector for luminally released EDRF. Each sandwich preparation is suspended in a 40-ml organ bath, filled with oxygenated Krebs-Ringer buffer at 37 °C containing 10 mM indomethacin. After connecting the detector strip to a force transducer, the angle between the detector strip and the donor segment is minimized and the distance between donor and detector tissue standardized. After one hour stabilization, the strips are brought to their optimum length-tension relationship by repeated exposure to 80 mM KCl. When a stable contractile response is established, the strips are precontracted with phenylephrine to 80–100% of their KCl-induced contraction. After stabilization of plateau phase, cumulative doses of acetylcholine (0.01–10 mM) are added to induce EDRF release from donor tissues.

EVALUATION

Relaxations of the detector strip induced by EDRF release from treated donor rabbit aortas are compared with aortas from control rabbits.

MODIFICATIONS OF THE METHOD

An other bioassay for measuring function of cultured endothelial cells using a computer system for the acquisition and analysis of vascular contractility has been published by Winn et al. (1992).

A.1.1.18.3 Isolated arteries with and without endothelium

PURPOSE AND RATIONALE

Endothelial cells are able to synthesize and release potent vasoconstrictive agents, such as endothelin and angiotensin as well as vasodilating agents, such as EDRF. In isolated arterial segments the endothelial surface can be functionally destroyed allowing a differentiation between a direct action of drugs on the smooth muscle cells and an indirect effect via the endothelium. Isolated rings of rabbit or rat aorta are useful models to study the effects of endothelium derived factors such as EDRF or endothelins and their antagonists (Linz et al. 1986; Tracey et al. 1990; Fujimoto et al. 1992; Fukuroda et al. 1992; Wiemer et al. 1992). A survey of the history and on techniques leading to the discovery of endothelium-dependent relaxation was given by Furchgott (1993).

PROCEDURE

The descending thoracic aorta from rabbits of either sex (weighing 2.5–3.5 kg) is excised and dissected free from connective tissue. Care is taken to avoid damage of the endothelium. The aorta is divided into 2 mm wide rings and cut off in small strips. From some strips, the endothelium is removed by gently rubbing the intimal surfaces between the fingers for approximately 30 s. The strips are suspended in a 25 ml organ bath containing Krebs-bicarbonate solution at 37 °C being gassed continuously with 5% CO_2 / 95% O_2. Contractions of the strips are recorded isometrically with a load of 2 g on the tissues. After an equilibration period of 2 h a stable baseline tone is reached.

To study the vasodilating effects of a compound, the strips are contracted with norepinephrine (10^{-8} M), or angiotensin II (10^{-7} M), or potassium chloride (20 mM). When a stable contraction plateau has been reached, the vasodilating agent is added in various concentrations. In these concentrations, norepinephrine, angiotensin II and KCl evoke a response of 60–80% of maximal contraction in intact rings of rabbit aorta. Rings without endothelium exhibit a response which is significantly enhanced in comparison with the response of the intact preparation after norepinephrine and angiotensin II precontraction.

To indicate the functional removal of the endothelium, the responsiveness of each preparation is tested with the known endothelium-dependent dilator, acetylcholine. In endothelium-intact rings, acetylcholine relaxes contractions induced by norepinephrine or angiotensin II. In precontracted rings devoid of endothelium, acetylcholine does not show any relaxing effect or causes contractions by itself at higher concentrations (Furchgott and Zawadzki 1980). As an example, atriopeptin III causes a similar concentration-dependent relaxation of all precontracted preparations with intact and with functionally destroyed endothelium indicating a direct effect on the smooth muscle cells. The relaxation is accompanied by an increase of cGMP.

EVALUATION

Statistical analyses are performed by regression analysis of dose response curves to determine EC_{50} values. Data are given as means ± standard deviation.

CRITICAL ASSESSMENT OF THE METHOD

The isolated aortic ring of rabbits with and without functionally intact endothelium is a useful tool to differentiate direct effects on the arterial smooth musculature from effects mediated by the endothelium.

MODIFICATIONS OF THE METHOD

Fujimoto et al. (1992) used the thoracic aorta from rats to study the effects between endothelin and an endothelin receptor antagonist. In transverse strips from *rat* thoracic aorta, 2 mm wide and 4–5 mm long, the endothelium was removed by gently rubbing the interior surface of the aorta. Concentration-response curves of contractions after ET-1 in the presence and the absence of the inhibitor were compared.

Pellisier et al. (1992) perfused the isolated mesenteric vascular bed of the **rat** with Tyrode solution and measured the perfusion pressure after injection of graded doses of norepinephrine and the dose-dependent relaxation due to acetylcholine in the vascular bed precontracted by norepinephrine infusion. In order to destroy the endothelial layer, the perfusate was changed to a hypotonic Tyrode solution containing all of the constituents present in normal Tyrode solution but in one-tenth of the concentration resulting in disruption of more than 95% of the endothelial cells. The effect of norepinephrine was enhanced, whereas the effect of acetylcholine was abolished.

Legan and Sisson (1990) described a method to denude **rat** aortic endothelium *in vitro* with saponin.

Bohn and Schönafinger (1989) used helical strips of pulmonary arteries of **guinea pigs** in which the endothelium has been removed for biological detection of NO.

Fukuroda et al. (1992) used spiral strips from **porcine** coronary artery and vein and from intrapulmonary artery and vein removing the intimal surface by lightly rubbing with wet filter paper. Concentration-

contraction curves for ET-1 and ET-3 were obtained with and without an endothelin antagonist.

Hayashi et al. (1988) described functional and anatomical recovery of endothelium after balloon denudation of the left circumflex coronary artery in **dogs**.

Endothelial denudation of the left circumflex coronary artery was used by Chu and Cobb (1987) to study the vasoactive effects of serotonin on proximal coronary arteries in awake **dogs**.

Experiments in isolated rings of the left circumflex or left anterior descending coronary artery of **dogs** with and without endothelium were performed by Desta et al. (1995).

Terrón (1996) analyzed the effects of 5-HT_1-receptor antagonists on 5-HT and sumatriptan induced isometric contractions in endothelium denuded segments of **canine** coronary arteries.

Ren et al. (1993) isolated coronary arteries from Japanese **monkeys** (*Macaca fuscata*) with and without endothelium to study muscarinic receptor subtypes mediating vasodilatation and vasoconstriction.

A.1.1.18.4 Nitric oxide formation by cultured endothelial cells

PURPOSE AND RATIONALE

Endothelial cells are able to synthesize and to release not only potent vasoconstrictor peptides such as angiotensin and endothelin but also potent dilators such as nitric oxide (NO), ATP, substance P, and bradykinin.

NO-formation can be assessed by determination of intracellular cyclic GMP in cultured endothelial cells, whereas release of NO from these cells can be measured by the stimulatory effect of NO on the activity of soluble guanylyl cyclase (Lückhoff et al. 1988; Wiemer et al. 1991; Linz et al. 1992; Bogle et al. 1992; review by Moncada et al. 1991).

PROCEDURE

Endothelial cell culture

Bovine or porcine aorta is obtained from local slaughter houses. Endothelial cells are isolated by digestion with dispase (Lückhoff et al. 1988). The cells are seeded on 6- or 24-well plates (e.g., Nunc Intermed®,

Wiesbaden, Germany) and grown to confluence. Dulbecco's modified Eagle's/Ham's F-12 medium containing 20% fetal calf serum is supplemented with penicillin (10 U/ml), streptomycin (10 µg/ml), L-glutamate (1 mM/l), glutathione (5 mg/ml), and L(+)ascorbic acid (5 mg/ml); (Biotect® protection medium).

Measurement of cyclic GMP

Primary cultures of endothelial cells are used. After removal of the culture medium by aspiration, the monolayer is washed twice with 2 ml HEPES-Tyrode's solution (37 °C). Thereafter, the cells are preincubated for 15 min at 37 °C with 3-isobutyl-1-methyl-xanthine (IBMX), (10^{-4} M/l). After this time, drugs or solvents are added. After predetermined periods, the incubation medium is quickly removed. The cells are then immediately extracted with 0.6 ml 6% trichloro-acetic acid and scraped off with a rubber scraper. The cell suspension is sonicated for 10 s before being centrifuged for 5 min at 4 000 *g*. The supernatants are extracted with four volumes of water saturated diethylether, and the samples frozen (–20 °C) until analysis. The protein contents of the samples are measured according to Lowry et al. (1951). Cyclic GMP can be determined in the acetylated samples by various methods (Heath et al. 1992), e.g., using a commercially available radio-immunoassay (New England Nuclear). Cyclic GMP content is expressed as picomoles GMP per milligram protein.

Measurement of NO release

Release of NO from endothelial cells is assayed on the basis of the stimulatory effect of NO on the activity of soluble guanylyl cyclase (purified from bovine lung) (Gerzer et al. 1981). The activity of the enzyme is determined in terms of the formation of cyclic [^{32}P]GMP from α-[^{32}P]GTP. Reactions are carried out in a reaction mixture containing 30 mM triethanolamine-HCl (pH 7.4), 1 mM reduced glutathione, 4 mM $MgCl_2$, 1 mM cGMP and 0.1 mg/ml bovine γ-globulin (total volume of 0.18 ml) at 37 °C in the presence of α-[^{32}P]GTP (0.03 mM; 0.2 µCi) and soluble gua-nylyl cyclase (4 µg). Ten-µl samples are quickly transferred to the reaction mixture. Enzymatic formation of cGMP is allowed to proceed for 60 s and then stopped by the addition of 450 µl zinc acetate (120 mM) and 500 µl sodium carbonate (120 mM). A complete inhibition of cGMP formation can be achieved by pre-incubation of the monolayers for 30 min with the stereospecific inhibitor of NO synthase, N^G-nitro-L-arginine.

EVALUATION

Time-response curves and dose-response curves after addition of various activators or inhibitors of NO synthase are established. Data are reported as mean values ±SEM of cGMP (pmol/mg protein) or guanylyl cyclase activity (nmol/mg/min). Statistical evaluation is performed with Student's *t*-test.

MODIFICATIONS OF THE METHOD

Isolation of porcine cerebral capillary endothelial cells has been described by Wiemer et al. (1994).

Feelisch and Noack (1987) and Nakazawa et al. (1992) used chemiluminescence techniques for determination of NO.

A method for on-line detection of nitric oxide formation in liquid aqueous phase by electron paramagnetic resonance spectroscopy was described by Mordvintcev et al. (1991). Similar methods were used by Ichimori et al. (1992), Lancester et al. (1992), Steel-Goodwin et al. (1992).

Hecker et al. (1995) used a cascade superfusion bioassay to characterize a stable L-arginine-derived relaxing factor released from cytokine-stimulated vascular smooth muscle cells.

Electrochemical microprobes for direct measurement of NO in tissues have been developed (Shibuki 1990; Ishida et al. 1996; Smits and Lefebvre 1997).

Malinski and Taha (1992), Linz et al. (1999) measured nitric oxide release by a porphyrinic-based microsensor with a detection limit of 10 nmol/L. The amperometric signal at a constant potential of 0.67 V was measured with a voltametric analyzer (PAR model 273, Princeton Applied Research) interfaced with an IBM 80486 computer with data acquisition and software.

Gabriel et al. (1997) developed a method for the detection of intracellular nitric oxide generation in dissociated cerebellar granule cells using dichlorofluorescin diacetate and flow cytometry.

Sumpio et al. (1987) found that cyclic mechanical stress stimulates cultured bovine aortic endothelial cells to proliferate.

Using this method, Rosales et al. (1997) found that exposure of endothelial cells to cyclic strain induces elevations of cytosolic Ca^{2+} concentration through mobilization of intracellular and extracellular pools.

A.1.1.18.5 Expression of nitric oxide synthase

PURPOSE AND RATIONALE

Properties of various forms of nitric oxide synthase (NOS) have been described by Mayer et al. (1992), Leone et al. (1992), Hevel et al. (1992), Förstermann et al. (1992, 1995), (Salter et al. 1992), Pollock et al. (1992), Schmidt et al. (1992), among them type I, which is constitutively expressed in neurons; the inducible type II which is found in macrophages and hepatocytes, but also in the brain (Moro et al. 1998), where it may contribute to NO-mediated neurotoxicity; and type III, which is constitutively expressed in endothelial cells (Knowles and Moncada 1994). NOS can be inhibited by several routes, e.g., competition with L-arginine, NADPH, flavin or tetrahydrobiopterin, interaction of the haeme group of NOS, interference with Ca^{2+} availability or calmodulin binding to the enzyme (Fukuto and Chaudhuri 1995). A widely used inhibitor is L-NAME (Vargas et al. 1991). Selective inhibition of constitutive NOS can by achieved by 7-nitroindazole (Moore et al. 1993); of the inducible NOS by aminoguanidine hydrochloride (Griffiths et al. 1993) and by 2-amino-5,6-dihydro-6-methyl-4H-1,3-thiazine (= AMT) (Nakane et al. 1995). Linz et al. (1999) determined NOS in the left cardiac ventricle of hypertensive rats.

PROCEDURE

Tissues are ground at the temperature of liquid nitrogen using a microdismembranator (Braun). The powders are extracted for 1 h on ice with 10 mmol/l Tris-HCl, pH 7.4, containing 1% SDS and protease inhibitors (complete, Boehringer Mannheim). Debris is removed by a 30-min centrifugation at 4 °C (>100 000 *g*). 100 µg of total of the protein extracts are subjected to SDS-PAGE electrophoresis and transferred to nitrocellulose membranes (Hybond, Amersham). The eNOS protein is detected by use of a specific antibody (monoclonal anti-NOS III), Transduction Laboratories) and visualized by enhanced chemifluorescence with a commercially available kit (Amersham). As a secondary antibody, an anti-mouse IgG antibody coupled to alkaline phosphatase is used (Jackson ImmunoResearch Laboratories). Chemifluorescence is analyzed and quantified by scanning with a Fluorimager 595-system (Molecular Dynamics).

EVALUATION

The data are given as mean ±SEM. ANOVA is used followed by Tuckey's test for post-ANOVA multiple pair comparisons.

MODIFICATIONS OF THE METHOD

Linz et al. (1997) measured expression of ecNOS in the carotid artery of hypertensive rats by Western blot analysis. Frozen (–70 °C) vessels were thawed and extracted with guanidium isothiocyanate/phenol/chloroform (Chomczynski and Sacchi 1987). Crude protein fractions were obtained by alcohol precipitation of the phenol phase. A total of 100 µg of the protein extracts was subjected to SDS-PAGE and transferred to nitrocellulose membranes (Bio-Rad). Ponceau staining was performed to verify the quality of the transfer and the equipartition of protein in each lane. EcNOS protein was detected with a specific antibody (mouse NOS III, Tansduction Laboratories) and visualized by enhanced chemifluorescence with a commercially available kit (Amersham). The autoradiographs were analyzed by scanning densitometry.

McCall et al. (1991) identified N-iminoethyl-L-ornithine as an irreversible inhibitor of nitric oxide synthase.

Bauersachs et al. (1998, 1999) measured vascular reactivity in isolated rat aortic rings mounted in an organ bath (Föhr Medical Instruments, Seeheim Germany) for isometric force measurement and determined superoxide anion production by lucigenin-enhanced chemiluminescence and endothelial nitric oxide synthase and soluble guanylyl cyclase expression by reverse transcription-polymerase chain reaction.

Von der Leyen et al. (1995) reported gene therapy inhibiting neointimal vascular lesions in rats. After denudation of the endothelium of carotid arteries by balloon injury, endothelial cell nitric oxidase expression in the vessel wall was restored by using the Sendai virus/liposome *in vivo* gene transfer technique.

A.1.1.19 Inhibition of Na^+/H^+ exchange

PURPOSE AND RATIONALE

Na^+/H^+ exchange was first described by Murer et al. (1976) in a study of intestinal and renal brush border vesicles. The plasma membrane Na^+/H^+ exchanger is an ubiquitous pH regulating cellular ion transport system. It is driven by the Na^+ gradient and extrudes protons from the cytosol in exchange for extracellular Na^+ ions (Aronson 1985; Frelin et al. 1988; Fliegel and Dyck 1995; Orlowski and Grinstein 1997; Wakabayashi et al. 1997; Dibrov and Fliegel 1998). Six mammalian Na^+/H^+ exchangers: NHE1, NHE2, NHE3; NHE4, NHE5 (Attaphitaya et al. 1999; Szabo et al. 2000), and NHE6 have been described (Tse et al. 1994; Orlowski 1999; Counillon and Pouysségur 2000).

In cardiac tissue the exchanger has a major role in the control of intracellular pH. At the onset of cardiac ischemia and during reperfusion, Na^+/H^+ exchange is excessively activated by low intracellular pH. Since the deleterious Na^+ influx in this condition was found to originate mainly from Na^+/H^+ exchange (Frelin et al. 1984; Schömig et al. 1988), the exchanger seems to be responsible for an increase of cytosolic sodium in ischemic cells. The accumulation of intracellular Na^+ causes an activation of Na^+/K^+ ATPase (Frelin et al. 1984; Rasmussen et al. 1989) which in turn increases ATP consumption.

During ischemia the aerobic metabolism of glucose terminates in lactic acid. A vicious circle leads to a further decrease of intracellular pH and to a further activation of Na^+/H^+ exchange, resulting in energy depletion, cellular Na^+ overload and finally due to the coupling of Na^+ and Ca^{2+} transport via Na^+/Ca^{2+} exchange, cellular Ca^{2+} overload (Lazdunski et al. 1985;

Tani and Neely 1990; Scholz and Albus 1993). Especially in ischemic cardiac tissue, where Na^+/H^+ exchange is the predominant pH regulating ion transport system (Weissenberg et al. 1989), these pathological events can lead to increased excitability and precipitation of cellular death. Therefore, it is desirable to find potent and well tolerated inhibitors of Na^+/H^+ exchange which should be able to interrupt this vicious cycle, to conserve cellular energy stores and to diminish cellular excitability and necrosis during cardiac ischemia. Such effects have been found with relatively weak inhibitors of Na^+/H^+ exchange at high toxic doses, such as amiloride and ethyl isopropyl amiloride (Scholz et al. 1992).

More potent Na^+/H^+ exchange inhibitors showed beneficial effects on ischemia/reperfusion injury (see A.5.0.7 and A.5.0.8) in rats (Aye et al. 1997; Myers et al. 1998; Aihara et al. 2000), dogs (Gumina et al. 1998, 2000) and pigs (Portman et al. 2001). Heart hypertrophy and heart failure after myocardial infarction is reduced (Yoshida and Karmazyn 2000; Kusumoto et al. 2001). Ischemia-induced apoptosis in isolated rat hearts is attenuated by sodium-hydrogen exchange inhibitors (Chakrabarti et al. 1997).

A.1.1.19.1 Inhibition of Na^+/H^+ exchange in thrombocytes

PURPOSE AND RATIONALE

The inhibition of Na^+/H^+ exchange has been studied in platelets by measuring the optical density after osmotic cell swelling (Rosskopf et al. 1991).

PROCEDURE

About 5 ml blood is withdrawn by venipuncture from human donors or from the vena jugularis externa of Beagle dogs or from the aorta of anesthetized Wistar rats (weighing 250–350 g). Coagulation is inhibited by 0.8 ml citrate acid dextrose (65 mM citric acid, 11 mM glucose, 85 mM trisodium citrate). Platelet-rich plasma (PRP) is obtained by centrifugation of whole blood at 90 *g* for 10 min at room temperature. Platelet count is measured, e.g., with a Casey 1 multichannelyser (Schärfe System, Reutlingen, Germany)

Each of the experiments is performed with 10–50 µl PRP containing 20×10^6 platelets in a volume of 100 µl with saline. To activate Na^+/H^+ exchange in the platelets by intracellular acidification, 500 µl propionate buffer (135 mM Na-propionate, 1 mM HCl, 1 mM $CaCl_2$, 1 mM $MgCl_2$, 10 mM glucose, 20 mM HEPES, pH 6.7, 22 °C) are added to the PRP/NaCl solution. Swelling of the platelets results in a decrease of optical density which can be measured with an aggregometer, e.g. with a Turbitimer (Behringwerke, Marburg, Germany). The system is activated photometrically by the addition of the propionate buffer to the cuvette. The experiments are performed with and without the addition of the Na^+/H^+ exchange inhibitor to be tested. The inhibitors are added in concentrations between 10^{-4} and 10^{-8} mol/l. 5-(N-ethyl-N-isopropyl)amiloride (EIPA) is used as standard. During the experiments all solutions are kept at 22 °C in a temperature controlled water bath.

EVALUATION

Results are given as means ±SD. Student's *t*-test is employed for statistical evaluation. IC_{50} values are calculated from dose-response curves.

A.1.1.19.2 Inhibition of Na^+/H^+ exchange in cholesterol activated rabbit erythrocytes

PURPOSE AND RATIONALE

The inhibition of Na^+/H^+ exchange has been studied in cholesterol activated rabbit erythrocytes by flame photometry of sodium (Scholz et al. 1992, 1993).

PROCEDURE

White rabbits (New Zealand strain, Ivanovas) are fed with a rabbit standard chow with 2% cholesterol for 6 weeks to increase the Na^+/H^+ exchange (Scholz et al. 1990) and to make the erythrocytes suitable for measurement of sodium influx via Na^+/H^+ exchange by flame photometry. Blood is drawn from the ear artery of the rabbits and coagulation prevented with 25 IU/ml potassium heparin. The hematocrit of the samples is determined in duplicate by centrifugation. Aliquots of 100 µl are taken to measure the initial sodium content of the erythrocytes.

To determine the amiloride sensitive sodium influx into erythrocytes, 100 µl of each blood sample are added to 5 ml of buffer made hyperosmolar by sucrose (140 mM NaCl, 3 mM KCl, 150 mM sucrose, 0.1 mM ouabain, 20 mM tris-hydroxy-methylamino-methane, pH 7.4) and incubated for 60 min at 37 °C. Subsequently, the erythrocytes are washed three times in ice-cold $MgCl_2$-ouabain-solution (112 mM $MgCl_2$, 0.1 mM ouabain).

For determination of intracellular sodium content, the cells are hemolyzed in distilled water, the cell membranes are centrifuged and the sodium concentration of the haemolysate is measured by flame photometry. Net influx of sodium into the erythrocytes is calculated from the difference between the initial sodium content and the sodium content after incubation. Amiloride-sensitive sodium influx is calculated from the difference between sodium content of erythrocytes incubated with and without amiloride (3×10^{-4} M). Each experiment is done with the erythrocytes from 6 different animals. In each case, the comparison of Na^+ contents is based on erythrocytes from the same animal. Doses between 10^{-4} and 10^{-7} M of the inhibitor are tested.

EVALUATION
Statistical analysis of the data obtained is performed with Student's *t*-test for paired groups. IC_{50} values are calculated from dose-response curves.

A.1.1.19.3 Sodium influx into cultured cardiac myocytes

PURPOSE AND RATIONALE
The inhibition of Na^+/H^+ exchange has been studied in cultured cardiac myocytes (Scholz et al. 1992).

PROCEDURE
Rat myocardial cells are isolated from hearts of neonatal rats by trypsin digestion. The cells are cultured in 35 mm dishes and grown to confluence in Dulbecco's Minimum Essential Medium (DMEM, GIBCO®) in an atmosphere containing 10% CO_2. After confluence, the cells are used for measurement of $^{22}Na^+$ influx. The cells are washed twice with Krebs-Ringer-solution buffered with HEPES/Tris (KRB) in which sodium chloride has been replaced by choline chloride (Choline chloride 130 mM, $CaCl_2$ 1.5 mM, KCl 5 mM, $MgCl_2$ 1 mM, HEPES 20 mM, pH 7.0 with Tris) and then incubated for 20 min at 37 °C in the same buffer with added 0.1% bovine serum albumin (BSA) and 10 mM/l glucose. The culture dishes are then incubated for another 10 min with Na^+-propionate for cytosolic acidification and stimulation of Na^+/H^+ exchange. The compounds are dissolved in 500 µl/dish KRB in which 50% of the sodium chloride has been replaced by choline chloride containing additionally 2 µCi/ml $^{22}Na^+$-bicarbonate, and 5-(N-ethyl-N-isopropyl)amiloride (EIPA). After the stimulation period, sodium influx is terminated by washing the cells twice with ice-cold stop solution (0.1 mM $MgCl_2$, 10 mM Tris, pH 7.0). Subsequently, the cells are lyzed with 250 µl trichloro-acetic acid and scraped from the dishes. Radioactivity is determined in a Packard gamma counter. Doses between 3×10^{-4} and 10^{-8} mM/l of standard and new compounds are tested. Six dishes are used for each concentration of test compounds.

EVALUATION
Mean values ±SD are compared with Student's *t*-test. IC_{50} values are calculated from dose-response curves.

A.1.1.19.4 Inhibition of Na^+/H^+ exchange into cultured aortic endothelial cells

PURPOSE AND RATIONALE
The inhibition of Na^+/H^+ exchange has been studied in endothelial cells (Scholz et al. 1993) by measuring the $^{22}Na^+$ influx.

PROCEDURE
Bovine aortic endothelial cells (BAEC) are isolated by dispase digestion form bovine aorta obtained from animals killed at the local slaughter house. The cells are cultured in 35 mm dishes and grown to confluence in Dulbecco's Minimum Essential Medium (DMEM, GIBCO®) in an atmosphere with 10% CO_2. Three days after confluence the cells are used for measurement of $^{22}Na^+$ influx. The cells are washed twice with Krebs-Ringer-solution buffered with HEPES/Tris (KRB) in which sodium chloride has been replaced by choline chloride (Choline chloride 130 mM, $CaCl_2$ 1.5 mM, KCl 5 mM, $MgCl_2$ 1 mM, HEPES 20 mM, pH 7.0 with Tris) and then incubated for 20 min at 37 °C in the same buffer with added 0.1% bovine serum albumin (BSA) and 10 mM glucose. To stimulate Na^+/H^+ exchange the culture dishes are incubated for another 10 min with 500 µl/dish KBR in which all sodium chloride has been replaced by 65 mM each of choline chloride and Na^+-propionate or with KBR in which 50% of the sodium chloride has been replaced by choline chloride for unstimulated controls. In addition, the buffer contains 2 µCi/ml $^{22}Na^+$ and the test compounds or the standard. After the stimulation period, the sodium influx is terminated by washing the cells twice with ice-cold stop solution (0.1 mM $MgCl_2$, 10 mM Tris, pH 7.0). Subsequently, the cells are lyzed with 250 µl trichloro-acetic acid and scraped from the dishes. Radioactivity is determined in a

Packard gamma counter. Doses between 10^{-5} and 10^{-7} mM/l of standard and new compounds are tested. Six dishes are used for each concentration of test compounds.

EVALUATION

Mean values ±SD are compared with Student's *t*-test. IC_{50} values are calculated from dose-response curves.

MODIFICATIONS OF THE METHOD

Ewart et al. (1997) studied lipoprotein lipase activity in cultured rat cardiomyocytes in the presence of insulin and dexamethasone.

A.1.1.19.5 NHE activity measured by intracellular pH in isolated ventricular myocytes

PURPOSE AND RATIONALE

Changes of the intracellular pH of cultured bovine endothelial cells have been fluorometrically monitored using the pH-dye 2',7'-bis(carboxyethyl)carboxyfluorescein (BCECF) by Kitazano et al. (1988). This method has been used to study the activity of inhibitors of Na^+/H^+ exchange (Scholz et al. 1995).

PROCEDURE

For preparation of isolated rat ventricular muscular cells (Yazawa et al. 1990), hearts of male Wistar rats are dissected, mounted on a Langendorff apparatus and perfused first at 37 °C for 3 min with Tyrode solution adjusted to pH 7.4, second for 5–7 min with nominally calcium free Tyrode solution and finally with calcium free Tyrode solution containing 0.12–0.2 mg/ml collagenase (Sigma type I). After 15–20 min collagenase treatment, the heart is washed with storage solution (composition in mmol/L: KOH 70, l-glutamic acid 50, KCl 40, taurine 20, KH_2PO_4 20, $MgCl_2$ 3, glucose 20, HEPES 10, and EGTA 0.5, pH 7.4). The ventricles are cut into small pieces and myocytes are dispersed by gently shaking and finally by filtration through a nylon mesh (365 µm). Thereafter, the cells are washed twice by centrifugation at 600–1 000 rpm for 5 min and kept at 4 °C until use. For the pH recovery experiment the cells are loaded with the membrane permeable acetoxymethyl ester (AM) form of the fluorescent indicator 2',7'-bis(carboxyethyl)-5(6)-carboxyfluorescein (BCECF). BCECF-AM is dissolved in DMSO and diluted to a 1.25 µM storage solution. Cardiomyocytes are loaded in this solution for 30 min at room temperature and are then centrifuged and resuspended in storage solution. The measurements are performed in bicarbonate-free NaCl solution (NaCl 140, KCl 4.7, $CaCl_2$ 1.3, $MgCl_2$ 1, glucose 10, and HEPES 10 mM/L, pH 7.4) at 34 °C using an apparatus according to Nitschke et al. (1991). The pH-dependent signal of BCECF is obtained by illuminating at 490 and 437 nm and dividing the emitted light signals (520–560 nm). The background signal, determined by closing the shutter, is subtracted from the total signal. The autofluorescence determined by illuminating unloaded cells can be ignored. In order to investigate the function of the Na^+/H^+ exchange system, the intracellular pH (pH_i) of the cells is decreased by the NH_4Cl prepulse technique and the rate of return to resting pH_i is determined. Test compounds are dissolved in the incubation medium. For each test concentration, the recovery of pH_i is first recorded in control NaCl solution.

EVALUATION

Data are analyzed by fitting a straight line to the initial (5 min) data points of the pH recovery curve. For statistical presentation, the slopes of the linear curves are demonstrated. All reported data are presented as means ±SEM. Statistical comparisons are made using either a paired or unpaired *t*-test.

MODIFICATIONS OF THE METHOD

The pH-sensitive fluorescence dye C-SNARF-1 (= carboxy-semi-naphtho-rhoda-fluor 1) was used by Yatsutake et al. (1996), Shipolini et al. (1997), and Yokoyama et al. (1998).

Fischer et al. (1999) tested new drugs for the Na^+/H^+ exchanger in Chinese hamster ovary cells which are enriched with the NHE-1 isoform of the Na^+/H^+ anti-porter. The Na^+/H^+ exchanger was stimulated with NaCl and the rate of extracellular acidification was quantified with the Cytosensor.

A.1.1.19.6 NHE subtype specificity

PURPOSE AND RATIONALE

Molecular identification of mammalian Na^+/H^+ exchanger subtypes has been pioneered by Pouysségour and coworkers (Sardet et al. 1989) who used genetic complementation of fibroblast cell lines that lack all endogenous NHEs. Schwark et al. (1998) studied an inhibitor of Na^+/H^+ exchanger subtype 3 in various cell types.

PROCEDURE

cDNAs for the NHE subtypes human NHE1, rabbit NHE2, rat NHE3 (Pouysségour) or cloned by reverse transcriptase-polymerase chain reaction from human kidney mRNA are used. These cDNAs are cloned into the mammalian expression vector pMAMneo and transferred into the NHE-deficient mouse fibroblast cell line LAP1. Cells expressing the NHE subtypes are selected by the acid load survival method (Sardet et al. 1989). Clonal cell lines for each subtype are used for intracellular pH (pH_i) recovery after acid load. For studies of pH_i recovery (Faber et al. 1996), cells are scraped off the culture dishes washed and incubated with 5 µmol/l BCECF-AM [2',7'-bis(2-carboxyethyl)-5,6-carboxy-fluorescein-acetoxy-methyl ester] for 20 min at 37 °C in a buffer containing 20 mM NH_4Cl. The cells are then washed to remove extracellular dye and resuspended in the loading buffer without BCECF-AM. Intracellular acidification is induced by addition of 975 µl NH_4Cl-free and HCO_3^--free solution (so-called recovery medium: HCO_3^--free to inhibit the Na^+-dependent Cl^-/HCO_3^- exchanger of LAP1 cells) to an 25-µl aliquot of cells (≅25 000 cells). The pH_i recovery is recorded with a dual-grating Deltascan single-photon counting fluorometer (Photon Technology International, South Brunswick, NJ, USA) with excitation wavelength of 505 nm and 440 nm and an emission wavelength of 535 nm. The measurement time varies between subtypes (120 s for NHE1, 300 s for NHE2, 180 s for NHE3). The inhibitors are first dissolved in DMSO, diluted in recovery medium and added in a volume of 975 µl to this medium.

A cloned opossum kidney cell line (Helmle-Kolb et al. 1990) is used additionally. Cells are grown as a monolayer in growth medium (1:1 mixture of nutrient mixture Ham F12 and Dulbecco's modified medium Eagle with 10% fetal calf serum). For subcultivation and pH-recovery experiments, the cells are detached from the surface of the culture vessels with trypsin-EDTA solution (2.5 g trypsin + 0.2 g EDTA per liter in Dulbecco's phosphate-buffered saline) and suspended in growth medium. Measurement time in pH_i recovery experiments is 400 s.

Porcine renal brush-border membrane vesicles (BBMV) prepared by a Mg^{2+} precipitation technique are loaded with 150 mmol/l NaCl, 5 mmol/l HEPES/Tris, pH 7.0, and pre-incubated for 10 min at 37 °C with various concentrations of NHE inhibitors. Intravesicular acidification through Na^+/H^+ exchange is started by diluting BBMV into Na^+-free buffer (150 mmol/l tetramethylammonium chloride, 5 mmol HEPES/Tris, pH 7.0) containing the appropriate concentrations of the NHE inhibitors and the fluorescent ΔpH indicator acridine orange (12 µmol/l). The fluorescence changes of acridine orange are recorded continuously by a Hitachi F-2000 spectrofluorometer at 495 nm excitation and 525 nm emission wavelength. The initial acridine orange fluorescence quenching in controls (no inhibitor) is set to 100%.

EVALUATION

Values are presented as means ±SD (four measurement per concentration). The IC_{50} values and Hill coefficients are calculated using the Sigma plot software. Statistical significance is calculated by means of the

distribution-independent *H*-test and non-parametric *U*-test. $P < 0.05$ is considered as significant.

MODIFICATIONS OF THE METHOD

Counillon et al. (1993), Scholz et al. (1995) determined the NHE subtype specificity of Na^+/H^+ antiporters by their ability to inhibit initial rates of amiloride sensitive $^{22}Na^+$ uptake in fibroblast cell lines separately expressing the NHE-1, NHE-2 and NHE-3 isoforms.

A.1.1.20 Inhibition of phosphodiesterase

PURPOSE AND RATIONALE

The enzyme phosphodiesterase (PDE) exists in various forms. At least 11 families of phosphodiesterases have been identified (Torphy and Page 2000).

The inhibition of cAMP-PDE and cGMP-PDE by various test compounds can be measured using a two-step radioisotopic procedure.

PROCEDURE

Materials

[8-^{3}H]cAMP (28 Ci/mmol), [8-^{3}H]-cGMP (15 Ci/mmol) and [U^{14}C]guanosine (528 mCi/mmol) are obtained from Du Pont de Nemours (Paris, France). Unlabelled cyclic nucleotides, 5'-nucleotidase (Ophiophagus hannah venom) are from the Sigma Chemical Co. (La Verpillére, France).

Tissue preparations

Male Sprague-Dawley rats (250–300 *g*) are decapitated. Hearts are perfused with 0.15 M NaCl through the aorta to remove the blood. The ventricles are minced in 5 vol. of 10 mM Tris-HCl buffer containing 0.32 M sucrose, 1 mM EDTA, 5 nM DTT and 0.1 mM PMSF at pH 7.5. The suspension is homogenized in a glass-glass Potter-Elvejhem. The homogenate is then centrifuged at 105 000 *g* for 60 min. The 105 000 *g* supernatant is stored at –75ºC until injection on the HPLC column.

Isolation of PDEs

The cytosolic fraction from rat ventricles (5–8 mg of protein) is loaded at the rate of 1 ml/min on a Mono Q HPLC column which has been previously equilibrated with buffer A (50 mM Tris-HCl, 2 mM EDTA, 14 mM 2-mercaptoethanol, 0.1 mM PMSF, pH 7.5). Under these conditions, greater than 95% of the PDE activity is bound to the column. PDE activity is eluted at a flow rate of 1 ml/min using the following step by step and linear gradients of NaCl in buffer A: 25 ml of 0.16 M NaCl, 20 ml of 0.23 M NaCl, 30 ml from 0.23 to 0.29 M NaCl, 15 ml of 0.29 M NaCl, 30 ml from 0.29 to 0.50 M NaCl. The separation is done at 4 °C. Fractions of 1 ml are collected and stored at –75 °C in the presence of 20% glycerol. The fractions are tested for PDE activity, and the peaks containing the different isoenzymes are identified. Fractions containing preferentially one isoenzyme are pooled.

PDE assay

PDE activity is assayed by a two-step radioisotopic procedure according to Thompson et al. (1974), Boudreau and Drummond (1975), Prigent et al. (1981). cAMP-PDE and cGMP-PDE activities are measured with a substrate concentration of 0.25 µM. To evaluate the cGMP-stimulated PDE activity, assays are performed with 5 µM cAMP in the absence or presence of 5 µM cGMP. Xanthine derivates are dissolved in DMSO. The stock solutions are appropriately diluted with 40 mM Tris-HCl buffer so that the final DMSO concentration in the PDE assay does not exceed 1%. At this concentration, DMSO has no significant effect on the PDE activity of any of the fractions. The inhibitory potency of the xanthine derivates is examined on each separated isoform.

EVALUATION

The IC_{50} values (concentration of a drug which inhibit 50% of the enzymatic activity) are calculated by plotting the percentage of residual enzymatic activity versus the logarithmic concentration of the drug. Confidence limits (95%) for the IC_{50} values are determined by linear regression analysis.

A.1.1.21 Stimulation of heart membrane adenylate cyclase

PURPOSE AND RATIONALE

Metzger and Lindner (1981) discovered that the positive inotropic and vasodilatory effects of forskolin were correlated with the stimulation of adenylate cyclase and cAMP-dependent protein kinase. Subsequent studies by Seamon (1981) demonstrated that forskolin, unlike hormones, guanine nucleotides, fluoride or cholera toxin could stimulate cyclase activity in the absence of the guanine nucleotide regulatory protein. Since those reports, hundreds of papers have been published on the effects of forskolin in numerous mammalian organ and cell systems. Several comprehensive review articles have also been published (Seamon and Daly 1981, 1983; Daly 1984).

While forskolin has proven to be an invaluable research tool for investigations of adenylate cyclase systems (Salomon et al. 1974; Seamon et al. 1981, 1983), reports on its effects on cardiovascular (Lindner et al. 1978), pulmonary (Chang et al. 1984) and ocular physiology (Caprioli and Sears 1983; Caprioli 1985) suggest a therapeutic potential (Seamon 1984) as well.

Described here is an *in vitro* assay which can be used to compare the potency of forskolin, forskolin analogs or other direct or indirect adenylate cyclase activators for the stimulation of adenylate cyclase in heart membranes. The purpose of this assay is to determine and compare the potency of direct or indirect activators of adenylate cyclase for an ability to stimulate heart membrane adenylate cyclase *in vitro*.

PROCEDURE

The hearts of the Wistar rat, Hartley guinea pig, golden Syrian hamster or cardiomyopathic hamster (CHF-146) are used as a source of adenylate cyclase for this assay.

Reagents

1. 0.5 M Tris buffer, pH 7.4
2. 0.05 M Tris buffer, pH 7.4, containing 0.1 M $CaCl_2$
3. Tris buffer mixture

   0.05 M Tris buffer, containing 1 mM IMBX (isobutylmethyl-xanthine), 0.2 mM EGTA, 5 mM $MgCl_2$, 0.5 mM ATP ($Na_2ATP \times 3\ H_2O$) and 20 mM creatine phosphate (Na_2 Creatine-$PO_4 \times 5\ H_2O$) (final concentrations in the incubation media).
4. Creatine phosphokinase (ATP:Creatine N-Phosphotransferase, EC 2.73.2), type I, from rabbit muscle is obtained from Sigma Chemical Co.

   The concentration of enzyme in the incubation media is 40 U/ml.
5. Test compounds

   For most assays, a 30 mM stock solution is made up in a suitable solvent (ethanol, ethyl acetate or DMSO for most forskolin analogs). Serial dilutions are made such that the final concentration in the assay ranges from 3×10^{-4} to 3×10^{-7} M. The concentration of vehicle in the assay is 1%.

Tissue preparation

One entire heart from rat, guinea pig or hamster is dissected, weighed and homogenized in 50 volumes of ice-cold 0.05 M Tris buffer, pH 7.4 containing 0.1 mM $CaCl_2$ (reagent 2) using a Brinkman Polytron (setting 7 for 15 s). The homogenate is centrifuged at 10 000 *g* for 20 min at 4 °C. The resulting pellet is resuspended in 50 volumes of homogenizing buffer and recentrifuged as before. The supernatant of this spin is discarded and the resulting pellet is finally resuspended in 10 volumes of the homogenizing buffer, for rat and hamster and 60 volumes for guinea pig tissue. This final preparation is filtered through a thin layer of gauze and kept on ice until used in the assay. The protein concentration is approximately 250–350 mg/ml.

Protein concentrations from an aliquot of the tissue suspension are determined on the day of the experiment by the method of Bradford (1976) using the BioRad assay kit.

Assay

300 µl Tris buffer mixture, pH 7.4 (reagent 3)
50 µl creatine phosphokinase
5 µl vehicle or appropriate concentration of test drug
95 µl H_2O
50 µl tissue suspension

The tubes are incubated for 5 min at 37 °C and the reaction is then stopped by placing the tubes into a boiling water bath for 4 min. The tubes are then centrifuged at 1 000 *g* for 10 min and cAMP levels determined in a 15 µl aliquot of the supernatant using a radioimmuno-assay kit (Code TRK432) obtained from Amersham according to the manufacturer's protocol.

Test principle: The method is based on the competition between unlabeled cAMP and a fixed quantity of ^{3}H-labelled cAMP for binding to a protein which has high specificity and affinity for cyclic AMP. The amount of labelled cAMP–protein complex formed is inversely related to the amount of unlabelled cAMP present in the assay sample. The concentration of cAMP in the unknown is determined by comparison with a linear standard curve.

EVALUATION

The data are expressed as pmol cAMP/mg protein/min and dose-response stimulation curves are subjected to logic analysis to determine the concentration of compound which exhibits 50% of maximal stimulation (ED_{50}).

The β-blocking activities of compounds can be determined by their activities, by which they counteract the isoproterenol and GTP induced stimulation of rat heart membrane bound adenylate cyclase (Greenslade et al. 1979).

A.1.1.22 ^{3}H-Forskolin binding assay

PURPOSE AND RATIONALE

This assay is used to identify compounds which demonstrate high affinity [nM] for association with forskolin binding sites *in vitro* as a preliminary screen in conjunction with stimulation of adenylate cyclase to determine the potential for cardiac chronotropic and inotropic and other effects of forskolin. Guinea pig heart tissue and rat brain tissue are used as sources of binding assays.

PROCEDURE FOR GUINEA PIG HEART TISSUE

A. Reagents

1. 0.05 M Tris-HCl buffer, pH 7.4
2. 0.05 M Tris-HCl, pH 8.0 containing 1 mM EGTA, 1 mM $MgCl_2$ and 0.32 M sucrose

3. [^{3}H]-Forskolin (specific activity 31.6 Ci/mmol) is obtained from New England Nuclear.

   Final concentration in the assay is approximately 15 nM.

4. Forskolin and test compounds

   Forskolin and forskolin analogs are diluted to 40 µM. A 100 µl addition of this solution to the final incubate of 200 µl tissue and 100 µl ^{3}H-forskolin results in a final concentration of 10^{-5} M.

   Appropriate serial dilutions of this stock solution are made such that the final concentrations in the assay range from 10^{-5} to 10^{-11} M with each concentration being done in triplicate.

B. Tissue preparation

Male Hartley guinea pigs (300–350 g) are sacrificed by decapitation. The heart is immediately removed, weighed, rinsed, diced and homogenized in 10 volumes of ice-cold 0.05 M buffer(reagent 2) using a Polytron homogenizer (setting 10, 30 s). The resulting homogenate is centrifuged at 12 000 *g* for 15 min at 4 °C. The clear supernatant of this spin is discarded, the remaining pellet (P_2) is resuspended in 5 volumes of the same ice-cold buffer and rehomogenized. This final suspension (approximately 0.8–1.0 mg protein/ml) is kept on ice until use. Protein concentrations are estimated according to the method of Lowry et al. (1951).

C. Binding assay

To generate a dose-response inhibition curve, ^{3}H-forskolin binding is performed according to the method of Seamon et al. (1984) with minor modifications.

200 µl tissue suspension
100 µl ^{3}H-forskolin
100 µl appropriate concentration of forskolin or forskolin analog, or buffer

Tubes are incubated at 30 °C for 10 min. The incubate is then diluted with 5 ml of ice-cold 0.05 M Tris-HCl buffer, pH 7.4 (reagent 1) and immediately vacuum filtered through glass fiber filters (Whatman GF/B) by using a Brandel Cell Harvester. The filters are rapidly washed 3 times with 5 ml aliquots of Tris-HCl buffer (reagent 1), added to 10 ml scintillation cocktail and analyzed for radioactivity.

PROCEDURE FOR RAT BRAIN TISSUE

A. Reagents

1. 0.32 M sucrose buffer
2. 0.05 M Tris-HCl buffer, pH 7.5
3. [^{3}H]-Forskolin (specific activity 31.6 Ci/mmol) is obtained from New England Nuclear.

   Final concentration in the assay is approximately 10 nM.

4. Forskolin and test compounds

   Forskolin and forskolin analogs are diluted to 40 µM. A 100 µl addition of this solution to the final incubate of 200 µl tissue and 100 µl ^{3}H-forskolin results in a final concentration of 10^{-5} M.

   Appropriate serial dilutions of this stock solution are made such that the final concentrations in the assay range from 10^{-5} to 10^{-11} M with each concentration being done in triplicate.

B. Tissue preparation

Male Sprague-Dawley rats (200–250 g) are sacrificed by decapitation. The brain is rapidly removed and dissected on ice. Striata are homogenized in 50 volumes of ice-cold 0.32 M sucrose buffer (reagent 1) using a Polytron homogenizer (setting 7, 15 s). The resulting homogenate is centrifuged at 1 000 *g* for 10 min at 0–4 °C. The supernatant is retained and recentrifuged at 20 000 *g* for 10 min at 0–4 °C. The clear supernatant of this spin is discarded and the remaining pellet (P_2) is resuspended in ice-cold Tris-HCl buffer, pH 7.5 such that the final protein concentration is approximately 3.0–4.0 mg/ml. Protein concentrations are estimated according to the method of Lowry et al. (1951).

C. Binding assay

To generate a dose-response inhibition curve, ^{3}H-forskolin binding is performed according to the method of Seamon et al. (1984) with minor modifications.

200 µl tissue suspension
100 µl ^{3}H-forskolin
100 µl appropriate concentration of forskolin or forskolin analog or buffer

Tubes are incubated at 23 °C for 60 min. The incubate is then diluted with 5 ml of ice-cold 0.05 M Tris-HCl buffer, pH 7.4 (reagent 2) and immediately vacuum filtered through glass fiber filters (Whatman GF/B) by using a Brandel Cell Harvester. The filters are rapidly washed three times with 5 ml aliquots of Tris-HCl buffer (reagent 2), added to 10 ml scintillation cocktail and analyzed for radioactivity.

EVALUATION

Specific binding is defined as the difference between binding of ^{3}H-forskolin in the absence and presence of 10 µM forskolin and represents 85–90% of total binding at 10 nM ^{3}H-forskolin.

Results of the dose-response inhibition curves are analyzed by determining the concentration of competing compound which inhibits 50% of the ^{3}H-forskolin binding sites (IC_{50}). This value is determined by computer-derived log-probit analysis.

The activity of various forskolin analogs are based on IC_{50} values and are categorized as follows:

	IC_{50} [M]
0 = Not determined	
1 = No activity	$>10^{-5}$
2 = Slight activity	10^{-5}–10^{-6}
3 = Moderate activity	10^{-6}–10^{-7}
4 = Marked activity	$<10^{-7}$

To compare the activity of various compounds from experiment to experiment, an inhibition constant (K_I) is determined as described by Cheng and Prusoff (1973). The K_I is determined from the equation:

$$K_I = IC_{50} / 1 + LC / K_D$$

IC_{50} = concentration of competing compound which inhibits 50% of the ^{3}H-forskolin binding sites
LC = determined ^{3}H-forskolin concentration (approximately 10 nM)
K_D = dissociation of affinity constant for ^{3}H-forskolin determined previously to be approximately 13.4 nM for rat striatum and 196 nM for guinea pig heart

Standard data:
Binding inhibition values for forskolin

	Striatum	Heart
IC_{50}	43.1 ±4.9 nM	34.2 ±5.0 nM
K_I	26.0 ±3.1 nM	31.6 ±4.6 nM

A.1.1.23 Patch clamp technique[2]

PURPOSE AND RATIONALE

The introduction of the patch clamp technique (Neher and Sakmann 1976) revolutionized the study of cellular physiology by providing a high-resolution method of observing the function of individual ionic channels in a variety of normal and pathological cell types. By the use of variations of the basic recording methodology, cellular function and regulation can be studied at a molecular level by observing currents through individual ionic channels (Liem et al. 1995; Sakmann and Neher 1995).

The most commonly used method is called the "on-cell" or "cell-attached" configuration, because ion channels can be recorded on an intact cell (Jackson 1993). This mode is well suited for investigation of ion channels, which are activated by hormonal stimulation and triggered by intracellular second messengers.

Another versatile mode is the "cell-excised" configuration (Hamill 1993). It is obtained by suddenly removing the patch-pipette from the cell, so that the membrane patch is pulled off the cell. This mode easily allows to expose the channel proteins to drugs by changing the bath solution. The single channel currents are recorded on a video-tape and are analyzed off-line by a computer system. Various parameters are evaluated, such as the single channel conductance, open-and closed-times of the channel, and the open-state probability, which is the percentage of time the channel stays in its open state.

Besides these modes, which enable the recording of single channel currents, it is also possible to measure the current flowing through the entire cell. This "whole-cell mode" is obtained by rupturing the membrane patch in the cell-attached mode (Hamill et al. 1981; Dietzel et al. 1993). This is achieved by applying suction to the interior of the patch-pipette. The "whole-cell mode" not only allows to record the electrical current, but also to measure the cell potential. Moreover, the cell interior is dialyzed by the electrolyte solution filled into the patch-pipette.

The fabrication of patch clamp pipettes has been described by Sakmann and Neher 1983; Corey and Stevens 1983; Cavalié et al. 1993).

Variations of the patch-clamp technique have been used for studying neurotransmitter transduction mechanisms (Smith 1995).

A.1.1.23.1 Patch clamp technique in isolated cardiac myocytes

PURPOSE AND RATIONALE

The generation of an action potential in heart muscle cells depends on the opening and closing of ion-selective channels in the plasma membrane. The patch-clamp technique enables the investigation of drug interactions with ion-channel forming proteins on the molecular level.

PROCEDURE

Isolated cells from rat ventricular muscle are prepared as described by Yazawa et al. (1990). Male Wistar rats are sacrificed by cervical dislocation. Hearts are dissected and mounted on a Langendorff-type apparatus and perfused first with Tyrode solution (in mM: 143 NaCl, 5.4 KCl, 1.8 $CaCl_2$, 0.5 $MgCl_2$, 0.25 NaH_2PO_4, 5 HEPES, pH adjusted to 7.4 with NaOH) at 37 °C for 3 min at a hydrostatic pressure of 60–70 cm H_2O, then with nominally Ca^{2+}-free Tyrode solution (no Ca^{2+} is added) for 5–7 min, and finally with nominally Ca^{2+}-free Tyrode solution containing 0.12–0.2 mg/ml collagenase (Sigma, type I). After 15–20 min of collagenase treatment, the heart is now soft and is washed with storage solution (in mM: 70 KOH, 50 L-glutamic acid, 40 KCl, 20 taurin, 20 KH_2PO_4, 3 $MgCl_2$, 10 glucose, 10 HEPES, 0.5 EGTA, pH adjusted to 7.4 with KOH). The ventricles are cut into pieces (about 5 × 5 mm) and poured into a beaker. The myocytes are dispersed by gently shaking the beaker and filtration through a nylon mesh (365 µm). Then, the myocytes are washed twice by centrifugation at 600–1 000 rpm (about 90 *g*) for 5 min and kept at 4 °C. The rod shape of the cell and the clear striations of sarcomeres are important criteria for selecting viable cells for the assay. Experiments are performed at 35–37 °C.

For investigation with the patch-clamp technique (Neher and Sakmann 1976; Hamill et al. 1981), the isolated cells are placed into a thermostat-controlled chamber, mounted on the stage of an inverted microscope equipped with differential interference contrast optics. Under optical control (magnification 400×) a glass micro-pipette, having a tip opening of about 1 µm, is placed onto the cell. The patch-pipettes are fabricated from borosilicate glass tubes (outer diameter 1.5 mm, inner diameter 0.9 mm) by means of an electrically heated puller. In order to prevent damage of the cell membrane, the tip of the micro-pipette is fire polished, by moving a heated platinum wire close to the tip. The patch-pipette is filled with either high NaCl or KCl solution and is mounted on a micro manipulator. A chlorided silver wire connects the pipette solution to the head stage of an electronical amplifier. A second chlorided silver wire is inserted into the bath and serves a ground electrode.

After having contact with the cell membrane, a slight negative pressure is applied to the inside of the patch-pipette by means of a syringe. Consequently, a small patch of membrane is slightly pulled into the opening of the micro pipette and a close contact between glass and membrane is formed, leading to an increase of the electrical input resistance into the gigaohm range (about 10^{10} Ohm). This high input resistance enables the recording of small electrical currents in the range of Picosiemens (10^{-12} S), which are flowing through channel-forming proteins situated in the membrane patch. The electrical current is driven by applying an electrical potential across the membrane patch, and/or by establishing an appropriated chemical gradient for the respective ion species.

The patch clamp methods allows to investigate the interaction of drugs with all ion channels involved in the functioning of the heart muscle cell (K^+, Na^+, Ca^{2+} and eventually Cl^- channels). Moreover, the different types of K^+ channels existing in cardiomyocytes can be distinguished by their different single-channel characteristics or by appropriate voltage-pulse protocols in the whole-cell mode.

EVALUATION

Concentration-response curves of drugs which either inhibit or activate ion channels can be recorded either on the single channel level or by measuring the whole-cell current. IC_{50} and EC_{50} values (50% inhibition or activation, respectively) can be obtained with both methods.

MODIFICATIONS OF THE METHOD

The patch-clamp technique has been used for evaluation of anti-arrhythmic agents (Bennett et al. 1987; Anno and Hondeghem 1990; Gwilt et al. 1991).

Gögelein et al. (1998) used isolated ventricular myocytes form guinea pigs to study a cardioselective inhibitor of the ATP-sensitive potassium channel.

Multiple types of calcium channels have been identified by patch clamp experiments (Tsien et al. 1988).

The effects of potassium channel openers have been measured (Terzic et al. 1994; Kon et al. 1994).

Ryttsén et al. (2000) characterized electroporation of single NG108-15 cells with carbon-fiber microelectrodes by patch-clamp recordings and fluorescence microscopy.

Monyer and Lambolez (1995) reviewed the molecular biology and physiology at the single-cell level discussing the value of the polymerase chain reaction at the single cell level and the use of patch pipettes to collect the contents of a single cell on which the reverse transcription is performed.

A.1.1.23.2 Voltage clamp studies on sodium channels

PURPOSE AND RATIONALE

The epithelial Na^+ channel plays an important role in epithelial Na^+ absorption in the distal colon, urinary bladder, salivary and sweat ducts, respiratory tract and, most importantly in the distal tubules of the kidney (Catterall 1986; Palmer 1992). Regulation of this epithelial Na^+ channel has a major impact on Na^+ balance, blood volume and blood pressure. Inhibition of epithelial Na^+-channel expression is used for the treatment of hypertension (Endou and Hosoyamada 1995). Busch et al. (1995) studied the blockade of epithelial Na^+ channels by triamterenes using two microelectrodes voltage clamp experiments in *Xenopus* oocytes expressing the three homologous subunits (α, β and γ) of the rat epithelial Na^+ channel (rENaC).

PROCEDURE

Xenopus laevis oocytes are injected with the appropriate cRNA encoding for the α, β and γ-subunits (Canessa et al. 1993) of the rat epithelial Na^+ channel (rENaC). The cRNA for the wild-type α-subunit and its deletion mutant Δ278–273, is always co-injected with an equal amount of β-and γ-subunit cRNA (10 ng/oocyte).

Two to 8 days after cRNA injection, the two-microelectrode voltage clamp is used to record currents from *Xenopus* oocytes. Recordings are performed at 22 °C using an Geneclamp amplifier (Axon Instruments, Foster City, CA, USA), and MacLab D/A converter and software for data acquisition and analysis (AD Instruments, Castle Hill Australia). The ND 96 solution (control) contains (mM): NaCl 96, KCl 2, $CaCl_2$ 1.8, $MgCl_2$ 1, HEPES 5, pH 7.0). In some experiments, Na^+ is replaced by *N*-methyl-D-glucamine (NMDG) solution. The microelectrodes are filled with 3 M KCl solution and have resistances in the range 0.5–0.9 MΩ. Chemicals (e.g., triamterene as standard) are added in concentrations between 0.2 to 100 μM). The amplitude of the induced currents varies considerably, depending on the day of channel expression and the batch of oocytes. The mutant channel induces considerably smaller currents than the wild-type channel. The total Na^+ current amplitude is determined at least once for each experimental day by superfusion with NMDG solution, or with 3 μM or 5 μM amiloride solution at the beginning and at the end of each set of experiments.

EVALUATION

Data are presented as means ±SEM. A paired Student's *t*-test is used. The level of statistical significance is set at $P < 0.05$.

MODIFICATIONS OF THE METHOD

Nawada et al. (1995) studied the effects of a sodium-, calcium, and potassium-antagonistic agent on the sodium current by the whole cell voltage clamp technique (tip resistance = 5 MΩ[Na]$_i$ and [Na]$_o$ 10 mmol/l at 20 °C) in guinea-pig isolated ventricular cells.

Sunami and Hiraoka (1996) studied the mechanism of cardiac Na^+ channel block by a charged class I antiarrhythmic agent, in guinea pig ventricular myocytes using patch-clamp techniques of whole-cell, cell-attached and inside-out configurations.

Erdõ et al. (1996) compared the effects of *Vinca* derivatives on voltage-gated Na^+ channels in cultured cells from rat embryonic cerebral cortex. Effects on Na^+ currents were measured applying voltage steps (20 ms duration) to –10 mV from a holding potential of –70 mV every 20 s. Steady state inactivation curves were obtained by clamping the membrane at one of a series of 15-s pre-pulse potentials, followed 1 ms later by a 20-ms test pulse to –10 mV.

Ragsdal et al. (1993) examined the actions of a Na^+ channel blocker in whole-cell voltage clamp recordings from Chinese hamster ovary cells transfected with a cDNA encoding the rat brain type IIA Na^+ channel and from dissociated rat brain neurons.

Taglialatela et al. (1996) studied cloned voltage-dependent Na^+ currents expressed in *Xenopus* oocytes upon injection of the cRNA encoding α-subunits from human and rat brain.

Eller et al. (2000) measured the effects of a calcium antagonist on inward Na^+ currents (I_{Na}) in GH3-cells with the whole-cell configuration of the patch clamp technique. I_{Na} was recorded after depolarization from a holding potential of –80 mV to a test potential of +5 mV. Initial 'tonic' block (resting state-dependent block) was defined as peak I_{Na} inhibition during the first pulse 2 min after drug application as compared with I_{Na} in the absence of drug. 'Use- (frequency-)-dependent' block of I_{Na} was measured during trains of 5 or 50 ms test pulses (3 Hz) applied from –80 mV to a test potential of +5 mV after a 2-min equilibrium period in the drug-containing solution. Use-dependent block was expressed as the percent decrease of peak I_{Na} during the last pulse of the train as compared with I_{Na} during the first pulse.

Khalifa et al. (1999) characterized the effects of an antidepressant agent on the fast inward current (I_{Na}) in isolated guinea pig ventricular myocytes. Currents were recorded in the whole-cell configuration of the patch-clamp technique in the presence of Ca^{2+} and K^+ channel blockers.

Haeseler et al. (1999) measured the effects of 4-chloro-m-cresol, a preservative added to a wide variety of drugs, on heterologously expressed wild type, Paramyotonia congenita (R1448H) and hyperkalemic periodic paralysis (M1360V) mutant α-subunits of human muscle sodium channels in whole-cell and inside-out voltage clamp experiments.

Song et al. (2000) studied the effects of *N*-ethylmaleimide, an alkylating agent to protein sulfhydryl groups, on tetrodotoxin-sensitive (TTX-S) and tetrodotoxin-resistant (TTX-R) sodium channels in rat dorsal root neurons using the whole cell configuration of the patch-clamp technique. Rats at the age of 2–6 days were anesthetized with isofluorane and the spinal cord was removed and cut longitudinally. Dorsal root ganglia were plucked from the area between the vertebrae of the spinal column, and incubated in phosphate-buffered saline solution containing 2.5 mg/ml trypsin at 37 °C for 30 min. After enzyme treatment, ganglia were rinsed with Dulbecco's Modified Eagle Medium supplemented with 10% horse serum. Single cells were mechanically dissociated by trituration with a fire-polished Pasteur pipette and plated on poly-L-lysine-coated glass coverslips. Cells attached to the coverslips were transferred into a recording chamber on the stage of an inverted microscope. Ionic currents were recorded under voltage-clamp conditions by the whole-cell patch-clamp technique. The solution of the pipette contained (in mM): CsCl 125, NaF 20, HEPES 5, EGTA 5. The pH was adjusted to 7.2 with CsOH and the osmolarity was 279 mosM/l on average. The external solution contained (in mM): NaCl 50, choline chloride 90, tetramethylammonium chloride 20, D-glucose 5, HEPES 5, $MgCl_2$ 1, $CaCl_2$ 1. Lanthanum ($LaCl_3$, 10 μM) was used to block calcium channel current. The solution was adjusted to pH 7.4 with tetramethylammonium hydroxide and the osmolarity was 304 mosM/l on average. An Ag–AgCl pellet/3 M KCl-agar bridge was used for the reference electrode. Membrane currents were recorded using an Axopatch-1D amplifier. Signals were digitized by a 12-bit analog-to-digital interface, filtered with a lowpass Bessel filter at 5 kHz and sampled at 50 kHz using pCLAMP6 software (Axon Instruments) on an IBM-compatible PC. Series resistance was compensated 60–70%. Capacitative and leakage currents were subtracted by using a P + P/4 procedure (Bezanilla and Armstrong 1977). The liquid junction potential between internal and external solution was on average –1.7 mV. TTX (100 nM) was used to separate TTX-R sodium currents from TTX-S sodium currents. For the study of TTX-S sodium channels, cells that expressed only TTX-S sodium channels were used. TTX-S sodium channels were completely inactivated within 2 ms when currents were evoked by depolarizing steps to 0 mV, while TTX-R sodium channels persisted for more than 20 ms. The difference in kinetics was used to identify the type of sodium current.

A.1.1.23.3 Voltage clamp studies on potassium channels

PURPOSE AND RATIONALE

Potassium channels represent a very large and diverse collection of membrane proteins which participate in important cellular functions regulating neuronal and cardial electrical patterns, release of neurotransmitters, muscle contractility, hormone secretion, secretion of fluids, and modulation of signal transduction pathways. Main categories of potassium channels are gated by voltage or an increase of intracellular calcium concentration (Escande and Henry 1993; Kaczorowski and Garcia 1999; Alexander et al. 2001). For ATP-sensitive potassium channels see Sect. K.6.1.9.

The delayed outward potassium current in heart muscle cells of several species in made up of a rapidly (I_{Kr}) and a slowly (I_{Ks}) activating component (Sanguinetti and Jurkiewicz 1990; Wang et al. 1994; Gintant 1996; Lei and Brown 1996; Carmeliet and Mubagawa 1998). Several potent and selective blockers for the I_{Kr} channel have been shown to prolong the effective refractory period, but have a reverse rate-dependent activity with both normal and elevated extracellular potassium concentrations (Colatsky et al. 1990). Inhibitors of the slow component I_{Ks} were developed in order to circumvent the negative rate dependence of I_{Kr} channel blockers on the effective refractory period (Busch et al. 1996; Suessbrich et al. 1996, 1997; Bosch et al. 1998). Gögelein et al. (2000) studied the effects of a potent inhibitor of I_{Ks} channels in *Xenopus* oocytes and guinea pig ventricular myocytes.

PROCEDURE

Studies in *Xenopus* oocytes are performed with the two microelectrode voltage clamp method. For isolation of the oocytes, the toads are anesthetized using a 1 g/l solution of 3-aminobenzoic acid ethyl ester and placed on ice. A small incision is made to retrieve sacs of oocytes and is subsequently closed with absorbable surgical suture. On waking up, the toads are placed back into the aquarium. The ovaries are cut up into small pieces and the oocytes are washed in Ca^{2+}-free Or-2 solution (82.5 mM NaCl, 2 mM KCl, 1 mM $MgCl_2$, 5 mM HEPES; pH 7.4) and subsequently collagenized in Or-2 containing collagenase A (1 mg/ml, Worthington, type II) until follicles are not longer detectable on the oocyte surface. The oocytes are stored at 18 °C in recording solution ND-96 (NaCl 96 mM, KCl 2 mM, $CaCl_2$ 1.8 mM, $MgCl_2$ 1 mM, HEPES 5 mM, pH 7.4) with additions of sodium pyruvate (275 mg/l), theophylline (90 mg/l) and gentamycin (50 mg/l).

For electrophysiological recordings, the two-microelectrode voltage-clamp configuration is used to record ion currents from *Xenopus* oocytes. Injection of cRNA is performed according to Methfessel et al. (1986), Golding (1992). Oocytes are injected individually with cRNA encoding for the human protein minK, guinea pig Kir2.1, human H*erg*, human Kv1.5, mouse Kv1.3, or human HNC2. In the case of minK the functional potassium channel is a heteromultimer composed of the endogenous (*Xenopus*) KvLQT1 and the injected human

minK. This heteromultimeric potassium current in then called I_{Ks} (Barhanin et al. 1996; Sanguinetti et al. 1996).

The electrophysiological recordings are performed at room temperature, using a Geneclamp amplifier (Axon Instruments, Foster City, CA, USA), and MacLab D/A converter. The amplitudes of the recorded currents are measured at the end of the test voltage steps. The control ND-96 solution contains (in mM): NaCl 96, KCl 2, $CaCl_2$ 1.8, $MgCl_2$ 1, HEPES 5, (pH 7.4). To amplify the inward potassium current through Kir2.1 and HNC2, the external potassium concentration is raised to 10 mM KCl and the NaCl concentration lowered to 88 mM (ND-88). The microelectrodes are filled with 3 M KCl and have a resistance between 0.5 MW and 1 MW. During the recordings the oocytes are continuously perfused with ND-96 (or ND-88 in the case of Kir2.1 and HCN2). The test compounds are dissolved in DMSO and added to the buffer ND-96 or ND-88. The current amplitude is determined after 5 min of wash-in time.

For the isolation of *ventricular myocytes*, guinea pigs (weight about 400 g) or Sprague-Dawley rats of either sex are sacrificed by cervical dislocation. The hearts are dissected and perfused retrogradely via the aorta at 37°C: first with nominally Ca^{2+}-free Tyrode solution (in mmol/l): 143 NaCl, 5.4 KCl, 0.5 $MgCl_2$, 0.25 NaH_2PO_4, 10 glucose, 5 HEPES, pH 7.2, then with Tyrode solution containing 20 mmol/l Ca^{2+} and 3 mg/ml collagenase type CLS II (Biochrom, Berlin Germany). After 5–10 min collagenase treatment the ventricles are cut up into small pieces in the storage solution (in mmol/l): 50 L-glutamic acid mono-potassium salt, 40 KCl, 20 taurine, 20 KH_2PO_4, 1 $MgCl_2$, 10 glucose, 0.2 EGTA, pH 7.2. The myocytes are then dispersed by gentle shaking followed by filtration through a nylon mesh (365 mm). The cells are finally washed twice by centrifugation at 90*g* for 5 min and kept in the storage solution at room temperature.

Whole cell currents are recorded in the tight-seal whole-cell mode of the patch-clamp technique, using an EPC-9 amplifier (HEKA Elektronik, Lambrecht, Germany). Patch pipettes are pulled from borosilicate glass capillaries (wall thickness 0.3 mm, outer diameter 1.5 mm) and their tips are fire-polished. Series resistance is in the range of 1–10 MW and 50% compensated by means of the EPC's compensation circuit.

The I_{Ks}, I_{Kr}, I_{K1} and currents are investigated in guinea pig ventricular myocytes. The voltage pulses for recording the current components are as follows: I_{Ks} current: holding potential –80 mV to –50 mV (200 ms) to +60 mV (3 s) to –40 mV (2 s) to –80 mV; I_{Kr} current: holding potential –80 mV to –50 mV (200 ms) to –10 mV (3 s) to –40 mV (2 s) to –80 mV. I_{Kr} is evaluated as the tail current evoked by a voltage pulse from –10 mV to –40 mV; I_{K1}: holding potential –80 mV to –120 mV (200 ms) to –80 mV. In order to suppress the L-type Ca^{2+} current, 5 mmol/l nifedipine is added to the bath solution.

EVALUATION

All average data are presented as means ±SEM. Student's *t*-test is used to determine the significance of paired observations. Differences are considered as significant at $P < 005$.

MODIFICATIONS OF THE METHOD

Using the whole-cell configuration of the patch-clamp technique, Grissmer et al. (1994) analyzed the biophysical and pharmacological properties of five cloned voltage-gated K^+ channels stably expressed in mammalian cell lines.

Sanchez-Chapula (1999) studied the block of the transient outward K^+ channel (I_{to}) by disopyramide in isolated rat ventricular myocytes using whole-cell patch-clamp techniques.

Using the patch clamp technique, Cao et al. (2001) investigated the effects of a centrally acting muscle relaxant and structurally related compounds on recombinant small-conductance Ca^{2+}-activated K^+ channels (rSK2 channels) in HEK mammalian cells.

Tagliatela et al. (2000) discussed the block of the K^+ channels encoded by the human *ether-á-go-go-related* gene (HERG), termed $K_{V(r)}$, which are the molecular determinants of the rapid component of the cardiac repolarizing current $I_{K(Vr)}$, involved in the cardiotoxic potential and CNS effects of first-generation antihistamines and may be therapeutic targets for antiarrhythmic agents (Vandenberg et al. 2001).

Chabbert et al. (2001) investigated the nature and electrophysiological properties of Ca^{2+}-independent depolarization-activated potassium currents in acutely isolated mouse vestibular neurons using the whole-cell configuration of the patch-clamp technique. Three types of currents were identified.

Caballero et al. (2001) analyzed the effects of angiotensin II type 1 receptor antagonists on cloned potassium channels (hKv1.5, HERG, KvLQT1+minK, Kv4.3) expressed in *Ltk*$^-$ or Chinese hamster ovary cells using the patch-clamp technique.

Longobardo et al. (2000) studied the effects of a quaternary bupivacaine derivative on delayed rectifier K^+ currents stably expressed in *Ltk*$^-$ cells using the whole-cell configuration of the patch-clamp technique.

A.1.1.23.4 Voltage clamp studies on calcium channels

PURPOSE AND RATIONALE

Calcium influx through voltage-gated Ca^{2+} channels mediates a range of cytoplasmatic responses, including muscle contraction, release of neurotransmitters, Ca^{2+} dependent gene transcription and the regulation of neuronal excitability has been reviewed by several authors (Augustine et al. 1987; Bean 1989; Miller 1987; Zamponi 1997; Snutch et al. 2001). In addition to their normal physiological function, Ca^{2+} channels as calcium antagonists are also implicated in a number of human disorders (see also A.4.0.1).

Using patch clamp techniques, the structure and regulation of voltage-gated Ca^{2+} channels has been studied by many authors (Sculptoreanu et al. 1993; Peterson et al. 1997; Catterall 2000).

Berjukow et al. (2000) analyzed the role of the inactivated channel conformation in molecular mechanism of Ca^{2+} channel block by a dihydropyridine derivative in L-type channel constructs and mutants in *Xenopus* oocytes and described the electrophysiological evaluation.

PROCEDURE

Inward barium currents (I_{Ba}) are studied with two microelectrode voltage-clamp of *Xenopus* oocytes 2–7 days after microinjection of approximately equimolar cRNA mixtures of constructs of L-channel mutants. All experiments are carried out at room temperature in a bath solution with the following composition: 40 mM $Ba(OH)_2$, 50 mM NaOH, 5 mM HEPES,

2 mM CsOH (pH adjusted to 7.4 with methanesulfonic acid). Voltage recording and current injecting microelectrodes are filled with 2.8 M CsCl, 0.2 M CsOH, 10 mM EGTA, 10 mM HEPES (pH 7.4) with resistances of 0.3–2 MΩ. Resting channel block is estimated as peak I_{Ba} inhibition during 100-ms test pulses from −80 to 20 mV at a frequency of 0.033 Hz until steady state is reached. The dose response curves of I_{Ba} inhibition were fitted using the Hill equation:

$$\frac{I_{Ba,drug}}{I_{Ba,control}}(\%) = \frac{100 - A}{1 + \left(\frac{C}{IC_{50}}\right)^{nH}} + A$$

where IC_{50} is the concentration at which I_{Ba} inhibition is half-maximal, C is the applied drug concentration, A is the fraction of I_{Ba} that is not blocked, and nH is the Hill coefficient.

Recovery from inactivation is studied at a holding potential of −80 mV after depolarizing Ca^{2+} channels during a 3-s prepulse to 20 mV by applying 30-ms test pulses (to 20 mV) at various time intervals after the conditioning prepulse. Peak I_{Ba} values are normalized to the peak current measured during the prepulse, and the time course of I_{Ba} recovery from inactivation is fitted to a mono- or biexponential function

$$I_{Ba,recovery} = A \times \exp\left(\frac{-t}{\tau_{fast}}\right) + B \times \exp\left(\frac{-t}{\tau_{slow}}\right) + C$$

Voltage dependence of inactivation under quasi-steady state conditions is measured using a multi step protocol to account for run-down (less than 10%). A control test pulse (50 ms to 20 mV) is followed by a 1.5-s step to−100 mV followed by a 30-s conditioning step, a 4-ms step to −100 mV, and a subsequent test pulse to 20 mV (corresponding to the peak potential of the *I-V* curves).

Inactivation during the 30 s conditioning pulse is calculated as follows.

$$I_{Ba,inactivation} = \frac{I_{Ba,test}(20\,mV)}{I_{Ba,control}(20\,mV)}$$

The pulse sequence is applied every 3 min from a holding potential of −100 mV. Inactivation curves are drawn according to the following Boltzmann equation.

$$I_{Ba,inactivation} = I_{SS} + (1 - I_{SS})\left(1 + \exp\left(\frac{V - V_{0.5}}{k}\right)\right)$$

where V is the membrane potential, $V_{0.5}$ is the midpoint voltage, k is the slope factor, and I_{SS} is the fraction of non inactivating current.

Steady state inactivation of the mutate channels at −80 mV is estimated by shifting the membrane holding potential from −80 to −100 mV. Subsequent monitoring of the corresponding changes in I_{Ba} amplitudes until steady state reveals the fraction of Ca^{2+} channels in the inactivated state at −80 mV. Steady state inactivation of different L-type channel constructs at −30 mV is estimated by fitting time course of current inactivation to a biexponential function.

The I_{Ba} inactivation time constants are estimated by fitting the I_{Ba} decay to a mono- or biexponential function.

EVALUATION

Data are given as the means ±SE. Statistical significance is calculated according to Student's unpaired *t*-test.

MODIFICATIONS OF THE METHOD

Besides *Xenopus* oocytes (Waard and Campell 1995; Hering et al. 1997; Kraus et al. 1998), several other cell types and constructs, such as CHO cells (Sculptoreanu et al. 1993; Stephens et al. 1997), HEK293 (human embryonic kidney) cells (Lacinová et al. 1999), tsA-201 cells, a subclone of HEK293, (Peterson et al. 1997; McHugh et al. 2000), cardiac myocytes from rats (Scamps et al. 1990; Tohse et al. 1992; Gomez et al. 1994) and rabbits (Xu et al. 2000), isolated atrial myocytes from failing and non-failing human hearts (Cheng et al. 1996), skeletal muscle myotubes from mice and rabbits, (Johnson et al. 1994), myocytes of guinea pig mesentery artery (Morita et al. 1999), dendrites from rat pyramidal and olfactory bulb neurons (Markram and Sakmann 1994; Stuart and Spruston 1995; Koester and Sakmann 1998; Margie et al. 2001), rat amygdala neurons (Foehring and Srcoggs 1994; Young et al. 2001) were used to study the function of calcium channels.

Using the whole-cell variation of the patch-clamp technique, Yang et al. (2000) studied cellular T-type and L-type calcium channel currents in mouse neuroblastoma N1E115 cells. The cells were cultured in Dulbecco's modified Eagle's medium containing 10% fetal bovine serum at 37 °C in a humidified atmosphere of 5% CO_2 in air. The medium was changed every 3–4 days. After mechanical agitation, 3×10^4 cells were replanted in 35-mm tissue culture dishes containing 4 ml of bath solution. After cell attachment, the dish was mounted on the stage of an inverted phase-contrast microscope for Ca^{2+} channel current recording. These cells expressed predominantly T channel currents. In experiments where L channels were specifically sought, the cells were grown and maintained at confluence for 3–4 weeks under the same culture condi-tions with the addition of 2% dimethylsulfoxide (Narahash et al. 1987). Three to 5 days before use, the

cells were replanted with the same medium. These cells expressed predominantly L channel currents. A small number of these cells also expressed T channel currents. Hence, cells were selected so that at a holding potential of –40 mV, the T channel component was very small and the inward current measured was conducted predominantly by L channels.

By using whole-cell and perforated patch-clamp techniques, Wu et al. (2000) showed that mifrabidile, a non-dihydropyridine compound, has an inhibitory effect on both T- and L-type Ca^{2+} currents in pancreatic β-cells.

A.1.1.23.5 Patch clamp studies on chloride channels

PURPOSE AND RATIONALE

Cl^- channels are a large, ubiquitous and highly diverse group of ion channels involved in many physiological key processes including: regulation of electrical excitability; muscle contraction; secretion; and sensory signal transduction. Cl^- channels belong to several distinct families characterized in detail: voltage-gated Cl^- channels, the cAMP-regulated channel CFTR (cystic fibrosis transmembrane conductance regulator), ligand-gated Cl^- channels that open upon binding to the neurotransmitters GABA or glycine, and Cl^- channels that are regulated by the cytosolic Ca^{2+} concentration (Jentsch and Günther 1997; Frings et al. 2000).

Cliff and Frizel (1990) studied the cAMP- and Ca^{2+}-activated secretory Cl^- conductances in the Cl^- secreting colonic tumor epithelial cell line T84 using the whole-cell voltage-clamp technique.

PROCEDURE

T84 cells are used 1–3 days after plating on collagen-coating cover-slips. The cells are maintained at 37 °C. At this temperature, the responsiveness of the cells to secretagogues, particularly to cAMP-dependent agonists, is improved. Increases in Cl^- and K^+ conductances are the major electrical events during stimulation of Cl^- secretion. Accordingly, bath-pipette ion gradients are chosen so that transmembrane Cl^- and K^+ currents can be monitored independently at clamp voltages equal to the reversal potentials of these ions. The pipette solution is: 115 MM KCl, 25 mM *N*-methyl-D-glucamine (NMDG) glutamate, 0.5 mM EGTA, 0.19 mM $CaCl_2$, 2 mM $MgCl_2$, 2 mM Na_2ATP, 0.05 mM Na_3GPT, 5 mM HEPES, pH 7.2. The bath solution is: 115 mM NaCl, 40 mM NMDG glutamate, 5 mM potassium glutamate, 2 mM $MgCl_2$, 1 mM $CaCl_2$, 5 mM HEPES, pH 7.2. Bath Na^+ and Cl^- concentrations are reduced by substituting NMDG chloride or sodium glutamate for NaCl. When Na^+ and K^+ free solutions are used, Na^+ and K^+ are replaced by $NMDG^+$, and Cl^- is reduced by replacing Cl^- by glutamate.

During whole-cell recording, the membrane potential is clamped alternately to three different voltages, each for 500-msec duration. Computer-controlled voltage-clamp protocols are used to generate current-voltage (*I-V*) relations when the transmembrane currents are relatively stable by stepping the clamp voltage between −100 and +100 mV at 20 mV intervals.

Test drugs (e.g., 8-(4-chlorophenylthio) adenosine 3',5'-cyclic monophosphate, A23187, forskolin, or ionomycin) are solubilized in stock solutions (ethanol of DMSO) and diluted.

EVALUATION

Instantaneous relations are constructed from currents recorded 6 msec after a voltage step.

MODIFICATIONS OF THE METHOD

Maertens et al. (2000) used the whole-cell patch-clamp technique to study the effect of an antimalarial drug on the volume-regulated anion channel (VRAC) in cultured bovine pulmonary artery endothelial cells. They also examined the effects on other Cl^- channels, i.e., the Ca^{2+} activated Cl^- channel and the cystic fibrosis transmembrane conductance regulator to assess the specificity for VRAC.

Pusch et al. (2000) characterized chloride channels belonging to the ClC family. Chiral clofibric acid derivates were tested on the human ClC-1 channel, a skeletal muscle chloride channel, after heterologous expression in *Xenopus laevis* oocytes by means of two microelectrode voltage clamp recordings.

A.1.1.24 Measurement of cytosolic calcium with fluorescent indicators

PURPOSE AND RATIONALE

Intracellular free Ca-concentration can be measured in cultured endothelial cells with a fluorometric methods (Tsien et al. 1982; Grynkiewicz et al. 1985; Lückhoff et al. 1988; Busse and Lamontagne 1991; Hock et al. 1991).

PROCEDURE

Cultured endothelial cells from the pig are seeded on quartz coverslips and grown to confluence. The cells are loaded with the fluorescent probe indo-1 by incubation with 2 µmol indo-1/AM and 0.025% Pluronic® F-127, a non-ionic detergent. Thereafter, the coverslips are washed and transferred to cuvettes, filled with HEPES buffer.

EVALUATION

Fluorescence is recorded in a temperature controlled (37 °C) spectrofluorophotometer (excitating wavelength 350 nm, emission wavelength simultaneously measured at 400 and 450 nm).

MODIFICATIONS OF THE METHOD

Lee et al. (1987) measured cytosolic calcium transients from the beating rabbit heart using indo-1 AM as indicator.

Yangisawa et al. (1989) measured intracellular Ca^{2+} concentrations in coronary arterial smooth muscle of dogs with fura-2.

Makujina et al. (1995) measured intracellular calcium by fura-2 fluorescence simultaneously with tension in everted rings of porcine coronary artery denuded of endothelium.

Hayashi and Miyata (1994) described the properties of the commonly used fluorescent indicators for intracellular calcium: Fura-2, Indo-1, and Fluo-3.

Monteith et al. (1994) studied the Ca^{2+} pump-mediated efflux in vascular in spontaneously hypertensive rats.

A.1.1.25 Measurement of contractile force of isolated cardiac myocytes

PURPOSE AND RATIONALE

Eschenhagen et al. (1997) developed a method for culturing embryonic cardiomyocytes in a collagen matrix to produce a coherently contracting 3-dimensional model heart tissue that allows direct measurement of isometric contractile force.

PROCEDURE

Ventricles from 9–11 day incubated chicken embryos (Cavanaugh 1955) are minced in Dulbecco's minimal essential medium (DMEM), washed once with 0.25% trypsin/0.1% EDTA in phosphate buffered saline (PBS), pH 7.45, and then digested in fresh trypsin/EDTA for 15 min at 37 °C. The supernatant is discarded and the pellet is subjected to digestion with 0.1% collagenase (144 U/mg) in PBS, pH 7.45, for 30 min at 37 °C. This supernatant is discarded and the pellet digested further with several cycles of collagenase for 10–20 min each until the pellet is completely digested. DNase I (40 µl, 1 mg/ml in PBS) is added between cycles depending on the presence of viscous DNA. The isolated cells are kept in Petri dishes in DMEM supplemented with 15% heat-inactivated fetal calf serum in the CO_2 incubator. After completion of the digestion, the cells are incubated for another 30–60 min in the CO_2 incubator (preplating). The cell suspension is centrifuged at 250 rpm (12 *g*). The pellet is resuspended in 10 ml culture medium (DMEM, 10% inactivated horse serum, 2% chicken embryo extract (Gibco BRL), 2 mmol/l glutamine, 10 µg/ml streptomycin, and 100 U/ml penicillin G, recentrifuged at 250 rpm, and finally resuspended in culture medium at $2–3 \times 10^6$ cells per ml.

For casting cardiomyocyte-populated collagen gels, strips of Velcro are glued with silicone rubber to glass tubes (13 mm length, 3 mm outer diameter, 2 mm inner diameter). Pairs of Velcro-coated tubes, kept at a fixed distance by a stainless steel wire spacer, are placed in rectangular wells ($15 \times 17 \times 4$ mm) cut into a layer of silicone rubber in a 100 mm polymethylenepentene Petri dish. This assembly is autoclaved before use. For each gel, 1 ml of an ice-cold collagen/cell mixture is poured into each well between the Velcro-coated glass tubes. This mixture has the same composition as the culture medium and contains in addition to 1 mg neutralized collagen I from rat tail (Upstate Biotechnol-

ogy, Inc.), 1×10^6 cardiomyocytes, the acetic acid in the collagen solution, and the NaOH to neutralize it. The mixture is allowed to gel at 37 °C for 60 min before culture medium is added to the dish. Medium changes are performed after overnight and then every other day.

After 6–11 days in culture, the gels are removed from the culture dish, the spacers are withdrawn, and one of the glass tubes is mounted on a fixed electrode; the other tube is connected by an inelastic silk string to an isometric force transducer attached to a Wekagraph thermal array recorder (Föhr Instruments, Heidelberg, Germany). The preparation is adjusted to its original (spacer) length before it is immersed in a convential water bath filled with modified Tyrode's solution maintained at 35 °C and continuously gassed with 95% O_2 and 5% CO_2.

After a 30–60 min equilibration period without pacing, force and frequency reaches a stable value. Gels are then electrically stimulated with rectangular pulses (10 ms, 20–40 V) at a standard frequency of 1.5 Hz. Preload is stepwise adjusted to L_{max}, the length at which the preparation develops maximal force. Cumulative doses of inotropic compounds, e.g. isoprenaline or forskoline, are added. All gels are exposed to a concentration-response curve for calcium (1.8–12.6 mmol/l) and one or two additional inotropic stimuli.

EVALUATION

All values are presented as arithmetic means ±SEM. Student's *t*-test for paired observations is used to compare force of contraction, resting tension, or beating frequency before and after other interventions.

MODIFICATIONS OF THE METHOD

Ferrara et al. (1997) studied the role of Gi-proteins and β-adrenoceptors in the age-related decline of contraction in guinea-pig ventricular myocytes. The isolated myocytes were placed in Krebs-Henseleit solution in a Perspex chamber on the stage of a Zeiss IM inverted microscope and superfused with Krebs-Henseleit solution containing 1 mmol/l Ca^{2+} at 2 ml/min and 32 °C. Cells were selected using the following criteria: rod shaped, without sarcolemmal blebs, no spontaneous contractions, stable baseline contraction to electrical stimulation at 0.5 Hz and sarcomere length not shorter than 1.67 µm. The image of the cells was displayed on a TV monitor and the length change measured with a video motion detector. Contraction amplitude and velocity was expressed as change in sarcomere length, calculated from the change in length of the myocyte and its original sarcomere length.

Using a similar technique, Harding et al. (1988) studied contractile responses of isolated rat and rabbit myocytes to isoproterenol and calcium, and Harding et al. (1992) isolated ventricular myocytes from failing and non-failing human heart.

A.1.1.26 Adrenomedullin

A.1.1.26.1 General considerations

Adrenomedullin is a 52-amino acid peptide originally discovered in human adrenal pheochromocytoma by monitoring the elevating activity of platelet cAMP (Kitamura et al. 1993). Molecular cloning of rat adrenomedullin was reported by Sakata et al. (1993). The genomic structure of human adrenomedullin gene was reported by Ishimitsu et al. (1994). Adrenomedullin and **proadrenomedullin N-terminal 20 peptide (PAMP)** which are both hypotensive and bronchodilating, are derived from **preproadrenomedullin** (Kanazawa et al. 1995; Iwasaki et al. 1996; Shimosawa and Fujita 1996; Hinson et al. 1998; Samson 1998; Autelitano and Tang 1999; Jimenez et al. 1999; Lopez et al. 1999; Tajima et al. 1999).

Adrenomedullin is found ubiquitously in tissues and organs, especially in cardiovascular tissues and in the kidney, lung, brain and endocrine glands (Wimalawansa 1996; Van Rossum et al. 1997; Eto et al. 1999; Jougasaki and Burnett 2000; Kitamuro et al. 2000). The main biological effect is vasodilatation (Ishiyama et al. 1993). A hypotensive effect has been found in rats (Khan 1997), rabbits (Fukuhara et al. 1995), and man (Lainchbury et al. 1997). Adrenomedullin belongs to the calcitonin gene-related peptide/calcitonin peptide family as it shares approximately 25% homology with calcitonin gene-related peptide (Kitamura et al. 1993). Several pharmacological studies are related to the vasodilating

effect of adrenomedullin, e.g., in the mesenteric vascular bed (see A.8.2.5), (Santiago et al. 1995), in the hind limb vascular bed (see A.8.2.1), (Santiago et al. 1994; Champion et al. 1996, 1997), in the pulmonary vascular bed (see A.8.2.6), (DeWitt et al. 1994; Lippton et al. 1994; Heaton et al. 1995; Nossaman et al. 1995), on cerebral blood flow in dogs (Baskaya et al. 1995) and in cats (Takao et al. (1999), on renal hemodynamics in dogs (see A.8.2.3) (Ebara et al. 1994; Yukawa 1998), or on vasodilation in perfused rat kidneys (Hayakawa et al. 1999). Intravenous infusion of adrenomedullin exerted diuresis and natriuresis without major changes in blood pressure and produced beneficial hemodynamic and renal vasodilator effects in rats with compensated heart failure (Vari et al. 1996; Nagaya et al. 1999). In isolated perfused, paced rat heart preparations, adrenomedullin showed a dose-dependent inotropic effect (Szokodi et al. 1998). Pulmonary vasodilator responses and vasorelaxant effects in isolated pulmonary artery rings were found by Gumusel et al. (1998). Adrenomedullin is a growth-promoting factor for cultured vascular smooth muscle cells (Iwasaki et al. 1998) and fibroblasts (Isumi et al. 1998).

Willenbrock et al. (1999) showed a beneficial effect of adrenomedullin on renal function in rats with aortocaval shunt.

Adrenomedullin inhibits gastric secretion in rats with chronic gastric fistula (see J.3.1.3), (Rossowski et al. 1997) and inhibits reserpine-induced gastric lesions in rats (Clementi et al. 1998). Tsuchida et al. (1999) found an inhibition of cholecystokinin-stimulated amylase secretion by adrenomedullin in rat pancreatic acini.

Lewis et al. (1998) described a specific and sensitive radioimmunoassay for human adrenomedullin.

Ohta et al. (1999) developed an one-step direct assay for adrenomedullin with monoclonal antibodies.

N-terminal fragments of adrenomedullin show vasopressor activities (Watanabe et al. 1996).

Adrenotensin, an other adrenomedullin gene product, contract in an endothelium-dependent manner pulmonary blood vessels (Gumusel et al. 1996).

A.1.1.26.2 Receptor binding of adrenomedullin

PURPOSE AND RATIONALE

Muff et al. (1995), Poyer (1997) reviewed the binding characteristics of the structurally related hormones calcitonin, calcitonin gene-related peptide, amylin, and adrenomedullin. Vine et al. (1996) compared *in vitro* binding of adrenomedullin, calcitonin gene-related peptide and amylin.

Specific adrenomedullin binding sites were described in human brain (Sone et al. 1997), in the rat spinal cord (Owji et al. 1996), in cultured brain cells (Zimmermann et al. 1996), and in cultured rat mesangial cells (Osajima et al. 1996).

PROCEDURE

Human brain is obtained at autopsy. For preparation of membranes, tissues are homogenized in ice-cold 50 mM HEPES buffer, pH 7.6; containing 0.25 M sucrose, 10 µg/ml soybean trypsin inhibitor, 0.5 µg/ml pepstatin, 0.5 µg/ml leupeptin, 0.5 µg/ml antipain, 0.1 mg/ml benzamidine, 0.1 mg/ml bacitracin, and 30 µg/ml aprotinin. The homogenates are centrifuged at 1 500 *g* for 20 min at 4 °C. The pellets are resuspended in 10 vol of the above buffer without sucrose and centrifuged at 100 000 *g* for 1 h at 4 °C. The final pellets are resuspended to a concentration of 2–10 mg protein/ml, aliquoted, and stored at –80 °C.

For the receptor binding assay, brain membranes (100 µg protein) are incubated at 4 °C in 0.5 ml binding buffer (20 mM HEPES buffer, pH 7.4, containing 5 mM $MgCl_2$, 10 mM NaCl, 4 mM KCl, 1 mM EDTA, and 0.3% BSA) containing 0.3 nM ^{125}I- human adrenomedullin in siliconized microcentrifuge tubes. Pellets are washed with 0.5 ml binding buffer at 4 °C and counted in a γ-counter.

EVALUATION

Nonspecific binding is determined in the presence of 200 nM unlabeled human adrenomedullin. Specific binding is defined as total binding minus nonspecific binding. Data are calculated as mean ±SEM.

MODIFICATIONS OF THE METHOD

Eguchi et al. (1994) studied the binding of human adrenomedullin and analogs and the adenylate cyclase activity in cultured rat vascular smooth muscle cells.

Moody et al. (1997) investigated the binding affinity of adrenomedullin in C6 glioma cells.

Findings of Belloni et al. (1998) suggested the existence of different receptor subtypes for adrenomedullin in the human adrenal cortex.

Mazzocchi et al. (1999) found abundant [^{125}I]-adrenomedullin binding sites in both zona glomerulosa and adrenal medulla in the rat adrenal gland.

A.1.1.27 Atrial natriuretic factor (ANF)

A.1.1.27.1 General considerations

PURPOSE AND RATIONALE

The atria of mammalian hearts synthesize and secrete peptides with potent natriuretic and vasoactive properties known as ANF = atrial natriuretic factor (de Bold et al. 1981). The atrial natriuretic peptide hormonal system consists of a 126-amino acids prohormone synthesized within myocytes of the heart and stored in storage granules within the heart before release into circulation (Kangawa and Matsuo 1984; Oikawa et al. 1984; Vesely 1992). This hormonal system contains several peptides from the 126-amino acid-prohormone with blood pressure lowering, natriuretic, diuretic and/or kaliuretic properties (Martin et al. 1990; Vesely et al. 1994). Thus, peptides consisting of amino acid 1 to 30 (LANP = long-acting natriuretic peptide), 31 to 67 (vessel dilator), 79 to 98 (kaliuretic peptide) and 99 to 126 (ANF) each have blood pressure lowering, natriuretic, diuretic and/or kaliuretic properties both in humans and

in animals. Human and rat atria predominantly secrete a peptide of 28 amino acid residues, ANF-(99-126), which represents the C-terminus of a precursor sequence of 126 amino acid residues. In addition, vessel dilator and LANP circulate as distinct entities after having been proteolytically cleaved from the rest of the amino terminus by proteases (Ackerman et al. 1997).

Plasma immunoreactive ANF-(99-126) concentration increases in normal rats after volume expansion, while infusion of the peptide lowers blood pressure in several animal models of hypertension.

An international standard for atrial natriuretic factor was established by an international collaborative study (Poole et al. 1988). Human ANF-(99-126) was synthesized, highly purified and distributed to several laboratories, who performed radioimmunoassays, radioreceptor assays and an *in vitro* assay using the vasorelaxant activity in precontracted rat aortic strips.

The C-type natriuretic peptide is a 22-amino acid peptide that was initially identified in the central nervous system (Ogawa et al. 1992; Barr et al. 1996; Amin et al. 1996). The distribution of C-type natriuretic peptide, which has structural homology with atrial and brain natriuretic peptides and also similar activities, is wide and includes the endothelium, myocardium, gastrointestinal and genito-urinary tracts.

Jiao and Baertschi (1993) reviewed the neural control of the endocrine rat heart. Stimulation of cardiac sympathetic nerves potently stimulates ANF secretion.

ANF inhibits proliferation in non-myocardial cells and is anti-hypertrophic in cardiomyocytes. Silberbach et al. (1999) reported that activation of an extracellular signal-regulated protein kinase is required for the anti-hypertrophic effect of atrial natriuretic factor in neonatal rat ventricular myocytes.

A.1.1.27.2 Bioassay for ANF

PURPOSE AND RATIONALE

Matsui et al. (1987) described a rapid bioassay for quantification of atrial natriuretic polypeptides in rats with continuous recording of the conductivity of the urine, urine flow and blood pressure.

PROCEDURE

Male Sprague Dawley rats weighing 180–240 g are anesthetized with 60 mg/kg i.p. pentobarbital sodium. Anesthesia is maintained by injection of supplemental doses of pentobarbital sodium. After tracheotomy, catheters are placed into the left jugular vein and the right carotid artery for injection of samples or infusion of 10% mannitol in 0.9% saline and for blood pressure recording. Through a small suprapubic incision the bladder is cannulated for collection of urine, and the cannula is connected to a device for continuous measurement of urine conductivity, by which the electrolyte concentration is estimated. Urine flow rate is recorded using a drop counter, and urine samples are collected in a plastic tube.

After completion of surgery, 0.6–0.8 ml of 10% mannitol in 0.9% saline is administered into the jugular vein and is continuously infused at a rate of 4.0 ml/h by a syringe pump. Following an equilibration of 45–60 min, the bioassay is started when the urine flow is increased to 50–75 µl/min. All test samples with a volume of 100 µl are directly injected into the jugular vein followed by a wash injection of ~30 µl of saline. Mean arterial blood pressure, urine conductivity, and urine flow rate are simultaneously recorded.

For dose-response curves, serial dilutions of human ANF (α-hANP) and of test substance are prepared. Vehicle and various doses of α-hANP or test substance are injected in a randomized sequence. Immediately after the injection, urine is collected for 10 min. Urine volumes are determined by weighing, and urinary sodium and potassium concentrations are measured by flame photometry.

EVALUATION

Linear-regression analyses by the method of least squares are used for evaluating dose-response relationship. One-way analysis of variance for repeated measures and the Newman-Keuls test are used to detect statistical differences.

MODIFICATIONS OF THE METHOD

Petersen et al. (1988) determined atrial content and plasma levels of atrial natriuretic peptides in rats with chronic renal failure. The natriuretic activity in the bioassay was estimated as the increase in Na excretion in urine samples from the control period to the maximal natriuretic response.

Allen and Gellai (1987) measured cardio-inhibitory effects of atrial peptide in conscious chronically instrumented rats. The hemodynamic and renal excretory responses were measured with and without replacement of urinary fluid losses.

Thibault et al. (1984) characterized the biological activities of atrial natriuretic factor-related peptides *in vivo* by a natriuretic bioassay and *in vitro* by relaxation of contracted intestinal smooth muscle (chick rectum).

Schiller et al. (1986) tested synthetic analogs of atrial natriuretic peptide in the rabbit aorta assay and in a bioassay monitoring suppression of aldosterone secretion from bovine zona glomerulosa cells.

Dlouha and McBroom (1986) measured diuretic and natriuretic activity of atrial extracts of taurine-treated normal and cardiomyopathic hamsters by urine flow and Na^+ excretion in the rat bioassay.

Kohse et al. (1992) described a bioassay for quantitative determination of natriuretic peptides in human biological samples using bovine aortic and bovine kidney epithelial cultured cells. The amount of cyclic AMP produced by these cells was measured by radioimmunoassay.

Kecskemeti et al. (1996) studied the effects of atrial natriuretic peptide (ANP) on action potential characteristics in various (human, rabbit, guinea-pig) atrial and guinea pig ventricular papillary muscles. The data suggested that ANP inhibits the slow inward Ca^{2+} channel activity and facilitates the K^+ channel activity.

Salt-sensitive hypertension was found in ANP knockout mice (Melo et al. 1998).

A.1.1.27.3 Receptor binding of ANF

PURPOSE AND RATIONALE

Schiffrin et al. (1985) described receptors for atrial natriuretic factor in the rat.

PROCEDURE

Synthetic ANF-(99-126) is iodinated with ^{125}I by a modification (Gutskowska et al. 1984) of the chloramine T method (Greenwood and Hunter 1963). Separation of radiolabeled ANF from free iodine is achieved by immuno-affinity chromatography followed by C-18 reverse phase high pressure liquid chromatography.

For preparation of membranes, Sprague Dawley rats weighing 300 g are sacrificed by decapitation. The atria, ventricles, renal arteries, mesentery, the mesentery vascular bed, and adrenals are processed for binding studies. Adrenal capsules are separated by manual compression. The tissues are immersed in 0.25 M sucrose solution, finely minced with scissors, and homogenized in a Polytron (setting 8, 10 s twice). The

homogenate is centrifuged at 1 550 *g* for 10 min at 4 °C; the supernatant is decanted and recentrifuged. The final supernatant is filtered through a cheesecloth, then centrifuged at 10 400 *g* for 30 min. The pellet is resuspended in a 0.05 M Tris-HCl buffer, pH 7.4, containing 120 mM NaCl, 5 mM $MgCl_2$, 0.5 mM phenyl methyl sulfonyl fluoride, 0.1% bacitracin, and 1 µM aprotinin. Proteins are measured by the Coomassie blue method (Spector 1978). Next, bovine serum is added at a concentration of 0.2%, and the membranes are diluted to a protein concentration of 0.25 to 1 mg/ml in the Tris-buffer containing 0.2% albumin.

The ^{125}I-AFN binding assay uses 30–50 pM of labeled ANF and 10^{-13} to 10^{-6} unlabeled ANF in competition experiments. In saturation experiments, increasing concentrations of ^{125}I-AFN (6–200 pM) are used, and nonspecific binding is determined by incubation in the presence of 1 µM unlabeled ANF for each point of the saturation curves. Incubation is done with 25–100 µg of receptor protein per tube, at 4 °C for 60 min. All assays are performed in duplicate. Separation of bound and free radioactivity is achieved by rapid filtration through polyethylenimine-treated Whatman GF/C filters soaked with the assay buffer. The filters are washed twice with 3 ml of 0.9% NaCl, then are allowed to dry and are counted in a gamma counter.

EVALUATION

Binding data are analyzed by computer assisted nonlinear regression analysis using the LIGAND program (Munson and Rodbard 1980). The inhibition constant K_i is calculated according the Cheng and Prussoff equation.

MODIFICATIONS OF THE METHOD

Misono (2000) found that the binding of atrial natriuretic factor to its receptor is dependent on chloride concentration.

A.1.1.27.4 ANF gene expression

PURPOSE AND RATIONALE

Production of atrial natriuretic factor and brain natriuretic peptide can be measured by gene expression using total RNA extraction and Northern blot analysis and the quantitative competitive reverse transcription polymerase chain reaction (Hama et al. 1995; Ogawa et al. 1996, 1997, 1998, 1999).

PROCEDURE

Extraction of plasma and tissue samples

Plasma samples are acidified by adding 100 µl/ml of 1 mol/l HCl and passed through Sep-Pak C_{18} cartridges (Millipore) that are prewetted with 5 ml of 80% acetonitrile in 0.1% trifluoroacetic acid (TFA) and 10 ml of 0.1% TFA. The cartridges with the absorbed peptides are washed with 20 ml of 0.1% TFA and eluted with 3 ml of 60% acetonitrile in 0.1% TFA. Tissue samples are homogenized in 10 vol of an extracting mixture consisting of 0.1 N HCl, 1.0 mol/l acetic acid, and 1% NaCl and centrifuged at 10 000 *g* for 30 min at 4 °C. The supernatants are then extracted with the use of Sep-Pak C_{18} cartridges by elution with 80% acetonitrile in 0.1% TFA. The eluates from tissue or plasma are freeze-dried and processed for RIA.

Total RNA extraction and northern blot analysis

Atrial and ventricular tissue samples from individual rats are extracted using Trizol (GIBCO BRL). Total RNA from the atrium (10 µg) and ventricle (20 µg) are electrophoretically separated in an agarose-formaldehyde gel followed by blotting to nylon membranes (Hybond N+, Amersham) overnight. Membranes are prehybridized in 2.5× Denhardt's solution, 5× SSC, 50% formamide, 25 mmol/l KH_2PO_4, pH 6.4, 0.2% SDS, and 0.2 mg/mL herring sssDNA for 3 h at 42 °C for cDNA probes, or prehybridized in 5× Denhardt's solution, 6× SSC, 50 mmol/l NaH_2PO_4, 0.5% SDS, and 0.2 mg/ml herring sssDNA for 3 h at 5 °C below the calculated T_m for oligonucleotide probes. Hybridization is then carried out for 16 h at the same temperature and the same solution as the prehybridization condition except for the presence of the radiolabeled probes. Five cDNA probes and two oligonucleotide probes are used. The cDNA probes used are as follows: (1) a 900-bp *Eco*RI/*Hin*dIII fragment containing the full-length rat ANF cDNA, (2) a 595-bp *Sal*I fragment containing full-length rat BNP cDNA, (3) a 5-kb *Eco*RI/*Sal*I fragment of the mouse 28S rRNA cDNA probe, (4) a 2-kb *Bam*HI/*Bgl*II fragment of the mouse PGK gene cDNA, and (5) rat α_1-III collagen

cDNA containing 1 300 bp of the 3' noncoding and coding regions. The two oligonucleotide probes are 39 and 24 base fragments specific for unique regions in the 3' untranslated regions of the rat α-MHC and β-MHC genes. The α-sequence is

5'GGGATAGCAACAGCGAGGCTCTTTCTGC-TGGACAGGTTA-3' (T_m = 60°C),

and the β-sequence is

5'-CTCCAGGTCTCAGGGCTTCACAGG-3' (T_m = 52°C).

The cDNAs are labeled with 5'-[α^{32}P]dCTP (3 000 Ci/mmol, Amersham) using the Megaprime DNA labeling system (Amersham). The oligonucleotides are labeled with [γ-^{32}P]ATP (3 000 Ci/mmol, Amersham) using a 5'-end-labeling kit (Amersham). At the end of hybridization, the membranes are washed twice at 42 °C with 2× SSC and 1% SDS and twice at 55 °C with 1× SSC and 0.1% SDS for the cDNA probes or are washed once at 30 °C with 5× SSC and 0.1% SDS and twice at the same temperature as the hybridization with 1× SSC and 0.1% SDS for the oligonucleotide probes. Before additional probing, bound counts are completely stripped from the membranes by washing twice in 10 mmol/l sodium citrate, pH 6.8, 0.25% SDS for 10 min at 100 °C. Autoradiographs are scanned with an Ultrascan XL laser densitometer (LKB Produckter) and LKB 2400 Gelscan XL software package. The scanning values of ANF, BNP, collagen-III, and α-MHC and β-MHC mRNAs are normalized to 28S ribosomal RNA or PGK mRNA as internal controls to correct for differences in the amount of RNA applied and transfer efficiency.

Plasma and cardiac tissue concentrations of immunoreactive ANF and BNP are determined by RIA with anti-rat $ANF_{99–126}$ and anti-rat $BNP_{64–95}$ sera, respectively, from Peninsula Laboratories.

Quantitative competitive reverse transcription polymerase chain reaction

RNA samples are reverse transcribed with Super Script II RNase H 2 Reverse Transcriptase and oligo(dT)12–18 primer with the use of a reverse transcription kit (GIBCO BRL). An aliquot of the cDNA product is used for PCR amplification with ANF primers. A dilution series of total RNA (5 mg) aliquots is prepared for each sample. Each dilution is spiked with competitor RNA. After the PCR, aliquots (5 ml) of the PCR product are electrophoresed on a 2% agarose gel and visualized by ethidium bromide staining. Photographs are taken with Polaroid 55 film, and the negatives are scanned with the use of an Ultrascan XL laser densitometer and Gelscan XL 2000 software package. The ratio of the density of the competitor RNA to the target RNA is plotted against the amount of the competitor RNA added to each reaction.

EVALUATION

All results are expressed as mean ±SEM. A level of $P < 0.5$ is considered significant. ANOVA is performed to determine statistical differences among multiple groups. When significance is obtained by ANOVA, Fisher's least squares difference post hoc analysis is used to determine pairwise differences.

MODIFICATIONS OF THE METHOD

Ramirez et al. (1997) reported that the nuclear δ_B isoform of Ca^{2+}/calmodulin-dependent protein kinase II regulates atrial natriuretic gene expression in cultured neonatal rat ventricular myocytes.

Thuerauf et al. (1998) found that the p38 mitogen-activated protein kinase mediates the transcriptional induction of the atrial natriuretic factor gene through a serum response element and discussed the potential role for the transcription factor ATF6.

Kakita et al. (1999) studied p300 protein as a co-activator of the transcription factor GATA-5 in the transcription of cardiac-restricted atrial natriuretic factor gene.

Bianciotti and de Bold (2000) investigated the effect of selective ET_A receptor blockade on natriuretic peptide gene expression in DOCA-salt hypertension in rats.

A.1.1.27.5 Radioimmunoassay for ANF

PURPOSE AND RATIONALE

Gutkowska et al. (1984) developed a direct radioimmunoassay of atrial natriuretic factor (ANF). The method uses a synthetic 26-amino-acid fragment (8–33 ANF) of the native peptide.

PROCEDURE

Because 8–33 ANF is a small molecule, it is necessary to covalently conjugate the peptide to a larger protein (bovine thyroglobulin) for immunization. To 50 mg thyroglobulin dissolved in 2 ml distilled water, pH 7.4, 30 mg CDI [1-ethyl-3-(3-dimethylaminopropyl) carbodiimide HCl] is added in 1 ml distilled water, pH 7.4. Then 5 mg 8–33 ANF in water is added dropwise while stirring. The solution is kept overnight at 4 °C, then another 30 mg CDI is added and the mixture is kept for 2 h at room temperature with constant stirring. The cloudy mixture is dialyzed for 24 h at 4 °C against 0.9% saline. The dialyzed material is then fractionated and stored at –70 °C.

For immunization, 100 µg of the ANF-thyroglobulin complex are suspended in 1 ml saline, thoroughly mixed with 1 ml complete Freund's adjuvant and injected into the shaved backs of New Zealand white rabbits. Each animal receives also 0.5 ml *Bordetella pertussis* vaccine subcutaneously with the primary immunization. The animals are re-immunized at monthly intervals with 100 µg of antigen in incomplete Freund's adjuvant and bled by ear artery 10 days after the booster injection.

For iodination, 5 µg ANF in 5 µl 0.01 M ammonium acetate, pH 5.0 is introduced in a 1.5 ml Eppendorf vial followed by the addition of 1 mCi Na ^{125}I in a volume of 25 µl. Chloramine T 10 µg/10 µl is added to the reaction vial and 30 s later sodium metabisulfide (20 µg/10 µl) is added. Each addition is followed by mixing. Purification of the iodinated tracer is achieved by HPLC on a µBondapax C_{18} column, eluted with a linear gradient of 20 to 50% acetonitrile with 0.1% trifluoroacetic acid with a slope of 0.5%/min and a flow rate of 1 ml/min.

The radioimmunoassay procedure is performed in polystyrene tubes at 4 °C by mixing 100 µl of standard or sample, 100 µl of antiserum diluted 1:4 000, 100 µl of ^{125}I-ANF and 300 µl of the same buffer containing 1% BSA. After incubation for 24 h at 4 °C the free from antigen-bound ^{125}I-ANF is separated by dextran-coated charcoal. One ml of dextran-charcoal suspension is added to each tube. After 5 s agitation the tubes are centrifuged at 4 000 rpm at 4 °C for 10 min. The supernatant is decanted and the radioactivity counted in a gamma counter.

EVALUATION

Dose-response curves are prepared and Scatchard analysis is performed.

MODIFICATIONS OF THE METHOD

Radioimmunoassays were also developed for long-acting natriuretic peptide and vessel dilator (Vesely et al. 1994; Winters et al. 1989).

A.1.2 Studies in isolated organs

A.1.2.1 α-Sympatholytic activity in isolated vascular smooth muscle

PURPOSE AND RATIONALE

Noradrenaline and other sympathomimetic drugs increase vascular smooth muscle tone by stimulation of α-adrenergic receptors. Contractions can be antagonized by α-adrenergic receptor blocking agents such as phentolamine. Drugs can be tested for their capacity of reducing vascular smooth muscle contractions induced by the adrenergic receptor-activating agent noradrenaline. Moreover, effects of peptides, such as bradykinin, can be tested with strips of aorta or pulmonary artery.

PROCEDURE

As donor animals Pirbright White guinea pigs of either sex weighing about 400 g, or Chinchilla rabbits weighing about 3.5 kg, or Sprague-Dawley rats weighing 200–300 g are used. The vessels to be tested are the thoracic aorta or the arteria pulmonalis. The animals are sacrificed by stunning and exsanguination. The pulmonary artery or the thoracic aorta is quickly removed and cut into helical strips of 1–2 mm width and 15–20 mm length. The strips are mounted in an organ bath with a preload of 1 g. Krebs-Henseleit buffer solution containing 11.5 M glucose is maintained at 37 °C and oxygenated with 95% O_2, 5% CO_2. Isotonic or isometric registration is performed. Changes in length are recorded isotonically using a lever transducer (368 type B, Hugo Sachs Elektronik Freiburg). Isometric force is measured with a force transducer (UC-2 Gould-Statham, Oxnard, USA).

Experimental course

Following an equilibration period of 60 min, contractions are induced by repeated administrations of (–)noradrenaline HCl in concentrations of 2×10^{-6} M for testing the contractions of the pulmonary artery and in concentrations of 2×10^{-8} M for testing the contractions of the aorta. After obtaining a stable plateau of identically sized contractions, cumulative doses of the test compound are added into the organ bath. Consecutive concentrations are given when the response of the previous dose has reached a plateau.

Controls at the end of the experiment: If a compound does not show vasorelaxing activity at any dose, the sensitivity of the preparation is tested by adding phentolamine (1×10^{-7} M).

If a compound shows vasorelaxing activity, the reversibility of the relaxation is tested by increasing the noradrenaline concentration.

EVALUATION

The contractile force is determined before and after drug administration.

Percent inhibition of spasmogen-induced contraction by test drug is calculated as compared to the maximal contraction with a spasmogen alone (= 100%).

IC_{50} values are determined from the individual dose-response curves. IC_{50} is defined as the dose of drug leading to a 50% relaxation of noradrenaline-induced contraction.

MODIFICATIONS OF THE METHOD

The isolated vena cava of rabbits can be used for assaying α-adrenolytic activity. The rabbit is sacrificed by CO_2 anesthesia. The vena cava inferior is removed and cut into strips. The percent inhibition of epinephrine or norepinephrine induced contractions is determined.

The effects of bradykinin and bradykinin antagonists can be tested in isolated guinea pig artery and isolated rabbit aorta which contains predominantly the BK_1-receptor type (Regoli and Barabé 1980; Hock et al. 1991).

Wisskirchen et al. (1998) tested agonists of calcitonin gene-related peptide, homologues and antagonists in rat isolated pulmonary artery. Endothelium-intact pulmonary artery rings were contracted with 3×10^{-8} M phenylephrine and a cumulative dose-response curve of relaxation was constructed.

A.1.2.2 α-Sympatholytic activity in the isolated guinea pig seminal vesicle

PURPOSE AND RATIONALE

The seminal vesicles of guinea pigs and rats are tubular organs whose longitudinal and annular muscles are innervated by the sympathetic system. The inhibition of contractions induced by norepinephrine or the α_1-selective agonist phenylephrine indicates α-sympatholytic activity. Sharif and Gokhale (1986) recommended the use the isolated rat seminal vesicle as a rather sensitive and specific model.

PROCEDURE

Male guinea pigs weighing 300 to 600 g are sacrificed by a blow to the neck. Both seminal vesicles are prepared and placed in Ringer's solution in an organ bath

maintained at 32 °C and being oxygenated with 95% O_2/5% CO_2. Isotonic or isometric registration is performed. Changes in length are recorded isotonically using a lever transducer (368 type B, Hugo Sachs Elektronik Freiburg). Isometric force is measured with a force transducer (UC-2 Gould-Statham, Oxnard, USA).

Following an equilibration period of 30 min, contractions are induced by repeated administration of (–)norepinephrine HCl in concentrations of 1 to 5 µg/ml or phenylephrine HCl in concentrations of 10 to 50 µg/ml. After obtaining a stable plateau of identical contractions, the test compound is added into the organ bath. Three min later, the previous concentration of norepinephrine or phenylephrine is added. As standard phentolamine is used in concentrations of 3 to 30×10^{-7} M.

EVALUATION

Contractions of the seminal vesicle induced by the α-adrenergic agonists after addition of the test compound are compared with the initial values and expressed as percentage thereof. For in depth analysis, full dose-response curves of the agonist are recorded before and after addition of various doses of the antagonist. A parallel shift to the right indicates competitive antagonism which can be evaluated as pA_x – values according to Schild (1947)

MODIFICATION OF THE METHOD

Leitch (1954) recommended the use of isolated seminal vesicles of rats for the assay of sympatholytic drugs.

A.1.2.3 α-Sympatholytic activity in the isolated vas deferens of the rat

PURPOSE AND RATIONALE

The vas deferens of the guinea pig or preferably the rat is used for quantitative evaluation of adrenergic antagonists. The response of this organ to α-adrenergic agonists consists of a strong rapid contraction followed by quick relaxation on washing the agonists out of the tissue.

PROCEDURE

Male Wistar rats weighing about 300 g are used. The animals are sacrificed by a sharp blow to the neck, the vasa deferentia are dissected free from the extraneous tissues and suspended in a organ bath containing Tyrode solution being oxygenated with a 95% O_2 and 5% CO_2 mixture at 32 °C. Isotonic registration is performed at a preload of 0.5 g. Changes in length are recorded isotonically using a lever transducer (e.g., 368 type B, Hugo Sachs Elektronik, Freiburg, FRG).

Following an equilibration period of 30 min, contractions are induced by repeated administration of (–)norepinephrine HCl in concentrations of 0.5, 1.0, 2.0, or 4.0 µg/ml. After obtaining a stable plateau of identical contractions, the test compound is added into the organ bath. Three min later, the previous concentration of norepinephrine is added. As standard phentolamine is used in concentrations of 3 to 30×10^{-7} M.

EVALUATION

Contractions of the vas deferens induced by the α-adrenergic agonist after addition of the test compound are compared with the initial values and expressed as percentage thereof. For in depth analysis, full dose-response curves of the agonist are recorded before and after addition of various doses of the antagonist. A parallel shift to the right indicates competitive antagonism which can be evaluated as pA_x – values according to Schild (1947).

MODIFICATIONS OF THE METHOD

Electrical stimulation of the isolated ductus deferens results in the release of norepinephrine. Stimulation induced contractions of this organ are inhibited by clonidine which impairs adrenergic neurotransmission by activating inhibitory α-receptors. The ductus deferens is suspended in an organ bath bubbled with carbogen and maintained at 37 °C. Tension is adjusted to 25 mN. Following a 45 min equilibration period, supramaximal amplitude stimulation by a HSE type 2 stimulator (Hugo Sachs Elektronik, Freiburg) is applied. After stabilization of the response, clonidine is added to the organ bath in accumulated doses. Test compounds are added 5 min prior to clonidine administration. The percent potentiation of clonidine induced inhibition of contractions is determined.

Taylor et al. (1983) used the rat deferens for pharmacological characterization of purinergic receptors.

Nerve-muscle preparations of the vas deferens have been reviewed by Holman (1975).

Hughes et al. (1974) used the electrically stimulated mouse vas deferens for assessment of the agonistic and antagonistic activities of narcotic analgesic drugs.

Ross et al. (2001) used the mouse vas deferens to study structure-activity relationship for the endogenous cannabinoid, anadamide, and certain of its analogues at vanilloid receptors.

Oka et al. (1980) recommended the vas deferens from rabbits as a specific bioassay for opioid κ-receptor agonists.

Mutafova-Yambolieva and Radmirov (1993) studied the effects of endothelin-1 on electrically- or drug-induced contractile responses mediated by purinergic or adrenergic receptors in the isolated prostatic portion of rat vas deferens.

Ward et al. (1990) used isolated vasa deferentia preparations from rat and mouse to study the pharmacological profile of the analgesic pravadoline.

Hukovic (1961) described an isolated ductus deferens preparation together with the sympathetic hypogastric nerve of the guinea pig.

Cordellini and Sannomiya (1984) pretreated guinea pigs with reserpine. In the isolated vasa deferentia concentration-effects curves to phenylephrine were established in the presence of cocaine. The antagonistic effect of phenoxybenzamine was used for receptor occupancy studies.

Donoso et al. (1992) studied neurotransmission in epididymal and prostatic segments of isolated superfused rat vas deferens preparations.

Vaupel and Su (1987) used the vas deferens preparation of guinea pigs to study sigma and phencyclidine receptors.

Eltze (1988) used the field-stimulated (95% of maximum voltage, 0.1 Hz, 0.5 ms) portion of rabbit vas deferens to study muscarinic M_1 and M_2-receptors.

Dumont et al. (1997) used the isolated guinea pig heart and the isolated rat vas deferens for *in vitro* bioassays of calcitonin gene-related peptide (CGRP) agonists and antagonists.

Poyner et al. (1999) found concentration-dependent inhibitions of the electrically stimulated twitch responses of guinea pig vas deferens by calcitonin gene-related peptide, amylin and adrenomedullin.

Wisskirchen et al. (1998) tested agonists of calcitonin gene-related peptide, homologues and antagonists in rat isolated vas deferens. The prostatic half was suspended under 0.5 g resting tension and equilibrated in Krebs solution at 37 °C. Contractile responses of the prostatic vas were induced by electrical field stimulation at 0.2 Hz, 1.0 ms and 60 V through parallel platinum electrodes either side of the tissue.

A.1.2.4 α-Sympatholytic activity in the isolated rat spleen

PURPOSE AND RATIONALE

α-Stimulant agents (such as epinephrine, norepinephrine) or electrical stimulation induce contractions in sympathetically innervated organs such as spleen smooth muscle. These effects can be antagonized by drugs with α-blocking activities such as phentolamine.

PROCEDURE

Male Sprague-Dawley rats weighing 180–220 g are used. The animal is sacrificed in CO_2 anesthesia. The spleen is removed and cut longitudinally into two halves. Each part is placed in an organ bath containing nutritive solution. The bath solution is bubbled with carbogen and maintained at 37 °C. Following a 30 min incubation period under a tension of 0.5 g, contractions are elicited by administration of epinephrine (10^{-6} g/ml) or norepinephrine 10^{-6} g/ml). After obtaining 3 approximately identical spasms, the test compound is administered followed by the addition of the spasmogen 5 min later. The contractile response is allowed to plateau and recorded.

Standard compound:

- phentolamine

EVALUATION

The contractile force is recorded at its maximal level before and after drug administration. The percent inhibition of epinephrine or norepinephrine induced contraction is determined.

A.1.2.5 α-Sympatholytic activity in the isolated rat anococcygeus muscle

PURPOSE AND RATIONALE

The rat anococcygeus muscle as pharmacological tool was introduced by Gillespie (1972, 1980), Gibson and Gillespie (1973). This smooth muscle has a dense adrenergic innervation and contracts to noradrenaline, acetylcholine, 5-hydroxytryptamine, but not to histamine. Moreover, the muscle contracts to field stimulation or stimulation of extrinsic nerves. The preparation can be used to assess the pre- and post-synaptic α-adrenoceptor blocking activity of drugs (Doggrell 1980, 1983).

PROCEDURE

The two anococcygeus muscles arise from the upper coccygeal vertebra close to one another in the midline of the pelvic cavity. The muscles pass caudally, lying first behind and the to one side of the colon, finally joining together to form a ventral bar in front of the colon a few mm from the anus. The extrinsic nerves pass in a branch of the perineal nerve on either side to enter the deep surface of each muscle just before the formation of the ventral bar.

After sacrifice, the abdomen of rats is opened in the mid-line, the pelvis split and the bladder and urethra removed. Care is required in clearing the lower part of the urethra to avoid damage to the ventral bar of muscle, the only region lying ventral to the colon. The colon is then cut through at the pelvic brim, the pelvic portion pulled forward and the delicate connective tissue behind cleared until the anococcygeus muscles come into view. The muscles are isolated, in some instances with the extrinsic nerve intact. The extrinsic nerves on either side run in the posterior scrotal branch of the perineal nerve and leave it to enter the deep surface of the anococcygeal muscles as the lie on the lateral surface of the colon. The ventral bar is cut through and each muscle mounted in a 100 ml bath containing Krebs solution at 36 °C. The solution is gassed with 95% O_2 + 5% CO_2. Tension is measured with isometric transducers and displayed on a polygraph. Field stimulation of the intramural nerves is applied after drawing the muscles through a pair of electrodes similar to those described by Burn and Rand (1960); when the muscles are stimulated through their extrinsic nerves the nerves are drawn through similar electrodes. Stimulation of either intramural or extrinsic nerves is with 1 ms pulses at 20 Hz, and at a supramaximal voltage.

Dose-response curves are established with doses of 2×10^{-7} to 4×10^{-6} M noradrenaline, 4×10^{-7} to 4×10^{-5} M acetylcholine or with graded frequencies of electrical stimulation.

The effect of noradrenaline is abolished by α-adrenergic antagonists, such as 10^{-6} M phentolamine. Dose-response curves show a parallel shift characteristic of competitive antagonism.

EVALUATION

Contractions of the anococcygeus muscle induced by an α-adrenergic agonist after addition of the test compound are compared with the initial values and expressed as percentage thereof. For in depth analysis,

full dose-response curves of the agonist are recorded before and after addition of various doses of the antagonist. A parallel shift to the right indicates competitive antagonism which can be evaluated as pA_x – values according to Schild (1947).

MODIFICATIONS OF THE METHOD

Gibson et al. (1990) found L-N^G-nitroarginine to be a potent inhibitor of non-adrenergic, non-cholinergic relaxations in the rat anococcygeus muscle.

Oliveira and Bendhack (1992) found that dopamine has a dual effect in the rat anococcygeus muscle: a partial effect due to an indirect sympathomimetic action and a partial effect due the interaction with postjunctional receptors.

Brave et al. (1993) investigated the interaction between motor sympathetic and inhibitory non-adrenergic, non-cholinergic nerves in the rat anococcygeus muscle using L-N^G-nitro-arginine, an inhibitor of L-arginine:NO synthase.

Cakici et al. (1993) described a co-axial bioassay system consisting of guinea pig trachea as donor organ for epithelial derived-relaxing factors and phenylepinephrine-precontracted rat anococcygeus muscle as assay tissue.

Iravani and Zar (1993) found differential effects of nifedipine on nerve-mediated and noradrenaline-evoked contractions of rat anococcygeus muscle.

Rand and Li (1993) studied the modulation of acetylcholine-induced contractions of the rat anococcygeus muscle by activation of nitrergic nerves.

Mudumbi and Leighton (1994) investigated the mechanisms of action of relaxation induced by bradykinin and by electrical field stimulation in isolated rat anococcygeus muscle, where contractile tone had been elevated with clonidine.

Gwee et al. (1995) investigated the prejunctional and postjunctional inhibition of adrenergic transmission in the rat isolated anococcygeus muscle by cimetidine.

Najbar et al. (1996) found that smooth muscle cells in the rat anococcygeus muscle are endowed with two distinct P-2-purinoreceptors which subserve contractions.

Pettibone et al. (1993) examined the inhibitory potency and selectivity of an oxytocin antagonist against oxytocin-stimulated contractions if the **mouse** anococcygeus muscle.

Dehpour et al. (1993) and Radjaee et al. (1996) used isolated anococcygeus muscles from **rabbits** and found an extremely regular activity induced by methoxamine or clonidine.

A.1.2.6 β_1-Sympatholytic activity in isolated guinea pig atria

PURPOSE AND RATIONALE

The β-agonist isoprenaline (isoproterenol) induces an increase in the frequency and force of contraction of spontaneously beating isolated right atrias and potentiates contractions of electrically stimulated isolated left atria. Drugs with β-sympatholytic activity inhibit these isoprenaline-induced effects. β-receptor blocking activity of drugs can be evaluated in isolated right (a) and left (b) guinea pig atria. Since the heart contains predominantly β_1-adrenoreceptors, β_1-blocking activity is assessed by this test.

PROCEDURE

Pirbright White guinea pigs of either sex weighing 250–300 g are used. The animal is sacrificed by stunning and exsanguination. The heart is removed, the right or the left atrium is cut off and mounted in a 50 ml organ bath with a preload of 100 mg. The Krebs-Henseleit solution is maintained at 32 °C and aerated with 95% O_2/5% CO_2. Contractions are recorded isotonically using a lever transducer (368 type B, Hugo Sachs Elektronik, Freiburg).

Right atrium

After an equilibration period of 30 min, isoprenaline is administered into the organ bath to potentiate inotropy and frequency of the isolated right atrium. Cumulative doses of isoprenaline are added starting from a concentration of 0.05 µg/ml; consecutive doses are administered at 3 min intervals.

When a stable maximum plateau of the effect is achieved, the organ bath is thoroughly flushed for 1 min; flushing is repeated twice 5 and 20 min later. The whole procedure is repeated with the same isoprenaline concentrations (control baseline values = 100%).

The test compound is then added into the organ bath and 5 min later, again isoprenaline is given at cumulative doses.

If the test compound has β-receptor blocking activity (β-sympatholytic),

1. higher isoprenaline concentrations are necessary to induce the same potentiation of inotropy and frequency or
2. at the same isoprenaline concentrations added as before, the increase in inotropy and frequency is reduced.

At the end of the experiment, again a cycle without test drug is performed.

Left atrium

The left atrium is stimulated by a square wave stimulator with 2 impulses/s at a voltage of 15 V and an impulse duration of 1 ms. After an equilibration period of 30 min, the β-agonist isoprenaline is added at concentrations of 0.05–0.1 mg/ml. The organ bath is then thoroughly flushed for 1 min. Flushing is repeated twice 5 and 20 min later. The whole procedure is repeated with the same cumulative isoprenaline concentrations (control baseline values = 100%) and flushing procedure.

When a stable plateau of contractions is achieved, the test compound is added into the organ bath and 3 min later, isoprenaline is added again at cumulative concentrations.

If the test compound has β-receptor blocking activity (β-sympatholytic), the isoprenaline-induced effects are inhibited.

In addition, refractory period is determined before and after drug administration.

EVALUATION

a) Percent inhibition of (a) isoprenaline-induced or (b) electrically-induced and isoprenaline-potentiated increased inotropy and frequency by test drug is calculated as compared to pre-drug activity (= 100%).
b) Percent change in refractory period is calculated.

IC_{50} values are determined from the individual dose-response curves.

Statistical evaluation is performed by means of the paired *t*-test.

Standard compounds:

- propranolol HCl,
- amrinon,
- nifedipine,
- and milrinone.

MODIFICATIONS OF THE METHOD

A detailed description of the use of isolated atrial preparations has been given by Levy (1971).

Instead of the right atrium, Doggrell and Hughes (1986) used the isolated right ventricle of the rat for the assessment of the β-adrenoreceptor blocking activity of propranolol and investigated the competitive nature of the isoproterenol antagonism at various doses with Schild-plot analysis. Doggrell (1988) used the isolated left atria of the rat for simultaneous assessment of membrane-stabilizing and β-adrenoreceptor blocking activity.

Berthold et al. (1990) described a method for testing cardiotonic sodium channel activators in isolated, electrically stimulated left guinea pig atria after potassium depolarization.

Olson et al. (1995) studied the function of isolated rat left atria and papillary muscles and quantified the voltage-response relationship between punctate and field electrical stimulation after pretreatment with reserpine or β-blockers.

A.1.2.7 β_2-Sympatholytic activity in the isolated tracheal chain

PURPOSE AND RATIONALE

Contraction of bronchial smooth muscle is induced by the cholinergic agonist carbachol. The carbachol effect can be antagonized by the β-agonist isoprenaline (isoproterenol). A compound has β-sympatholytic activity if the spasmolytic action of isoprenaline is inhibited. The ß-sympatholytic effect of drugs can be evaluated in an *in vitro*-model. Since the trachea contains predominantly β_2-adrenoreceptors, β_2-blocking activity can be assessed by this test.

PROCEDURE

Male Pirbright White guinea pigs weighing 250–300 g are used. The animals are sacrificed by stunning and exsanguination. The trachea is removed and cut into individual rings. Six rings are connected in series by means of short loops of silk thread. The tracheal chain is mounted in an 50 ml organ bath with a preload of 1 g for isotonic registration. To the nutritive solution (Tyrode) containing ascorbic acid and 1.0 g/L glucose, the α-receptor blocking agent phentolamine (0.1 µg/ml) and the spasmogen carbachol (80 ng/ml) are added. The solution is maintained at 34 °C and aerated with 95% O_2, 5% CO_2

Experimental course

After an equilibration period of 30 min, cumulative doses of 10^{-10} to 10^{-7} M of the spasmolytic agent isoprenaline are added. When maximal relaxation is obtained, the organ bath is flushed and the procedure repeated. After the two control relaxations with isoprenaline, the tissue is rinsed thoroughly and the first dose of the test compound is administered. Three min later, cumulative doses of isoprenaline are administered as before. Following a 10 min washout and recovery period, the next dose of the test compound is given. Up to 10 drug concentrations can be tested with one organ.

Standard compounds:
- propranolol
- practolol

EVALUATION

Percent inhibition of isoprenaline-induced relaxation under drug treatment is calculated compared to maximal relaxation induced by isoprenaline alone (control = 100%).

A competitive antagonism of test compound is evaluated and can be quantitated from the dose-response curve.

MODIFICATIONS OF THE METHOD

O'Donnell and Wanstall (1980) used guinea pig tracheal preparations, where K^+-depolarization was achieved by replacing all the Na^+ in Krebs solution by an equivalent amount of K^+ causing a sustained contraction of the preparations. A dose-dependent relaxation effect of isoprenaline could be obtained provided that the preparations were repolarized by washing in normal Krebs solution between curves. pA_2 values were in good agreement with values obtained in other types of tracheal preparations.

Guinea pig superfused trachea and dispersed tracheal cells have been used by Buckner et al. (1995) to compare the effects of isoproterenol and forskolin on immunologic and nonimmunologic histamine release.

The rat portal vein has been recommended as model for assessment of β_2 adrenoceptor blocking activity of drugs by Doggrell (1990).

A.1.2.8 Angiotensin converting enzyme inhibition in the isolated guinea pig ileum

PURPOSE AND RATIONALE

The angiotensin-converting enzyme (ACE) is responsible for the formation of the active angiotensin II from the inactive angiotensin I. The same enzyme is responsible for the degradation of the active peptide bradykinin to inactive products. ACE activity can therefore be measured in two ways: activity of the newly formed angiotensin II and inhibition of the activity of bradykinin. ACE inhibition results in decreased activity of the precursor angiotensin I and potentiation of the bradykinin effect. The guinea pig ileum contracts in response to both peptides, angiotensin II and bradykinin, and can be used for quantitative determination of ACE inhibiting activity.

PROCEDURE

Guinea pigs of either sex weighing 300 to 500 g are used. They are sacrificed by stunning and exsanguination. The abdomen is opened with scissors. Just distal to the pylorus, a cord is tied around the intestine which is then severed above the cord. The intestine is gradually removed, and the mesentery is being cut away as necessary. When the colon is reached, the intestine is cut free. Below the cord, the intestine is cut halfway through, so that a glass tube can be inserted. Tyrode's solution is passed through the tube and the intestine until the effluent is clear. Mesentery is cut away from the intestine that was joined to the colon. Pieces of 3 cm length are cut. Preferably, the most distal piece is used being the most sensitive one. This piece is fixed with a tissue clamp and brought into an organ bath with Tyrode's solution at 37 °C being oxygenated with O_2. The other end is fixed to an isometric force transducer (UC 2 Gould-Statham, Oxnard USA). Responses are recorded on a polygraph.

Angiotensin I antagonism

After an equilibrium time of 30 min, angiotensin I is added in a concentration of 10 ng/ml bath solution. The force of contraction is recorded and the angiotensin I dosage is repeated once or twice until the responses are identical. Then the potential ACE inhibitor is added. After 5 min incubation time, again angiotensin I is added. The contraction is diminished depending on the activity of the ACE inhibitor.

Bradykinin potentiation

Pieces of guinea pig ileum are prepared as described before. After an equilibrium time of 30 min bradykinin is added in a concentration of 15 ng/ml bath solution. The force of contraction is recorded and bradykinin additions are repeated once or twice until the response is identical. Then the potential ACE inhibitor is added. After 5 min incubation time, again bradykinin is added. The contraction is potentiated depending on the activity of the ACE inhibitor.

EVALUATION

Angiotensin I antagonism

The contraction after addition of the ACE inhibitor is expressed as percentage of contraction without the ACE inhibitor. Using various doses of the ACE inhibitor IC_{50} values (concentrations inducing 50% inhibition) are calculated. As standards ramipril, enalapril, and captopril are used.

Bradykinin potentiation

The increase of the contraction after addition of the ACE inhibitor is expressed as percentage of contraction without the ACE inhibitor. As standard ramipril is used.

CRITICAL ASSESSMENT OF THE METHOD

The classical method of the isolated guinea pig ileum has been proven to be a reliable method for screening of potential ACE inhibitors.

Rubin B, Laffan RJ, Kotler DG, O'Keefe EH, Demaio DA, Goldberg ME (1978) SQ 14,225 (D-3-mercapto-2-methylpropanoyl-L-proline), a novel orally active inhibitor of angiotensin I-converting enzyme. J Pharmacol Exp Ther 204:271–280

A.1.2.9 Contractile and relaxing activity on isolated blood vessels including effects of potassium channel openers

PURPOSE AND RATIONALE

The contractile process within the vascular smooth muscle results from an increase in the concentration of intracellular Ca^{2+}. Inhibition of vasoconstriction occurs by addition of calcium antagonists or by removal of extracellular calcium. The vasorelaxing effects of compounds can be tested in isolated rodent arteries (pulmonary artery, thoracic aorta). Arterial rings or strips with or without endothelial lining are contracted with different agents, e.g., extracellular K^+ and Ca^{2+}, the α-adrenoceptor agonists phenylephrine and noradrenaline, the Ca^{2+} ionophore A23187 or the thromboxane receptor agonist U46619. Compounds with vasodilating activity antagonize the induced contractions.

Potassium channel openers such as cromakalin, nicorandil, pinacidil or HOE 234 induce relaxation of contracted smooth musculature (Bolton et al. 1998). These effects are explained by data from patch clamp technique and ion flux experiments as well as by antagonism against potassium channel blockers. They indicate the potential use as antihypertensive and anti-asthmatic drugs (Hamilton and Weston 1989; Edwards and Weston 1990, 1993; Weston and Edwards 1992). The studies are complicated by the high diversity of potassium channels including ATP-sensitive, voltage-sensitive and Ca^{2+}-activated channels (Mourre et al. 1986; Blatz and Magleby 1987; Ashcroft and Ashcroft 1990; Jan and Jab 1990; Pongs 1992; Wann 1993). Since each functional channel appears to consist of four different subunits, the possibility exists that there may be hundreds of different voltage-sensitive K channels, depending on their subunit composition. Ashcroft and Gribble (2000) discussed new windows on the mechanism of action of K_{ATP} channel openers.

Glibenclamide is an antagonist of the ATP-modulated K^+ channel allowing the localization of the binding sites (Eltze 1989; French et al. 1990; Mourre et al. 1990; Miller et al. 1991).

PROCEDURE

Male Pirbright White guinea pigs weighing about 400 g, or Chinchilla rabbits weighing about 3.5 kg, or Sprague-Dawley rats weighing 250–400 g are used as donor animals. The tested vessels are the thoracic aorta or the arteria pulmonalis.

Materials and solutions

Physiological salt solutions (PSS) [mM]

	PSS I	PSS II	PSS III
NaCl	122	112	72 (92)
KCl	5.0	5	40 (20)
$CaCl_2$	1.2	–	–
$MgSO_4$	0.56	0.56	0.56
KH_2PO_4	1.2	1.2	1.2
$NaHCO_3$	25	25	25
EDTA	–	0.2	–
glucose	12	12	12

Contracting agents

$K^+ + Ca^{2+}$	40 mM + 0.5 mM
$K^+ + Ca^{2+}$	20 mM + 0.5 mM
U 46619 (thromboxane A_2 analogue)	1 μM
A 23187 (calcium ionophore)	5 μM
noradrenaline	1 μM
phenylephrine	0.1 μM
acetylcholine	1 μM
oxyhemoglobin	10 μM
methylene blue	10 μM

Animals are sacrificed by stunning and exsanguination. At least 4 isolated organs are tested per drug. The heart and the pulmonary artery are quickly removed and immersed in PSS I at room temperature. The artery is dissected into rings and endothelial cells are removed by gently rubbing the intimal surface. Spirally cut strips of 15–20 mm length and 1–1.5 mm width are suspended at a resting force of 380 mg in an organ bath containing 20 ml oxygenated (95% O_2, 5% CO_2) PSS I at 37 °C. Changes in length are recorded isotonically using a lever transducer (368 type B, Hugo Sachs Elektronic, Freiburg).

To test the effect of compounds on vessels with intact endothelial lining, the thoracic aorta of rats is isolated and dissected free from surrounding tissue. Rings of 3 mm width are cut and suspended in the organ bath containing PSS I. Isometric force is measured with a force transducer (UC-2, Gould-Statham, Oxnard, USA) under a resting tension of 500 mg.

The functional integrity of the endothelium is tested before drug administration. One μM acetylcholine in the organ bath should result in a transient relaxation.

After an equilibration period of 1 h, contraction of each vessel strip or ring is induced by addition of one of the contracting agents into the organ bath.

To induce contractions of potassium-depolarized vessels, three different PSS solutions are used (PSS I for 30 min, PSS II for 3×15 min and PSS III). Contraction is induced in the presence of PSS III by adding 0.5 mM Ca^{2+} into the organ bath.

When a stable plateau of contraction is achieved, cumulative concentrations of the test compound are added into the organ bath to obtain drug-response curves. Consecutive concentrations are added either at 1 h-intervals or when the response of the previous dose has reached a steady state level.

In order to study the time course of relaxation and the duration of action, only one concentration is tested.

To test whether the mechanism of action of a vasorelaxing agent is related to the liberation of nitric oxide, methylene blue or oxyhemoglobin (10 μM) are added to the organ bath 15–30 min prior to the cumulative administration of the test compound. Methylene blue or oxyhemoglobin block selectively NO induced relaxation.

EVALUATION

Mean values of relaxation ±SEM are calculated. The height of contraction before the first drug administration is taken as 100%.

IC^{50} values are determined from the individual dose-response curves. IC^{50} is defined as the dose of drug leading to a 50% relaxation of the contraction induced by KCl or other agonists.

Statistical evaluation is performed by means of the *t*-test.

MODIFICATIONS OF THE METHOD

Calderone et al. (1996) compared four **rat** aortic preparation (single ring, spiral strip, zig-zag strip, and multiple ring) on the basis of responses to noradrenaline and acetylcholine. They recommended the multiple ring preparation as the most suitable of all four for the study of vasoactive drugs because of the reproducibility of both contracturant and relaxing responses.

Kent et al. (1982) used rat aortic strips contracted to a stable tension by either phenylephrine or barium chloride for comparison of vasodilators.

Wilson et al. (1988) studied in isolated rings of rat aorta precontracted with noradrenaline the antagonism of glibenclamide against the vasorelaxation induced by cromakalin.

Nishimura and Suzuki (1995) tested the contractile responses to 5-HT in basilar arteries, superior mesenteric arteries and thoracic aortas from **stroke-prone spontaneously hypertensive rats** in comparison to normal Wistar-Kyoto rats and found that that the hyperresponsiveness to 5-HT is mediated by different 5-HT receptor subtypes.

Fouda et al. (1991) used **the isolated tail arteries from rats**. Differences of the vasoconstrictor response to potassium and norepinephrine between tail arteries from spontaneously hypertensive, renovascular hypertensive, and various strains of normotensive rats were found.

Hamilton et al. (1986), Dacquet et al. (1987) studied the effects of calcium entry blockers in **rat portal vein**.

Bråtveit and Helle (1984) studied the inhibition of vascular smooth muscle by vasoactive intestinal peptide (VIP) in the isolated rat portal vein.

Shetty and Weiss (1987) studied the inhibition of spontaneous rhythmic movements and norepinephrine-induced tension responses in the rat portal vein.

Smith et al. (1993) tested the ability of C-terminally truncated fragments of human α-calcitonin gene-related peptide to relax **mesenteric arteries** precontracted with norepinephrine

Chen et al. (1996) studied the contractile effects of noradrenaline and neuropeptide Y given alone or in combination on isolated rat mesenteric resistance vessels.

Gurden et al. (1993) used **guinea pig** aorta relaxation for functional characterization of adenosine receptor types.

Eltze (1989) studied the antagonism of glibenclamide against potassium channel openers in the isolated **guinea pig pulmonary artery**.

Szentmiklósi et al. (1995) used circular segments from the proximal part of the main pulmonary artery of guinea pigs to study contractile and relaxant effects of adenosine receptors.

Pikkers and Hughes (1995) examined the effect of hydrochlorothiazide on intracellular calcium concentration $[Ca^{2+}]_i$ and tone in **guinea pig mesenteric arteries**. Vessels were mounted on a microvascular myograph and loaded with the Ca^{2+}-sensitive fluorescent dye, Fura-2.

Meisheri et al. (1990) recommended the use of the isolated **rabbit mesentery artery** as a sensitive *in vitro* functional assay to detect K^+-channel-dependent vasodilators.

Mironneau and Gargouil (1979) studied the influence on electrophysiological and mechanical parameters of longitudinal smooth muscle strips isolated from **rabbit portal vein** by means of a double sucrose gap method associated with a photoelectric device for recording contractions.

McBean et al. (1986, 1988) used isolated segments of the arteria basilaris of **pigs** to detect compounds with antivasoconstrictive properties. Contraction is elicited by $PGF_{2\alpha}$, serotonin or norepinephrine. Specimens are

obtained from adult pigs (strain: Deutsche Landrasse) within 30 min after slaughter from the local slaughter house and stored in nutritive solution. The vessels are trimmed to a length of 4 mm, and the segments are suspended between 2 L-shaped metal hooks in a bath containing 20 ml modified Krebs Henseleit solution (NaCl 148 mM, KCl 5.4 mM, $CaCl_2$ 2.2 mM, $NaHCO_3$ 12 mM, glucose 12 mM). The bath solution is maintained at 37 °C and continuously gassed with carbogen to produce a resulting pH of 7.35–7.45. The preparation is incubated under a tension of 37.28 mN (optimal passive load producing the largest contractile response to 3×10^{-6} M $PGF_{2\alpha}$). Following a 60 minute stabilization period, the vessels are sensitized with 30 mM KCl for 10 min. The vessels are washed for 1 minute, and allowed to recover for 30 min with additional 1 minute washes at 15 and 30 min. Thereafter, contractions of the vessels are induced by adding $PGF_{2\alpha}$ at 3×10^{-6} M. The contractile response is allowed to plateau, then the test compound is administered at cumulative doses.

For each test compound a dose-response curve is recorded. The EC_{50} is obtained graphically or by means of a Hill plot. The EC_{50} is defined as the dose of drug producing half maximal response.

Werner et al. (1991) studied the vascular selectivity of calcium antagonists using **porcine** isolated ventricular trabeculae and right **coronary arteries**.

Merkel et al. (1992) used isolated porcine coronary artery rings precontracted with prostaglandin $F_{2\alpha}$ to demonstrate the vasorelaxant activity of an A_1-selective adenosine agonist.

Miwa et al. (1993) compared the effect of a K^+-channel opener with cromakalim, nitroglycerin and nifedipine on endothelin-1-induced contraction of porcine coronary artery.

Satoh et al. (1993) investigated in isolated porcine large coronary arteries whether or not the vasorelaxant actions of nicorandil and cromakalim would be selective using seven different vasoconstrictor agonists.

Yokoyama et al. (1994) studied the vasodilating mechanisms of several pyridinecarboximidamide derivatives in isolated porcine coronary arteries.

Makujina et al. (1995) described a procedure that facilitates the eversion of vascular smooth muscle. Vascular segments of porcine coronary artery, approximately 2 cm in length, were sutured to portions of polyethylene tubing inserted into the lumen of the vessel. After being secured and stabilized by the tubing, the vessel was everted while immersed in physiological buffer. Intracellular calcium concentrations (measured by fura-2AM fluorometry) and tension were registered simultaneously in everted rings denuded of endothelium.

Izumi et al. (1996) tested a K^+-channel opener and related compounds in isolated porcine coronary arteries contracted with 25 mM KCl.

Frøbert et al. (1996) described impedance planimetry as a new catheter-based technique to measure porcine coronary artery pharmacodynamics and compared the results with the commonly used wire-mounted isometric tension technique after *in vitro* application of nifedipine in various concentrations. A four-electrode impedance measuring system was located inside a 12-mm long balloon which was introduced into 3–4 cm long segments of the left anterior descending coronary artery obtained from 70–90-kg Danish Landrace-Yorkshire pigs.

Hamel et al. (1993) dissected segments (3–4 mm long) of temporal ramifications of the middle cerebral artery from **bovine** brains and mounted them between two L-shaped metal prongs in a tissue bath containing Krebs-Ringer solution at 37 °C. Changes in muscle tension were measured by a force displacement transducer and recorded on a polygraph. Several 5-HT receptor agonists were tested for their ability to induce vasoconstriction and their potencies were compared to that of 5-HT. The authors concluded that bovine pial arteries appear to be the best available model for the human cerebrovascular $5\text{-}HT_{1D}$ receptor.

De la Lande et al. (1996) used isolated segments from proximal (4.5 mm i.d.) and distal (0.5 mm i.d.) bovine coronary arteries and found a heterogeneity of response to glyceryl trinitrate.

The isolated **human** coronary artery was used to study the vasoconstriction by acutely acting antimigraine drugs (Saxena et al. 1996a,b, 1997)

A.1.2.10 Isolated guinea pig ureter

PURPOSE AND RATIONALE

The isolated guinea pig ureter shows phasic-rhythmic contractions after addition of KCl to the organ bath. Inhibition of this effect can be explained as a modulation of potassium channels.

PROCEDURE

Male unfasted guinea pigs weighing 400–500 g are sacrificed and both ureters removed immediately without the part directly connected to the pelvis in order to exclude the pacemaker region responsible for spontaneous activity. Each segment of 2 cm length is placed in a Petri dish containing Tyrode solution at 37 °C, freed of surrounding connective tissue and then suspended at a baseline tension of 0.5 p in a 25 ml organ bath containing Tyrode solution at 37 °C being aerated with 5% CO_2/95% O_2, pH 7.4. Contractions are measured isometrically using Gould/Statham UC 2 transducers. After a 15 min equilibration period, KCl is added to the bath in a final concentration of 3×10^{-2} Mol/l and left in the bath for 2 min. KCl induces a constant series of phasic-rhythmic contractions without a rise in baseline tone. Subsequent washing causes the immediate disappearance of the rhythmic contractions. This addition of KCl is repeated and the values of these two experiments are used as initial values. The antagonistic activity is studied by addition of the test drug one min prior to the KCl challenge. Percentage of the following parameters are determined: mean height of contractions, frequency of contractions and the product of mean height and frequency of contractions. For interaction studies the potassium channel blocker glibenclamide 10^{-6} mol/l is added 1 min prior to the test drug.

EVALUATION

Arithmetic means and standard deviations of the data are calculated and compared with initial values using Student's *t*-test.

CRITICAL ASSESSMENT OF THE METHOD

The isolated guinea pig ureter stimulated with KCl can be used for studies on the modulation of potassium channels.

MODIFICATIONS OF THE METHOD

Yoshida and Kuga (1980) recorded electrical activities in a preparation consisting of the pelvic region and the upper ureter of the guinea pig. Train field stimulation of the pelvic region evoked a train of nerve action potentials followed by a multiphasic smooth muscle action potential after a latency of about 2.5–8.0 s. This smooth muscle response was abolished by tetrodotoxin and dibucaine, and also by cholinergic blocking agents.

The effects of veratridine and of yohimbine on the efflux of norepinephrine from electrically stimulated guinea pig ureters were studied by Kalsner (1992).

Maggi and Giuliani (1994) studied the excitability and refractory period of the guinea pig ureter to electrical field stimulation.

Roza and Laird (1995), Laird and Cervero (1996) studied the pressor responses to distension of the ureter in anesthetized rats as a model of acute visceral pain.

A simple method for measurement of ureteric peristaltic function *in vivo* in anesthetized rats was published by Kontani et al. (1993).

A.1.2.11 Isolated corpus cavernosum

PURPOSE AND RATIONALE

The isolated corpus cavernosum of rabbits has gained interest as pharmacological model since selective inhibitors of cyclic guanosine monophosphate (cGMP) phosphodiesterase type 5 (PDE5) were found to be effective in the treatment of erectile dysfunction in man (Ballard et al. 1996; Jeremy et al. 1997; Chuang et al. 1998; Liu et al. 1998; Turko et al. 1999; Wallis 1999; Wallis et al. 1999; Stief 2000).

PROCEDURE

Male New Zealand White rabbits weighing 3–4 kg are sedated with an intramuscular injection of 25 mg/kg ketamine + 6 mg/kg xylazine. Anesthesia is maintained by intravenous injection of 25 mg/kg nembutal. The penis is removed at the level of the attachment of the corporal bodies to the ischium. The corpus cavernosum (total length about 20 mm) is sharply dissected from tunica albuginea and two longitudinal strips with unstretched length about 10 mm are made from the proximal, more muscular portion.

Corporal strips are placed in organ baths containing 10 ml Tyrode's buffer (NaCl 124.9 mmol/l, KCl 12.5 mmol/l, $MgCl_2 \cdot 6\,H_2O$ 0.5 mmol/l, $NaH_2PO_4\,H_2O$ 0.4 mmol/l, $CaCl_2$ 1.8 mmol/l and glucose 5.5.mmol/l) at 37 °C. Each tissue is equilibrated with a mixture of 95% O_2 and 5% CO_2 at pH 7.4. One end of each strip is connected to a force displacement transducer, and changes in muscle tension are measured and recorded with a polygraph. After zeroing and balancing transducers and strip chart, 2.0 g of tension is placed on each strip, and the strips are allowed to equilibrate for 30 min.

Each strip is prestimulated with 10 μM phenylephrine, then relaxed by electrical field stimulation with square wave pulses of 80 V, 1 ms duration at 2–16 Hz frequency. Then sodium nitroprusside (0.01–100 μM) is added ad NO donor. Finally, the standard (sildenafil 1 nM to 1 μM) or the test compound is added.

EVALUATION

The dose-dependent increase of relaxation after test compound and standard is measured. From dose-response curves activity ratios can be calculated.

MODIFICATIONS OF THE METHOD

Wallis et al. (1999) studied the inhibition of human phosphodiesterases PDE1 to PDE6 by sildenafil in various tissues, such as cardiac ventricle, corpus cavernosum, skeletal muscle and retina.

Park et al. (1997) reported functional characterization of angiotensin II receptors in rabbit corpus cavernosum.

Yildirim et al. (1997) investigated the effects of castration and testosterone on the constricting effect of phenylephrine and endothelium-dependent and -independent relaxing effects of different agonists in the corpus cavernosum of male rabbits.

Liu et al. (1998) analyzed the pharmacological effects of *in vitro* ischemia on rabbit corpus cavernosum.

Gupta et al. (1998) found that activation of G_i-coupled postsynaptic α_2-adrenoceptors causes contraction of smooth muscles in the corpus cavernosum of rabbits.

Teixeira et al. (1998) used a bioassay cascade to study the effect of *Tityus serrulatus scorpion* venom on the rabbit isolated corpus cavernosum.

Cellec and Moncada (1998) used the clitoral corpus cavernosum of female rabbits to study the role of nitrergic neurotransmission in non-adrenergic non-cholinergic relaxation responses.

The isolated corpus cavernosum of **rats** has been used by Tong and Cheng (1997), of **mice** by Gocmen et al. (1997), of **dogs** by Hayashida et al. (1996), Comiter et al. (1997), of **monkeys** by Okamura et al. (1998), of **horses** by Recio et al. (1997).

Studies in isolated **human** corpus cavernosum were performed by Cellek and Moncada (1997), Omote (1999), Lin et al. (2000), Stief et al. (2000).

In vivo studies measuring intracavernous pressure in **rats** were performed by Ari et al. (1996), Chan et al. (1996), Moody et al. (1997), Reilly et al. (1997), Chang et al. (1998), Mills et al. (1998).

In vivo studies on penile erection were performed in **cats** by Champion et al. (1997).

Intracavernous pressure was measured *in vivo* in anesthetized **dogs** by Ayajiki et al. (1997), Sarikaya et al. (1997), Carter et al. (1998).

A.1.3 Cardiovascular analysis *in vivo*

A.1.3.1 Hemodynamic screening in anesthetized rats

PURPOSE AND RATIONALE

The test is used to detect the effect of compounds on blood pressure and heart rate of anesthetized rats and to check for possible interference with adrenergic receptors. Antihypertensive agents with different mechanisms of action can be detected with this test.

PROCEDURE

Male Sprague-Dawley rats weighing 250–400 g are used. At least 2 animals are necessary for screening of one compound. The rats are anesthetized by intraperitoneal injection of 8 ml/kg of a solution of 8% urethane and 0.6% chloralose. The trachea is cannulated to facilitate spontaneous respiration. Body temperature is maintained at 38 °C by placing the animal on a heating pad.

The left femoral vein is cannulated for drug administration, which is standardized to injections of 0.2 ml/100 g body weight over a period of 1 min. For measurement of hemodynamic parameters and for intra-arterial administration of test compound, a cannula is inserted retrogradely into the right carotid artery. The tip of the catheter is positioned close to the origin of the subclavian artery. This allows most of the injected substances to reach the CNS via the vertebral artery before going into the general circulation.

For continuous monitoring of blood pressure (systolic and diastolic pressure) and heart rate, the catheter is connected to a pressure transducer (Statham DB 23).

When stable hemodynamic conditions are achieved for at least 20 min (control values), test boli of adrenaline (1 mg/kg) and isoprenaline (0.25 mg/kg) are administered. When baseline values are again established, increasing doses of the test substance (0.01, 0.1, 3.0 mg/kg) are given intra-arterially. In case of no effect, the interval between successive doses is 15 min, otherwise 60 min. To check for α- or β-blocking activity, adrenaline and isoprenaline administration is repeated after injection of the highest dose of test compound. If the test compound shows no effect, a standard antihypertensive compound is administered for control purpose.

Hemodynamic parameters are recorded continuously during the whole experiment.

EVALUATION

Changes in blood pressure and heart rate after drug administration are compared to control values obtained during the 20 min pre-drug period.

Maximal changes in BP and HR and duration of the effect are reported.

The results are scored relative to the efficacy of standard compounds for the degree of the effect and the duration of the effect.

Statistical significance is not tested because of the small number of animals used ($n = 2$, sometimes 3 or 4) but larger numbers of animals have to be used for quantitative evaluation.

CRITICAL ASSESSMENT OF THE METHOD

Due to the administration of the test compounds via the right common carotid artery not only peripherally acting vasodilators and neuron blockers but also compounds affecting the blood pressure regulating mechanisms in the CNS are detected. Bolus injections of adrenaline and isoprenaline reveal possible α- or β-antagonistic effects.

Standard data:
The following compounds at the doses indicated lead to a strong decrease in blood pressure:

• Clonidine	0.008	mg/kg
• Dihydralazine	1.0	mg/kg
• Phentolamine	3.0	mg/kg
• Prazosin	0.1	mg/kg
• Propranolol	1.0	mg/kg
• Urapidil	1.0	mg/kg
• Verapamil	0.1	mg/kg

MODIFICATIONS OF THE METHOD

A procedure for differential intra-arterial pressure recordings from different arteries in the rat was described by Pang and Chan (1985).

DeWildt and Sangster (1983) described the evaluation of derived aortic flow parameters measured by means of electromagnetic flowmetry as indices of myocardial contractility in anesthetized rats.

Using a special Millar ultraminiature catheter pressure transducer and a thermodilution microprobe, Zimmer et al. (1987, 1988) measured right ventricular functional parameters in anesthetized, closed-chest rats.

Veelken et al. (1990) published improved methods for baroreceptor investigations in chronically instrumented rats.

Salgado and Krieger (1988), de Abreu and Salgado (1990), Da Silva et al. (1994) studied the function of the **baroreceptor reflex** in thiopental anesthetized rats. The left aortic nerve was isolated and supported by a bipolar stainless steel electrode and carefully insulated with silicone rubber. Carotid pressure was recorded simultaneously with aortic nerve discharges on an oscilloscope and monitored with a loudspeaker.

King et al. (1987) developed a cross circulation technique in rats to distinguish central from peripheral cardiovascular actions of drugs. The right common carotid arteries were ligated, and the left common carotid arteries and left and right external jugular veins of two phenobarbital-anesthetized rats were connected with polyethylene tubing so that peripheral blood from one rat, A, supplied the head of another rat, B, and then returned to the body of A, and vice versa, for peripheral blood from rat B. Each rat was artificially ventilated with O_2, the chest was opened, and both subclavian arteries were ligated. Prior to the ligation of the subclavian arteries, blood flow from rat A supplied its own brain and both brain hemispheres but not the brain stem of rat B. Following subclavian artery ligation, blood flow from rat A did not supply A's brain, but supplied both hemispheres and brain stem of rat B. The head of each rat was, therefore, rendered dependent on the carotid arterial blood supply from another rat. This rat cross-circulation preparation can be used to separate the central and peripheral cardiovascular actions of drugs.

Zavisca et al. (1994) studied the hypertensive responses to defined electrical and mechanical stimuli in anesthetized rats. Rats were given etomidate, 3.8 mg/kg/h intravenously following carotid artery and jugular vein cannulation. At 15 min after beginning the infusion, 4 types of noxious stimuli were administered sequentially at 1-min intervals: Type 1: Square electrical waves 125 cps, 1.6 ms, 2-s duration, varying current from 0.4 to 12 mA; Type 2: A single 10-mA electrical stimulus, 5-s train duration; Type 3: Tail clamping; Type 4: Skin incision. After each stimulus, maximum change in systolic blood pressure was measured. Graded electrical stimulation allowed the best quantitative evaluation of the hypertensive response to noxious stimuli.

Hyman et al. (1998) described a novel catheterization technique for the *in vivo* measurements of **pulmonary vascular responses** in rats. Male Charles River rats weighing 26–340 g were anesthetized and strapped in supine position to a fluoroscopic table. They breathed air enriched with oxygen through an endotracheal tube inserted by tracheostomy. Catheters were inserted into the femoral blood vessels. The venous catheters were passed to the right atrium under fluoroscopy. A F-1 thermistor catheter was passed from the left carotid artery into the ascending aorta under fluoroscopy, and a PE-50, 150-mm plastic catheter with a specially constructed curved tip was passed fluoroscopically from the left jugular vein into the main pulmonary artery. A plastic radiopaque 22-gauge catheter 100 mm in length with a curved tip was passed with a 0.025 mm soft-tip coronary guiding catheter from the right jugular vein through the right atrium to the inferior vena cava. The coronary soft-tip guide was then withdrawn. A specially curved 102.5-mm transseptal needle, 0.4 mm in diameter, was then passed though the catheter. Both the needle and catheter were withdrawn into the superior portion of the right atrium under fluoroscopic guidance so that the needle and catheter both rotated freely. With the rat in a slight left anterior oblique position, the catheter and needle were carefully rotated anteriorly to the intra-atrial septum. With gentle pressure, the catheter and needle can be felt and seen fluoroscopically to pass through the atrial septum. As the needle was withdrawn, the curve of the catheter permitted passage of the tip into the vein draining either the left or right lower lobe. The catheter was carefully positioned near the pulmonary venoatrial junction and fixed in place. Mean pressures in the femoral artery, pulmonary artery and pulmonary vein at the venoatrial junction were measured with pressure transducers and recorded on a polygraph. Cardiac output was obtained in triplicate by delivering 0.1 ml normal saline at room temperature into the femoral venous catheter at the right venoatrial junction and determining thermodilution cardiac output with the thermistor catheter in the ascending aorta.

Hayes (1982) described a technique for determining contractility, intraventricular pressure, and heart rate in the **anesthetized guinea pig** by inserting a needle, attached to a pressure transducer, through the chest wall into the left ventricle.

Williams et al. (1995) used **castrated male ferrets** anesthetized by intramuscular injection of a mixture of 55 mg/kg ketamine and 4 mg/kg xylazine to measure the effects of a nonpeptidyl endothelin antagonist on endothelin-induced pressor responses.

A.1.3.2 Blood pressure in pithed rats

PURPOSE AND RATIONALE

The pithed rat has been proposed for assessing pressor substances by Shipley and Tilden (1947). The preparation is frequently used to evaluate drug action on the cardiovascular system since this preparation is devoid of neurogenic reflex control that may otherwise modulate the primary drug effect.

PROCEDURE

Male rats weighing 250–350 g are prepared for pithing under halothane anesthesia. The left carotid artery is cannulated for blood pressure monitoring and blood sampling. Furthermore, the trachea and the right jugular vein are cannulated. The rats are pithed inserting a steel rod, 2.2 mm in diameter and about 11 cm in length, through the orbit and foramen magnum down the whole length of the spinal canal. Via the tracheotomy tube, the animals are ventilated with a small animal ventilation pump. Inspirated air is oxygen-enriched by providing a flow of oxygen across a T-piece attached to the air intake of the ventilation pump (Harvard Apparatus model 680). The rats are ventilated at a frequency of 60 cycles/min with a tidal volume of 2 ml/100 body weight. Thirty min after pithing, a 0.3 ml blood sample is withdrawn from the carotid cannula and immediately analyzed for pO_2, pCO_2, pH, and derived bicarbonate concentration using an automatic blood gas analyzer. By alterations of the respiratory stroke volume of the pump, the values are adjusted to: pCO_2 30–43 mm Hg, pH 7.36–7.50, pO_2 87–105 mm Hg.

Continuous registration of blood pressure and cardiac frequency (Hellige He 19 device and Statham P 23 Db transducer) is performed via the left carotid artery.

In order to measure α_1 and α_2 antagonism, first dose-response curves are registered using doses of 0.1–30 µg/kg i.v. phenylephrine (a selective α_1 agonist), and 1–1 000 µg/kg i.v. BHT 920, (a selective α_2 agonist). The test drug is administered intravenously and the agonist dose-response curves are repeated again 15 min later.

EVALUATION

If the curve of blood pressure response to the agonists is shifted, dose-response curves are plotted on a logarithmic probit scale and potency ratios are calculated.

MODIFICATIONS OF THE METHOD

Gillespie and Muir (1967) described a method of stimulating the complete sympathetic outflow from the spinal cord to blood vessels in the pithed rat by coating those parts of the pithing rod which lay in the sacral and cervical region of the spinal cord with high-resistance varnish to restrict stimulation to the thoraco-lumbar region. The steel rod is insulated with an adhesive throughout its length except for a 5 cm section which provides sufficient a stimulation area of the lower thoraco-lumbar nerves. For stimulating nerves fibers supplying exclusively the heart, a pithing rod is used which is insulated throughout its length except for a 0.5 cm section 7 cm proximal to the tip. The spinal cord is stimulated electrically using the pithing rod as the cathode and a hypodermic needle which is inserted under the skin near the right hind-limb, as the anode. Varying the intensity and/or the duration of the stimulation, dose-response curves can be registered which are altered after treatment with drugs.

Curtis et al. (1986) described an improved pithed rat method by mounting the preparation vertically with the head pointing downward resulting in considerably higher blood pressure and heart rate.

MacLean and Hiley (1988) studied the effect of artificial respiratory volume on the cardiovascular responses to an α_1- and α_2-adrenoceptor agonist in the air-ventilated pithed rat using microsphere technique and analysis of arterial blood gases and pH.

Trolin (1975) used decerebrated rats to study the clonidine-induced circulatory changes.

A.1.3.3 Antihypertensive vasodilator activity in ganglion-blocked, angiotensin II supported rats

PURPOSE AND RATIONALE

The method is used to demonstrate direct vasodilator activity of potential antihypertensive agents. The experimental model is an anesthetized, ganglion-blocked rat whose blood pressure is maintained by an intravenous infusion of angiotensin II. The test allows to differentiate between centrally acting antihypertensives and peripheral vasodilators.

PROCEDURE

Male Wistar rats weighing 275–450 g are anesthetized with a combination of urethane (800 mg/kg) and chloralose (60 mg/kg) administered intraperitoneally in a volume of 10 ml/kg. Following induction of anesthesia, chlorisondamine (2.5 mg/kg) is injected into the peritoneal cavity to abolish sympathetic and parasympathetic nerve activity. The right femoral artery is cannulated to monitor blood pressure (Statham pressure transducer P23Db) and heart rate. Both femoral veins are cannulated to administer drugs or infuse angiotensin II. The trachea is intubated and animals are allowed to breathe spontaneously. Following a stabilization interval of 10–15 min, angiotensin II is infused at a rate of 0.25 or 3.5 µg/min in a volume equivalent to 0.05 ml/min (Harvard infusion pump).

After an increase of blood pressure, a new elevated steady-state pressure is established within 15–20 min. Drugs are subsequently injected intravenously over an interval of 3 min in a volume of 2 ml/kg. Mean arterial pressure is recorded on a polygraph at 5, 10, 15, 20 and 30 min after initiation of drug administration. Seven to 9 animals are used for each drug and dose level studied.

α-adrenoreceptor blockade can be determined in ganglion-blocked rats. Pressor responses to graded doses of phenylephrine injected intravenously are obtained before and 15 min after administration of test compounds. Sufficient concentrations of phenylephrine have to be given to ensure a rise in mean arterial blood pressure of 50 mm Hg or more. Data obtained from 5 or 6 animals are averaged and resultant dose-response curves plotted. The dose of phenylephrine required to elicit a 50 mm Hg increase in mean arterial blood pressure is interpolated from dose response curves.

Standard data:
The following compounds are used as standards and, at the doses indicated, lower mean arterial blood pressure by about 50 mm Hg:

• Cinnarizine	3.0	mg/kg, i.v.
• Hydralazine	1.0	mg/kg, i.v.
• Minoxidil	10.0	mg/kg, i.v.
• Saralasine	0.03	mg/kg, i.v.
• Molsidomine	0.1	mg/kg, i.v.

EVALUATION

Mean values ±SEM are given for mean arterial blood pressure and heart rate. Changes of these parameters after drug administration are compared to control val-

ues obtained immediately before the application of the test compound. Statistical significance is assessed by means of the paired *t*-test.

CRITICAL ASSESSMENT OF THE METHOD

A hypotensive response in this model appears to correlate more closely with antihypertensive activity in DOCA-salt hypertensive rats than does a vasodilator response in the perfused hind limb of anesthetized dogs and allows a distinction between central anti-hypertensive and vasodilators.

MODIFICATIONS OF THE METHOD

Santajuliana et al. (1996) developed a standard ganglionic blockade protocol to assess neurogenic pressor activity in conscious rats. Rats were instrumented with arterial and venous catheters for measurement of arterial pressure and heart rate and for administration of three different ganglionic blockers (trimethaphan, hexamethonium, and chlorisondamine).

A.1.3.4 Blood pressure in conscious hypertensive rats (tail cuff method)

PURPOSE AND RATIONALE

Rats with spontaneous or experimentally induced hypertension are widely used for screening of potentially antihypertensive compounds. The indirect tail cuff method allows the determination of systolic blood pressure according to the following principle: The cuff is quickly inflated to well above suspected systolic blood pressure; the pulse will then be obliterated. Thereafter, pressure in the cuff is slowly released and, as the pressure falls below systolic blood pressure, the pulse will reappear. The method is analogous to sphygmomanometry in human and can be applied not only at the tail of awake rats but also in dogs and small primates. The indirect tail cuff method is widely used to evaluate the influence of antihypertensive drugs in spontaneously and experimentally hypertensive rats.

PROCEDURE

Male spontaneous hypertensive rats (Charles River) weighing 300–350 g or rats with experimentally induced hypertension are used.

Surgical procedure to induce renal hypertension

Male Sprague-Dawley rats weighing 80–100 g are anesthetized by intraperitoneal injection of 0.8 ml 4% chloralhydrate solution. Both kidneys are exposed retroperitoneally. To induce renal hypertension, a silver clip (0.2 mm diameter, 4 mm length) is placed onto both renal arteries, the kidneys are reposed and the wound is closed by suture.

Within 5–6 weeks, operated animals attain a renal hypertension with a systolic blood pressure (BPs) of 170–200 mm Hg (mean normal physiological BPs for rats is 100 mm Hg). Only animals with a BPs = 180 mm Hg are used for the tests.

Test procedure

The procedure is the same for spontaneously andexperimentally hypertensive rats. Groups of 6 animals are used per dose. The control group receives saline only. To reduce spontaneous variations in blood pressure, animals are adjusted to the experimental cage by bringing them into the restraining cage which is enclosed in a 31–32 °C measuring chamber 3–4 times before the start of the experiment for a period of 30–60 min.

To measure blood pressure, a tubular inflatable cuff is placed around the base of the tail and a piezo-electric pulse detector is positioned distal to the cuff. The cuff is inflated to approximately 300 mm Hg. As the pressure in the cuff is slowly released, the systolic pressure is detected and subsequently recorded on a polygraph.

The test substance is administered intraperitoneally or by gavage once per day over a period of 5 days. The usual screening dose of a new compound is 25 mg/kg. Blood pressure and heart rate measurements are taken at the following times:

day 1: predose and 2 h postdrug
day 3: predose and 2 h postdrug
day 5: predose, 2 h postdrug and 4 h postdrug.

Between measurements, animals are returned to their home cages.

Standard compounds:

- endralazine (3 mg/kg p.o.)
- nifedipine (3 mg/kg p.o.)
- urapidil (5 mg/kg p.o.)

EVALUATION

Mean values in systolic blood pressure before and after drug administration and the duration of the effect are determined. Percent decrease in systolic blood pressure under drug treatment is calculated. Statistical significance is assessed by the Student's *t*-test.

Scores for % decrease in systolic blood pressure and for the duration of the effect are allotted.

CRITICAL ASSESSMENT OF THE METHOD

The indirect tail-cuff method is being used in many laboratories with many modifications of the devices. Pfeffer et al. (1971) found a good correlation between values obtained with the indirect tail-cuff method and values measured directly with indwelling carotid arterial cannulae, whereas Buñag et al. (1971) reported a lack of correlation between direct and indirect measurement of arterial pressure in unanesthetized rats and Patten and Engen (1971) found difficulties to measure accurate systolic values at higher blood pressure. A good correlation between direct blood pressure data from the carotid artery in rats and readings with the tail cuff method was found by Matsuda et al. (1987) who developed a six-channel automatic blood pressure measuring apparatus with a highly sensitive photoelectric sensor for the detection of tail arterial blood flow and a microcomputer system for automatic measurement of systolic blood pressure and heart rate and for data acquisition and processing.

MODIFICATIONS OF THE METHOD

Details of the tail-cuff method in rats have been discussed by Stanton (1971).

Special equipment for measuring blood pressure in rats is commercially available (e.g., Rhema Labortechnik, Hofheim, Germany).

Widdop and Li (1997) described a simple versatile method for measuring tail cuff systolic blood pressure in conscious rats. A tail cuff consisting of a metal T-piece tube with latex rubber inside the tube is placed around the tail at the proximal end. A piezo-electric transducer (model MLT1010) is strapped to the ventral surface of the tail to record the pulse signal from the caudal artery and connected directly to a MacLab® data-acquisition system ADInstruments Pty Ltd.).

The tail-cuff method for measurement blood pressure has been adapted for dogs, monkeys (Wiester and Iltis 1976), and cats (Mahoney and Brody 1978).

Blood pressure can be measured from the hind leg of the rat using a leg cuff and a photoelectric cell situated at the dorsal surface of the foot (Kersten et al. 1947). When the leg is occluded, the foot swells and the amount of light striking the photocell is reduced. When the pressure in the cuff is released, the arterial blood flow is restored, the increase of foot volume is decreased and the amount of light transversing the paw increases.

A.1.3.5 Direct measurement of blood pressure in conscious rats with indwelling catheter

PURPOSE AND RATIONALE

The method first described by Weeks (1960) allows the direct measurement of arterial pressure in conscious rats eliminating the influence of anesthesia on cardiovascular regulation.

PROCEDURE

Preparation of cannulae

In order to prepare the cannulae 7 cm and 12 cm long pieces are cut from PE 10 and PE 20 tubings respectively. A stylet wire is inserted into the PE 10 tubing and the PE 20 tubing is also slipped over the stylet wire. The ends of the tubings are heated in a current of hot air and fused together. Ridges are made to anchor the cannula in the animal's tissue. In order to make a ridge, the stylet wire is left inside the cannula and the cannula is heated in a fine jet of hot air. When the polyethylene at the point of heating becomes soft, the cannula is pressed slightly and thus a ridge is formed.

One ridge is formed at the PE 20 tubing, about 0.5 cm away from the junction with the PE 10 tubing, and 3 more ridges are formed on the PE 20 tubing at a distance of about 1 cm from each other, first one being situated about 3 cm away from the free end of the PE 20 tubing. The stylet wire is then removed from the cannula and the PE 10 portion of the cannula near the junction with the PE 20 tubing is wound around a glass rod with a diameter of 4 mm. Two rounds are made. Then it is dipped in a boiling water bath for about 5 s. When taken out of the bath, the cannula retains its circles, forming a spring-like structure.

Implantation of cannulae

Male Sprague-Dawley rats weighing about 300 g are used. The rat is anesthetized with 45 mg/kg pentobarbital i.p. The area of the neck and the abdomen are shaved and cleaned with 70% alcohol. The viscera are exposed through a midline abdominal incision. A segment of the abdominal aorta is exposed just above the bifurcation. A trocar is passed through the psoas muscles adjacent to this segment of the aorta, through the muscles of the back and under the skin until it emerges from the skin of the neck. Then the cannula is inserted into the trocar and the trocar is withdrawn from the body. The end of the cannula thus comes out from the neck, being anchored by silk sutures to the neck skin and to the psoas muscle. The cannula is filled with heparin solution and the end which is projecting out from the neck skin is blocked with a tight fitting stainless steel needle. Then the other end of the cannula is implanted into the aorta. The aorta is wiped with a cotton-tipped applicator stick above the bifurcation, occluded above this segment and punctured with a bent 27 gauge hypodermic needle. The tip of the PE 10 catheter is inserted through the needle and advanced up the aorta. The intestines are replaced and the wound sutured. The rats are allowed to recover for one week.

Measurement of blood pressure

The occluding stainless steel needle is removed and the cannula flushed with diluted heparin solution. The rat is placed in a small cage to restrict its movements, even so it is free to move. The cannula is connected to a Statham P 23 Db pressure transducer and blood pressure is recorded on a polygraph. Test drugs or standards are administered either subcutaneously or orally. Recordings are taken before and after administration of drug over a period of 1 h.

EVALUATION

Changes of blood pressure are measured for degree and duration. Five rats are used for each dose and compound. The maximal changes of each group are averaged and compared with the standard.

CRITICAL ASSESSMENT OF THE METHOD

Direct measurement of arterial blood pressure in unanesthetized rats originally introduced by Weeks (1960) has become a valuable and widely used tool in cardiovascular research.

MODIFICATIONS OF THE METHOD

A detailed description of a slightly modified Week's method has been given by Stanton (1971).

Improvements of the method for continuous direct recording of arterial blood pressure and heart rate in rats have been described by Buñag et al. (1971), Laffan et al. (1972), Buckingham (1976), Garthoff and Towart (1981), Garthoff (1983). A detailed description of permanent cannulation of the iliolumbar artery was given by Remie et al. (1990).

Wixson et al. (1987) described a technique for chronic catheterization of the carotid artery in the rat.

Prepared cannulas are commercially available (IRC Life Science, Woodland Hills CA).

A newer modification uses the access to the aorta via the common carotid artery (Linz et al. 1992). Rats are prepared under thiopental anesthesia with arterial PE-50 lines (Intramedic® from Clay Adams, USA). The lines are introduced into the ascending aorta via the right carotid artery for direct measurement of arterial blood pressure and into the jugular vein for i.v. application of test compounds. Both lines, filled with saline containing heparin, are surfaced on the neck. The animals are allowed to recover for at least 2 days. Blood pressure is monitored through Statham R P23 Db transducers connected to a recording device. During measurements the lines are kept open with counter current saline infusion at a rate of 1 ml/h.

Bao et al. (1991) placed one catheter via the right femoral artery in the abdominal aorta in rats for recording mean arterial pressure and two additional catheters via the left carotid artery into the descending aorta for application of bradykinin and bradykinin antagonists.

Arterial pressure was recorded in unanesthetized rats after induction of severe hypertension by complete ligation of the aorta between the origin of the renal arteries by Sweet and Columbo (1979).

Hilditch et al. (1978) described a device for the direct recording of blood pressure in conscious dogs.

Akrawi and Wiedlund (1987) described a method for chronic portal vein infusion in unrestrained rats. Hepatic drug metabolism can be studied by infusion into the portal vein and blood collection from the femoral vein.

Robineau (1988) described a method for recording electrocardiograms in conscious, unrestrained rats. Electrodes were implanted subcutaneously and a socket connector was sutured on the head of the animal. A flexible cord leading to a swivel collector was linked to an ECG amplifier.

Kurowski et al. (1991) reported on an improved method to implant, maintain, and protect arterial and venous catheters in conscious rats for extended periods of time.

Schenk et al. (1992) measured cardiac left ventricular pressure in conscious rats using a fluid-filled catheter.

Tsui et al. (1991) recommended a reliable technique for chronic carotid arterial catheterization in the rat.

Hagmüller et al. (1992) described a tail-artery cannulation method for the study of blood parameters in freely moving rats.

Liebmann et al. (1995) described an *in vivo* long-term perfusion system which is based on automated, computer-controlled high-frequency heparin (10 U/ml) flushing of a cannula inserted into the tail artery of freely moving rats.

Santajuliana et al. (1996) used conscious rats instrumented with arterial and venous catheters to assess neurogenic pressor activity after administration of ganglionic blockers.

Rezek and Havlicek (1975) described simple cannula systems for the infusion of experimental substances in chronic, unrestrained animals. A cannula with a removable cap is used for infusions into various parts of the digestive tract. Intravenous infusions can be performed through a closed system cannula which avoids a possible introduction of air into the circulation.

Kimura et al. (1988) described a method for chronic portal venous, aortic, and gastric cannulation to determine portal venous and aortic glucose and lactate levels in conscious rats.

A.1.3.6 Cannulation techniques in rodents

PURPOSE AND RATIONALE

Cardiovascular pharmacology requires special techniques for catheterization and permanent cannulation of vessels. A few methods are described below.

A comprehensive literature survey on methods for vascular access and collection of body fluids from the laboratory rat was written by Cocchetto and Bjornsson (1983).

REFERENCES

A.1.3.6.1 Permanent cannulation of the jugular vein in rats

PURPOSE AND RATIONALE
Permanent cannulation of the jugular vein in rats in combination with a head attachment apparatus allowing easy connection of cannulae was first introduced by Steffens (1969). Modifications were described by Brown and Hege (1972), Nicolaidis et al. (1974) and by Dons and Havlik (1986). A detailed description was given by Remie et al. (1990).

PROCEDURE
Rats are anesthetized with N_2O_2/O_2/halothane. The shaven neck of the animal on the right side is disinfected with chlorhexidine solution. The incision is made just above the right clavicle. Connective and adipose tissue are pushed aside with blunt forceps and the jugular vein is exposed. The external jugular vein is followed and the division into the maxillary vein, the facial and the linguofacial vein identified. The largest vein is chosen and mobilized for a distance of about 5 mm. Small artery forceps are used to clamp the vessel. The vein is then ligated rostral to the clamp with 6-0 silk, and a second ligature is put loosely around the vessel, but not tightened. Using iridectomy scissors, a V-shaped hole is cut in the vein 2 mm rostral from the bifurcation. Prior to its insertion into the vessel, a sterile cannula is connected to a 1 ml syringe filled with a heparinized saline solution. The vessel is dilated by means of a sharp pointed jeweler's forceps, the cannula slit between the legs of the forceps and gently pushed into the vessel until the tip is at the level of the right atrium. Then the forceps is removed, the caudal ligature gently tied, and the rostral ligature used to anchor the cannula to the vessel. The cannula is tunneled to emerge at the top of the head. While the skin in the neck is held firmly, the artery forceps is inserted subcutaneously in caudal direction over a distance of about 3 cm, then turned anti-clockwise in the direction of the incision in the neck. The cannula is grasped with the forceps. Then the forceps is pulled back until the cannula emerges at the crown of the head and closed by a small microvascular clamp. The cannula is slid over the short end of a 20G stainless steel needle bent to a 90° angle. The catheter is flushed with saline and filled with polyethylene/heparin solution. The long end of the L-shaped stainless steel adapter is closed with a piece of heat-sealed PE-tubing and the wounds are closed with sutures.

MODIFICATIONS OF THE METHOD
Hutchaleelaha et al. (1997) described a simple apparatus for serial blood sampling from the external jugular vein which permits simultaneous measurement of locomotor activity in freely moving rats.

A.1.3.6.2 Permanent cannulation of the renal vein in rats

PURPOSE AND RATIONALE
A detailed description for permanent cannulation of the renal vein in rats was given by Remie et al. (1990).

PROCEDURE
Rats are anesthetized with N_2O_2/O_2/halothane. After opening the abdominal wall, the intestines are lifted out and laid next to the animal on the right side (as viewed by the surgeon) on gauze moistened with warm saline solution. This provides an excellent view to the vena cava. At its confluence with the vena cava, the right renal vein is stripped of its adipose tissue and the peritoneum is opened. Using small anatomical forceps the peritoneum is detached from the vena cava by making small spreading movements with the forceps just beneath the peritoneum. Subsequently, the vena cava and the renal vein are mobilized for approximately 1.5 cm, to allow for clamping of the vessel. A four or five fine-stitch purse-string is placed in the vessel at the confluence of the vena cava and the right renal vein. Using a Barraquer needle holder and a cotton-wool

stick, the 7-0 silk suture, armed with a BV-1 needle, is guided through the vessel. After each stitch, any bleeding has to be immediately arrested by applying light pressure using a cotton-wool stick. Having completed the suture a single knot is made with the drawstrings. Three microvascular clips are then placed on the vena cava and the renal vein; first the proximal clip on the vena cava, followed by the clip on the renal vein and finally the distal vena cava clip. A small aperture is cut immediately inside the purse-string suture using iridectomy scissors and jeweler's forceps. The cannula, which is filled with a heparinized saline solution, is pushed into the opening as far as possible. Subsequently, the purse-string suture is pulled taut and the clip of the renal vein removed, while pushing the cannula further. The proximal clip on the vena cava is now removed as quickly as possible. The patency of the cannula is checked and the drawstrings of the purse-string suture are used to anchor the cannula. The cannula is laid kink-free in the abdominal cavity and sutured to the internal abdominal cavity near the xiphoid cartilage. The abdomen is closed in two layers and the cannula tunneled to the top of the head. The cannula together with a L-shaped adapter is fixed to the skull.

A.1.3.6.3 Permanent cannulation of the portal vein in rats

PURPOSE AND RATIONALE

Several techniques have been described for cannulation of the portal vein in rats (Hyun et al. 1967; Pelzmann and Havemeyer 1971; Suzuki et al. 1973; Sable-Amplis and Abadie 1973; Helman et al. 1984). A detailed description for permanent cannulation of the portal vein in rats was given by Remie et al. (1990). After additional application of platinum electrodes around the portal vein in close proximity to the catheter tip, this model can also be used to study the presynaptic regulation of neurotransmitter release from nonadrenergic nerve terminals (Remie and Zaagsma 1986; Remie et al. 1988, 1989).

PROCEDURE

Rats are anesthetized with N_2O_2/O_2/halothane. After opening the abdominal wall, the intestines are lifted out and laid next to the animal on the right side (as viewed by the surgeon) on gauze moistened with warm saline solution. Using a micro needle holder and a cotton-wool stick, a four or five, fine stitch purse-string suture (7-0 silk suture armed with a BV-1 needle) is placed in the wall of the portal vein at the side opposite the gastroduodenal vein. The diameter of the purse-string should be about 1 mm. After the suture has been completed a single knot is made with the drawstrings. The portal vein is clamped with a small curved hemostatic bulldog clamp. Using iridectomy scissors and a pair of jeweler's forceps the center of the purse-string is cut, a cannula filled with heparinized saline is inserted into the vessel and pushed upwards. The purse-string is gently tightened taking care not to obstruct the cannula. The drawstrings of the suture are used to anchor the cannula. The cannula is laid kink-free in the abdominal cavity and sutured to the internal abdominal cavity near the xiphoid cartilage. The abdomen is closed in two layers and the cannula tunneled to the top of the head. The cannula together with a L-shaped adapter is fixed to the skull.

A.1.3.6.4 Permanent cannulation of the thoracic duct in rats

PURPOSE AND RATIONALE

Collection of lymph is rather difficult and has performed mainly in dogs (Biedl and Offer 1907; Gryaz-

nova 1962, 1963; Vogel 1963). Some techniques have been described for the rat (Bollman et al. 1948; Girardet 1975). Remie et al. (1990) did not obstruct the duct by placing a purse-string suture in the wall of the duct, by which the cannula is secured. The animal's lymph can be collected during the experiment, and after refilling the cannula the lymph flow remains undisturbed.

PROCEDURE

Rats are anesthetized with N_2O_2/O_2/halothane. After opening the abdominal cavity, the intestines are placed in gauze moistened with warm saline and laid to the left of the animal. The suprarenal abdominal artery is located and mobilized by gently tearing the connective tissue. Using blunt dissection technique, the thoracic duct is mobilized along the dorsolateral surface of the aorta. A small three to four fine stitch purse-string suture is placed in the wall of the duct, using a 9-0 Ethilon suture. A hole is cut inside the purse-string with a very fine pair of scissors, while holding the wall with angled jeweler's forceps. The cannula which is filled with heparinized saline solution and is inserted into the duct using anatomical forceps. After the tip of the cannula has been inserted into the thoracic duct, the curved forceps are removed and the total tip is pushed into the duct. The ligature is then closed and some lymph will flow into the cannula. The cannula is secured within the abdominal cavity by attaching it to the abdominal muscle near the xiphoid cartilage with a 7-0 silk suture. Following the closure of the abdominal wall and the tunneling of the cannula to the crown of the head, a L-shaped adapter is placed on the cannula, filled with PVP-solution and closed with a heat-sealed polyethylene cap.

A.1.3.6.5 Portacaval anastomosis in rats

PURPOSE AND RATIONALE

In 1877 the Russian surgeon Eck reported the achievement of successful portacaval shunts in dogs. Lee and Fischer (1961), Funovics et al. (1975), de Boer et al. (1986), described portacaval shunt in the rat. A detailed description of surgery for portacaval anastomosis in rats was given by van Dongen et al. (1990).

PROCEDURE

Rats are anesthetized with N_2O_2/O_2 in combination with either enflurane, methoxyflurane or isoflurane. After opening the abdominal wall, the intestines are placed left to the animal on gauze moistened with warm saline solution. Proximally and distally to the animal's right renal vein, the vena cava is then stripped of its adipose and connective tissue, and the retroperitoneal cavity is opened. Using anatomical forceps the peritoneum is dissected from the vena cava by making small spreading movements with the forceps just above the vena cava. The portal vein is pulled slightly to the left using straight anatomical forceps and freed from the hepatic artery and the gastroduodenal artery with curved anatomical forceps. Rostral to the celiac artery, the abdominal artery which is covered with peritoneum is freed from its lateral muscle bed over a length of approximately 5 mm providing enough space for placing a small bulldog clamp at a later stage of the operation. Without occlusion a six fine-stitch purse-string is placed in the wall of the vena cava close to its confluence with the right renal vein. Using a Barraquer needle holder and a cotton wool stick, the 7-0 silk suture armed with a BV-1 needle is guided through the vessel. After each stitch, bleeding has to be arrested immediately, by applying light pressure on the area, again using the cotton wool stick. After the suture has been completed, a single knot is made with the drawstrings. The drawstrings should come together at the rostral part of the purse-string. A bulldog clamp, modified to resemble a Satinsky vascular clamp, is then placed on the vena cava.

Before clamping the abdominal aorta rostral to the celiac artery with a small bulldog clamp, a ligature (7-0 silk) is placed around the portal vein as close as possible to the hilus of the liver. Subsequently, the clamp is placed on the aorta and the ligature tightened. A Heifetz clip is then placed transversely onto the portal vein at its confluence with the gastroduodenal vein. The portal vein is cut just distally from the ligature. A prepared button is slipped over the left-hand straight small anatomical forceps, while the right-hand forceps are used to pass the portal vein to the left-hand ana-

tomical forceps. The vein is then grasped and pulled through the button. Subsequently, the button is pushed as close as possible to the Heifetz clip, and clamped to the clip using a Pilling bulldog clamp.

Using small straight, and curved anatomical forceps the portal vein is reversed around the button and fixed with a previously prepared 7-0 silk suture. The Pilling bulldog clamp is then removed and replaced at the end of the Satinsky clamp for reasons of stability. The vena cava is then somewhat elevated, bringing it into closer contact with the portal vein button.

A longitudinal cut is made in the purse-string suture using iridectomy scissors and jeweler's forceps. One drawstring of the suture is clamped with a small hemostat and put under slight tension in a rostral direction. The button manipulated by its grip, is pushed into the vena cava. The purse-string is tightened with the left hand whilst the right hand still holds the button in position. The button is released and two additional knots tied. The Satinsky clamp is removed first followed by the Heifetz clamp and the bulldog clamp on the aorta. After replacing the intestines the abdominal wall is closed in two layers.

A.1.3.7 Cardiovascular analysis in anesthetized mice

PURPOSE AND RATIONALE

To fully utilize the potential of mouse models with specific gene mutations, it is necessary to study the functional consequences of genetic manipulations in fully intact mice. Lorenz and Robbins (1997) developed and validated a methodology to study cardiovascular parameters in closed-chest mice.

PROCEDURE

Adult mice of either sex weighing 25–35 g are anesthetized by intraperitoneal injection of 50 mg/kg ketamine and 100 mg/kg thiobutabarbital. After the mice are placed on a thermally controlled surgical table with body temperature continually monitored via a rectal probe, a tracheotomy is performed with a short length (<1 cm) of PE-90 tubing. The right femoral artery is then cannulated with polyethylene tubing which is pulled over a flame to a small diameter (~0.4 mm OD). The catheter is advanced ~1 cm, near the level of the aorta, and connected directly to a low-compliance COBE CDXIII fixed-dome pressure transducer for the measurement of arterial blood pressure. The right femoral vein is then cannulated with the same type of small-diameter tubing and connected to a microinjection pump for the infusion of experimental drugs. To assess myocardial performance, the right carotid artery is cannulated with a 2F Millar MIKRO-TIP transducer (Model SPR-407, Millar Instruments, Houston TX). This high-fidelity transducer, which has a tip diameter of ~0.67 mm, has a reported frequency response that is flat up to 10 000 Hz and therefore can be used to accurately monitor the high frequency of the mouse ventricular pulse pressure. During continual monitoring of the blood pressure wave to ascertain the anatomic position of the catheter, the tip of the transducer is carefully advanced through the ascending aorta and into the left ventricle. When the stable waveform of the ventricular pressure profile is achieved, the transducer is anchored in place with 7-0 silk sutures. After completion of the surgery, all wounds are closed with cyanoacrylate to minimize evaporative loss of fluid, and the animals are allowed to stabilize for 30–45 min.

EVALUATION

Blood pressure signals from the COBE transducer and from the Millar transducer are amplified and the output is recorded and analyzed with a MacLab 4/s data acquisition system connected to a Macintosh 7100/80 computer which allows the calculation of the following parameters:

dP/dt	first derivative of the ventricular pressure wave,
MAP	mean arterial pressure,
HR	heart rate,
LVP	systolic and diastolic left ventricular pressure,
LVEDP	left ventricular enddiastolic pressure.

Further indices of ventricular performance can be calculated from *dP/dt*.

MODIFICATIONS OF THE METHOD

Champion et al. (2000) described a **right-heart catheterization technique** for *in vivo* measurement of vascular responses in lungs of intact mice. CD1 mice weighing

25–38 g were anesthetized with thiopentobarbital (85–95 mg/kg i.p.) and ketamine 3 mg/kg i.p.) and were strapped in supine position to a thermoregulated fluoroscopic table. The trachea was cannulated and the animals breathed with room air enriched with 95% O_2/5% CO_2. A femoral artery was cannulated for the measurement of systemic arterial pressure. Heart rate was electronically monitored from the systolic pressure pulses with a tachometer (Grass model 7P44A). The left jugular vein was cannulated for the administration of agonists and antagonists.

For measuring pulmonary arterial pressure, a special single lumen catheter was constructed. The catheter was 145 mm in length and 0.25 mm in outer diameter, with a specially curved tip to facilitate passage through the right heart, main pulmonary artery, and the left or right pulmonary artery. Before the catheter was introduced, the catheter curve was initially straightened with a 0.010-in. straight angioplastic guide wire to facilitate passage from the right jugular vein into the right atrium at the tricuspid valve under fluoroscopic guidance. As the straight wire was removed, the natural curve facilitated entry of the catheter into the right ventricle. A 0.010-in. soft-tip coronary artery guide wire was then inserted, and the catheter was passed over the guide wire into the main pulmonary artery under fluoroscopic guidance. Pressure in the main pulmonary artery was measured with a pressure transducer, and mean pulmonary artery pressure was derived electronically and recorded continuously.

Cardiac output was measured by the thermodilution technique. A known volume (20 µl plus catheter dead space) of 0.9% NaCl solution at 23 °C was injected into the right atrium, and changes in blood temperature were measured at the root of the aorta. A cardiac output computer equipped with a small-animal interface was used. The thermistor microprobe was inserted into the right carotid artery and advanced to the aortic arch, where changes in aortic blood temperature were measured. A catheter placed in the right jugular vein was advanced to the right atrium or main pulmonary artery for rapid bolus injection of saline. The saline solution was injected with a constant-rate syringe to ensure rapid and repeatable injection of the saline indicator solution. Thermodilution curves were recorded on a chart recorder and pulmonary and systemic blood pressure monitored continuously. Catheter placement was verified by postmortem examination.

A.1.3.8 Blood pressure in anesthetized cats

PURPOSE AND RATIONALE

Cats are the most sensitive species of cardiovascular regulation. They were used extensively for cardiovascular screening. Recently, experiments in dogs are preferred since this species can be bred more easily in homogeneous strains.

PROCEDURE

Adult cats of either sex weighing 2.5 to 4 kg are anesthetized by intraperitoneal injection of 35 mg/kg pentobarbital sodium. Tracheotomy is performed and a tracheal cannula is inserted so that the cat can be mechanically ventilated with room air. A femoral artery and two femoral veins are cannulated for measurement of arterial blood pressure and systemic administration of drugs. The arterial cannula is connected to a Statham model P23Gb transducer. All recordings are made on a polygraph. Heart rate is determined with a Beckman Cardiotach connected to a voltage/pressure-pulse coupler. Rectal temperature is monitored and maintained between 37 °C and 38 °C with a heating pad.

The following drugs are injected i.v. as challenges:

- epinephrine 0.1, 0.3, 0.5 µg/kg,
- norepinephrine 0.1, 0.3, 0.5 µg/kg,
- isoproterenol 0.1, 0.2, 0.4 µg/kg,
- carbachol 0.1, 0.2, 0.5 µg/kg.

At least 5 min are allowed between challenge doses to permit the measured parameters to return to baseline.

Test drugs are injected at various doses followed by injections of the challenging drugs.

EVALUATION

Dose-response curves of challenging drugs are established before and after injections of the test drugs.

CRITICAL ASSESSMENT OF THE METHOD

Blood pressure experiments in anesthetized cats are very valuable as screening techniques for cardiovascular agents. Moreover, potentiation of norepinephrine response has been used as screening procedure for antidepressants with norepinephrine uptake inhibiting activity.

MODIFICATIONS OF THE METHOD

Yardley et al. (1989) studied cardiovascular parameters in spinal cats. The animals were anesthetized with 80 mg/kg intravenously administered α-chloralose. The spinal cord was transected or crushed at the first cervical segment after tetracaine hydrochloride (0.125 mg

in 0.1 ml) had been injected into this region of the cord. Systemic blood pressure was supported at a level sufficient to maintain constricted pupils (mean value 45 ±5 mm Hg) by volume expansion with blood from a donor (10–20 ml) or an infusion of dextran.

A.1.3.9 Cardiovascular drug challenging experiments in anesthetized dogs

PURPOSE AND RATIONALE

Sympathomimetic and cholinomimetic compounds as well as angiotensin II and carotid occlusion exert characteristic responses in blood pressure of anesthetized dogs. Antagonism or potentiation of these responses allow to characterize the cardiovascular activity of a new compound.

PROCEDURE

Adult Beagle dogs of either sex weighing between 8 and 15 kg are anesthetized with 15 mg/kg sodium thiopental, 200 mg/kg sodium barbital and 75 mg/kg sodium pentobarbital. Additional doses of sodium pentobarbital are given as needed. The dogs are intubated with a cuffed endotracheal tube and placed on a Harvard respirator (20 ml/kg, 10–15 cycles/min). A femoral vein and artery are cannulated using polyethylene tubing for drug administration and determination of arterial blood pressure, respectively. The animals are bilaterally vagotomized.

The arterial cannula is connected to a Statham model P23Gb transducer. All recordings are made on a polygraph. Heart rate is determined with a Beckman Cardiotach connected to a voltage/pressure-pulse coupler.

Drug challenges: One of the following combinations of drugs is administered i.v. to the dogs. The challenges are given in a fixed order: at least twice prior to test drug administration to insure consistent responses and again starting 15 min post test drug. Epinephrine and norepinephrine (1 µg/kg), isoproterenol (0.25 µg/kg), carbachol (0.25 µg/kg), tyramine (100 µg/kg) are used; bilateral carotid occlusion (45 s), phenylephrine (10 µg/kg), isoproterenol (0.25 µg/kg) angiotensin II (0.2 µg/kg) and carbachol (0.25 µg/kg) for cardiovascular drugs. At least 5 min are allowed between challenge doses to permit the measured parameters to return to baseline. Challenge drug doses are sometimes varied to keep the mean arterial pressure within the following limits: epinephrine (+30 to +60 mm Hg), norepinephrine (–30 to +70 mm Hg), tyramine (+30 to +70 mm Hg), isoproterenol (–30 to –50 mm Hg), carbachol (–30 to –50 mm Hg), phenylephrine (–30 to +70 mm Hg), angiotensin II (+30 to +50 mm Hg), and bilateral carotid occlusion (+30 to +70 mm Hg).

EVALUATION

The recordings are studied to detect any changes in the arterial pressure response to the challenge drug before and after test-drug administration and to observe any changes in blood pressure and heart rate. Results are expressed as the percentage change from the predrug response.

A.1.3.10 Hemodynamic analysis in anaesthetized dogs

PURPOSE AND RATIONALE

The hemodynamic effects of compounds supposed to affect the cardiovascular system are evaluated by measuring preload and afterload of the heart, contractility,

heart rate, cardiac output and peripheral or coronary flow. To measure these cardiovascular parameters accurately, the use of larger animals such as dogs or pigs is necessary.

This experimental model allows the classification of test drugs according to their action as having:

- positive inotropic effects
- negative inotropic effects (Ca^{2+}-antagonist, anti-arrhythmic?)
- hypertensive effects
- hypotensive effects
- coronary-dilating effects
- β-blocking effects
- α-blocking effects
- anti-anginal effects
- peripheral-vasodilating effects

PROCEDURE

Male or female inbred Beagle or Labrador-Harrier dogs weighing between 15 and 25 kg are used. They are anesthetized with a bolus injection of 35–40 mg/kg pentobarbital, and continued with an infusion of 4–6 mg/kg/h. A catheter is placed into the cephalic vein for intravenous injections. Another catheter is placed into the duodenum for enteral administration. Respiration is maintained with room air through a tracheal tube using a positive pressure respirator, e.g., Bird-Mark-7-respirator. Blood gas analyses are performed at regular time intervals. Oxygen is supplied via the respirator as needed.

Preparation for hemodynamic measurements

Blood pressure is recorded through a cannula inserted into the left femoral artery and connected to a Statham pressure transducer (Statham P 23 DB).

For determination of LVP, a Millar microtip catheter (type PC 350) is inserted via the left common carotid artery into the left ventricle. LVEDP is measured on a high-sensitivity scale. From the pressure curve, dp/dt_{max} is differentiated and heart rate is counted. The LVP-signal also triggers a cardiotachometer.

Cardiac output, pulmonary artery pressure (PAP) and stroke volume are measured by a thermodilution technique using a Cardiac Output Computer (Gould/Statham SP 1245) and a balloon-tip triple lumen catheter (Gould SP 5105, 5F) with the thermistor positioned in the pulmonary artery via the jugular vein.

Myocardial oxygen consumption (MVO_2) is calculated as pressure-work-index according to Rooke and Feigl (1982).

Femoral blood flow and coronary flow are measured with electromagnetic flow probes attached to the femoral artery and the circumflex branch of the left coronary artery (LCX), respectively.

Experimental course

When stable hemodynamic conditions and blood gas values of $pO_2 > 100$ mm Hg and $pCO_2 < 35$ mm Hg are achieved for at least 20 min (control values), the test substance is administered through a catheter inserted into a cephalic vein in doses of 0.1, 0.3, 1.0, and 3.0 mg/kg or into the duodenum in doses of 0.3, 1.0, 3.0, and 10.0 mg/kg.

All parameters are recorded continuously during the whole experiment.

Characteristics

- blood pressure
  - systolic, BPs
  - diastolic, BPd
- left ventricular pressure, LVP
- left ventricular enddiastolic pressure, LVEDP
- maximal rate of pressure rise, *dp*/*dt* max
- heart rate, HR
- peripheral blood flow in A. femoralis, PF
- blood pressure A. pulmonalis, PAP
- coronary flow, CF
- cardiac output, CO
- stroke volume, SV
- total peripheral resistance, TPR
- left ventricular stroke work, LVSW
- left ventricular minute work, LVMW
- left ventricular myocardial oxygen consumption, MVO_2

CALCULATION OF RESULTS AND EVALUATION

Besides the different directly measured hemodynamic parameters, the following data are calculated according to the respective formulae

- stroke volume [ml/beat],

$$SV = \frac{CO}{HR}$$

- total peripheral resistance [dyn s/cm^5],

$$TPR = \frac{BPm}{CO} \times 79.9$$

- left ventricle stroke work [J/beat],

$$LVSW = (BPm - LVEDP) \times SV \times 0.333 \times 10^{-3}$$

- left ventricular minute work [J/min],

$$LVMW = LVSW \times HR$$

- left ventricular myocardial oxygen consumption [ml O_2/min/100 g],

$$MVO_2 = K_1(BPs \times HR) + K_2 \times \frac{(0.8BPs + 0.2BPd) \times HR \times SV}{BW} + 1.43$$

K_1 = 4.08×10^{-4}
K_2 = 3.25×10^{-4}
BPs = systolic blood pressure [mm Hg]
BPd = diastolic blood pressure [mm Hg]
BPm = mean blood pressure [mm Hg]
HR = heart rate [beats/min]
CO = cardiac output [ml/min]
SV = stroke volume [ml/beat]
LVEDP = left ventricular enddiastolic pressure [mm Hg]
BW = body weight [kg]

Changes in parameters measured after drug administration are compared to control values obtained during the 20 min pre-drug period.

Results are presented as mean ±SEM with $n > 3$.

Statistical significance is assessed by means of the paired *t*-test.

MODIFICATIONS OF THE METHOD

The effect of drugs on the carotid artery occlusion effect can be studied in anesthetized dogs. The occlusion of right and left common carotid arteries is performed by squeezing them between a polyethylene tubing and a twine which is passed inside the tubing and around the carotid artery. An occlusion of the carotid arteries for 30 s causes an increase of systolic blood pressure by 40–50 mm Hg. Inhibition of this effect by drugs is tested.

Studies in anesthetized dogs can be used to determine the influence of cardiotonic drugs on propranolol induced cardiac insufficiency (Rajagopalan et al. 1993)

Instead of dogs, **pigs (German landrace)** weighing between 20–35 kg can be used. They are pretreated with ketamine 500 mg/5 ml i.m., methomidate hydrochloride 200 mg/4 ml i.p., xylazine 60 mg/3 ml i.m., and anaesthetized with 15–20 mg/kg pentobarbital sodium, followed by continuous infusion of 12 mg/kg/h. The parameters are evaluated similarly to the experiments in dogs.

Measurement of cardiac output by the thermodilution method in **rats** was described by Richardson et al. (1962) and Müller and Mannesmann (1981).

Thermodilution methods were used by Rosas et al. (1964) in anesthetized rats, by Carbonell et al. (1985) and by Salyers et al. (1988) in conscious rats to determine hemodynamic parameters.

Oxygen pressure, carbon dioxide pressure and pH in coronary venous and common carotid arterial blood of anesthetized dogs has been measured using a blood gas analyzer (Aisaka et al. 1988).

Acute ischemic left ventricular failure can be induced in anesthetized dogs by repeated injections of plastic microspheres into the left coronary artery (Smiseth and Mjøs 1982; Sweet et al. 1984; Schölkens et al. 1986). A coronary catheter was introduced through the right femoral artery and advanced under fluoroscopy to the left coronary ostium, guided by injection of small amounts of contrast medium. After reaching baseline values, acute left ventricular failure was induced by subsequent intra-coronary injections of plastic microspheres (52.9 ±2.48 µm non-radioactive tracer microspheres). The microspheres were suspended in saline with a drop of Tween 80 and sonified before use, 1 mg microspheres/1 ml saline corresponding to approximately 12 000 microspheres. (13–16 injections of microspheres or 3.4–5.0 mg/kg). Microspheres were injected every 5 min for 70–90 min. Each microsphere injection effected an immediate and stepwise increase in LVEDP. With this procedure, LVEDP can be increased to a desired level in a very controlled manner. In the 30 min following embolization, LVEDP continued to increase by approximately 5 mm Hg. Animal with arrhythmias had to be excluded from the study. Thirty min after the end of embolization, when hemodynamic parameters had stabilized, drug administrations were started.

Valdes-Cruz et al. (1984) developed an **open-chest preparation in dogs** to validate the accuracy of a two-dimensional Doppler echocardiographic method for estimating pressure drops across discrete stenotic obstructions.

In order to assess the potential of a single breath technique (using freon-22) as an effective way to estimate cardiac output non-invasively, Franks et al. (1990) measured simultaneously with the single breath technique the aortic flow using an electromagnetic flowmeter in anesthetized dogs.

A.1.3.11 Hemodynamic measurements in conscious dogs

PURPOSE AND RATIONALE

The potency of a cardiovascular drug depends on the direct effects at the cellular level and on the response of the cardiovascular control mechanisms. The latter are often markedly influenced by anesthesia. The chronically instrumented conscious dog with renal hypertension is therefore a more realistic test model to evaluate the effects of antihypertensive, anti-anginal and cardiotonic compounds. The test is used to evaluate hemodynamic drug effects in conscious dogs, an experimental model with chronic arterial and ventricular catheterization and renal artery constriction.

PROCEDURE

Male or female Labrador-Harrier dogs weighing 15–25 kg are used. They are anaesthetized with 1 mg/kg xylazine i.m., followed by 1 mg/kg xylazine i.v. and 18 mg/kg pentobarbital sodium i.v. For chronic instrumentation and induction of renal hypertension, fluid-filled catheters are implanted into the abdominal aorta and into the left ventricle. The catheters are tunneled subcutaneously and exteriorized on the nape of the neck dorsally. Renal hypertension is induced by placing silastic constrictors around both renal arteries. Hemodynamic measurements are performed after a two-week recovery period or later.

To familiarize the dogs to the test surroundings, they are brought into the laboratory 2–3 times before the start of the study. Thus, drug testing is possible without sedation. During the experiment the animal rests quietly on a laboratory table.

Experimental protocol

Hemodynamic measurements are performed by connecting the two implanted catheters to Statham pressure transducers. Pressure signals, electronically differentiated LVP *dp/dt* max and heart rate are recorded with a polygraph.

After reaching stable hemodynamic conditions for at least 20 min (control baseline values), the test compound is administered either orally in a gelatin capsule or by intravenous injection into the cephalic vein.

Hemodynamic parameters are recorded continuously starting 30 min before to 120 min after drug administration, and thereafter at 1 h intervals until 6 h after dosage.

EVALUATION

The following parameters are monitored:

- systolic blood pressure [mm Hg]
- diastolic blood pressure [mm Hg]
- left ventricular enddiastolic blood pressure, LVEDP [mm Hg]
- left ventricular pressure at *dp/dt* max [mm Hg/s]
- heart rate [beats/min]

Mean values ±SEM are calculated with $n > 3$ as differences to pre-drug control values.

MODIFICATIONS OF THE METHOD

Mann et al. (1987) described a simple procedure for direct blood pressure measurement in conscious dogs using the Vascular-Access-Port™, consisting of a 33 × 13 mm reservoir body affixed to a silicon rubber catheter.

Müller-Schweinitzer (1984) described a method for the assessment of vasoconstrictor agents by recording venous compliance in the conscious dog. Changes in the diameter of the canine saphenous vein, produced by inflation to 45 mm Hg of a sphygmomanometer cuff placed on the upper hind leg, were recorded.

Hintze and Vatner (1983) compared the effects of nifedipine and nitroglycerin in conscious dogs, instrumented for instantaneous and continuous measurements of coronary arterial and left ventricular diameters with an ultrasonic dimension gauge, arterial and left ventricular pressure with implanted miniature gauges, and coronary blood flow with an electromagnetic flowmeter or a Doppler ultrasonic flowmeter.

Shimshak et al. (1986) studied the recovery of regional myocardial contractile function after a 10 min coronary artery occlusion in chronically instrumented conscious dogs.

Wright et al. (1987) described a minimally invasive technique which allows assessment of histamine H_1-receptor antagonist activity in conscious dogs based on the inhibition of tachycardia caused by intravenous administration of the H_1-receptor agonist, 2-pyridylethylamine.

Hashimoto et al. (1991) studied the coronary effects of nicorandil in comparison with nitroglycerin in chronic conscious dogs instrumented with ultrasonic crystals and electromagnetic flowmeters in the circumflex coronary artery.

Hartman and Warltier (1990) described a model of multivessel coronary artery disease using conscious, chronically instrumented dogs. A hydraulic occluder and Ameroid constrictor were implanted around the left anterior descending and the left circumflex coronary arteries. Pairs of piezoelectric crystals were implanted within the subendocardium of the left anterior descending and the left circumflex coronary artery perfusion territories to measure regional contractile function. A catheter was placed in the left atrial appendage for injection of radioactive microspheres to measure regional myocardial perfusion.

Hof et al. (1990) used the Doppler method for measuring cardiac output in **conscious rabbits**.

Grohs et al. (1993) simultaneously assessed cardiac output with pulsed Doppler and electromagnetic flowmeters during cardiac stimulation.

A.1.3.12 Hemodynamic studies in monkeys

PURPOSE AND RATIONALE

Prior to studies in human beings, studies of cardiovascular effects of new drugs in monkeys are necessary in some instances.

PROCEDURE

Rhesus monkeys of either sex, weighing between 5 and 8 kg are anesthetized with 20 mg/kg ketamine hydrochloride followed by 50 mg/kg pentobarbital-Na given slowly i.v. A small side-branch of the femoral or radial artery is surgically exposed and cannulated for blood pressure recordings using a blood pressure transducer (P23 ID). Heart rate is determined from a conventional ECG lead by a biotachometer. Compounds are administered either intravenously or via a gastric fibroscope, e.g., Olympus XP 10, into the duodenum

under visual control. The cardiovascular parameters are registered for a pretest period of 30 min and then during 60 min after intravenous administration or 2 h after intragastric administration of the test drug. Three to 6 animals are used for evaluation.

EVALUATION

Mean values ±SD are calculated for the pretest period and for the cardiovascular effects every min for 5 min after i.v. administration and then every 5 min. After intragastric administration the values are registered every 5 min up to 30 min and then every 10 min. The values after administration of the test compound are compared statistically with the pretest values using the Student's *t*-test.

MODIFICATIONS OF THE METHOD

Lacour et al. (1993) studied cardiovascular parameters in conscious **cynomolgus monkeys** (*Macaca fascicularis*). A silicone catheter (internal and external diameter 0.64 and 1.19 mm, respectively) was implanted under aseptic conditions into the thoracic aorta via a carotid artery after the monkeys had been anesthetized with 40 mg/kg ketamine and 0.5 mg/kg acepromazine intramuscularly. The vascular catheter (filled with an aqueous solution of 40% polyvinylpyrolidone and 20% heparin) was inserted into a carotid artery. A patch of silicone was sewn around the artery to maintain the catheter in position, the latter being routed subcutaneously and exteriorized at the top of the head into a stainless steel connector. This connector was fixed to the skull with screws and dental cement, and sealed with a plug to protect the catheter from damage. The monkeys were permitted a 3-week minimum recovery period. Before the experiment was performed the monkeys were placed in a primate-restraining chair on several occasions, of gradually increasing duration, for experiment acclimatization.

Pulsatile arterial pressure was recorded by connecting the arterial catheter to a polygraph via a Statham P23Id pressure transducer. Mean arterial pressure and heart rate were derived from the pulse pressure signal and recorded. A catheter was inserted acutely into a saphenous vein for administration of compounds.

A.1.3.13 Measurement of cardiac output and regional blood flow with microspheres

PURPOSE AND RATIONALE

The microsphere technique allows the measurement of cardiac output and regional blood flow. Using different radionuclides, repeated determinations are possible. The method is applicable not only for dogs, cats, and minipigs (Hof et al. 1980) but also for rats (McDevitt and Nies 1976; Bonnacrossi et al. 1978; Ishise et al. 1980; Stanek et al. 1985) using microspheres of appropriate size.

PROCEDURE

Male Sprague-Dawley rats weighing 265–375 g are anesthetized with 35 mg/kg i.p. pentobarbital. The right carotid and right femoral arteries are cannulated. Using pressure monitoring, a carotid cannula is manipulated into the left ventricle. Carbonized micro-spheres (15 ±5 μ diameter) labelled with ^{85}Sr are drawn into a glass injection chamber and suspended in 0.3 ml 6% dextran so that each chamber contains 60 000 to 80 000 microspheres. The radioactivity in each chamber is determined by gamma scintillation counting before and after microsphere injection, the difference being the amount of radioactivity injected. The microspheres are injected into the left ventricle in a total volume of 0.8 ml 6% dextran over 20 s. Simultaneously, arterial blood from the femoral artery is withdrawn at 0.8 ml/min for 90 s with a syringe withdrawal pump.

EVALUATION

This reference blood sample is used to calculate the cardiac output by the formula:

$$\text{cardiac output} = \text{counts injected} \times \frac{\text{reference sample withdrawal rate}}{\text{reference sample counts}}$$

After obtaining the reference sample, the animals are sacrificed with pentobarbital and the organs dissected, placed in counting vials, and counted for 5 min. Regional distribution of the cardiac output is calculated by comparing the radioactivity in each organ with the total injected radioactivity. Organ flow is determined by multiplying the cardiac output by the fractional distribution of the cardiac output to the organ.

CRITICAL ASSESSMENT OF THE METHOD

Problems associated with the microsphere technique in rats are the hemodynamic effects of the solutions

used to inject the microspheres and the effects of blood withdrawal after repeated determinations (Stanek et al. 1985).

MODIFICATIONS OF THE METHOD

For repeated determinations, other nuclides have been used, such as ^{46}Sc, ^{51}Cr, ^{141}Ce, ^{125}I (Hof et al. 1980).

Kovách et al. (1992) used up to 5 radiolabelled microspheres (^{57}Co, ^{113}Sn, ^{85}Sr, ^{95}Nb and ^{46}Sc) for measurement of regional cerebral blood flow in cats.

Faraci and Heistad (1992) measured blood flow with radioactive microspheres (15 µ diameter) labeled with ^{46}Sc, ^{95}Nb, ^{153}Gd, ^{85}Sr, and ^{141}Ce in anesthetized rabbits.

Grover et al. (1990), Gross et al. (1992) measured myocardial blood flow in dogs with the radioactive microsphere technique.

Kowallik et al. (1991) measured regional myocardial blood flow with multiple colored microspheres. The method yielded values very similar to those obtained with radioactive microspheres.

A.1.3.14 Carotid artery loop technique

PURPOSE AND RATIONALE

The carotid loop method, originally described by van Leersum (1911) for rabbits has been used by several authors (e.g., Child and Glenn 1938; Valli et al. 1967; O'Brien et al. 1971; Meyer et al. 1989) for measurement of blood pressure or blood sampling in conscious dogs and sheep (Lagutchik et al. 1992).

PROCEDURE

Male or female inbred Beagle or Labrador-Harrier dogs weighing between 15 and 25 kg are used. They are anesthetized with a bolus injection of 35–40 mg/kg pentobarbital, continued with an infusion of 4–6 mg/kg/h. The animal is placed on a heated operating table. The skin on the ventral side of the neck is carefully shaved and disinfected. The course of the carotid artery is outlined by palpation along the tracheal border. About 2 cm of skin is taken on each side marking the width of the flap. The medial incision is made slightly above the thyroid cartilage and is extended caudal to a point about 1 cm lateral and 1 cm above the manubrium sterni. The lateral incision again lies about 2 cm from the line of the carotid artery and parallel to it. The lateral incision is only half as long as the medial one. The incisions are made down to the subcutaneous tissue over the platysma muscle. Between the skin and the muscle, the flap is undermined. All bleeding points are carefully clamped and tied.

The subcutaneous tissue, the platysma myoides muscle and the anterior fascia of the neck are incised in the course of the midline incision down to the plane of cleavage between the sternohyoid and sternomastoid muscle. By blunt dissection, these muscles are separated, disclosing at their depth the neurovascular bundle over which lies the internal jugular vein. The floor of the space so isolated is formed by the longus capitis muscle. By careful dissection, these muscles are separated at least 1 cm above and below the limits of the incision in the skin. The superior thyroid artery marks the uppermost portion of the carotid artery suitable for exteriorization. The plane of cleavage is followed caudal to the origin of the sternocleidomastoid muscle at the manubrium sterni. Throughout the limits of the incision the artery is dissected free from the internal jugular vein and then from the vagus nerve.

The first step in the exteriorization of the artery is the re-approximation of the muscle borders beneath the vessel by mattress sutures. In order to prevent tension on the completed loop due to contraction of the sternomastoid and sternohyoid muscle, it is important to re-approximate these muscles throughout their course. Sutures are placed at the edges of skin. The tubular flap of skin is then approximated loosely around the carotid artery. It is essential that the skin flap fits loosely around the artery. A continuous suture of fine silk is started at the place where the vessel emerges from the muscle borders. The suture is so placed as to include the artery in a sling of skin which isolates the vessel from the line of suture of the under-side of the completed loop. Finally, the proximal and distal quarters of the flap are closed with sutures, while the skin tube is closed with a continuous suture. Antibiotics are given locally and systemically.

One thickness of gauze is placed beneath the loop and along each border a strip of gauze in order to relieve the loop from the pressure caused by the reminder of dressings. Around the neck is wrapped a gauze bandage several turns of which have passed behind the forelimbs in order to prevent the dressing from riding upwards on the animal's neck. Over this is placed a plaster roll protecting the loop from the animal's efforts of scratching. The dressings are changed on the fifth and seventh day when the sutures can be removed.

Blood pressure measurements can be made according to Riva-Rocci's principle by placing a inflatable cuff around the loop.

CRITICAL ASSESSMENT OF THE METHOD

The carotid artery loop method needs some surgical experience and very meticulous care-taking of the animals.

MODIFICATIONS OR THE METHOD

Lewis et al. (1980) placed a CO_2 sensor using mass spectrometry and its through flow cuvette in a common carotid artery-to-jugular vein loop in anesthetized cats.

Meyer et al. (1989a,b) studied pulmonary gas exchange in panting dogs with an exteriorized carotid artery loop.

Kaczmarczyk et al. (1979) used conscious, chronically instrumented dogs with electric flow probes around the left renal artery and a carotid loop to study postprandial volume regulation.

A.1.3.15 Measurement of heart dimensions in anesthetized dogs

PURPOSE AND RATIONALE

The measurement of the heart dimensions allows to localize the effect of a drug on the activity of the heart. An ultrasonic technique is used for continuous measurement of left ventricular dimensions. Compounds are tested with potential anti-anginal activity due to the reduction of left ventricular diameter. The test is used to evaluate the influence of drugs on left ventricular external and internal diameter in anesthetized dogs.

PROCEDURE

Male or female Beagle or Labrador-Harrier dogs weighing 15–25 kg are used for the test. The dog is anesthetized by intravenous injection of 35–40 mg/kg pentobarbital sodium followed by subcutaneous injection of 2 mg/kg morphine. Respiration is maintained through a tracheal tube with N_2O/O_2 (3:1) using a positive pressure respirator.

Implantation of ultrasonic transducers

Ultrasonic transducers are constructed and implanted as described by Stinson et al. (1974).

To measure left ventricular external diameter (LVED), two ultrasonic transducers are fixed to the left ventricular wall. One crystal is sutured to the posterior wall within the rectangular area formed by the left circumflex coronary artery and the left posterior descending artery. The other one is placed near the first diagonal branch of the left anterior descending coronary artery. Exact positioning is assured with an oscilloscope.

To measure left ventricular internal diameter (LVID), the transducers are placed in the same anatomical area as for the epicardial crystals. However, they are pushed through the wall of the left ventricle through stab

wound incisions. The crystals are positioned across the greatest transverse diameter of the left ventricle, one on the anterior and the other on the posterior endocardial wall.

Bleeding during the implantation procedure is controlled by umbilical tapes around the cranial and caudal veins and by purse string sutures at the implantation sites. The pericardial incision and the chest is closed by sutures and the transducer wires are connected to the recording equipment.

In each dog, either LVED or LVID is measured together with the other hemodynamic parameters.

Preparation for hemodynamic measurements

Blood pressure is recorded through a cannulated femoral artery by a pressure transducer (Statham P 23 DB).

For determination of LVP, a Millar microtip catheter (type PC 350) is inserted via the left A. carotis communis. LVEDP is measured on a high-sensitivity scale. From the pressure curve, *dp*/*dt* max is differentiated and heart rate is calculated.

Hemodynamic parameters are recorded continuously during the whole experiment.

Experimental course

When stable hemodynamic conditions are achieved for at least 30 min (control values), the test substance is administered by intravenous or intraduodenal injection.

Readings are taken at times 0, 15, 30, 45, 60, 75, 90 and 120 after drug administration. Left ventricular dimensions are measured at the end of the diastole and systole.

Characteristics:

- blood pressure
  - – systolic blood pressure
  - – diastolic blood pressure
- left ventricular pressure, LVP
- left ventricular enddiastolic pressure
- left ventricular contractility, dp/dt
- heart rate, HR
- left ventricular external diameter, LVED
- left ventricular internal diameter, LVID

EVALUATION

Hemodynamic parameters, LVED and LVID [mm] are determined.

Changes in parameters after drug administration are compared to control values obtained during the 30 min pre-drug period.

Statistical significance is assessed by means of the paired *t*-test.

Since a change in the diameter of the left ventricle is a reasonable accurate index of left ventricular volume, a reduction of LVED or LVID with no change in *dp*/*dt* and HR can be considered as a strong indicator for "venous pooling" and thus an anti-anginal activity of a compound.

Scores are allotted relative to the efficacy of standard compounds assessing the intensity as well as the duration of the effect.

Standard data:

		LVED [mm]		LVID [mm]	
Nitroglycerin	0.005 mg/kg, i.v.	–0.9	20 min	–1.2	30 min
Isosorbide-dinitrate	0.1 mg/kg, i.v.			–0.6	120 min
Molsidomine	0.2 mg/kg, i.v.	–2.1	>60 min	–1.4	>120 min
Nifedipine	0.1 mg/kg, i.v.			+1.2	120 min

MODIFICATIONS OF THE METHOD

Novosel et al. (1992) measured the dimensions of the right ventricle with microsonometry in anesthetized rabbits.

A.1.3.16 Telemetric monitoring of cardiovascular parameters in rats

PURPOSE AND RATIONALE

Radiotelemetry allows the recording of cardiovascular parameters in conscious, free-moving animals. Several authors (Brockway et al. 1991; Mattes and Lemmer

1991; Guiol et al. 1992; Morimoto et al. 1992; Basil et al. 1993; Brockway and Hassler 1993; Lemmer et al. 1993, 1994, 1995; Calhoun et al. 1994; Diamant et al. 1993; Kramer et al. 1993a, 1995; Griffin et al. 1994; Kuwahara et al. 1994; Sato et al. 1994, 1995; van den Buuse et al. 1994; Kinter 1996; Becker et al. 1997; Witte et al. 1998) used commercially available systems with some modifications to study the circadian rhythm of blood pressure and the influence of drugs on heart rate, blood pressure and motility in rats.

PROCEDURE

The telemetry and data acquisition system (e.g., Data Sciences International, Inc., St Paul MN) consists of four parts:

1. the implantable transmitter, which measures the pressure. This device contains a highly stable, ion-implant, semiconductor, strain-gauge sensor and battery-powered electronics to process the information from the pressure sensor and to telemeter it from within the animal. Arterial pressure is transmitted to the sensor via a 0.7-mm diameter, fluid-filled catheter;
2. the receiver which detects the signal from the implanted transmitter and converts it to a form readable by computer;
3. the pressure reference module, which measures atmospheric pressure to allow for the telemetered absolute pressure to be converted to a gauge pressure;
4. the data acquisition software, which accepts data from the reference module and the receivers, filters corrupt samples from the incoming data stream, converts the telemetered pressure to millimeters of mercury, subtracts atmospheric pressure from the telemetered pressure, and stores the data for retrieval, plotting, and analysis.

Under pentobarbital anesthesia, the telemetry transmitter is implanted into rats. The descending aorta is exposed between the renal arteries. A vascular clamp is made by putting two surgical threads on the proximal and distal part of the artery. The catheter tip is inserted through an incision in the vessel. A drop of cyanoacrylate glue is applied to the dried entry point. The transmitter is sutured to the abdominal musculature.

EVALUATION

Data from individual animals are recorded over long periods of time which allow the investigator to follow the circadian rhythm under several experimental conditions.

MODIFICATIONS OF THE METHOD

Hess et al. (1996) monitored pulmonary arterial pressure in freely moving **rats** by inserting the sensing catheter of a telemetric system through a small hole and pushing it into the pulmonary artery.

Further cardiovascular studies in rats using the telemetric system were reported by Sgoifo et al. (1998), Webb et al. (1998).

Kramer et al. (1993b) used telemetry to record electrocardiogram and heart rate in freely moving **mice**.

Carlson and Wyss (2000) used small telemetry probes for long term recording of arterial pressure and heart rate in mice after implantation to the carotid artery or the abdominal aorta.

DePasquale et al. (1994) used radio-telemetry to monitor cardiovascular function in conscious **guinea pigs**.

Telemetric ECG recordings in **cardiomyopathic hamsters** were reported by Desjardins et al. (1996).

Van den Buuse and Malpas (1997) studied cardiovascular parameters in **rabbits** by radio-telemetry.

Astley et al. (1991), Smith et al. (1993) used telemetric systems to monitor cardiovascular responses in **baboons**.

Schnell and Wood (1993) measured blood pressure and heart rate by telemetry in conscious, unrestrained **marmosets**.

An ultrasonic blood flowmeter telemetry system for **cats** and rabbits has been described by Yonezawa et al. (1989, 1992).

Telemetry was used by Symons et al. (1992) to monitor the severity of events representing myocardial dysfunction in **miniswine**.

Savory and Kostal (1997) applied the telemetric system for chronic measurement of cardiovascular and other parameters in **chicken**.

Radiotelemetry has also been used for other pharmacological experiments, such as field potential analysis by radioelectroencephalography (see Sect. E.1.2.6), step through passive avoidance (see Sect. F.3.1.2), shock-prod burying test in rats (see Sect. E.2.5.3), measurement of body temperature (see Sect. H.4.0.2) and motility in rats and mice (Clement et al. 1989; Guillet et al. 1990; Diamant et al. 1993; van den Buuse 1994).

A.1.3.17 Cardiovascular effects after intracerebroventricular administration

PURPOSE AND RATIONALE

Several drugs, like α_2-adrenergic agonists, act primarily at central sites. Their effects can be most clearly demonstrated after injection into the cerebroventricular system. The first experiments have been performed in cats. The method has been adapted to rats.

PROCEDURE

Rats of either sex weighing 250–350 g are anesthetized with 100 mg/kg hexobarbital i.p. The scalp is cut in a sagittal line. With a dental drill a hole of 1–1.5 mm diameter is drilled through the cranial bone 1 mm lateral and 2 mm caudal of the bregma. A PVC-catheter is introduced perpendicular to the bone to a depth of 3 mm in order to reach the lateral cerebral ventricle. The catheter is fixed with dental cement and the wound closed. Test substances are administered through the catheter. To measure blood pressure one catheter is placed in one carotid artery and connected to a Statham transducer. Blood pressure and heart rate are recorded on a polygraph over a period of at least 30 min. For long acting drugs registration periods up to 2 h are necessary. After the experiment, the animal is sacrificed and the brain removed to confirm the site of injection.

EVALUATION

Systolic and diastolic blood pressure as well as heart rate after intracerebroventricular injection are expressed as percentage of pretreatment values. The response is compared with the standard clonidine which is effective in doses of 4–60 µg.

MODIFICATIONS OF THE METHOD

Based on the work of Feldberg et al. (1954) and Hayden et al. (1966), Mastrianni et al. (1986) developed an intracerebroventricular perfusion system for the study of centrally acting antihypertensive drugs in the rat. The antihypertensive effect of clonidine could be observed over several hours.

Methods used to detect central hypotensive activity of drugs have been reviewed by Timmermans (1984).

A.1.3.18 Influence on orthostatic hypotension

PURPOSE AND RATIONALE

Orthostatic hypotension with dizziness up to unconsciousness is a syndrome occurring in many human individuals. Moreover, several drugs are known to cause orthostatic hypotension. In several animal species, such as rabbit, cat and dog, this syndrome can be evoked by changing the usual horizontal position into a vertical position with the head upwards using a tilting table.

PROCEDURE

Cats of either sex weighing 2.0–3.0 kg are temporarily anesthetized with ether. Anesthesia is maintained by intravenous injection of 70 mg/kg chloralose. The animal is fixed with its legs on a heated operating table which can be tilted by 90 degrees. The carotid artery is cannulated for measuring blood pressure through a Statham P 23 Db transducer on a 6 channel Hellige recorder. The femoral vein is cannulated for injection of the test compound. After the blood pressure is stabilized for 30 min, the animal is quickly tilted to a vertical position for 1 minute. Due to the change of position and gravitational force, there is a rapid fall in blood pressure which recovers as soon as the animal is restored to its original position. After taking the control reading, the test compound is administered intravenously and the same procedure is repeated. The fall in blood pressure is recorded.

EVALUATION

A significant increase in postural hypotension with respect to the control would indicate that the test compound may produce orthostatic hypotension in human. Moreover, some compounds, like sympathomimetics, can reduce or prevent postural hypotension.

MODIFICATIONS OF THE METHOD

Sponer et al. (1981) described a method for evaluating postural hypotension in conscious **rabbits** placed on a tilting table whereby blood pressure was measured from the central artery of the ear.

Humphrey and McCall (1982) described a model for predicting orthostatic hypotension during acute and chronic antihypertensive drug therapy in **rats** anesthetized with chloralose, urethane and pentobarbital using a heated tilting table.

Lee et al. (1982) evaluated postural hypotension induced by drugs in conscious restrained normotensive rats. Blood pressure was recorded after cannulation of the femoral artery under light ether anesthesia. A special tilting table was build for simultaneous studies in four rats.

Baum et al. (1981) studied antihypertensive and orthostatic responses to drugs in conscious **dogs**. A catheter was placed in the subclavian artery for measurement of blood pressure and exteriorized at the back of the neck some days prior to the experiment. The animals were placed into a sling and tilted to the 90° upright position for periods of 60 s. every hour by lifting their forelimbs. Blood pressure response before and after treatment with test drugs was measured.

A none human **primate** model for evaluating the potential of antihypertensive drugs to cause orthostatic hypotension was described by Pals and Orley (1983). Polyvinyl catheters were implanted in the abdominal aorta and the vena cava via an external iliac artery and vein to **cynomolgus monkeys** during ketamine anesthesia. The catheters were routed subcutaneously from the groin area to the top of the head and exteriorized. After recovery the animals were placed in restraining chairs allowing the change from vertical to horizontal position.

A.1.3.19 Bezold-Jarisch reflex

PURPOSE AND RATIONALE

The circulatory collapse after intravenous injection of veratrine has been first described in cats and is known as BEZOLD-JARISCH-reflex (Bezold and Hirt 1867; Jarisch and Richter 1939a,b, Jarisch 1940). Fleckenstein et al. (1950) recommended this as a suitable animal model of shock.

The original observation was a triphasic blood pressure response in cats or dogs characterized by a short lasting fall in blood pressure accompanied by bradycardia, followed by a short lasting increase and than a long-lasting decrease of blood pressure after intravenous injection of veratridin or other veratrum alkaloids.

Kalkman et al. (1984) showed that three distinct subtypes of serotonergic receptors mediate the triphasic blood pressure response to serotonin observed in the Bezold-Jarisch reflex.

The Bezold-Jarisch reflex has been studied in several species, such as cats (Takei et al. 1995; Vayssettes-Couchay et al. 1997), dogs (Zucker and Cornish 1981; Barron and Bishop 1982; Harron and Kobinger 1984; Giles and Sander 1986; Baugh et al. 1989; Watson et al. 1995), ferrets (Andrews and Bhandari 1993), rabbits (Chen 1979), guinea pigs, rats (Fozard 1984; Gylys et al. 1988; Cohen et al. 1989; Blower 1990; Miyata et al. 1991; Turconi et al. 1991; Matsumoto et al. 1992; Meller et al. 1992; Robertson et al. 1992; Kishibayashi et al. 1993; Geissler et al. 1993; Haga et al. 1994; Hegde et al. 1994; Eglen et al. 1995; Göthert et al. 1995; Delagrange et al. 1996; De Vries 1997) and mice (Eglen et al. 1994; Middlefell et al. 1996), whereby species differences have been observed (Yamono et al. 1995).

In cats and dogs, the Bezold-Jarisch reflex was elicited by veratrine and veratridine, but also by capsaicin and the 5-HT_3 receptor agonists 2-methyl-5-HT, phenylbiguanide, chloro-phenylbiguanide and serotonin itself.

In rats, mostly 5-HT or 2-methyl-5-HT were used as stimuli to characterize 5-HT_3 receptor antagonists.

PROCEDURE

Male Sprague Dawley rats weighing 250–380 g are given food and water ad libitum, except those used for intraduodenal drug administration; these rats are de-

prived of food overnight. The animals are anesthetized by intraperitoneal injection of 1.5 g/kg urethane. Body temperature is maintained at 37 °C by placing the animal on a heating pad. The left jugular vein or duodenum, trachea and left femoral vein are cannulated for drug administration (i.v. or i.d.), facilitation of respiration and injection of 2-methyl 5-HT, respectively. Heart rate is derived from a limb lead II ECG monitored via subdermal platinum electrodes and is recorded with amplifiers on a polygraph. A dose-response curve to 2-methyl 5-HT (5–100 µg/kg, i.v.) is constructed in each rat to establish a submaximal dose (usually 10 or 20 µg/kg, i.v.) which elicits a reproducible bradycardic response. Each rat receives then a single dose of test drug or standard and is then challenged with 2-methyl 5-HT at 5, 15, 30, 60, 120, 180, 240, 300, 360, 420, and 480 min post dosing. A separate group of rats receiving vehicle (saline for i.v., deionized water for i.d.) is similarly tested in each study.

EVALUATION

Duration of action of the compounds is assessed by determining the period of time for which the inhibitory effects remain significantly different from vehicle controls. Statistical analysis of the data is performed by a repeated measure analysis of variance (ANOVA) followed by pairwise comparisons against control at each time period using Fisher's LSD multiple comparison test.

MODIFICATIONS OF THE METHOD

Harron and Kobinger (1984) used capsaicin to elicit the Bezold-Jarisch reflex in anesthetized artificially respirated dogs pretreated with a beta-adrenoceptor antagonist to evaluate the activity of clonidine-like drugs on central alpha$_2$ adrenoceptors after intracisternal administration.

A.1.3.20 Endotoxin induced shock

PURPOSE AND RATIONALE

Many bacterial infections as well as allergic reactions are known to induce pathophysiological events that may lead to shock in man. When experimental animals are injected with endotoxin and galactosamine, shock and death occur in all untreated animals 5–7 h after injection. The endotoxin induced shock is marked by pulmonary embolism, bronchospasm and renal failure. Bacterial liposaccharides (endotoxins) play an important role in the pathogenicity of Gram-negative infections.

The reactivity of animals to endotoxin may be enhanced by simultaneous administration of galactosamine. Galactosamine is a specific hepatotoxic agent that leads to early metabolic alterations and consequent cellular liver damage. The following procedure is used to detect compounds that prevent the occurrence of endotoxin-induced shocks.

Cardiovascular parameters of endotoxin induced shock are greatly influenced by various anesthetics. For this reason, a model was proposed by Brackett et al. (1985) and Schaefer et al. (1987) to study the circulatory shock pattern after endotoxemia in conscious unrestrained rats.

PROCEDURE

Male Sprague-Dawley rats weighing 300 ±10 g are anesthetized with 5% enflurane. A tracheal cannula is connected to a rodent respirator delivering 2% enflurane. Via the right jugular vein the tip of one catheter is placed just adjacent to the right atrium for injection of endotoxin, monitoring of central venous pressure, and rapid injection of room-temperature saline to produce thermodilution curves for calculation of cardiac output. The right carotid artery is cannulated with a thermistor-catheter combination for measurement of thermodilution cardiac output curves and aortic blood pressure. The thermistor tip is placed in the aortic arch just distal to the aortic valve. The catheters are guided under the skin exiting through the back of the neck just below the base of the skull.

The animals are allowed to regain consciousness and are then placed in cages that allow unrestrained movements about the cage at all times throughout the study with no further handling. The experimental animals receive a 20-sec infusion of 40 mg/kg endotoxin (*E. coli*, Difco) being paired with sham animals with identical catheters but receiving an equal volume of saline. Test compounds are injected intravenously 10 min prior to endotoxin injection. Cardiac outputs are measured using the thermodilution technique by rapidly injecting a volume calculated to deliver 100 µl of room temperature saline to the circulatory system. Central venous and aortic blood pressure and heart rate are continuously monitored for the following 4 h. Cardiac output measurements are made 5, 15, 30, 60, 120, 180, and 240 min after endotoxin. At the end of the study, the animals are sacrificed and the catheters checked visually to ensure proper placement.

EVALUATION

Central venous pressure, arterial pressure, and cardiac output of drug treated animals receiving endotoxin are compared with animals receiving endotoxin only and saline sham treated animals. Furthermore, cardiac index, total peripheral resistance, and stroke volume are calculated. The small intestines of all rats are examined for severity of hemorrhage using a five point scale. Repeated-measures analysis of variance is used to analyze the data.

MODIFICATIONS OF THE METHOD

Lindenbaum et al. (1990) studied the effect of *E. coli* endotoxin on cardiovascular parameters of anesthetized dogs. Inhibition of the detoriation of metabolic functions and improvement of cardiovascular parameters were found after cocarboxylase treatment.

Endotoxin induced shock has been tested in **mice** (Galanos et al. 1979). Groups of 10 male C57 BL/6 mice weighing 20–22 g are injected intravenously with a mixture of 0.01 µg of Salmonella abortus equi lipopolysaccharide and 7.5–15 mg galactosamine in 0.02 ml phosphate buffered saline. The test compound is administered either intravenously at the same time or orally 45 min prior challenge. Twenty-four hours later, the number of surviving mice is determined.

Metz and Sheagren (1990) reviewed the effects of ibuprofen in animal models of septic shock.

Baldwin et al. (1991) tested the effect of Polymyxin B on experimental shock from meningococcal lipooligosaccharide and *Escherichia coli* lipopolysaccharide endotoxins in anesthetized **rabbits**.

Muacevic and Heuer (1992) tested the effect of platelet-activating factor antagonists in anesthetized rats.

Otterbein et al. (1993) tested the effects of peptides on survival of mice injected with 50 mg/kg lipopolysaccharide endotoxin in mice and on survival of rats with fecal peritonitis.

Mountz et al. (1995) reported an increased susceptibility of fas mutant **MRL-Ipr/Ipr mice** to staphylococcal enterotoxin B-induced septic shock.

A.1.3.21 Hemorrhagic shock

PURPOSE AND RATIONALE

Hemorrhagic shock is one of the most severe consequences of accidents. Several animal models in various species have been developed to resemble the conditions in man and to test therapeutic or prophylactic measures (Lamson and de Turk 1945; Selkurt and Rothe 1961; Mills 1976). A method for hemorrhagic shock in anesthetized as well as in unanesthetized rats has been described by van der Meer et al. (1987). Experimental hemorrhagic shock is defined as a situation in which the cardiovascular system, after a period of hypovolemia followed by complete re-infusion of the shed blood, gradually detoriates ending in the death of the animal.

PROCEDURE

Female rats weighing 170–190 g are anesthetized by i.p. injection of sodium pentobarbital, 25 m/kg, followed after 20 min by 20 mg/kg, and kept in a chamber at 30 °C and relative humidity over 80%. The left femoral vein is cannulated for application of the test drug. The right common iliac artery is cannulated and the cannula (polyvinyl chloride, 14 cm long, inner diameter 2 mm) is filled with heparin and exteriorized in the neck. After intraarterial injection of 0.2 ml heparin 500 IU/ml, the cannula is connected to a siliconized calibrated glass reservoir (inner diameter 18 mm), the height of which can be changed to adjust the surface of the shed blood to a fixed level.

The test drug is injected i.v. 5 min prior to bleeding. Bleeding is performed against (at heart level) 30 mm Hg for 1 h, 25 mm Hg for 0.5 h, 30 mm Hg for 1 h, 25 mm Hg for 0.5 h, and finally 30 mm Hg for 1 h. The shed blood is partially taken up again spontaneously. After 4 h, re-infusion is started by increasing the pressure to 60 mm Hg for 5 min, to 80 mm Hg for 5 min, and (if necessary) to 100 mm Hg. During the hypovolemic phase respiration becomes gradually slower. If respiration arrest is imminent 0.5 ml 5% glucose are injected intra-arterially, thus avoiding death during the period of hypovolemia. Practically all rats die at an average of 4 h after complete re-infusion.

EVALUATION

Survival time is taken as the time between complete reinfusion and death. Average survival time of treated animals is compared with that of controls. Furthermore, after autopsy the number of gastrointestinal lesions, subendocardial hemorrhage, kidney tubular necrosis and liver cell necrosis are registered by histological examination.

CRITICAL ASSESSMENT OF THE METHOD

In spite of the fact that hemorrhagic shock does not reflect the situation of traumatic shock in man in every aspect, the condition is close enough to use the model for testing compounds which potentially inhibit or ameliorate shock in man.

MODIFICATIONS OF THE METHOD

A method to study hemorrhagic shock in dogs has been described in detail by Mills (1967). Large dogs weighing 20–30 kg are anesthetized by an i.v. injection of 25 mg/kg sodium pentobarbital. The animals are respirated by means of a Harvard respirator set at a stroke volume of 400 ml and a rate of 20 respiration/min. Blood pH is regulated between 7.37 and 7.42 by varying the gas flow between 100% O_2 and a mixture of 95% O_2 and 5% CO_2. Central arterial blood pressure is recorded by inserting a catheter through one femoral artery to the aortic arch. Pulmonary artery pressure is measured by inserting a PE 50 catheter through a small neck vein, reaching the right ventricle and allowing to float into the pulmonary artery. The right atrial catheter is also inserted through a small neck vein. After the chest is opened, the left atrial catheter is tied in place through a small opening in the left atrial appendage. Blood flow is measured in the ascending aorta (cardiac output), carotid, superior mesenteric, renal and femoral arteries using electromagnetic flowmeters. Furthermore, pulse rate is monitored from the electrocardiogram.

The test drug is injected i.v. 10 min prior bleeding. Blood is removed either at a specific volume or until a selected reduction of blood pressure has occurred. The cardiovascular parameters of treated animals are compared with those of controls.

Shock associated with hemoconcentration was produced in dogs by Davis (1941) by bleeding from the carotid artery and injections of 25% sodium chloride solution subcutaneously in doses of 25 ml.

The effect of insulin on glucose uptake in the soleus muscle of rats during hemorrhagic shock was studied by Chaudry et al. (1975).

Bauer et al. (1995) used hemorrhagic shock in rats to evaluate the influence of interleukin-1 on leukocyte-endothelial cell interactions and the microcirculation in the liver by means of intravital microscopy after application of an interleukin-1 receptor antagonist.

Kitajima et al. (1995) studied gastric mucosal injury induced by hemorrhagic shock in rats.

A.1.3.22 Tourniquet shock

PURPOSE AND RATIONALE

Compression of extremities in man by heavy objects for periods of several hours results in the so-called crush syndrome. The rescued individual shows immediately a favorable response to therapy, but within a few hours symptoms of shock develop followed by signs of progressive renal damage leading to death (Duncan and Blalock 1942). Moreover, arterial bleeding after accidents needs the applications of tourniquets. During surgical procedures on extremities a tourniquet may be necessary (Wilgis 1971), the time of which has to be limited in order to avoid fatal consequences. The pathophysiological mechanisms of tourniquet induced shock remain still to be elucidated. Nevertheless, animal models in rats (Chandra and Dave 1970), rabbits (Little 1974), and dogs (Goto et al. 1988) had to be developed to evaluate drugs capable to inhibit the fatal consequences of crush and tourniquet shock.

PROCEDURE

Wistar rats of either sex weighing 250–280 g are anesthetized with phenobarbital. The tourniquets consist of

rubber tubes (internal diameter 4 mm, external diameter 5.8 mm). Both tights are fastened by the rubber tubes and the pressure which is monitored by a miniature pressure sensor and an amplifier (e.g. Kyowa Electronic Instruments Co, Tokyo) is adjusted to 1.5 kg/cm^2. The rubber tubes are knotted and the sensor removed. After 3 h the animals are treated with the test compound or the control solution. The tourniquet is left in place for 6 h while the animals remain under pentobarbital anesthesia. Then, the rubber tubes are removed, and the rats are returned to their cages. Within a few min, the reperfused hind limbs, which have been pale blue, turn pink. The animals are then allowed free access to food and water. Blood is withdrawn at different intervals during the tourniquet and afterwards for measurement of hematocrit, transaminases, urea nitrogen and total protein. Time to death is registered.

EVALUATION

Statistical evaluation of the survival intervals is performed with the log rank test according to Peto et al. (1976). Blood chemical data are analyzed using the Kruskal-Wallis (1952) rank sum test. Multiple comparisons are corrected by the Bonferroni's method (1980).

CRITICAL EVALUATION OF THE METHOD

These methods are valuable to find drugs effective in this life-threatening situation.

MODIFICATIONS OF THE METHOD

Ghussen et al. (1979) studied the effect of methylprednisolone on the experimental tourniquet shock in **dogs**.

Haugan and Kirkebo (1984) used a model in anesthetized **rats** with tourniquet shock by bilateral hindlimb occlusion for 3 1/2 h, and burn shock by scalding the hind 50% of the body surface for 30 s in 90 °C water.

Horl and Horl (1985) investigated the effect of tourniquet ischemia on carbohydrate metabolism in **dog** skeletal muscle

Sáez et al. (1982) followed the time course of appearance of lactic dehydrogenase enzymes in the serum of **rats** after different periods of ischemia by bilateral application of rubber band tourniquets to the hind legs.

Sáez et al. (1986) studied the effects of allopurinol on biochemical changes of the gastrocnemius muscle in rats subjected to tourniquet shock followed by reperfusion.

A.1.3.23 Heat stroke

PURPOSE AND RATIONALE

Heat stroke is a medical emergency where quick diagnosis and treatment of victims are essential for positive prognosis. Several animal models have been established by investigators in heat related studies. Rats (Francesconi and Mager 1978; Hubbard et al. 1977, 1979; Kielblock et al. 1982), rabbits (Shih et al. 1984), dogs (Bynum et al. 1977) and sheep (Tayeb and Mar-

zouki 1990) are considered to be the most suitable models because of their similarity to man in response to high temperature.

PROCEDURE

Male Sprague Dawley rats weighing 450 to 550 g are fasted 18–24 h before the experiment. For prevention studies the animals are treated subcutaneously 1 h before either being restrained in an appropriate wire cage which is placed into an environmental chamber set at 41.5 °C ambient temperature or being exercised in a motor-driven treadmill. Core temperature (rectal probe inserted 6.5 cm) are measured using copper/constantan thermocouples in conjunction with a thermocouple reference oven and a 10-channel data acquisition system with a teletype printout. After reaching exhaustion or a predetermined core temperature, all rats are monitored at 26 °C ambient temperature while resting in plastic cages lined with wood shavings. After recovery, animals are returned to their cages and allowed water but no food for 24 h.

EVALUATION

LD_{50} values are determined in treated and control animals.

MODIFICATIONS OF THE METHOD

Kielblock et al. (1982) analyzed cardiovascular function by direct recording of arterial blood pressure and ECG-analysis.

Francesconi and Mager (1978) studied pathochemical indices, such as serum lactate concentration, potassium levels and plasma creatine phosphokinase.

Kregel et al. (1988) investigated peripheral vascular responses to hyperthermia in the rat by implantation of Doppler flow probes on the superior mesenteric, left iliac or left renal, and external caudal arteries. They concluded that a selective loss of compensatory vasoconstriction triggers the cascade of events that characterize heat stroke.

Shido and Nagasaka (1990) studied thermoregulatory responses to acute body heating in rats acclimated to continuous heat exposure. Indirect external warming was performed by raising the jacket water temperature surrounding the calorimeter from 24 to 39 °C. Intraperitoneal heating was made through an electric heater implanted chronically in the peritoneal cavity.

Chiu et al. (1995) reported an increased survival in rat heatstroke by reducing hypothalamic serotonin release after administration of interleukin-1 receptor antagonist.

A.1.3.24 α- and β-adrenoreceptors in the mouse iris

PURPOSE AND RATIONALE

A simple method to test mydriatic substances is the test on the mouse pupil as described by Pulewka (1932). The diameter of the pupil is narrowed by intensive light illumination. A dose-dependent increase of pupil diameter can be achieved by intraperitoneal application of atropine and synthetic mydriatics (Ing et al. 1950; Burn et al. 1950). The mydriatic effect of hexamethonium analogues has been measured by Blackman et al. (1956). Mydriasis is induced by norepinephrine, epinephrine and isoproterenol and can be antagonized by α- or β-blockers (Freundt 1965).

PROCEDURE

Male mice weighing 15–20 g are used. They are kept for at least 30 min in separate beakers under bright illumination before the pupil diameters are measured with a dissecting microscope containing an arbitrary scale in the eyepiece. To make the illumination as uniform as possible, the beakers containing the mice are placed beneath long low-power fluorescent tubes and on top of glossy white paper. The pupil diameter is measured in mm before and at various time intervals

after treatment. Groups of 5–10 mice are used for each dose of compound and for vehicle control.

To test sympatholytic activity, various doses of the α- or β-blocker are injected subcutaneously 30 min prior to intravenous injection of 0.1 mg/kg norepinephrine, or 0.05 mg/kg epinephrine, or 20 mg/kg isoproterenol. The effect of norepinephrine is blocked by α-blockers, but not by β-blockers, the effect of epinephrine by both α- and β-blockers, and the effect of isoproterenol by β-blockers, but not by α-blockers.

EVALUATION

The mean values of diameters in the groups treated with α- or β-blockers are compared with those of animals treated with norepinephrine, epinephrine or isoproterenol only.

MODIFICATIONS OF THE METHOD

Edge (1953) used mydriasis in the mouse as a quantitative method of estimating parasympathetic ganglion block.

Håkanson et al. (1987) used the isolated iris sphincter of pigmented rabbits to test multiple tachykinin pools in sensory nerve fibres. The eyes were taken out within 1 min after sacrifice and opened by an incision 2–3 mm posterior to the limbus, followed by excision of the iris from the ciliary margin. The iris sphincter muscle was then opened, cut in half and mounted vertically on a Perspex holder in a 7 ml tissue bath maintained at 35ºC. The mechanical activity after electrical stimulation was recorded isometrically using a force displacement transducer and a polygraph.

Kern (1970) used isolated sphincter and dilator muscles from human eyes obtained at autopsy for studies on sympathomimetics and adrenergic blocking agents. Cholinotropic and α- and β-adrenergic receptors were identified.

Responses to bradykinin and or capsaicin of the isolated iris sphincter were considered to be mediated by substance P released from the trigeminal nerve (Ueda et al. 1984).

Pupillary dilatation can be used as an index for central nervous system α_2-adrenoreceptor activation (Koss 1986).

Clonidine induces mydriasis which is mediated by α_2-adrenoreceptors located in the brain (Berridge et al. 1983; Hey et al. 1985). Blockade of presynaptically located α_2-adrenoreceptors is considered as a possible mechanism for antidepressant drugs. Mianserin was able to antagonize clonidine-induced mydriasis in the rat.

Gower at al (1988) studied a large number of psychotropic drugs in this model with the aim to reveal *in vivo* α_2-adrenoreceptor blocking effects of new compounds.

Male Wistar rats weighing 230–300 g were anesthetized with pentobarbital, 60 mg/kg i.p., and a polyethylene catheter was inserted into the femoral vein for drug administration. The rat's head rested on the base platform of a binocular Olympus microscope positioned so that the pupil diameter of the right eye could be measured by means of a micrometer inserted into one eyepiece of the microscope. A constant light intensity was maintained throughout the experiment. Rats were first injected with saline 25 min after anesthesia induction. The pupil diameter was measured 1 min after injection. Five min after measurement, mydriasis was induced by clonidine (0.1 mg/kg, i.v.) and the diameter was measured 1 min after injection. This was followed by the test compound, injected at 6 min intervals at increasing doses. The pupil was measured at 1 min after each injection. The dose inhibiting 50% of the clonidine-induced mydriasis (ID_{50}) was determined per rat from the cumulative dose-response curve.

Savontaus et al. (1997) studied the effect of an imidazoline derivative against detomidine-induced mydriasis in anesthetized rats.

A.1.3.25
α_2-adrenoreceptor blockade measured *in vivo* by clonidine-induced sleep in chicks

PURPOSE AND RATIONALE
In young chicks, clonidine causes a loss of righting reflex which is antagonized by mianserin (Pommier et al. 1982). This phenomenon was used to measure α_2-adrenoceptor blockade *in vivo* by Gower et al. (1988).

PROCEDURE
Male white Leghorn chicks are used either a few hours after hatching or 1 or 2 days later. Clonidine-induced loss of righting reflex (sleep) is determined with 8 animals at a time. Two animals are treated with placebo and 2 with each of 3 dose levels of the test compound. Tests with groups of 8 animals are continued until 10 animals are tested per dose level or placebo treatment. The chicks are marked with ink and injected intraperitoneally with placebo or the test compound. Ten min later, 1.2 mg/kg clonidine is injected into a leg muscle and the animals are placed individually in small Macrolon cages. The beginning of sleep time is defined as the moment at which the animals can be placed on their back and remain in this position. Sleep time is recorded until they return to their feet spontaneously or another attempt to put them on their back fails. Sleep time is recorded for a maximum period of 30 min.

EVALUATION
Statistical evaluations of differences in median sleeping times are done with the Mann-Whitney *U*-test. Dose-response relations for various drugs can be calculated.

CRITICAL ASSESSMENT OF THE METHOD
Compounds with known α_2-adrenoceptor blocking activity antagonize clonidine-induced sleep in chicks dose-dependently. Yohimbine is one of the most active compounds. However, also other centrally active compounds of which their main effect is not α_2-blockade, reduce clonidine-induced sleeping time. One of the most potent is apomorphine acting on dopamine D_2-receptors. Therefore, the clonidine-induced sleeping test in chicks can not be regarded as highly specific for α_2-adrenoceptors.

A.1.3.26
Activity at β_1- and β_2-adrenoreceptors in the rat

PURPOSE AND RATIONALE
The relative potency of catecholamines as stimulants of β-adrenoreceptor mediated responses vary in different tissues indicating the existence of two subtypes of β-receptors (β_1 and β_2) (Lands et al. 1967). β-adrenoreceptors in the heart have been classified as being of the β_1-subtype. β-adrenoreceptors in the uterus, diaphragm, bronchioles and small intestine have been classified as being of the β_2-subtype, since in these tissues, epinephrine is more potent than norepinephrine. These observations led to the development of selective agonists and antagonists. Isolated organs (see below) having predominantly one receptor subtype, such as the isolated heart and the isolated atrium for β_1, and the isolated uterus or the isolated tracheal chain for β_2, are used to test compounds for selective activity. Assessing both activities in the same animal *in vivo* results in the advantage that pharmacokinetic and metabolic influences of the drug being tested are the same for both parameters.

PROCEDURE
Female Sprague-Dawley rats (200–220 g) are anesthetized with 60 mg/kg pentobarbital i.p. prior to pithing (Gillespie and Muir 1967). The animals are artificially respired with room air using a Harvard small animal ventilator (90 strokes/min at a pressure of 7 cm H_2O). Body temperature is maintained by placing the animals on a heated operating table. The left carotid artery is cannulated for continuous monitoring of blood pressure via a Statham p23Id pressure transducer. The

blood pressure signal is used to trigger an instantaneous rate meter for continuous monitoring of heart rate. A femoral vein is cannulated for intravenous administration of drugs.

A midline incision is made to expose one horn of the uterus. The ovarian artery is cut, tied and one horn dissected free from the ovary leaving the myometrial blood supply intact. A cotton thread is attached to the free end of the uterine horn, passed through a glass-jacketed organ bath and connected to an isometric (Pioden UF1) transducer for measurement of spontaneous contractions. A cannula is inserted into the peritoneal cavity for administration of drugs by the i.p. route. The organ bath is positioned such that it surrounds the uterine horn without touching it. The tissue is perifused with Krebs-Henseleit solution being gassed with 95% O_2/5% CO_2 and maintained at 37 °C. A resting tension of 0.2 g is applied to the tissue, which is allowed to stabilize until spontaneous contractions are constant over a period of 5–10 min. All recordings are made on a polygraph.

EVALUATION OF AGONISTS

Dose-response curves after i.v. injection are established for isoprenaline (nonselective between β_1- and β_2-adrenoreceptors), salbutamol (selective for β_2-adrenoreceptors), and noradrenaline (selective for β_1-adrenoreceptors) in increasing heart rate (beats/min) and decreasing the height of uterine contraction (calculated as percentage of the original amplitude). Animals given noradrenaline are pretreated with phenoxybenzamine (3.3 mmol/kg i.v.) in order to antagonize irreversibly the α-adrenoreceptors. Agonist dose-response curves ($n > 4$) on heart rate and uterine relaxation are carried out by assessing the activity of at least 3 doses of each agonist. New synthetic compounds can be tested after intraperitoneal administration additionally.

EVALUATION OF ANTAGONISTS

The ability of a non-selective β-blocker, such as propranolol (1 mmol/kg i.v.), a β_1-selective β-blockerββ, such as atenolol, and a β_2-selective β-blockerββ to inhibit responses to isoprenaline on both heart rate and uterine relaxation is assessed by comparing the log linear portion of the dose-response curve to isoprenaline in the absence and in the presence of the β-adrenoreceptor antagonist in the same animal. Dose ratios for each antagonist are calculated.

CRITICAL ASSESSMENT OF THE METHOD

The method described by Piercy (1988) has the advantage to measure both agonistic and antagonistic activity and to differentiate between effects on β_1- and β_2-adrenoreceptors. Compared to tests in isolated organs, *in vivo* activity can be determined after intraperitoneal or intraduodenal administration.

MODIFICATIONS OF THE METHOD

Härtfelder et al. (1958) studied the influence of various agents on the contractions of electrically stimulated **isolated uteri of rabbits and guinea pigs**.

Nathason (1985) evaluated the activity of beta-blockers to inhibit the cardio-acceleratory effect of systemically administered isoproterenol in **unanesthetized, restrained albino rabbits** together with the effect on membrane bound adenylate cyclase in homogenized ciliary process villi in order to find compounds selectively lowering intraocular pressure.

A.1.3.27
β_1- and β_2-sympatholytic activity in dogs

PURPOSE AND RATIONALE

Intravenous administration of isoprenaline (isoproterenol) stimulates β_1-receptors of the heart which can be detected as an increase in contractility (*dp*/*dt* max). Intraarterial injection of isoprenaline stimulates β_2-receptors of peripheral blood vessels leading to an increased peripheral blood flow. Therefore, a β_1- or β_2-blocking activity of a compound is revealed by the inhibition of the effects of isoprenaline. The following tests are used to evaluate β-blocking activity of drugs. A β-blocker screening is done in anesthetized dogs (a); in addition, the test allows a differentiation between

β_1- and β_2-receptor activity and the determination of ED_{50} values (b).

PROCEDURE

Male or female Beagle dogs weighing about 20 kg are used. Animals are premedicated with 1 g Inactin® (i.v.) and anesthetized by intravenous administration of 20 mg/kg chloralose and 250 mg/kg urethane. In addition, they receive a subcutaneous injection of 2 mg/kg morphine 1 h after the start of anesthesia. Animals are heparinized. Respiration is maintained through a tracheal tube using a positive pressure respirator. End-expiratory CO_2 content is measured continuously; respiratory rate and depth of respiration are adjusted to 4.5–6 vol% end-expiratory CO_2. For administration of isoprenaline, a peripheral vein is cannulated.

Preparation for hemodynamic measurements

For recording of peripheral systolic and diastolic blood pressure, a cannula inserted into a femoral artery is connected to a pressure transducer (Statham p 23 DB). For determination of LVP, a Millar microtip catheter (PC 350) is inserted via the left arteria carotis communis. LVEDP is measured from a high-sensitivity scale. From the pressure curve, *dp*/*dt* max is differentiated and heart rate is counted. Peripheral blood flow in the femoral artery is measured with an electromagnetic flow probe.

Screening for β-blocking effects in anesthetized dogs

Following a steady-state period of 30–60 min, isoprenaline is administered intravenously 2–3 times to the anesthetized animal and hemodynamic parameters are recorded (control values = 100%). Then, the test substance is injected intravenously at cumulative doses (final concentrations of 0.01, 0.05 and 0.15 mg/kg). For each dose, 10 min "drug effects" are monitored by measuring hemodynamic parameters. Then the effect of isoprenaline is tested again (3 times).

In other experiments, a single dose of the drug is administered to determine the duration of action.

If a test compound does not show an inhibitory influence on isoprenaline effects, a second test compound is administered.

All hemodynamic parameters are registered continuously during the whole experiment.

Testing for β_1- and β_2-blocking effects; determination of ED_{50}

Following a steady-state period of 30–60 min, isoprenaline is administered for i.v. administration (β_1-test) twice at a dose of 0.5 µg/kg and for intraarterial administration (β_2-test) twice at a dose of 0.05 µg/kg. Hemodynamic parameters are recorded (control values = 100%). Then, the test substance is injected intravenously at cumulative doses. Consecutively increasing doses are given at 15 min-intervals. For each dose, 10 min "drug effects" are monitored by measuring hemodynamic parameters. Thereafter isoprenaline is given intravenously and 5 min later intra-arterially.

All hemodynamic parameters are registered continuously during the whole experiment.

Characteristics:
- blood pressure
  - systolic, BPs
  - diastolic, BPd
- heart rate
- left ventricular pressure, LVP
- left ventricular enddiastolic pressure, LVEDP
- *dp*/*dt* max
- peripheral flow, A. femoralis
- ECG, lead II

Standard compounds:
- propranolol HCl
- practolol
- metoprolol tartrate

EVALUATION

β_1-receptor antagonism is measured as a decrease in contractility (*dp*/*dt* max).

Inhibition of the isoprenaline-induced elevation of heart rate is considered as an indicator for non-selective β-blockade. For cardioselective β-receptor blockers the increase in *dp*/*dt* max is inhibited with lower doses of test drug than the rise in heart rate.

β_2-receptor blockade by a test drug is measured as inhibition of the isoprenaline-induced increase in peripheral blood flow.

The different hemodynamic parameters are determined.

Percent inhibition of the isoprenaline-induced effects by a test compound is calculated and compared to the isoprenaline effects before drug administration (= 100%).

ED_{50} values for β_1- and β_2-antagonism are calculated by log-probit analyses. ED_{50} is defined as the dose of drug leading to a 50% inhibition of the isoprenaline effects.

An ED_{50} β_1/ED_{50} β_2-ratio of >1 indicates that a β-blocking agent predominantly influences β_1-receptors (cardioselectivity).

A.1.3.28 Intrinsic β-sympathomimetic activity in reserpine-pretreated dogs

PURPOSE AND RATIONALE

β-blocking agents can be classified as

- β-blocking agents with intrinsic sympathomimetic activity (ISA),
- β-blocking agents with membrane stabilizing activity (MSA),
- β-blocking agents with organ selectivity (high affinity to heart β_1-receptors).

In the following procedure with reserpine-pretreated dogs, β-blocking agents with intrinsic sympathomimetic activity can be identified. Reserpine administration 24 h before the start of the experiment leads to a depletion of catecholamine depots. Thus, it is possible to differentiate between indirectly acting sympathomimetics such as tyramine and directly acting ones such as noradrenaline.

This test is used to identify β-blocking drugs with intrinsic sympathomimetic activity.

PROCEDURE

Male or female Beagle dogs weighing about 15 kg are used. Twenty-four h before the test, dogs receive an intramuscular injection of 0.3 mg/kg reserpine. At the day of the experiment, the animals are anesthetized by intravenous administration of 10–20 mg/kg pentobarbital sodium. Respiration through a tracheal tube using a positive pressure respirator is controlled by measuring end-expiratory CO_2 concentrations (4–5 vol%).

Preparation for hemodynamic measurements

For recording of peripheral systolic and diastolic blood pressure, a femoral artery is cannulated and connected to a pressure transducer (Statham p 23 DB). For determination of LVP, a Millar microtip catheter (PC 350) is inserted into the left ventricle via the left common carotid artery. LVEDP is measured from a high-sensitivity scale. From the pressure curve, *dp/dt* max is differentiated and heart rate is counted.

Experimental course

The test substance is administered by continuous intravenous infusion of 0.02 mg/kg (1 ml/min) until a cumulative dose of 3 mg/kg is achieved (within approximately 150 min). Thereafter, the velocity of infusion is doubled (0.04 mg/kg, 2 ml/min). The test is finished when a cumulative dose of 7 mg/kg is achieved (after a total time of approximately 250 min).

Hemodynamic parameters are registered continuously during the entire experiment.

Characteristics:

- blood pressure
  - systolic blood pressure
  - diastolic blood pressure
- left ventricular pressure, LVP
- left ventricular enddiastolic pressure, LVED
- *dp/dt* max
- heart rate, HR

EVALUATION

The different hemodynamic parameters are determined. As a measure for intrinsic sympathomimetic activity (ISA), the increase in *dp/dt* max and in heart rate are evaluated. Absolute and relative differences of these parameters in drug-treated animals are compared to vehicle control values.

Statistical evaluations are performed by means of the Student's *t*-test if $n > 4$.

Scores are allotted relative to the efficacy of standard compounds for intensity as well as for duration of the effect.

A.1.3.29 Cat nictitating membrane preparation (ganglion blocking activity)

PURPOSE AND RATIONALE

Nicotinic acetylcholine receptors are involved in the ganglionic neurotransmission. Various subtypes are described for nicotinic acetylcholine receptors (Sargent 1993; McGehee and Role 1995; Karlin and Akabas 1995; Alexander et al. 2001).

The nictitating membrane of the cat has been used extensively in pharmacological studies to evaluate ganglion blocking activity because of the ease with which its movements can be recorded, because of the simplicity of its innervation (the purely adrenergic fibres have their cell bodies in the easily accessible superior cervical ganglion of the same site) and because its blood supply (via the external carotid artery) is accessible for intraarterial injections. Preganglionic and

postganglionic stimulation allow the interpretation of the mode of action of vasoactive drugs.

PROCEDURE

The animal is anesthetized with 35 mg/kg pentobarbital sodium i.p. Tracheostomy is performed and a tracheal cannula is inserted. On one side, the sympathetic nerve is exposed, separated from the vagus nerve and prepared in order to place electrodes for preganglionic and postganglionic stimulation. Preferably, the vagus nerve at this site is severed at the central end. The head of the animal is fixed in a head holder to prevent head movements. A linear transducer is fixed at the mid of the border of the nictitating membrane allowing the registration of the contractions on a polygraph. Preganglionic and postganglionic stimuli are exerted by a square wave stimulator, with a pulse width of 0.3 to 0.5 ms, an amplitude of 1–3 V, and a frequency of 20/min. The amplitude and pulse width varies from animal to animal. The sympathetic nerve is stimulated before and after the administration of the compound and the changes in the contraction of the nictitating membrane are noted. Furthermore, the response of the nictitating membrane to exogenous adrenaline is registered.

EVALUATION

The decrease of the response after drug application is expressed as percentage of the control before drug. Ganglionic blockers decrease the response to preganglionic stimulation but have no influence on postganglionic stimulation or exogenous adrenaline. Neuronal blockers decrease the response to both preganglionic and postganglionic stimulation but do not affect the response to exogenous adrenaline which may even be enhanced. α-receptor blockers decrease the response to both preganglionic and postganglionic stimulation as well as decrease the effect of exogenous adrenaline. Catecholamine uptake inhibitors increase the response to both preganglionic and postganglionic stimulation as well as enhance the response to exogenous adrenaline.

CRITICAL ASSESSMENT OF THE METHOD

The nictitating membrane preparation has been widely used for differentiation of cardiovascular effects. Since the use of higher animals such as cats has been limited to a great extent, this model is now being used only exceptionally.

As alternative, the contraction of the inferior eyelid of anesthetized *rats* after preganglionic electrical stimulation of the superior cervical ganglion has been recommended (Gertner 1956; Steinbrecher and Schmid-Wand 1986). In the modification used by Steinbrecher and Schmid-Wand (1986) the method is suitable for testing compounds with potential adrenergic and antiadrenergic activity but not for testing ganglion blocking activities.

Male Sprague Dawley rats are anesthetized with 100 mg/kg thiobutabarbital i.p. and kept on a heated operation table at a rectal temperature of 37 °C. One femoral vein is cannulated and filled with 4% heparin solution. One femoral artery is cannulated for registration of blood pressure. Tracheotomy is performed and a polyethylene catheter of 5 cm length inserted. The head of the animal is fixed carefully. The vibrissae at the lower eyelid on the right side are cut, a thread attached at the margin of this eyelid and attached to a strain-gauge. To immobilize the musculature of the face, the mouth of the animal is sutured and the head support attached. The right sympathetic nerve is exposed, separated from the vagus nerve and prepared in order to place electrodes for preganglionic stimulation. For calibration, stimulation is performed twice with an interval until contraction is back to baseline. Furthermore, a dose of 0.001 mg/kg adrenaline is given as bolus injection. Eyelid contraction and blood pressure increase are recorded. Then the putative adrenergic blocker or the standard 1.0 mg/mg phentolamine are injected intravenously. Eyelid contraction after electrical stimulation or after adrenaline is reduced dose-dependently.

CRITICAL ASSESSMENT OF THE METHOD

The vibrissae at the lower eyelid on the right side are cut, a thread attached at the margin of this eyelid and attached to a strain-gauge. To immobilize the musculature of the face, the mouth of the animal is sutured and the head support attached. The right sympathetic nerve is exposed, separated from the vagus nerve and prepared in order

to place electrodes for preganglionic stimulation. For calibration, stimulation is performed twice with an interval until contraction is back to baseline. Furthermore, a dose of 0.001 mg/kg adrenaline is given as bolus injection. Eyelid contraction and blood pressure increase are recorded. Then the putative adrenergic blocker or the standard 1.0 mg/mg phentolamine are injected intravenously. Eyelid contraction after electrical stimulation or after adrenaline is reduced dose-dependently.

MODIFICATIONS OF THE METHOD

Quilliam and Shand (1964) assessed the selectivity of drugs by comparing the effects on ganglionic transmission and on the pre- and post-ganglionic nerves in the isolated superior cervical ganglion preparation of the rat.

Langer and Trendelenburg (1969) performed experiments with normal nictitating membranes of pithed cats as well as with isolated normal nictitating membranes.

Koss and Hey (1992) used frequency-dependent nictitating membrane responses by sympathetic nerve stimulation in anesthetized cats to determine the potential role of prejunctional histamine H_3 receptors.

Gurtu et al. (1992) used contractions of the cat nictitating membrane to explore the effects of calcium channel blockers on neurotransmission *in vivo*, by comparing the effects of verapamil and nifedipine on contractions of nictitating membrane following either electrical stimulation of the superior cervical ganglion or intravenous injection of phenylephrine.

Koss (1992) compared the peripheral and central nervous system sympatholytic actions of prazosin using the cat nictitating membrane. Submaximal contractions of the nictitating membranes were evoked by electrical stimulation of the preganglionic cervical sympathetic nerve trunk and by stimulation of the posterior hypothalamus in anesthetized cats.

Badio et al. (1996) evaluated spiropyrrolizidines, a new structural class of blockers of nicotinic receptor channels with selectivity for ganglionic type receptors in rat pheochromocytoma PC12 cells (with an $\alpha_3\beta_{4(5)}$-nicotinic receptor) and human medulloblastoma TE671 cells (with an $\alpha_1\beta_1\gamma\delta$-nicotinic receptor).

A.1.3.30
Assessment of ganglion-blocking activity in the isolated bovine retractor penis muscle

PURPOSE AND RATIONALE

The use of the bovine retractor penis muscle for the assessment of ganglion-blocking activity of neuromuscular blocking drugs has been recommended by Ala-

ranta et al. (1990) and Klinge et al. (1993). Klinge and Sjöstrand (1974) performed not only extensive studies on the physiology and pharmacology of the retractor penis in the bull, but also discussed the various hypotheses on inhibitory and excitatory innervation of this muscle, which is present in many vertebrates such as horses, cats, dogs and rats, but not in men and rabbits. They also found that the effects on the isolated retractor penis muscle and on penile arteries are rather similar. The excitatory innervation was found to be predominantly α-adrenergic (Klinge et al. 1970; Klinge and Sjöstrand 1977) whereas other transmitters such as histamine and bradykinin were effective only in some species. Relaxation of the isolated retractor penis muscle could be elicited by nicotine and other nicotinic agonists (Klinge et al. 1988). In the studies on ganglion-blocking activity, strips of the retractor penis muscle are precontracted by 5-hydroxytryptamine. Relaxation induced by nicotine is antagonized by ganglion-blockers.

PROCEDURE

Retractor penis muscles are obtained from bulls of different breeds weighing 250–500 kg. Samples are dissected 10–30 cm distal to the points where the paired muscle bundles pass the anal orifice. Immediately after slaughter, the samples are freed from fat and other surrounding tissue and placed into Tyrode solution at 2–4 °C. Strips, 15–25 mm in length and 2–3 mm wide, are prepared and mounted in 20-ml organ baths containing Tyrode solution at 35 °C aerated with 95% O_2 and 5% CO_2. An equilibrium time of 2 to 4 h is allowed. During the equilibrium period washed are performed at about 60-min intervals. Changes in tension are recorded by means of Grass FT 03 force displacement transducers coupled to a polygraph.

A high-enough tone for studying the nicotine-induced relaxation, usually 8–15 g, is generated by adding 5-HP in a concentration between 0.1 and 6 μM to the organ bath. Washing is performed 2 min after application of nicotine; 60–80 min later the tone is again raised and the application of nicotine is repeated. The effect of a neuromuscular blocking drug is studied only if the relaxations caused by nicotine in two consecutive controls are equal in size.

EVALUATION

The blocking activity of a certain concentration of a drug is expressed as % reduction in the relaxation of the muscle strip, according to the following equation:

$$\frac{A - B}{A} \times 100$$

Where A is the size of the control relaxation in millimeters, and B is the size of the relaxation of the blocking drug. In order to construct regression lines, the activity of four or five dose levels from the assumed linear part of the concentration-effect curve is studied. The activity of each dose level is studied in at least 5 strips obtained from different animals. IC_{50} values are calculated from the regression lines. The parallelism of the regression lines is tested by covariance analysis.

CRITICAL ASSESSMENT OF THE METHOD

Molar potency ratios of known ganglion-blocking agents obtained with this method were compared with the results of other methods, such as inhibition of contraction of cat nictitating membrane evoked by preganglionic sympathetic stimulation (Bowman and Webb 1972; see 1.3.29), inhibition of nicotine-induced contraction of the isolated guinea pig ileum (Feldberg 1951), inhibition of contraction of guinea pig vas deferens evoked by preganglionic stimulation of the hypogastric nerve *in vitro* (Birmingham and Hussain 1980), depression of postganglionic action potentials evoked by preganglionic stimulation of the superior cervical ganglion of the rat *in vitro* (Quilliam and Shand 1964), induction of mydriasis in mouse by blocking the ciliary ganglion (Edge 1953). A fair but not a complete agreement between the results obtained with various methods was found.

MODIFICATIONS OF THE METHOD

Gillespie and Sheng (1990) studied the effects of pyrogallol and hydroquinone on the response to non-adrenergic, non-cholinergic nerve stimulation in the rat anococcygeus and the bovine retractor penis muscles.

Parkkisenniemi and Klinge (1996) used samples of retractor penis muscles and penile arteries from bulls for functional characterization of endothelin receptors.

La et al. (1997) studied the inhibition of nitrergic nerve-induced relaxations in rat anococcygeus and bovine retractor penis muscles by hydroxycobalamin.

A.1.3.31 Angiotensin II antagonism

PURPOSE AND RATIONALE

Angiotensin II antagonists can be tested in rats after elimination of cardiovascular reflexes by vagotomy and ganglionic blockade. Several angiotensin II antagonists possess intrinsic agonistic activity. This can be tested by injection of various doses to the vagotomized, ganglion-blocked animal. The antagonistic activity of the angiotensin II antagonist can be evaluated by antagonism against graded doses of angiotensin II. The duration of activity can be tested during continuous infusion of angiotensin II.

PROCEDURE

Male Sprague-Dawley rats weighing about 300 g are used. They are anesthetized with 60 mg/kg pentobarbital sodium i.v. One carotid artery is cannulated and connected with a Statham transducer P 23 Db. Blood pressure is recorded on a polygraph. Both jugular veins are cannulated for application of test compounds and for infusion. Both vagal nerves are cut 3 mm dorsal of the larynx. For ganglionic blockade, 10 mg/kg pentolinium tartrate are injected intravenously. At least 5 animals are used for evaluation of one test drug.

Intrinsic agonistic activity

After the blood pressure has reached a constant value, doses of 1, 2, 4 and 16 µg/kg of the test compound are injected via the jugular vein. Blood pressure is recorded.

Antagonistic activity

In 10 min intervals doses of 0.5; 1.0; and 2.0 µg/kg angiotensin II are injected to establish dose-response curves. After 10 min, continuous infusion is started of the potential angiotensin II blocker in a dosage of 10 µg/kg/0.1 ml/min. Ten min after beginning of the infusion, again doses of 0.5; 1.0; and 2.0 µg/kg angiotensin II are injected.

Duration of activity

In this set-up, angiotensin II is administered as continuous infusion at a dosage of 1 µg/kg/0.02 ml/min. When blood pressure has reached an elevated steady state level, 0.1 mg/kg of the angiotensin II antagonist is administered.

Intensity and duration of the fall of blood pressure are recorded.

EVALUATION

Intrinsic agonistic activity

An increase of blood pressure indicates the intrinsic agonistic activity.

Antagonistic activity

Increases of blood pressure after graduated doses of angiotensin II during the infusion is expressed as percentage of the increase before infusion. The results are compared with known angiotensin II antagonists.

CRITICAL ASSESSMENT OF THE METHOD

In this test not only potency and duration of activity but also the intrinsic agonistic activity of an angiotensin II antagonist can be tested.

MODIFICATIONS OF THE METHOD

Various other pharmacological models have been used to test angiotensin II antagonists:

Blood pressure in conscious unrestrained rats with chronically implanted catheters with normal blood pressure, spontaneous hypertension and chronic renal hypertension (Vogel et al. 1976; Chiu et al. 1989; Brooks et al. 1992; Aiyar et al. 1995; Deprez et al. 1995; Gabel et al. 1995; Hilditch et al. 1995; Keiser et al. 1995; Nagura et al. 1995; Nozawa et al. 1995; Renzetti et al. 1995; Wong 1995; Junggren et al. 1996),

Blood pressure in conscious spontaneously hypertensive and in anesthetized ganglion-blocked rats (Olins et al. 1993),

Blood pressure in pithed and in conscious renovascular hypertensive rats (Criscone et al. 1993; Wienen et al. 1993; Deprez et al. 1995; Kivlighn et al. 1995a; Kushida et al. 1995),

Blood pressure in rats after intracerebroventricularly injected angiotensin II (Vogel et al. 1976; Batt et al. 1988),

Blood pressure in conscious angiotensin I-infused and renin-dependent **hypertensive dogs** (Brooks et al. 1992; Cazaubon et al. 1993; Aiyar et al. 1995; Deprez et al. 1995; Gabel et al. 1995; Keiser et al. 1995; Wong et al. 1995),

Blood pressure and heart rate in conscious sodium-depleted and sodium-repleted **cynomolgus monkeys** (Lacour et al. 1993; Cazaubon et al. 1993; Keiser et al. 1995),

Angiotensin II induced pressor responses in **marmosets** (Nagura et al. 1995),

Blood pressure and heart rate in conscious **rhesus monkeys** and anesthetized **chimpanzees** (Gabel et al. 1995; Kivlighn et al. 1995b; Kivlighn et al. 1995c),

Inhibition of angiotensin II-induced contraction in isolated **aorta** rings or strips from **rabbits** (Chui et al. 1989, 1990; Criscione et al. 1993; Cazaubon et al. 1993; Olins et al. 1993; Wienen et al. 1993; Aiyar et al. 1995; Caussade et al. 1995; Hilditch et al. 1995; Keiser et al. 1995; Kushida et al. 1995; Nagura et al. 1995; Renzetti et al. 1995; Wong et al. 1995), from **rats** (Nozawa et al. 1997), from **neonatal rats** (Keiser et al. 1993), from **guinea pigs** (Mizuno et al. 1995),

Inhibition of angiotensin II-induced contraction in isolated rat pulmonary artery (Chang et al. 1995),

Antagonism against angiotensin II in isolated strips of rabbit aorta, rabbit jugular vein, rabbit pulmonary artery, rat portal vein, rat stomach, rat urinary bladder, human urinary bladder, human colon, human ileum (Rhaleb et al. 1991),

Contractions of **guinea pig ileum** *in situ* (Khairallah and Page 1961),

Antagonism against angiotensin II in the **isolated rat uterus** (Wahhab et al. 1993),

Contractile force and prostaglandin E synthesis in electrically stimulated **rabbit isolated vas deferens** (Trachte et al. 1990),

Antagonism against angiotensin II-induced aldosterone release in **bovine adrenal glomerulosa cells**. (Criscione et al. 1993), and in rat dispersed adrenal capsular cells (Chang et al. 1995),

Antagonism against angiotensin II-induced inhibition of guanylate cyclase activity in the **rat pheochromocytoma cell line** PC12W (Brechler et al. 1993).

Brooks et al. (1995) compared the cardiovascular and renal effects of an angiotensin II receptor antagonist and captopril in **rats with chronic renal failure** induced by 5/6 nephrectomy. Under sodium pentobarbital anesthesia the right kidney was removed and approximately two thirds of the left kidney was infarcted by ligating two or three branches of the left renal artery.

Kim et al. (1997) studied the effects of an angiotensin AT_1 receptor antagonist on volume overload-induced cardiac gene expression in rats. An abdominal aorta-caval shunt was prepared in 9-weeks old male Wistar rats under sodium pentobarbital anesthesia. The vena cava and the abdominal aorta were exposed by opening the abdominal cavity via a midline incision. The aorta was punctured at the union of the segment two thirds caudal to the renal artery and one third cephalic to the aortic bifurcation with a 18-gauge disposable needle. The needle was advanced into the aorta, perforating its adjacent wall and penetrating the vena cava. After the aorta was clamped, the needle was withdrawn, and a drop of cyanoacrylate glue was used to seal the aortic puncture point. The patency of the shunt was verified visually by swelling of the vena cava and mixing of arterial and venous blood. The rats were treated either with vehicle or the angiotensin antagonist. Four days after the preparation of the AC shunt, 24 h-urine volume, electrolytes and aldosterone were measured. Six days after the AC shunt blood was collected by puncture of a tail vein and plasma renin activity and aldosterone were measured. Seven days after AC shunt, hemodynamic studies were performed in pentobarbital anesthesia. Afterwards, the heart was rapidly excised, left and right atria and ventricles were separated and frozen in liquid nitrogen for the extraction and measurement of cardiac tissue RNA.

Shibasaki et al. (1997) tested the effect on the renin-angiotensin-aldosterone system in **conscious rats** after cannulation of the abdominal aorta under anesthesia 3–4 days before the experiment. After oral dosing of the angiotensin II receptor antagonist blood samples were withdrawn and plasma renin and aldosterone determined by radioimmunoassay.

Similar to the effects of ACE inhibitors, lifespan of hypertensive rats could be doubled by long-term treatment with an angiotensin II type 1 receptor blocker (Linz et al. 2000).

Ledingham and Laverty (1996) treated **genetically hypertensive New Zealand rats** with a specific AT_1 receptor antagonist via osmotic mini-pumps for several weeks and measured the effects on blood pressure, cardiac hypertrophy and the structure of resistance arteries.

Transgenic animals were recommended for further studies to influence the human renin-angiotensin system (Müller et al. 1995; Wagner et al. 1995; Bohlender et al. 1996).

A.1.3.32
ACE inhibition measured *in vivo* in the rat

PURPOSE AND RATIONALE

The angiotensin-converting enzyme (ACE) is responsible for the cleavage of the almost inactive angiotensin I to the active angiotensin II. The same enzyme (kininase II) is responsible for the degradation of the active peptide bradykinin to inactive products. ACE activity can therefore be measured in two ways: activity of the newly formed angiotensin II and diminution of the activity of bradykinin. ACE inhibition results in decreased activity of the precursor angiotensin I and potentiation of the bradykinin effect. The cardiovascular system is sensitive to both peptides, reacting with an increase of blood pressure to angiotensin II and with a decrease to bradykinin. These reactions can be used for quantitative determination of ACE inhibiting activity.

PROCEDURE

Male Sprague-Dawley rats weighing 300–400 g are used. The animals are anesthetized by i.p. injection of 70 mg/hg pentobarbital. After intubation of the trachea they are artificially respirated with 30 strokes/min and a stroke volume of 6–8 ml. The right carotid artery is cannulated and blood pressure registered with a Statham-element (P 23 Db) and a polygraph. One jugular vein is cannulated for i.v. injections. After laparotomy a catheter is inserted into the duodenum for enteral administration and the wound closed again. Blood pressure is stabilized 30% below the normal level by i.m. injection of 5 mg/kg pentolinium. In order to prevent excessive mucus production in the bronchial system, 40 µg/kg atropine sulfate are injected intramuscularly.

Inhibition of angiotensin I cleavage

After stabilization of blood pressure, 310 ng/kg angiotensin I is injected intravenously in 0.1 ml saline. The injection is repeated in 5-min intervals until an identical pressure reaction occurs. The test compounds are administered at doses of 1 and 10 mg/kg intravenously or 25 mg/kg intraduodenally. 3 min after iv. injection or 10 min after i.d. administration, again 310 ng/kg angiotensin I is injected. Standards are ramipril, enalapril or captopril.

Potentiation of bradykinin-induced vasodepression

A low dose of bradykinin has to be chosen in order to visualize the bradykinin potentiation. One µg/kg, eventually 3 µg/kg bradykinin are injected intravenously at 5 min intervals until a stable reaction is achieved. Three min after i.v. injection or 10 min after intraduodenal administration of the test substance, the bradykinin injection is repeated.

EVALUATION

Inhibition of angiotensin I cleavage

The diminution of the pressure reaction to angiotensin I after administration of a potential ACE inhibitor is the parameter for the activity of the new compound. The inhibition is calculated as percent of controls. Using various doses of the ACE inhibitor, dose-response curves can be established and ID_{50} values be calculated.

Potentiation of bradykinin-induced vasodepression

Potentiation of bradykinin induced vasodepression is expressed as percentage of controls. Using various doses of the test compound and the standard, dose-response curves can be established and potency ratios calculated.

CRITICAL ASSESSMENT OF THE METHOD

Both parameters, inhibition of angiotensin I response and potentiation of bradykinin-induced vasodepression have been proven as reliable parameters for evaluation of ACE inhibitors.

MODIFICATIONS OF THE METHOD

Natoff et al. (1981) used the ratio of responses to angiotensin I and angiotensin II in spontaneously hypertensive rats, either pithed or anesthetized with urethane, to determine the degree and the duration of effect of captopril.

Blood levels of angiotensin II can also be measured by radioimmunoassay.

Several studies in rats showed the beneficial effects of prolonged treatment with ACE inhibitors. Postoperative mortality in rats with left ventricular hypertrophy and myocardial infarction was decreased by ACE inhibition (Linz et al. 1996).

Inhibition of angiotensin I-induced pressure response by administration of ACE-inhibitors can be measured not only in anesthetized rats, but also in anesthetized dogs, conscious rats and conscious dogs (Becker et al. 1984).

Life-long ACE inhibition doubles lifespan of hypertensive rats not only if the treatment is started at the age of one month (Linz et al. 1997), but ramipril also increases survival in old spontaneously hypertensive rats if treatment is started at the age of 15 months (Linz et al. 1999).

A.1.3.33 Evaluation of renin inhibitors in dogs

PURPOSE AND RATIONALE

Highly specific inhibitors of the enzyme renin are considered to be potential antihypertensive agents. These agents cause a fall in blood pressure of sodium-deficient dogs and decrease plasma renin activity as well as angiotensin II level.

PROCEDURE

Animal experiment

Adult mongrel dogs (8–14 kg) of either sex are given water ad libitum and maintained on a low sodium diet for 1–2 weeks before the experiment. A single intramuscular injection of 5 mg/kg furosemide is given 48 h before the experiment. On the day of the experiment the dogs are anesthetized with sodium pentobarbital (30 mg/kg i.v.) and a cuffed endotracheal tube is positioned to allow artificial respiration. To measure arterial blood pressure a femoral artery is catheterized with polyethylene tubing. The right and left femoral veins are catheterized for drug administration and delivery

of a maintenance infusion of sodium pentobarbital (5 mg/kg/h). Blood pressure is measured directly through the catheter which is connected to a Gould-Statham pressure transducer. Blood samples are collected from the arterial catheter.

Increasing doses of the potential renin inhibitor are infused over 30 min followed by a 30 min recovery period. Immediately after the last recovery period, the dogs are given an i.v. infusion of the angiotensin receptor antagonist saralasin (20 µg/kg/min) for 30 min. For measurement of plasma renin activity and angiotensin II levels, the dogs are infused over a period of 30 min with the test compound and blood is withdrawn at 0, 15, 30, 60, 90, 120, 180, and 240 min after the start of the infusion. After the final blood drawing, 20 µg/kg/min saralasin is infused for 30 min.

Analytical procedures

The antibody-trapping method is preferred to measure plasma renin activity (PRA). In this procedure PRA is determined at pH 7.4 by RIA quantification of angiotensin I (ANG I) generated and then trapped by excess anti-ANG I antibody (Poulsen and Jorgensen 1973; Nussberger et al. 1987). In tubes coated with rabbit anti-ANG I antibody (Gamma Coat™ ^{125}I Plasma renin activity RIA kit; Baxter Travenol Diagnostics) and incubated in an ice-water bath, 75 µl plasma are mixed with 7 µl 3 M TRIS base buffer (pH 7.2) containing 200 mM EDTA, and 3 µl 0.2 M TRIS base (pH 7.5) containing 3 g/L human serum albumin (fraction V, Sigma). Tubes are vortexed and incubated at 37 °C for 60 min. The incubation is terminated by placing the tubes in an ice-water bath. Next, 75 µl of the TRIS albumin buffer are added, followed by 1 ml phosphate RIA buffer (Gamma Coat™) containing 15 000 cpm of ^{125}I ANG I. Standard ANG I (0.2–50 ng/ml) is also incubated at 37 °C for 60 min with 10 µl TRIS/albumin buffer. In an ice-water bath, low renin plasma (75 µl) is added to the standards before the addition of a 1 ml tracer solution. Samples and standards are incubated for 24 h at 4 °C. Tubes are then aspirated and counted in a gamma counter.

Levels of immunoreactive angiotensin II (ir-ANG II) are measured using a procedure described by Nussberger et al. (1985). Two–three ml of whole blood are collected in prechilled glass tubes containing 125 µl of the following "inhibitor" solution: 2% ethanol, 25 mM phenanthroline, 125 mM EDTA, 0.5 mM pepstatin A, 0.1 mM captopril, 2 g/l neomycin sulfate, and 0.1 mM of the renin inhibitor CGP 38560. The tubes are then centrifuged and the plasma quickly frozen in liquid nitrogen and stored at –70 °C.For extraction of angiotensin peptides, Bond-Elut cartridges (Bond-Elut-pH) containing 100 mg phenylsilica are used, along with a Vac Elut SPS24 vacuum manifold (Analytichem; Harbor City, CA). Each cartridge is preconditioned with 1.0 ml methanol (HPLC grade) followed by 1.0 ml of water (HPLC grade) at a vacuum pressure of 5 mm Hg. One ml of the thawed sample is then applied to the cartridge and washed with 3 ml HPLC grade water. The angiotensin peptides retained at the columns are eluted with 0.5 ml methanol (HPLC grade, vacuum pressure less than 5 mm Hg) into polypropylene tubes coated with a buffer containing 0.2 M TRIS, 0.02% NaN_3, and 2.5 mg/ml fatty acid-free bovine serum albumin (pH 7.4 with glacial ace-tic acid). The methanol is evaporated at 40 °C and ir-ANG II measured using an antibody (IgG Corp., Nashville, TN) with greater than 1 000-fold selectivity for ANG II.

EVALUATION

All data are expressed as mean ±SEM. The hypotensive responses after various doses of the renin antagonist are compared with the inhibition of plasma renin activity and the decrease of immunoreactive angiotensin II.

CRITICAL ASSESSMENT OF THE METHOD

The antibody-trapping method, reported here, gives a better correlation with the blood pressure lowering effect in dogs than the conventional method based on RIA for generated ANG I (Palmer et al. 1993).

MODIFICATIONS OF THE METHOD

Pals et al. (1990) described a rat model for evaluating inhibitors of human renin using anesthetized, nephrectomized, ganglion-blocked rats. The blood pressure rise induced by sustained infusion of renin was dose-dependently decreased by a renin inhibitor.

A.1.3.34 Evaluation of renin inhibitors in monkeys

PURPOSE AND RATIONALE

The renin-angiotensin-system as the main regulator of blood pressure can be influenced in several ways. One approach involves the inhibition of renin. Renin is an aspartyl protease that hydrolyzes angiotensinogen to release the dekapeptide angiotensin I, which is subsequently converted to angiotensin II by angiotensin-converting-enzyme. Sequencing of renin and angiotensinogen from various species revealed marked species differences for both the enzyme and the substrate. Inhibitors developed for human renin show a high specificity for primate renin and show only weak inhibition of renin from sub-primate species. This means that the most common laboratory animals, such as rats and dogs, are not suitable for the *in vivo* evaluation of renin inhibitors. The marmoset was chosen by Wood et al. (1985, 1989) as a primate model.

PROCEDURE

Marmosets (*Callithrix jacchus*) of both sexes weighing between 300 and 400 g are fed a pellet diet supplemented with fruit. Two days prior to the experiment the animals are anesthetized and catheters are implanted in a femoral artery for measurement of blood pressure and in a lateral tail vein for injection or infusion of test substances. Thirty min before the experiment, the animals receive an intravenous injection of 5 mg/kg furosemide in order to stimulate renin release. During the experiment, the marmosets are sedated with diazepam (0.3 mg/kg i.p.) and kept in restraining boxes. Mean blood pressure is recorded continuously, and heart rate is measured at fixed intervals. The test compound or the standard are injected at various doses by intravenous infusion or administered orally.

EVALUATION

Blood pressure is recorded after 30 min of intravenous infusion and 30 min after stopping the infusion. Comparing the changes from pretreatment values after various doses, dose-response curves can be established.

MODIFICATIONS OF THE METHOD

Fischli et al. (1991) monitored arterial pressure in conscious and chronically instrumented monkeys using a telemetry system. One week before the experiment, the animals were anesthetized, and a 3F high fidelity pressure tip transducer (Millar Instruments, Inc.) was inserted into the abdominal aorta through the right femoral artery. Then the catheter was tunneled subcutaneously to the back of the monkey in the interscapular region. The proximal part of the catheter was connected to a transmitter located in a jacket worn by the monkey. The blood pressure was transmitted continuously to a receiver, which transformed the signal to an analogue value of blood pressure.

Linz et al. (1994) reported on the effects of renin inhibitors in anesthetized rhesus monkeys weighing between 5 and 13 kg. The animals are sodium-depleted by administration of 10 mg/kg/day furosemide-Na for 6 consecutive days. At day 7, 10 mg/kg furosemide is given i.v. 30 min before the start of the experiment. Anesthesia is induced with 20 mg/kg ketamine-hydrochloride i.m. and continued with 40 mg/kg pentobarbitone-Na, slow i.v. drip. After completion of surgical procedures and after insertion of catheters under fluoroscopic control, the following hemodynamic parameters are measured: Pulse rate, and systolic and diastolic blood pressures are registered with a transducer (Statham P23 ID) in one femoral artery. A catheter tip manometer (Millar Instruments, Houston, Texas, USA) is introduced into the left ventricular cavity for the determination of left ventricular pressure. Contractility is electronically deduced from left ventricular pressure with appropriate amplifiers (Hellige GmbH, Freiburg, Germany). The electrocardiogram (ECG) from conventional lead II is taken using an ECG transducer (Hellige GmbH). Heart rate is measured from QRS-peaks using a biotachometer (Hellige GmbH). Cardiac output is determined using the thermodilution method. Thermodilution is integrated and converted to cardiac output readings by commercially available equipment (HMV 7905, Hoyer, Bremen). To determine cardiac output, 2 ml chilled 0–5 °C isotonic glucose solution (5%) is injected rapidly into the right ventricle by a catheter via the right jugular vein. A thermistor is placed into the aortic arch via the right carotid artery.

Hemodynamics are monitored for 30 min following i.v. injection of various doses of the potential renin inhibitor. At the end of the experiments the ACE inhibitor ramiprilat 100 µg/kg is given i.v. to probe for an additional blood pressure lowering effect. Blood samples for the determination of ANG II concentration, renin inhibition and plasma drug levels are withdrawn at 10, 30 and 60 min after i.v. injection of the renin inhibitor. The volume is replaced by i.v. injections of isotonic glucose solution (5%). After all data and blood samples have been obtained, animals are sacrificed by an overdose of pentobarbitone-Na.

For experiments after intraduodenal administration sodium depletion and anesthesia are done as described above. A small side branch of the femoral or radial artery is surgically exposed and cannulated for blood pressure measurements using a pressure transducer (P23 ID). Heart rate is determined from a conventional ECG lead by a biotachometer. Blood samples are withdrawn via a catheter placed into the saphenous vein. A

gastric fiberscope (Olympus XP 10) is introduced into the duodenum under visual control and the renin inhibitor is administered intraduodenally through the service channel of the fiberscope in a volume of 5 ml. Blood samples are withdrawn before and at 15, 30, 45, 60, 90 and 120 min after intraduodenal administration.

CRITICAL ASSESSMENT OF THE METHOD

Due to the high species specificity of renin and its substrate, angiotensinogen, renin inhibitors for treatment of hypertension have to be tested in primate models. The marmoset as well as the rhesus monkey have been proven to be suitable models.

A.1.4 Cardiovascular safety studies

A.1.4.1 General considerations

PURPOSE AND RATIONALE

The necessity to perform pharmacological tests in preclinical safety evaluation is obvious (Zbinden 1966; Alder and Zbinden 1973)

More recently, severe concern has been expressed on the cardiovascular safety of drugs. Some drugs have been reported to induce severe ventricular arrhythmias, including torsades de pointes, and have been responsible in some cases for sudden death of patients. Although the mechanisms of these arrhythmias are not well understood, they are often, but not always, associated with QT interval prolongation (Dessertenne et al. 1966; Motté et al. 1970; Jackman et al. 1988; Weissenburger et al. 1993; Cavero et al. 2000; Taglialatela et al. 2000). Regulatory agencies, such as the Committee for Propriety Medical Pruducts (CPMP), an arm of the European Agency for the Evaluation of Medicinal Products have pointed out the necessity to assess most carefully the potential for QT prolongation, especially for non-cardiovascular drugs (1997, 2000). *In vivo* studies, preferably in unrestrained animals, are requested.

The outcome of a Policy Conference on *The Potential of QT Prolongation and Pro-arrhythmia by Non-anti-arrhythmic Drugs. Clinical and Regulatory Implications* held in 1999 under the auspices of the European Society of Cardiology, Committee for Scientific and Clinical Initiatives, was published by Haverkamp et al. (2000). In this review not only the electrophysiological mechanisms of QT prolongation are discussed but also proposals for preclinical and clinical evaluations were made.

A concept paper is available on an ICH harmonized tripartite guideline on nonclinical studies for assessing risk of repolarization-associated ventricular tachyarrhythmias for human pharmaceuticals including advantages and limitations of the various models.

Eckardt et al. (1998) reviewed *in vitro* and *in vivo* experimental models of torsade de pointes.

Pourrias et al. (1999) proposed a three phase strategy for assessment of cardiac risk for non-cardiovascular drugs: first, telemetry in freely moving dogs, second, studying monophasic action potentials in anesthetized dogs under paced and nonpaced conditions, and finally, analysis by *in vitro* techniques, such as isolated Purkinje fibers. Lacroix and Provost (2000) proposed a similar strategy: First complete hemodynamic evaluation in anesthetized dogs, then electrical activity evaluation *in vivo* and *in vitro*, and finally autonomic nervous system evaluation as required by Japanese guidelines.

Another strategy using first *in vitro* and then *in vivo* preclinical models was proposed by Champeroux et al. (2000). A similar strategy was proposed by Gralinski (2000): First using *in vitro* single-cell techniques (channel blockade and action potential recordings), then isolated tissue models, followed by *in vivo* approaches to cardiac electrophysiology and *in vivo* models of pro-arrhythmia and finally clinical studies to examine potential for QT interval prolongation.

In this book, methods of cardiovascular analysis are described in A.1.3.1 to A.1.3.5 for rats, in A.1.3.6 for cats, in A.1.3.7 for mice, in A.1.3.8 to A.1.3.10 for dogs, and in A.1.3.11 for monkeys. Methods using animals chronically instrumented for telemetry are described in A.1.3.15.

Moreover, detailed studies on ECG *in vivo* are requested by the authorities for safety pharmacology. The methods for evaluation of ECG in various animal species are described in A.5.0.2.

Methods to detect arrhythmogenic properties of drugs are described below.

A.1.4.2 Cardiovascular safety studies in dogs and other species

PURPOSE AND RATIONALE

Dogs are recommended as primary animal models to detect electrocardiographic changes, such as torsades de pointes, and effects of proarrhythmic drugs (Weissenburger et al. 1993; Salata et al. 1995; Matsunaga et al. 1998; Usui et al. 1998; Champeroux et al. 2000).

PROCEDURE

Mongrel dogs (8–12 kg) are anesthetized with 80–100 mg/kg i.v. α-chloralose and ventilated with a volume-cycled respirator. The right femoral artery and vein are isolated and cannulated for the measurement of systemic arterial pressure and for test agent administration, respectively. A left thoracotomy is performed in the fourth intercostal space, the percardium incised, and the heart suspended in a pericardial cradle. A platinum epicardial bipolar electrode is sutured to the left atrial appendage for atrial pacing, and a stainless steel bipolar plunge electrode is sutured to the anterior surface of the left ventricle for determination of ventricular excitation threshold and refractory periods. Limb electrodes are attached for continuous recording of the lead II electrocardiogram.

The following parameters are determined before and after cumulative intravenous administration of test agents: sinus heart rate, systemic arterial pressure, electrocardiographic intervals including a rate-corrected QTc interval according to Bazett's formula (Bazett 1920):

$$QTc = (QT\ [\text{ms}])\ (R - Rs)^{-1/2}$$

and a "paced QT" interval determined during 2.5-Hz atrial pacing, ventricular excitation threshold (VET), and ventricular effective refractory period (VERP, determined at two times ventricular excitation threshold). Groups of five to seven dogs are randomized to the intravenous administration of cumulative doses of test drugs. Each dose of test drug is administered over

5 min, with electrophysiological recording 15 min after termination of intravenous infusion.

Prolongation of QTc and ventricular effective refractory period indicate the risk for torsades de pointes.

EVALUATION

Data are expressed as mean ±SEM. Dunnett's *t*-test is used to determine significance of individual treatment means compared with control mean values. A multivariate repeated-measures ANOVA with comparison to the vehicle control group is used to identify significant within-group changes in electrocardiographic and electrophysiological parameters.

MODIFICATIONS OF THE METHOD

Champeroux et al. (2000) recommended the use of telemetric measurement of ECG in dogs for evaluation of the potential QT interval prolongation by drugs.

The use of Bazett's formula for heart rate correction of QT interval has been challenged. Sarma et al. (1984), Kovács (1985) proposed new exponential formulas to characterize the RR-QT relation in human beings.

Matsunaga et al. (1998) investigated the QT-RR relation in Beagle dogs by analysis of the QT and preceding RR intervals obtained from 24-hs ambulatory electrocardiograms. The acceptability of 14 QT prediction formulas was evaluated by use of 100–150 selected pairs of QT-RR points per animal in seven male and seven female Beagles. The accuracy of fit with the measured data was assessed. The one-parameter logarithmic formula

$$QTc = \log 600 \times QT / \log RR$$

was proposed for correcting the QT interval at a heart rate of 100 beats/min.

Champeroux et al. (2000) calculated the a, b and c parameters of Sarma's formula:

$$QT = a\, e^{(b\,RR)} + c$$

by fitting the QT/RR relationship from pairs of QT/RR values measured by telemetry from control dogs.

Hey et al. (1996) analyzed the ECG wave in anesthetized **guinea pigs** to determine QT interval, QTc interval, PR interval QRS interval and heart rate after the administration of the second generation antihistamines ebastine and terfenadine. In separate studies in conscious guinea pigs, the effect of oral ketoconazole on the ECG parameters after oral ebastine and terfenadine was studied.

Carlsson et al. (1990, 1993, 1997) studied class III effects and proarrhythmic properties of drugs in **rabbits** anesthetized with methohexital-sodium and α-chloralose. After base-line measurements of ECG, arterial blood pressure and heart rate, a continuous infusion of the α_1-agonist methoxamine (70 nmol/kg/min) was started. Ten min later, test drugs or vehicle were continuously infused for 10 min and the ECG was continuously monitored. The ECG analysis was subsequently performed on averaged ECG complexes. The T wave usually has a bifid appearance in the rabbit (TU complex). The QTU interval was defined as the time between the first deviation from the isoelectric line during the PR interval and the second peak of the TU complex. Torsades de pointes was defined as a transient tachyarrhythmia seen in the presence of QTU interval lengthening, with a typical initiation ("short-long-short sequence) and more than five consecutive undulating peaks of sequential QRS com-plexes observed in at least two leads.

A.1.4.3 Monophasic action potentials in dogs

PURPOSE AND RATIONALE

Registration of monophasic action potential (MAP) in anesthetized dogs for evaluation of arrhythmogenic activity of drugs was recommended by Usui et al. (1998), Weissenburger et al. (2000).

PROCEDURE

Beagle dogs of either sex are initially anesthetized with 30 mg/kg i.v. thiopental sodium. After intubation, 1% halothane is inhaled with a volume-limited ventilator. Systemic blood pressure is measured at the right femoral artery. An ECG is obtained from the limb electrodes. A thermodilution catheter is inserted through the right femoral vein and positioned at the right side of the heart. Cardiac output is measured by a standard thermodilution method using a cardiac output computer. A pig-tail catheter is inserted through the right femoral artery and positioned at the left ventricle to measure the left ventricular pressure. The maximum upstroke velocity of the left ventricular pressure (LV dP/dt) and the left ventricular end-diastolic pressure (LVEDP) are measured to estimate the contractility and the preload of the ventricle, respectively.

A quad-polar electrode catheter is inserted through the left femoral artery and positioned at the non-coronary cup of the aortic valve to record a His bundle electrogram. A bi-directional steerable monophasic action potential (MAP) recording/pacing combination catheter is inserted through the left femoral vein and positioned at the endocardium to obtain MAP signals. The signals are amplified with a DC amplifier.

The amplitude of MAP is measured as the distance from the diastolic baseline to the crest of the MAP plateau phase. The duration of the MAP signal is measured as an interval from the MAP upstroke to the desired repolarization level along a line horizontal to the diastolic baseline. The interval [ms] at 90% repolarization is defined as MAP_{90}. The heart is driven electrically through the pacing electrodes of the combination catheter. Stimulation pulses are rectangular in shape, about twice the threshold voltage (1.5–2.2 V) and of 1 ms duration. The MAP_{90} is measured during sinus rhythm (MAP_{90}(sinus)), and at a pacing cycle length of 400 ms (MAP_{90}(400)) and 300 ms (MAP_{90}(300)).

The effective refractory period (ERP) of the right ventricle is assessed with a programmed electrical stimulator. The pacing protocol consists of 8 beats of basal stimuli in a cycle length of 400 ms followed by an extra stimulus of various coupling intervals. Starting in late diastole, the coupling interval is shortened by 5–10 ms steps until refractoriness occurs. The difference ERP – MAP_{90}(400) is calculated to predict the vulnerability of the myocardium.

The amplified MAP signals together with systemic blood pressure, left ventricular pressure, heart rate and ECG are continuously monitored using a polygraph system. Each value of ECG and MAP represents the mean of three consecutive complexes. Corrected QT interval (QTc) is obtained using the formula of Bazett (1920).

EVALUATION

Data are presented as mean ± SM. The statistical significance of the effect of tested drugs on each parameter is evaluated by one-way repeated-measured analysis of variance (ANOVA). When a P-value is less than 0.05 by ANOVA, the statistical significance between a group is determined by a computer program, Contrast for mean values comparison. The differences of the control values between the groups is analyzed by a paired t-test.

MODIFICATIONS OF THE METHOD

Chen et al. (1999), Hsieh et al. (2000) developed a canine model of pacing induced cardiomyopathy to study the possible mechanisms of drug-induced torsades de pointes. Twelve-lead ECG and right and left ventricle monophasic action potentials were recorded at different right ventricle pacing cycle lengths from 600 ms to 1 200 ms.

A.1.4.4 Studies of arrhythmogenic effects in isolated heart preparations

PURPOSE AND RATIONALE

The evaluation of arrhythmogenic, anti-arrhythmic and antifibrillatory effects in the LANGENDORFF heart preparation is described in Sect. A.3.1.2.

Eckardt et al. (1998), Johna et al. (1998) proposed the isolated perfused rabbit heart as a model to study proarrhythmia induced by class III antiarrhythmic drugs.

PROCEDURE

Male New Zealand white rabbits weighing 2.5–3.0 kg are anti-coagulated with heparin sodium (2000 IU) and anesthetized with thiopental sodium via a marginal ear vein. After transecting the carotid arteries, the chest is opened and the heart rapidly excised. A cannula is inserted into the aortic stump, the pulmonary artery incised, and the spontaneously beating heart perfused through the coronary arteries at 37 °C in a non-circulating system at a constant pressure of 70 mm Hg with Krebs-Henseleit buffer containing (in mM): $CaCl_2$ 2.52; KCl 4.70; KH_2PO_4 1.18; $MgSO_4$ 1.66; NaCl 118; $NaHCO_3$ 24.88, Na-pyruvate 2.00; glucose 5.55 (= solution I). The buffer is gassed with 95% O_2 and 5% CO_2 yielding a pH of 7.4. Solution II contains KCl for a total of 2.0 mM K^+ and Mg^{2+} 0.5 mM; the other components are left unchanged. The heart is immersed in an organ bath at 37 °C. The coronary flow is estimated by collecting the outflow of the bath in a bowl placed on an electronic balance from which the values are read out by a computer at 10 s intervals. Electrocardiograms are touchlessly recorded from the bath via Ag/AgCl electrodes (filter settings: 0.1–300 Hz) in two perpendicular directions in the horizontal plane. QT intervals are measured from the beginning of the QPS complex to the intersection of the descending part of the T wave with the baseline in either ECG lead. The larger value is used for further analysis. The corrected QT (QTc) is calculated using Bazett's formula. Monophasic action potentials (MAP) are obtained using a commercially available Franz combination catheter (Franz 1994) (EP Technologies Inc., Sunnyvale, CA, USA) placed epicardially on the left ventricular posterior wall. Isovolumetric left ventricular pressure (LVP) is measured via a pressure transducer connected to a water-filled latex balloon attached to a rigid catheter and inserted through the left atrium into the ventricle (preload 5–10 mm Hg). ECGs, MAPs, and LVP are registered with a strip chart recorder, digitized at a rate of 1 kHz with 12 bit resolution and stored on discs for further analysis. Drugs are infused through an injection port above the aorta.

After a baseline period of 10 min, the test drug or a standard drug (Clofilium, a class III antiarrhythmic drug, Steinberg and Molloy 1979; Friedrichs et al. 1994) is infused for 20 min and MAP recordings are started. Following 5 more min of solution I (K^+ 5.88 mM, Mg^{2+} 1.66 mM) the perfusion is switched to solution II (K^+ 2.0 mM, Mg^{2+} 0.5 mM). During the subsequent 5 min the cardiac rhythm is described in consecutive 5 s windows by means of the ECG. The following patterns are distinguished: normal sinus rhythm, bigeminal pattern, monomorphic ventricular activity, ventricular rhythm with two alternating QRS morphologies and polymorphic ventricular tachyarrhythmias of the TdP type with undulating peaks of sequential QRS complexes (Jackman et al. 1988). MAP durations are measured at the 50%, 70% and 90% repolarization level. Subsequently, the hearts are again perfused with solution I.

EVALUATION

All values are expressed as mean ±SD. Statistical evaluation is carried out by two-tailed *t*-test for paired or unpaired observations.

A.1.4.5 Studies in isolated Purkinje fibres

PURPOSE AND RATIONALE

Studies in isolated rabbit Purkinje fibers were recommended to assess the risk of QT interval prolongation by drugs (Adamantidis et al. 1995, 1998; Cavero et al. 1999; Dumotier et al. 1999; Champeroux et al. 2000).

PROCEDURE

New Zealand white rabbits of either sex weighing 1.5–2 kg are sacrificed by cervical, dislocation and exsanguinated. Their hearts are quickly excised and placed in potassium- and glucose-enriched Tyrode solution (in mM: NaCl 108.2; KCl 27; $CaCl_2$ 1.8; $MgCl_2$ 1; NaH_2PO_4 1.8; $NaHCO_3$ 25; glucose 55; pH 7.35 ±0.05)

oxygenated (95% O_2/5% CO_2) at a temperature of about 32 °C. The left ventricle is opened through an incision into the anterior intraventricular groove. Purkinje fibers still attached to the ventricular muscle are carefully dissected and pinned to the silicone base of the experimental chamber. The pins are exclusively placed in ventricular muscle to avoid stretching of the Purkinje fibers. The preparations are superfused for 30 min, at a flow rate of 2 ml/min with the above-described solution maintained at 36.5 ±0.5 °C. Then the superfusate is switched to normal Tyrode's solution (in mM: NaCl 108.2; KCl 4; $CaCl_2$ 1.8; $MgCl_2$ 1; NaH_2PO_4 1.8; $NaHCO_3$ 25; glucose 11). The preparations are electrically stimulated by rectangular pulses of 1 ms with a frequency of 120 pulses per min and an intensity 1.5 times the diastolic threshold. After 30 min at least, the stimulation frequency is turned to 60 pulses per min.

Transmembrane action potentials are recorded using 3M KCl glass microelectrodes with a tip resistance of 10–15 megohms, which are coupled with an Ag-AgCl bath electrode and connected to an impedance amplifier, and are displayed on an oscilloscope with numerical memory, analyzed by an external computer system and stored on a digital magnetic type recorder which allows display on paper recordings of the occurrence and development of electrical abnormalities. The following parameters are measured: testing membrane potential, action potential and overshoot, maximal rate of depolarization and action potential duration at 50% and 90% of repolarization.

The studied drug is added to the Tyrode's solution in increasing cumulative concentrations, each concentration being tested for 30 min. The stimulation frequency is 60 pulses per min except between the 20th and 22nd min, when the frequency is reduced to 12 and then switched bach to 60 pulses per min. Action potentials are measured after 15 and 30 min of each concentration superfusion and at the end of the 2-min stimulation of 12 pulses per min.

EVALUATION

The results are expressed as means ±SEM. Comparisons vs. controls are performed statistically using an analysis of variance for repeated measures completed by the corrected Dunnett's *t*-est.

MODIFICATIONS OF THE METHOD

Kondo et al. (1999) studied the antagonism of potassium channel openers against the effect of class III antiarrhythmic agents in Purkinje fibers of **dogs**.

Studenik et al. (1999) used isolated spontaneously beating Purkinje fibers from **guinea pigs** to study the proarrhythmic potential of antidepressant and neuroleptic drugs.

A.1.4.6 Studies in isolated ventricular myocytes

PURPOSE AND RATIONALE

Analysis of action potential and patch-clamp techniques in isolated ventricular myocytes are used to clarify the mechanisms underlying the development of torsade de pointes ventricular arrhythmias (Salata et al. 1995; Drolet et al. 1999; Kalifa et al. 1999).

PROCEDURE

Preparation of single cells

Guinea pigs weighing 250–350 g are sacrificed by decapitation and their hearts quickly removed (Jurkiewicz et al. 1993). They are perfused retrogradely through the aorta at a rate of 10 ml/min with an oxygenated Ca^{2+}-free HEPES-buffered saline (containing 132 mM NaCl, 4 mM KCl, 1.2 mM $MgCl_2$, 10 mM HEPES, and 10 mM glucose, pH 7.2) at 37 °C for 5 min, then with the same solution containing 300 U/ml type II collagenase and 0.5 to 1.0 U/ml type XIV protease for 8 min, and finally with free HEPES-buffered saline containing 0.2 mM $CaCl_2$ for an additional 5 min. The enzyme-digested heart is cut into small pieces, placed in 20 ml HEPES-buffered saline containing 0.2 mM $CaCl_2$ and

shaken until single cells are dissociated from the small pieces. The cells are then filtered through a 200-μm nylon mesh and resuspended in HEPES-buffered saline containing 1.8 mM $CaCl_2$ and stored at 24 °C until use.

Action potential studies

Transmembrane potentials are recorded using conventional glass electrodes filled with 3 M KCl (tip resistances, 35–60 MΩ). They are connected to the headstage of an Axoclamp 2A amplifier (Axon Instruments. Cells are superfused with HEPES-buffered saline containing 1.8 mM $CaCl_2$ at a rate of 2 ml/min at 37 °C. Action potentials are evoked by passing brief current pulses (1 ms, 1.2 times threshold) through the recording electrode using an active bridge circuit. Cells are stimulated at a frequency of 1 Hz during a 10–15-min stabilization period before control measurements are obtained. Action potential are studied at frequencies of 1 and 3 Hz during control and at 10 min after superfusion with test agents at cumulatively increasing drug concentrations. Individual action potentials are sampled after 10-s trains of stimuli at each frequency, and four samples are digitally averaged and then measured for each condition.

Voltage-clamp studies

Microelectrodes made from square-bore (1.0 mm outer diameter) borosilicate capillary tubing are filled with 0.5 M K^+ gluconate, 25 mM KCl, 5 mM K_2ATP having a resistance of 3–7 MΩ (Sanguinetti and Jurkiewicz 1990). A List EPC-7 clamp amplifier is used to voltage clamp the isolated cells. Series resistance is compensated 40% to 70%, and current is low-pass filtered at a cutoff frequency of 1 kHz.

Voltage clamp is performed using the whole-cell recording mode, and cell perfusion is minimized by maintaining constant negative pressure on the electrode using a 1-ml gas-tight syringe attached to the suction port of the microelectrode holder via air-tight tubing.

Outward potassium currents are measured during superfusion of the cells at a rate of 2 ml/min with Ca^{2+}-free HEPES-buffered saline (35 °C) containing 0.4 μM nisoldipine to block L-type Ca^{2+} current (I_{Ca}). Cells are voltage-clamped at a holding potential (V_h) of either −50 or −40 mV to inactivate inward Na^+ current (I_{Na}). The "steady-state" current-voltage (I–V) relation for K^+ currents is examined initially by using a slowly depolarizing voltage ramp beginning at −110 mV and ending at +50 mV at a rate of 32 mV/s. I_K is measured as the difference from the initial instantaneous current, following the settling of the capacity transient, to the final (steady-state) current level during depolarization voltage steps to various test potentials (V_t). Tail current amplitude (I_{Ktail}) is measured as the difference from the holding current level to the peak I_{Ktail} on return to V_h. Inward rectifier K^+ current (I_{Ki}) is measured as the absolute current, uncorrected for leak, either during depolarizing voltage ramps or at the end of 225-ms hyperpolarizing voltage steps from a V_h of −40 mV.

Concentration-response relations are determined by measuring action potentials of currents in each cell during control conditions and during superfusion with two successively increasing concentrations of a given drug. Concentration-response curves are fit to a logistic equation, $Y = (a - d) / [1 + (X / c)^b] + d$, using a Marquardt-Levenburg algorithm for least-squares nonlinear regression analysis. Using this equation, a and d are maximal and minimal responses estimated for infinite and zero concentrations, respectively; c is the inflection point that estimates the 50% effective concentration (IC_{50}); and b is the slope factor (Hill coefficient). During the time required (4 to 8 min) to achieve steady-state drug effects, I_{Ktail} measured after a voltage step from −50 to −10 mV, which is used to quantify I_{Kr}, decreases by an average of 5% even in the absence of drug or vehicle. Because of this "rundown" of the current the concentration-response curves are fit with a minimal inhibition of 5%.

EVALUATION

Data are expressed as mean ±SEM. Action potentials are assessed using a three-way ANOVA to determine significant within-treatment variations. Dunnett's t-test is used to determine significance of individual treatment means compared with control mean values. A multivariate repeated-measures ANOVA with comparison to the vehicle control group is used to identify significant within-group changes in electrophysiological parameters.

MODIFICATIONS OF THE METHOD

Carlsson et al. (1997) performed voltage clamp studies in isolated ventricular myocytes from **rabbits**.

A.2 Methods to induce experimental hypertension

A.2.0.1 Acute renal hypertension in rats

PURPOSE AND RATIONALE

Since the classical experiments of Goldblatt et al. (1934) there is clear evidence that the ischemia of the kidneys causes elevation of blood pressure by activation of the renin-angiotensin system. The principle can be used both for acute and chronic hypertension. In rats acute renal hypertension is induced by clamping the left renal artery for 4 h. After reopening of the vessel, accumulated renin is released into circulation. The protease renin catalyzes the first and rate-limiting step in the formation of angiotensin II leading to acute hypertension. The test is used to evaluate antihypertensive activities of drugs.

PROCEDURE

Male Sprague-Dawley rats weighing 300 g are used. The animals are anesthetized by intraperitoneal injection of 100 mg/kg hexobarbital sodium. A PVC-coated Dieffenbach clip is placed onto the left hilum of the kidney and fixed to the back muscles. The renal artery is occluded for 3.5–4 h.

3.5 h following the surgery, the animals are anesthetized by intraperitoneal injection of 30–40 mg/kg pentobarbital sodium. The trachea is cannulated to facilitate spontaneous respiration. To measure systolic and diastolic blood pressure, the cannula in the carotid artery is connected to a pressure transducer (Statham P 23 Db).

For administration of the test compound, a jugular vein is cannulated.

Following a stable blood pressure state, ganglionic blockade is performed with pentolinium (10 mg/kg i.v.). After obtaining stable reduced blood pressure values, the renal arterial clip is removed. This leads to a rise in blood pressure as a consequence of elevated plasma renin level. Within 15 min a stable hypertension is achieved (control = 100%).

The test substance is then administered by intravenous injection at doses of 10 and 100 µg/kg.

Blood pressure is monitored continuously until a renewed increase to the starting level is obtained.

Ten–twelve animals are used per compound.

EVALUATION

Increase in blood pressure after reopening of the renal artery and reduction in blood pressure after administration of the test drug are determined [mm Hg]. Percent inhibition of hypertensive blood pressure values under drug treatment are calculated as compared to pretreatment hypertension values. Duration of the effect is determined [min]. Statistical significance is assessed by the paired *t*-test.

MODIFICATIONS OF THE METHOD

A sharp and transient in systemic arterial blood pressure associated with reflex bradycardia can be elicited by injection of 5-hydroxytryptamine, cyanide, nicotine or lobeline into the coronary artery blood stream of dogs (Berthold et al. 1989). The phenomenon is named the cardiogenic hypertensive chemoreflex and 5-HT proved to be the most powerful agent for its initiation (James et al. 1975).

A.2.0.2 Chronic renal hypertension in rats

PURPOSE AND RATIONALE

On the basis of the findings of Goldblatt et al. (1934) that ischemia of the kidneys induces hypertension, various modifications of the technique have been described for several animal species. One of the most effective modifications in rats is the so called 1-kidney-1-clip method.

PROCEDURE

Male Sprague-Dawley rats weighing 200–250 g are anaesthetized with 50 mg/kg i.p. pentobarbital. The fur on the back is shaved and the skin disinfected. In the left lumbar area a flank incision is made parallel to the long axis of the rat. The renal pedicel is exposed with the kidney retracted to the abdomen. The renal artery is dissected clean and a U-shaped silver clip is slipped around it near the aorta. Using a special forceps (Schaffenburg 1959) the size of the clip is adjusted so that the internal gap ranges from 0.25–0.38 mm. The right kidney is removed through a flank incision after tying off the renal pedicle. The skin incisions are closed by wound clips.

4–5 weeks after clipping blood pressure is measured and rats with values higher than 150 mm Hg selected for the experiments. Blood pressure readings are taken on each of 3 days prior to drug treatment. Drugs are administered orally in volumes of 10 ml/kg. The rats are divided into 4 animals per dose and each animal is used as his own control. Compounds are administered for 3 days and predrug and 2 h postdrug blood pressure readings are taken.

EVALUATION

Changes in systolic blood pressure are expressed in mm Hg. Activity is determined by comparing treatment blood pressure values with the control blood pressure value (Day 1, predrug blood pressure). Comparisons are made using the paired *t*-test for evaluation of statistical significance.

MODIFICATIONS OF THE METHOD

Duan et al. (1996) induced renal hypertension in male Hartley **guinea pigs** by a two-step procedure consisting of ligation of the left caudal renal artery and right nephrectomy. Arterial blood pressure and heart rate were monitored in conscious animals. ACE-inhibitors reduced blood pressure in sham-operated and in renal hypertensive guinea pigs, whereas renin inhibitors were effective only in renal hypertensive animals.

A.2.0.3 Chronic renal hypertension in dogs

PURPOSE AND RATIONALE

Production of hypertension by clamping renal arteries has been first described by Goldblatt et al. (1934) in dogs. Later on, the method has been modified, e.g., as the "wrapping" technique (Abram and Sobin 1947).

PROCEDURE

Dogs weighing 8–12 kg are anesthetized with i.v. injection of 15 mg/kg thiopental. Anesthesia is maintained with a halothane-oxygen mixture. Under aseptic conditions, a midline abdominal incision is made. One kidney is exposed and wrapped in cellophane and then replaced. The contralateral kidney is exposed. The artery, vein and ureter are ligated and the kidney is removed. The abdomen is closed by sutures and clips. On the day of surgery and for 3 days following, the dogs are given antibiotics. Body temperature is measured twice daily for 4 days following surgery.

Six weeks following surgery, blood pressure is measured using a tail-cuff method. For recording, the tail-cuff is attached to a polygraph. Only animals with a systolic blood pressure higher than 150 mm Hg are considered to be hypertensive and can participate in studies evaluating potential antihypertensive compounds.

For the experiment, blood pressure is recorded either by the indirect tail-cuff method or by direct measurement via an implanted arterial cannula. On day 1 readings are made every 2 h, just before, and 2 and 4 h after oral treatment with the potential antihypertensive compound. Drug administration is repeated for 5 days. On days 3 and 5 blood pressure readings are taken before and 2 and 4 h after treatment. At least 3 dogs are used per dose and compound.

EVALUATION

The starting value is the average of the 2 readings before application of the drug. Each of the following readings is subtracted from this value and recorded as fall of blood pressure at the various recording times.

MODIFICATIONS OF THE METHOD

Renal hypertension in rats has been achieved by many modifications of the method (Stanton 1971) such as

the technique according to Grollman (1944). The kidney is exposed through a lumbar incision, the renal capsule is removed by gentle traction, and a figure-8 ligature is applied being tight enough to deform the kidney but not tight enough to cut the tissue.

Renal hypertension may be induced in the **rat** by encapsulating both kidneys with latex rubber capsules (Abrams and Sobin 1947). Moulds are formed from plastic using a rat kidney as a model. The capsules are prepared by dipping the moulds in liquid latex allowing them to dry in the air. Three applications of latex are applied before the capsules are toughened by placing them under warm running tap water. The kidney is exposed by lumbar incision, the renal capsule gently removed and the capsule applied.

A.2.0.4 Neurogenic hypertension in dogs

PURPOSE AND RATIONALE

Vasodilator and depressor reflexes, originating in the baroreceptor areas of the carotid sinus and aortic arch, play an important part in the regulation of blood pressure. Stimulation of the afferent buffer fibres exerts an inhibitory influence on the vasomotor center, and their sectioning leads to a persistent rise in blood pressure. In this way, acute neurogenic hypertension can be induced in dogs.

PROCEDURE

Adult dogs of either sex weighing 10–15 kg are anesthetized using 15 mg/kg sodium thiopental, 200 mg/kg sodium barbital and 60 mg/kg sodium pentobarbital i.v. A femoral vein and artery are cannulated using polyethylene tubing to administer compounds i.v. and record arterial pressure and heart rate, respectively. Left ventricular pressure and *dp*/*dt* are recorded via the left common carotid artery (post-deafferentiation) using a Millar microtip pressure transducer. P_{max} is recorded by speeding up the chart paper. Cardiac output is determined by introducing a Swan-Ganz catheter into the right heart and pulmonary artery via a jugular vein. Five ml of cold 5% dextrose is injected into the right atrium and an Edwards Cardiac output computer is used to calculate the cardiac output from the temperature change in the pulmonary artery. All recordings are made with a polygraph.

Both of the carotid arteries are cleared up to the bifurcation of the internal and external carotid arteries. The carotid sinus nerves are isolated, ligated and sectioned and a bilateral vagotomy is performed to produce neurogenic hypertension (mean arterial pressure more than 150 mm Hg). The dog is allowed to equilibrate for approximately 30 min and a bolus of the test compound is administered by intravenous injection. Heart rate, arterial pressure, left ventricular pressure, *P*max and *dp*/*dt* are monitored for 90 min. A minimum of 3 dogs are used for each compound.

EVALUATION

Changes of the cardiovascular parameters are expressed as percentage of the values before administration of the drug.

MODIFICATIONS OF THE METHOD

Neurogenic hypertension through baroreceptor denervation has also been described in **rabbits** (Angell-James 1984) and in rats (Krieger 1984).

CRITICAL ASSESSMENT OF THE METHOD

The neurogenic hypertension is useful for acute experiments. However, it is less useful for chronic experiments since the elevated blood pressure caused by buffer nerve section is more labile than that caused by renal ischemia.

A.2.0.5 DOCA-salt induced hypertension in rats

PURPOSE AND RATIONALE

Mineralocorticoid-induced hypertension is thought to be due to the sodium retaining properties of the steroid causing increases in plasma and extracellular volume. The hypertensive effect is increased by salt loading and unilateral nephrectomy in rats.

PROCEDURE

Male Sprague Dawley rats weighing 250–300 g are anesthetized with ether. Through a flank incision the left kidney is removed. The rats are injected twice weekly with 20 mg/kg s.c. desoxycorticosterone-acetate in olive oil for 4 weeks. Drinking water is replaced with a 1% NaCl solution. Blood pressure starts to rise after one week and reaches systolic values between 160 and 180 mm Hg after 4 weeks.

MODIFICATIONS OF THE METHOD

The regimen to induce DOCA-salt hypertension has been modified by many authors (Stanton 1971).

DOCA pellets (Peterfalvi and Jequier 1960; Passmore and Jimenez 1990) or implants in silastic devices (Ormsbee and Ryan 1973; King and Webb 1988) were used instead of repeated injections.

DOCA-salt hypertension can also be achieved without nephrectomy (Bockman et al. 1992).

Using kininogen-deficient Brown Norway Katholiek (BN-Ka) rats, Majima et al. (1991, 1993) showed suppression of rat desoxycorticosterone-salt hypertension by the kallikrein-kinin system.

Li et al. (1996) examined small-artery structure on a wire myograph and quantified endothelin-1 messenger RNA by Northern blot analysis in DOCA-salt hypertensive rats after administration of an ACE-inhibitor, a calcium channel antagonist and a nitric oxide synthase inhibitor.

Ullian (1997) described the **Wistar-Furth rat** as a model of mineralocorticoid resistance. These rats developed two-kidney, one-clip hypertension to the same degree as did Wistar rats and reacted to glucocorticoid treatment with a rapid onset of hypertension, but were resistant to the development of DOCA-NaCl hypertension.

Studies in DOCA-salt hypertensive **mice** were reported by Gross et al. (1998, 1999), Honeck et al. (2000), Peng et al. (2001).

A.2.0.6
Fructose induced hypertension in rats

PURPOSE AND RATIONALE

Increases in dietary carbohydrate intake can raise blood pressure in experimental animals. The increased intake of either sucrose or glucose was shown to enhance the development of either spontaneous hypertension or salt hypertension in rats (Hall and Hall 1966; Preuss and Preuss 1980; Young and Landsberg 1981). Hwang et al. (1987) first reported that hypertension could be induced in normal rats by feeding a high-fructose diet. Fructose feeding was also found to cause insulin resistance, hyperinsulinemia, and hypertriglyceridemia in normal rats (Zavaroni et al. 1980; Tobey et al. 1982). Dai and McNeill (1995) studied the concentration- and duration-dependence of fructose-induced hypertension in rats.

PROCEDURE

Groups of 8 male Wistar rats weighing 210–250 g are used. The are housed two per cage on a 12-h light 12-h dark cycle and are allowed free access to standard laboratory diet (Purina rat chow) and drinking fluid. Drinking fluid consists either of tap water or 10%-fructose solution. Body weight, food intake and fluid intake of each rat are measured every week during treatment. Using the tail-cuff method, systolic blood pressure and pulse rate is measured before and every week during treatment. Blood samples are collected before and every second week during treatment for determination of plasma glucose, insulin, and triglycerides.

EVALUATION

Since maximum effects on the chosen parameters are achieved after 6 weeks, the duration of treatment can be limited to this time. Statistical analysis is performed using a one-way or two-way analysis of variance, followed by the Newman-Keuls test.

MODIFICATIONS OF THE METHOD

Reaven et al. (1988, 1989) found an attenuation of fructose-induced hypertension by exercise training and an inhibition by somatostatin treatment.

Brands et al. (1991, 1992) found an increase of arterial pressure during chronic hyperinsulinemia in conscious rats.

Hall et al. (1995) reported the effects of 6 weeks of a high-fat diet on cardiovascular, renal, and endocrine functions in chronically instrumented conscious **dogs**. Body weight increased by approximately 16.9 kg, whereas MAP, cardiac output, and heart rate increased by 28%, 77%, and 68%, respectively.

A.2.0.7
Genetic hypertension in rats

SURVEY

Inherited hypertension in rats has been described by Smik and Hall 1958; Phelan and Smirk 1960; Laverty and Smirk 1961; Phelan 1968 as **genetically hypertensive (GH) rats** (Simpson and Phelan 1984).

Okamoto et al. (1963, 1966) reported the development of a strain of spontaneously hypertensive rats from mating one Wistar male rat with spontaneously occurring high blood pressure with a female with slightly elevated blood pressure. By inbreeding over several generations a high incidence of hypertension with blood pressure values of 200 mm Hg or more was achieved. These strains were called "**Spontaneously hyperten-**

sive rats (Akamoto-Aoki)" = SHR or **"Wistar-Kyoto rats" = WKY**. Hypertension in these rats is clearly hereditary and genetically determined, thus comparable to primary hypertension in humans. Cardiac hypertrophy (Sen et al. 1974) and cellular ionic transport abnormalities have been observed (Yamori 1984).

Inbred strains being **salt-hypertension-sensitive (DS)** and **salt-hypertension-resistant (RD)** have been developed by Dahl et al. (1962, 1963), Rapp (1984), Cicila et al. (1993).

Two strains of rats with inbred dissimilar sensitivity to DOCA-salt hypertension (**"Sabra strain", SBH, SBN**) have been separated by Ben-Ishay et al. (1972, 1984).

Another hypertensive strain derived from Wistar rats was produced by brother-sister mating in the group of Bianchi et al. (1974, 1986) at the University of Milan called **"Milan hypertensive strain" = MHS**. These rats show a cell membrane defect resulting in abnormal kidney function. Salvati et al. (1990) studied the diuretic effect of bumetanide in isolated perfused kidneys of Milan hypertensive rats.

Furthermore, the ***"Lyon"*** strains of hypertensive, normotensive and low-blood-pressure rats were developed (Dupont et al. 1973; Vincent et al. 1984; Dubay et al. 1993). These rats show a genetically determined defect in central nervous function.

Several substrains of spontaneous hypertensive rats were separated by the group of Okamoto et al. (1974) including the **stroke-prone strain SHR = SHRSP**. These rats have an increased sympathetic tone and show a high incidence of hemorrhagic lesions of the brain with motor disturbances followed by death (Yamori 1984; Feron et al. 1996).

A strain of obese spontaneously hypertensive rats has been described by Koletsky (1975), Ernsberger et al. (1993).

Increase of blood pressure of spontaneously hypertensive rat is determined by multiple genetic loci (Deng and Rapp 1992; Dubay et al. 1993). With new technology not only these loci can be defined but also with **transgenic animals** new models in hypertension research and models to detect antihypertensive drugs can be established. A newly established **rat strain TGR(mREN2)27** as a monogenetic model in hypertension research was described by Peters et al. (1993).

CRITICAL ASSESSMENT OF THE METHOD

The use of spontaneously hypertensive rats to detect potential antihypertensive compounds is well established. On the basis of available data no preference can be given to a particular strain. The most abundant experience has been gained with the Wistar-Kyoto strain. Transgenic rats with well defined genomes are gaining more importance.

MODIFICATIONS OF THE METHOD

Pijl et al. (1994) described streptozotocin-induced diabetes mellitus in spontaneously hypertensive rats as a pathophysiological model for the combined effects of hypertension and diabetes.

Rosenthal et al. (1997) used rats of the Cohen-Rosenthal diabetic hypertensive strain to examine the effects of an ACE-inhibitor, an ATII antagonist and a calcium antagonist on systolic pressure and spontaneous blood glucose levels.

Linz et al. (1997) compared the outcome of lifelong treatment with the ACE inhibitor ramipril in young prehypertensive stroke-prone spontaneously hypertensive rats and age-matched normotensive Wistar-Kyoto rats. Lifelong ACE inhibition doubled the lifespan in hypertensive rats matching that of normotensive rats.

Studies in **genetically hypertensive mice** were reported by Rosenberg et al. (1985), Hamet et al. (1990) Meneton et al. (2000).

A.2.0.8 Pulmonary hypertension induced by monocrotaline

PURPOSE AND RATIONALE

The pyrrolizidine alkaloid monocrotaline, derived from *Crotalaria spectabilis*, is hepatotoxic and pneumotoxic in the rat. A single injection of monocrotaline leads to progressive pulmonary hypertension resulting in right ventricular hypertrophy and cardiac failure (Gillespie et al. 1986, 1988; Todorovich-Hunter et al. 1988). Pathologic changes and hemodynamic changes associated with monocrotaline administration include blebbing of the lung, degeneration and fragmentation of endothelial cells, perivascular edema, extravasation of red blood cells, and muscularization of the pulmonary arteries and arterioles (Valdiva et al. 1967; Lalich et al. 1977; Huxtable et al. 1978; Hislop and Reid 1979; Meyrick and Reid 1979; Meyrick et al. 1980; Ghodsi and Will 1981; Hilliker et al. 1982; Sugita et al. 1983; Hilliker and Roth 1985; Stenmark et al. 1985; Altieri et al. 1986; Molteni et al. 1986; Lai et al. 1996). Rats given monocrotaline develop severe right ventricular hypertrophy often accompanied by ascites and pleural effusions (Ceconi et al. 1989).

Amelioration by angiotensin-converting enzyme inhibitors and by penicillamine has been demonstrated (Molteni et al. 1985, 1986).

PROCEDURE

Treatment of male Sprague Dawley rats weighing 200–225 g with the test drug (angiotensin converting enzyme inhibitor or vehicle) is started one week prior to a single subcutaneous injection of 100 mg/kg monocrotaline up to sacrifice 4, 7, or 14 days later by pentobarbital anesthesia and exsanguination. Heart and lungs are excised from thoracic cavity. After removing atria from the heart, the right ventricle is separated from the left ventricle plus septum which are blotted and weighed separately. Left lung is blotted, weighed, minced and reweighed after drying at room temperature for 14 days. Three pulmonary artery segments, main pulmonary artery, right extrapulmonary artery and an intrapulmonary artery from the from the right lower lobe, are isolated for study of vascular responsiveness. Cylindrical segments of each vessel are suspended between stainless steel hooks in 10-ml isolated tissue baths containing modified Krebs-Henseleit buffer aerated with 95% O_2/5% CO_2 at 37 °C. At the end of each experiment, vessel segments are blotted and weighed and their dimensions measured. Cross-sectional area of each artery is determined from tissue weight and diameter.

Arteries are equilibrated for 1 h at 1 g of passive applied load and then are made to contract to KCl (6×10^{-2} M). After washout, the procedure is repeated with applied loads increased by 1 g increments. Responses are normalized to the maximum active force development generated by an artery in each experiment and the data are plotted as a function of applied force. Changes in isometric force are monitored through force displacement transducers (Grass FT03) and recorded on a polygraph.

Responsiveness to contractile and relaxant agonists is assessed in pulmonary arteries from saline- and monocrotaline-treated rats both in verum- and placebo-treated groups. Cumulative concentration-response curves to hypertonic KCl, angiotensin II and norepinephrine are generated sequentially in vessels at resting tone. Arteries are then contracted submaximally with norepinephrine and cumulative concentration-response curves to the vasorelaxants isoproterenol and acetylcholine are determined.

EVALUATION

Contractions are expressed as active tension development, force generated per cross-sectional area and relaxations are normalized to precontraction tone. Both contractile and relaxation responses are plotted as a function of the negative logarithm of agonist concentration. Differences in mean responses are compared by a *t*-test for grouped data.

MODIFICATIONS OF THE METHOD

Molteni et al. (1986) treated rats continuously with monocrotaline in the drinking water at a concentration of 2.4 mg/kg/day for a period of 6 weeks. Test rats received an ACE-inhibitor during this time in the drinking water and controls the vehicle only. At the end of the experiment, hearts and lungs were weighed and examined by light and electron microscopy.

Madden et al. (1995) determined L-arginine-related responses to pressure and vasoactive agents in monocrotaline-treated rat pulmonary arteries.

Ono et al. (1995) studied the effects of prostaglandin E_1 (PGE_1) on pulmonary hypertension and lung vascular remodelling in the rat monocrotaline model of human pulmonary hypertension.

Yamauchi et al. (1996) studied the effects of an orally active endothelin antagonist on monocrotaline-induced pulmonary hypertension in rats.

Gout et al. (1999) evaluated the effects of adrenomedullin in isolated vascular rings from rats treated with monocrotaline (60 mg/kg s.c.) causing pulmonary hypertension and ventricular hypertrophy within 3 to 4 weeks.

A.3
Coronary (cardiac) drugs

A.3.1
Isolated organs

A.3.1.1
Heart-lung preparation

PURPOSE AND RATIONALE

The isolated heart-lung of the dog was introduced by Knowlton and Starling (1912). Since then, the dog model has been used for many physiological and pharmacological studies (Krayer 1931; Krayer and Mendez 1942; Somani and Blum 1966; Takeda et al. 1973; Ishikawa et al. 1978, 1983; Ono et al. 1984a,b; Caffrey et al. 1986; Hausknecht et al. 1986; Fessler et al. 1988; Seifen et al. 1987, 1988; Naka et al. 1989). More recently, the rat model has been preferred (Dietz 1984, 1987; Onwochei et al. 1987, 1988; Kashimoto et al. 1987, 1990, 1994,1995, Fukuse et al. 1995).

PROCEDURE

Wistar rats weighing 300–320 g are anesthetized with 50 mg/kg pentobarbitone i.p. Tracheotomy is per-

formed and intermittent positive pressure ventilation is instituted with air. The chest is opened and flooded with ice-cold saline and the heart arrested. Cannulae are inserted into the aorta and the superior (for measurement of central venous pressure) and inferior venae cavae. The heart-lung preparation is perfused with a solution containing rat blood cells from another rat and Krebs-Ringer bicarbonate buffer, with hematocrit and pH of 25% and 7.4, respectively. Concentration of the buffer constituents (mM): NaCl 127, KCl 5.1, $CaCl_2$ 2.2, KH_2PO_4 1.3, $MgSO_4$ 2.6, $NaHCO_3$ 15, glucose 5.5 and heparin. The perfusate pumped from the aorta passes through a pneumatic resistance and is collected in a reservoir maintained at 37 °C and then returned to the inferior vena cava. In this model, no other organs except the heart and lung are perfused. Cardiac output is determined by the inflow as long as the heart does not fail. Mean arterial pressure is regulated by the pneumatic resistance. Heart rate is recorded by a bioelectric amplifier and cardiac output is measured with an electromagnetic blood flow meter. Arterial pressure and right atrial pressure are measured with transducers and amplifiers. The heart is perfused initially with cardiac output of 30 ml/min and mean arterial pressure of 80 mm Hg. Test drugs are administered into the perfusate 5 min after start of the experiment.

EVALUATION

Hemodynamic data within groups are analyzed by two-way analysis of variance (ANOVA) with repeated measures. Recovery time is measured by the Kruskal-Wallis test. The other data are analyzed by one-way ANOVA followed by the Dunnett test for multiple comparisons.

MODIFICATIONS OF THE METHOD

Using the Starling heart-lung preparation in dogs, Wollenberger (1947) studied the energy-rich phosphate supply of the failing heart.

Shigei and Hashimoto (1960) studied the mechanism of the heart failure induced by pentobarbital, quinine, fluoroacetate and dinitrophenol in dog's heart-lung preparation and effects of sympathomimetic amines and ouabain on it.

Imai et al. (1961) used heart-lung preparations of the dog to study the cardiac actions of methoxamine with special reference to its antagonistic action to epinephrine.

Capri and Oliverio (1965), Beaconsfield et al. (1974) used the heart-lung preparation of the **guinea pig**.

Robicsek et al. (1985) studied the metabolism and function of an autoperfused heart-lung preparation of the **dog**.

The **dog heart-lung preparation** was used by Seifen et al. (1988) to study the interaction of a calcium channel agonist with the effects of digoxin, by Somani and Blum (1966) to study blockade of epinephrine- and ouabain-induced cardiac arrhythmias in the dog,

by Riveron et al. (1988) to investigate the energy expenditure of an autoperfusing heart-lung preparation,

by Namakura et al. (1987) to study the role of pulmonary innervation in an *in situ* lung-perfusion preparation as a new model of neurogenic pulmonary edema,

by Hausknecht et al. (1986) to investigate the effects of lung inflation on blood flow during cardiopulmonary resuscitation,

by Caffrey et al. (1986) to evaluate the effect of naloxone on myocardial responses to isoproterenol,

by Ono et al. (1984) to estimate the cardiodepressant potency of various beta-blocking agents,

by Ishikawa et al. (1983) for a graphical analysis of drug effects in the dog heart-lung preparation – with particular reference to the pulmonary circulation and effects of norepinephrine and 5-hydroxytryptamine,

by Iizuka (1983) to study the cardiac effects of acetylcholine and its congeners,

by Fessler et al. (988) to investigate the mechanism of reduced LV afterload by systolic and diastolic positive pleural pressure,

by Takeda et al. (1973) to study the cardiac actions of oxprenolol.

Beaconsfield et al. (1974) used the heart-lung preparation of **guinea pigs** to study the cardiac effect of delta-9-tetrahydrocannabinol.

The **rabbit** autoperfusing heart-lung preparation was used by Muskett et al. (1986, 1988).

The isolated heart-lung preparation in the **cat** was described by Beaufort et al. (1993).

Kontos et al. (1987, 1988) harvested heart-lung blocks from **calves**.

A.3.1.2 Isolated heart according to LANGENDORFF

PURPOSE AND RATIONALE

More than 100 years ago Langendorff (1895) described studies on isolated surviving mammalian hearts using mainly cats as donors. Since then, the method has been improved from the technical site and is nowadays used for studies with guinea-pig, rabbit or rat hearts. In principle, the heart is perfused in retrograde direction from the aorta either at constant pressure or at constant flow with oxygenated saline solutions. Retrograde perfusion closes the aortic valves, just as in the *in situ* heart during diastole. The perfusate is displaced through the coronary arteries flowing off the coronary sinus and the opened right atrium. In this original set-up the ventricles do not fill with perfusate and therefore do not perform pressure-volume work. Parameters usually measured are: contractile force, coronary flow and cardiac rhythm.

PROCEDURE

Guinea pigs of either sex weighing 300–500 g are sacrificed by stunning. For studies of biochemical parameters in tissue and perfusate, removal of the heart during barbiturate anesthesia and artificial respiration is recommended. The heart is removed as quickly as possible and placed in a dish containing Ringer's solution at 37 °C. Associated pericardial and lung tissue are removed. The aorta is located and cut just below the point of its division. A glass or plastic cannula is introduced into the aorta, tied with two threads and perfusion is started with oxygenated Ringer's solution or Krebs-Henseleit buffer. The heart is transferred to a double walled plexi-glass perfusion apparatus which is kept at 37 °C by the water from a thermostat. Oxygenated Ringer's solution is perfused at a constant pressure of 40 mm Hg and at a temperature of 37 °C from a reservoir. A small steel hook with a string is attached to the apex of the heart. Contractile force is measured isometrically by a force transducer with a preload of 2.5 g and recorded on a polygraph. Coronary flow is measured by a drop counter. Alternatively, flow measurements can be performed using a mechanic-electronic flow meter consisting of a vertical pipe and a magnetic valve (Hugo Sachs Electronic KG, Germany). Heart rate is measured through a chronometer coupled to the polygraph. Drugs are injected into the perfusion medium just above the aortic cannula.

CRITICAL ASSESSMENT OF THE METHOD

A reappraisal of the LANGENDORFF heart preparation was given by Broadley (1979) underlining the usefulness to test coronary vasodilating drugs. The value of the LANGENDORFF method can be best assessed by demonstrating a few of its applications in physiology and pharmacology. Direct effects can be measured as well as the antagonism against various physiological and pharmacological agents.

MODIFICATIONS OF THE METHOD

A survey on various modifications of the LANGENDORFF-technique and the **isolated working heart preparation** has been given by Ross (1972).

Neely et al. (1967) inserted a second cannula into a pulmonary vein or the left atrium. Perfusate from a reservoir flows via this cannula through the mitral valve into the left ventricle. During the systole of the heart, the left ventricle re-pumps the perfusate through the aorta into the reservoir. The perfusate flowing through the coronary arteries and dripping off from the outside of the heart is collected in a vessel below the heart and recirculated into the reservoir with a roller pump.

Flynn et al. (1978) underlined the difference of this working heart preparation to the original LANGENDORFF method and reported the effects of histamine and noradrenaline on peak left ventricular systolic pressure, contractility, sinus rate, coronary flow, aortic flow, total cardiac output, and external pressure-volume work. Therefore, this method is reported separately.

Ishiu et al. (1996) measured simultaneously Ca^{2+}-dependent indo-1 fluorescence and left ventricular pressure on a beat-to-beat basis in Langendorff guinea pig hearts and investigated the changes in Ca^{+2} transient and left ventricular function during positive inotropic stimulation and myocardial ischemia.

Hukovic and Muscholl (1962) described the preparation of the isolated **rabbit** heart with intact sympathic nervous supply from the right stellate ganglion.

Hendrikx et al. (1994) used the isolated perfused rabbit heart to test the effects of an Na^+/H^+ exchange inhibitor on postischemic function, resynthesis of high-energy phosphate and reduction of Ca^{2+} overload.

Michio et al. (1985) modified the Langendorff method in rabbits to a working heart preparation by cannulating the left atrium. At a pressure of 20 cm H_2O in the left atrium, the heart pumped the solution against a hydrostatic pressure of 100 cm H_2O. Aortic flow, systolic aortic pressure, coronary flow, and heart rate were measured.

The influence of an ACE-inhibitor on heart rate, lactate in the coronary effluate and GTP-level in the myocardium after 60-min hypothermic cardiac arrest was studied in working heart preparation of rabbits by Zegner et al. (1996).

Gottlieb and Magnus (1904) introduced the so called **"balloon method"**. A small balloon fixed to the tip of

a catheter is filled with water and inserted into the left ventricle via one of the pulmonary veins, the left atrium and the mitral valve. The balloon size has to fit the volume of the left ventricle and therefore its size depends on the animal species and body weight. The catheter can be fixed by tying the pulmonary vein stems. Via a three-way valve, the balloon can be extended to a given preload. The beating heart now exerts a rhythmic force to the balloon and thus to the membrane of a pressure transducer. The advantages of this method are that force development and preload can be stated reproducibly in pressure units [mm Hg], left ventricular contraction curves can be used for further calculations, and continuous heart rate recordings can be carried out without any problems when using a rate meter.

Sakai et al. (1983) reported a similar method adapted to **mice**.

Bardenheuer and Schrader (1983) described a method whereby the balloon is inserted into the left ventricle as described above. However, isovolumetric pressure in the left ventricle is not measured. Instead, the fluid in the balloon is pumped through the cannula into a closed extra corporal circulation. The fluid is forced into one direction by 2 recoil valves. The balloon is made of silicone material using a Teflon form (Linz et al. 1986). The dimensions of the form are derived from casts of the left ventricle of K^+-arrested heart by injection of dental cement (Palavit 55®, Kulzer and Co, GmbH, Germany). During each heart beat the fluid volume expelled from the balloon corresponding to the stroke volume of the heart, can be recorded by means of a flow meter probe and an integrator connected in series. Preload and afterload can be adjusted independently from each other. The perfusate flow (retrograde into the aorta and through the coronary arteries) is recorded separately.

The following parameters were measured in isolated **rat** hearts (Linz et al. 1986; Linz et al. 1990):

- LVP (left ventricular pressure) with Statham pressure transducer P 23 DB, which on differentiation yielded LV dp/dt_{max} and HR (heart rate). Cardiac output and coronary flow (CF) are determined by electromagnetic flow probes in the outflow system and in the aortic cannula, respectively. Coronary venous pO_2 is measured with a catheter placed in the pulmonary artery by a type E 5046 electrode connected to a PMH 73 pH/blood gas monitor (Radiometer). An epicardial electrocardiogram recording is obtained via two silver electrodes attached to the heart. All parameters are recorded on a Brush 2600 recorder.
- Myocardial oxygen consumption (MWO_2) [ml/min/g wet weight] is calculated according to the equation:

$$MVO_2 = CF \times (P_a - P_v) \times (c/760) \times 100$$

where CF is the coronary flow [ml/min/g], P_a is the oxygen partial pressure of arterial perfusate (650 mm Hg), P_v is the oxygen partial pressure of the venous effluent perfusate [mm Hg], and c is the 0.0227 ml O_2/ml perfusate representing the Bunsen solubility coefficient of oxygen dissolved in perfusate at 37 °C (Zander and Euler 1976).

For the determination of lactate dehydrogenase (LDH) and creatine kinase (CK) activities in the perfusate, samples are taken from the coronary effluent.

After the experiments, hearts are rapidly frozen in liquid nitrogen and stored at –80 °C. Of the left ventricle, 500 mg are taken, put into 5 ml ice-cold $HClO_4$ and disrupted with an Ultra-Turrax (Junke and Kunkel, Ika-Werk, Type TP). Glycogen is hydrolyzed with amyloglycosidase (pH 4.8) and determined as glucose. Furthermore, ATP and creatine phosphate are measured.

Avkiran and Curtis (1991) constructed a dual lumen aortic cannula which permits independent perfusion of left and right coronary beds in isolated rat hearts without necessitating the cannulation of individual arteries.

Igic (1996) described a modification of the isolated perfused working rat heart. A special double cannula was designed consisting of an outer cannula that is inserted into the aorta and an inner cannula that is advanced into the left ventricle. The perfusion fluid flows through the inner cannula into the left ventricle, and is ejected from there into the aorta. If the outer cannula system is closed, the fluid perfuses the coronary vessels and drips off outside the heart. When the outer cannula is open and certain pressure resistance is applied, a fraction of the ejected fluid perfuses coronary vessels and the rest is expelled. Because the inner cannula can be easily retracted into the outer cannula, which is placed in the aorta, the preparation provides an opportunity to use the same heart as a "working" or "non-working" model for investigating functions of the heart.

By labeling glucose, lactate, or fatty acids in the perfusate with ^3H or ^{14}C, Barr and Lopaschuk (1997) directly measured energy metabolism in the isolated rat heart.

Krzeminski et al. (1991) described a new concept of the isolated heart preparation with on-line computerized data evaluation. Left ventricular pressure was recorded by means of a balloon-catheter, while special suction electrodes obtained the high-amplitude, noise-free electrogram recordings. The coronary effluent partial pressure of oxygen was continuously monitored, which enabled the calculation of myocar-

dial oxygen consumption (MVO_2). The effluent partial pressure of carbon dioxide and pH value were also measured simultaneously. A computerized system of data acquisition, calculation, storage, and end report was described.

Döring and Dehnert (1988) described continuous simultaneous **ultrasonic recording** of two cardiac diameters in an isolated perfused guinea-pig heart. For the measurement of the left ventricular transversal diameter the ultrasonic transmitter was positioned at the epicardium at the largest cardiac diameter. The corresponding ultrasonic receiver was inserted through the right atrium into the right ventricle to approximately the same height as the transmitter. In the right ventricle, which is empty in the isolated perfused LANGENDORFF-heart, it was automatically positioned opposite to the transmitter. Additional transducers were placed both at the heart's base and apex for assessment of the ventricular longitudinal diameter.

Several authors used the **isolated perfused mouse heart**.

Bittner et al. (1996) described a work-performing heart preparation for myocardial performance analysis in murine hearts using a modified Langendorff apparatus.

Sumaray and Yellon (1998a,b) constructed a specially designed Langendorff apparatus that allows perfusion of the isolated **mouse** heart. These authors reported that ischemic preconditioning reduces infarct size following global ischemia in the murine myocardium.

Brooks and Apstein (1996) measured left ventricular systolic and diastolic pressures in the isovolumically contracting (balloon in the left ventricle) mouse hearts.

Plumier et al. (1995) generated **transgenic mice** expressing the human heart heat shock protein 70. Upon reperfusion of the hearts after 30 min of ischemia in the Langendorff preparation, transgenic hearts versus non transgenic hearts showed significantly improved recovery of contractile force.

Hannan et al. (2000) compared ENOS knockout and wild-type mouse hearts which were perfused in a Langendorff apparatus with Krebs bicarbonate buffer and subjected to 20 min of global normothermic ischemia followed by 30 min of reperfusion. Myocardial function was measured using a ventricular balloon to determine time to onset of contraction, left ventricular developed pressure (LVDP), left ventricular end-diastolic pressure (LVEDP), and heart rate-pressure product (RPP).

Sheikh et al. (2001) generated transgenic mice overexpressing fibroblast growth factor (FGF)-2 protein in the heart. An isolated mouse heart model of ischemia-reperfusion injury was used to assess the potential of endogenous FGF-2 for cardioprotection.

APPLICATIONS

Positive inotropic effects

While negative inotropic substances can be tested in a heart beating with normal force, the evaluation of a positive inotropic compound usually requires that cardiac force is first reduced. Acute experimental heart failure can be induced by an overdose of barbiturates, such as sodium thiopental, or calcium antagonists. This kind of cardiac failure can be reversed by β-sympathomimetic drugs, cardiac glycosides, or increased Ca^{+2} concentration. In this way, the potential β-sympathomimetic activity of a new drug can be measured using isoproterenol as standard. After thiopental-Na treatment, left ventricular pressure (LVP) and dp/dt_{max} decrease considerably, whereas coronary flow is slightly enhanced. β-Sympathomimetic drugs restore LVP and dp/dt_{max} and keep coronary blood flow elevated.

Cardiac glycosides increase LVP and dp/dt_{max} and leave coronary flow unchanged.

Negative inotropic effects

The effects of a β-sympathomimetic drug such as isoproterenol at doses of 0.05 to 0.2 µg increasing contractile force as well as heart frequency are registered. After injection of a β-blocker, the effects of isoproterenol are attenuated. The effects of a potential β-blocking agent can be tested comparing the isoproterenol inhibition versus a standard such as propranolol (0.1 mg).

Coronary vessel dilating effect

The LANGENDORFF heart has been extensively used for assessing the coronary dilating activity of drugs (Broadley 1979). Rothaul and Broadley (1982) demonstrated the release of coronary vasodilator mediators from guinea pig isolated hearts by a technique employing donor and recipient hearts in series.

Calcium-antagonism

In order to demonstrate the effect of calcium-antagonists, 1 to 5 mg $BaCl_2$ are injected which induce a pronounced spasm of the coronary arteries thereby reducing the coronary flow. Five min later, the test drug is injected. Active compounds have a relaxing effect on coronary arteries indicated by an increase of coronary flow. After this effect has weaned, $BaCl_2$ is injected again and the test drug or a standard drug, e.g. nifedipine, is tested. The increase of coronary flow is expressed as percentage of flow during $BaCl_2$ spasm and compared with the effect of the standard. Using various doses, dose-response curves can be established.

Effect on potassium outflow induced by cardiac glycosides

Lindner and Hajdu (1968) described a method using the LANGENDORFF heart in which contractile force, coronary flow, and the potassium content in the coronary outflow was determined by flame photometry. Increase in potassium outflow correlates well with the positive inotropic effect.

Gradual determination of hypoxic damage

Lindner and Grötsch (1973) measured the enzymes creatine phosphokinase (CPK), lactate dehydrogenase (LDH), α-hydroxy-butyrate dehydrogenase (α-HBDH), and glutamic-oxalacetic transaminase (GOT) in the effluent of a guinea pig heart preparation under varying degrees of hypoxia. Potassium content and oxygen tension in the inflowing and outflowing solution were determined. The heart rate, the amplitude of contraction and the rate of coronary vessel perfusion were recorded additionally.

Metabolic studies with nuclear magnetic resonance

Using ^{31}P, studies on metabolism of nucleotides and phosphorylated intermediates of carbohydrates in isolated hearts have been performed (Garlick et al. 1977; Jacobus et al. 1977; Hollis et al. 1978; Matthews and Radda 1984).

Arrhythmogenic, anti-arrhythmic and antifibrillatory effects

The LANGENDORFF heart preparation is also used to test the influence of compounds on cardiac rhythm. For recording monophasic action potentials, suction electrodes are applied on the heart. Ventricular fibrillation can be induced by simultaneous injection of digitoxin (12.5–25.0 µg) and aconitine (12.5–25.0 µg) into the perfusion fluid (Lindner 1963). Cardiac glycosides shorten the refractory period, decrease the conduction velocity and increase heterotopic stimulus generation. Aconitine increases markedly heterotopic stimulus generation. Both compounds together induce invariably ventricular fibrillation. Anti-arrhythmic compounds can be tested in this way. Fibrillation is inhibited, at least partially, by 20 µg prenylamine, 10–20 µg quinidine or 20 µg ajmaline.

Takeo et al. (1992) described protective effects of anti-arrhythmic agents on oxygen-deficiency-induced contractile dysfunction of isolated perfused hearts. Hypoxia in isolated rabbit hearts was induced by perfusing the heart for 20 min with Krebs-Henseleit buffer saturated with a gas mixture of 95% N_2 and 5% CO_2 containing 11 mM mannitol. After hypoxic perfusion, the heart was reoxygenated for 45 min with oxygenated buffer containing glucose.

Dhein et al. (1989) studied the pathway and time course of the epicardial electrical activation process by means of a computer-assisted epicardial potential mapping, using a matrix of 256 unipolar AgCl electrodes (1 mm spatial and 0.25 ms temporal resolution) in isolated rabbit hearts perfused according to the Langendorff technique. From the activation times of the surrounding electrodes, the direction and velocity of activation for each electrode were calculated, thereby allowing construction of an epicardial vector field. The method was used for the assessment of arrhythmogenic and anti-arrhythmic drug activity.

Electrical stimulation and antifibrillatory effect

Ventricular fibrillation can be induced in the LANGENDORFF preparation by reducing the glucose content of the perfusion medium to 0.25 g/1 000 ml and the KCl content to 0.12 g/1 000 ml. (Burn et al. 1957, 1960; Lindner 1963). After a perfusion period of 20 min, 10 µg epinephrine are injected into the perfusion cannula. Immediately afterwards, the heart is stimulated with a current of 40 Hz and 5 mA for 2 min. This procedure is repeated every 10 min. Standard conditions are achieved when the fibrillation continues without further electrical stimulation. Hearts treated in this way serve as controls. Other hearts stimulated in the same way are treated with continuous infusion of the test drug or the standard via the perfusion medium. Differences in the incidence of fibrillations are calculated using the χ^2 test.

Electrophysiological evaluation of cardiovascular agents

Balderston et al. (1991) modified the Langendorff technique in rabbit hearts in order to perform electrophysiologic studies. His bundle electrograms were measured with a plunge electrode and allowed atrioventricular nodal physiology to be evaluated directly. Atrial conduction and refractoriness, atrioventricular node conduction and refractoriness, His-Purkinje conduction, and ventricular conduction and refractoriness could be accurately measured. The effects of verapamil and flecainide were described.

EDRF release from the coronary vascular bed

Lamontagne et al. (1992) isolated platelets from blood of healthy human donors and injected platelets boluses into the perfusion line of the Langendorff preparation of a rabbit heart. In the effluent cyclic GMP was determined as an index for EDRF release.

A.3.1.3 Coronary artery ligation in isolated working rat heart

PURPOSE AND RATIONALE

In working heart preparations of rats, ischemia can be induced by clamping the left coronary artery close to its origin. After removal of the clip, changes in the reperfusion period can be observed. Prevention of these symptoms can be an indicator of the efficacy of coronary drugs.

PROCEDURE

The preparation used is a modification of an isolated working heart preparation originally used for guinea pig hearts (Bardenheuer and Schrader 1983). Wistar rats of either sex weighing 280–300 g are sacrificed by decapitation. The hearts are removed and dissected free from the epicard and surrounding connective tissue. A cannula is introduced into the aorta from where the coronary vessels are perfused with the non-recirculated perfusion medium according to the Langendorff technique. In the left ventricle a balloon closely fitting the ventricular cavity is placed and connected to an artificial systemic circulation. The fluid in the balloon is pumped through a cannula into the closed extra corporal circulation being forced into one direction by 2 recoil valves. The balloon is made of silicone material using a Teflon form (Linz et al. 1986). The dimensions of the form are derived from casts of the left ventricle of K^+-arrested heart by injection of dental cement (Pala-vit 55®, Kulzer and Co, GmbH, Germany). During each heart beat the fluid volume pressed from the balloon, corresponding to the stroke volume of the heart, can be recorded by means of a flow meter probe and an integrator connected in series. Preload and afterload can be adjusted independently from each other. The per-fusate flow (retrograde into the aorta and through the coronary arteries) is recorded separately.

The following parameters were measured in isolated rat hearts (Linz et al. 1986):

LVP (left ventricular pressure) with Statham pressure transducer P 23 DB, which on differentiation yielded LV dp/dt_{max} and HR (heart rate). Cardiac output and coronary flow (CF) are determined by electromagnetic flow probes in the outflow system and in the aortic cannula, respectively. Coronary venous pO_2 is measured with a catheter placed in the pulmonary artery by a type E 5046 electrode connected to a PMH 73 pH/blood gas monitor (Radiometer). An epicardial electrocardiogram recording is obtained via two silver electrodes attached to the heart. All parameters are recorded on a Brush 2600 recorder.

Myocardial oxygen consumption (MWO_2) [ml/min/g wet weight] is calculated according to the equation:

$$MVO_2 = CF \times (P_a - P_v) \times (c/760) \times 100$$

where CF is the coronary flow [ml/min/g], P_a is the oxygen partial pressure of arterial perfusate (650 mm Hg), P_v is the oxygen partial pressure of the venous effluent perfusate [mm Hg], and c is the 0.0227 ml O_2/ml perfusate representing the Bunsen solubility coefficient of oxygen dissolved in perfusate at 37 °C (Zander and Euler 1976).

Coronary artery ligation

For coronary artery occlusion experiment (Scholz et al. 1992, 1993), the isolated working hearts are perfused for a period of 20 min (pre-ischemic period) with modified Krebs-Henseleit buffer at a constant pressure of 65 mm Hg. Thereafter, acute myocardial ischemia is produced by clamping the left coronary artery close to is origin for 15 min (ischemic period). The clip is then reopened, and changes during reperfusion are moni-

tored for 30 min (reperfusion period). After coronary artery ligation and reperfusion the hearts develop ventricular fibrillation.

From the coronary effluent samples are taken for lactate, lactate dehydrogenase (LDH), and creatine kinase (CK) determinations. After the experiment, glycogen, lactate, ATP, and creatine phosphate in myocardial tissue are measured.

The test drugs are given into the perfusion medium either before occlusion or 5 min before reperfusion. For *ex vivo* studies, the rats are treated orally with the test drug 1 h before sacrifice and preparation of the isolated working heart.

EVALUATION

The incidence and duration of ventricular fibrillation after treatment with coronary drugs is compared with controls. Left ventricular pressure, LV *dP/dt* max, and coronary flow are reduced after coronary constriction by angiotensin II, whereas enzyme activities in the effluent are increased and the myocardial content of glycogen, ATP and creatine phosphate are decreased. Cardiac protective drugs have the opposite effects. The values of each parameter are statistically compared with controls.

MODIFICATIONS OF THE METHOD

Vogel and Lucchesi (1980) described an isolated, blood perfused, **feline** heart preparation for evaluating pharmacological interventions during myocardial ischemia. Ventricular function was measured with a fluid-filled latex balloon within the left ventricle.

Vleeming et al. (1989) ligated the left coronary artery in rats after thoracotomy in ether anesthesia. Forty-eight hours after the operation, the hearts were prepared for retrograde constant pressure perfusion, according to the Langendorff technique.

Igic (1996) presented a new method for the isolated working rat heart. A special double cannula was designed consisting of an outer cannula that is inserted in the aorta and an inner cannula that is advanced into the left ventricle. The perfusion fluid flows through the inner cannula into the left ventricle, and is ejected from there into the aorta. If the outer cannula system is closed, the fluid perfuses the coronary vessels and drips off outside the heart. When the outer cannula is open and certain pressure resistance is applied, a fraction of the ejected fluid perfuses the coronary vessels and the rest is expelled. Because the inner cannula can easily be retracted into the outer cannula, which is placed in the aorta, this preparation provides an opportunity to use the same heart as a "working" or "non-working" model for investigating functions of the heart.

Pepe and McLennan (1993) described a maintained afterload model of ischemia in erythrocyte-perfused isolated working hearts of rats.

Further characterization of the pathophysiological reactions or the isolated working heart was performed by Linz et al. (1999). The external heart power (EHP) [mJ/min/g] was calculated using the formula:

$$EHP_{LV} = \text{pressure} - \text{volume work} + \text{acceleration work}$$

$$= \{[SV\,(MAP - LAP)] + [1/2\,SV \times d \times (SV/\pi\, r^2\, e^2)]\}\, HR\, g_{LVwwt}{}^{-1}$$

SV indicates stroke volume; *MAP*, mean aortic pressure; *LAP*, mean left arterial pressure; *d*, specific weight perfusate (1.004 g/cm^3); *r*, inner radius of aortic cannula; *e*, ejection time; *HR*, heart rate; LV, left ventricle; LVwwt, left ventricular wet weight.

The function of the left ventricle was altered by changing the aortic pressure (afterload) at constant left atrial filling load (preload). By adjusting the Starling resistance, the aortic outflow could be switched during 1 min from the fixed baseline afterload to a preset higher afterload producing step-wise rises in mean arterial pressure.

Lee et al. (1988) studied the effects of acute global ischemia on cytosolic calcium transients in perfused isolated **rabbit** hearts with the fluorescent calcium indicator indo 1. Indo 1-loaded hearts were illuminated at 360 nm, and fluorescence was recorded simultaneously at 400 and 550 nm from the epicardial surface of the left ventricle. The F_{400}/F_{550} ratio was calculated by an analog circuit, which allowed cancellation of optical motion artifact. The resulting calcium transients were registered simultaneously with the ventricular pressure and demonstrated a rapid upstroke and slow decay similar to those recorded in isolated ventricular myocytes. Global ischemia rapidly suppressed contraction, but it produced a concurrent increase in the systolic and diastolic levels of calcium transients, together with an increase in the duration of the peak.

A.3.1.4
Relaxation of bovine coronary artery

PURPOSE AND RATIONALE

Eicosanoids can regulate the tonus of coronary arteries. Prostacyclin induces relaxation, whereas thromboxane A_2 causes contraction. Spiral strips from bovine coronary artery can be used for assaying relaxation activity of test compounds (Dusting et al. 1977)

PROCEDURE

Freshly slaughtered beef hearts are immersed in cold oxygenated Krebs solution and immediately transported in a thermos flask to the laboratory. The left descending coronary artery and several of its primary branches are cut into spiral strips (about 20 mm long and 2–3 mm wide). The specimens can be stored up to 48 h at 4 °C. The artery strips are suspended in a 4 ml organ bath under an initial tension of 2 g and immersed in a Krebs' bicarbonate solution at 37 °C being gassed with oxygen containing 5% CO_2 throughout the experiment. The Krebs solution contains a mixture of antagonists to inhibit any actions from endogenous acetylcholine, 5-hydroxytryptamine, histamine or catecholamines (hyoscine hydro-bromide 10^{-7} g/ml, methysergide maleate 2×10^{-7} g/ml, mepyramine maleate 10^{-7} g/ml, propranolol hydrochloride 2×10^{-6} g/ml). The strips are superfused with a solution of the test compounds in concentrations of 0.01, 0.1, 1.0 µg/ml at a rate of 10–20 ml/min with oxygenated Krebs solution containing the mixture of antagonists. Isometric contractions are recorded with Grass force-displacement transducers (type FT 03 C) on a Grass polygraph. The strips are superfused with Krebs' solution 3 h prior to the experiment. Standard compounds are 100 ng/ml PGE_2 inducing contraction and 100 ng/ml PGI_2 inducing pronounced relaxation.

EVALUATION

The relaxation induced by the test compound is expressed as percentage of maximal response to 100 ng/ml PGI_2.

MODIFICATIONS OF THE METHOD

Campell and Paul (1993) measured the effects of diltiazem on isometric force generation, $[Ca^{2+}]_i$, and energy metabolism in the isolated **porcine** coronary artery.

Li et al. (1997) determined the ability of analogues of human α-calcitonin gene-related peptide to relax isolated porcine coronary arteries precontracted with 20 mM KCl.

A.3.2 *In vivo* methods

A.3.2.1 Isoproterenol induced myocardial necrosis in rats

PURPOSE AND RATIONALE

Cardiac necrosis can be produced by injection of natural and synthetic sympathomimetics in high doses. Infarct-like myocardial lesions in the rat by isoproterenol have been described by Rona et al. (1959). These lesions can be totally or partially prevented by several drugs such as sympatholytics or calcium-antagonists.

PROCEDURE

Groups of 10 male Wistar rats weighing 150–200 g are pretreated with the test drug or the standard either s.c. or orally for 1 week. Then, they receive 5.25 and 8.5 mg/kg isoproterenol s.c. on two consecutive days. Symptoms and mortality in each group are recorded and compared with those of rats given isoproterenol alone. Forty-eight hours after the first isoproterenol administration, the rats are sacrificed and autopsied. The hearts are removed and weighed, and frontal sections are embedded for histological examination.

EVALUATION

Microscopic examination allows the following grading:

Grade 0: no change
Grade 1: focal interstitial response
Grade 2: focal lesions in many sections, consisting of mottled staining and fragmentation of muscle fibres
Grade 3: confluent retrogressive lesions with hyaline necrosis and fragmentation of muscle fibres and sequestrating mucoid edema
Grade 4: massive infarct with occasionally acute aneurysm and mural thrombi

For each group the main grade is calculated with the standard deviation to reveal significant differences.

CRITICAL ASSESSMENT OF THE METHOD

The test has been used by many authors for evaluation of coronary active drugs, such as calcium-antagonists and other cardioprotective drugs like nitroglycerin and molsidomine (Vértesy et al. 1991; Classen et al. 1993).

MODIFICATIONS OF THE METHOD

Yang et al. (1996) reported a protective effect of human adrenomedullin[13–52], a C-terminal fragment of adrenomedullin[10–52] on the myocardial injury produced by subcutaneous injection of isoproterenol into rats.

A.3.2.2 Myocardial infarction after coronary ligation

PURPOSE AND RATIONALE

Ligation of the left coronary artery in rats as described by Selye (1960) induces an acute reduction in pump function and a dilatation of left ventricular chamber. The method has been used to evaluate beneficial effects of drugs after acute (Chiariello et al. 1980; Flaim and Zelis 1981; Bernauer 1985) or chronic (Innes and Weisman 1981; Pfeffer et al. 1985; Linz et al. 1996) treatment.

PROCEDURE

Male Sprague Dawley rats weighing 200–300 g are anesthetized with diethyl-ether. The chest is opened by a left thoracotomy, and a thread is inserted near the middle of the lateral margin of the cutaneous wound and carried through a tunnel of the left pectoral muscle around the cranial half of the incision. The heart is gently exteriorized by pressure on the abdomen. A ligature is placed around the left coronary artery, near its origin, and is tightened. Within seconds, the heart is repositioned in the thoracic cavity, and the ends of the musculocutaneous thread are tightened to close the chest wall and enable the animal to breathe spontaneously. The speed of the procedure renders mechanical respiration unnecessary.

To evaluate drug effects, the rats are treated 5 min after and 24 h after occlusion by subcutaneous injection (standard 5 mg/kg propranolol).

Two days after surgery, the rats are anesthetized with 60 mg/kg i.p. pentobarbital and the right carotid artery is cannulated with a polyethylene catheter connected to a pressure transducer. The fluid-filled catheter is then advanced into the left ventricle through the aortic valve for measurement of left ventricular systolic and end-diastolic pressure.

After hemodynamic measurements, the heart is arrested by injecting 2 ml of 2.5 M potassium chloride. The chest is opened, and the hearts are isolated and rinsed with 300 mM KCl to maintain a complete diastole. A double-lumen catheter is advanced into the left ventricle through the ascending aorta, the right and left atria are tied off with a ligature, and the right ventricle is opened. The left ventricular chamber is filled with a cryostatic freeze medium through the smaller of the two catheter lumens and connected to a hydrostatic pressure reservoir maintained at a level corresponding to the end-diastolic pressure measured *in vivo*. The outlet (larger lumen) is then raised to the same level as the inlet to allow fluid in the two lumens to equilibrate. The heart is rapidly frozen with hexane and dry-ice.

The hearts are serially cut with a cryostat into 40-µm-thick transverse sections perpendicularly to the longitudinal axis from apex to base. At a fixed distance, eight sections are obtained from each heart and collected on gelatin-coated glass slides. Sections are air-dried and incubated at 25 °C for 30 min with 490 µM nitroblue tetrazolium and 50 mM succinic acid in 0.2 M phosphate buffer (pH 7.6), rinsed in cold distilled water, dehydrated in 95% ethyl alcohol, cleared in xylene, and mounted with a synthetic resin medium. Viable tissue appears dark blue, contrasting with the unstained necrotic tissue.

EVALUATION

The infarct size can be determined by planimetry and expressed as percentage of left ventricular area, and thickness can be expressed as percentage of non-infarcted ventricular wall thickness (MacLean et al. 1978; Chiariello 1980; Roberts et al. 1983). An automatic method for morphometric analysis with image acquisition and computer processing was described by Porzio et al. (1995).

CRITICAL ASSESSMENT OF THE METHOD

Hearse et al. (1988) challenged the value of the model of coronary ligation in the rat because of inappropriate interpretations.

MODIFICATIONS OF THE METHOD

Johns and Olson (1954) described the coronary artery patterns for mouse, rat, hamster and guinea pig.

Kaufman et al. (1959), Fishbein et al. (1978, 1980) used various histochemical methods for identification and quantification of border zones during the evolution of myocardial infarction.

Ytrehus et al. (1994) analyzed the effects of anesthesia, perfusate, risk zone, and method of infarct sizing in rat and rabbit heart infarction.

Scholz et al. (1995) described a dose-dependent reduction of myocardial infarct size in rabbits by a selective sodium-hydrogen exchange subtype 1 inhibitor.

Chiariello et al. (1976) compared the effects of nitroprusside and nitroglycerin on ischemic injury during acute myocardial infarction in dogs.

Leprán et al. (1981) placed a loose ligature of atraumatic silk around the left anterior descending coronary artery under ether anesthesia in rats. Ten days later, acute myocardial infarction was produced by tightening the ligature.

Gomoll and Lekich (1990) discussed the use of the ferret for a myocardial ischemia/salvage model.

Holmborn et al. (1993) compared triphenyltetrazolium chloride staining versus detection of fibronectin in experimental myocardial infarction in pigs.

Michael et al. (1995) described in detail the surgical procedure to induce myocardial ischemia in mice by ligation of the left anterior descending branch of the left coronary artery.

Kouchi et al. (2000) found an increase in $G_{i\alpha}$ protein accompanying progression of post-infarction remodelling in hypertensive cardiomyopathy in rats. G protein α subunits were studied with immuno-blotting techniques (Böhm et al. 1990). The polyclonal antiserum MB1 was raised in rabbits against the carboxyl-terminal decapeptide of retinal transduction (KENLKDCGLF) coupled to keyhole limpet hemocyanine. The MB1 recognized $G_{i\alpha1}$ and $G_{i\alpha2}$ but not $G_{0\alpha}$ and $G_{i\alpha3}$ (Böhm et al. 1994). The membrane fractions were electrophoresed in SDS-polyacrylamide gels and were transferred to nitrocellulose filters. The filters were incubated with the first antibodies for $G_{i\alpha}$ (MB1) or $G_{s\alpha}$ (RM/1) and then with the second antibody (horseradish peroxidase-conjugated goat anti-rabbit IgG, Amersham). Immunoreactive signals were detected by means of the ECL kit (Amersham).

A.3.2.3 Occlusion of coronary artery in anesthetized dogs

PURPOSE AND RATIONALE

The size of infarcts is studied after proximal occlusion of the left anterior descending coronary artery in open-chest dogs. Compounds potentially reducing infarct-size are tested. To delineate the post-mortem area at risk, coronary arteriograms are made after injection of a $BaSO_4$-gelatin mass into the left coronary ostium. The infarct's area is visualized with nitro-blue tetrazolium chloride in myocardial sections.

PROCEDURE

Dogs of either sex weighing approximately 30 kg are used. The animals are anesthetized by intravenous injection of pentobarbital sodium (bolus of 35 mg/kg followed by continuous infusion of 4 mg/kg/h). The animals are placed in the right lateral position. Respiration is maintained through a tracheal tube using a positive pressure respirator. Arterial blood gases are checked, and the ventilation rate and/or oxygen flow rate are adjusted to achieve physiological blood gas values (P_{O2}: 100–140 mm Hg, P_{CO2}: 32–40 mm Hg, and pH 7.47). A peripheral vein (saphenous vein) is cannulated for the administration of test compound. The ECG is recorded continuously from lead II (Einthoven).

Preparation for hemodynamic measurements

For recording of peripheral systolic and diastolic blood pressure, the cannula of a femoral vein is connected to a pressure transducer (Statham P 23 DB). For determination of left ventricular pressure (LVP), a Millar microtip catheter (PC 350) is inserted via the left carotid artery. Left ventricular enddiastolic pressure (LVEDP) is measured from a high-sensitivity scale. From the pressure curve, *dp*/*dt* max is differentiated and heart rate is counted.

Experimental procedure

The heart is exposed through a left thoracotomy between the fourth and fifth intercostal space, the pericard is opened and the left anterior descending coronary artery (LAD) is exposed. After reaching steady state conditions for the hemodynamic parameters (approx. 45 min), the LAD is ligated just below the first diagonal branch for 360 min. No attempt is made to suppress arrhythmic activity after the ligation.

The test substance or the vehicle (controls) is administered by intravenous bolus injection and/or continuous infusion. The schedule of administration may vary. Hemodynamic parameters are registered continuously during the whole experiment. At the end of the experiment, the animals are sacrificed with an overdose of pentobarbital sodium and the heart is dissected.

Preparation to determine area at risk

Coronary arteriograms are made according to Schaper et al. (1979) to delineate the anatomic post-mortem area at risk. A purse-string suture is placed around the left coronary ostium in the sinus of Valsalva; a cannula is then placed in the ostium and the purse-string suture is tightened. Micronized $BaSO_4$ suspended in 12% gelatin solution (37 °C) is injected under increasing pressure (2 min at 100 mm Hg, 2 min at 150 mm Hg and 2 min at 200 mm Hg). The heart is placed in crushed ice to gel the injectate. The right ventricle is removed and the left ventricle plus septum is cut into transverse sections (approx. 1 cm thick) from the apex to the level of the occlusion (near the base). From each slice angiograms are made with a X-ray tube at 40 kV to assess the post-mortem area at risk (by defect opacity: reduction of $BaSO_4$-filled vessels in infarct tissue).

Preparation to determine infarct size

The slices are then incubated in p-nitro-blue tetrazolium solution (0.25 g/L in Sörensen phosphate buffer, pH 7.4, containing 100 mM D,L-maleate) in order to visualize the infarct tissue (blue/violet-stained healthy tissue, unstained necrotic tissue). The slices are photographed on color transparency film for the determination of the infarct area.

Left ventricle and infarct area, and area at risk are measured by planimetry from projections of all slices with the exclusion of the apex and of the slice containing the ligature.

EVALUATION

Mortality and the different hemodynamic parameters are determined. Changes of parameters in drug-treated animals are compared to vehicle controls. The different characteristics are evaluated separately. Mean values ±SEM of infarct area and of area at risk are calculated. Statistical analyses consist of regression and correlation analyses and of the Student's *t*-test. Results are considered significant at $p < 0.05$.

MODIFICATIONS OF THE METHOD

Nachlas and Shnitka (1963) described the macroscopic identification of early myocardial infarcts by alterations in dehydrogenase activity in dogs by staining the cardiac tissue with Nitro-BT [2,2'-di-p-nitrophenyl-5,5'diphenyl-3,3'-(3,3'-dimethoxy-4,4'-biphenylene) ditetrazolium chloride] yielding a dark blue formazan in viable muscle but not in necrotic muscle fibers.

Black et al. (1995) studied the cardioprotective effects of heparin or N-acetylheparin in an *in vivo* dog model of myocardial and ischemic reperfusion injury.

The hearts were removed after 90 min of coronary occlusion and a 6 h-reperfusion period. Area at risk was determined by the absence of Evans blue dye after perfusion of the aorta in a retrograde fashion and infarct zone by the absence of formazan pigment within the area at risk after perfusion of the circumflex coronary artery with triphenyltetrazolium chloride.

Reimer et al. (1985) tested the effect of drugs to protect ischemic myocardium in unconscious and conscious dogs. In the conscious model, dogs of either sex weighing 10–25 kg were anesthetized with thiamyal sodium (30–40 mg/kg i.v.) and underwent thoracotomy through the 4th intercostal space. Heparin-filled polyvinyl chloride catheters were positioned in the aortic root, the left atrium via the left atrial appendage, and a systemic vein. A mechanical adjustable snare type occluder was placed around the proximal left circumflex coronary artery above or below the first marginal branch, so that temporary occlusion resulted in cyanosis of at least 75% of the inferior wall. The catheters and snare were either exteriorized or positioned in a subcutaneous pocket at the back of the neck. Penicillin, 1 000 000 units, and streptomycin, 1.0 g, were given i.m. for the first 4 postoperative days, and at least 7 days were allowed for recovery from surgery.

Dogs were fasted overnight prior to the study. After exteriorization and flushing of the catheters, 30–40 min were allowed for the animals to adjust to laboratory conditions. Morphine sulfate, 0.25 mg/kg, i.m., was given 30 min before occlusion, and an additional 0.25 mg/kg, i.v., was given 20 min later. Heart rate and aortic and left atrial pressures were monitored continuously. Permanent coronary occlusion was produced by a sudden one-stage tightening of the snare occluder. Drugs were administered by continuous i.v. infusion over 6 h. Hemodynamic measurements were taken 5 min before occlusion and 10, 25, 105, 180, and 360 min after occlusion.

Raberger et al. (1986) described a model of **transient myocardial dysfunction in conscious dogs**. Mongrel dogs, trained to run on a treadmill, were chronically instrumented with a miniature pressure transducer in the left ventricle and a hydraulic occluder placed around the circumflex branch of the left coronary artery. Two pairs of piecoelectrical crystals for sonomicrometry were implanted subendocardially to measure regional myocardial functions. Comparable episodes of regional dysfunction of the left coronary artery area during treadmill runs were found after partial left coronary artery stenosis induced by external filling of the occluder.

Hartman and Warltier (1990) described a model of **multivessel coronary artery disease** using conscious, chronically instrumented dogs. A hydraulic occluder was implanted around the left anterior descending coronary artery (LAD) and an Ameroid constrictor around the left circumflex coronary artery (LCCA). Pairs of piecoelectric crystals were implanted within the subendocardium of the LAD and LCCA perfusion territories to measure regional contractile function. A catheter was placed in the left atrial appendage for injection of radioactive microspheres to measure regional myocardial perfusion. Bolus injections of adenosine were administered daily via the left atrium to evaluate LAD and LCCA coronary reserve. After stenosis by the Ameroid constrictor, radioactive microspheres were administered to compare regional perfusion within normal myocardium to flow in myocardium supplied by the occluded or stenotic coronary arteries.

Johns and Olson (1954) described a method of experimental **myocardial infarction by coronary occlusion in small animals**, such as **mouse**, **hamster**, **rat** and **guinea pig**.

Sakai et al. (1981) described an **experimental model of angina pectoris in the intact anesthetized rat**. In anesthetized rats the tip of a special carotid cannula was placed closely to the right and left coronary ostium. Single intra-aortic injections of methacholine or acetylcholine (in the presence of physostigmine) developed a reproducible elevation of the ST segment and the T wave of the electrocardiogram. Coronary drugs were tested to prevent these changes.

Gomoll and Lekich (1990) tested the **ferret** for a myocardial ischemia/salvage model. Varying combinations of duration of left anterior descending coronary occlusion and reperfusion were evaluated.

Klein et al. (1995) used intact **pigs** and found myocardial protection by Na^+/H^+ exchange inhibition in ischemic reperfused hearts.

Klein et al. (1997) measured the time delay of cell death by Na^+/H^+ exchange inhibition in regionally ischemic, reperfused **porcine** hearts.

Garcia-Dorado et al. (1997) determined the effect of Na^+/H^+ exchange blockade in ischemic rigor contracture and reperfusion-induced hypercontracture in *pigs* submitted to 55 min of coronary occlusion and 5 h reperfusion. Myocardial segment length analysis with ultrasonic microcristals was used to detect ischemic rigor (reduction in passive segment length change) and hypercontracture (reduction in end-diastolic length).

Symons et al. (1998) tested the attenuation of regional dysfunction in response to 25 cycles of ischemia (2 min) and reperfusion (8 min) of the left circumflex coronary artery in **conscious swine** after administration of a Na^+/H^+ exchange inhibitor. The animals were instrumented to measure arterial blood pressure, regional myocardial blood flow (colored microspheres), systolic wall thickening in the normally perfused left anterior descending and left circumflex coronary artery regions (sonomicrometry), left circumflex coronary artery blood flow velocity (Doppler) and reversibility to occlude the left circumflex coronary artery (hydraulic occluder).

A.3.2.4
Acute ischemia by injection of microspheres in dogs

PURPOSE AND RATIONALE

Severe left ventricular failure is induced by repeated injections of 50 µm plastic microspheres into the left main coronary artery of anesthetized dogs. Hemodynamic measurements are performed under theses conditions testing drugs which potentially improve cardiac performance. The test can be used to evaluate the influence of drugs on myocardial performance during acute ischemic left ventricular failure in dogs.

PROCEDURE

Dogs of either sex weighing approximately 30 kg are anesthetized by an intravenous bolus injection of 35–40 mg/kg pentobarbital sodium continued by an infusion of 4 mg/kg/h. The animals are placed in the right lateral position. Respiration is maintained through a tracheal tube using a positive pressure respirator and controlled by measuring end-expiratory CO_2 concentration as well as blood gases. Two peripheral veins are cannulated for the administration of narcotic (brachial vein) and test compounds (saphenous vein). The ECG is recorded continuously in lead II (Einthoven).

Preparation for hemodynamic measurements

For recording of peripheral systolic and diastolic blood pressure, the cannula of the right femoral vein is connected to a pressure transducer (Statham P 23 DB). For determination of left ventricular pressure (LVP), a Millar microtip catheter (Gould PC 350) is inserted via the left carotid artery. Left ventricular enddiastolic pressure (LVEDP) is measured on a high-sensitivity scale. From the pressure curve, *dp*/*dt* max is differentiated and heart rate (HR) is counted. To measure right ventricular pressure, a Millar microtip catheter is inserted via the right femoral vein. Systolic, diastolic and mean pulmonary artery pressure (PAP), mean pulmonary capillary pressure, and cardiac output are measured by a thermodilution technique using a Cardiac Index Computer (Gould SP 1435) and a balloon-tip triple lumen catheter (Gould SP 5105, 5F) with the thermistor positioned in the pulmonary artery via the jugular vein.

The heart is exposed through a left thoracotomy between the fourth and fifth intercostal space, the pericard is opened and the left circumflex coronary artery (LCX) is exposed. To measure coronary blood flow, an electromagnetic flow probe (Hellige Recomed) is placed on the proximal part of the LCX.

Polystyrol microspheres (3M Company, St. Paul, Minnesota, USA) with a diameter of 52.5 ±2.24 µm

are diluted with dextran 70, 60 mg/ml and saline at a concentration of 1 mg microspheres/ml (1 mg = approx. 12 000 beads). For administration of microspheres, an angiogram catheter (Judkins-Schmidt Femoral-Torque, William Cook, Europe Aps. BP 7) is inserted into the left ostium via the left femoral artery.

Induction of failure

The microspheres are injected through the angiogram catheter into the left ostium initially as 10 ml and later as 5 ml boluses about 5 min apart. The microsphere injections produce stepwise elevations of LVEDP. Embolization is terminated when LVEDP has increased to 16–18 mm Hg and/or PAPm has increased to 20 mm Hg and/or heart rate has reached 200 beats/min. The embolization is completed in about 70 min and by injection of an average dose of 3–5 mg/kg microspheres. Hemodynamic variables are allowed to stabilize after coronary embolization for at least 30 min.

Experimental course

The test substance or the vehicle (controls) is then administered by intravenous bolus injection or continuous infusion, or by intraduodenal application.

Recordings are obtained

- before embolization
- after embolization
- before administration of test compound
- 5, 30, 45, 60, 90, 120 and, eventually, 150 and 180 min following administration of test drug. At the end of the experiment, the animal is sacrificed by an overdose of pentobarbital sodium.

EVALUATION

Besides the different directly measured hemodynamic parameters, the following data are calculated according to the respective formula:

stroke volume [ml/s],

$$SV = \frac{\text{cardiac output}}{\text{heart rate}}$$

tension index [mm Hg s],

$$IT = \frac{BPs \times \text{heart rate}}{1\,000}$$

Coronary vascular resistance [mm Hg min/ml],

$$CVR = \frac{BPm \times RAPm}{CBF}$$

total peripheral resistance [dyn s/cm^5],

$$TPR = \frac{BPm - RAPm}{\text{cardiac output}} \times 79.9$$

Pulmonary artery resistance [dyn s/cm^5],

$$PAR = \frac{PAPm - PCPm}{\text{cardiac output}} \times 79.9$$

right ventricle work [kg m/min],

$$\text{RVW} = (PAPm - RAPm) \times \text{cardiac output} \times 0.0136$$

left ventricle work [kg m/min],

$$LVW = (BPm - LVEDP) \times \text{cardiac output} \times 0.0136$$

left ventricular myocardial oxygen consumption [ml O_2/min/100 g],

$$MVO_2 = K_1(BPs \times HR) + K_2 \frac{(0.8BPs + 0.2BPd) \times HR \times SV}{BW} + 1.43$$

K_1 = 4.08×10^{-4}
K_2 = 3.25×10^{-4}
BPs = systolic blood pressure [mm Hg]
BPd = diastolic blood pressure [mm Hg]
BPm = mean blood pressure [mm Hg]
CBF = coronary blood flow in left circumflex coronary artery [ml/min]
RAPm = mean right atrial pressure [mm Hg]
PAPm = mean blood pressure A. pulmonalis [mm Hg]
PCPm = mean pulmonary capillary pressure
HR = heart rate [beats/min]
SV = stroke volume [ml]
BW = body weight [kg]

Changes of parameters in drug-treated animals are compared to vehicle controls; statistical significance of the differences is calculated with the Student's *t*-test.

Mean embolization times, doses of microspheres and number of microsphere applications are evaluated.

MODIFICATIONS OF THE METHOD

Gorodetskaya et al. (1990) described a simple method to produce acute heart failure by coronary vessel embolization with microspheres in rats.

A.3.2.5 Influence on myocardial preconditioning

PURPOSE AND RATIONALE

Damage to the mammalian heart produced by prolonged ischemia and reperfusion can be reduced by "preconditioning" the myocardium via a brief cycle of ischemia and reperfusion prior to the protracted ischemic event. Ischemic preconditioning has been shown to decrease infarct size and increase recovery of post-ischemic ventricular function (Murray et al. 1986), and to reduce leakage of cellular marker proteins indicative for cardiac myocyte death (Volovsek et al. 1992). In addition, preliminary preconditioning also attenuates cardiac arrhythmia associated with subsequent occlusion and reperfusion (Vegh et al. 1990).

The mechanistic basis of this phenomenon is under discussion (Parratt 1994; Parratt and Vegh 1994). Adenosine receptor involvement in myocardial protection after ischemic preconditioning in rabbits has been shown by Baxter et al. (1994). Adenosine (A_1 receptor) antagonists have been demonstrated to block the protection produced by preconditioning (Liu et al. 1991), and short term administration of adenosine was shown to simulate the protective effects of ischemic preconditioning (Toombs et al. 1993). These observations together suggest that adenosine is generated by the short preconditioning ischemia. Other recent pharmacological studies (Gross and Auchampach 1992; Yao and Gross 1994) indicate the involvement of the ATP-sensitive potassium channel. Recent investigations indicate that an increase of NO production after ACE inhibitors may be a part of the protective mechanism (Linz et al. 1992, 1994). Moreover, the involvement of prostanoids and bradykinin in the preconditioning process has been discussed (Wiemer et al. 1991). Gho et al. (1994) found a limitation of myocardial infarct size in the rat by transient renal ischemia, supporting the hypothesis that the mechanism leading to cardiac protection by ischemic preconditioning may not only reside in the heart itself.

PROCEDURE

New Zealand rabbits of either sex weighing 2.5–3.5 kg are initially anesthetized with an intramuscular injection of ketamine (50 mg/ml) /xylazine (10 mg/ml) solution at a dose of 0.6 ml per kg body weight. A tracheotomy is performed to facilitate artificial respiration. The left external jugular vein is cannulated to permit a constant infusion (0.15–0.25 ml/min) of xylazine (2 mg/ml in heparinized saline) to assist in maintaining anesthesia and fluid volume. Anesthesia is also maintained by i.m. injections (0.4–0.6 ml) of ketamine (80 mg/ml) and xylazine (5 mg/ml) solution. After the xylazine infusion is started, animals are respired with room air at a tidal volume of 10 ml/kg and a frequency of 30 inflations per min (Harvard Apparatus, USA). Thereafter, ventilation is adjusted or inspiratory room air is supplemented (5% CO_2/95% O_2) to maintain arterial blood chemistry within the following ranges: pH 7.35–7.45, P_{CO2} 25–45 mm Hg, P_{O2} 90–135 mm Hg. The right femoral artery and vein are isolated and catheterized for measurement of arterial pressure and administration of drugs, respectively.

A thoracotomy is performed in the fourth intercostal space, and the lungs are retracted to expose the heart. The pericardium is cut to expose the left ventricle, and a solid-state pressure transducer catheter (e.g., MicroTip 3F, Millar Instruments, Houston, USA) is inserted through an apical incision and secured to enable measurement of pulsatile left ventricular pressure. The maximal rate of increase in left ventricular pressure (LV*dP*/*dt* max) is determined by electronic differentiation of the left ventricular pressure wave form. A segment of 4-0 prolene suture is looped loosely around a marginal branch of the left main coronary artery to facilitate coronary occlusion during the experiment. Needle electrodes are inserted subcutaneously in a lead II configuration to enable recording of an ECG in order to determine heart rate and help confirm the occurrence of ischemia (ST segment elevation) and reperfusion of the myocardium distal to the coronary occlusion. Continuous recording of pulsatile pressure, ECG, heart rate, and LV*dP*/*dt* are simultaneously displayed on a polygraph (e.g. Gould chart recorder, Gould Inc., Valley View, USA) and digitized in real time by a personal computer. Hemodynamic data are condensed for summary and later statistical analysis.

Ischemic preconditioning is induced by tightening the prolene loop around the coronary artery for 5 min and then loosening to reperfuse the affected myocardium for 10 min prior to a subsequent 30 min occlusion. After surgical preparation, and prior to 30 min of occlusion, rabbits are randomly selected to receive

ischemic preconditioning, no preconditioning, or ischemic preconditioning plus treatment with test drugs. After 30 min of occlusion, the ligature is released and followed by 120 min of reperfusion. Occlusion is verified by epicardial cyanosis distal to the suture, which is usually accompanied by alterations in hemodynamics and ECG. Reperfusion is validated by return of original color. Systemic hemodynamics are summarized for each experimental period. The experiment is terminated after 120 min of reperfusion, and the heart is excised for determinations of infarct size and area at risk.

Immediately before the animal is sacrificed, the marginal branch of the left coronary artery is reoccluded and India ink is rapidly injected by syringe with a 18-g needle into the left ventricular chamber to demarcate blackened normal myocardium from unstained area at risk. After the rabbits are sacrificed, the heart is removed and sectioned in a breadloaf fashion from apex to base perpendicular to the long axis. The right ventricle is removed from each slice leaving only the left ventricle and septum. After each slice is weighed, the portions are washed and incubated in a phosphate buffered saline solution of triphenyl tetrazolium chloride (1 g/ml, Sigma) for 10–15 min. Salvaged myocardium in the area at risk stains brick red, whereas infarcted tissue remains unaltered in color. Slices are then placed between sheets of Plexiglas and the areas (normal, risk, infarct) of each slice are traced on a sheet of clear acetate. Traces are then digitized and analyzed using computerized planimetry to compare the relative composition of each slice with respect to normal tissue, area at risk, and infarcted myocardium. Planimetry is performed with a computerized analysis system, e.g., Quantimet 570C image analysis system (Leica, Deerfield, USA).

Surface areas of normal tissue, area at risk, and infarcted myocardium on both sides of each slide are averaged for the individual slide. The contribution of each slide to total infarcted and area at risk (%) and area at risk as a percentage of total left ventricular mass for the entire left ventricle is prorated by the weight of each slice (Garcia-Dorado et al. 1987). By adding the adjusted contributions from each slice to infarcted tissue, area at risk, and left ventricular mass, a three-dimensional mathematical representation of total myocardial infarct size and risk zone can be calculated for each rabbit, and a mean tabulated for each treatment group for statistical comparison.

EVALUATION

All data are presented as mean ±SD. Systemic hemodynamic data are analyzed by ANOVA using Statistica/W software. Means are considered significantly different at $p < 0.05$.

MODIFICATIONS OF THE METHOD

Li et al. (1990) found in dog experiments that preconditioning with one brief ischemic interval is as effective as preconditioning with multiple ischemic periods.

In contrast, Vegh et al. (1990) found in other dog experiments that two brief preconditioning periods of coronary occlusion, with an adequate period of reperfusion between, reduce the severity of arrhythmias.

Yang et al. (1996) found a second window of protection after ischemic preconditioning in conscious rabbits which minimizes both infarction and arrhythmias.

Late preconditioning against myocardial stunning in conscious pigs together with an increase of heat stress protein (HSP) 70 was described Sun et al. (1995).

Szilvassy et al. (1994) described the anti-ischemic effect induced by ventricular overdrive pacing as a conscious rabbit model of preconditioning. Rabbits were equipped with right ventricular electrode catheters for pacing and intracavital recording and polyethylene cannulae in the left ventricle and right carotid artery to measure intraventricular pressure and blood pressure. One week after surgery in conscious animals, ventricular overdrive pacing at 500 beats/min over 2, 5, or 10 min resulted in an intracavital S-T segment elevation, shortening of ventricular effective refractory period, decrease in maximum rate of pressure development and blood pressure, and increase in left ventricular end-diastolic pressure proportional to the duration of stimulus. A 5-min preconditioning ventricular overdrive pacing applied 5 or 30 min before a 10-min ventricular overdrive pacing markedly attenuated ischemic changes, whereas a 2-min ventricular overdrive pacing had no effect.

The ventricular overdrive pacing induced preconditioning effect was lost in atherosclerotic rabbits (Szilvassy et al. 1995), however, delayed cardiac protection could be induced in these animals (Szekeres et al. 1997).

A.3.3
Ex vivo methods

A.3.3.1
Plastic casts from coronary vasculature bed

PURPOSE AND RATIONALE

Prolonged administration of coronary drugs has been shown to increase the number and size of interarterial collaterals of dogs and pigs after coronary occlusion (Vineberg et al. 1962; Meesmann and Bachmann 1966). An increased rate of development of collateral arteries was observed after physical exercise in dogs (Schaper et al. 1965), as well as after chronic administration of coronary dilating drugs (Lumb and Hardy 1963). An even more effective stimulus for collateral development is an acute or gradual occlusion of one or several major coronary branches. Filling the arterial coronary bed with a plastic provides the possibility to make the collaterals visible and to quantify them (Schmidt and Schmier 1966; Kadatz 1969).

PROCEDURE

Dogs weighing 10–15 kg are anesthetized with pentobarbital sodium 30 mg/kg i.v. They are respirated artificially and the thorax is opened. After opening of the pericard, Ameroid® cuffs are placed around major coronary branches. Gradual swelling of the plastic material occludes the lumen within 3–4 weeks. The dogs are treated daily with the test drug or placebo. After 1 week recovery period they are submitted to exercise on a treadmill ergometer. After 6 weeks treatment, the animals are sacrificed, the heart removed and the coronary bed flushed with saline. The liquid plastic Araldite® is used to fill the whole coronary tree from the bulbus aortae. The aortic valves are glued together in order to prevent filling of the left ventricle. Red colored Araldite® is used to fill the arterial tree. The venous part of the coronary vasculature can be filled

with blue colored Araldite® from the venous sinus. The uniformity of the filling pressure, the filling time, and the viscosity of the material are important. Polymerization is complete after several hours. Then, the tissue is digested with 35% potassium hydroxide. The method gives stable preparations which can be preserved for a long time.

EVALUATION

Plastic casts from drug treated animals are compared with casts from dogs submitted to the same procedure without drug treatment.

CRITICAL ASSESSMENT OF THE METHOD

The procedure allows impressive demonstration of the formation of arterial collaterals. The results of post mortem Araldit® impletion agree with the functional results of experimental coronary occlusion.

MODIFICATIONS OF THE METHOD

Boor and Reynolds (1977) described a simple planimetric method for determination of left ventricular mass and necrotic myocardial mass in postmortem hearts.

A.4
Calcium uptake inhibiting activity

A.4.0.1
General considerations

Cellular calcium flux is regulated by receptor-operated and voltage-dependent channels which are sensitive to inhibition by calcium entry blockers. The term calcium antagonist was introduced by Fleckenstein (1964, 1967) when two drugs, prenylamine and verapamil, originally found as coronary dilators in the LANGENDORFF-experiment, were shown to mimic the cardiac effects of simple Ca^{2+}-withdrawal, diminishing Ca^{2+}-dependent high energy phosphate utilization, contractile force, and oxygen requirement of the beating heart without impairing the Na^+-dependent action potential parameters. These effects were clearly distinguishable from β-receptor blockade and could promptly be neutralized by elevated Ca^{2+}, β-adrenergic catecholamines, or cardiac glycosides, measures that restore the Ca^{2+} supply to the contractile system. In the following years many Ca^{2+}-antagonists were introduced to therapy. Specific Ca^{2+}-antagonists interfere with the uptake of Ca^{2+} into the myocardium and prevent myocardial necrotization arising from deleterious intracellular Ca^{2+} overload. They act basically as specific inhibitors of the slow transsarcolemnal Ca^{2+} influx but do not or only slightly affect the fast Na^+ current that initiates normal myocardial excitation.

Calcium channels and the sites of action of drugs modifying channel function have been classified (Bean 1989; Porzig 1990; Tsien and Tsien 1990; Spedding and Paoletti 1992). Four main types of voltage dependent calcium channels are described:

1. L type (for long lasting),
2. T type (for transient),
3. N type (for neuronal), and
4. P type (for Purkinje cells).

They differ not only by their function (Dolphin 1991) and localization in tissues and cells but also by their sensitivity to pharmacological agents (Ferrante and Triggle 1990; Dascal 1990; Kitamura et al. 1997) and by their specificity to radioligands.

The widely distributed L-type channels exist in isoforms (L1, 2, 3, 4) and consist of several subunits, known as α_1, α_2, β, γ, δ. They are sensitive to dihydropyridines, phenylalkylamines or benzothia-zepines, but insensitive to ω-conotoxin and ω-agatoxin. The segments required for antagonist binding have been analyzed (Peterson et al. (1996, Schuster et al. 1996; Mit-

terdorfer et al. 1996; Hockerman et al. 1997; Striessnig et al. 1998; Catterall 1998).

The T-type channels are located mainly in the cardiac sinoatrial node and have different electrophysiological characteristics from L-type channels (Massie 1997; Perez-Reyes et al. 1998).

N- and P-type calcium channels blockers occur in neuronal cells and are involved in neurotransmitter release (Olivera et al. 1987; Bertolino and Llinás 1992; Mintz et al. 1992; Woppmann et al. 1994; Diversé-Pierluissi et al. 1995; Miljanich and Ramachandran 1995; Fisher and Bourque 1996; Ikeda 1996; Ertel et al. 1997; Sinnegger et al. 1997).

A.4.1 *In vitro* methods

A.4.1.1 ^{3}H-nitrendipine binding *in vitro*

PURPOSE AND RATIONALE

Radiolabeled dihydropyridine calcium channel antagonists such as ^{3}H-nitrendipine are selective ligands for a drug receptor site associated with the voltage-dependent calcium channel. A constant concentration of the radioligand ^{3}H-nitrendipine (0.3–0.4 nM) is incubated with increasing concentrations of a non-labeled test drug (0.1 nM–1 mM) in the presence of plasma membranes from bovine cerebral cortices. If the test drug exhibits any affinity to calcium channels, it is able to compete with the radioligand for channel binding sites. Thus, the lower the concentration range of the test drug, in which the competition reaction occurs, the more potent is the test drug.

PROCEDURE

Materials and solutions:

Preparation buffer	Tris-HCl pH 7.4	50 mM
Incubation buffer	Tris-HCl Genapol pH 7.4	50 mM 0.001%
Radioligand	^{3}H-nitrendipine Specific activity 2.59–3.22 TBq/mmol (70–87 Ci/mmol) (NEN)	
For inhibition of ^{3}H-ni-trendipine binding in non-specific binding experiments	Nifedipine (Sigma)	

Two freshly-slaughtered bovine brains are obtained from the slaughter house and placed in ice-cold preparation buffer. In the laboratory, approx. 5 g wet weight of the two frontal cerebral cortices are separated from the brains.

Membrane preparation

The tissue is homogenized (glass Teflon potter) in ice-cold preparation buffer, corresponding to 1 g cerebral wet weight/50 ml buffer, and centrifuged at 48 000 *g* (4 °C) for 10 min. The resulting pellets are resuspended in approx. 270 ml preparation buffer, and the homogenate is centrifuged as before. The final pellets are dissolved in preparation buffer, corresponding to 1 g cerebral cortex wet weight/30 ml buffer. The membrane suspension is immediately stored in aliquots of 5–10 ml at –77 °C. Protein content of the membrane suspension is determined according to the method of Lowry et al. (1951) with bovine serum albumin as a standard.

At the day of the experiment, the required volume of the membrane suspension is slowly thawed and centrifuged at 48 000 *g* (4 °C) for 10 min. The resulting pellets are resuspended in a volume of ice-cold incubation buffer, yielding a membrane suspension with a protein content of 0.6–0.8 mg/ml. After homogenization (glass Teflon potter), the membrane suspension is stirred under cooling for 20–30 min until the start of the experiment.

Experimental course

As 1,4-dihydropyridines tend to bind to plastic material, all dilution steps are done in glass tubes.

For each concentration samples are prepared in triplicate. The total volume of each incubation sample is 200 µl (microtiter plates).

Saturation experiments

total binding:

- 50 µl ^{3}H-nitrendipine (12 concentrations, 5×10^{-11}–4×10^{-9} M)
- 50 µl incubation buffer

non-specific-binding:

- 50 µl ^{3}H-nitrendipine (4 concentrations, 5×10^{-11}–4×10^{-9} M)
- 50 µl nifedipine (5×10^{-7} M)

Competition experiments

- 50 µl ^{3}H-nitrendipine (1 constant concentration, 3–4×10^{-10} M)
- 50 µl incubation buffer without or with non-labeled test drug (15 concentrations, 10^{-10}–10^{-3} M)

The binding reaction is started by adding 100 µl membrane suspension per incubation sample (0.6–0.8 mg protein/ml). The samples are incubated for 60 min in a bath shaker at 25 °C. The reaction is stopped by subjecting the total incubation volume to rapid vacuum filtration over glass fibre filters. Thereby the membrane-bound is separated from the free radioactivity. Filters are washed immediately with approx. 20 ml ice-cold rinse buffer per sample. The retained membrane-bound radioactivity on the filter is measured after addition of 2 ml liquid scintillation cocktail per sample in a Packard liquid scintillation counter.

EVALUATION

The following parameters are calculated:

- total binding
- non-specific binding
- specific binding = total binding – non-specific binding

The dissociation constant (K_i) of the test drug is determined from the competition experiment of ^{3}H-nitrendipine versus non-labeled drug by a computer-supported analysis of the binding data.

$$K_i = \frac{K_D{}^3\mathrm{H} \times IC_{50}}{K_D{}^3\mathrm{H} + [^3\mathrm{H}]}$$

IC_{50} = concentration of the test drug, which displaces 50% of specifically bound ^{3}H-nitrendipine in the competition experiment

$[^3\mathrm{H}]$ = concentration of ^{3}H-nitrendipine in the competition experiment.

$K_D{}^3\mathrm{H}$ = dissociation constant of ^{3}H-nitrendipine, determined from the saturation experiment.

The K_i-value of the test drug is the concentration, at which 50% of the receptors are occupied by the test drug.

The affinity constant K_i [mol/l] is recorded and serves as a parameter to assess the efficacy of the test drug.

Standard data:

- nifedipine $K_i = 2$–4×10^{-9} mol/l

MODIFICATIONS OF THE METHOD

Several other calcium entry blockers, such as nimodipine, diltiazem, verapamil and desmethoxyverapamil, have been labelled and used for binding studies in order to elucidate the calcium channel recognition sites and may be used for further classification of calcium antagonists (Ferry and Glossmann 1982; Glossmann et al. 1983; Goll et al. 1984; Lee et al. 1984; Glossmann et al. 1985; Schoemaker and Langer 1985; Ruth et al. 1985; Reynolds et al. 1986).

Tissue heterogeneity of calcium channel antagonist binding sites has been demonstrated by Gould et al. (1983).

Photoaffinity labeling of the cardiac calcium channel with 1,4-dihydropyridine(–)-[3H]azidopine was described by Ferry at al (1987).

Binding sites for ω-conotoxin appear to be primarily associated with the N-type of voltage-dependent calcium channels (Feigenbaum et al. 1988; Wagner et al. 1988).

Cohen et al. (1992) recommended the peptide ω-agatoxin IIIA as a valuable pharmacological tool being the only known ligand that blocks L-type calcium channels with high affinity at all voltages and causes, unlike the 1,4-dihydropyridines, no block of T-type calcium channels.

A.4.2
Isolated organs

A.4.2.1
Calcium antagonism on action potential of isolated guinea pig papillary muscle

PURPOSE AND RATIONALE

Intracellular action potential in the guinea pig papillary muscle is recorded. Partial depolarization is achieved by potassium enriched Ringer solution and by addition of isoproterenol. Resting potential is increased to 40 mV resulting in inactivation of the fast sodium channel. Under these conditions, upstroke velocity is an indicator for calcium flux through the membrane, which is decreased by calcium blockers.

PROCEDURE

Guinea pigs of either sex (Pirbright White strain) weighing 300–400 g are sacrificed by stunning, the carotid arteries are severed, and the thoracic cage is opened immediately. The heart is removed, placed in a container of prewarmed, pre-oxygenated Ringer solution, and the pericardium and the atria are trimmed away. The left ventricle is opened and the two strongest papillary muscles removed. They are fixed between a suction electrode for electrical stimulation and a force transducer for registration of contractions. Initially, normal Ringer solution oxygenated with carbogen (95% O_2/5% CO_2) at a temperature of 36 °C is used. A standard micro electrode technique is applied to measure the action potential via a glass micro elec-

trode containing 3 M KCl solution, which is inserted intracellularly. The papillary muscle is stimulated with rectangular pulses of 1 V and of 1 ms duration at intervals of 500 ms. The interval between two stimuli is variable in order to determine refractory periods. The intensity of the electrical current is just below the stimulation threshold. The intracellular action potential is amplified, differentiated for registration of upstroke velocity (Hugo Sachs micro electrode amplifier), together with the contraction force displayed on an oscilloscope (Gould digital storage oscilloscope OS 4000), and recorded (Gould 2400 recorder).

After an incubation period of 30 min the Ringer solution is changed to the following composition containing 5 times more potassium and 10% less sodium.

- NaCl 8,1 g/L
- KCl 1,0 g/L
- $CaCl_2$ 0,2 g/L
- $NaHCO_3$ 0,1 g/L
- glucose 5,0 g/L

For further depolarization, isoproterenol (1.0 mg per 100 ml) is added. By this measure, resting potential is increased to about 40 mV, resulting in inactivation of the fast inward sodium channel. The resulting slow rising action potential is sensitive to calcium antagonistic drugs (Kohlhardt and Fleckenstein 1977).

The test compound is added at a concentration of 1 µg/ml. Effective compounds are tested at lower concentrations and compared with the standard (nifedipin at concentrations of 0.01 and 0.1 µg/ml)

EVALUATION

The decrease of upstroke velocity is tested at various concentrations of the test compound and compared with the standard.

A.4.2.2 Calcium antagonism in the isolated guinea pig atrium

PURPOSE AND RATIONALE

k-Strophanthine (and other cardiac glycosides) inhibit the membrane-bound Na^+/K^+-activated ATP-ase which leads to an increase in intracellular Ca^{2+}-concentration. Ca^{2+} ions activate the contractile apparatus, causing a distinctive enhancement of contractions. The procedure can be used to evaluate a compound's calcium channel blocking activity by measuring its ability to decrease atrial contractions induced by k-strophanthine.

PROCEDURE

Apparatus

HSE-stimulator 1 (Hugo Sachs Elektronik, D-79232 March-Hugstetten, Germany)

Stimulation data:

- frequency 1.5 Hz
- duration 3 ms
- voltage 3–8 V

Experiment

Guinea pigs of either sex weighing 200–500 g are sacrificed with a blow to the nape of the neck and exsanguinated. The left atrium is removed, placed in an organ bath and attached to an isotonic strain gauge, its base being wired to an electrode of the stimulator. The Ringer-solution is aerated with carbogen and kept at 36 °C. The atrium is continuously stimulated via stimulator 1, the voltage being slowly increased up to the threshold level. Contractions are recorded on a polygraph. Prior to drug administration, two prevalues are obtained by adding 2 µg/ml k-strophanthine-α (Cymarin) to the organ bath and measuring the increase in contractile force. Following a 15 min washout and recovery period, the test drug is added to the bath followed by administration of k-strophanthine-α 10 min later. The change in contractile force is always measured 10 min after the addition of k-strophanthine-α.

Standard compounds:

- Verapamil hydrochloride
- Nifedipine

EVALUATION

The percent inhibition of k-strophanthine-α induced contraction is determined.

MODIFICATIONS OF THE METHOD

Calcium antagonists can also be evaluated in the LANGENDORFF heart preparation (Lindner and Ruppert 1982).

Leboeuf et al. (1992) reported the protective effect of bepridil and flunarizine against veratrine-induced contracture in rat atria concluding from the results in this model that these agents may be more effective as L-type calcium ion-channel blockers in protecting against calcium overload during ischaemia and reperfusion injury.

A.4.2.3 Calcium antagonism in the isolated rabbit aorta

PURPOSE AND RATIONALE

Contraction of aorta rings is induced by adding potassium chloride or norepinephrine to the organ bath containing slightly modified Krebs bicarbonate buffer. Test drugs with calcium channel blocking activity have a relaxing effect.

PROCEDURE

Rabbits of either sex weighing 3–4 kg are sacrificed with an overdose of pentobarbital sodium. The chest cavity is opened and the descending thoracic aorta (from the level of the aortic arch to the level of the diaphragm) is rapidly removed and placed in a beaker of oxygenated Krebs bicarbonate buffer at 37 °C.

The content of magnesium and calcium is slightly diminished in the Krebs bicarbonate buffer resulting in the following composition:

• NaCl	118.4	mMol
• KCl	4.7	mMol
• KH_2PO_4	1.2	mMol
• $MgSO_4 \cdot 2\,H_2O$	1.2	mMol
• $CaCl_2 \cdot 2\,H_2O$	1.9	mMol
• $NaHCO_3$	25.0	mMol
• dextrose	10.0	mMol
• EDTA	0.013	mMol

The tissue is then transferred to a dish containing fresh oxygenated, warmed Krebs solution. Fat and loose connective tissue are carefully removed while keeping the tissue moist with the solution. Eight rings of 4–5 mm width are obtained and each is mounted in a 20 ml tissue bath which contains the oxygenated warmed Krebs solution. Initial tension is set at 1.0 g. The tissue is allowed to incubate over a period of 2 h, during which time the Krebs solution is changed every 15 min. Also during this time, tension is maintained at 1.0 g. Just prior to the end of the 2 h equilibration period, the Krebs solution is changed again and the tissue is allowed to stabilize at 1.0 g tension. A sustained contraction is then generated by addition of either 40 mM KCl or 2.9×10^{-3} mM norepinephrine.

Twenty min after addition of the agonist, the test drug is added so that the final concentration in the bath is 1×10^{-5} M. The percent relaxation reading is taken 30 min after addition of the test drug. If at least 30% relaxation occurs, an accumulative concentration-relaxation curve is established. There is a 30 min period of time between the addition of each concentration of test compound.

EVALUATION

Active tension is calculated for the tissue at the time point just prior to the addition of the test compound and also at the point 30 min after the addition of each concentration of test compound. Active tension is defined as the difference between the generated tension and the baseline tension. The percent relaxation from the predrug, precontracted level is calculated for each concentration of test compound. A number of 5 experiments constitutes a dose range. An ID_{50} is calculated by linear regression analysis.

MODIFICATIONS OF THE METHOD

Hof and Vuorela (1983) compared three methods for assessing calcium antagonism on rabbit aorta smooth muscle.

Matsuo et al. (1989) reported a simple and specific screening method for Ca-entry blockers. In the presence of various Ca-channel blockers, 1×10^{-4} M Ca^{2+} causes relaxation of rat uterine smooth muscle that has been tonically contracted with oxytocin in calcium-free medium after prolonged preincubation with 3 mM EGTA.

Micheli et al. (1990) used spirally cut preparations of rat aorta and rings of rabbit ear artery to test calcium entry blocker activity.

Rüegg et al. (1985) described a smooth muscle cell line originating from fetal rat aorta to be suitable for the study of voltage sensitive calcium channels. Calcium channel antagonists inhibited both the basal and the potassium chloride stimulated $^{45}Ca^{2+}$ uptake.

A.4.2.4 Calcium antagonism in the isolated guinea pig pulmonary artery

PURPOSE AND RATIONALE

Contraction of the pulmonary artery is induced by changing the normal Tyrode solution in the organ bath against a potassium enriched solution. This contraction can be inhibited by calcium blockers.

PROCEDURE

The following solutions are used:

	Normal Tyrode solution [mMol]	Potassium enriched Tyrode solution [mMol]
NaCl	135.0	89.0
KCl	3.7	50.0
$MgSO_4$	0.81	0.81
NaH_2PO_4	0.41	0.41
$NaHCO_3$	11.0	11.0
$CaCl_2$	2.25	2.25
Glucose	5.6	5.6

Guinea pigs (Pirbright White strain) of either sex weighing 400–500 g are sacrificed by stunning. The pulmonary artery is removed and cut spirally at an angle of 45°. The resulting strip is cut to lengths of 2 cm and one piece is suspended in oxygenated normal Tyrode solution in an organ bath at 37 °C with a preload of 1 g. Contractions are registered with an isotonic strain transducer and recorded on a polygraph.

After 1 h equilibrium time, normal solution is exchanged with potassium enriched Tyrode solution. The artery strip reacts with a contraction which achieves after 10 min 90–95% of its maximum. After an additional 10 min, exchange to normal Tyrode solution is performed. Ten min later again a contraction is induced by potassium enriched solution. When the height of the contraction has reached a constant level, the test substance is added and again potassium induced contraction recorded. The height of the contraction is expressed as percent of initial potassium induced contraction.

After lavage, the procedure is repeated with a higher dose or the standard.

EVALUATION

For calculation of a regression line, the decrease of contraction versus control after various doses is measured in mm. The percentage of inhibition after various doses is taken for calculation of an ED_{50}.

A.4.3 *In vivo* methods

A.4.3.1 Evaluation of calcium blockers in the pithed rat

PURPOSE AND RATIONALE

Using the cardioaccelerator response in pithed rats, calcium entry blockers can be distinguished from other agents which have modes of action not involving direct blockade of calcium entry (Clapham 1988).

PROCEDURE

Male Sprague-Dawley rats (250–350 g) are anaesthetized with methohexitone sodium (50 mg/kg i.p.). Following cannulation of the trachea, the rats are pithed through one orbit with a stainless steel rod and immediately artificially respired with room air (78 strokes/min, 1 ml/100 g body weight) via a Palmer small animal respiration pump. A jugular vein is cannulated for administration of drugs. Arterial blood pressure is recorded from a carotid artery using a pressure transducer. Heart rate is derived from the phasic arterial pressure signal with a phase lock loop ratemeter (BRL Instrument Services). Both parameters are displayed on a recorder. The animals are kept warm by an incandescent lamp positioned about 25 cm above them. The pithing rod is withdrawn so that the tip lays in the thoracic portion of the spinal cord. All rats then receive (+)tubocurarine (1.5 mg/kg i.v.) and are bilaterally vagotomized.

The cardioaccelerator response is obtained by continuous electrical stimulation of the thoracic spinal cord with square wave pulses of 0.5 ms duration, at supramaximal voltage at a frequency of 0.5 Hz using the pithing rod as a stimulating electrode. An indifferent electrode is inserted subcutaneously in the femoral region. Only rats with a resulting tachycardia of more than 100 beats/min are included into the experiments.

When the cardioaccelerator response has stabilized for about 3–5 min, cumulative intravenous doses of drug or corresponding vehicle are administered. Succeeding doses are given when the response to the previous dose has stabilized.

Calcium antagonists and β-blockers inhibit dose-dependent the tachycardia elicited by electrical stimulation of the spinal cord, whereas lignocaine and nicorandil are not effective.

Doses of β-blockers or calcium-antagonists, which reduce the tachycardia to 50% are tested again. Three min after administration of the drug, calcium gluconate (1 mg/min) or water (0.1 ml/min) are infused using a Harvard apparatus compact infusion pump. The effects of calcium entry blockers, but not of β-adrenoreceptor blockers, are antagonized.

EVALUATION

The level of tachycardia immediately prior to drug administration is taken as 100% and responses to drugs are expressed as a percentage of this predose tachycardia. If an inhibitory effect >50% is seen, then an ID_{50} (with 95% confidence limits) is interpolated from linear regression analysis. Significance of differences between the groups receiving calcium gluconate and their parallel vehicle controls is calculated by Student's *t*-test.

CRITICAL ASSESSMENT OF THE METHOD

Differentiation between the effects of β-blockers and calcium-antagonists can be achieved in a relatively simple *in vivo* model.

A.5 Anti-arrhythmic activity

A.5.0.1 General considerations

Guidelines for the study of arrhythmias in man and animals regarding the experimental design as well as the classification, quantification, and analysis were given as the Lambeth Conventions by Walker et al. (1988).

Classification

Anti-arrhythmic drugs have been classified into various groups and subgroups (Vaughan Williams 1970, 1975, 1984, 1988, 1991, 1992; Borchard et al. 1989; Frumin et al. 1989; Harumi et al. 1989; Colatsky and Follmer 1990; Podrid 1990; Coromilas 1991; Nattel 1991; Rosen and Schwartz 1991; Scholz 1991; Woosley 1991; Ravens 1992; Sanguinetti 1992; Grant 1992; Nattel 1993; Scholz 1994). This classification is based on electrophysiological effects (e.g., action potential) and on interaction with membrane receptors and ion channels. The heterogeneity of classification criteria resulted in vivid discussions (The Sicilian Gambit 1991; Vaughan Williams 1991, 1992). In particular, a clinical study (CAST investigators 1990) challenged the therapeutic value of some anti-arrhythmic drugs.

Weirich and Antoni (1990, 1991) proposed a subdivision of class-1-anti-arrhythmic drugs according to the saturation behavior of frequency-dependent block and its onset-kinetics.

Class I anti-arrhythmic drugs directly alter membrane conductance of cations, particularly those of Na^+ and K^+. They reduce upstroke velocity, V_{max}, of the cardiac action potential by blockade of the fast Na^+ channel. This leads to a depression of conduction velocity, a prolongation of the voltage- and time-dependent refractory period and an increase in the threshold of excitability in cardiac muscle. Class I anti-arrhythmic drugs are subclassified according their effect on the action potential duration.

Class I A anti-arrhythmic drugs (Quinidine-like substances, e.g., disopyramide, procainamide, ajmaline) lengthen the action potential duration which is reflected in the ECG as lengthening of the QT-interval. This effect is added to that on fast sodium channel resulting in delayed recovery from inactivation.

Class I B anti-arrhythmic drugs (lidoacaine-like drugs, e.g., mexiletine, phenytoin, tocainide), in contrast, shorten the action potential duration.

Class I C anti-arrhythmic drugs (e.g., encainide, flecainide, propafenone, indecainide) produce quinidine- and lidocaine-like effects and exert differential actions on the duration of action potential in Purkinje fibres (shortening) and ventricular muscle.

Class II anti-arrhythmic drugs are β-adrenergic antagonists. They exert their anti-arrhythmic effects by antagonizing the electrophysiological effects of catecholamines which are mainly mediated by an increase in slow calcium inward current.

Class III anti-arrhythmic drugs (e.g., amiodarone, bretylium, sotalol) prolong the action potential and lead to a corresponding increase in the effective refractory period. The action is mainly due to a block of outward repolarizing currents. However, activation of sodium and calcium inward currents that prolong the plateau of the action potential may also be involved.

Class IV anti-arrhythmic drugs (e.g., verapamil, diltiazem) are slow calcium channel blockers suppressing the slow calcium inward current and calcium-dependent slow action potentials.

Experimentally induced arrhythmias

Winslow (1984) reviewed the methods for the detection and assessment of antiarrhythmic activity.

Szekeres (1979) suggested a rational screening program for the selection of effective antiarrhythmic drugs.

Arrhythmia models in the rat were reviewed by Cheung et al. (1993).

Arrhythmogenic stimuli can be divided into three groups: chemical, electrical and mechanical (Szekeres and Papp 1975; Wilson 1984).

Chemically induced arrhythmias

A large number of chemical agents alone or in combination are capable of inducing arrhythmias. Administration of anesthetics like chloroform, ether, halothane (sensitizing agents) followed by a precipitating stimulus, such as intravenous adrenaline, or cardiac glycosides (usually ouabain), aconitine, and veratrum alkaloids cause arrhythmias. The sensitivity to these arrhythmogenic substances differs among various species.

Electrically induced arrhythmias

The possibilities to produce arrhythmias by electrical stimulation of the heart and the difficulties for evaluation of anti-arrhythmic drugs by this approach have been discussed by Szekeres (1971). Serial electrical stimulation result in flutter and fibrillation and it is possible to reproduce some of the main types of arrhythmias of clinical importance. The flutter threshold or the ventricular multiple response threshold may be determined in anesthetized dogs before or after the administration of the test drug.

Mechanically induced arrhythmias

Arrhythmias can be induced directly by ischemia or by reperfusion. After ischemia either by infarction or by coronary ligation several phases of arrhythmias are found. The two stage coronary artery ligation technique described by Harris (1950) focuses on late arrhythmias.

Curtis and Walker (1988) examined seven scores in an attempt to validate the use of arrhythmia scores in an *in vivo* model of conscious rats.

The influence on reperfusion arrhythmias can be tested in various species, e g., rat, pig, dog and cat (Bergey et al. 1982; Winslow 1984; Curtis et al. 1987; Brooks et al. 1989).

A.5.0.2 Electrocardiography in animals

PURPOSE AND RATIONALE

Recording of the electrocardiogram is an essential tool in the evaluation of anti-arrhythmic drugs (Johnston et al. 1983; Curtis and Walker 1986; Adaikan et al. 1992). Similar to the heart rate, the electrocardiogram is different between various species (Bazett 1920; Kisch 1953; Heise and Kimbel 1955; Beinfield and Lehr 1968; Budden et al. 1981; Driscoll 1981; Osborn 1981; Hayes et al. 1994). Many authors used the bipolar lead II between right foreleg and left hindleg, which is in line with the neutrally placed heart. Additionally, lead I (between right and left foreleg) stated to lie in the axis of the horizontal heart, and lead III (between left foreleg and left hindleg) in line with the vertical heart, may be used as well as unipolar leads (usually designed as V_1 to V_6) and the unipolar leads designed as aVL, aVR, and aVF. Out of several species being used the procedure for rats (Penz et al. 1992; Hayes et al. 1994) is described.

PROCEDURE

Male Sprague Dawley rats weighing 250–300 g are anesthetized by intraperitoneal injection of 60 mg/kg pentobarbitone. The right jugular vein is cannulated for injections, while the left coronary artery is cannulated for recording blood pressure on a polygraph. The ECG is recorded using a Lead type II of configuration along the anatomical axis of the heart as determined by palpation. ECGs are recorded at a standard chart speed of 100 mm/s on a polygraph and simultaneously on a storage oscilloscope. Measurements of intervals are made on the chart recorder and from the memory trace of the monitor.

Since in the rat it is difficult to detect a T-wave that corresponds exactly with the T-wave seen in other species (Beinfeld and Lehr 1968; Driscoll 1981; Surawicz 1987) T-wave calculations are made on the basis of the repolarization wave that follows the QRS complex. The following variables are measured:

σT = time for the depolarization wave to cross the atria, *P-R* interval, *QRS* interval, *Q-T* interval, and *RSh* (the height between the peak of R and S wave). The *RSh* magnitude is taken as a measure of the extent of S-wave depression as exerted by class I sodium channel blocking antiarrhythmics.

EVALUATION

Statistical analyses are based on ANOVA followed by Duncan's test for differences of means. In order to demonstrate the relationships between and drug effects, standard cumulative dose-response curves are constructed.

MODIFICATIONS OF THE METHOD

Osborne (1973, 1981) described a restraining device facilitating electrocardiogram recording in **conscious rats**.

Curtis and Walker (1986), Johnston et al. (1983) studied the responses to ligation of a coronary artery and the actions of antiarrhythmics in conscious rats.

Hayes et al. (1994) studied the ECG in **guinea pigs**, rabbits and primates.

Stark et al. (1989) described an epicardic surface and stimulation technique (SST-ECG) in Langendorff perfused guinea pig hearts.

Epicardial His bundle recordings in the guinea pig *in vivo* were described by Todt and Raberger (1992).

Chronic recording from the His bundle in awake nonsedated **dogs** was reported by Karpawich et al. (1983) and by Atlee et al. (1984).

Van de Water et al. (1989) reported a formula to correct the QT interval of the electrocardiogram in dogs for changes in heart rate.

Wu et al. (1990) described a dual electrophysiologic test for atrial anti-reentry and ventricular antifibrillatory studies in anesthetized dogs. The reentry portion of the model was created surgically by a Y-shaped crushing around the tissue between the superior and inferior vena cava and tissue parallel to the AV groove. The pacing induced tachycardia that results from circus movements around the tricuspid ring was very persistent in duration and regular in cycle length. The antifibrillatory activities were assessed by determination of the ventricular fibrillation threshold using a train-stimuli method.

Weissenburger et al. (1991) developed an experimental model of the long QT syndrome in conscious dogs for screening the bradycardia-dependent proarrhythmic effects of drugs and for studying the electrophysiology of "torsades de pointes".

Holter monitoring in conscious dogs was described by Krumpl et al. (1989a,b).

Coker (1989) recommended the anesthetized **rabbit** as a model for ischemia- and reperfusion-induced arrhythmias.

Baboons and **monkeys** *(Macaca sp.)* were used by Adaikan et al. (1992).

A.5.0.3 Aconitine antagonism in rats

PURPOSE AND RATIONALE

The plant alkaloid aconitine persistently activates sodium channels. Infusion of aconitine in the anesthetized rat causes ventricular arrhythmias. Drugs considered to have anti-arrhythmic properties can be tested in aconitine-intoxicated rats.

PROCEDURE

Male Ivanovas rats weighing 300–400 g are used. The animals are anesthetized by intraperitoneal injection of 1.25 g/kg urethane. Five µg/kg aconitine dissolved in 0.1 N HNO_3 is administered by continuous infusion into the saphenous vein of 0.1 ml/min and the ECG in lead II is recorded every 30 seconds. The test compound is injected orally or intravenously at a screening dose of 3 mg/kg 5 min before the start of the aconitine infusion. Eight–ten animals are used per compound.

EVALUATION

The anti-arrhythmic effect of a test compound is measured by the amount of aconitine/100 g animal (duration of infusion) which induces

- ventricular extrasystoles
- ventricular tachycardia
- ventricular fibrillation
- and death.

Higher doses of aconitine in the treated group as compared to an untreated control group are an indication of anti-arrhythmic activity.

Statistical significance between the groups is assessed by the Student's *t*-test.

The scores are allotted for the intensity and the duration of the effect relative to the efficacy of standard compounds.

Standard data:

- Procainamid, 5 mg/kg i.v. and lidocaine, 5 mg/kg, i.v. lead to an increase in LD_{100} by 65% (corresponds to LD_{100} of approximately 9 µg/100 g).

CRITICAL ASSESSMENT OF THE METHOD

Aconitine – antagonism *in vivo* has been proven as a valuable screening method for anti-arrhythmic activity.

MODIFICATIONS OF THE METHOD

Scherf (1947) studied the auricular tachycardia caused by aconitine administration in **dogs**.

Scherf et al. (1960) provoked atrial flutter and fibrillation in anesthetized dogs by application of a few crystals of aconitine or delphinine to the surface of the right atrium in the appendix area near the head of the sinus node.

Mc Leod and Reynold (1962) induced arrhythmia by aconitine in the isolated **rabbit** atrium.

Nwangwu et al. (1977) used aconitine as arrhythmogenic agent for screening of anti-arrhythmic agents in **mice**.

Yamamoto et al. (1993) used urethane-anesthetized rats under artificial respiration with tubocurarine pretreatment. After thoracotomy and incision of the pericardium, a piece of filter paper soaked with aconitine solution was applied to the right atrium. Test drugs were applied by continuous i.v. infusion. In addition to ECG lead II, intra-atrial ECG was monitored.

Aconitine-antagonism in conscious mice as screening procedure has been recommended by Dadkar and Bhattacharya (1974) and in anesthetized mice by Winslow (1980).

Nakayama et al. (1971) described the topical application of aconitine in a small cup placed on the right atrium of dogs to induce supraventricular arrhythmias.

A method using the **cat** has been developed by Winslow (1981).

Other arrhythmogenic agents

In addition to the aconitine model Vaille et al. (1992) demonstrated the selectivity of a $CaCl_2$ continuous infusion screening method in rats for the evaluation of antiarrhythmic calcium antagonists.

A mouse chloroform model was recommended by Lawson (1968).

Vargaftig et al. (1969) induced ventricular fibrillation in mice by inhalation of chloroform.

Papp et al. (1967) proposed the experimental $BaCl_2$-arrhythmia as a quantitative assay of anti-arrhythmic drugs.

Al-Obaid et al. (1998) used calcium chloride-induced arrhythmias for anti-arrhythmic activity evaluation in anesthetized male rats. Cardiac arrhythmias were induced by a single intravenous injection of 10% $CaCl_2$ (50 mg/kg). The induced arrhythmias were then analyzed for magnitude of initial bradycardia, onset, incidence and duration of the induced fibrillations. After the induction of the arrhythmia, the animal was allowed to recover completely (15–20 min) and the test compound was injected in different doses intravenously. The effect of the test compound on the basal heart rate was then examined and the percentage change in the heart rate was calculated. Seven min later, the arrhythmogenic dose of $CaCl_2$ was re-administered and the effect of the treatment on the induced arrhythmia parameters was evaluated as percentage change in the measured parameters or as protection or non-protections against the induced fibrillations.

Tripathi and Thomas (1986) described a method for the production of ventricular tachycardia in the rat and guinea pig by exposing the animals to benzene vapors for 2 min followed by an intravenous adrenaline injection.

Arrhythmias could be induced by changing the medium of cultured rat heart muscle cells (Wenzel and Kloeppel 1978).

In isolated rat hearts ventricular fibrillation was induced by isoprenaline and a catechol-O-methyl transferase inhibitor at high perfusion temperature (Sono et al. 1985).

Takei (1994) described experimental arrhythmia in guinea pigs induced by grayanotoxin-I, a biologically active diterpenoid from the plant family of Ericaceae.

A.5.0.4
Digoxin-induced ventricular arrhythmias in anesthetized guinea pigs

PURPOSE AND RATIONALE

Overdose of cardiac glycosides, such as digoxin, induces ventricular extrasystoles, ventricular fibrillation, and finally death. The occurrence of these symptoms can be delayed by anti-arrhythmic drugs.

PROCEDURE

Male guinea pigs (Marioth strain) weighing 350–500 g are anesthetized with 35 mg/kg pentobarbital sodium intraperitoneally. Trachea, one jugular vein and one carotid artery are catheterized. Positive pressure ventilation is applied with a respiratory pump (Rhema GmbH, Germany) at 45 breaths/min. The carotid artery is used for monitoring systemic blood pressure via a pressure transducer. Digoxin is infused into the jugular vein with a perfusion pump (ASID BONZ PP 50) at a rate of 85 µg/kg in 0.266 ml/min until cardiac arrest. The electrocardiogram (lead III) is recorded with subcutaneous steel-needle electrodes (Hellige 19).

Treated groups ($n = 5–10$ animals) receive the test drug either orally 1 h or intravenously 1 min prior to the infusion. The control group (n = at least 5 animals) receives the digoxin infusion only. The period until the onset of ventricular extrasystoles, ventricular fibrillation, and cardiac arrest is recorded. The total amount of infused digoxin (µg/kg) to induce ventricular fibrillation is calculated. Standard drugs are lidocaine (3 mg/kg i.v.) or ramipril (1 mg/kg p.o.).

EVALUATION

Using Student's *t*-test the doses of digoxin needed to induce ventricular extrasystoles, or ventricular fibrillation, or cardiac arrest, respectively, after treatment with anti-arrhythmic drugs are compared statistically with controls receiving digoxin only.

A.5.0.5
Strophanthin or ouabain induced arrhythmia

PURPOSE AND RATIONALE

Acute intoxication with the cardiac glycoside strophanthin K induces ventricular tachycardia and multifocal ventricular arrhythmias in dogs. This can be used as a test model to evaluate the effect of potential anti-arrhythmic drugs on ventricular arrhythmias.

PROCEDURE

Male or female dogs of either sex weighing approximately 20 kg are used. The animals are anesthetized by intravenous injection of 30–40 mg/kg pentobarbital sodium. Two peripheral veins are cannulated for the administration of the arrhythmia-inducing substance (*V. brachialis*) and the test compound (*V. cephalica antebrachii*). For intraduodenal administration of the test drug, the duodenum is cannulated. Electrocardiogram is registered with needle electrodes from lead II. Heart frequency is derived from R-peaks of ECG. Two–three animals are used for one compound.

Strophanthin K is administered by continuous i.v.-infusion at a rate of 3 µg/kg/min. Thirty–fourty min later, signs of cardiac glycoside intoxication appear leading to ventricular tachycardia or to multifocal ventricular arrhythmias. When this state is achieved, the strophanthin infusion is terminated. When the arrhythmias are stable for 10 min, the test substance is administered intravenously in doses between 1.0 and 5.0 mg/kg or intraduodenally in doses between 10 and 30 mg/kg.

ECG II recordings are obtained at times: –0.5, 1, 2, 5 and 10 min following administration of test drug.

For i.v. administration: A test compound is considered to have an anti-arrhythmic effect if the extrasystoles immediately disappear. If the test compound does not show a positive effect, increasing doses are administered at 15 min-intervals. If the test substance does reverse arrhythmias, the next dose is administered after the reappearance of stable arrhythmias.

For i.d. administration: A test compound is considered to have a definite anti-arrhythmic effect if the extrasystoles disappear within 15 min. The test drug is considered to have "no effect" if it does not improve strophanthin intoxication within 60 min following drug administration.

EVALUATION

Evaluation of the therapeutic effect of a drug is difficult and somewhat arbitrary since there is no clear-cut correlation between effectiveness of a test compound and duration of its effect, i.e. return to normal ECGs. The standard drugs ajmaline, quinidine and lidocaine re-establish normal sinus rhythm at doses of 1 and 3 mg/kg (i.v.) and 10 mg/kg (i.d.). Arrhythmias are eliminated for 20 min (i.v.) and for >60 min (i.d.) following drug administration.

MODIFICATIONS OF THE METHOD

Ettinger et al. (1969) used arrhythmias in dogs induced by ouabain to study the effects of phentolamine in arrhythmia.

Garrett et al. (1964) studied the antiarrhythmic activity of *N,N*-diisopropyl-*N*'-diethylaminoethylurea hydrochloride in anesthetized dogs with arrhythmias induced by ouabain, aconitine or acetylcholine. Furthermore, ultra-low frequency ballistocardiograms with ECG registration were performed in dogs.

Raper and Wale (1968) studied the effects on ouabain- and adrenaline-induced arrhythmias in **cats**.

Kerr et al. (1985) studied the effects of a vasodilator drug on ouabain-induced arrhythmias in anesthetized dogs.

A modified method for the production of cardiac arrhythmias by ouabain in anesthetized cats was published by Rao et al. (1988).

Brooks et al. (1989) infused ouabain intravenously to **guinea pigs** and determined the onset of ventricular extrasystoles and of fibrillation.

Thomas and Tripathi (1986) studied the effects of α-adrenoreceptor agonists and antagonists with different affinity for α_1- and α_2-receptors on ouabain-induced arrhythmias and cardiac arrest in guinea pigs.

Krzeminski (1991) and Wascher et al. (1991) used of ouabain-induced arrhythmia in guinea pigs for the evaluation of potential antidysrhythmic agents.

Al-Obaid et al. (1998) used ouabain-induced arrhythmias in anesthetized **Wistar rats** for evaluation of cyclopenteno[b]thiophene derivatives as antiarrhythmic agents.

A.5.0.6 Ventricular fibrillation electrical threshold

PURPOSE AND RATIONALE

The use of anti-arrhythmic drugs in the treatment of ventricular arrhythmias aims to prevent the development of ventricular fibrillation. Several electrical stimulation techniques have been used to measure ventricular fibrillation threshold such as single pulse stimulation, train of pulses stimulation, continuous 50-Hz stimulation and sequential pulse stimulation.

PROCEDURE

Adult dogs weighing 8–12 kg are anesthetized with sodium pentobarbital (35 mg/kg) and ventilated with air using a Harvard respiratory pump. Systolic arterial pressure is monitored and body temperature maintained by a thermal blanket. The chest is opened by a midline sternotomy and the heart suspended in a pericardial cradle. The sinus node is crushed and a 2.0 mm diameter Ag-AgCl stimulating electrode is embedded in a Teflon disc sutured to the anterior surface of the left ventricle. The heart is then driven by 3-ms square anodal constant current pulses for 400 ms of the basic cycle and is prematurely stimulated by one 3-ms test

stimulus through the driving electrode. Electrical stimulation is programmed by a digital stimulator. A recording electrode is placed on the surface of each ventricle. A silver plate is implanted under the skin in the right femoral region as indifferent electrode. Lead II of the body surface electrocardiogram is monitored. To determine ventricular fibrillation threshold (VFT), a 0.2- to 1.8-second train of 50-Hz pulses is delivered 100 ms after every eighteenth basic driving stimulus. The current intensity is increased from the diastolic threshold in increments of 10 μA to 1.0 mA or until ventricular fibrillation occurs. The minimal current intensity of the pulse train required to induce sustained ventricular fibrillation is defined as the VFT. When ventricular fibrillation occurs, the heart is immediately defibrillated and allowed to recover to control conditions for 15 to 20 min. Anti-arrhythmic drugs are administered through the femoral vein.

EVALUATION

Ventricular fibrillation threshold (VFT) is determined before and after administration of test drugs at given time intervals. The mean values of 10 experiments are compared using Student's *t*-test.

MODIFICATIONS OF THE METHOD

Marshall et al. (1981) and Winslow (1984) suggested to determine VFT in the pentobarbitone anesthetized rat.

Wu et al. (1989) recommended a conscious dog model for re-entrant atrial tachycardia.

Wu et al. (1990) described a dual electrophysiologic test for atrial anti-re-entry and ventricular antifibrillatory studies in dogs. The re-entry portion of the model was created surgically by a Y-shaped crushing around the tissue between the superior and inferior vena cava and tissue parallel to the AV groove. The antifibrillatory activities were assessed by determination of the ventricular fibrillation threshold using a train-stimuli method.

A chronically prepared rat model of electrically induced arrhythmias was described by Walker and Beatch (1988).

A.5.0.7 Coronary artery ligation, reperfusion arrhythmia and infarct size in rats

PURPOSE AND RATIONALE

Coronary artery ligation in anesthetized rats results in arrhythmias and myocardial infarction. Following occlusion of the left main coronary artery, very marked ventricular dysrhythmias occur. Electrocardiogram is recorded during ligation and subsequent reperfusion. The amount of infarcted tissue is measured by means of p-nitro-blue tetrazolium chloride-staining in myocardial sections. The model is used to test drugs with potential anti-arrhythmic activities.

PROCEDURE

Groups of 8–10 male Sprague-Dawley rats weighing 350–400 g are used. The animals are anesthetized by intraperitoneal injection of 60 mg/kg pentobarbital sodium. The trachea is intubated to allow artificial ventilation (Starling pump). A catheter is placed in an external jugular vein for administration of test compounds. Peripheral blood pressure is recorded from the common carotid artery using a pressure transducer and a polygraph. The chest is opened by left thoracotomy at the forth intercostal space. After opening the pericard, the heart is exteriorized by gentle pressure on the chest walls and a thin silk thread (Ethicon 1.5 metric, 4-0) attached to an atraumatic needle is placed around the left coronary artery about 2–3 mm distal of the origin of the left coronary artery for later ligation. From that point on, the animal is ventilated with room air using a stroke volume of 1 ml/100 g body

weight at a rate of 54 strokes/min. The heart is then placed back in the chest cavity. Any animal in which this procedure itself produces dysrhythmias or a sustained fall in mean arterial blood pressure to less than 70 mm Hg has to be discarded from the study.

After an equilibration time of approx. 45 min, the test substance or the vehicle (control) is administered by intravenous injection. Five min later, the ligature at the left coronary artery is closed either for 15 or 90 min (in case infarct-size is assessed) and subsequently reperfused for 30 min. For oral application, the test compounds are dissolved or suspended in the vehicle 30 min before occlusion. Peripheral blood pressure and ECG lead II are recorded continuously during the whole experiment. Rectal temperature is maintained at 38 °C. The numbers of ventricular premature beats (VPB), ventricular tachycardia (VT) and ventricular fibrillation (VF) are counted in the occlusion and reperfusion periods and evaluated according to the guidelines of the Lambeth Convention (Walker et al. 1988).

Preparation to determine infarct size

At the end of the reperfusion period, the animal is sacrificed with an overdose of pentobarbital sodium, the heart is dissected and cut into transversal sections (approx. 1 mm thick) from the apex to the base. The slices are stained with p-nitro-blue tetrazolium chloride solution (0.25 g/L p-nitroblue-tetrazolium chloride in Sörensen phosphate buffer, containing 100 mM D, L-maleate) in order to visualize the infarct tissue (blue/violet-stained healthy tissue, unstained necrotic tissue). The slices are photographed on color transparency film for the determination of infarct area. Left ventricle and infarct area are measured by planimetry from projections of all slices with the exclusion of the apex and the slice containing the ligature.

EVALUATION

The following parameters are evaluated:

- mortality
- hemodynamics
  - peripheral blood pressure [mm Hg]
  - heart rate [beats/min]
  - pressure rate index (PRI) (BPs × HR) [mm Hg × beats/1 000]
- arrhythmias
  - ventricular extrasystoles (= premature ventricular contractions) (PVC)
    - percent animals with PVC
    - number of PVC/5 or 30 min
  - ventricular tachycardia (VT) (VT defined as any run of seven or more consecutive ventricular extrasystoles)
    - percent animals with VT
    - duration [s] of VT/5 or 30 min
  - ventricular fibrillation (VF)
    - percent animals with VF
    - duration [s] of VF/5 or 30 min
- infarct size (area)

The different characteristics are evaluated separately and compared with a positive control (5 mg/kg nicainoprol i.v.).

Changes of parameters in drug-treated animals are compared to vehicle control values.

Statistical significance is assessed by the Student's *t*-test.

MODIFICATIONS OF THE METHOD

Leprán et al. (1983) placed a loose silk loop around the left coronary artery and passed the thread through a cylinder shaped polyethylene tube outside the thorax. The rats were allowed to recover from primary surgery. The loose ligature was tightened 7–10 days thereafter and arrhythmias recorded by ECG tracings.

Johnston et al. (1983) described the responses to ligation of a coronary artery in conscious rats and the actions of anti-arrhythmics.

As reported in Sect. A.3.1.2 and A.3.1.3, the isolated heart according to LANGENDORFF and the isolated working rat heart preparation can be used for ligation experiments inducing arrhythmias. Lubbe et al. (1978) reported ventricular arrhythmias associated with coronary artery occlusion and reperfusion in the isolated perfused rat heart as a model for assessment of antifibrillatory action of anti-arrhythmic agents.

Bernier et al. (1986) described reperfusion-induced arrhythmias in the isolated perfused rat heart. The isolated rat heart was perfused according the LANGENDORFF-technique. A ligature was placed around the left anterior descending coronary artery close to its origin. The arterial occlusion was maintained for 10 min followed by reperfusion. Test compounds were included in the perfusion medium. With epicardial ECG-electrodes the number of premature ventricular complexes, the incidence and duration of ventricular fibrillation, and the incidence of ventricular tachycardia were recorded.

Abraham et al. (1989) tested antiarrhythmic properties of tetrodotoxin against occlusion-induced arrhythmias produced by ligation of the left anterior descending coronary artery in the rat.

MacLeod et al. (1989) tested a long acting analogue of verapamil for its actions against arrhythmias induced by ischemia and reperfusion in conscious and anesthetized rats, as well as for effects on epicardial intracellular action potentials.

Aye et al. (1997) tested the effects of a Na^+/H^+ exchange inhibitor on reperfusion ventricular arrhythmias in rat hearts.

Ferrara et al. (1990) studied the effect of flecainide acetate on reperfusion- and barium-induced ventricular tachyarrhythmias in the isolated perfused rat heart by monitoring heart rate, coronary flow rate, left ventricular systolic pressure, dp/dt_{max}, and the voltage of the epicardial electrogram.

Heterogeneity of ventricular remodeling after acute myocardial infarction in rats has been reported by Capasso et al. (1992).

Bellemin-Baurreau et al. (1994) described an *in vitro* method for evaluation of antiarrhythmic and antiischemic agents by using programmed electrical stimulation of the isolated rabbit heart after ligation of the left ventricular branch of the coronary artery and a reperfusion period of 15 min.

The use of the rat in models for the study of arrhythmias in myocardial ischemia and infarction has been reviewed by Curtis et al. (1987).

Black and Rodger (1996), Black (2000) reviewed the methods used to study experimental myocardial ischemic and reperfusion injury in various animal species.

Linz et al. (1997) reported that in isolated rat hearts with ischemia-reperfusion injuries, perfusion with bradykinin reduces the duration and incidence of ventricular fibrillations, improves cardiodynamics, reduces release of cytosolic enzyme, end preserves energy-rich phosphate and glycogen stores.

Mulder et al. (1998) studied the effects of chronic treatment with calcium antagonists in rats with chronic heart failure induced by coronary artery ligation.

A.5.0.8
Ventricular arrhythmia after coronary occlusion

A.5.0.8.1
Ventricular fibrillation after coronary occlusion and reperfusion in anesthetized dogs

PURPOSE AND RATIONALE

Coronary artery occlusion in anesthetized dogs is accompanied by an increase in heart rate, heart contractility, left ventricular end-diastolic pressure, and blood pressure as well as by ventricular arrhythmias. During a subsequent reperfusion period, a high percentage of control animals die from ventricular fibrillation. Drugs with potential protective effects are tested which reduce both hemodynamic and electrical changes.

PROCEDURE

Dogs of either sex weighing 20–25 kg are used. Anesthesia is induced by intravenous injection of 30 mg/kg thiobutobarbital sodium and maintained by i.v. administration of 20 mg/kg chloralose and 250 mg/kg urethane followed by subcutaneous administration of 2 mg/kg morphine. The animals are placed in the right lateral position. Respiration is maintained through a tracheal tube using a positive pressure respirator (Bird Mark 7). A peripheral vein (saphenous vein) is cannulated for the administration of test compound. The ECG is recorded continuously in lead II (Einthoven).

Preparation for hemodynamic measurements

For recording of peripheral systolic and diastolic blood pressure, the cannula of a femoral artery is connected to a pressure transducer (Statham P 23 DB). For determination of left ventricular pressure (LVP), a Millar microtip catheter (PC 350) is inserted via the left carotid artery. Left ventricular end-diastolic pressure (LVEDP) is measured on a high-sensitivity scale; heart rate (HR) is determined from the LVP wave form. Myocardial contractility is measured as the rate of rise of LVP (dp/dt max). The sum of ST-segment elevations is calculated from five values of the peripheral limbs in ECG lead II. The pressure-rate index ($PRI = BPs \times HR$) serves as a measure of oxygen consumption.

Experimental course

The heart is exposed through a left thoracotomy between the fourth and fifth intercostal space, the pericard is opened and the left anterior descending coronary artery (LAD) is prepared. A silk suture is placed around the LAD, just below the first diagonal branch. After an equilibration period of approx. 45 min., the test substance or the vehicle (controls) is administered as an intravenous bolus. Twenty min later, the ligature at the coronary artery is closed for 90 min. During the occlusion period, the test compound or the vehicle (controls) are given by continuous infusion. After release of the coronary obstruction, the animal is monitored for a 30 min reperfusion period. All parameters are recorded during the whole experiment. At the end of the test, surviving animals are sacrificed by an overdose of pentobarbital sodium.

EVALUATION

The following parameters are evaluated:

- mortality
- hemodynamics
- arrhythmias
  - ventricular extrasystoles (= premature ventricular contractions) (PVC)
  - percent animals with PVC

- number of PVC/5 or 30 min
- ventricular tachycardia (VT) (VT defined as any sequence of seven or more consecutive ventricular extrasystoles)
- duration [s] of VT/5 or 30 min
- ventricular fibrillation (VF)
- percent animals with VF

The different characteristics are evaluated separately. Changes of parameters in drug-treated animals are compared to vehicle controls. Statistical significance of the differences is calculated by means of the Student's *t*-test.

Standard data:
Mortality: In an representative experiment, 10 out of 12 of control animals died from ventricular fibrillation during the 30 min reperfusion period. One out of 8 molsidomine-treated animals died and the death was also from ventricular fibrillation during the reperfusion phase. (Molsidomine was given as a continuous infusion of 0.5 mg/kg/ml/min during the occlusion period; controls received saline).

MODIFICATIONS OF THE METHOD

Varma and Melville (1963) described ventricular fibrillation induced by coronary occlusion during hypothermia in **dogs**.

Wilkerson and Downey (1978) described a technique for producing ventricular arrhythmias in dogs through coronary occlusion by an embolus (glass beads) being introduced into the coronary circulation via a rigid cannula which is inserted through the carotid artery.

Weissenburger et al. (1991) described a model in dogs suitable for screening the bradycardia-dependent proarrhythmic effects of drugs and for studying the electrophysiology of "torsades de pointes".

Coker (1989) recommended the anesthetized **rabbit** as a model for ischemia- and reperfusion-induced arrhythmias.

Thiemermann et al. (1989) described a rabbit model of experimental myocardial ischemia and reperfusion. Drugs were administered by intravenous infusion 5 min after the occlusion of the left anterior-lateral coronary artery and continued during the 60 min occlusion and subsequent 3 h reperfusion periods.

Barrett et al. (1997) described a method of recording epicardial monophasic action potentials and ischemia-induced arrhythmias following coronary artery ligation in intact rabbits.

Naslund et al. (1992) described a closed chest model in *pigs*. Occlusion was induced in pentobarbitone anesthetized, mechanically ventilated **pigs** by injection of a 2 mm ball into a preselected coronary artery. Reperfusion was achieved by retraction of the ball via an attached filament.

D'Alonzo et al. (1994) evaluated the effects of potassium channel openers on pacing- and ischemia-induced ventricular fibrillation in anesthetized pigs.

Premaratne et al. (1995) used a **baboon** open chest model of myocardial ischemia and reperfusion. Baboons underwent occlusion of the left anterior descending coronary artery for 2 h. Fifteen min after occlusion, the treated group received hyaluronidase i.v. over a 10-min period. The ischemic period was followed by 22 h of reperfusion. At the end of the reperfusion period, the hearts were excised and the perfusion bed at risk for infarction was determined by infusion of a microvascular dye.

A.5.0.8.2 Harris dog model of ventricular tachycardia

PURPOSE AND RATIONALE

In 1950, Harris found that the mortality in dogs after coronary occlusion with a 2-stage ligation procedure was lower than with 1-stage ligation. The left descending coronary artery is partially occluded for 30 min after which time total ligation is performed. Under these conditions arrhythmias develop within 4–7 h, reach a peak between 24 and 48 h and abate within 3–5 days.

PROCEDURE

Surgical procedure

Dogs of either sex are anesthetized by intravenous injection of methohexitone sodium (10 mg/kg), an endotracheal tube is inserted, and anesthesia maintained with halothane. The heart is exposed through an incision in the fourth or fifth intercostal space. The anterior descending branch of the left coronary artery is dissected free below its second branch and ligated in two stages. Two ligatures are placed around the artery and a 21 gauge needle. The first ligature is tied round the artery and the needle, which is then removed. Thirty min later, the second ligature is tied tightly round the artery. The chest is closed in layers 30 min after the second ligature has been tied, and the dog is allowed to recover.

Test procedure

Further observations are made when the dogs are conscious, e.g., 22–24 h after ligation of the coronary artery. The dogs are positioned to lie on their side and remain in this position throughout the experiment. Mean blood pressure is recorded from a catheter placed in the femoral artery. Lead II and aV_L of the electrocardiogram and blood pressure are continuously recorded for a control period of 30 min before and during drug administration. Drugs are administered either by injection or by continuous infusion via a hind leg vein.

EVALUATION

The number of sinus and ectopic beats are counted for each successive 5-min period. Beats with a distinct P wave preceding a mean frontal QRS vector of normal duration are counted as sinus in origin; all others are denoted as ectopic.

MODIFICATIONS OF THE METHOD

The model which resembles late arrhythmias occurring in postinfarction patients has been used with modifications by many authors (e.g., Kerr et al. 1985; Reynolds and Brown 1986; Gomoll 1987; Garthwaite et al. 1989; Krumpl et al. 1989a,b; Trolese-Mongheal et al. 1985, 1991; Spinelli et al. 1991).

Methods for producing experimental complete atrioventricular block in dogs were described and reviewed by Dubray et al. (1983) and by Boucher and Duchene-Marullaz (1985).

A.5.0.8.3 Protection against sudden coronary death

PURPOSE AND RATIONALE

The group of Lucchesi described an experimental dog model to test protection against sudden coronary death (Patterson et al. 1982; Uprichard et al. 1989a,b; Chi et al. 1990a,b, 1991; Kitzen et al. 1990; Black et al. 1991, 1993).

Surgical preparation

Purpose-bred male mongrel dogs weighing 14–22 kg are anesthetized with 30 mg/kg pentobarbital i.v. The dogs are ventilated with room air through a cuffed endotracheal tube and a Harvard respirator. A cannula is inserted in the left external jugular vein. A left thoracotomy is performed between the fourth and fifth ribs, and the heart is exposed and suspended in a pericardial cradle. The left anterior descending coronary artery (LAD) is isolated at the tip of the left atrial appendage, and the left circumflex coronary artery (LCX) is isolated ~1 cm from its origin. After a 20-gauge hypodermic needle has been placed on the LAD, a ligature is tied around the artery and the needle. The needle is then removed, resulting in critical stenosis of the vessel. The LAD is perfused for 5 min in the presence of the critical stenosis. Ischemic injury of the anterior ventricular myocardium is achieved by 2-h occlusion of the LAD by a silicon rubber snare. The vessel is reperfused after 2 h in the presence of the critical stenosis. During the period of LAD reperfusion, an epicardial bipolar electrode (1-mm silver posts, 3-mm inter-electrode separation) is sutured on the left atrial appendage for subsequent atrial pacing. A bipolar plunge electrode (25-gauge stainless steel, 5 mm long, 3 mm separation) is sutured on the interventricular septum, adjacent to the occlusion site and overlying the right ventricular outflow tract (RVOT). Two similar stainless steel bipolar plunge electrodes are sutured to the left ventricular (LV) wall: one at the distribution of the LAD distal to the occlusion (infarct zone, IZ), and the second in the distribution of the LCX (non-infarct zone, NZ). A 30-gauge silver-coated copper wire electrode is passed through the wall and into the lumen of the LCX and sutured to the adjacent surface of the heart. Silver disc electrodes are implanted subcutaneously for ECG monitoring. The surgical incision is closed and the animals are allowed to recover.

Drug treatment

The animals are treated after the recovery period during the 3 days of programmed electrical stimulation either with the test drug or with the solvent.

Electrophysiologic studies and programmed electrical stimulation

Programmed electrical stimulation (PES) is performed between days 3 and 5 after induction of anterior myocardial infarction by occlusion/perfusion of the LAD. Animals are studied while conscious and unsedated. Heart rate, ECG intervals and other electrophysiologic parameters (for details see original publications) are determined before PES is started. Premature ventricular stimuli are introduced in the region of the right ventricular outflow tract. The extra stimuli are triggered from the R-wave of the ECG, and the R-S_2 coupling interval is decreased from 350 ms until ventricular refractoriness occurs. At this time, double and triple ventricular extra stimuli are introduced during sinus rhythm. Ventricular tachyarrhythmias are defined as 'non- sustained', if five or more repetitive ventricular responses are initiated reproducibly, but terminated spontaneously. Ventricular tachyarrhythmias are defined as 'sustained', if they persist for at least 30 s or, in the event of hemodynamic compromise, require ventricular burst pacing for their termination.

Sudden cardiac death

A direct anodal 15 μA current from a 9-V nickel-cadmium battery is passed through a 250 Ohm resistor and applied to the electrode in the lumen of the left circumflex coronary artery. The cathode of the battery is connected to a s.c. implanted disc electrode. Lead II ECG is recorded for 30 s every 15 min on a cardiocassette recorder. After 24 h of constant anodal current or development of ventricular fibrillation, the animals are sacrificed, the hearts are excised and the thrombus mass in the LCX is removed and weighed. The heart is sectioned transversely and incubated for 15 min at 37 °C in a 0.4% solution of tetrazolium triphenyl chloride for identification of infarcted areas. Time of onset of ventricular ectopy and of lethal arrhythmia is provided from recordings of the cardiocassette.

EVALUATION

Non-sustained and sustained tachyarrhythmias are evaluated.

CRITICAL ASSESSMENT OF THE METHOD

Sudden coronary death is one of the leading causes of death in developed countries. These facts warrant the use of complicated models in higher animals for search of active drugs.

MODIFICATIONS OF THE METHOD

Cahn and Cervoni (1990) reviewed of the use of animal models of sudden cardiac death for drug development.

A.5.0.8.4 Ventricular fibrillation induced by cardial ischemia during exercise

PURPOSE AND RATIONALE

Billman and his group developed methods to evaluate antiarrhythmic drugs for their activity in cardiovascular parameters in an exercise-plus-ischemia test.

PROCEDURE

Surgical preparation

Mongrel dogs, weighing 15.4 to 19.1 kg, are anesthetized and instrumented to measure left circumflex CBF, left ventricular pressure and ventricular electrogram (Billman and Hamlin 1996; Billman et al. 1993, 1997; Schwartz et al. 1984). The animals are given Innovar Vet (0.02 mg/kg fentanyl citrate and 1 mg/kg hydroperidol i.v.) as a pre-anesthetic, whereas a surgical plane of anesthesia is induced with sodium pentobarbital (10 mg/kg i.v.). A left thoracotomy is made in the fourth intercostal space, and the heart is exposed and supported by a pericardial cradle. A 20-MHz pulsed Doppler flow transducer and a hydraulic occluder are placed around the left circumflex artery. A pair of insulated silver-coated wires are sutured to the epicardial surface of both the left and right ventricles. These electrodes are used for ventricular pacing or to record a ventricular electrogram from which HR is determined using a Gould Biotachometer (Gould Instruments, Cleveland, OH). A pre-calibrated solid-state pressure transducer (Konigsberg Instruments, Pasadena, CA) is inserted into the left ventricle via a stab wound in the apical dimple. Finally, a two-stage occlusion of the left anterior descending coronary artery is performed approximately one third the distance from the origin to induce an anterior wall myocardial infarction. This vessel is partially occluded for 20 min and then tied off. All leads from the cardiovascular instrumentation are tunneled under the skin to exit on the back of the animal's neck. A transdermal fentanyl patch that delivers 75 µg/h for 72 h is placed on the back of the neck (secured with adhesive tape) to decrease post-operative discomfort. In addition, bupivacaine HCl, a long-acting local anesthetic, is injected to block the intercostal nerves (i.e., pain fibers) in the area of the incision. Each animal is placed on prophylactic antibiotic therapy (amoxicillin 500 mg p.o.) three times daily for 7 days. The animals are placed in an "intensive care" setting for the first 24 h and placed on antiarrhythmic therapy (Billman and Hamlin 1996; Billman et al. 1993, 1997; Schwartz et al. 1984).

Exercise-plus-ischemia test

The studies begin 3 to 4 weeks after the production of the myocardial infarction. The animals are walked on a motor-driven treadmill and trained to lie quietly without restraint on a laboratory table during this recovery period. Susceptibility to VF is then tested. The animals run on a motor-driven treadmill while workload is increased every 3 min for a total of 18 min. The protocol begins with a 3-min warm-up period, during which the animals run at 4.8 km/h at 0% grade. The speed is increased to 6.4 km/h, and the grade is in-

creased every 3 min as follows: 0%, 4%, 8%, 12% and 16%. During the last minute of exercise, the left circumflex coronary artery is occluded, the treadmill is stopped and the occlusion is maintained for 1 additional min (total occlusion time, 2 min). Large metal plates (diameter, 11 cm) are placed across the animal's chest so that electrical defibrillation can be achieved with minimal delay but only after the animal is unconscious (10–20 s after VF begin). The occlusion is immediately released if VF occur.

The animals then receive one or more of the following treatments:

1. the exercise-plus-ischemia test is repeated after pretreatment with the standard drug glibenclamide (1.0 mg/kg i.v.). The drug is injected in a cephalic vein; 3 min before exercise begins.
2. The exercise-plus-ischemia test is repeated after pretreatment with the test drug
3. Finally, a second control (saline) exercise plus ischemia test is performed 1 week after the last drug test. At least 5 days are intermitted between drug treatments. Drugs are given in a random order.

Refractory period determination

On a subsequent day, the effective refractory period is determined using a Medtronic model 5325 programmable stimulator, both at rest and during myocardial ischemia. The heart is paced for 8 beats (S_1; intrastimulus interval, 300 ms; pulse duration, 1.8 ms at twice-diastolic threshold of ~6 mA). The intrastimulus interval is progressively shortened between the last paced beat and a single extra-stimulus (S_2). The refractory period represents the shortest interval capable of generating a cardiac response and is measured using either the left or right ventricular electrodes. This procedure is completed within 30 s. Once the control values are determined, refractory period measurements are repeated after the standard drug glibenclamide (1.0 mg/kg i.v.), or the test drug. After the completion of these studies, refractory period is determined during myocardial ischemia (2-min occlusion of the left circumflex coronary artery) ~60 s after the onset of the coronary occlusion.

Reactive hyperemia studies

The K_{ATP} has been implicated in vascular regulation, particularly CBF (Aversano et al. 1991; Belloni and Hintze 1991; Daut et al. 1990). Therefore, the effects of standard and test drug on the response to brief interruptions in CBF are also evaluated. Animals are placed on a laboratory table, and the left circumflex coronary is occluded three or four times for 15 s. At least 2 min (or until CBF had returned to preocclusion base line) elapse between occlusions. The occlusions are then repeated 5 min after standard and test drug. On the subsequent day, the studies are repeated with the drug that had not been given the previous day.

EVALUATION

All hemodynamic data are recorded on a Gould model 2800S eight-channel recorder (Cleveland, OH) and a Teac model MR-30 FM tape recorder (Tokyo, Japan). Coronary blood flow is measured with a University of Iowa Bioengineering flowmeter model 545 C-4 (Iowa City, IA). The rate of change of left ventricular pressure [$d(LVP)/dt$] is obtained by passing the left ventricular pressure through a Gould differentiator that has a frequency response linear to >300 Hz. The data are averaged over the past 5 s of each exercise level. The coronary occlusion data are averaged over the last 5 s before and at the 60-s line point (or VF onset) after occlusion onset. The total area between the peak CBF and return to base line is measured for each 15-s occlusion, and the percent repayment is calculated. The reactive hyperemia response to each occlusion is then averaged to obtain one value for each animal. The data are then analyzed using analysis of variance for repeated measures. When the F ratio is found to exceed a critical value ($P < 0.05$), Scheffe's test is used to compare the mean values. The effects of the drug intervention on arrhythmia formation are determined using a χ^2 test with Yates' correction for continuity. All data are reported as mean ±SEM. Cardiac arrhythmias, PR interval and QT interval are evaluated at a paper speed of 100 mm/s. QT interval is corrected for HR using Bazett's method.

CRITICAL ASSESSMENT OF THE METHOD

Tests combining coronary constriction with physical exercise may resemble most closely the situation in coronary patients.

A.5.0.9
Characterization of anti-arrhythmic activity in the isolated right ventricular guinea pig papillary muscle

PURPOSE AND RATIONALE

According to Vaughan-Williams (1970) anti-arrhythmic drugs are divided into 4 different classes depending on their mode of action. Class I anti-arrhythmic agents decrease the upstroke velocity of the action potential through blockade of Na^+ channels. Class II drugs block β-receptors. Class III anti-arrhythmic agents prolong action potential duration, presumably through blockade of K^+ channels. Class IV anti-arrhythmic agents inhibit the slow calcium influx during the plateau of the action potential through Ca^{2+} channel blockade. These electrophysiological actions also have functional manifestations, e.g., Na^+ channel blockade decreases excitability, K^+ channel blockade lengthens refractory period, and Ca^{2+} channel blockade decreases tension of cardiac muscle. A simple and accurate non-microelectrode method is necessary to identify and classify potential anti-arrhythmic drugs into the classes I, III, and IV. In right ventricular guinea pig papillary muscle developed tension (DT), excitability (EX), and effective refractory period (ERP) are measured.

PROCEDURE

Guinea pigs of either sex weighing 200–400 g are stunned, the carotid arteries are severed, and the thoracic cage is opened immediately. The heart is removed, placed into a container of pre-warmed, pre-oxygenated physiologic solution and the pericardium, atria, and other tissues are removed. The heart is then pinned to a dissection dish, and the right ventricle is opened. The tendinous end of the papillary muscle is ligated with a silk thread, and the chordae tendinae are freed from the ventricle. The opposite end of the papillary muscle is then cut free close to the ventricular wall. The non-ligated end of the papillary muscle is clamped into a tissue holder, the end of which is a leucite block containing platinum wire field electrodes.

The preparation is transferred to a tissue bath containing 75 ml of a physiological salt solution that is gassed continuously with 95% O_2/5% CO_2 and maintained at a temperature of 35 °C and a pH of 7.4. The silk thread is used to connect the muscle to a Grass FT03C force transducer. An initial resting tension of 1 g is established. Muscles are field stimulated to contract isometrically. The stimulus duration is 1 ms, the frequency 1 Hz, and the voltage twice threshold. Pulses are delivered with the use of a Grass S88 constant voltage stimulator, and developed tension is recorded with the use of a polygraph recorder. The preparation is equilibrated in this manner for 90 min with bath solution changes every 15 min. Control measurements of the force-frequency curve, stimulus strength-duration curve and the effective refractory period are made following the 75 min bath exchange, i.e., during the last 15 min of equilibration.

The force-frequency curve is obtained by measuring developed tension over a range of stimulation frequencies (0.3, 0.5, 0.8, 1.0, and 1.2 Hz). The tissue is contracted for 90 s at each of these frequencies with a brief period of stimulation at 1.5 Hz inserted between increments. The purpose of the 1.5 Hz insert is to keep "pacing history" constant as well as to minimize progressive, nonspecific depression during the lower frequency stimulation series. Both pre- and postdrug developed tension (at each frequency) are expressed as a percentage of the predrug developed tension at 1 Hz. The percent change in post treatment (versus pretreatment) developed tension at 1 Hz is used to quantitate an agent's inotropic effect.

The stimulus strength-duration curves are determined by varying the stimulus duration (0.1, 0.4, 0.8, 1.0, 1.5, 3.0, and 3.4 ms) and finding the threshold voltage that produced a 1:1 correspondence between stimulus and response at each duration. The degree of shift in the strength-duration curve is measured by computing the area between the pre- and post-treatment curves. The boundaries for the area are determined by the first (x-axis parallel) and the last (x-axis perpendicular) durations and by lines from the origin to the second and fourth durations.

Effective refractory period (ERP) is measured at 1 Hz using twin pulse stimuli. After every 8–10 pulses, a second delayed stimulus (S_2) identical to the basic drive pulse (S_1) is introduced. This procedure is repeated, shortening the delay ($S_1 - S_2$) by 5 ms increments. The value of the ERP is taken as the longest delay ($S_1 - S_2$) for which there is a single response to twin pulses. The change in ERP is computed as the difference (ms) between the pre- and post-treatment

At the conclusion of the 90 min predrug equilibration period, an aliquot of the test drug designed to achieve the desired final concentration is added to the bath. The tissue must equilibrate for 1 h in the drug solution before postdrug measurements of the force-frequency curve, stimulus strength-duration curve, and effective refractory period are obtained.

EVALUATION

The changes in effective refractory period (ERP) (post treatment minus pretreatment), the degree of shift in the strength-duration curve (geometrical area between pre- and post-treatment curves), and the percent changes in post treatment developed tension at 1 Hz are calculated. The results of these calculations are used to classify the compound as a class I, III, or IV anti-arrhythmic agent on the basis of its effect on developed tension, excitability, and effective refractory period. An upward and right shift of the strength-duration curve (decrease in excitability) is characteristic for a class I anti-arrhythmic agent, such disopyramide. Selective prolongation of effective refractory period is characteristic for class III anti-arrhythmic agents, such as sotalol. Depression of developed tension, and/or flattening or reversal of the force-frequency curve is characteristic for a class IV anti-arrhythmic agent, such as verapamil.

CRITICAL ASSESSMENT OF THE METHOD

The model of the electrically stimulated isolated guinea pig papillary muscle is a simple method to classify anti-arrhythmic agents. Some drugs have multiple actions and, therefore, belong in more than one class. For further characterization analysis of the action potential is necessary.

MODIFICATIONS OF THE METHOD

O'Donoghue and Platia (1991) recommended the use of monophasic action potential recordings for the evaluation of anti-arrhythmic drugs.

Shibuya et al. (1993) studied the effects of the local anesthetic bupivacaine on contraction and membrane potential in isolated canine right ventricular papillary muscles. From analysis of action potential it is concluded that at low concentrations contraction is depressed mainly due to a Na^+ channel block, whereas at high concentrations also Ca^{2+} channels may be blocked.

Kodama et al. (1992), Maryuama et al. (1995) studied the effects of potential antiarrhythmics on maximum upstroke velocity and duration of action potential in isolated right papillary muscles of guinea pigs as well as the influence of these agents on single ventricular myocytes.

Borchard et al. (1982) described a method for inducing arrhythmias or asystolia by the application of 50 Hz alternating current (ac) to electrically driven isolated left atria and right papillary muscles of the guinea pig. An increase in driving frequency from 1 to 3 Hz effected a significant reduction of the threshold of ac-arrhythmia in guinea pig papillary muscle, but no change in atria. A decrease in temperature from 31 °C to 25 °C and an increase in Ca^{2+} from 1.25 to 5 mmol/l elevated the threshold for ac-arrhythmia and -asystolia. Fast sodium channel inhibitors increased threshold of ac-arrhythmia in left atria and papillary muscles, whereas the slow channel inhibitor verapamil was ineffective in concentrations up to 6 µmol/l.

A.5.0.10
Action potential and refractory period in isolated left ventricular guinea pig papillary muscle

PURPOSE AND RATIONALE

Intracellular action potential in the left ventricular guinea pig papillary muscle is recorded after electrical stimulation. The stimulation frequency is varied in order to determine the refractory period. Resting potential, upstroke velocity, duration of action potential, threshold, refractory period and contractile force can be measured *in vitro*. Compounds which affect the duration of the effective refractory period may have anti-arrhythmic or pro-arrhythmic effects. In addition, the inotropic effect (positive or negative) of the test compound is determined.

PROCEDURE

Guinea pigs of either sex (Marioth strain) weighing 250–300 g are sacrificed by stunning, the carotid arteries are severed, and the thoracic cage is opened immediately. The heart is removed, placed in a container of prewarmed, pre-oxygenated Ringer solution, and the pericardium and the atria are trimmed away. The left ventricle is opened and the two strongest papillary muscles removed. They are fixed between a suction electrode for electrical stimulation and a force transducer for registration of contractions. Ringer solution oxygenated with carbogen (95% O_2/5% CO_2) at a temperature of 36 °C is used.

A standard micro electrode technique is applied to measure the action potential via a glass micro electrode containing 3 M KCl solution, which is inserted intracellularly. The papillary muscle is stimulated with rectangular pulses of 1 V and of 1 ms duration at an interval of 500 ms. The interval between two stimuli is variable in order to determine refractory periods. The intensity of the electrical current is just below the stimulation threshold.

The intracellular action potential is amplified, differentiated for registration of upstroke velocity (dV/dt) (Hugo Sachs micro electrode amplifier), together with the contraction force displayed on an oscilloscope (Gould digital storage oscilloscope OS 4000), and recorded (Gould 2400 recorder).

The effects on fast sodium channels as well as on calcium channels can be studied. The former requires measurement of the normal action potential and the latter the slow action potential obtained at 30 mM K^+. To estimate the relative refractory periods, the second stimuli are set in decremental intervals until contraction ceases. Relative refractory period is defined as the minimum time interval of two stimuli at which each of the stimuli is answered by a contraction. The stimulation threshold is also measured.

After an equilibrium time of 30 min the test compound is added. After 15 and 30 min the following parameters are compared with the predrug values:

- Resting potential mV
- upstroke velocity V/s
- duration of action potential ms
- stimulation threshold V
- refractory period ms
- contraction force mg

The organ bath is flushed thoroughly between two consecutive applications of increasing test drug doses.

EVALUATION

Contractile force [mm] and relative refractory period [ms] are determined before and after drug administration. ED_{25ms}- and ED_{50ms}-values are determined. ED_{25ms} or ED_{50ms} is defined as the concentration of test drug in the organ bath at which the relative refractory period is reduced or prolonged by 25 ms or 50 ms.

Since many anti-arrhythmic agents possess additionally negative inotropic effects, changes in the force of contraction are also determined.

ED_{50} values are calculated from log-probit analyses. Scores are allotted relative to the efficacy of standard compounds (lidocaine, propranolol, quinidine).

The following changes are indicators for anti-arrhythmic activity:

- increase of stimulation threshold
- decrease of upstroke velocity
- prolongation of action potential
- increase of refractory period.

Upstroke velocity and duration of action potential are used for **classification purposes**.

MODIFICATIONS OF THE METHOD

Tande et al. (1990) studied the electromechanical effects of a class III anti-arrhythmic drug on guinea pig and rat papillary muscles and atria using conventional microelectrode technique.

Shirayama et al. (1991) studied with a similar technique the electrophysiological effects of sodium channel blockers in isolated guinea pig left atria.

Dawes (1946) described a method of examining substances acting on the refractory period of cardiac muscle using isolated rabbit auricles.

The same method was recommended as first step of a screening program for quinidine-like activity by Schallek (1956).

Wellens et al. (1971) studied the decrease of maximum driving frequency of isolated guinea pig auricles after antiarrhythmic drugs and beta-blockers.

Salako et al. (1976) recorded electropotentials along the conducting system after stimulation of the proximal part of the His bundle in rabbits.

Brown (1989), Wu et al. (1989), Gwilt et al. (1991a,b) measured *in vitro* transmembrane action potential in Purkinje fibers and endocardial ventricular muscles from dogs.

Voltage clamp techniques in isolated cardiac myocytes from guinea pigs have been used by Wettwer et al. (1991).

A.6
Methods to induce cardiac hypertrophy and insufficiency

A.6.0.1
Aortic banding in rats

PURPOSE AND RATIONALE

Blood flow restriction of the aorta in rats induces not only hypertension but also cardiac hypertrophy within several weeks. Angiotensin converting enzyme inhibitors, even at subantihypertensive doses, but not other antihypertensive drugs, inhibit cardiac hypertrophy (Linz et al. 1991; Schölkens et al. 1991; Gohlke et al. 1992; Linz 1992a; Linz et al. 1996; Ogawa et al. 1998).

PROCEDURE

Male Sprague Dawley rats weighing 270–280 g are fasted 12 h before surgery. Anesthesia is induced by i.p. injection of 200 mg/kg hexobarbital. The abdomen is shaved, moistened with a disinfectant and opened by a cut parallel to the linea alba. The intestine is moistened with saline and placed in a plastic cover to prevent desiccation. The aorta is prepared free from connective tissue above the left renal artery and underlaid with a silk thread. Then, a cannula no. 1 (0.9×40 mm) is placed longitudinally to the aorta and both aorta and cannula are tied. The cannula is removed, leaving the aortic lumen determined by the diameter of the cannula. The intestine is placed back into the abdominal cavity with the application of 5.0 mg rolitetracycline (Reverin®). In sham-operated controls no banding is performed. The skin is closed by clipping.

The animals are treated once daily over a period of 6 weeks with doses of the ACE-inhibitor or other antihypertensive drugs found previously effective to lower blood pressure in rats. At the end of the experiment blood pressure is measured under hexobarbital anesthesia (200 mg/kg i.p.) via indwelling catheters in the left carotid artery. Blood pressure measurement in conscious rats with the convential tail-cuff method is not possible due to the large pressure difference across the ligature. Therefore, only one measurement at the end of the study is possible. The hearts are removed, rinsed in saline until free of blood and gently blotted to dryness. Total cardiac mass is determined by weighing on an electronic balance to the nearest 0.1 mg. The atria and all adjacent tissues are trimmed off and the weight of the left ventricle including the septum as well as the remaining cardiac tissue representing the right ventricle are determined separately. Weights are calculated per 100 g body weight.

EVALUATION

Total cardiac mass, weight of left and right ventricle of treated rats are compared with operated controls and sham-operated controls.

MODIFICATIONS OF THE METHOD

Uetmasu et al. (1989) described a simple method for producing graded aortic insufficiencies in rats and subsequent development of cardiac hypertrophy. Selective perforation of the right cup of the aortic valve or in combination with that of the left valve cup was performed using a plastic rod inserted from the right common carotid artery. Hypertrophy of the heart, but no hypertension or cardiac insufficiency, was observed.

Similar methods were used by Yamazaki et al. (1989) to study the alterations of cardiac adrenoceptors and calcium channels subsequent to aortic insufficiency, by Umemura et al. (1992) to study baroreflex and β-adrenoceptor function and by Ishiye et al. (1995) to study the effects of an angiotensin II antagonist on the development of cardiac hypertrophy due to volume overload.

Hyperplastic growth response of vascular smooth muscle cells in the thoracic aorta was found following induction of acute hypertension in rats by aortic coarctation by Owens and Reidy (1985).

Prevention of cardiac hypertrophy after aortic banding by ACE inhibitors probably mediated by bradykinin could be shown (Linz et al. 1989, 1992a,b, 1993, 1994; Linz and Schölkens 1992; Schölkens et al. 1991).

Weinberg et al. (1997) studied the effect of angiotensin AT_1 receptor inhibition on hypertrophic remodelling and ACE expression in rats with pressure-overload hypertrophy due to ascending aortic stenosis.

A simple and rapid method of developing high output heart failure and cardiac hypertrophy in rats by producing **aortacaval shunts** was described by Garcia and Diebold (1990). Rats weighing 180–200 g were anesthetized with 30 mg/kg i.p. pentobarbitone. The vena cava and the abdominal aorta were exposed by opening the abdominal cavity via a midline incision. The aorta was punctured at the union of the segment two thirds caudal to the renal artery and one third cephalic to the aortic bifurcation with a 18 gauge disposable needle. The needle was advanced into the aorta, perforating its adjacent wall and penetrating in the vena cava. A bulldog vascular clamp was placed across the aorta caudal to the left renal artery. Once the aorta was clamped, the needle was fully withdrawn and a drop of cyanoacrylate glue was used to seal the aorta punctured point. The clamp was removed 30 s later. The patency of the shunt was verified visually by swelling vena cava and the mixing of arterial and venous blood. The peritoneal cavity was closed with silk thread stitches and the skin with metallic clips. Rats with aorta-caval shunts developed cardiac hypertrophy with significantly higher absolute and relative heart weights.

A.6.0.2 Cardiac hypertrophy in mice

PURPOSE AND RATIONALE

Rockman et al. (1991, 1993) developed a model of ventricular hypertrophy in the intact mouse by use of microsurgical techniques.

PROCEDURE

Eight week old adult mice weighing 18–22 g are anesthetized by intraperitoneal injection of a mixture of 100 mg/kg ketamine, 5 mg/kg xylazine, and 2.5 mg/kg morphine. Animals are placed under a dissecting microscope in the supine position and a midline cervical incision is made to expose the trachea and carotid arteries. After endotracheal intubation, the cannula is connected to a volume cycled rodent ventilator on supplemental oxygen with a tidal volume of 0.2 ml and a respiratory rate of 110 per min. Both left and right carotid arteries are cannulated with flame stretched PE50 tubing. Catheters are connected to modified P50 Statham transducers.

The chest cavity is entered in the second intercostal space at the left upper sternal border through a small incision and the thymus is gently deflected out of the field of view to expose the aortic arch. After the transverse aorta is isolated between the carotid arteries, it is constricted by a 7.0 nylon suture ligature against a 27-gauge needle, the latter being promptly removed to yield a constriction of 0.4 mm diameter and provide a reproducible transverse aortic constriction of 65–75%.

The hemodynamic effects of acute and chronic constriction are followed by monitoring the pressure gradient between the two carotid arteries in anesthetized animals. Systolic and mean arterial pressure at baseline, during total occlusion when the ligature is tied, and early (15 min) and late (7 days) after transverse aortic constriction are recorded. The increase in systolic pressure provides an adequate mechanical stimulus for the development of cardial hypertrophy.

To confirm myocardial hypertrophy, both sham-operated and aortic-constricted hearts are examined 7 days after operation. Hearts examined for *cell size* are perfused with 4% paraformaldehyde/1% glutaraldehyde through the apex, immersed in osmium tetroxide, dehydrated in graded alcohols, and embedded in araldite. Tissue blocks are sectioned at a thickness of 1 µm, mounted on slides, and stained with toluidine blue. Cell areas are measured by manually tracing the cell outline on an imaging system connected to a computer.

At the end of the experiment, mice were sacrificed in anesthesia, heart excised and weighed, the atria and ventricles separately frozen in liquid nitrogen for Northern blot analysis. Total RNA is extracted by a single step extraction with guanidinium thiocyanate. The RNA is size fractionated by agarose gel electrophoresis, transferred to nylon membranes by vacuum blotting, and hybridized with the appropriate complementary DNA probes labeled with ^{32}P by random priming to a specific activity of $0.95–1.2 \times 10^6$ cpm/ng.

EVALUATION

Variables measured are expressed as mean ±SD. Statistical significance of differences between sham-operated and thoracic aortic-constricted animals is assessed by Student's *t*-test.

MODIFICATIONS OF THE METHOD

Chien (1995) described cardiac muscle diseases in genetically engineered mice:

A.6.0.3 Cardiac insufficiency in guinea pigs

PURPOSE AND RATIONALE

Congestive heart failure in man is characterized by cardiac hypertrophy, peripheral edema, lung and liver congestion, dyspnea, hydrothorax and ascites. Effective treatment is achieved by cardiac glycosides. Based on techniques reported by Selye et al. (1960) a method was developed to induce congestive heart failure in guinea pigs with symptoms very close to human pathology (Vogel and Marx 1964; Vogel et al. 1965).

PROCEDURE

Male guinea pigs weighing 250–400 g are used. The fur at the ventral thorax is shaved and the skin disinfected. The animal is anesthetized with ether. The skin is cut with scissors on the left side at a length of 4 cm. The left musculus pectoralis is cut at the costal insertion and elevated. The forth intercostal space is opened with two blunted forceps. The heart is pressed against the opening with the left hand. The pericard is opened with a fine forceps and pulled back to the basis of the heart. The beating heart is extruded from the thorax wound by pressure with the left hand on the right thorax wall. A ring-shaped clamp covered with a thin rubber tube is placed around the basis of the heart keeping the heart outside of the thorax without closing off the blood circulation. A thread soaked with diluted disinfectant solution is placed as a loop around the apex of the heart and tightened so that the apical third of both ventricles is tied off. The degree of tightening of the loop is essential. Complete interruption of blood supply to the apical third resulting in necrosis has to be avoided as well as the loop's slipping off. Technical skill is necessary to place the loop around the beating heart into the correct position. After removal of the clamp the heart is placed back, the incision between the forth and fifth costal rib closed and the musculus pectoralis placed over the wound. Intrathoracal air forming a pneumothorax is removed by pressure on both sides of the thorax. After application of an antibiotic emulsion the skin wound is closed. The surgical procedure has to be finished within a short period of time.

The animals develop symptoms of severe congestive heart failure with a death rate of 80% within 14 days. Lung weight and relative heart weight are significantly increased. Exudate in the thorax cavity and ascites amount between 3.5 and 7.5 ml with extreme values of 17.5 ml. Lung edema and liver congestion are found histologically. Peripheral edema and preterminal dyspnea and tachypnea are observed. When treated with various doses (0.1 to 100 µg/kg) of cardiac glycosides s.c. or i.m. over a period of 14 days the symptoms of cardiac insufficiency, e.g., volumes of transudate as well as death rate, are dose-dependent diminished.

EVALUATION

From survival rate, ED_{50} values of cardiac glycosides can be calculated which are in the same dosage range as therapeutic doses in man.

CRITICAL ASSESSMENT OF THE METHOD

The experimental model in guinea pigs reflects very closely the symptoms of cardiac insufficiency in man, e.g., lung congestion, hydrothorax, liver congestion, ascites, peripheral edema and cardiac hypertrophy. The therapeutic potency of cardiac glycosides can be evaluated with this method. Additional factors being known to enhance the symptoms of congestive heart failure in man, like salt load and diphtheria toxin, further increase mortality and hydropic symptoms. The method can be used for special purposes, however, it needs considerable training and technical skill.

MODIFICATIONS OF THE METHOD

Pfeffer et al. (1987) induced myocardial infarction in **rats** by ligation of the left coronary artery and found hemodynamic benefits and prolonged survival with long-term captopril therapy.

Acute ischemic left ventricular failure can be induced in anesthetized **dogs** by repeated injections of plastic microspheres into the left coronary artery (see A.3.2.4).

Kinney et al. (1991) published a method to induce acute, reversible tricuspid insufficiency in anesthetized dogs. A wire spiral is advanced through the atrioventricular canal from the right atrium. The spiral causes regurgitation by preventing complete apposition of the valve leaflets while permitting retrograde flow to occur through the spiral lumen. The degree of regurgitation can be controlled by the use of spirals of different size. Creation of tricuspid insufficiency was demonstrated by onset of right atrial pressure V waves, a ballooning of the right atrium during ventricular systole, palpation of an atrial thrill, or by color Doppler echocardiography. The model is reversible and allows repeated trials of various grades of regurgitation.

Huang et al. (1997) created congestive heart failure in **sheep** by selective sequential intracoronary injection of 90 µm microspheres under 1.5% isofluorane injection.

A.6.0.4 Cardiomyopathic Syrian hamster

PURPOSE AND RATIONALE

Cardiomyopathy in Syrian hamsters has been described by Bajusz et al. (1966), Bajusz and Lossnitzer (1968), Bajusz (1969), Bajusz et al. (1969a,b), Homburger and Bajusz (1970), Gertz (1972). The disease originates from an autosomal, recessively transmissible disorder which leads to degenerative lesions in all striated muscles and in particular in the myocardium. Histopathological changes consist of myocytolytic necrosis followed by fibrosis and calcification. The evolution of the cardiomyopathic disease can be characterized by five distinct phases: A prenecrotic stage, in which no pathology is evident, a time of active myocytolysis and cellular necrosis, a phase of fibrosis and calcium deposition, an overlapping period of reactive hypertrophy of the remaining viable myocytes, and a final stage of depressed myocardial performance and failure.

PROCEDURE

The model of cardiomyopathy in Syrian hamsters has been used by several authors. One has to note, that several strains of cardiomyopathic hamsters have been used: strain Bio 53:58 by Capasso et al. (1989, 1990) and by Chemla et al. (1992, 1993), strain BIO 14.6 by Tapp et al. (1989) and by Sen et al. (1990), strain CHF 146 CM by van Meel et al. (1989) and by Haleen et al. (1991), strain BIO82.62 by ver Donck et al. (1991), strain J-2-N by Kato et al. (1992), strain CHF 147 by Desjardins et al. (1989), Hanton et al. (1993).

Various experimental protocols have been described. Most authors use survival rate and heart weight as end point (e.g., van Meel et al. 1989; ver Donck et al. 1991; Hanton et al. 1993). Generally, the experiments are started with animals at an age of 120 to 200 days.

Capasso et al. (1989, 1990) studied the mechanical and electrical properties of cardiomyopathic hearts of Syrian hamsters using isolated left ventricular posterior papillary muscles.

Tapp et al. (1989) tested stress-induced mortality in cardiomyopathic hamsters by five consecutive daily 2-h periods supine immobilizations at 4 °C.

Sen et al. (1990) tested the inotropic and calcium kinetic effects of calcium channel agonists and antagonists in primary cultures of isolated cardiac myocytes.

Haleen et al. (1991) tested the effects of an angiotensin converting enzyme inhibitor not only on survival, but also on left ventricular failure in the isolated Langendorff heart by measurement of left ventricular end-diastolic pressure, dP/dt_{max} and mean coronary flow.

Dixon et al. (1997) tested the effect of an AT_1 receptor antagonist on cardiac collagen remodelling in the cardiomyopathic Syrian hamster.

In addition to the effects on left ventricular papillary muscles strips, Chemla et al. (1992) tested the effects on diaphragm contractility in the cardiomyopathic Syrian hamster.

CRITICAL ASSESSMENT OF THE METHOD

Positive effects of various drugs have been found in the cardiomyopathic hamster, such as cardiac glycosides, inotropic compounds, beta-blockers, calcium antagonists, and ACE-inhibitors. The specificity of the effects has to be challenged.

MODIFICATIONS OF THE METHOD

The **tight-skin (TSK) mouse** is a genetic model of pulmonary emphysema connected with right ventricular hypertrophy (Martorana et al. 1990; Gardi et al. 1994).

Valentine et al. (1988) and Devaux et al. (1993) described **X-linked muscular dystrophy in dogs** with cardiac insufficiency similar to Duchenne muscular dystrophy in men and recommended this as an animal model for cardiac insufficiency.

A.6.0.5 Hypertrophy of cultured cardiac cells

PURPOSE AND RATIONALE

Kojima et al. (1994), Komuro et al. (1990, 1991, 1993), Yamazaki et al. (1993, 1994, 1996) described a method to induce hypertrophy of cardiomyocytes by mechanical stress *in vitro*.

PROCEDURE

Primary cultures from cardiomyocytes are prepared from ventricles of 1-day-old neonatal Wistar Kyoto rats. According to the method of Simpson and Savion (1982), the cultures are treated for 3 days with 0.1 mM bromodeoxyuridine to suppress proliferation of nonmyocardial cells. Elastic culture dishes ($2 \times 4 \times 1$ cm) are made by vulcanizing liquid silicone rubber consisting of methylvinyl polysiloxane and dimethyl hydrogen silicone resin using platinum as a catalyst. The bottom of the disc is 1-mm thick, and it is highly transparent because of no inorganic filler in either component. Cells are plated in a field density of 1×10^5 cells/cm^2 in culture medium consisting of Dulbecco's modified Eagle's medium with 10% fetal bovine serum. Mechanical

stress on cardiac cells is applied by gently pulling and hanging the dish on pegs. A 10% change in length of the dish results in an almost identical change in the length of the cell along a single axis (Kimuro et al. 1990). Cardiocytes are stretched by 5%, 10%, or 20%. Drugs, e.g., an angiotensin-II receptor antagonist, are added 30 min before stretch.

For protein analysis, the silicone dishes are stretched for 24 h after 2 days of serum starvation and [^{3}H]phenylalanine (1 μCi/ml) is added for 60 min. At the end of each stress, the cells are rapidly rinsed four times with ice-cold phosphate-buffered saline and incubated for 20 min on ice with 1 ml of 5% trichloroacetic acid. The total trichloroacetic acid-insoluble radioactivity in each dish is determined by liquid scintillation counting.

For determination of mitogen-activated protein kinase, cardiomyocytes are lysed on ice and centrifuged. Aliquots of the supernatants of myocyte extracts are incubated in kinase buffer (25 mM/l Tris-HCl, pH 7.4, 10 mM/l $MgCl_2$, 1 mM/l dithiothreitol, 40 μM/l APT, 2 μCi [γ-^{32}P]ATP, 2 μM/l protein kinase inhibitor peptide, and 0.5 mM/l EGTA) and substrates (25 μg myelin basic protein). The reaction is stopped by adding stopping solution containing 0.6% HCl, 1 mM/l ATP, and 1% bovine serum albumin. Aliquots of the supernatant are spotted on P81 paper (Whatman), washed in 0.5% phosphoric acid, dried and counted.

For determination of *c-fos mRNA*, Northern blot analysis is performed.

EVALUATION

Values are expressed as mean ±SEM. Comparisons between groups are made by one-way ANOVA followed by Dunnett's modified *t*-test.

CRITICAL ASSESSMENT OF THE METHOD

The interesting approach to induce hypertrophy of cardiac cells *in vitro* has been used predominantly by one research group. Confirmation by other research groups including modifications of the mechanical procedures seems to be necessary.

A.7 Positive inotropic activity (cardiac glycosides)

A.7.0.1 General considerations

Biological standardization of cardiac glycosides was necessary as long as the drugs used in therapy were plant extracts or mixtures of various glycosides. They were standardized in units of an international standard. Some of the pharmacological methods used for these purposes and adopted by many pharmacopoeias have nowadays *historical interest* only. This holds true for the frog method and the pigeon method (Burn et al. 1950).

Particularly, the **frog method** was used for standardization. The method adopted by the U.S Pharmacopoeia X was the 1 h test. Healthy frogs (*Rana pipiens*) weighing 20–30 g were selected from the cold storage room. One hour before assay, their weight was recorded and they were placed in wire cages with a water depth of 1 cm. The doses of digitalis were calculated so that they approximated 0.015 ml/g body weight. Injections were made into the ventral lymph sac. One hour later, the animals were pithed and the heart removed and examined. Systolic arrest of the ventricle and widely dilated atrium indicated the typical result. Calculations of activity in terms of International Units were made from the percentage of dead animals in the test group versus those in the group receiving the international standard.

The **pigeon method** introduced by Hanzlik (1929) and adopted by USP XVII depends on the observation that intravenously injected cardiac glycosides have an emetic action in pigeons. In the original test, adult pigeons weighing 300–400 g are injected with a solution of the cardiac

glycoside into a suitable wing vein in the axillary region. Vomiting occurring within 15 min is regarded as positive result. Two doses of test solution and standard are injected and percentage of vomiting pigeons registered. This 4 point assay allows calculation of ED_{50} values and of the potency ratio compared with the standard.

Modifications of other methods, such as the **cat method** introduced by Hatcher and Brody (1910) and described in detail by Lind van Wijngarden (1926), the **guinea pig method** described by Knaffl-Lenz (1926) and the **isolated cat papillary muscle** method introduced by Catell and Gold (1938) still being used for evaluation of synthetic cardioglycosides and other positive inotropic compounds are referenced in detail below.

Surveys on the evaluation of cardiac glycosides have been given by Bahrmann and Greef (1981), for the use of the isolated papillary muscle by Reiter (1981) and for other isolated heart preparations by Greef and Hafner (1981). Moreover, the influence on Na^+/K^+-ATPase, an *in vitro* model specific for cardiac glycosides (Gundert-Remy and Weber 1981), is described.

The mechanisms of action have been reviewed by Scholz (1984) and Grupp (1987).

Analogous to antiarrhythmic agents, Feldmann (1993) proposed a classification system that categorizes inotropic agents according to their supposed mode of action:

Class I: Inotropic agents that increase intracellular cyloAMP, including β-adrenergic agonists and phosphodiesterase inhibitors,
Class II: Inotropic agents affecting sarcolemmal ion pumps and channels, in particular cardiac glycosides inhibiting Na^+/K^+-ATPase,
Class III: Agents that modulate intracellular calcium mechanisms (no therapeutic inotropic agents in this kind yet available),
Class IV: Inotropic agents having multiple mechanisms of action

A.7.1 *In vitro* tests

A.7.1.1 Ouabain binding

PURPOSE AND RATIONALE

Cardiac glycosides can be characterized by their binding kinetics (association process, equilibrium binding, and dissociation process) on the ouabain receptor.

PROCEDURE

Heart sarcolemma preparations are obtained from rat or dog heart. From a canine heart or from rat hearts submitted to coronary perfusion myocytes are isolated by collagenase digestion. The isolated membrane fractions consist mainly of myocyte sarcolemma. [^{3}H]ouabain with a specific radioactivity of about 20 Ci/mmol is incubated with ligands to be tested in 10 ml of binding medium consisting of 1 mM $MgCl_2$, 1 mM inorganic phosphate, and 50 mM Tris-HCl, pH 7.4 at 37 °C for 10 min.

Association process: After temperature equilibration in the presence of either 10 or 100 nM [^{3}H]ouabain, 200 µg of membrane preparation are added to initiate the reaction. At various times, 4.5 ml are removed and rapidly filtered.

Equilibrium binding: At the end of the temperature equilibration carried out in the presence of increasing concentrations of [^{3}H]ouabain ranging from 10 nM to 3 µM, 40 µg of membranes are added. After 30 min, duplicate aliquots of 4.5 ml are removed and filtered.

Dissociation process: Once equilibrium has been achieved under the experimental conditions used to study association, 10 ml of prewarmed Mg^{2+} plus P_i Tris-HCl solution supplemented with 0.2 mM unlabeled ouabain are added to initiate dissociation of [^{3}H]ouabain. At various times, aliquots of 0.9 ml are removed and rapidly filtered.

All aliquots are filtered under vacuum on HAWP Millipore filters (0.45 µm) and rinsed three times with 4 ml of ice-cold buffer. The radioactivity bound to the filters and the specific binding measurements are determined.

EVALUATION

Kinetic parameters for the association and the dissociation process are calculated. The results of equilibrium binding are analyzed by Scatchard plots.

A.7.1.2 Influence on Na^+/K^+ ATPase

PURPOSE AND RATIONALE

The enzyme Na^+/K^+ ATPase is the transport system for Na^+ and K^+ in the cell membranes. The membrane bound enzyme couples ATP hydrolysis to the translocation of Na^+ and K^+ ions across the plasma membrane through a series of conformational transitions between the E_1 and E_2 states of the enzyme. The enzyme is a heterodimer consisting of a catalytic subunit (110 kDa) associated with a glycosylated β subunit (55 kDa). Three alpha (α_1, α_2, α_3) subunits have been identified by cDNA cloning. In the heart, enzyme Na^+/K^+ ATPase is the target of the positive inotropic glycosides. Therefore, it is of interest for the characterization of positive inotropic compounds. The test is based on the determination of phosphate generated from ATP under special conditions. Inhibition of bovine cerebral Na^+/K^+ ATPase prepared according to Schoner et al. (1967) is measured after addition of various concentrations of the test compound compared with those of the standard (Erdmann et al. 1980).

PROCEDURE

Solutions

1.00 ml	133 mM imidazole pH 7.3
0.04 ml	160 mM $MgCl_2$
0.02 ml	DPNH (10 mg/ml)
0.04 ml	310 mM NH_4Cl
0.04 ml	100 mM ATP
0.02 ml	40 mM phospho-enolpyruvate
0.05 ml	pyruvate-kinase (1 mg/ml = 150 U/ml)
0.04 ml	lactate-dehydrogenase (0.5 mg/ml = 180 U/ml)
0.20 ml	1 M NaCl
0.01–0.02 ml	bovine cerebral ATPase (depending on activity of the enzyme) up to 2.0 ml distilled water

Test

The enzyme activity is started by addition of the ATP solution at 37 °C. After 4 min the inhibitor (various concentrations of the cardiac glycoside) is added. Na^+/K^+ ATPase activity is measured by a coupled optical assay. The reaction is continuously recorded and corrected for Mg^{2+}-activated ATPase by inhibition of Na^+/K^+ ATPase with 10^{-3} M ouabain.

EVALUATION

Inhibition of ATPase is measured after addition of various concentrations of the test compound. Dose-response curves are established and compared with the standard (k-strophanthin). Potency ratios can be calculated.

MODIFICATIONS OF THE METHOD

Brooker and Jelliffe (1972) and Marcus et al. (1975) described an *in vitro* assay based on displacement of radiolabeled ouabain bound to ATPase by various glycosides. Another method is based on the inhibition

of rubidium uptake into erythrocytes (Lowenstein 1965; Belz 1981).

Erdmann et al. (1980) prepared (Na^++K^+)-ATPase-containing cardiac cell membranes from rat hearts.

Maixent et al. (1987, 1991) described two Na,K-ATPase isoenzymes in canine cardiac myocytes as the molecular basis of inotropic and toxic effects of digitalis.

The effect of ouabain on Na^+/K^+ATPase activity in cells of the human rhabdomyosarcoma cell line TE671 was studied by Miller et al. (1993) with a special equipment, the microphysiometer (McConnell et al. 1992).

CRITICAL ASSESSMENT OF THE METHOD

The *in vitro* methods being used for determinations of plasma levels of glycosides (Maixent et al. 1995) have been largely substituted by radio-immunoassays specific for individual glycosides. Nevertheless, the inhibition of Na^+/K^+ ATPase can be used as an indicator of activity of new semisynthetic cardiac glycosides.

A.7.2
Tests in isolated tissues and organs

A.7.2.1
Isolated cat papillary muscle

PURPOSE AND RATIONALE

Isolated cardiac tissue has been chosen to study the decrease of performance after prolonged electrical stimulation and during restoration of force under the influence of cardiac glycosides. Cattell and Gold (1938) described a method using cat papillary muscle.

PROCEDURE

Cats of either sex weighing 2.5–3 kg are used. The animal is anesthetized with ether and the thorax is opened rapidly. The heart is removed and a papillary muscle from the right ventricle is isolated and fixed in an organ bath containing oxygenated Ringer's solution at 36 °C. One end of the muscle is tied to an tissue holder and the other one to a strain gauge. The muscle is stimulated electrically with 4–6 V, 2 ms duration and a rate of 30/min. The contractions are recorded on a polygraph. After 1 h, the muscle begins to fail and the force of contraction diminishes to a fraction of control. At this point, the cardiac glycoside is added to the bath, restoring the contractile force to levels approaching control. The standard dose is 300 ng/ml ouabain. The potency of natural and semisynthetic glycosides can be determined with this method. Catecholamines, like adrenaline (10 ng/ml) or isoprenaline (10 ng/ml), are active as well.

EVALUATION

The increase of contractile force is calculated as percentage of the predose level. Dose-response curves can be established using various doses.

CRITICAL ASSESSMENT OF THE METHOD

The use of isolated papillary muscle strips can be recommended for evaluation of inotropic compounds of various chemical classes.

MODIFICATIONS OF THE METHOD

Instead of cat papillary muscle the isolated left atrium of guinea pigs can be used (see Sect. A.1.2.6). For testing cardiac glycosides, the calcium content in the Ringer solution is reduced to 50%.

Andersom (1983) compared responses of guinea pig paced left atria to various positive inotropic agents at two different calcium concentrations (1.25 and 2.50 mM). Consistently good results were obtained at the lower calcium concentration with isoproterenol, ouabain, amrinone, and 3-isobutyl-1-methylxanthine.

Böhm et al. (1989) studied positive inotropic substances like isoprenaline and milrinone in isolated cardiac preparations from different sources. They used isolated papillary muscles from Wistar-Kyoto rats and from spontaneously hypertensive rats, but also human papillary muscle strips from patients with moderate heart failure (NYHA II–III) and compared the effects with papillary muscle strips from patients with severe heart failure (NYHA IV). They recommended that new positive inotropic agents should be screened in human myocardial tissue from patients with heart failure.

Labow et al. (1991) recommended a human atrial trabecular preparation for evaluation of inotropic substances.

Böhm et al. (1989) tested positive inotropic agents in isolated cardiac preparations from different sources, e.g., human papillary muscle strips from patients with severe heart failure (NYHA IV), human papillary muscle strips from patients with moderate heart failure (NYHA II–III), human atrial trabeculae, isolated papillary muscles from Wistar-Kyoto rats, and isolated papillary muscles from spontaneous hypertensive rats. They suggested that positive inotropic effects should be screened in isolated myocardium from patients with heart failure.

A.7.2.2 Isolated hamster cardiomyopathic heart

PURPOSE AND RATIONALE

Special strains of Syrian hamsters develop cardiomyopathy. These animals can be used for evaluation of cardiotonic drugs (see Sect. A.6.0.4).

PROCEDURE

Hamsters with cardiomyopathy (Bio 14/6) at the age of 50 weeks are used. Controls are normal Syrian hamsters (FIB hybrids) at the same age. The animals are pretreated with heparin (5 mg/kg i.p.) and 20 min later the heart is prepared according the method of Langendorff and perfused with heart Ringer solution under 75 mm H_2O hydrostatic pressure. The preparation is allowed to equilibrate in the isolated state for 60 min at 32 °C with a diastolic preload of 1.5 g. The force of contractions is recorded isometrically by a strain gauge transducer on a polygraph, e.g., Heliscriptor He 19 recorder (Hellige GmbH, Freiburg, Germany). From these signals, the heart rate is measured by a chronometer. The coronary flow is measured by an electromagnetic flowmeter. Compounds are injected via the aortic cannula into the inflowing heart-Ringer solution.

EVALUATION

The contractile force and the coronary flow in hearts from diseased and normal animals is registered before and after application of the test drugs. Mean values and standard deviation are calculated before and after drug application and statistically compared using Student's *t*-test.

MODIFICATION OF THE METHOD

Jasmin et al. (1979) showed after prolonged *in vivo* administration beneficial effects of a variety of cardiovascular drugs, including verapamil, prenylamine, dibenamine and propranolol.

After chronic administration (4 or 12 weeks subcutaneously), Weishaar et al. (1987) found beneficial effects of the calcium channel blocker diltiazem, but not by the administration of digitalis.

In contrast, in the experiments of Ottenweller et al. (1987) hamsters treated orally with digoxin survived and showed significant amelioration of the pathological syndrome of heart failure.

A.7.2.3 Potassium loss from the isolated guinea pig heart

PURPOSE AND RATIONALE

Cardiac glycosides induce a net loss of potassium from cardiac tissue due to their inhibition of the Na^+/K^+ ATPase. Therefore, potassium is increased in the effluent of the isolated guinea pig heart. This phenomenon can be used as parameter for the activity of digitalis-like compounds (Lindner and Hajdu 1968).

PROCEDURE

The isolated heart of guinea pigs according to LANGENDORFF is prepared as described in Sect. A.3.1.1. The coronary outflow is measured by counting the drops of the effluent by a photocell. The effluent is collected in a funnel with a thin upwards shaped outlet allowing to withdraw small fluid samples for analysis by a flame photometer. A pump attached to a 4-way valve changes the samples to the flame photometer every 15 s in the following sequence: effluent Tyrode-solution from the heart, distilled water, Tyrode-solution used for perfusion, distilled water. The potassium content of affluent and effluent Tyrode-solution is compared and registered on a Varian®-recorder. The difference is attributed to the potassium outflow from the heart. The dose-response curve is flat in the therapeutic range, much steeper in the toxic range.

EVALUATION

The following parameters are recorded and calculated:

- coronary flow [ml/min]
- contractile force
- potassium loss [mVal/min]

CRITICAL ASSESSMENT OF THE METHOD

A good correlation was found between the measured potassium loss and the positive inotropic effect of cardiac glycosides. The method is suitable for the quick determination of efficacy of digitalis-like substances and facilitates the discrimination from other positive inotropic compounds like adrenaline.

A.7.3 *In vivo* tests

A.7.3.1 Cardiac toxicity in cats (Hatcher's method)

PURPOSE AND RATIONALE

The purpose of the method, originally introduced by Hatcher and Brody (1910) and described in detail by Lind van Wijingaarden (1926), was to establish "cat units" for cardiac glycoside preparations. Hatcher and Brody defined "the cat unit as the amount of crystalline ouabain which is fatal within about ninety minutes to a kilogram of a cat when the drug in injected slowly and almost continuously into the femoral vein". Time to cardiac arrest after intravenous infusion of a solution with defined concentration of the standard was used as reference and the unknown solution of the test preparation compared with the standard. The method can be used for testing natural and semisynthetic glycosides.

PROCEDURE

Cats of either sex weighing 2–3.5 kg are temporarily anesthetized with ether. Anesthesia is maintained with 70 mg/kg chloralose given intravenously. The animal is fixed on its legs on a heated operating table. Tracheostomy is performed and a tracheal cannula is inserted. ECG is recorded from lead II. Then, intravenous infusion of the test solution is started. The endpoint is cardiac arrest which should be reached within 30–60 min by proper adjustment of the concentration of the infused solution.

MODIFICATIONS OF THE METHOD

Hatcher's original method has been modified by many authors. The method using **guinea pigs**, introduced by Knaffl-Lenz (1926) is in its essentials similar to the cat method.

Guinea pigs weighing 400–600 g are anesthetized with urethane (1.75 g/kg i.m.) The animal is secured on a operating table and the trachea is cannulated. The jugular vein is cannulated for infusion of the test preparation. Cardiac arrest is recorded from ECG lead II.

Dogs and guinea pigs were used by Dörner (1955).

A.7.3.2 Decay rate and enteral absorption rate of cardiac glycosides

PURPOSE AND RATIONALE

The basic principle of Hatcher's or Knaffl-Lenz's method is suitable to determine decay rates of cardiac glycosides. The decay of efficacy can by due to excretion or metabolic degradation of the glycoside.

PROCEDURE

Beagle dogs of either sex weighing 8–20 kg are anesthetized with 35 mg/kg pentobarbital sodium i.v. The animal is fixed on its legs on a heated operating table. Tracheostomy is performed and a tracheal cannula inserted. The vena femoralis is cannulated for continuous infusion of a defined concentration (μg/kg/min) of the test compound. ECG is recorded from lead II. The signs of first toxic effects, e.g., extra systoles, AV-block) are recorded. At this time, the infusion is terminated and the total dose/kg of the applied glycoside registered. After 4, 8, 12, or 24 h the infusion procedure is repeated. Within this period of time the glycoside administered with the first dose is only partially metabolized or excreted. Therefore, the dose needed for observation of ECG changes during the second infusion will be lower than in the first experiment.

EVALUATION

The dose required in the second experiment for induction of ECG changes is equal to the amount of metabolized or excreted glycoside. This value is expressed as percentage of the amount required in the first experiment and indicates the decay rate of the glycoside. Testing after various time intervals, the decay rate can be visualized graphically and half life times be calculated.

MODIFICATIONS OF THE METHOD

Rhesus monkeys have been used since their response to cardiac glycosides is more similar to that of man than that of dogs (Lindner et al. 1979).

The basic principle of Hatcher's or Knaffl-Lenz's method is also suitable to determine *enteral absorption of cardiac glycosides*. Again, for this purpose dogs

are preferred instead of cats or guinea pigs. The dose to induce cardiac arrest is determined in 3–6 dogs. To other dogs, the same test compound is given intraduodenally at a dose below the intravenous lethal dose. Ninety or 180 min afterwards, the intravenous infusion with the same infusion speed and the same concentration of the test compound as in the previous experiments is started and time until cardiac arrest determined. The higher the duodenal resorption of the compound, the lower the dose of the intravenous infusion will be. For evaluation, the intravenous dose needed in the second experimental series (with enteral predosing) is subtracted from the dose of the first series (without enteral predosing) and indicates the amount of absorbed compound. This value is expressed as percentage of the value of the first series and indicates the absorption rate.

The efficacy and safety of a novel Na^+,K^+-ATPase inhibitor has been tested in dogs with propranolol-induced heart failure by Maixent et al. (1992).

Effects on blood supply and on arterial and venous tonus

A.8.1
Models for stroke and multi-infarct cerebral dysfunction

A.8.1.1
Cerebral ischemia by carotid artery occlusion in Mongolian gerbils

PURPOSE AND RATIONALE

The Mongolian gerbil (*Meriones unguiculatus*) is extremely susceptible to carotid occlusion because of the peculiar anatomical occurrence of an incomplete circle of Willis without posterior communicating artery and a frequently rudimentary anterior communicating artery. Clamping of both carotid arteries induces a bilateral temporary brain ischemia (Levine and Sohn 1969; Bosma et al. 1981; Mršulja et al. 1983; Hossmann et al. 1983; Chandler et al. 1985). This pathological animal model allows the simulation of circulatory disturbances in the human brain. The hippocampus is one of the most vulnerable regions of the brain to ischemia and anoxia. The gerbil is known to develop selective neuronal damage in the CA1 sector of the hippocampus following brief periods of forebrain ischemia. This damage differs from conventionally described ischemic neuronal injury because of its slow development (Ito et al. 1975; Kirino 1982; Hossmann et al. 1983). The occlusion time can be varied allowing determination of various parameters, e.g. ischemia induced amnesia (see Sect. F.3.1.8).

PROCEDURE

Male Mongolian gerbils (strain: Hoe GerK jirds) weighing 48–88 g are randomly divided into groups (10–15 animals for each test and control group). Prior to testing, the animals are housed in a climate-controlled environment (21 °C) with food and water available ad libitum. Fifteen minutes before surgery, the gerbils receive the test compound by oral or intraperitoneal administration. The control group is treated with vehicle alone.

The exposure of the common carotid arteries is performed under anesthesia with sodium pentobarbital (32 mg/kg i.p.), chloralhydrate (100 mg/kg i.p.) and atropine sulfate (0.8 mg/kg i.p.). The carotid arteries are isolated from surrounding tissue and a loop of unwaxed dental floss is placed around each artery. A 2 cm length of double lumen catheter is passed from the level of carotid artery through the muscle layers of the dorsal surface of the neck. Each end of dental floss is threaded through a separate lumen, leaving a loose loop around the artery. Two days later, occlusion of each artery is produced by gently pulling the dental floss until the artery is completely occluded between the floss and the center wall of the catheter. Heifitz clips are placed on the floss against the exterior end of the tubing to maintain occlusion. After various intervals (5 to 30 min), the clips are removed and circulation is restored.

Complete bilateral occlusion of the arteries is confirmed by behavioral symptoms, i.e., depression of spontaneous motor activity, shallow and rapid respiration, and ptosis. Care is taken to avoid a drop of body temperature during any stage of the experiment. After experimental manipulations, animals are placed on a heating pad until complete recovery of motor activity.

Subjects are placed in individual observation glasses which are kept at a temperature of 29 °C. They are observed for neurological symptoms (such as circling behavior, jumping and rolling seizures, opisthotonus, tonic convulsions, etc.) for 90 min.

After various intervals, the gerbils are sacrificed and their brains are removed.

EVALUATION

The following parameters are measured two hours after occlusion:

Degree of brain edema: water content (difference in weight of wet and dry brain)

Content of sodium and potassium. The hemispheres are separated and put on pre-weighted watch glasses to determine the wet weight. Then the hemispheres are dried in an open Petri dish for 2 days at a temperature of 95 °C. After cooling off, the dry weight is noted. Sodium and potassium concentrations in the dried brain hemispheres are determined by flame photometry. The Na^+/K^+-ratio is calculated.

For *histological examinations*, the animals are sacrificed at 2 or 4 days after ischemia under ether anesthesia by decapitation. The brains are then removed and frozen in CO_2. Hippocampi are sectioned coronally with a cryostat at –14 °C. The section thickness for Nissl and glial fibrillary acid protein (GFAP) staining is 20 µm and for the histochemical localization of calcium 30 µm.

Nissl staining and its quantitative evaluation. The sections are mounted by thawing on glass slides, Nissl stained, and cover slipped with Permount. In order to standardize the histological procedure and to rule out the possibility that differences in the staining intensity were due to technical inconsistency, slides from control and experimental groups are processed together, stained for 5 min, and differentiated in a series of alcohols for 3 min each. The extent of hippocampal nerve cell damage (as reflected by cell loss and decreased stainability) is assessed by measuring the amount of Nissl-stained material in a predetermined representative region of the CA1 area with the aid of a guided densitometer (Leitz Texture Analysis System). The measuring field is 50×500 µm, fitting to the width of the CA1 soma layer (about 40 µm).

Calcium localization. A modification of technique described by Kashiwa and Atkinson (1963) is used for the cytochemical localization of ionic calcium. The principle of the technique is that calcium complexes with a chelating agent producing an insoluble chromophore.

Stock solutions: Two solutions were used: a) glyoxal-bis-(2-hydroxyanil) (GBHA), 0.4 g/100 ml absolute ethanol (2 ml 0.4% GBHA); and b) NaOH, 5 g/100 ml distilled water (0.3 ml 5% NaOH).

Staining procedure: First, cryostat sections are placed immediately in cold absolute acetone for rapid fixation for 5 min. Next, floating sections are transferred into 96% alcohol for 5 min and then transferred to staining solution for 3–4 min. Sections are then placed in 96% alcohol and mounted on glass slides. Because of quenching, it is necessary to view and photograph immediately.

GFAP (glial fibrillary acid protein) fluorescencemicroscopy. Following slide mounting, cryostat sections are fixed for 15 min in 3.5% formaldehyde solution in 0.01 M phosphate-buffered saline (PBS). The sections are incubated with mouse primary antibody against GFAP (Boehringer, Mannheim, FRG) for 30 min diluted 1:50 PBS. This antibody shows cross reactions also with GFAP from pigs and rats, indicating low species selectivity (Graber and Kreutzberg, 1986). The sections are rinsed in PBS and incubated to tetramethylrhodamine isothiocyanate (TRITC) specific for mouse immunoglobulin G (T-5393 from Sigma) diluted 1:50 in PBS. Control sections are incubated with PBS instead of primary antibody.

Measurements, expressed as extinction units per measuring field, are taken from three slides of each animal and averaged. Statistical analysis is done by Student's *t*-test.

MODIFICATIONS OF THE METHOD

"Sensitive" gerbils can be selected according to the method of Delbarre et al. (1988). In this method, pupil dilatation is obtained with atropine sulfate (1%) 20 min before anesthesia. Ocular fundus is examined with direct ophthalmoscope (Heine) before ligation and 5 min later. Only animals with an absence of retinal blood flow after ligation are considered as positive.

Using ^{31}P nuclear magnetic resonance spectroscopy, Sasaki et al. (1989) studied energy metabolism of the ischemic brain of gerbils *in vivo*.

An unanesthetized-gerbil model of cerebral ischemia was described by Chandler et al. (1985).

Using microdialysis, adenosine and its metabolites were measured directly in the brain of male gerbils by Dux et al. (1990). Two microdialysis probes (CMA/10, Carnegie Medicine, Sweden) were implanted stereotactically in the brain of the animals, one in the left dorsal hippocampus and one in the right striatum. The fibres were fixed to the cranium using dental wax. The dialysate was collected in 5 min intervals, and the concentrations of adenosine, hypoxanthine and inosine were determined by HPLC (Zetterström et al. 1982; Fredholm et al. 1984).

Kindy et al. (1992) measured glial fibrillary acid protein and vimentine on mRNA level by Northern blot analysis and protein content by immunoblot analysis in the gerbil neocortex, striatum and hippocampus after transient ischemia.

McRae et al. (1994) studied the effect of drug treatment on activated microglial antigens in hippocampal sections after ischemia in gerbils with cerebral fluid from patients with Alzheimer's disease and the amyloid precursor protein.

Nurse and Corbett (1996) found neuroprotection in gerbils with global cerebral ischemia after several days of mild, drug-induced hypothermia. The protection by the AMPA-antagonist NBQX may be due to a decrease in body temperature. A protracted period of subnormal temperature during the postischemic period can obscure the interpretation of preclinical studies.

A.8.1.2 Forebrain ischemia in rats

PURPOSE AND RATIONALE

Smith et al. (1984) described a model of forebrain ischemia in rats induced by transient occlusion of both carotid arteries and exsanguination to a blood pressure of 40 mm Hg. This method has been used extensively (Nuglisch et al. 1990; Oberpichler et al. 1990; Rischke and Krieglstein 1990; Krieglstein and Peruche 1991; Nuglisch et al. 1991; Prehn et al. 1991; Rischke and Krieglstein 1991; Seif el Nasr et al. 1992; Peruche et al. 1995).

PROCEDURE

Male Wistar rats weighing 250–300 g are anesthetized with 3.5% halothane and then connected to a Starling type respirator delivering 0.8% halothane and 30% O_2 in N_2O. The jugular vein and the tail artery are catheterized for withdrawal of blood and for monitoring blood pressure. Anticoagulation is achieved by intravenous heparin (200 IU/kg) application. Blood gases, blood pH, blood pressure, and blood glucose are measured 5 min prior to ischemia and 10 min after ischemia.

Halothane, but not N_2O, is discontinued and the rats are allowed to recover for 30 min. During this period, muscle paralysis is maintained with 5 mg/kg suxamethonium chloride, repeated every 15 min. After injection of trimethaphan camphor sulfonate (5 mg/kg),

forebrain ischemia is induced by clamping of both carotid arteries and exsanguination to a blood pressure of 40 mm Hg. To prevent decay of intra-ischemic brain temperature, the environmental temperature is adjusted to 30 °C by means of a infrared heating lamp. After 10 min of ischemia, the carotid clamps are removed and blood pressure is restored by re-infusing the shed blood. To minimize systemic acidosis, the rats receive intravenously 50 mg/kg $NaHCO_3$. The animals are removed from the respirator when they regain spontaneous respiration.

EVALUATION

Various parameters are used to evaluate the consequences of transient forebrain ischemia and the effectiveness of drug treatment:

- Local cerebral blood flow determination with the [^{14}C]iodoantipyrine method (Sakurada et al. 1978),
- Histological assessment of ischemic cell damage in the hippocampus on day 7 after ischemia (Seif el Nasr et al. 1990; Nuglisch et al. 1990),
- Local cerebral glucose utilization using the [^{14}C]deoxyglucose method described by Sokoloff et al. (1977),
- Quantitative analysis of the electrocorticogram (Peruche et al. 1995).

MODIFICATIONS OF THE METHOD

Kochhar et al. (1988) used two focal cerebral ischemia models in **rabbits**: a multiple cerebral embolic model by injection of microspheres into the internal carotid circulation and a spinal chord ischemia model by occluding the aorta for predetermined periods.

Gilboe et al. (1965) described the isolation and mechanical maintenance of the **dog** brain.

Andjus et al. (1967) and Krieglstein et al. (1972) described the preparation of the isolated perfused rat brain for studying effects on cerebral metabolism.

A cerebral ischemia model with conscious **mice** was described by Himori et al. (1990).

A.8.1.3 Hypoxia tolerance test in rats

PURPOSE AND RATIONALE

The electrical activity of the brain is dependent on a continuous energy supply. Hypoxia is induced in test animals by inhalation of nitrogen. Marked hypoxia depresses cerebral metabolism resulting in an electri-

cal failure of the brain. The procedure is used to investigate the ability of test compounds to antagonize the hypoxia-induced electrical failure of the brain by measuring the hypoxia-tolerance and the EEG recovery.

PROCEDURE

Male Sprague Dawley rats or stroke-prone rats weighing 250–300 g are used. They are anesthetized with hexobarbital sodium (100–120 mg/kg, i.p) and surgically implanted with 2 epidural EEG-electrodes and a reference electrode to the parietal frontal cortex. After a minimum of a one week recovery period, testing can be started. The rats receive the test compound by intravenous or intraperitoneal administration. The control group is treated with vehicle alone. Thirty to 60 min after i.p. administration (immediately after i.v. administration) the animals are anaesthetized by hexobarbital sodium at 100–120 mg/kg, i.p. When the stage of surgical anesthesia is reached, the animals are placed in a hypoxia chamber. EEG and ECG are recorded using a Hellige recorder.

Hypoxia is induced by inhalation of nitrogen (1 200 l/h). On reaching an isoelectric EEG, the nitrogen inhalation is terminated and the animals are allowed to breath room air. The recording is continued until EEG potentials can again be registered.

EVALUATION

The following parameters are measured in the test and control groups

- Hypoxia tolerance (HT): The time from the start of nitrogen inhalation until the onset of isoelectric EEG.
- Latency of EEG recovery: The time from the end of nitrogen inhalation until the onset of EEG potentials.
- The values of test and control groups are compared.

The percent change is calculated.
Statistics: Student's *t*-test by unpaired comparison.

A.8.1.4 Middle cerebral artery occlusion in rats

PURPOSE AND RATIONALE

The permanent middle cerebral artery (MCA) occlusion technique in rats has been widely employed to evaluate various kinds of neuroprotective agents in cerebral ischemia (Ginsberg and Busto 1989). Focal cerebral infarction is achieved using a modification of the MCA occlusion model described by Tamura et al. (1981) and Pak et al. (1992).

PROCEDURE

Adult male Sprague-Dawley rats weighing 300–400 g are used in the experiments. The animals are anesthetized with a nitrous oxide-oxygen mixture (70:30%) containing 1.0 to 1.2% halothane. A mask is put on the nose and self-respiration is maintained during surgery, which takes around 20 to 30 min. The right femoral artery and vein are catheterized for monitoring blood pressure, blood sampling and administration of the drug. Left MCA occlusion is performed via a subtemporal approach without removal of zygomatic arch or temporal muscle. Under high magnification of a surgical microscope, the left MCA is coagulated with a microbipolar coagulator from the olfactory tract to the most proximal portion of the MCA through a cranial window, about 3 to 4 mm in diameter, and cut afterward. Anesthesia is stopped just after MCA occlusion. The arterial catheter is removed soon after MCA occlusion, but the venous catheter is maintained for constant infusion of the drug by a swivel system (Harvard Apparatus, UK.). The animals are maintained normothermic (37 °C) by a homeothermic system (Homeothermic Blanket System, Harvard Apparatus, UK.). During the surgery, mean arterial blood pressure (MABP) is recorded continuously (Model 7E polygraph, Grass, USA). Arterial gases and pH (178 pH/blood gas analyzer, Corning, USA) as well as hematocrit and blood glucose are measured twice, once about 15 min before MCA occlusion and the other just following MCA occlusion. Bilateral temporal muscle temperature (Therm 2250-1, Ahlborn Mess- und Regelungstechnik, Germany) is monitored during the surgery and several minutes before sacrifice.

Two, six, twelve and twenty-four hours after discontinuing anesthesia, each rat's level of consciousness and motor activity are evaluated using a grading scale of 0 to 3 (0: normal activity; 1: spontaneous activity+/–; 2: not arousable by tactile stimulation; 3: not arousable by painful stimulation, no spontaneous activity). Immediately before sacrifice, neurological status is examined using a grading scale of 0 to 3 (0: no observable deficit; 1: forelimb flexion; 2: decreased resistance to lateral push without circling; 3: the same status as grade 2, with circling). Four groups of rats are studied: vehicle-treated controls, and drug-treated animals at 3 different doses.

All the rats are re-anesthetized 24 h after MCA occlusion and sacrificed by intravenous injection of KCl. Immediately after sacrifice the brain is removed and frozen at –10 °C for 10 min. The forebrain is cut into eight coronal slices by a rat brain slicer which are proc-

essed with the tetrazolium chloride (TTC) emulsion technique. Areas of brain not stained by TTC are drawn on a diagram at 8 preselected coronal levels of forebrain without knowledge of the experimental treatment. The areas of ischemic damage in the cerebral hemisphere, cerebral cortex, and caudate nucleus, drawn in the diagram are measured with a planimeter (KP-21, Koizumi, Japan) and integrated to determine the volumes.

EVALUATION

Significance of the differences between the control and the treated groups is assessed by analysis of variance with subsequent inter group comparison by Student's *t*-test with Bonferroni correction. $P < 0.05$ is required for significance.

MODIFICATIONS OF THE METHOD

Hossmann (1982) reviewed the experimental models of cerebral ischemia.

Yamamoto et al. (1992) studied the inhibition of NO biosynthesis on the volume of focal ischemic infarction produced by occlusion of the middle cerebral artery in spontaneously hypertensive rats.

Shigeno et al. (1985) described a recirculation model following middle cerebral artery occlusion in rats. The trunk of the middle cerebral artery was isolated between the rhinocortical branch and the lenticulostriate artery and encircled with a loose-fitting suture of nylon thread. The thread was exteriorized through a small polyethylene catheter, which was previously introduced into the craniectomy site through a burr hole in the zygoma. The artery was occluded by retraction of the thread, which was then fixed with biological glue. Recirculation was achieved by cutting and removing the thread.

Bederson et al. (1986a) occluded the middle cerebral artery at different sites in six groups of normal rats and characterized the anatomical sites that produce uniform cerebral infarction. A neurological system was developed that can be used to evaluate the effects of cerebral ischemia.

Bederson et al. (1986b) evaluated the use of 2,3,5-triphenyltetrazolium chloride as a histopathological stain for identification and quantification of infarcted brain tissue after middle cerebral artery occlusion in rats.

Yang et al. (1992) found a reduction of Na,K-ATPase activity in the ischemic hemisphere shortly after middle cerebral artery occlusion in rats.

Du et al. (1996) induced transient focal cerebral ischemia in rats by a 90 min period of ligation of the right middle cerebral artery and both common carotid arteries.

Germano et al. (1987) found a decrease of stroke size and deficits in rats with middle cerebral artery occlusion after treatment with kynurenic acid, a broad spectrum antagonist of excitatory amino acid receptors.

Gotti et al. (1988) found a reduction of the volume of infarcted tissue due to occlusion of the middle cerebral artery in **rats** and **cats** after administration of NMDA receptor antagonists.

Hossmann and Schuier (1980) studied experimental brain infarcts in **cats** after occlusion of the left middle cerebral artery.

Retro-orbital occlusion of the middle cerebral artery in cats was performed by Sundt and Waltz (1966) and by Gotti et al. (1988).

Welsh et al. (1987), Backhauß et al. (1992) described focal cerebral ischemia in **mice** after permanent occlusion of the middle cerebral artery.

Hara et al. (1997) found a reduction of ischemic and excitotoxic neuronal damage by inhibition of interleukin 1β-converting enzyme family proteases after occlusion of the middle cerebral artery in **mice** and **rats**. Nylon filaments were introduced from the carotid artery which were withdrawn after 2 h. One day later, the animals were tested for neurological deficits and the brains analyzed for infarct size and interleukin 1β levels.

Huang et al. (1994) produced **knock-out mice** deficient in the neuronal isoform of NO synthase by targeted disruption of the neuronal nitric oxide synthase gene. In these mice, Hara et al. (1996) found reduced brain edema and infarction volume after transient middle coronary artery occlusion.

Nishimura et al. (1998) described an experimental model of thromboembolic stroke without craniotomy in **cynomolgus monkeys** by delivering an autologous blood clot to the middle cerebral artery. A chronic catheter was implanted in the left carotid artery in male cynomolgus monkeys. A 5 cm long piece of an autologous blood clot was flushed into the internal carotid artery with physiological saline. A neurological score was assigned at 0.167, 0.5, 1, 2, 4, 6, and 24 h after embolization. In the acute phase after embolization, typical behavior consisted of circling gait and moderate deviation towards the side of embolization, long-lasting and strong extensor hypotonia of the contralateral lower and upper limbs, and mild to severe incoordination. Contralateral hemiplegia was observed over the following 24 h. At 24 h the animals were sacrificed immediately after the last neurological scoring, and the cerebral vasculature was inspected for the location of the clot. The brain was then cut into 2 mm thick coronal sections. Cerebral infarction size and location were ascertained by the triphenyl-2H-tetrazolium chloride staining method. The lesions involved mostly the caudate nucleus, internal capsule, putamen and thalamus.

Salom et al. (1999) subjected female **goats** to 20 min global cerebral ischemia under halothane/N_2O anes-

thesia. An episode of transient global ischemia was achieved by occlusion of the two external carotid arteries and simultaneous external compression of the jugular veins by a neck tourniquet. A reperfusion period started when the occlusions were released, and it was monitored for 2 h.

De Ley et al. (1988) studied experimental thromboembolic stroke induced by injection of a single autologous blood clot into the internal cerebral artery in dogs by **positron emission tomography**.

Functional magnetic resonance imaging has been developed as **pharmacological magnetic resonance imaging** for pharmacodynamic assays and to establish brain-penetrating parameters (Leslie and James 2000). Although regional cerebral metabolic rate of glucose is strongly increased during cerebral activity, the cerebral metabolic rate of O_2 is not increased in direct proportion. The result is that the relative uptake of O_2 from blood actually decreases. The veins and capillaries draining from the activated region are 'arterialized' and their deoxyhemoglobin concentration is reduced. Deoxygenated and oxygenated hemoglobin have different magnetization properties; thus the changes in the ratio of these two entities can be detected by blood-oxygen-level-dependent (BOLD) magnetic resonance imaging. At least for studies in animals, these methods may be preferred to positron emission tomography (Cherry and Phelps (1996).

Edema following middle cerebral artery occlusion in spontaneously hypertensive rats was measured by magnetic resonance imaging (Seega and Elger 1993; Elger et al. 1994a). Magnetic resonance imaging was also used to determine the size of intracerebral hem-orrhage in rats induced by stereotactic microinfusion of collagenase into the caudate putamen (Elger et al. 1994b).

A.8.1.5 Photochemically induced focal cerebral ischemia in rats

PURPOSE AND RATIONALE

Focal cerebral ischemia in rats can be induced by irradiation with intensive green light via a fibre optic through the skull after injection of the dye Rose Bengal. The resulting cerebral infarct can be studied for various parameters, such as infarct volume, water content, local cerebral blood flow and glucose utilization.

PROCEDURE

Male Sprague-Dawley rats (300–350 g) are used. Anesthesia is induced with 3% halothane in oxygen and is maintained with 1% halothane in oxygen applied via a face mask. A small incision is made in the skin over the right femoral vein and a thin catheter is inserted. One ml of the dye Rose Bengal (in a concentration of 5 mg/ml of saline) is injected. A midline head incision is made and the right side of the skull is exposed. An intense green light, produced by a xenon lamp (75W, Zeiss, FRG) and then passed through a filter (wavelength 570 nm, Schott, Mainz, FRG) and a heat filter (Schott, Mainz, FRG), is directed on the skull at the level of the bregma for 15 min. The 3 mm diameter of the illuminated circle is determined by passing the light through a fibre optic (Schott, Mainz, FRG) while in close contact to the skull. The temperature of the skull underneath the fibre optic does not change during the time of illumination. At the end of the induction period, the temporary catheter is removed from the femoral vein which remains patent following the closure of the catheterization site with liquid suture (Histoacryl, Braun, Melsungen, FRG), and the incisions in the leg and head are likewise sutured after liberal application of local anesthetic. The anesthetic gas mixture is discontinued and the rats are allowed to recover consciousness in a warm environment until such times as the appropriate experiment is to be performed. Due to the non-invasive nature of this technique it is not possible to measure blood pressure or blood gases during the ischemic period. However, rectal temperature and plasma glucose concentrations are controlled.

Measurement of infarct volume

Osmotically controlled mini-pumps (Model 2ML1 Alzet®, USA) are placed into the peritoneum of two groups of six male Sprague Dawley rats (body weight 300–350 g). The mini-pumps are fitted via thin polyethylene catheters to the femoral vein of the rats. Each pump contains either 2 ml of physiological saline or 2 ml of a solution of the drug to be studied. The animals are then given an ischemic insult as described in the previous section. Seventy-two hours after the induction of ischemia, the rats are sacrificed by decapitation and the brains removed and frozen at –50 °C. Coronal sections (20 μ) are cut in a cryotome at –20 °C, fixed in Haidenhain's Susa and stained with Cresyl Violet. The ischemic area on 90 sections is measured and the volume of ischemic change is then calculated using a linear trapezoidal extrapolation of the areas measured.

Measurement of brain water content

Three groups each of six rats are used. One group receives no ischemic lesion (the illumination with green light is omitted from the experimental protocol) and two groups are lesioned as described above. One lesioned group receives the test drug orally at 15 min, 30 min, 1, 3 and 5 h after the induction of the ischemia or sham operation. The other group is treated with saline at the same time-points. Twenty-four hours later the rats are sacrificed by decapitation. The brains are rapidly removed and placed on a cutting block with 1 mm gradations. Two cuts are made 1 mm or less anterior and posterior to the lesion. The thick section so produced is then divided into left (non-lesioned) and right (lesioned) halves and placed in pre-weighed vials and the wet weights of the tissue samples are carefully measured. The tissue is then frozen in liquid nitrogen and then left under vacuum (less than 0.1 Torr) for 24 h. On removal the vials are sealed to prevent rehydration and reweighed to obtain the dry weight of tissue from which the water content (expressed as percentage of wet weight of tissue) is calculated.

EVALUATION

All data are presented as mean ±SD of the mean. For left (contralateral to the lesion) against right (ipsilateral to the lesion) comparisons, a *t*-test with paired com-

parison was used ($p < 0.05$). Statistical differences between groups were calculated using the unpaired *t*-test.

MODIFICATIONS OF THE METHOD

Boquillon et al. (1992) produced cerebral infarction in mice by intravenous injection of 10 mg/kg rose bengal, and by focal illumination of the intact skull surface for 3 min with a laser source, operating at 570 nm with power levels of 2, 5, 10, and 20 mW.

Matsuno et al. (1993) used a similar model to induce cerebral ischemia in rats based on middle cerebral artery occlusion by the photochemical reaction of rose bengal after irradiation with high intensity green light.

A.8.1.6 Microdialysis and neuroprotection experiments after global ischemia in rats

PURPOSE AND RATIONALE

Transient global ischemia can be induced in rats by electrocauterization of the vertebral arteries followed by clamping of the carotid arteries.

PROCEDURE

Male Wistar rats weighing 280–340 g are used. The rats are anesthetized with methohexital sodium (60 mg/kg i.v.) and the vertebral arteries are electrocauterized (Pulsinelli and Brierley 1979). The rats are fasted overnight and re-anesthetized on the following day with halothane and intubated. The femoral artery and vein are cannulated to allow blood sampling, blood withdrawal and recording of mean arterial pressure (MAP). Samples of blood are taken at regular time intervals and blood gas/acid base status is analyzed (Instrumentation Laboratory, 1306). Rectal temperature is measured with a thermistor and controlled at 37 °C by means of a heating lamp. Four-vessel occlusion ischemia is induced for 20 min by bilateral carotid clamping followed by a period of reflow.

Microdialysis experiments

The head of the rat is fixed in a stereotactic frame. The skin is incised over the head, pulled apart and a 3×3 mm hole is drilled through the cranium. A microdialysis probe (Sandberg et al. 1986) is implanted into CA1 region of the hippocampus (2.2 mm lateral and 3.8 mm dorsal to bregma, and the window of the dialysis membrane 1.4–2.9 mm below the cortical surface). The electroencephalogram (EEG) is measured continuously with a tungsten electrode attached to the dialysis probe. The probe is perfused at a rate of 2.5 µl/min with a modified Ringer solution. Dialysates are sampled every 10 min and analyzed for purines (Hagberg et al. 1987) and amino acids (Lindroth et al. 1985). One group receives the test drug i.p. 15 min prior to ischemia whereas the control group obtains saline. The animals are followed during 20 min of ischemia and 2 h of reflow.

HPLC analyses are carried out using a reverse-phase C_{18} column (Waters 10 µm µBondapak) with isocratic elution, a flow rate of 1.0 ml/min and at ambient temperature. For adenosine, inosine and hypoxanthine the mobile phase is 10 mM $NH_4H_2PO_4$, pH 6.0, 13% methanol.

Neuroprotection experiments

During ischemic insult and for 20 min of reflow, the temperature of the temporalis muscle is controlled at 37 °C. Immediately following ischemia the rats are divided into two groups. One group is treated with the test drug and the other with saline. A bolus injection is administered i.p. 15 min after ischemia and a mini-osmotic pump is implanted into the abdominal cavity which delivers the test drug for 7 days. Control animals receive a bolus of saline and mini-osmotic pumps filled with saline. Seven days later the rats are anesthetized with pentobarbital and perfusion-fixed with formol saline. The histological evaluation is done "blind". The hippocampal damage is semiquantified according to the following scoring system:

0 = no damage
1 = scanty damage,
2 = moderate damage
3 = severe damage
4 = complete loss of pyramidal cells in the hippocampus.

EVALUATION

The purine and amino acid data are expressed as means ±SEM and differences are evaluated with the non-parametric Mann-Whitney test. The neuroprotective efficacy of the test drug is evaluated with two-tailed Student's *t*-test.

MODIFICATIONS OF THE TEST

In addition to the assessment of neuronal damage, Block et al. (1996) tested spatial learning of treated rats one week after 4-vessel occlusion in a Morris water maze.

A.8.1.7 Hypoxia/hypoglycemia in hippocampal slices

PURPOSE AND RATIONALE

The *in vitro* release of adenosine, inosine, and hypoxanthine from rat hippocampal slices can be determined with and without drug.

PROCEDURE

Male Sprague-Dawley rats weighing 150–275 g are decapitated, the hippocampi isolated and cut into 400 µm thick slices which are placed into KRB (4 °C) containing (mM) NaCl (118), KCl (4.85), $MgSO_4$ (1.15), KH_2PO_4 (1.15), $NaHCO_3$ (25), glucose (5.5), $CaCl_2$ (1.3) equilibrated with 95% O_2/5% CO_2. The incubation medium is brought up to room temperature over a period of 30 min. The KRB is then replaced with fresh medium and the slices are incubated for a further 30 min at room temperature, followed by 30 min at 37 °C in fresh KRB. Following the initial incubations, slices are labelled for 45 min with ^{3}H-adenine (5 µCi/ml) at 37 °C. Two labelled slices are transferred into plastic cylinders which have nylon net bases and these, together with the slices, are placed into glass superfusion chambers. Slices are superfused at a flow rate of 0.5 ml/min with KRB at 37 °C. After a 60 min wash, collection of 5 min fractions begins, which continues throughout the remainder of the experiment. A 1.25 ml aliquot of the fractions is taken for determination of radioactivity using scintillation spectrometry (scintillation fluid: Picofluor 15). The remaining 1.25 ml is taken for HPLC analysis of purines and amino acids.

Hypoxia/hypoglycemia is induced by superfusion with KRB containing no glucose and 95% N_2 and 5% CO_2 for 35 min followed by recovery. All other procedures are as described above. The test drug is added to the perfusion fluid at an appropriate concentration. The 1.25 ml aliquots taken for HPLC analysis are pooled with two other aliquots (total 3.75 ml), lyophilized and concentrated 10 fold before analysis. Samples are analyzed for adenosine, inosine and hypoxanthine with HPLC. The radioactivity associated with each of these fractions is also determined by collecting the eluent from the column at the appropriate times. HPLC- analyses are carried out using a reverse-phase C_{18} column (Waters 10 µm µBondapak) with isocratic elution, a flow rate of 1.0 ml/min and at ambient temperature. For adenosine, inosine and hypoxanthine the mobile phase is 10 mM $NH_4H_2PO_4$, pH 6.0, 13% methanol.

EVALUATION

Values for adenosine, inosine and hypoxanthine can be expressed in two ways: (1) release rate per slice (pmol/min × slice); (2) percentage of the total amount of released radioactivity (% total $_3$H-label released). The purine data are expressed as means ±SEM and differences are evaluated with the non-parametric Mann-Whitney test.

A.8.1.8 Measurement of local cerebral blood flow and glucose utilization in rats

PURPOSE AND RATIONALE

Cerebral glucose utilization can be determined using [^{14}C]-2-deoxyglucose according to Sokoloff et al. (1977). Local cerebral blood flow using [^{14}C]-iodoantipyrine is measured as described by Sakurada et al. (1978).

PROCEDURE

Animal preparation

The experiments are performed on male Sprague-Dawley rats (260–300 g). Catheters are placed, under light halothane (1%) anesthesia, into the femoral vein and artery of each hind limb (for the measurement of mean arterial pressure, the sampling of arterial blood and the intravenous administration of drugs and radioisotopic tracer). The wound sites are then infused with local anesthetic, sutured, and protected by pads. The lower abdomen is covered by an elastic stocking, followed by a loose-fitting plaster coat. Anesthesia is discontinued and the rats are allowed at least two hours to recover before any further manipulations are performed.

Experimental protocol

The rats are given an intravenous infusion (50 µl/min) of either saline or the test drug dissolved in saline. This infusion is maintained throughout the measurement of local cerebral blood flow or local cerebral glucose utilization.

Local cerebral glucose utilization

A full description of the method for measuring local cerebral glucose utilization using [^{14}C]-2-deoxyglucose has been published (Sokoloff et al. 1977). Five minutes after the administration of the test drug, the experiment is started with the intravenous administration of [^{14}C]-2-deoxyglucose (125 µCi/kg). Fourteen timed arterial blood samples are taken during the following forty-five minutes. These samples are centrifuged and the plasma is measured for glucose concentration (using an automated glucose analyzer) and [^{14}C] levels (by liquid scintillation counting). At the end of this period the rats are sacrificed by decapitation, the brain rapidly removed and frozen at –45 °C. Twenty micron thick coronal sections are cut in a cryostat (–22 °C) and autoradiograms are prepared by placing these sections in an array against Kodak SB-5 X-ray film along with pre-calibrated plastic standards range (55–851 nCi/g) for seven days in light-tight cassettes.

Local cerebral blood flow

The autoradiographic measurement of local cerebral blood flow using [^{14}C]-iodoantipyrine is carried out as described by Sakurada et al. (1978). [^{14}C]-iodoantipyrine (125 µCi/kg) is administered fifteen minutes after the infusion of the test drug has commenced. In a period of sixty seconds, eighteen timed arterial samples are collected in pre-weighed filter-paper discs from a free flowing arterial catheter. The discs are reweighed and the [^{14}C] concentration of each is measured by liquid scintillation counting. At the end of one minute, the rat is decapitated and autoradiograms are prepared in the same manner as for the measurement of local cerebral glucose utilization.

Densitometric analysis of autoradiograms

Tissue [^{14}C] concentrations were determined using a densitometer system (Zeiss, FRG) by reference to the images of the precalibrated standards. For each structure of interest, bilateral determination of optical densities are made on six different autoradiographic images in which the structure is best defined.

The mean optical density is used to calculate [^{14}C] concentrations. From this value, and the history of [^{14}C] in the blood, values of local cerebral blood flow and glucose utilization are obtained using the respective operational equations of these methods (Sakurada et al. 1978; Sokoloff et al. 1977).

EVALUATION

Groups of data are statistically compared by *t*-test with unpaired comparison using the BONFERRONI correction factor for multiple group analyses. Linear regression data for comparing cerebral blood flow (CBF) and glucose utilization (GU) undergo log transformation as recommended by McCulloch et al. (1982).

MODIFICATIONS OF THE METHOD

Ito et al. (1990) measured glucose utilization in the mouse brain by the simultaneous use of [^{14}C]2-deoxyglucose and [^{3}H]3-O-methylglucose.

High-resolution animal positron emission tomography (PET) was recommended by Magata et al. (1995) for noninvasive measurement of cerebral blood flow with ^{15}O-water and glucose metabolic rate with ^{18}F-2-fluoro-2-deoxy-glucose.

The effect of ginseng pretreatment on cerebral glucose metabolism in ischemic rats using animal positron emission tomography (PET) with [^{18}F]-2 fluoro-2-deoxy-D-glucose ([^{18}F]-FDG) was described by Choi et al. (1997).

Hawkins et al. (1993) developed a method for evaluating tumor glycolytic rates *in vivo* with nude mice injected with 2-[^{18}F]fluoro-2-deoxy-D-glucose and a dedicated animal positron emission tomography scanner.

Positron emission tomography has been used with specific ligands for CNS imaging (de la Sayette 1991; Jones et al. 1991; Kung 1993).

Rogers et al. (1994) synthesized ^{18}F-labelled vesamicol derivates to be evaluated in small animal positron emission tomography.

Hume et al. (1997) measured *in vivo* saturation kinetics of two dopamine transporter probes using a small animal positron emission tomography scanner.

A.8.1.9 Cerebrovascular resistance in anesthetized baboons

PURPOSE AND RATIONALE

Cerebral blood flow and cerebrovascular resistance can be measured by injection of inert radioactive gas (^{133}Xenon) and evaluation of the ^{133}Xe clearance curve in anesthetized baboons.

PROCEDURE

Animal preparation

The experiments are performed on baboons (*Papio anubis* or *cynocephalus*) weighing 9–13 kg. Initial sedation with phencyclidine (10 mg i.m.) is followed by an intravenous injection of sodium thiopental (75 mg/kg). The animals are intubated to a positive pressure ventilator delivering 70:30% nitrous oxide and oxygen in open circuit. A continuous intravenous infusion of phencyclidine (0.01 mg/kg/min) is given throughout the course of the experiment. Suxamethonium (50 mg i.m.) is administered every 30 min in order to assist control of ventilation with the respiratory pump.

During the experiments, the end tidal concentration of CO_2 is continuously measured and the ventilating pump adjusted to maintain an arterial CO_2 tension ($PaCO_2$) of between 37 and 40 mm Hg for the control measurements. Arterial blood samples are taken during every measurement of cerebral blood flow (CBF) to measure $PaCO_2$, PaO_2, and pH by direct reading electrodes (Corning). Body temperature is maintained

around 37 °C by means of an electrically heated blanket and infrared heating lamps.

Catheters are inserted into the aorta via femoral arteries for the continuous measurement of arterial blood pressure and for the withdrawal of arterial blood samples. Both femoral veins are cannulated, one for the continuous infusion of phencyclidine and the other for the infusion of the test drug. A catheter is inserted into the right lingual artery so that its tip lays just distal to the carotid bifurcation. This catheter is flushed at regular intervals with heparinized saline to prevent platelet aggregation at the tip. In the studies with required intravenous administration of test drug, the other branches of the external carotid artery are ligated. Where the requirement is for intracarotid administration of test drug, another catheter is retrogradely advanced into the external carotid artery so that its tip lays next to the tip of the lingual catheter. This catheter is then attached to a constant-rate infusion pump (Sage Instruments). Heparinized saline is infused at a rate of 0.2 ml/min to act as a control for drug infusion.

A burr hole is made over the midline fissure and a catheter inserted into the sagittal sinus for the withdrawal of cerebral venous blood samples. The hole is sealed with plaster of Paris. The scalp and temporalis muscle are removed with diathermy down to the level of the zygomatic arch.

Measurement of cerebral blood flow, cerebral oxygen utilization, and cerebrovascular resistance

A collimated scintillation crystal is placed over the temporal region of the exposed skull on the right side and angled in such a way that viewed only brain and overlying skull.

Approximately 260 μCi of ^{133}Xenon dissolved in 0.5 ml sterile heparinized saline (500 IU) is injected over 1 s into the catheter in the lingual branch of the carotid artery. The gamma-ray emission of the $_{133}$Xe are detected by the scintillation counter attached to a photomultiplier. The pulses are amplified and subjected to pulse height analysis (peak 81 KeV ±8 KeV) to reduce Compton scatter before fed into a rate meter and scaler. The output from the rate meter is displayed on a chart recorder. Cerebral blood flow is calculated from the height/area equation (Høedt-Rasmussen et al. 1966). The formula used is

$$F = (H_1 - H_{10}) \times 100 / \lambda A_{10},$$

where F is CBF in ml blood per 100 g brain tissue per min; λ = brain tissue/blood partition coefficient for ^{133}Xe (the figure of 1.1 is used [Veall and Mallett 1966]); H_i = maximum initial height of the ^{133}Xe clearance curve in counts per min as taken from the chart recorder; H_{10} = height of the clearance curve 10 min after the peak height in counts per s; A_{10} = total integrated counts over the 10 min of clearance as taken from the scaler and corrected for background activity over that period.

Cerebral oxygen consumption is measured from the product of the DBF and the difference in oxygen content between the arterial blood and cerebral venous blood sampled from the sagittal sinus. Blood oxygen is measured by a charcoal-fuel cell system (Lex-O_2-Con).

An estimate of cerebrovascular resistance is obtained by subtracting the mean sagittal sinus pressure from the mean arterial pressure and dividing this pressure difference by the CBF.

EEG recording

Electroencephalographic readings are recorded bilaterally throughout the experiment. A series of holes are drilled in the calvarium 10 mm apart in two rows. Each row is 14 mm lateral to the sagittal suture. The holes are threaded to receive nylon screws in which silver-silver chloride ball electrodes are fixed loosely. The electrodes are positioned epidurally and the free ends are soldered to a multi-channel socket which is mounted on the calvarium with plaster of Paris.

Experimental procedure

Following completion of the surgery, the animals are left undisturbed for 1 h. At least three control estimations of CBF and other parameters are made until steady conditions of flow, arterial blood pressure, and blood gas tensions are obtained.

Protocols

Intravenous administration. After stable control values have been established, the infusion is started. The CBF is measured at 5 min after the start and again at 25 min. The infusion is stopped 10 min after this flow period, giving a total infusion time of 35 min. Further flow measurements are made at 10, 30, and 50 min after stopping the infusion.

Intracarotid administration. After establishing control values, the intracarotid infusion of the test drug is begun. The CBF is measured at 10, 30, 50 and 70 min. The infusion is stopped 80 min after commencing, and post infusion measurements are made after 20, 40, and 60 min.

EVALUATION

Data are presented as mean values ±SEM Evaluation of statistical significance is performed by means of Student's *t*-test with Bonferroni correction.

MODIFICATIONS OF THE METHOD

Kozniewska et al. (1992), Wang et al. (1992) measured cerebral blood flow in **rats** by intracarotid injection of ^{133}Xe.

Delayed cerebral vasospasm was induced in anesthetized **dogs** by removal of 4 ml cerebrospinal fluid and injection of the same volume of fresh autologous arterial nonheparinized blood into the cisterna magna by Varsos et al. (1983) as a model of subarachnoid hemorrhage. The procedure was repeated on the third day and angiograms were taken of the vertebral-basilar vessels. The reduction of diameter of the basilar artery was taken as endpoint.

Imaizumi et al. (1996) produced experimental subarachnoid hemorrhage by intracisternal injection of arterial blood in **rabbits**. The degree of vasospasm and the effect of calcitonin gene-related peptide were evaluated angiographically by measuring the basilar artery diameter.

Inoue et al. (1996) produced experimental subarachnoid hemorrhage in **cynomolgus monkeys** by placing a clot around the internal carotid artery. A series of angiographic analyses were performed, before subarachnoid hemorrhage and on days 7 and 14 after treatment with calcitonin gene-related peptide to examine changes in the diameter of the ipsilateral internal carotid artery, middle cerebral artery, and anterior cerebral artery.

Hughes et al. (1994) adapted the ^{133}xenon clearance technique for simultaneous measurement of cutaneous blood flow in **rabbits** at a large number of skin sites within the same animal.

Solomon et al. (1985), Clozel and Watanabe (1993) induced cerebral vasoconstriction by injection of autologous blood in the cisterna magna of rats. Cerebral blood flow was measured with the radioactive microsphere technique.

A.8.1.10 Effect on cerebral blood flow in cats (Fluvography)

PURPOSE AND RATIONALE

Cerebral blood flow in anaesthetized cats an be measured by fluvography. The heat transfer coefficient of the brain can be measured with a probe representing an indirect blood flow value.

In this method, the measuring device consists of a thermo probe, which is attached to the tissue in order to record continually the heat transport (Hensel, 1956). The device depends on having an electrically heated part and an unheated reference point. The difference in temperature between the heated part of the device and the unheated reference point is a function of local blood flow. An increase in flow tends to lower the local temperature by carrying away the heat gain and vice versa.

PROCEDURE

Cats of either sex weighing 2.5–4.0 kg are anaesthetized by intraperitoneal administration of pentobarbital sodium (35 mg/kg) and intubated with a tracheal tube. The left femoral vein and the right femoral artery are cannulated for i.v. drug administration and determination of arterial blood pressure, respectively. The arterial cannula is connected to a Statham transducer P 23 Db.

For intraduodenal drug administration the duodenum is cannulated following laparotomy.

Before actually starting the experiment, the arterial blood gas concentrations are determined.

Animals are only used for further testing if they show normal blood gas concentrations. During the course of the experiment, blood flow, blood pressure and blood gas concentrations are regularly monitored.

The head of the animal is fixed in a stereotactic device. The skull cap and the dura are opened, the probes are placed on the surface of the cortex in the region of the marginal frontal gyrus, and the exposed brain is covered with moist swabs. The Fluvograph (Hartmann + Braun, Frankfurt) is used with the appropriate thermo probes.

To test the correct position of the thermocouple and the response of the animal, inhalations of carbon dioxide/ air or injections of epinephrine (adrenaline) are used, leading to a distinctive increase in cerebral blood flow. Following stabilization of the parameters mentioned above, the standard compound is administered and the change in blood flow is recorded. Five min after obtaining the original values, the test compound is administered.

Standard compound:

- pentoxifylline
  1 and 3 mg/kg (i.v. administration)
  10 and 30 mg/kg (i.d. administration)

EVALUATION

The percent change in the heat transfer coefficient is used as an indirect measure for the change of cerebral blood flow. Statistics: Student's *t*-test is performed by unpaired comparison.

A.8.1.11 Effect on cerebral blood flow and in ischemic skeletal muscle in rats (Laser-Doppler-Effect)

PURPOSE AND RATIONALE

The principle of the Laser Doppler effect is based on the fact that a laser light beam directed on tissue is scattered in static structures as well as in moving cells. Light beams scattered in moving red cells undergo a frequency shift according to the Doppler effect, while beams scattered in static tissue alone remain unshifted in frequency. The number of Doppler shifts per time is recorded as a measure for erythrocyte flow in a given volume. This means, that the direction of flow cannot be determined, but relative changes in micro circulatory blood flow can be recorded. The procedure can be used to detect test compounds that improve the blood supply of the brain or the flow of red blood cells in the ischemic skeletal muscle.

PROCEDURE

Male Sprague-Dawley rats weighing 300–500 g are anaesthetized with pentobarbital sodium (60 mg/kg i.p.). The trachea is exposed and intubated with a short tracheal tube to allow ventilation. The following vessels have to be cannulated: The femoral vein is cannulated for test drug administration. The femoral artery is cannulated for blood pressure recording and blood gas analysis.

Before actually starting the experiment, the arterial blood gas concentrations are determined. Animals are only used for further testing if they show normal blood gas concentrations (pa CO_2: 32–42 mm Hg; pa O_2: 70–110 mm Hg). The mean arterial blood pressure should not drop below 100 mm Hg. During the course of the experiment, blood flow, blood pressure and blood gas concentrations are regularly monitored.

For cerebral blood flow

The head of the animal is fixed in a stereotactic device. After trepanation of the skull (opening 3 mm in diameter), the Laser Doppler probe is placed 1 mm above the surface of the brain. Values are measured with the Laser Doppler apparatus (Periflux F2, Perimed KB, Stockholm).

Following stabilization of the parameters mentioned above, the standard compound is administered and the change in blood flow is recorded. Five min after obtaining the original values, the test compound is infused. Following two administrations of the test compound, the standard compound is administered again. Duration of the effect is measured as half life in seconds.

For peripheral blood flow

A small area of the femoral artery of the right hind limb is exposed and the Laser Doppler probe is placed 1 mm above the muscle surface. Before actually starting the experiment, the arterial blood gas concentrations are determined. Animals are only used for further proceeding if they show normal blood gas concentrations. During the course of the experiment, the blood pressure is recorded. The RBC flux is recorded

continuously and after stabilization of the output signal, the femoral artery is occluded leading to underperfusion of the muscles of the right pelvic limb. At this stage, the test compound is administered by intravenous infusion for 10 min (0.05 ml/min).

Standard compound for cerebral blood flow is propentofylline (1 mg/kg, i.v.). The percent increase in blood flow produced by propentofylline ranges between 40% and 60%.

EVALUATION

The percent increase in blood flow after test drug administration is determined (compared to the value before drug administration).

Statistics: Student's *t*-test by unpaired comparison, test substance versus standard.

MODIFICATIONS OF THE METHOD

Iadecola (1992), Prado et al. (1992), Raszkiewicz et al. (1992) measured the influence of nitric oxide on cortical cerebral blood flow in anesthetized rats by Laser-Doppler flowmetry.

Benessiano et al. (1985) measured aortic blood flow with range-gated Doppler flowmeter in anesthetized rats.

Partridge (1991) measured nerve blood flow in the sciatic nerve of anesthetized rats with a Laser Doppler Flowmeter after application of local anesthetics and of epinephrine.

A.8.1.12 Traumatic brain injury

PURPOSE AND RATIONALE

A major goal in research into mechanisms of brain damage and dysfunction in patients with severe head injury and in discovery of potential therapies is the development of a suitable animal model. While a variety of experimental techniques have been developed (Denny-Brown and Russell 1941; Gurdjian et al. 1954; Ommaya and Gennarelli 1974; Sullivan et al. 1976; Nilsson et al. 1977; Hayes et al. 1984; Marmarou et al. 1994; Mésenge et al. 1996), the most widely employed technique is fluid percussion, which produces brain injury by rapid injection of fluid into the closed cranial cavity (Sullivan et al. 1976; McIntosh et al. 1989, 1990; Faden et al. 1989; Dixon et al. 1991; Sun and Faden 1995; Petty et al. 1996). Most authors used rats, however, other species, such ad cats (Sullivan et al. 1976; Hayes et al. 1983, 1984), rabbits (Lindgren and Rinder 1969) and mice (Hall et al. 1988; Mésenge et al. 1996) were employed.

PROCEDURE

Surgical preparation

Male Sprague Dawley rats weighing from 400 to 500 g are anesthetized with ketamine (80 mg/kg, i.m.) and sodium pentobarbital (20 mg/kg, i.p.). During surgical preparation and throughout the experiment, all wounds are infused with a topical anesthetic (lidocaine hydrochloride 2.0%). Catheters are inserted into the femoral vein for drug administration and into the femoral artery for blood pressure/blood gas monitoring. A 2.0 mm hollow female Leur-Loc fitting (to induce trauma) is rigidly fixed with dental cement to the animal's skull in a craniectomy centered over the left parietal cortex 5 mm from lambda, 5 mm from bregma, 4 mm from sagittal suture. The dura is left intact at this opening. Immediately following surgical preparation, a constant i.v. infusion of sodium barbital (15 mg/kg/h) is begun and maintained for the duration of the studies.

Drug administration

Drugs or equal volumes of saline are administered through the femoral vein over 10 min by constant infusion beginning 15 min before trauma.

Fluid-percussion injury

The fluid-percussion device consists of a Plexiglas cylindrical reservoir, 60 cm long and 4.5 cm in diameter, bounded at one end by a Plexiglas, cork-covered

piston mounted on O-rings. The opposite of the reservoir is fitted with a 2-cm-long metal housing on which a transducer is mounted and connected to a 5-mm tube (2 mm inner diameter) that terminates with a male Leur-Loc fitting. At the time of injury the tube is connected with the female Leur-Loc fitting that has been chronically implanted over the exposed dura of the rat. After the entire system is filled with 37°C isotonic saline, injury is induced by a metal pendulum which strikes the piston of the device from a predetermined height. The device produces a pulse of increased intracranial pressure of fairly constant duration (21–23 ms) by injecting various volumes of saline into the closed cranial cavity. Brief displacement and deformation of neural tissue results from the rapid epidural injection of saline. The magnitude of injury is regulated by varying the height of the pendulum, which results in corresponding variations of the intracranial pressure expressed in atmospheres. The pressure pulses are measured extracranially by a transducer and recorded on a storage oscilloscope.

EVALUATION

Behavioral outcome

Posttraumatic deficits are evaluated at 24 h, 1 week and 2 weeks following trauma. Outcomes include forelimb flexion (right and left), lateral pulsion (right and left) and angle score (left, right and vertical position). Scores range from 0 (maximal deficits) to 5 (normal) for each task, By combining scores of all tests, a composite neuroscore is determined, ranging from 0 to 35 (Faden 1993).

Histopathology

At 2 weeks, following final neurological scoring, the rats are sacrificed by decapitation. The brain is removed, quickly frozen in isopentane and stored in a –80°C freezer until sectioning. Coronal brain sections are selected to span the longitudinal axis of the dorsal hippocampus between –3.2 and –3.8 Bregma. Sections (16 mm thick) are cut at –18°C in a microtome-cryostat and thaw-mounted onto chrome-gelatin rubbed microscope glass slides and kept at –80°C for histological study.

Sections are stained with Crystal violet. CA1 and CA3 pyramidal cells with a distinct nucleus and nucleolus are counted as viable neurons, in one reticle within CA3 and in three reticles (R1, R2 and R3) within the subfield of the hippocampus, in both right and left hemispheres. The number of viable neurons is counted twice at 400× microscope field.

An immunochemical method is used to detect glial fibrillary acidic protein (GFAP)-positive astrocytes in the hippocampus (Faddis and Vijayan 1988). Counting of the number of cells is done under 400× light microscopy in the dorsal CA1 subfield between medial and lateral regions.

Statistical analysis

Neuroscores from forelimb flexion tests, lateral pulsion tests and angle board tests are statistically analyzed by non-parametric Mann-Whitney U-tests. Histological data are analyzed by one way ANOVA test, followed by Scheffe's test.

MODIFICATIONS OF THE METHOD

Shohami et al. (1995) tested the effect of a non-psychotropic cannabinoid which acts as a non-competitive NMDA antagonist on motor and memory functions after closed head injury in the **rat**.

Fox et al. (1998) developed a **mouse** model of traumatic brain injury using a device that produces controlled cortical impact, permitting independent manipulation of tissue deformation and impact velocity and resulting in sustained sensory/motor and cognitive defects.

Tang et al. (1997) reported impairment in learning and memory in an experimental model of concussive brain injury in **mice**.

Bemana and Nago (1998) induced acute intercranial hypertension in **cats** by continuous inflation of an extradural balloon with physiological saline at a constant rate of 0.5 ml/h for 3 h. At this point, inflation was discontinued and the balloon remained expanded for an additional hour after which it was deflated.

A model of **traumatic injury to the spinal cord** was used by Springer et al. (1997). Female Long Evans rats weighing 200–250 g were anesthetized with pentobarbital and a dorsal laminectomy was performed to expose the spinal cord at thoracic level T 10. The vertebral column was stabilized by clamping the column at vertebra 8 and 11. The New York University (NYU) impactor device was used which produces accurate and reproducible damage to the rat spinal cord (Gruner 1992; Basso et al. 1996). This device is a weight drop apparatus that uses optical potentiometers to record the movement of a 10-g impact rod and the vertebral column following impact and is connected to a PC that monitors rod and vertebral movements during impact.

A.8.2
Peripheral blood supply

A.8.2.1
Perfused hindquarter preparation with sympathetic nerve stimulation in rats

PURPOSE AND RATIONALE

Perfusion of the hindquarter in rats with a constant flow rate allows the evaluation of the effect of drugs on the peripheral vascular bed. Since constant blood flow is maintained, changes in the vascular resistance of the perfused bed are directly proportional to changes in the perfusion pressure.

PROCEDURE

Male Wistar rats weighing between 250 and 300 g are pre-treated with heparin (1 000 units/kg i.v.) and anesthetized with pentobarbital sodium (50 mg/kg i.p.) The animals are intubated with a tracheal tube and positive pressure ventilation is maintained with a Harvard Rodent Respirator at 4–6 ml/stroke and 50 strokes/min. The right jugular vein is cannulated with polyethylene tubing for administration of drugs.

The lumbar sympathetic chain is isolated dorsal to the inferior mesenteric branches via an abdominal midline incision. The aorta is freed from the vena cava and two silk ligatures are placed around the aorta. The aorta is ligated and cannulated proximal as well as distally with polyethylene tubings. A short piece of rubber tubing is inserted at the distal end to allow intraarterial injections of drugs. Two "T" junctions allow the measurement of arterial pressure and perfusion pressure by Statham P 23 Db pressure transducers being recorded through a Hellige physiological recorder. From the proximal part of the aorta, blood is forced to its distal part by a peristaltic pump (Desaga) through a glass coil kept at 40 °C. Flow rate is adjusted to produce a stable perfusion pressure as close to the systemic pressure as possible. After initial adjustment, flow rate is not altered for the remainder of the experiment.

Following perfusion pressure stabilization, the sympathetic chain is isolated and a small (1 mm wide, 2 mm long) curved bipolar electrode is placed around the nerve for electrical stimulation. Square-wave pulses from a Grass stimulator are used to activate the nerve with a constant current of 2.5 milliamps, supramaximal voltage and varying frequencies of 5 ms duration.

A dose-response curve is established for norepinephrine by giving doses of 0.01 µg, 0.03 µg, 0.1 µg, 0.3 µg, 1.0 µg, and 3.0 µg intra-arterially and measuring perfusion pressure changes. Similarly, a frequency-response curve to nerve stimulation is established by stimulation at 3 Hz, 6 Hz, and 10 Hz for 30 s. Two predrug readings are taken to insure consistent responses.

A minimum of four animals is used for each test compound.

EVALUATION

The first predrug dose-response curves are compared with the second predrug, 5 min and 60 min postdrug dose-response curves. From regression equations for norepinephrine and nerve stimulation, mean responses and potency values with 95% confidence limits are calculated.

MODIFICATIONS OF THE METHOD

Folkow et al. (1970) perfused the hindquarters of spontaneously hypertensive rats and control rats at a constant rate of flow with an oxygenated plasma substitute in order to study the increased flow resistance and vascular reactivity. The hindquarters were isolated from the upper part of the body by standardized mass ligatures at identical levels until the aorta and the inferior caval vein provided the only intact circulatory connections between the two parts of each animal.

Thimm et al. (1984) described reflex increases in heart-rate induced by perfusing the hind leg of the rat with solutions containing lactic acid.

Thimm and Baum (1987) obtained spike recordings from chemosensitive nerve fibres of group III and IV of the rat nervus peroneus. Applications were performed either by perfusion of the circulatory isolated hindleg or by superfusion of the isolated musculus extensor digitorum longus.

Kitzen et al. (1978) used the perfused hind limb of the **dog** with sympathetic nerve stimulation for cardiovascular analysis.

Reitan et al. (1991) developed a near anesthetic-free isolated hindlimb model in the **dog** and studied the effects of halothane and atropine sulfate on vascular resistance.

Wiegershausen and Deptalla (1969) used the isolated perfused hindlimb of the **cat** to study the influence of local anesthetics on the vasoconstrictor actions induced by bradykinin, epinephrine and histamine.

Santiago et al. (1994) analyzed the responses to bradykinin in the hindquarters vascular bed of the cat.

Champion et al. (1996, 1997) analyzed the responses of human synthetic adrenomedullin, an analog of adrenomedullin and calcitonin gene-related peptides in the hindlimb vascular bed of the cat.

A.8.2.2 Effect on peripheral blood flow in rats

PURPOSE AND RATIONALE

Various methods exist to measure peripheral blood flow in rats, such as the microsphere technique, electromagnetic flowmetry and Doppler ultrasonic flowmetry.

Radioactive microspheres are used to calculate the distribution of blood from the heart to various organs and tissues before and after the administration of test compounds. In this method, microspheres are injected into the left cardiac ventricle. It is postulated that the first contraction of the cardiac muscle will expel these spheres into the circulation. Consequently the microspheres can be trapped in different organs according to the organ's perfusion rate. It is not a primary screening method but it is a useful test for distinguishing compounds with blood flow altering activities.

The microspheres used are 14 μ in diameter. They are marked with isotopes. In this test, four different radioactive elements are used (Cr^{51}, Sr^{85}, Sc^{46}, Ce^{141}), allowing the determination of blood flow before dosing and after the administration of 3 different compounds or 3 different doses (of the same compound).

PROCEDURE

Male Wistar rats weighing 500–550 g are anaesthetized with pentobarbital. The trachea is exposed and intubated with a short endotracheal tube to allow ventilation. Prior to testing the jugular vein is cannulated for administration of test drugs. The carotid artery is cannulated and later on the catheter is passed retrograde into the ventricle. Ventricular pressure is recorded to assure the correct emplacement of the catheter tip in the ventricle. This catheter is connected to another catheter allowing the injection of microspheres into the left ventricle later on. The right arteria brachialis is cannulated and connected to a Hellige blood pressure recorder. During the course of the test, blood pressure will be measured continuously. The left femoral artery is cannulated and connected to an infusion pump. During the experiment blood will be withdrawn from this artery.

After these preparations the rat is allowed 15–30 min to recover. Before actually starting the experiment, the arterial blood gas concentration of each animal is measured. Animals are only used for the experiment if they show normal blood gas concentrations. During the following procedure blood pressure, ventricular pressure and the heart rate are continuously recorded. To determine baseline blood flow animals receive 0.2 ml vehicle/min over a 3 min period. In the 4th minute rats receive the first injection of microspheres (Cr^{51}). Simultaneously 0.5 ml/min blood is withdrawn from the femoral artery catheter for one minute, the pump thus being used as a reference organ. The animals are allowed 20 min to recover before the administration of drugs. The test compound is infused into the jugular vein at a rate of 0.2 ml/min for 3 min followed by injection of the second microsphere (Sr^{85}). The same procedure is repeated using the other two microspheres (Sc^{46} and Ce^{141}) following administration of the second and third test compound.

At the end of the experiment blood gas concentrations are measured. The animals are killed and their organs are removed. Usually blood flow is determined in the following organs:

- brain (right and left hemisphere; right hemisphere showing slight ischemia due to cannulation of carotis)
- cerebellum
- lungs
- heart
- kidney (right and left)
- skeletal muscle (right hind extremity)
- duodenum
- stomach
- spleen
- diaphragm
- adrenal gland (right and left)

To determine effects of test compounds on the blood flow in the underperfused skeletal muscle the same experiment can be performed with the right femoral artery being clamped. In this way effects of the test drug on the ischemic and normal skeletal muscle (left thoracic limb) can be compared in the same animal.

EVALUATION

The rate of blood flow/tissue at a certain time is determined by measuring radioactivity in the different tissues and comparing the results to that of the blood sample.

MODIFICATIONS OF THE METHOD

Blood flow in various peripheral organs, e.g., renal blood, flow can be measured with electromagnetic flowmeters (e.g., Transflow 601, Skalar Medical, Holland) or with Doppler ultrasonic flowmetry (Shaffer and Medvedev 1991).

Lappe et al. (1986) studied regional vascular resistance in conscious spontaneously hypertensive rats

which were chronically instrumented with pulse Doppler flow probes to allow measurement of renal, mesenteric and hind quarters blood flow.

Hartman et al. (1994) validated a transit-time ultrasonic volume flow meter by simultaneous measurements with an electromagnetic flow metering method.

Lepore et al. (1999) used electron paramagnetic resonance to investigate the time course of nitric oxide generation and its susceptibility of nitric oxide synthase in ischemia-reperfusion injury to rat skeletal muscle *in vivo*. Total hind limb ischemia was applied for 2 h using a rubber band tourniquet method. At the end of ischemia the tourniquet was removed and the limb allowed to reperfuse for various time intervals.

Beattie et al. (1995) measured carotid arterial vascular resistance in anesthetized **rabbits**. Carotid blood flow was measured by a Doppler flow probe placed around the right common carotid artery. Dose-response curves of reduction of carotid arterial vascular resistance were constructed after injection of various doses of substance P-methyl ester via the right lingual artery. Intravenous injection of various doses of a selective tachykinin NK_1 receptor antagonist inhibited this effect dose-dependently.

A.8.2.3
Effect on peripheral blood flow in anesthetized dogs

PURPOSE AND RATIONALE

Effects on blood pressure have to be analyzed whether they are mediated by central, cardial, or peripheral action. By injecting small doses of the test compound directly into a vascular bed, thus avoiding changes of central hemodynamics, peripheral vasodilating activity of a compound can be tested. This test is used to evaluate direct vasodilating or constricting activities of drugs *in vivo*-measurements of blood flow.

PROCEDURE

Male or female Beagle or Labrador-Harrier dogs weighing 15–25 kg are used. The dogs are premedicated intravenously with heparin (bolus of 500 IU/kg and successive injections of 50 IU/kg every 30 min) and anesthetized by intravenous injection of thiobarbital sodium (0.5 mg/kg i.v.), chloralose (20 mg/kg i.v.) and urethane (250 mg/kg i.v.). Respiration is maintained with room air through a tracheal tube using a positive pressure respirator. Blood gas analysis is performed at regular time intervals. Oxygen is supplied via the respirator as needed.

Preparation for hemodynamic measurements

To measure peripheral blood flow and to administer the test substance, a bypass is inserted into a femoral artery incorporating an electromagnetic flow probe and a port for injections. The other femoral artery is also equipped with a bypass used for the administration of a reference compound or a second test drug.

For recording of peripheral blood pressure and heart rate, one of the bypasses is connected to a pressure transducer (Statham P 23 BD).

All parameters are recorded continuously during the whole experiment.

Experimental course

When stable hemodynamic conditions are achieved for at least 20 min, the vehicle is administered (control), and 10 min later the test compound. Immediately after each administration, the port is flushed with physiological saline. Successive doses are administered after recovery to baseline values.

Readings are taken at times 0, 0.5, 1, 2, 5 and 10 min, and, if necessary, at additional 10 min-intervals following drug administration.

Standard compound:

- carbocromene 1 mg/kg

Characteristics:
- blood pressure
  - systolic, BPs
  - diastolic, BPd
- heart rate, HR
- peripheral blood flow, PF

EVALUATION

Changes in blood pressure, heart rate and peripheral blood flow at different times after drug administration are compared to vehicle control values obtained in the 10 min pre-drug period.

With $n > 2$, results are presented as mean ±SEM. Statistical significance is assessed by means of the paired *t*-test. Scores are compared to the efficacy of standard compounds for intensity and for duration of the effect.

MODIFICATIONS OF THE METHOD

Regional blood flow can be determined by the use of microspheres (Rudolph and Heyman 1967). The method is based on the principle that biologically inert microspheres will be trapped due their diameter in the microvasculature (Hales and Cliff 1977). The use of radioactive microspheres has some disadvantages (Buckberg et al. 1971). The use of fluorescent labeled microspheres for measurement of regional organ perfusion has been recommended (Glenny et al. 1993; Prinzen and Glenny 1994; van Oosterhout et al. 1995). Raab et al. (1999), Thein et al. (2000) described the automation of the use of fluorescent microspheres using a special sample processing unit. A Zymate-Robotic System (Zymark, Idstein, Germany) was modified to handle a special filtration device.

Ebara et al. (1994) measured renal blood flow in dogs after intrarenal arterial infusion of adrenomedullin.

A.8.2.4 Effect on peripheral blood supply measured by local oxygen pressure

PURPOSE AND RATIONALE

Local oxygen pressure is directly related to oxygen supply to peripheral organs, e.g., muscle (Luebbers 1969; Kessler 1969). The local oxygen pressure (PO_2) is recorded directly on the muscle surface. In the following procedure the effect of test compounds on the local oxygen pressure (PO_2) of the normal and the ischemic skeletal muscle is determined.

PROCEDURE

Male Beagle dogs weighing 15–20 kg are used. The dog is anesthetized by intraperitoneal administration of pentobarbital sodium (Nembutal®). Prior to testing, the following vessels have to be cannulated: The V. femoralis of the left pelvic limb is cannulated for administration of test compounds. The A. femoralis of the left pelvic limb is cannulated for blood pressure recording. The V. femoralis of the right pelvic limb is cannulated. During the course of this test blood will be withdrawn from this vein to monitor lactate concentrations.

Small areas of muscles of the right pelvic limb and the right thoracic limb are exposed. Muscle relaxation is induced by intravenous injection of 0.1 mg/kg alcuronium chloride (Alloferin®) and maintained by i.p. administration of 0.05 mg/kg Alloferin at 30 min intervals. The trachea is exposed and intubated to assist the dog's respiration.

A PO_2 electrode is placed on the exposed muscle area of the right hind limb. After stabilization of PO_2 curves, the femoral artery of the right hind limb is occluded by putting a clip around the vessel. Muscle PO_2 drops rapidly. Following stabilization, test compounds are given by intravenous infusion for 10 min or by intraduodenal administration at this stage. The PO_2 of the non ischemic muscle is recorded simultaneously

via a second electrode on the right thoracic extremity. The clip is removed after maximally one hour. This procedure can be repeated up to four times in one animal. Blood gas concentrations and pH are determined at the beginning and end of each experiment.

Standard compound:
- pentoxifylline

EVALUATION
The following parameters are determined:

- Maximal increase in PO_2 (mm Hg) after administration of test drug
- duration of effect by determining the half life

A.8.2.5 Effect on mesenteric blood flow in rats

PURPOSE AND RATIONALE
Blood flow in the mesenteric vascular bed *in situ* (Bhattacharya et al. 1977; Eikenburg 1984; Randall et al. 1989; Jackson and Inagami 1990) can be studied in rats in a way similar to that of the perfused hindquarter.

PROCEDURE
Wistar rats of either sex weighing 250–300 g are anesthetized with a combination of urethane (500 mg/kg i.v.) and sodium pentobarbitone (30 mg/kg). The abdomen is opened by a midline incision and a segment of the superior mesenteric artery is exposed by careful dissection of the surrounding tissue. Care is taken to avoid damage to the accompanying nerve terminals. One cannula is inserted into the carotid artery and the other into the superior mesenteric artery. Blood from the carotid artery is forced by a peristaltic pump (Desaga) into the superior mesenteric artery, using a glass coil kept at 40 °C. Blood required to fill the tubing initially is obtained from donor rats. Heparin is administered intravenously to the animals prior to cannulation of the mesenteric artery. The blood pressure and the perfusion pressure are measured by Statham P 23 Db pressure transducers and recorded through a 2-channel Hellige recorder. The pump speed is initially adjusted so that the perfusion pressure equals the systemic blood pressure. Intraarterial injections into the mesenteric vascular bed are made by puncturing the tubing going towards the periphery. Intravenous injections are made through a cannula inserted into the external jugular vein.

EVALUATION
Changes in the vascular resistance are measured by comparing perfusion pressure before and after drug administration. If constant blood flow is maintained, changes in the vascular resistance of the perfused bed are directly proportional to changes in the perfusion pressure.

MODIFICATIONS OF THE METHOD
Reactivity in the mesenteric vascular bed can be tested in an isolated preparation (McGregor 1965; Kawasaki and Takasaki 1984; Laher and Triggle 1984; McAdams 1984; Foy and Nuhu 1985; Longhurst and Head 1985; Soma et al. 1985; Hsueh et al. 1986; Longhurst et al. 1986; Manzini and Perretti 1988; Nassar et al. 1988; Randall and Hiley 1988). The abdomen of anesthetized rats is opened and the superior mesenteric artery is separated from surrounding tissue in the region of the aorta. A cannula is inserted into the superior mesenteric artery at its origin from the abdominal aorta. The cannula is filled with heparinized Krebs solution. The ileocoeliac branch of the artery is tied off and the intestine separated from the mesentery by cutting close to the intestinal border of the mesentery. The cannulated artery and its vascular bed are dissected out and mounted in an organ bath. The preparation is perfused with oxygenated Krebs-bicarbonate buffer (pH 7.4) at 37 °C. Perfusion pressure is recorded via a side arm of the arterial cannula using a Statham pressure transducer. The flow rate is adjusted to give a baseline perfusion pressure of 20–30 mm Hg. The test substances are infused into another side arm of the arterial cannula for 15 s using an infusion pump. After three stimuli with norepinephrine (1 µg) or potassium chloride (1 mg), the test drugs are infused followed by further stimulation. The inhibition of increase of perfusion pressure after test drugs is expressed as percentage of control.

Nuki et al. (1994) compared the vasodilating activity of chicken calcitonin gene-related peptide with human α-CGRP and rat CGRP in the precontracted mesenteric vascular bed of rats.

The **rabbit** isolated arterially perfused intestinal segment preparation was used by Brown et al. (1983) as a model for vascular dopamine receptors.

Komidori et al. (1992) recommended the isolated rat mesenteric vascular-intestinal loop preparation as an excellent model fort demonstrating resistance changes in isolated vascular beds while simultaneously measuring endogenous catecholamine overflow.

Pelissier et al. (1992) showed that perfusion with hypotonic solutions removed the endothelial layer in the isolated perfused mesenteric vascular bed of the rat, allowing the study of endothelial-dependent vascular responses.

Santiago et al. (1993) used the mesenteric vascular bed of the **cat** to study the inhibitory effects of the bradykinin receptor antagonist Hoe 140 on vascular responses to bradykinin.

The responses of adrenomedullin and adrenomedullin analogs in the mesenteric vascular bed of the cat were compared by Santiago et al. (1995).

Chu and Beilin (1994) studied the mesenteric vascular reactivity which is reduced in pregnant rats after application of bradykinin and the bradykinin receptor antagonist Hoe 140.

Mulavi and Halpern (1977), Qiu et al. (1995) studied the mechanical and contractile properties of *in situ* localized mesenteric arteries in normotensive and spontaneously hypertensive rats.

A.8.2.6 Effect on pulmonary blood flow

PURPOSE AND RATIONALE

During controlled pulmonary blood flow, lobar arterial pressure can be measured in anesthetized cats (Lippton et al. 1984; Hyman et al. 1989; McMahon and Kadowitz 1993; deWitt et al. 1994).

PROCEDURE

Adult cats of either sex weighing 2.5 to 4.5 kg are sedated with ketamine hydrochloride (10–15 mg/kg i.m.) and anesthetized with pentobarbital sodium (30 mg/kg i.v.). The animals are fixed in supine position and supplemental doses of anesthetic are administered to maintain a uniform level of anesthesia. The trachea is intubated and the animals breath room air enriched with 95% O_2/5% CO_2. Systemic arterial pressure is measured from a catheter inserted into the aorta from a femoral artery, and intravenous injections are made from a catheter positioned in the inferior vena cava from a femoral vein.

For perfusion of the left lower lung lobe, a special designed 28-cm 6F triple-lumen balloon perfusion catheter (Arrow International, Reading, PA) is passed under fluoroscopic guidance from the left external jugular vein into the artery to the left lower lobe. The animal is heparinized by 1 000 IU/kg i.v., and the lobar artery is isolated by distension of the balloon cuff on the perfusion catheter. The lobe is then perfused by way of the catheter lumen beyond the balloon cuff, with blood withdrawn from a femoral artery with a perfusion pump. Lobar arterial pressure is measured from a second port 5 mm from the cuff on the perfusion catheter. The perfusion rate is adjusted so that lobar arterial perfusion pressure approximates mean pressure in the main pulmonary artery. Left atrial pressure is measured with a 6F double-lumen catheter passed transseptally into the vein draining the left lower lobe. The catheter tip is positioned so that the left atrial pressure port on the distal lumen is 1–2 cm into the lobar vein and the second catheter port is near the venoatrial junction.

Lobar arterial pressure can be elevated to an high steady state level by the administration of N^{ω}-nitro-L-arginine$^{\omega}$, followed by an intralobar infusion of the stable prostaglandin/endoperoxide analogue U-46619.

EVALUATION

Dose-response curves after administration of graded doses of drugs, e.g., decrease of lobar arterial pressure after various doses of bradykinin, are established. The effects of antagonists, e.g. HOE 140, can be studied.

MODIFICATIONS OF THE METHOD

Liu et al. (1992) used a blood-perfused rat lung preparation to study pulmonary vasoconstriction or endothelium-dependent relaxation.

Byron et al. (1986) studied the deposition and airway-to-perfusate transfer of disodium fluorescein from 3–4 μm solid aerosols in an isolated perfused lung preparation of rats.

Mor et al. (1990) determined angiotensin-converting enzyme activity in the isolated perfused **guinea pig** lung.

Franks et al. (1990) used in Beagle **dogs** a single breath technique employing freon-22 as the soluble marker gas simultaneously with measurement of aortic blood flow by an electromagnetic flowmeter.

Tanaka et al. (1992) measured lung water content in dogs with acute pulmonary hypertension induced by injection of glass beads.

Drake et al. (1978) studied filtration characteristics of the exchange vessels in isolated dog lung by calculating the volume conductance with use of different components of the weight-gain curve following changes in capillary pressure.

Heaton et al. (1995) studied the effects of human adrenomedullin on the pulmonary vascular bed of isolated, blood perfused rat lung.

DeWitt et al. (1994), Lippton et al. (1994) investigated the effects of adrenomedullin in the pulmonary and systemic vascular bed of the **cat**.

Nossaman et al. (1995) compared the effects of adrenomedullin, an adrenomedullin analog, and CGRP in the pulmonary vascular bed of the cat and the rat.

A.8.2.7
Effect on contractile force of ischemic muscle

PURPOSE AND RATIONALE

Skeletal muscle is stimulated until it reaches its maximal force of contraction. This means that the muscle is forced to function at a level near exhaustion and has to use maximally the substrate supplied by the circulation. Then, the femoral artery is occluded, leading to underperfusion and a subsequent lack of substrate. As a consequence, the muscle's force of contraction decreases rapidly. Measuring the change in contractile force caused by drug administration reveals a drug's ability to restore ischemic muscle functions. In the following procedure, the drugs are tested for their effect on the force of contraction of the ischemic skeletal muscle.

PROCEDURE

Male Wistar rats weighing 400–450 g are anaesthetized by intraperitoneal administration of pentobarbital (Nembutal®) (35 mg/kg). A tracheal tube is placed to assist the rat's ventilation. The left carotid artery is cannulated for blood pressure recording and the left jugular vein is cannulated for the i.v. administration of test drugs. An incision is made to the skin of the right pelvic limb distal to the groin and the skeletal muscle is exposed down to the ankle. The skin is carefully trimmed away from the muscle to assure that contractions cannot be impaired by retraction of the skin. The major nerve supply is severed and a small length of the descending branch of the femoral artery is prepared free. The freely hanging muscle is attached to the force transducer (range 0–500 g, Z 6, Rhema, Germany) and a resting tension of 50 g is placed on the muscle. To prevent dehydration, the skin is left attached to the muscle and the muscle is kept moist by the continuous drip of a 0.9% NaCl-solution.

After these preparations, the rat is allowed to recover at least 30 min. Two needle electrodes are inserted into the muscle. Square impulses of 40 ms are generated with Stimulator 1 (Hugo Sachs Elektronik, Freiburg, Germany). The muscle is stimulated with a frequency of about 80 contractions per minute. The amplitude is increased gradually up to the muscle's maximal contractile force (usually between 2.0 and 3 mA). Following stabilization, the femoral artery is occluded with a clip for 5 min and subsequently reopened. After at least 15 min, test drugs are administered by intravenous infusion (0.075 ml/min) for 10 min. Five minutes after starting drug infusion, the artery is clamped again (for 5 min) while drug infusion is still going on. The force of contraction is continuously recorded. After declamping the artery, the rat is allowed to recover for at least 30 min before the whole procedure is repeated with another test drug. In this way, 3 different compounds can be tested in the same animal.

Standard compound:
- pentoxifylline

EVALUATION

The following parameters are measured:

- the percent inhibition of contractile force before drug administration (artery being clamped)
- the percent inhibition of contractile force after drug administration (artery being clamped)

The percent increase in contractile force after drug administration is calculated.

CRITICAL ASSESSMENT OF THE METHOD

An attempt is made to measure not only the effects of the drug on vasculature tonus but also on muscle metabolism.

MODIFICATIONS OF THE METHOD

Weselcouch and Demusz (1990) studied drug effects in the ischemic hindlimbs of **ferrets**. The hindlimb was stimulated to contract isometrically via supramaximal electrical stimulation of the sciatic nerve. Ischemia was induced by partial occlusion of the abdominal aorta. Pentoxifylline attenuated the loss of function in a dose-related manner.

Okyayuz-Baklouti et al. (1992) studied the functional, histomorphological and biochemical changes in atrophying skeletal muscle using a novel immobilization model in the rat.

Le Tallec et al. (1996) reported the effects of dimethylformamide on *in vivo* fatigue and metabolism in rat skeletal muscle measured by 31P nuclear magnetic resonance spectroscopy.

A.8.2.8 Effect on perfusion of rabbit ear (Pissemski method)

PURPOSE AND RATIONALE

The procedure was described as early as 1914 by Pissemski, based on experiments of Krawkow (1913) in fish gills. It can be used to elucidate vasoactive properties (both vasoconstrictive and vasodilating) of compounds. The isolated rabbit's ear is used to determine the effect of test compounds on its perfusion rate. Administration of norfenephrine induces vasoconstriction leading to a decrease in perfusion rate. A compound with vasodilatory properties will inhibit the norfenephrine induced fall in perfusion rate whereas a vasoconstrictor will potentiate this effect.

PROCEDURE

A rabbit of either sex weighing 1.5–3 kg is sacrificed by CO_2 narcosis and its ears are severed immediately. The ear is placed on a glass disc, the posterior auricular artery is exposed and cannulated. The cannula is connected to a tubing with a T-branch allowing the infusion of different solutions. Ringer's solution, kept at room temperature, is infused under 40 cm water column pressure via the cannula. The perfusion flow volume is recorded using a time ordinate recorder and a CONDON tipper or a photoelectric drop counter.

Prior to drug administration, the pH of the Ringer solution (containing test compound) must be determined. If the pH is greater than 8.5 or smaller than 6.5, it should be adjusted by adding a diluted NaOH- or HCl-solution.

Testing for vasodilatory (norfenephrine antagonistic) activity

Norfenephrine is infused at a concentration of 0.5 µg/ml until the maximal contraction is reached. The test compound is prepared in Ringer's solution at a concentration of 100 µg/ml. A volume of 30 ml is infused via the cannula over a 15 min period under constant pressure. The change of perfusion rate is determined. If there is a positive response (increase in perfusion rate), the test may be repeated using lower concentrations. If there is a negative response (further decrease in perfusion rate), the compound can be tested for vasoconstrictive activity.

Testing for vasoconstrictive activity

This test is repeated as described above without administration of norfenephrine.

Standard compounds:

- as vasodilator
  - dihydralazine
  - theophylline
  - pentoxyfylline 100 µg/ml
- as vasoconstrictor
  - norfenephrine (Novadral®)

EVALUATION

Testing for vasodilatory activity

The perfusion rate of the ear vessel is determined during the course of the test:

R = perfusion rate of vehicle perfused vessel
RN = perfusion rate of norfenephrine constricted vessel
RNP = perfusion rate of norfenephrine constricted vessel following compound administration

The percent inhibition of norfenephrine induced decrease in perfusion pressure is calculated using the following formula:

$$\% \text{ inhibition} = \frac{(RN - RNP)}{R - RN} \times 100$$

Testing for vasoconstrictive activity

The normal perfusion rate (ear vessel perfused with Ringer's solution) is taken as 100%. The percent inhibition of perfusion rate following compound administration is determined.

MODIFICATIONS OF THE METHOD

Schlossmann (1927) used the isolated rabbit ear preparation according to Pissemski for determination of the adrenaline content in blood.

De la Lande and Rand (1965), de la Lande et al. (1967) described a method of perfusing the isolated central artery of the rabbit ear. Small segments of the artery, taken from the base of the ear, were perfused at a constant rate with Krebs solution at 37°C. To enable drugs to be applied either to the intima or the adventitia, the artery was double cannulated so that the intraluminal and extraluminal perfusion media did not mix. Constrictor responses were measured by the maximum rise in perfusion pressure.

Steinsland et al. (1973) studied the inhibition of adrenergic transmission by parasympathicomimetics in the isolated central ear artery of the rabbit. Perfusion was performed at a constant flow rate with Krebs' solution and perfusion pressure was recorded with a transducer.

Allen et al. (1973) incubated isolated segments of rabbit ear artery with (^{3}H)-(−)-noradrenaline and measured the amount of tritium released into the luminal perfusate and into the extraluminal superfusate.

Budai et al. (1990) used isolated proximal 3–4-cm segments of the rabbit ear artery or rat tail artery in a low volume perfusion-superfusion system for measurement of transmitter release from blood vessels *in vitro*.

Miyahara et al. (1993) used arterial rings rabbit ear arteries *in vitro* which were contracted by perivascular nerve stimulation, or 5×10^{-7} noradrenaline or high potassium (29.6 mM) solution. High doses of dexamethasone or clobetasol-17-propionate decreased the amplitude of contractions. Furthermore, the authors performed *in vivo* experiments in albino rabbits, whereby the fur was removed from the distal parts of the ear by applying a depilatory cream at least 24 h before the experiments. The apical regions of the ear were then stripped with adhesive tape 7 times to remove the keratinous epidermal layer. The rabbit was anesthetized and the experimental parts of the ear were placed under a high resolution magnifying camera and immobilized using bilayer adhesive tapes. The vascular reactions induced by topical application of corticosteroids were recorded chronically using video-tapes.

Aoki and Chiba (1993) described a method for separate intraluminal and extraluminal perfusion of the **basilar artery** in dogs. A polyethylene roof was designed to cover the canine basilary artery so that an extraluminal superfusion stream could pass over the artery that simultaneously received an intraluminal perfusion.

A.8.2.9
Effect on venous tonus *in situ* in dogs

PURPOSE AND RATIONALE

Veins can be classified into two groups: those that respond and those that do not respond to epinephrine, acetylcholine and sympathetic nerve stimulation. As studies in dogs have shown (Rice et al. 1966) the reactive veins have a considerable amount of smooth muscle whereas the nonreactive ones lack any appreciable amount of smooth muscle fibres in the tunica media. A special preparation allows the registration of localized venous vasoconstriction.

PROCEDURE

Dogs weighing 20–30 kg are anesthetized with 35 mg/kg pentobarbital sodium i.v. The trachea is cannulated and the dog ventilated with a respiration pump. The femoral vein is cannulated for systemic injections. After administration of 5 mg/kg heparin sodium i.v., the saphenous vein and the femoral artery are cannulated. The venous cannula is placed approximately 1 cm distal to its junction with another vein. After the nonperfused branch of the junction is ligated, constant blood flow is maintained from the femoral artery by using a Sigmamotor® pump. The flow is adjusted so that a normal physiologic pressure in the vein is maintained. Perfusion pressure is measured between the pump and the vein so that any changes in pressure reflect changes in venous resistance. The peak changes in perfusion pressure are used to measure pressure changes from recorded data. The blood flow is maintained on a constant level. Therefore, changes in pressure must reflect changes in resistance. Pressure is recorded with a polygraph using an Statham pressure transducer (P23AA). In addition to recording perfusion pressure, venous pressure is measured at two additional points along the vein. In order to record venous pressure centrally from the site of perfusion, the shaft of a 27-gauge needle is placed into the end of a 10 cm piece of a thin Silastic tubing. At the other end, a 27 gauge needle is inserted and attached to a Statham pressure transducer (P23B). Pressure is recorded on a polygraph. One needle is inserted into the vein just proximal of the junction of the two veins. The second needle is placed into the vein so that the distance between the tip of the perfusion cannula and the first needle is the same as the distance between the two needles. In this way pressure decreases across the junction and an adjacent segment can be measured simultaneously. Injections of test compounds are made into the cannula between the pump and the saphenous vein. Changes in pressure measured by the three transducers are recorded. As standard, doses of 0.1–1.0 µg norepinephrine are injected.

EVALUATION

Responses to test drugs are measured in mm Hg and calculated as percentage of response to norepinephrine.

A.8.3
Angiogenesis and anti-angiogenesis

A.8.3.1
General considerations

Regulation of new blood vessel formation, angiogenesis, is precisely programmed throughout the lifetime of vertebrates. Besides the role of angiogenesis in normal function, it is an essential component of disease processes, including tumor growth, rheumatoid arthritis, psoriasis, and diabetic retinopathy (Folkman and Klagsbrun 1987; Klagsbrun and D'Amore 1991; Folkman and Shing 1992). Multiple factors that stimulate angiogenesis either directly or indirectly have been described, including the fibroblast growth factor family (Esch et al. 1985), vascular endothelial growth factor (Leung et al. 1990; Thomas 1996; Ferrara and Davis-Smyth 1997), epidermal growth factor (Gospadarowicz et al. 1979), transforming growth factor-α and -β (Schreiber et a 1986; Yang and Moses 1990), tumor necrosis factor-α (Leibovich et al. 1987), angiogenin (Fett et al. 1985), CYR61, a product of a growth factor-inducible immediate early gene (Babic et al. 1998) ect. The pharmacological inhibition of angiogenesis is of considerable interest in the development of new therapeutic modalities for the treatment of diseases such as diabetic retinopathy, atherosclerosis, hemangiomas, rheumatoid arthritis and cancer, in which pathological angiogenesis occurs (Ezekowitz et al. 1992; Folkman and Shing 1992; Fan and Brem 1992; O'Brien et al. 1994). Several natural inhibitors of angiogenesis were described, such as thrombospondin (Good et al. 1990), somatostatin (Barrie et al. (1993), angiostatin, isolated from a subclone of Lewis lung carcinoma, (O'Reilly et al. 1994, 1996), endostatin, a 20 kDa angiogenesis inhibitor from a murine hemangioendothelioma which is a C-terminal fragment of collagen XVIII (O'Reilly et al. 1997; Dhanabal et al. 1999), vasostatin (Pike et al. 1998).

A.8.3.2 Endothelial cell proliferation

PURPOSE AND RATIONALE

Human umbilical vein endothelial cells (HUVEC) were used by various authors to study endothelial cell proliferation (Bussolino et al. 1992; Benelli et al. 1995; Danesi et al. 1997; Hu 1998; Iurlaro et al. 1998; Vacca et al. 1999; Xin et al. 1999).

PROCEDURE

The HUV-EC-C human endothelial cells (American Type Culture Collection, Rockville, MD) are cultured at 37 °C and 5% CO_2 in 90% Ham's F12K, 10% fetal bovine serum, 30 µg/ml endothelial cell growth factor, 100 µg/ml heparin, and 4 mM L-glutamine. The effect of test compound on HUV-EC-C cell proliferation is evaluated on 3×10^3 cells/well in 24-well plates. After 24 h, the test compound in various concentrations of the vehicle are added, and plates are incubated for 72 h. Cells are then harvested with trypsin/EDTA and counted by an hemocytometer.

EVALUATION

Results are expressed as number of cells in vehicle and compound-treated cultures and are the mean of three separate experiments ±SE.

MODIFICATIONS OF THE METHOD

In addition to human umbilical veil endothelial cells, Pike et al. (1998) used fetal bovine heart endothelial cells and measured DNA synthesis by [^{3}H]thymidine deoxyribose uptake.

Oikawa et al. (1991) used vascular cells from bovine carotid arteries and tested cell proliferation in a collagen gel and cell migration in a Boyden chamber.

Bovine capillary endothelial cells were used by Folkman et al. (1979), Clapp et al. (1993), O'Reilly et al. (1997), Cao et al. (1999).

A.8.3.3 Chorioallantoic membrane assay

PURPOSE AND RATIONALE

The chick chorioallantoic membrane assay, originally described by Auerbach et al. (1974), has been used with some modifications by several authors to test angiogenesis and inhibition of angiogenesis, e.g., by Taylor and Folkman (1982), Crum et al. (1985), Vu et al. (1985), McNatt et al. (1992, 1999), Barrie et al. (1993), Clapp et al. (1993), Gagliardi and Collins (1993), Benelli et al. (1995), Ribatti et al. (1995), Klauber et al. (1996), Oikawa and Shimamura (1996), Danesi et al. (1997), O'Reilly et al. (1997), Iurlaro et al. (1998), Cao et al. (1999), Vacca et al. (1999).

PROCEDURE

Fertilized White Leghorn chicken eggs are incubated at 37 °C at constant humidity. On incubation day 3, a square window is opened in the shell and 2 to 3 ml of albumen is removed to allow detachment of the developing chorioallantoic membrane (CAM). The window is sealed with a glass and the eggs are returned to the incubator. On day 8, 1 mm^3 gelatin sponges loaded with 3 µl phosphate-buffered saline alone as the negative control or containing 3 µg (1 mg/ml) of the angiogenic recombinant basic fibroblast growth factor alone as positive control, or together with various doses of test compound, are implanted on top of the CAM. The sponge traps the sample and allows slow release of the product. CAM are examined daily until day 12, when the angiogenic response peaks. On day 12, blood vessels entering the sponge within the focal plane of the CAM are recognized microscopically, counted by two observers in a double-blind fashion under a Zeiss SR stereomicroscope, and photographed in ovo with the MC63 Camera system (Zeiss, Oberkochen, Germany). To better highlight vessels, the CAM are injected into a large allantoic vein with India ink solution, fixed in Serra's fluid, dehydrated in graded ethanols, and rendered transparent in methylbenzoate. On day 12, after microscopic counting, the embryos and their membranes are fixed in ovo in Bouin's fluid. The sponges and the underlying and immediately adjacent CAM portions are removed, embedded in paraffin, sectioned at 8 µm along a plane parallel to the CAM surface, and stained with a 0.5% aqueous solution of toluidine blue.

EVALUATION

Angiogenesis is measured by a planimetric point count method (Ribatti et al. 1999): four to six 250× magnification fields covering almost the whole of every third section within 30 serial slides of each sponge per sample are analyzed within a superimposed 144 intersection point square reticulum of 0.125 mm^2. Only transversely sectioned microvessels, ie, capillaries and venules with or without a 3 to 10 µm lumen occupying the intersection points, are counted and calculated as the mean ±1 SD per section, per CAM, and groups of CAM. Statistical significance of differences is cal-

culated by comparing the data from each experiment to their controls using Student's *t*-test.

MODIFICATIONS OF THE METHOD

Oh et al. (1997) studied the lymphatics of differentiated avian chorioallantoic membrane using microinjection of Mercox resin, semi- and ultrathin sectioning, immunohistochemical detection of fibronectin and α-smooth muscle actin, and *in situ* hybridization with vascular endothelial growth factor VEGFR-2 and VEGFR-3 probes.

A.8.3.4 Cornea neovascularization

PURPOSE AND RATIONALE

Neovascularization of the rabbit cornea has been used by several authors to study inhibition of angiogenesis (Gimbrone et al. 1974; Crum et al. 1985; BenEzra et al. 1987, 1997; Klauber et al. 1996; McNatt et al. 1999; Joussen et al. 1999).

PROCEDURE

New Zealand White rabbits are anesthetized for surgery and quantification of newly developed blood vessels with 5 mg/kg xylazine hydrochloride and 35 mg/kg ketamine hydrochloride i.m. Corneal blood vessels are induced by basic fibroblast growth factor which is applied in carrier pellets. These pellets are produced by dispersing 50 µl of 2% methylcellulose containing 500 ng human recombinant basic fibroblast growth factor diluted in 10 µl phosphate-buffered saline in plastic rods with a diameter of 4 mm. Dried pellets are folded twice and implanted intrastromally in the 12 o'clock position into a corneal tunnel. This tunnel is created by a central cut of approximately 50% depth and extended into the peripheral cornea to a point 2.0 mm away from the limbus. Following implantation, the central entrance of the tunnel is closed with a single 10-0 nylon suture in order to ensure that the tear film does not dissolve the pellet and uncontrolled liberation of the growth factor is prevented.

The test substance is dissolved in a viscous gel containing 0.002% polyacrylic acid, 0.04% sorbitol, and 0.001% cetrimide in a watery base. The eyes are treated once daily with 0.1 ml of this gel which is applied in the lower conjunctiva sac. The eyes are closed for sev-

eral seconds to avoid loss of the substance. Each animal's contralateral eye receives gel without test substance and serves as control. Control animals receive the viscous gel without test substance.

Animals are observed daily under an operating microscope, and vascular growth is documented on days 6, 9, 12, and 16 after surgery. The number of blood vessels, their length and the dimension of the vascularized area are quantified with a caliper under the operating microscope as well as on standardized photographs. On every observation day corneas are stained with fluorescein in order to show epithelial irregularities due to the topical treatment.

EVALUATION

Differences between treated eyes and controls are tested for significance using unpaired Student's *t*-test.

MODIFICATIONS OF THE METHOD

Damms et al. (1997) characterized the neovascularization that follows the intracorneal injection of bovine albumin in rabbits as a model of angiogenesis. New Zealand white rabbits received intracorneal injections of phosphate buffered saline with and without various amounts of bovine albumin. The rabbits were co-sensitized or pre-sensitized by intramuscular bovine albumin. The corneal response was quantified by ranking photographs taken periodically after the injection.

Babic et al. (1998) tested an angiogenesis promotor in the corneal pocket angiogenesis assay in **rats**.

Xin et al. (1999) studied inhibitors of angiogenesis in the corneal angiogenesis assay in rats. A 1.5 mm incision was made approximately 1 mm from the center of the cornea in anesthetized Sprague Dawley rats. Using a curved spatula, the incision was bluntly dissected through the stroma toward the outer canthus of the eye. A hydron pellet (2×20 mm) containing 200 ng vascular endothelial growth factor and 100 ng sucralfrate was inserted into the base of the pocket.

Foschi et al. (1994), Benelli et al. (1995), Danesi et al. (1997) studied neovascularization of rat cornea induced by **chemical injury**. Both eyes of ether-anesthetized rats were cauterized by applying a $AgNO_3$/KNO_3 (1:1, w/w) applicator to the surface of the cornea eccentrically at a point approximately 2 mm from the corneoscleral limbus. Rats were treated 4 times daily for 6 days with eye drops. The eyes were examined by slit-lamp microscopy daily for 6 days to the evaluate the growth of the vessels. On the 6^{th} day after cauterization, the rats were anesthetized and the upper body perfused through a cannula inserted in the ascending aorta with Ringer's solution until the normal pink color of the fundi disappeared and then with a mixture of 10% India ink/6% gelatin in Ringer's solution. The eyes were enucleated and placed in 4% formaldehyde. The cornea and a 1 mm rim of adjacent scleral tissue were dissected from the rest of the globe and three full thickness peripheral radial cuts were made to allow flattening of the cornea. The corneas were then placed on a glass slide in mounting media, magnified, and photographed. The area occupied by blood vessels was calculated and the area vascularization of drug treated animals was compared to that of control rats.

Kenyon et al. (1996), Cao et al. (1999) performed the corneal micropocket assay in **mice**.

A.8.3.5 Rat subcutaneous air sac model

PURPOSE AND RATIONALE

Lichtenberg et al. (1997, 1999) recommended the subcutaneous air sac model in rats as a simple method for *in vivo* screening of antiangiogenesis. Subcutaneous injection of air in the rat results in the formation of an air pouch. If air pouches are kept inflated by repeated injections of air the develop a structure of synovial lining (Edwards et al. 1981). The subcutaneous air pouch appears more like a bursal cavity than a synovial joint (Kowanko et al. 1986) and after 8–10 days the cells of the air sac appear as a transparent membrane on which the formation of new vessels can be studied.

PROCEDURE

Under anesthesia 10–15 ml of air is introduced dorsally to female Sprague Dawley rats weighing 150–180 g by subcutaneous injections using a 25 gauge needle to produce an air sac located approximately 4–5 cm behind the head of the animal. The air sacs are re-inflated every forth day. The wall of the air sac becomes progressively thicker with time and after approximately 10 days a sufficient lining of cells has been established. For sponge implantation, the animals are anesthetized again. A 1.5 cm incision is made through the clipped skin covering the air sac and blunt dissection is used to open a 2 cm deep cavity towards the cranial base of the air sac by careful separation of the skin from the membrane. A cellulose implant (Spontex® sponge) with a diameter of 8 mm is carefully pressed into the cavity of the membrane away from the incision site and the incision closed by sutures. The animals are treated for 10 days with various doses of test compound in a volume of 10 ml/kg or vehicle. The subcutaneous injection is made under light CO_2/O_2 anesthesia into the hind leg 5–7 cm away from the air sac. This injection site is chosen to eliminate any risk of inducing irritative side-effects on the membrane. After 10 days treatment, the animals are sacrificed after having received 20 min before an injection of 1 μCi of ^{125}I-labelled immunoglobulin via the tail vein. The overlying skin of the air sac is removed to expose the transparent membrane. The extent of vascular proliferation is scored *in situ*:

1+: slight background vascularization;
2+: few new vessels reach the sponge;
3+: many new vessels reach and penetrate the implant;
4+: very intense formation of new vessels which reach and penetrate the implant.

Following *in situ* scoring, the implant and the membrane from each animal are placed in the same plastic vial containing 10% formalin and the radioactivity is measured in a γ-counter. The implants are examined microscopically after staining with haematoxylin and eosin.

EVALUATION

The extent of vascular proliferation scored *in situ* is compared between vehicle and treated animals by the Wilcoxon test. The angiogenic response measured by ^{125}I-activity in cpm is subjected to analysis of variance followed by Dunnett's *t*-test to compare each dose with the vehicle. The cpm's are log-transformed to obtain variance homogeneity. The correlation between *in situ* scores and cpm is estimated by Spearman's rank correlation coefficient after ranking cpm values.

MODIFICATIONS OF THE METHOD

In a further study, Lichtenberg et al. (1999) inoculated vascular endothelial growth factor producing tumor cells subcutaneously directly on the membrane, and the formation of vessels was measured 8 days later. Furthermore, slow-release pellets containing angiogenic factors, basic fibroblast growth factor or vascular endothelial growth factor, were implanted on the subcutaneous membrane.

Nakamura et al. (1999) studied suppression of angiogenesis induced by S-180 mouse tumor cells in the dorsal air sac assay in **mice**.

Funahashi et al. (1999) developed a mouse dorsal air sac model for quantifying *in vivo* tumor-induced angiogenesis which is determined by measuring the blood volume in an area of skin held in contact with a tumor cell-containing chamber, using ^{51}Cr-labeled red blood cells.

Schreiber et al. (1986) described the **hamster cheek pouch assay** for testing angiogenic/antiangiogenic activity.

A.8.3.6
Mesenteric window angiogenesis model

PURPOSE AND RATIONALE

Norrby et al. (1986, 1990, 1995) described the mesenteric window assay in rats for quantitative measurement of induction and inhibition of angiogenesis. The tissue being used is the membranous, 'window'-like parts of the mesentery which is normally vascularized and appears to lack significant physiologic angiogenesis. Since the mesenteric window natively measures only 5–10 μm in thickness, the vasculature is virtually two-dimensional. Due to the structural and metabolic simplicity of the test tissue, the mesenteric window microvasculature is regarded as an ideal test system for establishing the functional influences of defined factors (Zweifach 1973).

PROCEDURE

Angiogenesis is induced by i.p. injection of the mast-cell secretagogue compound 48/80 twice daily for 4.5 days to male Sprague Dawley rats weighing about 225 g. Test compounds or saline are injected s.c. 1 h before each injection of compound 48/80.

Angiogenesis is quantified by microscopically counting the number of vessel profiles per unit length of the mesenteric window in 4 microtome sections per specimen, cut perpendicularly to the surface, from the central part of the window. This reflects the degree of branching, the degree of tortuosity and the degree of spatial expansion of the vasculature. Four specimens per animal are analyzed.

Four mesenteric window specimens are spread, fixed on objective slides and stained with toluidine blue to measure the relative vascularized area. Three randomly selected vascular view fields per mesenteric-window spread are analyzed for microvascular length per unit area of vascularized tissue. The total microvascular length is computed from the vascularized area of each animal multiplied by the mean microvascular length for the corresponding treatment group.

EVALUATION

The non-parametric two-tailed Mann-Whitney U rank sum test for unpaired observations is used for statistical analysis.

B.1 *In vitro* tests

B.1.1 Blood coagulation tests

PURPOSE AND RATIONALE

The coagulation cascade consists of a complex network of interactions resulting in thrombin-mediated cleavage of fibrinogen to fibrin which is one major component of a thrombus. The coagulation cascade can be initiated either by the "exogenous pathway", the release of thromboplastin (tissue factor) leading to activation of factor VII to the tissue factor/factor VIIa complex, or by the "endogenous pathway", so-called contact activation leading via factors XII, XI and IX to the assembly of the tenase complex consisting of activated factors VIII and IX and Ca^{2+} on a phospholipid surface. Both complexes can activate factor X which induces the formation of the prothrombinase complex consisting of factor X_a, factor Va and Ca^{2+} on a phospholipid surface. The latter leads to the activation of thrombin which in turn cleaves fibrinogen to fibrin. The three coagulation tests (PT, APTT and TT) allow to differentiate between effects on the exogenous or endogenous pathway or on fibrin formation. The influence of compounds on the plasmatic blood coagulation is determined by measuring the coagulation parameters prothrombin time (PT), activated partial thromboplastin time (APTT) and thrombin time (TT) *ex vivo*.

PROCEDURE

Male Sprague-Dawley rats weighing 200–220 g receive the test compound or the vehicle (controls) by oral, intraperitoneal or intravenous administration. After the end of the absorption time, they are anesthetized by intravenous injection of 60 mg/kg sodium pentobarbital. The caudal caval vein is exposed by a mid-line incision and 1.8 ml blood are collected into a plastic syringe containing 0.2 ml 100 mM citrate buffer pH 4.5 (Behring Werke, Marburg). The sample is immediately agitated and centrifuged in a plastic tube at 1 500 *g* for 10 min. Plasma is transferred to another plastic tube and the coagulation tests for the determination of thrombin time (TT), thromboplastin time (PT) and activated partial thromboplastin time (APTT) are performed within 3 h.

In general, citrated plasma is coagulated by the addition of the respective compounds (see below) and the time to clot formation is determined in the coagulometer (= coagulation time).

Prothrombin Time (PT). An aliquot of 0.1 ml of citrated plasma is incubated for 1 min at 37 °C. Then 0.2 ml of human thromboplastin (Thromborel®, Behring Werke, Marburg) is added and the coagulometer (Schnittger + Gross coagulometer, Amelung, Brake) is started. The time to clot formation is determined. The PT measures effects on the exogenous pathway of coagulation.

Activated Partial Thromboplastin Time (APTT). To 0.1 ml of citrated plasma 0.1 ml of human placenta lipid extract (Pathrombin®, Behring Werke, Marburg) is added and the mixture is incubated for 2 min at 37 °C. The coagulation process is initiated by the addition of 0.1 ml 25 mM calcium chloride when the coagulometer is started and the time to clot formation is determined. The APTT measures effects on the endogenous pathway of coagulation.

Thrombin Time (TT). To 0.1 ml of citrated plasma 0.1 ml of diethylbarbiturate-citrate buffer, pH 7.6 (Behring Werke Marburg) is added and the mixture is incubated for 1 min at 37 °C. Then 0.1 ml of bovine test-thrombin (30 IU/ml, Behring Werke Marburg) is added and the coagulometer is started. The time to clot formation is determined. The TT measures effects on fibrin formation.

EVALUATION

Mean values of TT, PT and PTT are calculated in dosage groups and vehicle controls. Statistical evaluation is performed by means of the unpaired Student's *t*-test.

B.1.2 Thrombelastography

PURPOSE AND RATIONALE

Thrombelastography (TEG) was developed first by Hartert (1948). The thrombelastograph (Haemoscope Corp., Skokie, Illinois, USA) is a device that provides a continuous recording of the process of blood coagulation and subsequent clot retraction. The blood samples are transferred to cuvettes and maintained at 37 °C. The cuvettes are set in motion around their vertical axes. Originally, a torsion-wire suspended mirror in the plasma remains immobile as long as the plasma is fluid. The cuvette and the mirror become dynamically related as fibrin forms, resulting in transmission of cuvette motion to the mirror. The mirror then oscillates with an amplitude governed by the specific mechanical properties of the clot and reflects its light to a thermopaper. The modern thrombelastograph transfers the analogous recording to a digital signal which is evaluated by a computer program.

PROCEDURE

Thrombelastography can be performed in either whole blood, or in citrated platelet rich or platelet poor plasma after recalcification. Blood samples are obtained from Beagle dogs, weighing 12–20 kg, from rabbits, weighing 1.7–2.5 kg or from Wistar rats weighing 150–300 g or from humans. The test subjects receive the compound by intravenous, subcutaneous or by oral administration. Ten or 20 min post dosing (i.v., s.c. ad-ministration) or 60, 90 or 180 min post dosing (oral administration) blood is collected. The blood samples are mixed with 3.8% trisodium citrate solution (one part citrate solution to 9 parts blood) as anticoaglant. The citrated whole blood is recalcified by adding 0.4 ml isotonic calcium chloride solution. An aliquot of 0.36 ml of the re-calcified whole blood is transferred to the pre-warmed cup of the thrombelastograph.After the apparatus has been correctly adjusted and the samples sealed with liquid paraffin to prevent drying, the time for the whole procedure is noted. The thrombelastogram is recorded for 2 h.

CRITICAL ASSESSMENT OF THE METHOD

Zuckerman et al. (1981) compared thrombelastography with other common coagulation tests (fibrinogen, prothrombin time, activated thromboplastin time, platelet count and fibrin split products) and found that there is a strong relationship between the thrombelastographic variables and these common laboratory tests. Moreover, TEG has an increased sensitivity for detecting blood clotting anomalies, it contains additional information on the hemostatic process. This is due to (1) the fact that most laboratory measurements end with the formation of the first fibrin strands while TEG measures the coagulation process on whole blood from initiation of clotting to the final stages of clot lysis and retraction, (2) the possibility of TEG to use whole non-anticoagulated blood without influence of citrate or other anticoagulants.

EVALUATION

The following measurements are the standard variables of TEG:

- **Reaction time (*r*):** the time from sample placement in the cup until onset of clotting (defined as amplitude of 1 mm). This represents the rate of initial fibrin formation.
- **Clot formation time (*k*):** the difference from the 1 mm *r* to 20 mm amplitude. *k* represents the time taken for a fixed degree of viscoelasticity achieved by the forming clot, caused by fibrin build up and cross linking.
- **Alpha angle (α°):** angle formed by the slope of the TEG tracing from the *r* to *k* value. It denotes speed at which solid clot forms.
- **Maximum amplitude (*MA*):** greatest amplitude on the TEG trace. *MA* represents the absolute strength of the fibrin clot and is a direct function of the maximum dynamic strength of fibrin and platelets.
- **Clot strength (*G* in dynes per square centimeter):** defined by $G = (5\,000\,MA) / (96 - MA)$. In a tissue factor-modified TEG (Khurana et al. 1997), clot strength is clearly a function of platelet concentration.
- **Lysis 30, Lysis 60 (*Ly30*, *Ly60*):** Reduction of amplitude relative to maximum amplitude at 30 and 60 min after time of maximum amplitude. These parameters represent the influence of clot retraction and fibrinolysis.

MODIFICATIONS OF THE METHOD

Bhargava et al. (1980) compared the anticoagulant effect of a new potent heparin preparation with a commercially available heparin by thrombelastography *in vitro* using citrated dog and human blood. Barabas et al. (1993) used fibrin plate assay and thrombelastography to assess the antifibrinolytic effects of synthetic thrombin inhibitors. Scherer et al. (1995) described a short-time, endotoxin-induced rabbit model of hypercoagulability for the study of the coagulation cascade and the therapeutic effects of coagulation inhibitors using various parameters including thrombelastography.

Khurana et al. (1997) introduced tissue factor-modified TEG to study platelet glycoprotein IIb/IIIa function and to establish a quantitative assay of platelet function. With this modification, Mousa et al. (2000) found two classes of glycoprotein IIb/IIIa antagonists, one with high binding affinity for resting and activated platelets and slow platelet dissociation rates (class I) demonstrating potent inhibition of platelet function, in contrast to those with fast platelet dissociation rates (class II).

B.1.3 Chandler loop

PURPOSE AND RATIONALE

The Chandler loop technique allows to produce *in vitro* thrombi in a moving column of blood (Chandler 1958). The thrombi generated in the Chandler device show morphology very similar to human thrombi formed *in vivo* (Robbie et al. 1997) with platelet-rich upstream sections ("white heads") that are relatively resistant to t-PA-mediated thrombolysis in contrast to the red blood-cell-rich downstream parts ("red tails") (Stringer et al. 1994).

PROCEDURE

One millimeter of non-anticoagulated whole blood is drawn directly into a polyvinyl tube with a length of 25 cm and an internal diameter of 0.375 cm (1 mm = 9.9 cm tubing). The two ends of the tube are then brought together and closed by an outside plastic collar. The circular tube is placed and centered on a turntable, tilted to an angle of 23 degrees, and rotated at 17 rpm. At the moment the developing thrombus inside the tube becomes large enough to occlude the lumen, the blood column becomes static and moves around in the direction of rotation of the tube.

EVALUATION

Time to occlusion of the tube by the thrombus establishes a definite end point in this system.

MODIFICATIONS OF THE METHOD

Stringer et al. (1994) used this method to determine the influence of an anti-PAI-1 antibody (CLB-2C8) on the t-PA induced lysis of Chandler thrombi *in vitro*. They used citrated blood and supplemented it with 5.8 µM [^{125}I]-labelled fibrinogen prior to recalcification. After generation in the Chandler loop, the thrombi were washed with isotonic saline and then cut transversally into an upstream (head) and a downstream part (tail). The radioactivity of both parts was determined in a gamma counter (pre-value). The head and the tail were then subjected to thrombolysis by adding 300 µl phosphate-buffered saline containing plasminogen (2 µM) and t-PA (0.9 nM). During the observation time of 240 min aliquots of 10 µl were taken at 30, 60, 120, 180 and 240 min, and the radioactivity was determined. The relation of the measured radioactivity to the pre-value was expressed as percentage of clot lysis.

Van Giezen et al. (1998) used this method to differentiate the effect of an anti-PAI-1 polyclonal antibody (PRAP-1) on human or rat thrombi.

B.1.4 Platelet aggregation and deaggregation in platelet rich plasma or washed platelets (BORN method)

PURPOSE AND RATIONALE

Platelets play a crucial role in primary hemostasis by forming hemostatic plugs at sites of vascular injury. Moreover, they contribute to intravascular thrombus formation mostly upon rupture of an atherosclerotic plaque. The contact of unactivated platelets to exposed subendothelial tissue leads to adhesion via two main mechanisms: binding of subendothelial von Willebrand factor (vWF) to the platelet GPIb-IX-V-complex at high shear rates and binding of collagen to two receptors, integrin $\alpha 2\beta 1$ and GPVI. Platelet adhesion initiates the reactions of shape change, secretion, and activation of GPIIb-IIIa-ligand binding sites. These reactions result in the formation of platelet aggregates. Activation of GPIIb-IIIa is also achieved through signaling by a number of agonists that bind to G-protein-coupled receptors. Consequently, for the measurement of platelet aggregation platelets are activated by the addition of one of the following agonists to platelet rich plasma (PRP) or washed platelets: ADP, arachidonic acid (forming thromboxane A2) or U 46619, collagen, thrombin or TRAP, serotonin, epinephrine, PAF. The formation of platelet aggregates with stirring leads to changes in optical density which are monitored photometrically usually for 4 min The test has been developed originally by Born (1962) and is used to evaluate quantitatively the effect of compounds on induced platelet aggregation *in vitro* or *ex vivo*. For *in vitro* studies, human PRP is preferred.

PROCEDURE

Materials and solutions

Anticoagulating substances:		
hirudin (Sigma)	200	µg/ml
trisodium citrate	0.11	M
ACD solution		
citric acid	38	mM
sodium citrate	75	mM
glucose	124	mM
Platelet aggregating substances: (final concentrations in the test)		
ADP: for reversible or biphasic aggregation	0.1–5	µM
ADP: for irreversible aggregation (Sigma)	3–6	µM
Sodium arachidonate (Biodata)	0.33	mM
Calcium ionophore A 23187 (Calbiochem)	10	µM
Collagen (Hormonchemie)	3	µg/ml
PAF-acether (C 16-PAF, Bachem)	0.1	µM
Thrombin (Sigma)	0.02–0.05	IU/ml
TRAP (SFLLRNP, Bachem)	10	µM
U 46619 (ICN)	1	µM
Ristocetin	1	mg/ml
GPRP (fibrin antipolymerant, Bachem)	0.5	mM
4-channel aggregometer (PAP 4, Bio Data)		

The test is carried out either *ex vivo* or *in vitro*.

For *ex vivo*-assays, mice, rats, or guinea pigs from either sex receive the test compound or the vehicle (for controls) by oral, intraperitoneal or intravenous administration. At the end of the absorption time, blood is collected by caval vein-puncture under pentobarbital sodium anesthesia and xylazine (8 mg/kg i.m.) premedication.

From rabbits (Chinchilla strain, weighing 3 kg), blood is withdrawn by cardiopuncture under xylazine (20 mg/kg i.m.) sedation. The first blood sample (control) is collected before administration of the test compound, the second sample at the end of the absorption time of the test agent.

For *in vitro*-assays, human blood is collected from the antecubital vein of adult volunteers, who had not received any medication for the last two weeks.

Preparation of PRP, PPP, and WP

The entire procedure is performed in plastic (polystyrene) tubes and carried out at room temperature. Freshly collected venous blood is anticoagulated with hirudin (1 volume + 9 volumes of animal blood) or ACD solution (1 volume + 9 volumes of human blood) and centrifuged at 170 *g* for 15 min to obtain platelet rich plasma (PRP). The PRP-supernatant is carefully removed, and the rest is further centrifuged at 1 500 *g* for 10 min to obtain platelet poor plasma (PPP). PRP is diluted with PPP to a platelet count of 3×10^8/ml before use in the aggregation assays. To obtain washed platelets (WP), 8.5 volumes of human blood are collected into 1.5 volumes of ACD and centrifuged as for PRP. PRP is acidified to a pH of 6.5 by addition of approximately 1 ml ACD to 10 ml PRP. Acidified PRP is centrifuged for 20 min at 430 *g*. The pellet is resuspended in the original volume with Tyrode's solution (mM: NaCl 120, KCl 2.6, $NaHCO_3$ 12, NaH_2PO_4 0.39, HEPES 10, glucose 5.5; albumin 0.35%) and set to platelet count of 3×10^8/ml.

EXPERIMENTAL COURSE

Studies should be completed within 3 h after blood withdrawal.

For *ex vivo*-assays, duplicate samples of 320 µl PRP from drug-treated and vehicle control subjects (for rabbits: control samples before drug administration) are inserted into the aggregometer at 37 °C under continuous magnetic stirring at 1 000 rpm. After the addition of 40 µl physiological saline and 40 µl aggregating agent, changes in optical density are monitored continuously at 697 nm.

For *in vitro*-assays, 40 µl of the test solution are added to samples of 320 µl PRP or WP from untreated subjects. The samples are inserted into the aggregometer and incubated at 37 °C for 2 min under continuous magnetic stirring at 1 000 rpm. After the addition of 40 µl aggregating agent, changes in optical density are monitored continuously at 697 nm either for 4 min or until constant values for aggregation are achieved. In cases of thrombin activation of PRP, GPRP is added in order to avoid fibrin formation.

In order to measure deaggregation, experimental compounds are added to stimulated PRP at 70 or 100% of control aggregation and monitoring is performed for further 10 min. Deaggregation is measured by the decrease of light transmission (see Haskel et al. 1989).

EVALUATION

The transmission maximum serves as a scale for platelet aggregation (0% = transmission of PRP, 100% = transmission of PPP).

For *in vitro*-assays:

1. Percent inhibition of platelet aggregation is determined in concentration groups relative to vehicle controls.

Statistical significance is evaluated by means of the unpaired Student's *t*-test.

2. IC_{50} values are determined from the non-linear curve fitting of concentration-effect relationships. IC_{50} is defined as the concentration of test drug for half maximal inhibition of aggregation.
3. Percent deaggregation is determined at 10 min after addition of compound; IC_{50} is calculated from the concentration-effect relationship.

For *ex vivo*-assays:

1. Mean values for aggregation in dosage groups are compared to the vehicle control groups (for rabbits: control values before drug administration).
   Statistical significance is evaluated by means of the Student's *t*-test (paired for rabbits; unpaired for others).
2. ED_{50} values are determined from the dose-response curves. ED_{50} is defined as the dose of drug leading to 50% inhibition of aggregation in the animals.

CRITICAL ASSESSMENT OF THE METHOD

The assay, introduced by Born (1962), has become a standard method in clinical diagnosis of platelet function disorders and of aspirin-intake. Furthermore, the method is used in the discovery of antiplatelet drugs with the advantage of rapid measurement of a functional parameter in intact human platelets

MODIFICATIONS OF THE METHOD

Several authors described modifications of the assay procedure. Breddin (1975) described spontaneous aggregation of platelets from vascular patients in a rotating cuvette. Klose et al. (1975) measured platelet aggregation under laminar flow conditions using a thermostated cone-plate streaming chamber in which shear rates are continuously augmented and platelet aggregation is measured from light transmission through a transilluminating system. Marguerie et al. (1979, 1980) developed a method measuring two phases of platelet aggregation after gel filtration of a platelet suspension (see below). Lumley and Humphrey (1981) described a method to measure platelet aggregation in whole blood (see below). Fratantoni et al. (1990) performed aggregation measurements using a microtiter plate reader with specific modification of the agitation of samples. Comparison of the 96well microtiterplate method with conventional aggregometry showed similar dose-response curves for thrombin, ADP, and arachidonic acid.

Ammit and O'Neil (1991) used a quantitative bioassay of platelet aggregation for rapid and selective measurement of platelet-activating factor.

B.1.5 Platelet aggregation after gel filtration

PURPOSE AND RATIONALE

Triggering of platelet activation by low concentrations of ADP, epinephrine or serotonin – so-called weak platelet agonists – in plasma- and fibrinogen-free platelet suspensions does not result in platelet aggregation unless exogenous fibrinogen is added. As opposed to this, platelet aggregation induced by thrombin, collagen or prostaglandin-endoperoxide – so-called strong agonists – is independent of exogenous fibrinogen because these substances lead to the secretion of intracellular platelet ADP and fibrinogen. Studies of platelet aggregation in gel-filtered platelets are performed in cases where the adhesive ligand fibrinogen or vWF is needed in a defined concentration or where plasma proteins could negatively interfere with the effect of compounds. The assay is mostly used to evaluate the influence of compounds on platelet GPIIb-IIIa or other integrins or on GPIb-IX-V.

PROCEDURE

Materials and solutions

Acid-citrate-dextrose (ACD) solution:		
citric acid	0.8	%
sodium citrate	2.2	%
glucose	2.45	%
hirudin	0.6	U/ml
Tyrode's solution:		
NaCl	137	mM
KCl	2.7	mM
$MgCl_2$	5.5	mM
NaH_2PO_4	3.0	mM
HEPES	3.5	mM
glucose	5.5	mM
albumin	0.2	%
hirudin	0.06	U/ml
apyrase	40	µg/ml
pH	7.2	
Epinephrine (different concentrations; µM range)		
ADP	10	µM
Thrombin	0.02–0.05	U/ml
$CaCl_2$	0.5	mM
Fibrinogen (American Diagnostica)	1	mg/ml
von Willebrand factor	10	µg/ml
Sepharose CL 2B (Pharmacia)		
Acrylic glass column (Reichelt Chemietechnik, 3 cm inner diameter, 18 cm length)		
Aggregometer (PAP 4, Biodata)		

Preparation of gel filtered platelets

The entire procedure is performed in plastic (polystyrene) tubes at room temperature according to Marguerie et al.(1979).

Blood is drawn from healthy adult volunteers, who had no medication for the last two weeks. Venous blood (8.4 ml) is collected into 1.4 ml ACD-solution and centrifuged for 10 min at 120 *g*. The platelet rich plasma (PRP) is carefully removed, the pH adjusted to 6.5 with ACD-solution and centrifuged at 285 *g* for 20 min. The resulting pellet is resuspended in Tyrode's buffer (approx. 500 µl buffer/10 ml PRP). The platelet suspension is applied immediately to a Sepharose CL 2B column; equilibration and elution at 2 ml/min flow rate is done with Tyrode's buffer without hirudin and apyrase. Platelets are recovered in the void volume. Final platelet suspension is adjusted to 4×10^8/ml. Gel filtered platelets (GFP) are kept at room temperature for 1 h until the test is started.

Experimental course

For the aggregation studies, GFP in Tyrode's buffer is incubated with $CaCl_2$ (final concentration 0.5 mM) with or without fibrinogen (final conc. 1 mg/ml) in polystyrene tubes. After 1 min, 20 µl of the test compound or the vehicle (controls) are added and the samples are incubated for another 2 min. After the addition of 20 µl platelet agonist, changes in light transmission are recorded. The whole procedure is done under continuous magnetic stirring at 37 °C (1 000 rpm) in the aggregometer. Samples with added $CaCl_2$ but without fibrinogen identify proper exclusion of plasma proteins if neither spontaneous aggregation occurs nor aggregation in the presence of weak agonists. Full aggregatory response of GFP to 10 µM ADP shows intact platelets (with only minor pre-activation with gel-filtration).

EVALUATION

The transmission maximum serves as a scale for platelet aggregation. Each test compound is assayed with at least two different donor-GFP's; in the case of an anti-aggregating effect, the test is performed with 4–6 GFP's.

Mean values of the dosage groups are compared to the controls. Statistical significance is evaluated by means of the Student' *t*-test.

The percent inhibition of platelet aggregation in the dos-age groups is calculated relative to the vehicle controls.

IC_{50} values (50% inhibition of aggregation) are determined from the concentration-effect curves.

B.1.6 Platelet aggregation in whole blood

PURPOSE AND RATIONALE

The method uses a whole blood platelet counter which counts single platelets and does not require their separation from other blood cell types. Platelet aggregation is induced in anti-coagulated human whole blood samples by the addition of the aggregating agents arachidonic acid or collagen. The number of platelets is determined in drug-treated and vehicle control samples; the percentage of inhibition of aggregation and IC_{50} values are calculated in dosage groups. The effect of compounds on other blood cells which secondarily can influence platelet aggregation is included in this test system. The method has been described by Lumley et al. (1981).

PROCEDURE

Materials and solutions

Anticoagulant: sodium citrate to induce platelet aggregation	3.8	%
Sodium arachidonate (Biodata)	3.6×10^{-4}	M
Collagen (Hormonchemie)	10	µg/ml
Serono Hematology System 9000 or Sysmex Micrcellcounter F 800		

The entire procedure is performed in plastic (polystyrene) tubes and carried out at room temperature. Blood is drawn from healthy adult volunteers, who had not received medication for the last 2 weeks. Nine ml venous blood are anti-coagulated with 1 ml of sodium citrate and kept in a closed tube at room temperature for 30–60 min until the start of the test.

For the aggregation studies, 10 µl test substance or vehicle (controls) are added to 480 µl citrated blood. Samples in closed tubes are pre-incubated for 5 min in a 37°C water shaker bath at 75 strokes/min. Ten µl aggregating agent are added and samples are incubated for another 10 min. The number of platelets (platelet count) is determined in 10 µl samples immediately before and 10 min after the addition of the aggregating agent ('initial platelet count', '10-min-platelet count') in a hematology cell counter.

The following samples for the determination of the platelet count are prepared in duplicate:

- control aggregation = spontaneous aggregation (without aggregating agent):
  480 µl blood + 20 µl vehicle
  Blood samples with >20% spontaneous aggregation are not used to test for induced aggregation.
- maximal aggregation:
  480 µl blood + 10 µl vehicle + 10 µl aggregating agent
  Values represent the maximal induced aggregation rate of the blood sample.
- test substance aggregation:
  480 µl blood + 10 µl test substance
  + 10 µl aggregating agent

EVALUATION

1. From the samples for maximal aggregation (vehicle), the percentage of maximal aggregation is calculated according to the following formula:

$$\%\ \text{maximal aggregation} = 100 - \frac{\text{10-min-platelet count} \times 100}{\text{initial platelet count}}$$

This value for maximal aggregation is taken as 100%.

2. From the samples for test substance induced aggregation, the percentage of aggregation in dosage groups is calculated according to the following formula:

$$\%\ \text{aggregation} = \frac{\text{10-min-platelet count} \times 100}{\text{initial platelet count}}$$

3. IC_{50} values (50% inhibition of aggregation) are determined from the dose-response curves (log concentration test substance versus % inhibition of aggregation).

B.1.7 Euglobulin lysis time

PURPOSE AND RATIONALE

The euglobulin lysis time is used as an indicator for the influence of compounds on the fibrinolytic activity in rat blood. The euglobulin fraction of plasma is separated from inhibitors of fibrinolysis by acid precipitation and centrifugation. Euglobulin predominantly consists of plasmin, plasminogen, plasminogen activator and fibrinogen. By addition of thrombin to this fraction, fibrin clots are formed. The lysis time of these clots is determined as a measurement of the activity of activators of fibrinolysis (e.g. plasminogen activators). Thus, compounds can be detected which stimulate the release of tissue-type plasminogen activator from the vessel wall.

PROCEDURE

Rats are anesthetized by intraperitoneal injection of 60 mg/kg pentobarbital sodium and placed on a heating pad (37 °C). At the same time, the test solution or the vehicle (controls) is administered intravenously or intra-peritoneally. Twenty-five min later, the animals receive another intraperitoneal injection of 12 mg/kg sodium pentobarbital to keep them in deep narcosis for 45 min.

Plasma preparation

After the test compound is absorbed, blood is withdrawn from the inferior caval vein exposed by a midline excision. Blood (1.8 ml) is removed with a plastic syringe containing 0.2 ml 3.8% sodium citrate solution. The sample is thoroughly mixed, transferred to a plastic tube and immediately immersed in ice. Plasma is prepared by centrifugation at 2 000 *g* for 10 min at 2 °C.

Euglobulin preparation

A 0.5 ml portion of plasma is added to 9.5 ml of ice-cold distilled water; the pH is brought to 5.3 by the addition of 0.13 ml of 1% acetic acid. The diluted plasma is kept on ice for 10 min and the precipitated euglobulin fraction is collected by centrifugation at 2 000 *g* for 10 min at 2 °C. The supernatant is discharged and the remaining fluid is removed by drying the tube on a filter paper for 1 min. The euglobulin precipitate is dissolved in 1 ml of 0.12 M sodium acetate solution.

Euglobulin lysis assay

Aliquots (0.45 ml) of the euglobulin solution are transferred to test tubes, and 0.05 ml thrombin (Test Thrombin, Behring Werke) (25 U/ml) are added. The tubes are transferred to a water bath at 37 °C. The time interval between the addition of thrombin and the complete lysis of the clots is measured.

EVALUATION

The lysis time [min] is determined. ELT is shortened when activators of fibrinolysis are increased.

Percent lysis time is calculated in dosage groups as compared to controls.

Statistical evaluation is performed by means of the Student's *t*-test.

B.1.8 Fibrinogen receptor binding[2]

PURPOSE AND RATIONALE

The assay is used to evaluate the binding characteristics of drugs at the fibrinogen receptor. A constant concentration of the radioligand ^{125}I-fibrinogen (30–50 nM) is incubated with increasing concentrations of a non-labeled test drug (0.1 nM–1 mM) in the presence of gel-filtered human platelets. If the test drug exhibits any affinity to fibrinogen receptors, it is able to compete with the radioligand for receptor binding sites. Thus, the lower the concentration range of the test drug, in which the competition reaction occurs, the more potent the test drug is.

Platelets are activated with 10 mmol/l ADP to stimulate the ^{125}I-fibrinogen binding at the glycoprotein IIb-IIIa receptor.

[2] Contribution in the first edition by B. Jablonka.

PROCEDURE

Preparation of gel-filtered platelets

From a healthy volunteer 200 ml blood is collected. An aliquot of 8.4 ml blood is mixed with 1.4 ml ACD-buffer in polystyrol tubes and centrifuged at 1 000 rpm for 15 min. The resulting platelet rich plasma (PRP) is collected and an aliquot is taken for platelet counting. Ten ml PRP are mixed with 1 ml ACD-buffer (ACD-PRP, pH ~ 6.5); 5 ml portions of ACD-PRP are transferred to plastic tubes and centrifuged at 1 600 rpm for 20 min. The resulting supernatant is decanted, and each pellet is resuspended in 500 µl Tyrode buffer C. An aliquot is taken for platelet counting to calculate the loss of platelets. The platelet suspension is then transferred to the Sepharose-packed column which has been eluated with approx. 100 ml degassed Tyrode buffer B (2 ml/min). The column is closed and eluated with degassed Tyrode buffer B (2 ml/min). The first platelets appear after 18–20 min and are then collected for 10 min in a closed plastic cup. Gel-filtered platelets (GFP) are set to 4×10^8 platelets/ml with Tyrode buffer B and kept at room temperature until the start of the test.

Experimental course

For each concentration, samples are tested in triplicate (test tubes No. 72708, Sarstedt).The total volume of each incubation sample is 500 µl. The concentration of ^{125}I-fibrinogen is constant for all samples (10 µg/500 µl).

Competition experiments

The competition reaction is characterized by one buffer value (bidistilled water) and various concentrations of non-labeled fibrinogen or test compound.

- 100 µl ^{125}I-fibrinogen
- 100 µl non-labeled fibrinogen or test drug (various concentrations, 10^{-10}–10^{-3} M)
- 50 µl ADP

Non-specific-binding: The non-specific binding of ^{125}I-fibrinogen is defined as the radioligand binding in the presence of 10^{-5} M of non-labeled fibrinogen.

The binding reaction is started by adding 250 µl GFP (4×10^8 platelets/ml). The samples are incubated for 30 min at room temperature. Subsequently, a 100 µl aliquot of the incubation sample is transferred to a microtainer tube containing 400 µl glucose solution. The tubes are centrifuged at 11 750 rpm for 2 min to separate ^{125}I-fibrinogen bound at the platelet glycoprotein IIb–IIIa receptor from free radio-ligand. The supernatant is carefully decanted and is allowed to run off for approx. 30 min. Radioactivity of the platelet pellets is counted for 1 min in a gamma counter with an efficiency of 65.3%.

EVALUATION

The quantity of the specific ^{125}I-fibrinogen binding results from the difference between the total and the non-specific binding.

Platelet glycoprotein IIb-IIIa receptor binding is given as fmol ^{125}I-fibrinogen/10^8 platelets or ^{125}I-fibrinogen molecules bound per platelet.

The dissociation constant (K_i) of the test drug is determined from the competition experiment of ^{125}I-fibrinogen versus non-labeled drug by a computer-supported analysis of the binding data.

$$K = \frac{K_D{}^{125}\mathrm{I} \times IC_{50}}{K_D{}^{125}\mathrm{I} + [^{125}\mathrm{I}]}$$

IC_{50} = concentration of the test drug, which displaces 50% of the specifically glyco-protein IIb-IIIa receptor bound ^{125}I-fibrinogen in the competition experiment.

$[^{125}\mathrm{I}]$ = concentration of ^{125}I-fibrinogen in the competition experiment.

$K_D{}^{125}\mathrm{I}$ = dissociation constant of ^{125}I-fibrinogen, determined from the saturation experiment.

The K_i-value of the test drug is the concentration, at which 50% of the fibrinogen receptors are occupied by the test drug.

B.1.9 PAF antagonism

PURPOSE AND RATIONALE

PAF-antagonism is studied *in vitro* and *in vivo* in the following models (see respective method described):

- platelet aggregation in platelet rich plasma or washed platelets (Sect. B.1.4)

- experimental thrombocytopenia and leucocytopenia (Sect. B.2.9)
- coronary thrombosis in dogs and pigs (Sect. B.2.1)
- bronchospasmolytic activity in anesthetized guinea pigs (Sect. D.2.2.1, D.2.2.2)

Compounds are characterized as PAF antagonists by selective inhibition of PAF-induced effects as compared to effects of other agonists in these models.

B.1.10 Flow behavior of erythrocytes

PURPOSE AND RATIONALE

The deformation of erythrocytes is an important rheological phenomenon in blood circulation. It allows the passage of normal red cells through capillaries with diameters smaller than that of the discoid cells and reduces the bulk viscosity of blood flowing in large vessels. In the following test, the initial flow of filtration is taken as a criterion for erythrocyte deformability. A prolonged time of filtration can be due to 2 basic pathologic phenomena: an increased rigidity of the individual red cells or an increased tendency of the cells to aggregate. To simulate decreased red blood cell deformability, the erythrocytes are artificially modified by one (or by the combination) of the following stress factors:

- addition of calcium ions (increase in erythrocyte rigidity)
- addition of lactic acid (decrease in pH value)
- addition of 350–400 mmol NaCl (hyperosmolarity)
- storing the sample for at least 4 h (cellular ageing, depletion of ADP)

The following procedure can be used to evaluate the effect of test compounds on the flow behavior of erythrocytes.

PROCEDURE

Apparatus

Erythrocyte filtrometer MF 4 (Fa. Myrenne, 52159 Roetgen, Germany)

Membrane filter (Nuclepore Corp.) pore diameter: 5–10 µm, pore density: 4×10^5 pores/cm^2.

Ex vivo

Blood is collected from Beagle dogs, weighing 12–20 kg, or from rabbits, weighing 1.2–2.5 kg, or from Wistar rats, weighing 150–300 g. The test subjects receive the test compound by oral, subcutaneous or intravenous administration 15, 60, 90 or 180 min before the withdrawal of blood.

In vitro

Following addition of the test compound, blood is incubated at 37 °C for 5 or 30 min.

Freshly collected venous blood is anticoagulated with K-EDTA. (1 mg/ml blood) or heparin (5 IU/ml heparin sodium) and centrifuged at 3 000 rpm for 7 min. The supernatant (plasma) and the buffy coat are removed and discarded. The packed erythrocytes are resuspended in autologous plasma containing 0.25% human albumin and the haematocrit value is fixed at 10%. The red blood cells are altered by one or several of the stress factors mentioned above.

A sample of 2 ml of the stressed suspension is applied to the filtrometer and the initial flow rate is determined. The filtration curve is plotted automatically.

EVALUATION

The cumulative volume of the filtered suspension is recorded per time unit (10 min)

The slope of the curve is determined at different time intervals.

The initial flow rate (10% of the cell suspension having passed the filter) is recorded.

Statistics:
Data of each set are first tested for normal distribution using the Kolmogoroff/Smirnow test. The normal distribution hypothesis is eliminated if the data having a significance level of 5% are not normally distributed. In case that both data sets to be compared are normally distributed the F-test is applied. The hypothesis of homogeneity of variance of both test series is eliminated when the significance level for homogeneity of variance is 5%. The *t*-test for paired and non-paired data is performed when homogeneity of variance is present. In any case, a paired difference test (for paired data) or the U-test (for non-paired data) is likewise carried out (paired of difference test = Wilcoxon test; U-test = Wilcoxon-Mann-Withney or Mann-Whitney test, respectively).

B.1.11 Filterability of erythrocytes

PURPOSE AND RATIONALE

The Single Erythrocyte Rigidometer (SER) allows the measurement of deformability of individual red blood cells by determining their passage time through a pore under constant shear stress. In this test, the passage times of single erythrocytes through one pore in a syn-

thetic membrane are determined. The pore in the membrane practically represents a capillary with defined diameter and length. The driving pressure is produced by the constant shear stress. The passage of the red blood cells is measured with the help of an electrical device. A constant current of 50–200 nA is applied. When an erythrocyte passes through the pore the current is interrupted. The test is used to detect compounds that improve filterability of erythrocytes. To simulate decreased red blood cell deformability, the erythrocytes are artificially modified either by one or by a combination of the following stress factors:

- addition of calcium ions (increase in erythrocyte rigidity)
- addition of lactic acid (decrease in pH value)
- addition of 350–400 mmol NaCl (hyperosmolarity)
- storing the sample for at least 4 h (cellular ageing, depletion of ADP)

PROCEDURE

Apparatus

Single erythrocyte rigidometer (Myrenne, 52159 Roetgen, Germany)

Data:
driving pressure: $dp = 70$ Pa (dog, rabbit, rat),
$dp = 100$ Pa (man),
wall shear stress: $\tau = 3$ Pa

Single pore membrane:
length: 30 µm
diameter: 3.5 µm (rat)
4.0 µm (rabbit, dog)
4.5 µm (man)

Ex vivo

Blood is collected from Beagle dogs, weighing 12–20 kg, or from rabbits, weighing 1.2–2.5 kg, or from Wistar rats, weighing 150–300 g, or from man. The test subjects receive the test compound by oral, subcutaneous or intravenous administration 15, 60, 90 or 180 min before the withdrawal of blood.

In vitro

Following addition of the test compound, the blood samples are incubated at 37ºC for 5 or 30 min.

The blood samples are mixed with K-EDTA (1 mg/ml blood) or heparin (5 IE/ml heparin sodium) to prevent clotting. The blood is centrifuged at 3 000 rpm for 7 min. The plasma and the buffy coat are removed and discarded. The packed erythrocytes are resuspended in filtrated HEPES-buffer containing 0.25% human albumin and the haematocrit value is fixed to < 1%. The red blood cells are altered by one or several stress factors mentioned above. A sample of 2 ml of the stressed suspension is applied to the measuring device and the passage time of a population of 250 erythrocytes (tm) is determined. Cells remaining in the pore for more than 100 ms (tm > 100 ms) lead to a rheological occlusion.

Untreated red blood cell suspensions serve as control.

EVALUATION

The mean passage time of 250 single erythrocytes and the number of rheological occlusions/250 erythrocytes is determined.

Statistics:
The statistical significance is evaluated according to the procedure described for flow behavior of erythrocytes described above.

B.1.12 Erythrocyte aggregation

PURPOSE AND RATIONALE

The aggregation of red blood cells into rouleaux and from rouleaux into 3-dimensional cell networks is a rheological parameter that decisively influences the flow behavior of blood especially in disturbed microcirculation. In the following procedure an apparatus (erythrocyte aggregometer) is used to measure erythrocyte aggregation. The transparent measuring chamber (cone/ plate configuration) is transilluminated by light of a defined wave length. The intensity of the transmitted light, which is modified by the aggregation process, is recorded. The method can be used to determine the effect of test compounds on erythrocyte aggregation.

PROCEDURE

Apparatus

Selective Erythrocyte Rigidometer (Fa. Myrenne, 52159 Roetgen, Germany)

Ex vivo

Blood is collected from Beagle dogs, weighing 12–20 kg, or from rabbits, weighing 1.2–2.5 kg, or from Wistar rats, weighing 150–300 g. The test subjects receive the test compound by oral, subcutaneous or intravenous administration 15, 60, 90 or 180 min before the withdrawal of blood.

In vitro

Following addition of the test compound, the blood sample is incubated at 37 °C for 5 or 30 min.

Blood is obtained from the test subjects by venipuncture and mixed with K-EDTA (1 mg/ml) or heparin (5 IU/ml heparin sodium) to prevent clotting. Erythrocyte aggregation is determined in whole blood of 40% haematocrit. A sample of 40 µl blood is transferred to the measuring device. The red cells are dispersed at a shear rate of 600/s. After 20 s, flow is switched to stasis and the extent of erythrocyte aggregation is determined photometrically.

EVALUATION

Statistics:

The statistical significance is evaluated according to the procedure described for flow behavior of erythrocytes described above.

B.1.13 Determination of plasma viscosity

PURPOSE AND RATIONALE

One of the principal methods for measuring viscosity is based on the rate of flow of a liquid through an orifice. In this test, a defined volume of plasma is transferred into a capillary viscometer and the efflux time required for the plasma to flow from the upper to the lower mark is measured. Using this procedure, the effect of test compounds on the viscosity of blood plasma can be determined. The test can be carried out either *ex vivo* or *in vitro:*

PROCEDURE

Ex vivo

Beagle dogs weighing 12–20 kg, or rabbits weighing 2.0–3.0 kg or Wistar rats weighing 150–300 of either sex are used as test animals. Likewise, the test procedure can be performed in man. The test subjects receive the test compound by oral, subcutaneous or intravenous administration 15, 60, 90 or 180 min before the withdrawal of blood.

In vitro

Following addition of the test compound, plasma (obtained as described below) is incubated at 37 °C for 5 or 30 min.

Freshly collected venous blood is anticoagulated with 1 mg/ ml blood K^+-EDTA or heparin sodium (5 IU/ml blood) and centrifuged at 3 000 rpm for 5 min. The supernatant (plasma) is removed and a sample of 0.9 ml plasma is transferred into a capillary viscometer (Coulter Harkness, Coulter Electr. LTD, England) provided with a glass capillary of 0.5 mm inside diameter. The temperature during measurement is 37 °C. The flow time t, required for the plasma to flow through the capillary is measured. Untreated plasma serves as control.

EVALUATION

The viscosity of each sample can be determined using the following formula:

$$\eta = K \times t \times \rho$$

η = viscosity of plasma
K = calibration constant of viscometer
t = flow time of 0.9 ml plasma
ρ = density of plasma

The change in viscosity relative to the control group is determined.

Statistical evaluation is carried out using the Student's t-test.

B.2 *In vivo* or *ex vivo* models

GENERAL CONSIDERATIONS

The general understanding of the pathophysiology of thrombosis is based on the observations of Virchow in 1856. He proposed three factors responsible for thrombogenesis: obstruction of blood flow, changes in the

properties of blood constituents (hypercoagulability), and vessel wall injury. Experimental models of thrombosis focus on one, two or all three factors of Virchow's triad. Therefore, they differ with respect to the prothrombotic challenge – either stenosis, stasis, vessel wall injury (mechanical, electrical, chemical, photochemical, Laser-light), insertion of foreign surface, or injection of a prothrombotic factor –, with respect to the vessel type, and with respect to the animal species. Roughly, two types of models can be differentiated (Didisheim 1972): (1) models in which thrombi are produced in veins by stasis and/or injection of a procoagulant factor resulting in fibrin rich "red" venous type thrombi. (2) models in which thrombi are produced in arteries by vessel wall injury and/or stenosis resulting in platelet rich "white" mural thrombi. But the differentiation is not strict because platelets and the coagulation system influence each other. Drugs preventing fibrin formation may well act in arterial models and vice versa. Thrombosis models are usually performed in healthy animals. The underlying chronic diseases in men, namely atherosclerosis or thrombophilias are not included in the models. Thus, any model is limited regarding its clinical relevance. The pharmacological effectiveness of a new antithrombotic drug should be studied in more than one animal model. Inspite of these limitations animal models predict clinical effectiveness of drugs for the treatment and prevention of thrombotic diseases fairly well. A list of such drugs is presented in a recent review by Leadleey et al. (2000).

Furthermore, the clinical usefulness of an antithrombotic drug is determined by its safety/efficacy ratio regarding the bleeding risk. Assessment of a parameter of the hemostatic system should therefore be included in the models if possible.

B.2.1 Stenosis- and mechanical injury-induced coronary thrombosis (Folts-model)

PURPOSE AND RATIONALE

Thrombosis in stenosed human coronary arteries is one of the most common thrombotic diseases leading to unstable angina, acute myocardial infarction or sudden death. Treatment with angioplasty, thrombolysis, or by-pass grafts can expose new thrombogenic surfaces and re-thrombosis may occur. The mechanisms responsible for this process include interactions of platelets with the damaged arterial wall and platelet aggregation.

In order to study new drugs for their antithrombotic potential in coronary arteries, Folts (1974) developed the model of periodic acute platelet thrombosis and cyclic flow reductions (CFR's) in stenosed canine coronary arteries. Uchida described a similar model in 1975. The model includes various aspects of unstable angina pectoris, i.e. critical stenosis, vascular damage, downstream vasospasm induced by vasoconstrictors released or generated by platelets. The cyclic variations in coronary blood flow are a result of acute platelet thrombi which may occlude the vessel but which either embolize spontaneously or can easily be embolized by shaking the constricting plastic cylinder. They are not a result of vasospasm (Folts 1982). Clinically, aspirin can reduce the morbidity and mortality of coronary thrombotic diseases but its effect is limited. Similarly, CFR's in the Folts model are abolished by aspirin but the effect can be reversed by increases in catecholamines and shear forces (Folts 1988). As part of an expert meeting on animal models of thrombosis, a review of the Folts model has been published (Folts 1991).

Five different protocols are described in the following section for the induction of coronary thrombosis.

Coronary thrombosis induced by stenosis

The described preparations are characterized by episodic, spontaneous decreases in coronary blood flow interrupted by restorations of blood flow. These alterations in coronary blood flow, called cyclic flow reductions (CFR), are associated with transient platelet aggregation at the site of the coronary constriction and abrupt increase in blood flow after embolization of platelet-rich thrombi.

Damage of the vessel wall is produced by shortly placing a hemostatic clamp on the coronary artery; a fixed amount of stenosis is produced by an externally applied obstructive plastic cylinder upon the damaged part of the vessel. In dogs, the stenosis is critical, i.e. the reactive hyperemic response to a 10 second-occlusion is abolished (protocol 1); in pigs, the stenosis is subcritical, i.e. there is a partial reactive hyperemia left (Just et al. 1991; protocol 2).

For some animals, especially for young dogs, damage of the vessel wall and stenosis are not sufficient to induce thrombotic cyclic flow variations. In these cases, an additional activation of platelets by infusion of epinephrine (protocol 3) is required leading to the formation of measurable thrombi. In another preparation (protocol 4), thrombus formation is induced by subcritical

stenosis without prior clamping of the artery and infusion of platelet activating factor (PAF) according to the model described by Apprill et al. (1985). In addition to these protocols, coronary spasms induced by released platelet components can influence coronary blood flow. Therefore, this model includes the main pathological factors of unstable angina pectoris.

Coronary thrombosis induced by electrical stimulation

In this preparation, coronary thrombosis is induced by delivery of low amperage electrical current to the intimal surface of the artery according to the method described by Romson et al. (1980a). In contrast to the stenosis protocols, an occluding thrombosis is formed gradually without embolism after some hours (protocol 5). As a consequence of this time course, the thrombi formed are of the mixed type and contain more fibrin than the platelet thrombi with critical stenosis.

PROCEDURE

Coronary thrombosis induced by stenosis

Protocol 1: Critical stenosis

Dogs of either sex weighing 15–40 kg, at least 8 months of age, are anesthetized with pentobarbital sodium (bolus of 30–40 mg/kg and continuous infusion of approx. 0.1 mg/kg/min); respiration is maintained through a tracheal tube using a positive pressure respirator. The heart is exposed through a left thoracotomy at the fourth or fifth intercostal space, the pericard is opened and the left circumflex coronary artery (LCX) is exposed. An electromagnetic or Doppler flowprobe is placed on the proximal part of the LCX to measure coronary blood flow. Distal to the flowprobe, the vessel is squeezed with a 2 mm hemostatic clamp for 5 s. A small cylindrical plastic constrictor, 2–4 mm in length and with an internal diameter of 1.2 to 1.8 mm (depending on the size of the LCX) is then placed around the artery at the site of the damage. Usually, the constrictor has to be changed several times (2–5 times) until the appropriate narrowing of the vessel is achieved, and cyclic flow variations are observed. In case of an occlusion of the artery without spontaneous embolization of the formed thrombus, reflow is induced by shortly lifting the vessel with a thread placed beneath the stenotic site.

Only dogs with regularly repeated cyclic flow reductions (CFR's) of similar intensity within a pre-treatment phase of 60 min are used in these experiments.

The test substance is then administered by intravenous bolus injection or continuous infusion, or by intraduodenal application. CFR's are registered for 2 to 4×60 min and compared to pre-treatment values.

Prior to testing, preparations for additional hemodynamic measurements are performed (see below).

Protocol 2: Subcritical stenosis

Male castrated pigs (German landrace, weighing (20–40 kg) are anesthetized with ketamine (2 mg/kg i.m.), metomidate (10 mg/kg i.p.) and xylazine (1–2 mg/kg i.m.). In order to maintain the stage of surgical anesthesia, animals receive a continuous i.v. infusion of 0.1–0.2 mg/kg/min pentobarbital sodium. Respiration is maintained through a tracheal tube using a positive pressure respirator. The heart is exposed through a left thoracotomy at the fourth and fifth intercostal space, the pericard is opened and the left descending coronary artery (LAD) is exposed. An electromagnetic or Doppler flowprobe is placed on the proximal part of the LAD to measure coronary blood flow. Distal to the flowprobe, the vessel is squeezed with a 1 mm hemostatic clamp for 5 s. A small cylindrical plastic constrictor, 2 mm in length, is then placed around the artery at the site of the damage. Usually, the constrictor has to be changed several times until the appropriate narrowing of the vessel is achieved, which produces cyclic flow reductions. CFR's are similar to those in dogs; pigs, however, show a reactive hyperemic response. If embolization does not occur spontaneously, the formed thrombus is released at 2/3 reduction of blood flow by shortly lifting the vessel with forceps.

Only pigs with regularly repeated CFR's of similar intensity within a pre-treatment phase of 60 min are used in these experiments.

The test substance is then administered by intravenous bolus injection or continuous infusion, or by intraduodenal application. CFR's are registered for 2×60 min and compared to pre-treatment values.

Protocol 3: Stenosis + epinephrine infusion

If protocol 1 does not lead to CFR's, additionally epinephrine (0.2 µg/kg/min) is infused into a peripheral vein for 2×60 min (60 min before and 60 min following drug administration). CFR's are registered and compared in the 60 min post-drug phase to the 60 min pre-drug phase.

Protocol 4: Stenosis + PAF infusion

The LCX is stenosed without prior mechanical wall injury. This preparation does not lead to thrombus formation (subcritical stenosis). For the induction of CFR's, in addition PAF (C 16-PAF, Bachem) (0.2 nmol/kg/min) is infused into one cannulated lateral branch of the coronary artery.

After 30 min, PAF infusion is terminated and blood flow returns to its normal, continuous course. Thirty min later, concomitantly the test substance is administered and a second PAF infusion is started for 30 min.

CFR's are registered and compared in the drug treated, second PAF phase to the pre-drug, first PAF phase.

Coronary thrombosis induced by electrical stimulation

Protocol 5
The LCX is punctuated distal to the flow probe with a chrome-vanadium-steel electrode (3 mm length, 1 mm diameter). The electrode (anode) is placed in the vessel in contact with the intimal lining and connected over a Teflon coated wire to a 9 Volt battery, a potentiometer and an amperemeter. A disc electrode (cathode) is secured to a subcutaneous thoracal muscle layer to complete the electrical circuit. The intima is stimulated with 150 µA for 6 h. During this time, gradually an occluding thrombosis is formed.

The test substance or the vehicle (control) is administered either at the start of the electrical stimulation or 30 min following the start.

The time interval until the thrombotic occlusion of the vessel occurs and the thrombus size (wet weight measured immediately after removal at the end of the experiment) are determined.

Prior to testing, preparations for additional hemodynamic measurements are performed (see below).

For all protocols the following preparations and measurements are performed:

- To measure peripheral arterial blood pressure (BP) [mm Hg], the right femoral artery is cannulated and connected to a Statham pressure transducer.
- Left ventricular pressure (LVP) [mm Hg] is determined by inserting a micro-tip-catheter via the carotid artery retrogradely.
- Left ventricular enddiastolic pressure (LVEDP) [mm Hg] is evaluated through sensitive amplification of the LVP.
- Contractility (LV *dp*/*dt* max) [mm Hg/s] is determined from the initial slope of the LVP curve.
- Heart rate [min^{-1}] is determined from the pulsatile blood pressure curve.
- The ECG is recorded in lead II.
- Arterial pH and concentrations of blood gases are kept at physiological levels by adjusting respiration and infusion of sodium bicarbonate.
- Blood hematocrit values (37–40%) and number of erythrocytes are kept constant by infusion of oxypolygelatine in dogs and electrolyte solution in pigs.
- Body temperature is monitored with a rectal thermistor probe and kept constant by placing the animals on a heated metal pad with automatic regulation of temperature.
- Template buccal mucosal bleeding time using the Simplate® device

At the end of the test, animals are sacrificed by an overdose of pentobarbital sodium.

EVALUATION
For all protocols, the mean maximal reduction of blood pressure (systolic/diastolic) [mm Hg] is determined.

Protocol 1–4
The following parameters are determined to quantify stenosis-induced coronary thrombosis:

- Frequency of cyclic flow reductions
  = cycle number per time
- Magnitude of cyclic flow reductions
  = cycle area [mm^2] (total area of all CVR's per time, measured by planimetry)

Percent change in cycle number and cycle area after drug treatment is calculated compared to pre-treatment controls.

Statistical significance is assessed by the paired Student's *t*-test.

Protocol 5
The following parameters are determined to quantify electrically-induced coronary thrombosis:

- Occlusion time [min]
  = time to zero blood flow
- Thrombus size [mg]
  = wet weight of the thrombus immediately after removal

Percent change in mean values for occlusion time and thrombus size in drug-treated groups is compared to the control group.

Statistical significance is assessed by the non-paired Student's *t*-test.

Standard data:

Standard	Dose	% decrease in CFV's		Protocol	Species
		Number	Area		
Acetylsalicylic acid	1 mg/kg, i.v.	56	80	1	dog
	20 mg/kg, i.d.	87	95	1	dog
	30 mg/kg, i.v.	56	77	2	pig

CRITICAL ASSESSMENT

Both, the stenosis (Folts) and the electrical (Romson/Lucchesi) model of coronary thrombosis are widely used to study the role of mediators in the thrombotic process and the effect of new antithrombotic drugs. Bush (1986) reviewed the role of the endothelium in arterial thrombosis and the effect of some inhibitors and mediators in the Folts model, e.g. thromboxane, prostacyclin, cyclooxigenase, serotonin, NO-donors and other vasodilators. The effect of an NO-donor could be reversed by the NO-scavenger oxyhemoglobin indication that indeed NO was responsible for the antithrombotic action (Just et al. 1991). Recent mechanisms of antithrombotic drug action which have been studied in either of the two coronary thrombosis models are: the oral GP IIb/IIIa antagonist DMP 728 (Mousa et al. 1996); the LMWH enoxaparin (Leadley et al. 1998) which inhibited CFR's in contrast to unfractionated heparin; the thrombin-inhibitors PEG-hirudin (Ruebsamen et al. 1998) and melagatran (Mehta et al. 1998); an anti-P-selectin antibody (Ikeda et al. 1999); and activated protein C (Jackson et al. 2000).

The clinical relevance of studies in the Folts-model has been questioned because the model is very sensitive to antithrombotic compounds. However, the lack of a reversal of the effect by epinephrine or increase in degree of stenosis differentiates any new drug from aspirin. Electrical coronary thrombosis is less sensitive: e.g. aspirin has no effect and with some drugs higher dose levels are required; but in principle, most drug mechanisms act in both models if at all.

MODIFICATIONS OF THE METHOD

Romson et al. (1980b) described a simple technique for the induction of coronary artery thrombosis in the conscious dog by delivery of low amperage electric current to the intimal surface of the artery.

Benedict et al. (1986) modified the electrical induction of thrombosis by use of two Doppler flow probes proximal and distal to the needle electrode in order to measure changes in blood flow velocity. The electrical current was stopped at 50% increase in flow velocity and thrombosis then occurred spontaneously. The important role of serotonin was demonstrated by increases in coronary sinus serotonin levels just prior to occlusion.

Warltier et al. (1987) described a canine model of thrombin-induced coronary artery thrombosis: and the effects of intracoronary streptokinase on regional myocardial blood flow, contractile function, and infarct size.

Al-Wathiqui et al. (1988) described the induction of cyclic flow reduction in the coronary, carotid, and femoral arteries of conscious chronically instrumented dogs.

The method of Folts-thrombosis has also been applied to carotid arteries in **monkeys**. Coller et al. (1989) induced CFR's in carotid arteries of anesthetized cynomologus monkeys and showed abolition by the GP Iib/IIIa antibody abciximab.

B.2.2
Stenosis-and mechanical injury-induced arterial and venous thrombosis (Harbauer-model)

PURPOSE AND RATIONALE

Harbauer (1984) first described a venous model of thrombosis induced by mechanical injury and stenosis of the jugular vein. In a modification, both arterial and venous thrombosis is produced in rabbits by stenosis of the carotid artery and the jugular vein with simultaneous mechanical damage of the endothelium. This activates platelets and the coagulation system and leads to changes in the bloodstream pattern. As a consequence, occluding thrombi are formed as detected by blood flow measurement. The dominant role of platelets in this model is shown by the inhibitory effect of an antiplatelet serum in both types of vessels (Just 1986). The test is used to evaluate the antithrombotic capacity of compounds in an *in vivo*-model of arterial and venous thrombosis where thrombus formation is highly dependent on platelet activation.

PROCEDURE

Male Chinchilla rabbits weighing 3–4 kg receive the test compound or the vehicle (controls) by oral, intravenous or intraperitoneal administration. The first ligature (vein, preparation see below) is performed at the end of absorption (i.p. approx. 30 min, p.o. approx. 60 min, i.v. variable).

Sixty-five min before stenosis, the animals are sedated by intramuscular injection of 8 mg/kg xylazine (Rompun®) and anesthetized by intravenous injection of 30–40 mg/kg pentobarbital sodium 5 min later. During the course of the test, anesthesia is maintained by continuous infusion of pentobarbital sodium (30–40 mg/kg/h) into one femoral vein.

A Statham pressure transducer is placed into the right femoral artery for continuous measurement of blood pressure. Spontaneous respiration is maintained through a tracheal tube.

One jugular vein and one carotid artery are exposed on opposite sides. Small branches of the vein are clamped to avoid blood flow in spite of vessel occlusion.

Electromagnetic or Doppler flow probes are placed on the vein (directly central to the vein branching) and on the artery (as far central as possible). Blood flow [ml/min] is measured continuously.

After reaching steady state (approx. 15–30 min), a metal rod with a diameter of 1.3 mm is placed on the jugular vein (2 cm central to the vein branching) and a ligature is tightened. After 1 min, the rod is removed from the ligature. Immediately thereafter (approx. 1.5 min), the carotid artery is damaged by shortly squeezing it with forceps. Then a small plastic constricting cylinder with 1.2 mm diameter and 2 mm length is placed around the site of the endothelial damage.

Registration of parameters is terminated after 30 min.

In addition, the template bleeding time is measured at various time interval before and after drug treatment (depending on the route of administration) in the shaved inner ear using the Simplate® device. Care is taken to select parts of the skin without larger vessels.

EVALUATION

Percent thrombus formation (= thrombosis incidence) is judged by determination of the number of occluded vessels (blood flow = 0).

Percent inhibition of thrombosis incidence is calculated in dosed groups as compared to vehicle controls.

Thrombosis incidence is always 100% in vehicle controls.

Statistical significance is assessed by means of the Fisher-exact-test.

If initial values for blood flow do not significantly differ in dosage and control groups, the area below the blood flow curves is measured by planimetry in addition and mean values in dosed groups are compared to controls by means of the unpaired Student's *t*-test.

Mean values of occlusion times [min] in dosage and control groups are calculated and compared by means of the t-test.

The maximal change in systolic and diastolic blood pressure during the time period of stenosis as compared to the initial values before drug administration is determined. There is no standardized assessment score. As an example, a reduction of systolic blood pressure by 30 mm Hg and of diastolic blood pressure by 20 mm Hg is quoted as a strong reduction in blood pressure.

CRITICAL ASSESSMENT

Two main factors of arterial thrombosis in men are essential in this model: high grade stenosis and vessel wall damage. In the absence of either no thrombus is found. The occlusive thrombus is formed fast and in a highly reproducible manner. In both vessels thrombus formation is equally dependent on platelet function as shown by antiplatelet serum. Therefore, the jugular vein thrombosis in this model differs from stasis-induced deep vein thrombosis with predominant fibrin formation. On the other hand, these occlusive thrombi are more stable than the pure platelet thrombi in the Folts model (see B.2.1) since carotid blood flow cannot be restored by shaking the constrictor. The following antithrombotic drugs are effective: i) antiplatelet drugs like ticlopidine, prostacyclin/iloprost, NO-donors (SNP, molsidomine) but not aspirin, thromboxane-synthase-inhibitors; ii) anticoagulants like hirudin, high-dose heparin, warfarin; iii) streptokinase/t-PA (Bevilacqua 1991; Just 1986 and unpublished). In contrast, drugs which only lower blood pressure such as hydralazine, clonidine, prazosin have no effect on thrombus formation in this model.

MODIFICATIONS OF THE METHOD

Bevilacqua et al. (1991) performed the same model in rabbit carotid arteries but compared the procedure in one artery before drug treatment with the contralateral artery after drug treatment. Heparin, the synthetic thrombin inhibitor FPRCH2Cl, iloprost and t-PA inhibited carotid occlusion in this model but not aspirin.

Spokas and Wun (1992) produced venous thrombosis in the vena cava of rabbits by vascular damage and stasis. The vascular wall was damaged by crushing with hemostat clamps. A segment of the vena cava was looped with two ligatures, 2.5 cm apart. At 2 h after ligation, the isolated venous sac was dissected and the clot removed for determination of dry weight.

Lyle et al. (1995) searched for a animal model mimicking the thrombotic re-occlusion and restenosis occurring in several cases after successful coronary angioplasty in man. The authors developed a model of angioplasty-induced injury in atherosclerotic rabbit femoral arteries. Acute ^{111}indium-labelled platelet deposition and thrombosis were assessed four hours after balloon-injury in arteries subjected to prior endothelial damage (air desiccation) and cholesterol supplementation (one month). The effects of inhibitors of factor X_a or platelet adhesion, heparin, and aspirin on platelet deposition were studied.

Thrombosis induced by supercooling

Meng (1975), Meng and Seuter (1977) and Seuter et al. (1979) described a method to induce arterial thrombosis in rats by chilling of the carotid artery. Rats were anesthetized, the left carotid artery was exposed and occluded proximal by means of a small clamp. The artery was placed for 2 min into a metal groove which was cooled to –15 °C. The vessel was compressed by a weight of 200 g. In addition, a silver clip was fixed to the vessel distally from the injured area to produce a disturbed and slow blood flow. After 4 min, the proximal clamp was removed and the blood flow reestablished in the injured artery. In the rabbit, slightly different conditions were used: the chilling temperature was –12 °C for a period of 5 min, and the compressing weight was 500 g. The wound was closed and the animal allowed to recover from anesthesia. Antithrombotic compounds were administered in various doses at different time intervals before surgery. After 4 h, the animals received heparin and were re-anesthetized. The lesioned carotid artery was removed and thrombus wet-weight was immediately measured.

The method has been modified by Granzer (1986) using a cryo-forceps perfused with methanol at –21 °C by which the exposed carotid artery or jugular vein was compressed over a length of 12 mm with a load of 500 g for two min.

B.2.3 Electrical-induced thrombosis

PURPOSE AND RATIONALE

The use of electrical current to induce thrombosis in hamster and dog has been described in the early 1950s by Lutz et al. (1951) and Sawyer and Pate (1953a,b). In general, two different approaches exist. One method produces electrical damage by means of two externally applied hook-like electrodes (Hladovec 1973; Philp et al. 1978). The other method uses a needle electrode which is advanced through the walls of the blood vessels and positioned in their lumen, the second electrode is placed into a subcutaneous site completing the circuit (Salazar 1961; Romson et al. 1980; Benedict et al. 1986).

PROCEDURE

Anaesthetized rats weighing 200–300 g are intubated and a femoral artery is cannulated for administration of drugs. One carotid artery is isolated from surrounding tissues over a distance of 10–15 mm.

A pair of rigid stainless-steel wire hook-like electrodes with a distance of 4 mm are adjusted to the artery by means of a rack and pinion gear manipulator. The artery is raised slightly away from the surrounding tissue. Isolation of the electrodes is achieved by the insertion of a small piece of parafilm under the artery. Blood flow is measured with an ultrasonic Doppler flowmeter (Transonic, Ithaca NY, USA), the flow probe (1RB) is placed proximal to the damaged area.

Thrombus formation is induced in the carotid arteries by the application of an electrical current (350 V, DC, 2 mA) delivered by an electrical stimulator (Stoelting Co, Chicago, Cat. No 58040) for 5 min to the exterior surface of the artery.

EVALUATION

- Blood flow before and after induction of thrombus for 60 min
- Time to occlusion [min]: the time between onset of the electrical current and the time at which blood flow decreases under 0.3 ml/min
- Patency of the blood vessel over 30 min

CRITICAL ASSESSMENT

The electrical-induced thrombus is composed of densely packed platelets with some red cells. Moreover, the electrical injury causes extensive damage to intimal and subintimal layers. The endothelium is completely destroyed and this damage extends to subendothelial structures including smooth muscle cells. The deep damage could reduce the possibility of discrimination between drugs on the basis of their antithrombotic activity. However, Philp et al. (1978) could show that unfractionated heparin completely blocked thrombus formation, whereas other antiplatelet agents displayed differentiated antithrombotic action. He concluded that this relatively simple model of arterial thrombosis might prove a useful screening test for drugs with antithrombotic potential.

MODIFICATIONS OF THE METHOD

The technique described by Salazar et al. (1961) uses a stainless steel electrode which is inserted into a coronary artery in the dog and which delivers anodal current to the intravascular lumen. The electrode is positioned under fluoroscopic control which complicates the method. The technique was modified by Romson et al. (1980). They placed the electrode directly into the coronary artery of open-chest anaesthetized dogs.

Rote et al. (1993, 1994) used a carotid thrombosis model in dogs. A calibrated electromagnetic flow meter was placed on each common carotid artery proximal to both the point of insertion of an intravascular electrode and a mechanical constrictor. The external constrictor was adjusted with a screw until the pulsatile flow pattern decreased by 25% without altering the mean blood flow. Electrolytic injury to the intimal surface was accomplished with the use of an intravascular electrode composed of a Teflon-insulated silver-coated copper wire connected to the positive pole of a 9-V nickel-cadmium battery in series with a 250 000 ohm variable resistor. The cathode was connected to a sub-

cutaneous site. Injury was initiated in the right carotid artery by application of a 150 µA continuous pulse anodal direct current to the intimal surface of the vessel for a maximum duration of 3 h or for 30 min beyond the time of complete vessel occlusion as determined by the blood flow recording. Upon completion of the study on the right carotid, the procedure for induction of vessel wall injury was repeated on the left carotid artery after administration of the test drug.

Benedict et al. (1986) introduced a procedure in which anodal current is discontinued when mean distal coronary flow velocity increased by approximately 50%, reflecting disruption of normal flow by the growing thrombus. Occlusive thrombosis occurred within 1 h after stopping the electrical current. It was observed that the final phase of thrombosis occurred independently of electrical injury.

A ferret model of acute arterial thrombosis was developed by Schumacher et al. (1996). A 10-min anodal electrical stimulation of 1 mA was delivered to the external surface of the carotid artery while measuring carotid blood flow. This produced an occlusive thrombus in all vehicle treated ferrets within 41 ±3 min with an average weight of 8 ±1 mg. Thrombus weight was reduced by aspirin or a thromboxan receptor antagonist.

Guarini (1996) produced a completely occlusive thrombus in the common carotid artery of rats by applying an electrical current to the arterial wall (2 mA for 5 min) while simultaneously constricting the artery with a hemostatic clamp placed immediately downstream from the electrodes.

B.2.4 $FeCl_3$-induced thrombosis

PURPOSE AND RATIONALE

A variety of chemical agents has been used to induce thrombosis in animals. Topical $FeCl_3$ was described by Reimann-Hunziger (1944) as thrombogenic stimulus in veins. Kurz et al. (1990) showed that the thrombus produced with this method in the carotid arteries of rats is composed of platelets and red blood cells enmeshed in a fibrin network. This model is used as a simple and reproducible test for evaluation of antithrombotic (Broersma et al. 1991) and profibrinolytic test compounds (van Giezen et al. 1997).

PROCEDURE

Rats weighing between 250 and 300 g are anaesthetized with Inactin (100 mg/kg) and a polyethylene catheter (PE-205) is inserted into the trachea via a tracheotomy to facilitate breathing. Catheters are also placed in the femoral artery for blood samples and measurement of arterial blood pressure and in the jugular vein for administration of test agents. The right carotid artery is isolated and an ultrasonic Doppler flowprobe (probe 1RB, Transonic, Ithaca NY, USA) is placed on the vessel to measure blood flow. A small piece of Parafilm "M" (American Can Co., Greenwich, CT) is placed under the vessel to isolate it from surrounding tissues throughout the experiment.

The test agent is administered by gavage or as an intravenous injection at a defined time prior to initiation of thrombus formation. Thrombus formation is induced by the application of filter paper (2×5 mm), saturated with 25% $FeCl_3$ solution, to the carotid artery. The paper is allowed to remain on the vessel 10 min before removal. The experiment is continued for 60 min after the induction of thrombosis. At that time, the thrombus is removed and weighed.

EVALUATION

- Blood flow before and after induction of thrombus for 60 min

- Time to occlusion [min]: the time between $FeCl_3$ application and the time at which blood flow decreases under 0.3 ml/min
- Thrombus weight after blotting the thrombus on filter paper

B.2.5 Laser-induced thrombosis

PURPOSE AND RATIONALE

Thrombus formation in rat or rabbit mesenteric arterioles or venules is induced by laser beams. The test can be performed in normal or pretreated (induction of arteriosclerosis or adjuvant arthritis) animals. The mediators for thrombus formation in this method are platelet adhesion to the injured endothelial vessel wall on one hand and ADP-induced platelet aggregation on the other. Most probably, ADP is primarily released by laser beam lysed erythrocytes, due to the fact that erythrocyte hemoglobin exerts strong adsorbability to frequencies emitted by laser beams. There is a further, secondary, aggregation stimulus following the release reaction induced by the platelets themselves.

PROCEDURE

Apparatus

4W Argon laser (Spectra Physics, Darmstadt, FRG) wave length: 514,5 nm, energy below the objective: 15 mW, duration of exposure: 1/30 or 1/15 s

- Microscope ICM 405, LD-Epipland 40/0.60 (Zeiss, Oberkochen, FRG)
- Video camera (Sony, Trinicon tube)
- Recorder (Sony, U-matic 3/4")
- Videoanalyzer and correlator to determine blood flow velocity

In vivo experiment

Male Sprague Dawley or spontaneously hypertensive stroke prone Wistar or Lewis rats with adjuvant induced arthritis weighing 150–300 g or New Zealand rabbits with arteriosclerosis induced by cholesterol feeding for 3 months are used. The animals receive the test compound by oral, intravenous, intraperitoneal, or subcutaneous administration. Control animals are treated with vehicle alone. Prior to thrombus induction, the animals are pretreated by s.c. injection of 0.1 mg/kg atropine sulfate solution and anaesthetized by intraperitoneal administration of 100 mg/kg ketamine hydrochloride and 4 mg/kg xylazine.

Thrombus formation is induced 15, 30, 60 or 90 min post dosing. Investigations are performed in arterioles or venules of 13 ±1 µm in diameter of the fat-free ileocaecal portion of the mesentery. During the test procedure, the mesenterium is superfused with physiological saline solution or degassed paraffin liquid (37 °C). The ray of the argon laser is led into the inverted ray path of the microscope by means of a ray adaptation and adjusting device. The frequency of injuries is 1 per 2 min. The exposure time for a single laser shot is 1/30 or 1/15 s. The number of injuries necessary to induce a defined thrombus is determined. All thrombi formed during the observation period with a minimum length of 13 µm or an area of at least 25 μm^2 are evaluated. All measuring procedures are photographed by a video system.

Standard compounds:

- acetylsalicylic acid (10 mg/kg, per os)
- pentoxifylline (10 mg/kg, per os)

EVALUATION

The number of laser shots required to produce a defined thrombus is determined. Mean values and SEM are calculated. Results are shown graphically.

For statistical evaluation the χ^2-test is used.

B.2.6 Photochemical-induced thrombosis

PURPOSE AND RATIONALE

In 1977, Rosenblum and Sabban reported that ultraviolet light can produce platelet aggregation in cerebral microvessels of the mouse after intravascular administration of sodium fluorescein. They found that in contrast to heparin, both aspirin and indomethacin prolonged the time to first platelet aggregate. Herrmann (1983) provided a detailed study in which he showed that scavengers of singlet oxygen, not of hydroxyl radicals, inhibited platelet aggregation induced by the photochemical reaction. He postulated that by exciting the intravascularly administrated fluorescein, singlet oxygen damages endothelial cells which subsequently leads to platelet adhesion and aggregation.

PROCEDURE

Studies are performed in mesenteric arteries of 15–30 μm diameter in anesthetized rats. After intravenous injection of fluorescein isothiocyanate-dextran 70 (FITC-dextran, Sigma, 10%, 0.3 ml), the FITC-dextran in arterioles is exposed to ultraviolet light (wavelength of excitation 490 nm, wavelength of emission 510 nm).

EVALUATION

Thrombus formation is quantitated by determining the time between onset of excitation and appearance of the first platelet aggregate adhering to the vessel wall.

MODIFICATIONS OF THE METHOD

Matsuno et al. (1991) reports a method to induce thrombosis in the rat femoral artery by means of a photochemical reaction after injection of a fluorescent dye (rose Bengal, 10 mg/kg i.v.) and transillumination with a filtered xenon lamp (wave length: 540 nm). Blood flow is monitored by a pulsed Doppler flow meter. Occlusion is achieved after approximately 5–6 min. Pretreatment with heparin dose-dependently prolongs the time required to interrupt the blood flow. The model also enables to study thrombolytic mechanisms, which had been evaluated with t-PA.

CRITICAL ASSESSMENT

In contrast to other thrombosis induction methods, photochemically-induced thrombosis can be easily used in smaller animals. Thrombi are composed primarily of platelets, however the primary target of the photochemical insult is the endothelial cells by means of a oxygen radical damage. So, it might be disadvantageous that beneath platelet inhibitors also scavenger are effective.

B.2.7 Foreign-surface thrombosis

The presence of foreign materials in the circulation produces activation of the coagulation and the platelet system. Various prothrombotic surfaces have been used to develop experimental animal models. In contrast to many other thrombosis models, the thrombosis induced by foreign surfaces does not presuppose endothelial damage.

B.2.7.1 Wire-coil induced thrombosis

PURPOSE AND RATIONALE

A classical method to produce thrombosis is based on the insertion of wire coils into the lumen of blood vessels. The model was first described by Stone and Lord (1951) in aorta of dog's and was further modified to be used in arterial coronary vessels of opened-chest dogs. The use in venous vessels was described by Kumada et al. (1980).

The formation of thrombotic material around the coil is reproducible and can be easily standardized to study pharmacological agents (Just and Schönafinger 1991; Mellott et al. 1993; Rübsamen and Hornberger 1996).

Venous thrombosis is produced in rats by insertion of a stainless steel wire coil into the inferior caval vein. Platelets as well as plasmatic coagulation are activated on the wire coil. Thrombus formation onto the wire is quantitated by measuring the protein content of the thrombotic material isolated. The kinetics of thrombus formation show an increase in weight and protein content within the first 30 min followed by a steady state between thrombus formation and endogenous thrombolysis leading to a constant protein content of thrombi between 1 and up to 48 h following implantation of the wire coil. Thrombosis incidence in untreated control ani-

mals in this model is 100%. The test is used to evaluate antithrombotic and thrombolytic properties of compounds in an *in vivo*-model of venous thrombosis in rats.

PROCEDURE

Male Sprague-Dawley rats weighing 260–300 g receive the test compound or the vehicle (controls) by oral, intravenous or intraperitoneal administration. At the end of absorption (i.v. 1 min, i.p. 30 min, p.o. 60 min), the animals are anesthetized by intraperitoneal injection of 1.3 g/kg urethane. Through a mid-line incision the caudal caval vein is exposed and a stainless steel wire coil (a dental pate carrier, Zipperer® size 40(st), Zdarsky Erler KG, München) is inserted into the lumen of the vein just below the left renal vein branching by gently twisting of the wire towards the iliac vein. The handle of the carrier is cut off so as to hold the back end of the wire at the vein wall. The incision is sutured and the animal is placed on its back on a heating pad (37 °C). The wound is reopened after 2 h, the wire coil is carefully removed together with the thrombus on it and rinsed with 0.9% saline. The thrombotic material is dissolved in 2 ml alkaline sodium carbonate solution (2% Na_2CO_3 in 0.1 N NaOH) in a boiling water bath for 3 min. The protein content is determined in 100 µl aliquots by the colorimetric method of Lowry.

Thrombolysis

In addition to the described preparation, for continuous infusion of a thrombolytic test solution a poly-ethylene catheter is inserted in the jugular vein. One and a half h after implantation of the wire coil, the test compound or the vehicle (controls) is infused for up to 2.5 h. The wire coil is then removed and the protein content of thrombi is determined (see above). Bernat et al. (1986) demonstrated the fibrinolytic activity of urokinase and streptokinase-human plasminogen complex in this model.

EVALUATION

Thrombosis incidence (= number of animals with thrombi in dosage groups as compared to vehicle controls) is assessed.

The mean protein content [mg] of the thrombotic material in dosage groups and vehicle controls is determined. Percent change in protein content is calculated in dosage groups as compared to controls.

Statistical significance is assessed by means of the unpaired Student's *t*-test.

B.2.7.2 Eversion-graft induced thrombosis

PURPOSE AND RATIONALE

The eversion graft model for producing thrombosis in the rabbit artery was first described by Hergrueter et al. (1988) and later modified by Jang et al. (1989, 1990) and Gold et al. (1991). A 4- to 6-mm segment of the rabbit femoral or the dog left circumflex artery is excised, everted and then re-implanted into the vessel by end-to-end anastomoses. After restoration of the blood flow, a platelet-rich occlusive thrombus forms rapidly leading to complete occlusion of the vessel. This model mimics a deep arterial injury since the adventitial surface is a non-endothelial tissue containing tissue factor and collagen. The rabbit model described here uses a carotid graft inserted into the femoral graft to avoid vasoconstriction often occurring in the inverted femoral segments.

PROCEDURE

In anaesthetized New Zealand White rabbits, the right A. carotis is exposed. After double ligation, a 3 mm segment of the artery is excised, everted and immersed in pre-warmed (37 °C) isotonic saline. Thereafter, the right femoral artery is exposed and occluded by means of a double-occluder (2 cm distance). The femoral artery is transected and the everted graft from the carotid artery is inserted by end-to-end anastomosis using 12 sutures with 9-0 nylon (Prolene, Ethicon, Norderstedt, Germany) under a surgical microscope (Wild M650, Leitz, Heerbrugg, Switzerland). Perfusion of the graft is measured by means of an ultrasonic flowmeter (Model T106, Transonic, Ithaca NY, USA), The flow probe is positioned 2 cm distal from the graft.

After a stabilization period of 15 min, the test substance is given intravenously through the catheterized right V. jugularis. 10 min after substance administration, the vessel clamps are released and the blood flow is monitored by the flowmeter for 120 min.

Arterial blood is collected from the left carotid artery at baseline (immediately before substance administration), 10 min, 60 min and 120 min after substance administration.

EVALUATION

- Time until occlusion (Time after restoring of vessel blood flow until occlusion of the vessel indicated by a flow less than 3.0 ml/min)
- Patency (Time during which perfusion of graft is measured related to an observation period of 120 min after administration of test compounds).

Statistical analysis:
Time until occlusion and patency are expressed as median and the interquartile range/2 (IQR/2). Significant differences ($p < 0.05$) are calculated by the non-parametric Kruskal-Wallis test.

CRITICAL ASSESSMENT
The eversion graft is very thrombogenic, although technically difficult and time consuming. The deep occlusive thrombi can prevented only by intraarterially administered thrombolytics or aggressive antithrombotic treatments such as recombinant hirudin at high dosages, or PEG-hirudin. The adventitial surface is a non-endothelial tissue containing tissue-factor and collagen. Thus, both the coagulation system and blood platelets are activated.

MODIFICATIONS OF THE METHOD
Gold et al. (1991) modified the model to be used in thoracotomized dogs in partial obstructed left circumflexed coronary arteries. The combination of reduced blood flow due to the constrictor, along with an abnormal non-endothelial surface, produces total thrombotic occlusion within 5 min.

B.2.7.3 Arterio-venous shunt thrombosis

PURPOSE AND RATIONALE
A method for the direct observation of extracorporal thrombus formation has been introduced by Rowntree and Shionoya (1927). These first studies could provide evidence that anticoagulants like heparin and hirudin do inhibit thrombus development in arteriovenous shunts. Since today, the A-V-shunt thrombosis models have been often used to evaluate the antithrombotic potential of new compounds in different species including rabbits (Knabb et al. 1992), rats (Hara et al. 1995), pigs (Scott et al. 1994), dogs and cats (Best et al. 1938), and non-human primates (Yokoyama et al. 1995).

PROCEDURE
Rats are anaesthetized and fixed in supine position on a temperature-controlled heating plate to maintain body temperature. The left carotid artery and the right jugular vein are catheterized with short polyethylene catheters. The catheters are filled with isotonic saline solution and clamped. The two ends of the catheters are connected with a 2 cm glass capillary with an internal diameter of 1 mm. This glass capillary provides the thrombogenic surface. At a defined time after administration of the test compound, the clamps which are occluding the A-V-shunt are opened.

The measurement of the patency of the shunt is performed indirectly with a NiCrNi-thermocouple which is fixed distal to the glass capillary. If blood is flowing the temperature rises from room temperature to body temperature. In contrast, decreases of temperature indicates the formation of an occluding thrombus. The temperature is measured continuously over 30 min after opening of the shunt.

CRITICAL ASSESSMENT
It has been shown by Best et al. (1938) that the thrombi formed in the AV-shunt are to a greater part white arterial thrombi. This might be due to the high pressure and shear rate inside the shunts, the thrombi tend to be more arterial in character (Chi et al. 1999).

B.2.7.4 Thread-induced venous thrombosis

PURPOSE AND RATIONALE

Compared to the arterial system, it seems to be more difficult to develop a thrombosis model in venous blood vessels with respect to reproducibility and variability (Chi et al. 1999). Complete stasis together with a thrombogenic stimulus (Wessler-type) is used by numerous investigators to evaluate the effect of compounds on venous thrombosis. Hollenbach et al. (1994) developed a rabbit model of venous thrombosis by inducingcotton threads into the abdominal vena cava of rabbits. The cotton threads serve as a thrombogenic surface, and a thrombus forms around it growing to a maximum mass after 2–3 h. The prolonged non-occlusive character of thrombogenesis in this model focuses on progression of thrombus formation rather than initiation. Therefore, the conditions more closely resemble pathophysiology in humans because blood continues to flow throughout the experiment (Chi et al. 1999).

PROCEDURE

Rabbits weighing between 2.5 and 3.5 kg are anaesthetized with isofluorane inhalation anesthesia and a polyethylene catheter is inserted into the left carotid artery. A polyethylene tube (PE 240, inner diameter 1.67 mm) of 14 cm length is filled with isotonic saline and a copper wire with 5 fixed cotton threads (length 6 cm) is inserted into the tube (after determination of the net weight of the cotton threads). A laparotomy is performed and the V. cava and V. iliaca are dissected free from surrounded tissue. The test agent is administered by a rabbit intragastric tube 60 min (depending on the *ex vivo* study) prior to initiation of thrombus formation. Blood samples will be measured at 60, 90, 120 and 150 and 210 min after oral administration of the test compound.

Thrombus formation is induced by the inserting the thrombosis catheter into the caval vein via the V. iliaca (7 cm). Then the copper wire is pushed forward 3 cm to liberate the cotton threads into the vessel lumen. 150 min after thrombus initiation, the caval segment containing the cotton threads and the developed thrombus will be removed, longitudinally opened and the content is blotted on filter paper. After weighing the cotton thread with the thrombus, the net thread weight will be subtracted to determine the corrected thrombus weight.

EVALUATION

- Corrected thrombus weight after blotting the thrombus on filter paper and subtraction of the net weight of the cotton thread.
- Mean arterial blood pressure (MAP)
- APTT, HepTest, antiFIIa- and antiFXa-activity

CRITICAL ASSESSMENT

The composition of the cotton threaded thrombus shows a composition of fibrin together with tightly aggregated and distorted erythrocytes thus being in accordance with human deep vein thrombosis structure. Non-occlusive thrombus formation has been successfully inhibited by heparins, prothrombinase complex inhibitors and thrombin inhibitors (Hollenbach et al. 1994, 1995).

MODIFICATIONS OF THE METHOD

In addition to the originally described method, it is possible to measure blood flow by means of a ultrasonic flow probe, attached distally to the position of the cotton threads on the vein.

B.2.7.5 Thrombus formation on superfused tendon

PURPOSE AND RATIONALE

In all models which include vessel wall damage blood gets in contact with adhesive proteins of the subendothelial matrix, i.e. von Willebrand factor, collagens, fibronectin, laminin and others. Gryglewski et al. (1978) described an *in vivo* method where blood of an unanes-thetized animal is in contact *ex vivo* with a foreign surface consisting mainly of collagen. The foreign surface is produced out of the tendon of another animal species. After superfusion of the tendon, blood is recirculated to the unanesthetized animal. The method aims at the quantitation of the antiplatelet potency of drugs based on the for-mation of platelet thrombi onto the surface of the tendons or of aortic strips from atherosclerotic rabbits.

PROCEDURE

Blood was withdrawn from the carotid artery of anesthetized and heparinized cats by a roller pump at a speed of 6 ml/min. After a passage through a warmed jacket (37 °C), blood was separated into 2 streams, each flowing at a speed of 3 ml/min superfusing in parallel 2 twin strips of the central part of longitudinally cut rabbit Achilles tendon (30 × 3 mm). Instead of rabbit tendons, spirally cut strips from aortas of atherosclerotic rabbits were used. The blood superfusing the strips dripped into collectors and by its gravity was returned to the venous system of the animals through the left jugular vein. The tissue strips were freely suspended in air and the upper end was tied to an auxotonic lever of a smooth muscle/heart Harvard transducer, while the lower end was loaded with a weight (1–2 g) to keep the lever with its counterweight in a neutral position. When superfused with blood, the strips were successively covered with clots changing the weight of the strips. The weight changes were continuously recorded. After a control period of 30 min, the formed thrombi were gently removed and fixed in formalin for histological examination. Then, the strips were superfused with Tyrode solution and the animals injected with the antithrombotic drug. After 10 min, blood superfusion was renewed for another 30 min.

EVALUATION

The ratio of an increase in weight of the strips after the drug treatment to the increase in weight before drug treatment was considered as an index of antiaggregatory activity.

CRITICAL ASSESSMENT

The method described needs two different animal species (rabbit and cat). The reproducibility is not very high. Replacing cats by rabbits was not successful in our hands (Just).

B.2.8 Stasis-induced thrombosis (Wessler model)

PURPOSE AND RATIONALE

The "Wessler model" is a classical method of inducing venous thrombosis in animals. Wessler (1952, 1953, 1955, 1957, 1959) combined local venous stasis with hypercoagulability produced by injection of human or dog serum into the systemic circulation of dogs or rabbits. The jugular vein of these animals is occluded by clamps 1 min after the injection of the procoagulatory stimulus into the circulation. Within a few min after clamping, a red clot is formed in the isolated venous segment. Fareed et al. (1985) summarized a variety of substances which can be used as pro-coagulatory stimuli. Aronson and Thomas (1985) found an inverse correlation between the duration of stasis and the amount of the hypercoagulating agents to produce the clot.

PROCEDURE

Anaesthetized rabbits are fixed in supine position on a temperature-controlled (37 °C) heating-table. Following cannulation of both carotid arteries (the left in cranial direction) and the right V. femoralis, segments of 2 cm length of the two external jugular veins are exposed and isolated between two loose sutures. 0.3 ml/kg calcium thromboplastin (SIGMA, Deisenhofen, Germany, FRG) is administered via the left carotid artery. Meticulous care is taken to maintain a standard injection time of 30 s followed by injection of 0.5 ml physiological saline within 15 s. 45 s later, both jugular vein segments are occluded by distal and proximal sutures. Stasis is maintained for 30 min. Blood samples are taken immediately before occlusion and 30 s before end of stasis. After excision, the occluded vessel segments are placed on a soaked sponge and opened by a longitudinal incision.

EVALUATION

The size of the clots is assessed using a score system: (0: blood only; 1: very small clot piece(s), filling out at

most 1/4 of the vessel; 2: larger clot piece(s), filling out at most 1/2 of the vessel; 3: very large clot(s), filling out at most 3/4 of the vessel; 4: one large clot, filling out the whole vessel). The scores of the left and the right jugular vein are added forming the thrombus size value of one animal. Additionally, the thrombus weight is measured after blotting the thrombus on filter paper.

Thrombus score is expressed as median (minimum – maximum). Thrombus weight is given as mean ±SEM. For the statistical evaluation of the antithrombotic effect, the nonparametric U-Test of Mann and Whitney (thrombus score) or Student's *t*-test for unpaired samples (thrombus weight) is used. Significance is expressed as $p < 0.05$.

CRITICAL ASSESSMENT

Breddin (1989) described the Wessler model because of its static character as the retransformation of an *in vitro* experiment into a very artificial test situation. One of the major drawbacks is the relative independence of platelet function and hemodynamic changes that largely influence thrombus formation *in vivo*. However, the model has been shown to be very useful for evaluation of the antithrombotic effect of compounds like heparin and hirudin.

MODIFICATIONS OF THE METHOD

There are a number of different procoagulant agents which had been used to induce thrombosis in this model, such as human serum, Russel viper venom, thromboplastin, thrombin, activated prothrombin complex concentrates and factor X_a. (Aronson ant Thomas 1985; Fareed et al. 1985). The sensitivity and accuracy of the model can be improved by injecting iodinated fibrinogen into the animals before injecting the thrombogenic agent and then measuring the specific radioactivity in the clot.

The general drawback of the Wessler model is the static nature of the venous thrombus development. To overcome this problem some investigators have developed more dynamic models with reperfusion of the occluded vessel segments after clot development. Depending on the time of test compound administration (pre- or post-thrombus initiation), the effect on thrombus growth and fibrinolysis can be evaluated. Levi et al. (1992) have used this model to assess the effects of a murine monoclonal anti-human PAI-1 antibody and Biemond et al. (1996) compared the effect of thrombin- and factor X_a-inhibitors with a low molecular weight heparin.

Venous reperfusion model: New Zealand white rabbits weighing 2.5 kg are anesthetized with 0.1 ml atropine, 1.0 mg/kg diazepam, and 0.3 ml Hypnorm (Duphar, 10 mg/ml fluanisone and 0.2 ml fentanyl). Further anesthesia is maintained with 4 mg/kg i.v. thiopental. The carotid artery is cannulated after exposition through an incision in the neck. The jugular vein is dissected free from tissue and small side branches are ligated over a distance of 2 cm. The vein is clamped proximally and distally to isolate the vein segment. Citrated rabbit blood (from another rabbit) is mixed with ^{131}I-radiolabeled fibrinogen (final radioactivity, approximately 25 mCi/ml). 150 µl of this blood is then aspirated in a 1-ml syringe containing 25 µl thrombin (3.75 IU) and 45 µl 0.25 mol $CaCl_2$, and 200 µl of the clotting blood is immediately injected into the isolated segment. 30 min after clot injection the vessel clamps are removed and blood flow is restored. ^{125}I-radiolabeled fibrinogen (approximately 5 µCi) is injected through the cannula in the carotid artery, (in case of the fibrinolysis studies immediately followed by 0.5 mg/kg recombinant tissue-type plasminogen activator). For each dosage group, four thrombi are analyzed. The extent of thrombolysis is assessed by measurement of the remaining ^{131}I-fibrinogen in the clot and compared with the initial clot radioactivity. The comparison between blood and thrombus ^{125}I-radioactivity reveals the extent of thrombus growth (blood volume accreted to the blood). The thrombus lysis and extension are monitored 60 or 120 min after thrombus formation and are expressed as percentage of the initial thrombus volume. Statistics is performed as variance analysis and the Newman-Keuls test. Statistical significance is expressed at the level of $p < 0.05$.

B.2.9 Experimental thrombocytopenia or leucocytopenia

PURPOSE AND RATIONALE

Intravenous administration of collagen, arachidonic acid, ADP, PAF (platelet activating factor) or thrombin activates thrombocytes leading to a maximal thrombocytopenia within a few minutes. The effect is reinforced by additional injections of epinephrine. Activation of platelets leads to intravasal aggregation and temporary sequestration of aggregates in the lungs and other organs. Depending on the dose of agonist, this experimentally induced reduction of the number of circulating platelets is reversible within 60 min after induction. Following administration of PAF, a leucocytopenia is induced in addition. The assay is used to test the inhibitory capacity of drugs against thrombocytopenia or leucocytopenia as a consequence of *in vivo* platelet or leukocyte stimulation.

PROCEDURE

Materials and solutions

Substances used to induce thrombocytopenia/ leucocytopenia (intravenous administration)

In rabbits:		
arachidonic acid (Sigma)	1	mg/kg
collagen (Hormonchemie)	30	µg/ml
In mice:		
collagen	90	µg/kg
+ adrenaline (Hormonchemie)	+ 20	µg/kg
In hamsters:		
collagen	50	µg/kg
+ adrenaline	+ 10	µg/kg
In guinea pigs:		
PAF (Paf-acether, Bachem)	0.03–0.04	µg/kg
thrombin (Hoffman-LaRoche)	60	U/kg
Anesthetics:		
pentobarbital sodium (i.p.)	30	mg/kg
xylazine (i.m.)	8	mg/kg
urethane (i.p.)	1.5	g/kg

Platelet analyzer: Sysmex microcellcounter F-800

Male guinea pigs (Pirbright White) weighing 300–600 g, or male NMRI mice (25–36 g), or Chinchilla rabbits of either sex weighing 2–3 kg are used. Animals receive the test compound or the vehicle (controls) by oral, intraperitoneal or intravenous administration. After the end of the absorption time (p.o. 60 min, i.p. 30 min, i.v. variable), the marginal vein of the ear of rabbits is cannulated and the thrombocytopenia-inducing substances collagen or arachidonic acid are injected slowly. Blood is collected from the ear artery.

Guinea pigs, hamsters, or mice are anesthetized with pentobarbital sodium (i.p.) and Rompun® (i.m.) and placed on an electrically warmed table at 37 °C. The carotid artery is cannulated for blood withdrawal and the jugular vein is cannulated to administer the thrombocytopenia-inducing substances collagen + adrenaline (injection of the mixture of both within 10 s) or PAF or thrombin. In mice collagen + adrenaline are injected into a tail vein.

Approx. 50–100 µl blood are collected into potassium-EDTA-coated tubes at times –1, 1 and 2 min (guinea pigs and mice) or 5, 10 and 15 min (rabbits) following the injection of the inducer. The number of platelets and leukocytes is determined within 1 h after withdrawal in 10 µl samples of whole blood using a microcellcounter suitable for blood of various animal species.

EVALUATION

The percentage of thrombocytes (or leukocytes) is determined in vehicle control and dosage groups at the different times following injection of the inducer relative to the initial value of control or dosage group, respectively. Calculated percent values of controls are taken as 100%.

Percent inhibition of thrombocytopenia (or leucocytopenia) is calculated in dosage groups relative to controls.

Statistical significance is evaluated by means of the unpaired Student's *t*-test.

CRITICAL ASSESSMENT

The method of collagen + epinephrine induced thrombocytopenia is presently widely used to study the phenotype of mice knocked out for a specific gene with suspected role in hemostasis /thrombosis. A recent example is the Gas 6 –/– mouse (Angelillo-Scherrer et al. 2001) and mice lacking the gene for the G protein G(z) (Yang et al. 2000). The advantage of the method for this purpose is the simple experimental procedure and the small volume of blood necessary. In general, application of the method in small animals (mice, hamsters) needs only small amounts of drug substance. The model is a useful first step of *in vivo* antithrombotic efficacy of antiplatelet drugs.

B.2.10 Collagenase-induced thrombocytopenia

PURPOSE AND RATIONALE

Intravenous administration of the proteolytic enzyme collagenase leads to formation of endothelial gaps and to exposure of deeper layers of the vessel wall. This vascular endothelial injury is mainly involved in triggering thrombus formation by activation of platelets through contact with the basal lamina. As a consequence, thrombocytopenia is induced, which is maximal within 5–10 min following collagenase injection and reversible within 30 min after induction. The model is used to test the inhibitory capacity of compounds against thrombocytopenia in a model of collagenase-induced thrombocytopenia in rats as an alternative to the model described before

PROCEDURE

Materials and solutions

Anesthetic: pentobarbital sodium (i.p.)	60	mg/kg
Heparin (Liquemin®) (i.v.)	500	U/kg
To induce thrombocytopenia (intravenous administration): collagenase (E.C. 3.4.24.3), (Boehringer, Mannheim)	10	mg/ml/kg
Platelet analyzer: Sysmex microcellcounter F-800		

Male Sprague-Dawley rats weighing 260–300 g are used. The animals receive the test compound or the vehicle (controls) by oral, intraperitoneal or intravenous administration. After the end of the absorption time (i.p. 30 min, p.o. 60 min, i.v. variable), rats are anesthetized with pentobarbital sodium (i.p.). One carotid artery is cannulated for blood withdrawal and one jugular vein is cannulated for inducer injection. The animals receive an intravenous injection of heparin and 20 min later, approx. 100 µl blood are collected (initial value). Ten min later, the thrombocytopenia-inducing substance collagenase is administered intravenously.

At times 5, 10, 20 and 30 min following the injection of collagenase, samples of approx. 100 µl blood are collected into potassium-EDTA-coated tubes. The number of platelets is determined in 10 µl samples of whole blood within 1 h after blood withdrawal using a microcellcounter.

EVALUATION

1. The percentage of platelets is determined in vehicle control and dosage groups at the different times following injection of collagenase relative to the initial value of control or dosage group, respectively. Calculated percent values of controls are set 100%.
2. Percent inhibition of thrombocytopenia is calculated in dosage groups relative to controls.

Statistical significance is evaluated by means of the unpaired Student's *t*-test.

REFERENCES

Völkl K-P, Dierichs R (1986) Effect of intravenously injected collagenase on the concentration of circulating platelets in rats. Thromb. Res. 42:11–20

B.2.11 Reversible intravital aggregation of platelets

PURPOSE AND RATIONALE

Isotopic labeling of platelets can be employed to monitor platelet aggregation and desegregation *in vivo*. ADP, (adenosine diphosphate), PAF (platelet activating factor), arachidonic acid, thrombin and collagen are known to induce platelet aggregation. In the following procedure, labelled platelets are continuously monitored in the thoracic (A) and abdominal (B) region of test animals. Administration of aggregation promoting agents produces an increase in counts in A and a fall in counts in B. This observation implies that platelets are being aggregated within the vascular system and accumulate in the pulmonary microvasculature. The *in-vivo* method can be used to evaluate platelet anti-aggregatory properties of test compounds.

PROCEDURE

Preparation of labelled platelets

Blood is obtained from rats by cardiopuncture. After centrifugation at 240 *g* for 10 min, the platelet rich plasma (PRP) is transferred into a tube and suspended in calcium free Tyrode solution containing 250 ng/ml PGE_1. The suspension is centrifuged at 640 *g* for 10 min. The supernatant is discarded and the sediment is suspended by gentle shaking with calcium free Tyrode solution containing 250 ng/ml PGE_1. ^{51}Cr is added to 1 ml of the platelet suspension. Following a 20 min incubation period at 37 °C, the suspension is again centrifuged at 640 *g* for 10 min. The supernatant is removed and the labelled platelets are finally resuspended in 1 ml calcium free Tyrode solution containing 250 ng/ml PGE_1.

In vivo experiment

Male Sprague-Dawley or stroke-prone spontaneously hypertensive rats weighing 150–300 g are used. The animals are anaesthetized with pentobarbital sodium (30 mg/kg, i.p.). Following tracheotomy, the vena femoralis is exposed and cannulated. The labelled platelets are administered via the cannula. The circulating platelets are monitored continuously in the thoracic (A) and abdominal (B) region. The counts are collected using a dual channel gamma spectrometer (Nuclear Enterprise 4681) incorporating a microcomputer (AM 9080A). One h after administration of labelled platelets (when counts in A and B have stabilized), the aggregation promoting agent (ADP, PAF, arachidonic acid, thrombin or collagen) is administered twice by intravenous injection. One hour is allowed to elapse between each i.v. injection.

The test compound is administered 2 h after platelet injection concurrently with the fourth administration of the aggregating agent. Thirty minutes (ADP, PAF, arachidonic acid, thrombin), or 1 h (collagen) after compound administration another control injection of the aggregating agent is given. This injection is either used as an additional control or it may reveal long-term efficacy of a test compound.

Standard compound:

- PGI_2 (prostacyclin)

EVALUATION

The microcomputer continuously reveals information about aggregation and desegregation of labelled platelets.

The following parameters are recorded

- A = counts over thorax
- B = counts over abdomen
- Difference: $A - B$
- ratio: A / B

The time course of response is shown in a curve. The area under the curve is calculated by a computer program.

Statistical significance is calculated using the Student's *t*-test.

MODIFICATION OF THE METHOD

Oyekan and Botting (1986) described a method for monitoring platelet aggregation *in vivo* in rats, using platelets labeled with indium^{3+} oxine and recording the increase in radioactivity count in the lung after injection of adenosine diphosphate or collagen.

Smith et al. (1989) monitored continuously the intrathoracic content of intravenously injected ^{111}indium labeled platelets in anesthetized guinea pigs using a microcomputer-based system.

B.3
Bleeding models

B.3.1
Subaqueous tail bleeding time in rodents

PURPOSE AND RATIONALE

The damage of a blood vessel results in the formation of a hemostatic plug, which is achieved by several different mechanisms including vascular spasm, formation of a platelet plug, blood coagulation, and growth of fibrous tissue into the blood clot.

A diagnostic parameter for specific defects of the hemostatic system and for the influence of drugs affecting hemostasis is the length of time that it takes for bleeding to stop from a standard incision, the so-called bleeding time.

Bleeding-time measurements in animals are used to evaluate the hemorrhagic properties of antithrombotic drugs. The transection of the tail of a rodent was first established by Döttl and Ripke (1936) and is commonly used in experimental pharmacology.

PROCEDURE

Anaesthetized rats are fixed in supine position on a temperature-controlled (37 °C) heating-table. Following catheterization of a carotid artery (for measurement of blood pressure) and a jugular vein, the test compound is administered. After a defined latency period, the tail of the rat is transected with a razor-blade mounted on a self-constructed device at a distance of 4 mm from the tip of the tail. Immediately after transection, the tail is immersed into a bath filled with isotonic saline solution (37 °C).

EVALUATION

The time until bleeding stops is determined within a maximum observation time of 600 s.

CRITICAL ASSESSMENT OF THE METHOD

There are numerous variables which can influence rodent's bleeding time measurements as discussed by Dejana et al. (1982): position of the tail (horizontal or vertical), the environment (air or saline), temperature, anesthesia, procedure of injury (Simplate method, transsection). All these variables are responsible for the different results reported in literature on compounds like aspirin and heparin under different assay condition (Stella et al. 1975; Minsker and Kling 1977).

Furthermore, it is impossible to transect exactly one blood vessel, because the transected tail region consists of a few major arteries and veins with mutual interaction between one another.

B.3.2 Arterial bleeding time in mesentery

PURPOSE AND RATIONALE

Arterial bleeding is induced by micropuncture of small arteries in the area supplied by the mesenteric artery. Bleeding is arrested in living blood vessels by the formation of a hemostatic plug due to the aggregation of platelets and to fibrin formation. In this test, compounds are evaluated which inhibit thrombus formation thus prolonging arterial bleeding time. The test is used to detect agents which interfere with primary hemostasis in small arteries.

PROCEDURE

Male Sprague-Dawley rats weighing 180–240 g receive the test compound or the vehicle (controls) by oral, intraperitoneal or intravenous administration. After the end of the absorption time (i.p. 30 min, p.o. 60 min, i.v. variable), the animals are anesthetized by intraperitoneal injection of 60 mg/kg pentobarbital sodium. Rats are placed on an electrically warmed table at 37 °C.

The abdomen is opened by a mid-line incision and the mesentery is lifted to display the mesenteric arteries. The mesentery is draped over a plastic plate and superfused continuously with Tyrode's solution maintained at 37 °C. Bleeding times are determined with small mesenteric arteries (125–250 µm external diameter) at the junction of mesentery with intestines. Adipose tissue surrounding the vessels is carefully cut with a surgical blade.

Arteries are punctured with a hypodermic needle (25 gauge: 16 × 5/10 mm). The bleeding time of the mesenteric blood vessels is observed through a microscope at a magnification of 40×. The time in seconds is determined from the puncturing until the bleeding is arrested by a hemostatic plug.

EVALUATION

1. Mean values of bleeding times [s] are determined for each dosage group (4–6 animals, 4–6 punctures each) and compared to the controls.

   The significance of the results is assessed with the unpaired Student's *t*-test.
2. The percent prolongation of bleeding time in dosage groups relative to the vehicle controls is calculated.

B.3.3 Template bleeding time method

PURPOSE AND RATIONALE

The template bleeding time methods is used to produce a standardized linear incision into the skin of humans to detect abnormalities of primary hemostasis due to deficiencies in the platelet or coagulation system. The method has been modified with the develop-

ment of a spring-loaded cassette with two disposable blades (Simplate II, Organon Teknika, Durham, NC). These template devices ensure reproducibility of length and depth of dermal incisions. Forsythe and Willis (1989) described a method which enables the Simplate technique as a method to analyze the bleeding time in the oral mucosa of dogs.

PROCEDURE

The dog is positioned in sternal or lateral recumbency. A strip of gauze is tied around both the mandible and maxilla as a muzzle. The template device is placed evenly against the buccal mucosa, parallel to the lip margin, and triggered. Simultaneously, a stopwatch is started. Blood flow from the incision is blotted using circular filter paper (Whatman No. 1, Fisher Scientific Co., Clifton, NJ) held directly below, but not touching the wounds. The position of the filter paper is changed every 15 s. The end point for each bleeding is determined when the filter paper no longer develops a red crescent.

EVALUATION

The time from triggering the device until blood no longer appears on the paper is recorded as the bleeding time. The normal range lies between two to four minutes.

CRITICAL ASSESSMENT OF THE METHOD

The template bleeding time varies considerably between laboratories as well as between species and strains. Therefore, it is important to perform the incisions and the blotting in an identical fashion. Prolonged bleeding times in dogs have been recognized with thrombocytopenia, von Willebrand's disease, uremia, treatment with aspirin, anticoagulants, and dextran (Forsythe and Willis 1989; Klement et al. 1998). Brassard and Meyers (1991) describe the buccal mucosa bleeding time as a test which is sensitive to platelet adhesion and aggregation deficits. Generally, results of antithrombotic drugs in bleeding time models in animals do not exactly predict bleeding risks in clinical situations. But the models allow comparison between drugs with different actions (Dejana et al. 1979; Lind et al. 1991).

MODIFICATIONS OF THE METHOD

The Simplate device can also be used to perform incisions at the shaved inner ear of rabbits taking care to avoid major vessels. The normal range of bleeding time in anaesthetized rabbits is approximately 100 s (77 ±4 s, $n = 20$) in our own laboratory (Just et al. unpublished).

Klement et al. (1998) described another ear bleeding model in anaesthetized rabbits. The shaved ear was immersed in a beaker containing saline at 37 °C. Five full-thickness cuts were made with a no. 11 Bard-Parker scalpel blade avoiding major vessels and the ear was immediately re-immersed in saline. At different times thereafter (5 to 30 min) aliquots of the saline solution were removed, red cells were sedimented and lysed, and cyanohemoglobin was determined as a measure of blood loss. In this study, hirudin produced more bleeding than standard heparin.

A cuticle bleeding time (toenail bleeding time) measurement in dogs has been described by Giles et al. (1982). A guillotine type toenail clipper is used to sever the apex of the nail cuticle. A clean transection of the nail is made just into the quick, to produce a free flow of blood. The nail is left to bleed freely. The time until bleeding stops is recorded as the bleeding time. Several nails can be cut at one time to ensure appropriate technique. The normal range lies between two to eight minutes.

B.4 Genetically modified animals

B.4.1 Knock out mice

PURPOSE AND RATIONALE

Genetically modified animals, in particular knock-out mice, help to understand the role of various factors in blood clotting, thrombolysis, and platelet function. They are useful to verify the mode of action of new drugs.

Factor I (Fibrinogen)

Phenotype

Born in normal appearance, ~10% die shortly after birth and another 40% around 1–2 months after birth due to bleeding, failure of pregnancy, blood samples fail to clot or support platelet aggregation *in vitro*.

References
Suh TT, Holmback K, Jensen NJ, Daugherty CC, Small K, Simon DI, Potter SS, Degen JL (1995) Resolution of spontaneous bleeding events but failure of pregnancy in fibrinogen-deficient mice. Genes Dev 9:2020–2033

Factor II (Prothrombin)

Phenotype
Partial embryonic lethality: 50% between embryonic day (E) 9.5–11.5; at least 1/4 survive to term, but fatal hemorrhage few days after birth; factor II important in maintaining vascular integrity during development as well as postnatal life.

References
Sun WY, Witte DP, Degen JL, Colbert MC, Burkart MC, Holmbäck K, Xiao Q, Bugge TH, Degen SJF (1998) Prothrombin deficiency results in embryonic and neonatal lethality in mice. Proc Natl Acad Sci USA 95:7597–7602

Factor V

Phenotype
Half of the embryos die at E9–10, possibly as a result of abnormal yolk sac vasculature, remaining 50% progress normally to term, but die from massive hemorrhage within 2 h of birth, more severe in mouse than in human (due to residual activity in humans).

References

Yang TL, Cui J, Taylor JM, Yang A, Gruber SB. Ginsburg D (2000) Rescue of fatal neonatal hemorrhage in factor V deficient mice by low level transgene expression. Thromb Haemost 83:70–77

Factor VII

Phenotype
Develop normally but suffer fatal perinatal bleeding.

References
Rosen ED, Chan JCY, Idusogie E, Clotman F, Vlasuk G, Luther T, Jalbert LR, Albrecht S, Zhong L, Lissens A, Schoonjans L, Moons L, Collen D, Castellino FJ, Carmeliet P (1997) Mice lacking factor VII develop normally but suffer fatal perinatal bleeding. Nature 390:290–294

Factor VIII

Phenotype
Mild phenotype compared with severe hemophilia A in humans; no spontaneous bleeding, illness or reduced activity during the first year of life; have residual clotting activity (APTT).

References
Bi L, Lawler AM, Antonarakis SE, High KA, Gearhart JD, Kazaazian HH (1995) Targeted disruption of the mouse factor VIII gene produces a model of haemophilia A. Nat Genet 10: 119–121

Factor IX

Phenotype
Factor IX coagulant activities (APTT): +/+ 92%, +/– 53%, –/– <5%; bleeding disorder (extensive bleeding after clipping a portion of the tail, bleeding to death if not cauterized.

References
Kundu RK, Sangiorgi F, Wu LY, Karachi K, Anderson WF, Maxson R, Gordon EM (1998) Targeted inactivation of the coagulation factor IX gene causes hemophilia B in mice. Blood 92: 168–174

Factor X

Phenotype
Partial embryonic lethality (1/3 died on E11.5-12.5); fatal neonatal bleeding between postnatal day (P) 5-20.

References
Dewerchin M,, Liang Z, Moons L, Carmeliet P, Castellino FJ, Collen D, Rosen ED (2000) Blood coagulation factor X deficiency causes partial embryonic lethality and fatal neonatal bleeding in mice. Thromb Haemost 83:185–190

Factor XI

Phenotype
APTT prolonged in –/– (158–200 s) compared with +/+ (25–34 s) and +/– (40–61 s); no factor XI activity and antigen, did not result in intrauterine death, –/– similar bleeding as +/+ with a tendency to prolongation.

References
Gailani D, Lasky NM, Broze GJ (1997) A murine model of factor XI deficiency. Blood Coagul Fibrinolysis 8:134–144

Factor XII
Not described

Factor XIII
Not described

TF (tissue factor)

Phenotype
Abnormal circulation from yolk sac to embryo ~E8.5 leading to embryo wasting and death; TF has a role in blood vessel development.

References
Bugge TH, Xiao Q, Kombrinck KW, Flick MJ, Holmback K (1996) Fatal embryonic bleeding events in mice lacking tissue factor, the cell-associated initiator of blood coagulation. Proc Natl Acad Sci U S A 93:6258–6263

TFPI (tissue factor pathway inhibitor)

Phenotype
None survive the neonatal period; 60% die between E9.5–11.5 with signs of yolk sac hemorrhage.

References
Huang ZF, Higuchi D, Lasky N, Broze GJ (1997) Tissue factor pathway inhibitor gene disruption produces intrauterine lethality in mice. Blood 90:944–951

Thrombin receptor

Phenotype
50% die at E9–10; 50% survive and become grossly normal adult mice with no bleeding diathesis; –/– platelets strongly respond to thrombin; –/– fibroblast loose their ability to respond to thrombin → second TR must exist.

References

Protein C

Phenotype
KO mice appeared to develop normally macroscopically, but possessed obvious signs of bleeding and thrombosis; did not survive beyond 24 h after delivery; microvascular thrombosis in the brain and necrosis in the liver; plasma clottable fibrinogen was not detectable suggesting fibrinogen depletion and secondary consumptive coagulopathy.

TAFI (thrombin activatable fibrinolysis inhibitor)

Not described

Vitronectin

Phenotype

Normal development, fertility, and survival; serum is completely deficient in "serum spreading factor" and plasminogen activator inhibitor 1 binding activities; delayed arterial and venous thrombus formation.

References

Eitzman DT, Westrick RJ, Nabel EG, Ginsburg D (2000) Plasminogenactivator inhibitor-1 and vitronectin promote vascular thrombosis in mice. Blood 95:577–580

Zheng X, Sunders TL, Camper SA, Samuelson LC, Ginsburg D (1995) Vitronectin is not essential for normal mammalian development and fertility. Proc Natl Acad Sci USA 92: 12426–12430

Urokinase, u-PA (urinary-type plasminogen activator)

Phenotype

Single u-PA deficiency: viable, fertile, normal life span; occasionally spontaneous fibrin deposits in normal and inflamed tissue; higher incidence of endotoxin-induced thrombosis. Combined t-PA and u-PA deficiency: mice survive embryonic development; retarded growth, reduced fertility, shortened life span; spontaneous fibrin deposits more extensively and in more organs.

Transgenic mice carrying the u-PA gene linked to the albumin enhancer/promoter exhibit spontaneous intestinal and intraabdominal bleeding directly related to transgene expression in the liver and elevated plasma u-PA levels. 50% die between 3 and 84 h after birth; severe hypofibrinogenemia, loss of clotting function.

Gas 6 (growth arrest-specific gene 6 product)

Phenotype

Mice are viable, fertile, appear normal; do not suffer spontaneous bleeding or thrombosis; have normal tail bleeding time. Platelets fail to aggregate irreversibly to ADP, collagen, or U 46619. Arterial and venous thrombosis is inhibited and mice are protected from fatal thromboembolism after injection of collagen plus epinephrine.

GPIbalpha (glycoprotein Ib alpha, part of the GP Ib-V-IX complex)

Phenotype

Bleeding, thrombocytopenia and giant platelets (similar to human Bernard Soulier syndrome).

References

Ware J, Russell S, Ruggeri ZM (2000) Generation and rescue of a murine model of platelet dysfunction: the Bernard-Soulier syndrome. Proc Natl Acad Sci USA 97:2803–2808

GPV (glycoprotein V, part of the GP Ib-V-IX complex)

Phenotype

Increased thrombin responsiveness, GpV–/– platelets are normal in size, normal amounts in GpIb-IX, functional in vWF-binding; platelets are hyperresponsive to thrombin → increased aggregation response; shorter bleeding time; → GpV = negative modulator of platelet function.

References

GP IIa (glycoprotein IIa, integrin beta 1, part of the GP Ia-IIa complex)

Phenotype

Integrin beta1 null platelets from conditional knockout mice develop normally, platelet count is normal.

Collagen induced platelet aggregation is delayed but otherwise normal; tyrosine phosphorylation pattern is normal but phosphorylation is delayed. Bleeding time in bone marrow chimeric mice is normal; no major *in vivo* defects.

References

Pallid (Pa)

Phenotype

Among 13 hypopigment mouse mutants with storage pool deficiency, the pallid mouse is a model of the human Hermansky Pudlak syndrome (the beige mouse is a model of the Chediak Higashi syndrome). Pallid mice exhibit prolonged bleeding time, pigment dilution, kidney lysosomal enzyme elevation serum alpha 1 antitrypsin deficiency and abnormal otolith formation. The gene defective in pallid mice encodes the highly charged 172-amino acid protein pallidin which interacts with syntaxin 13, a protein mediating vesicle docking and fusion.

Arachidonate 12-lipoxygenase (P-12LO)

Phenotype

Platelets exhibit a selective hypersensitivity to ADP, manifested as a marked increase in slope and percent aggregation in *ex vivo* assays and increased mortality in an ADP-induced mouse model of thromboembolism.

References

Johnson EN, Brass LF, Funk CD (1998) Increased platelet sensitivity to ADP in mice lacking platelet-type 12-lipoxygenase. Proc Natl Acad Sci USA 95:3100–3105

Arachidonate 5-lipoxygenase (P-5LO)

Phenotype

Develop normally and are healthy. No difference in their reaction to endotoxin shock, however resist the lethal effects of shock induced by platelet-activating factor. Inflammation induced by arachidonic acid is markedly reduced.

References

Chen XS, Sheller JR, Johnson EN, Funk CD (1994) Role of leukotrienes revealed by targeted disruption of the 5-lipoxygenase gene. Nature 372:179–182

Thrombopoietin

Phenotype

TPO –/– and c-mpl –/–: both exhibit a 90% reduction in megakaryocyte and platelet levels; but even with these small platelet levels the mice do not have excessive bleeding; all platelets which are present are morphologically normal + functionally; *in vivo* TPO is required for control of megakaryocyte and platelet number but not for their maturation.

C.1
Diuretic and saluretic activity

C.1.1
In vitro methods

C.1.1.1
Carbonic anhydrase inhibition *in vitro*

PURPOSE AND RATIONALE

Acetazolamide (Diamox®) was one of the first synthetic non-mercurial diuretics. The mode of action was found to be inhibition of carbonic anhydrase. Carbonic anhydrase is a zinc-containing enzyme that catalyzes the reversible hydration (or hydroxylation) of CO_2 to form H_2CO_3 which dissociates non-enzymatically into HCO_3^- and H^+. At least three isoenzymes, designated as I, II and II or A, B and C, are known to exist. The chemistry, physiology and pharmacology of carbonic anhydrase has been extensively reviewed by Maren (1967). In spite of the fact that newer diuretics are based on

other modes of action, the test for inhibition of carbonic anhydrase should be performed for evaluation of a new compound. Moreover, the specific use of carbonic anhydrase inhibitors as antiglaucoma drugs has been described (Friedland and Maren 1984; Caprioli 1985). The mechanism by which carbonic anhydrase inhibitors lower intraocular pressure is through a reduction in aqueous humor formation, by affecting electrolyte and water balance in the nonpigmented ciliary epithelium (Friedland and Maren 1984; Caprioli 1985). Although many methods to measure carbonic anhydrase activity have been developed (Philpot and Philpot 1936), the micro method described by Maren (1960) is relatively simple, sensitive and reliable. The enzyme source are red cells, a rich source of the same isoenzymes found in the eye (Maren 1967; Armstrong et al. 1966; Wistrand et al. 1986; Wistrand and Knuutila 1980).

PROCEDURE

Materials and solutions

- phenol red indicator solution:
  12.5 mg phenol red/liter 2.6 mM $NaHCO_3$, pH 8.3 + 218 mM Na_2CO_3
- 1 M sodium carbonate/bicarbonate buffer, pH 9.8
- Enzyme: Carbonic anhydrase from dog blood; Blood is collected into a heparinized tube and diluted 1:100 with deionized water.
- Equipment
  - Reaction vessel – custom made by Labglass Inc., Vineland, NJ, USA
  - Monostat bench mounted flowmeter
  - 30% CO_2 – M&G Gases, Branchburg, NJ, USA

Assay

CO_2 flow rate is adjusted to 30 (45) ml/min. The following solutions are added to the reaction vessel:

400 µl phenol red indicator solution
100 µl enzyme
200 µl H_2O or appropriate drug concentration after 3 min for equilibration:
100 µl carbonate/bicarbonate buffer is added.

The following parameters are determined in duplicate samples:

T_u = (uncatalyzed time) = time for the color change to occur in the absence of enzyme.
T_e = (catalyzed time) = time for the color change to occur in the presence of the enzyme.
$T_u - T_e$ = enzyme rate
T_i = enzyme rate in the presence of various concentrations of inhibitor

EVALUATION

Percent inhibition of carbonic anhydrase is calculated according to the following formula:

$$\% \text{ Inhibition} = 1 - \frac{(T_u - T_e) - (T_i - T_e)}{T_u - T_e} \times 100$$

Standard data:

Compound	IC_{50} [M]
Acetazolamide	9.0×10^{-9}
Chlorothiazide	9.0×10^{-7}

CRITICAL ASSESSMENT OF THE METHOD

Determination of carbonic anhydrase inhibition is of value to characterize the activity spectrum of sulfonamide diuretics.

MODIFICATIONS OF THE METHOD

Landolfi et al. (1997) reported a modified procedure for the measurement of carbonic anhydrase activity. The measure of carbonic anhydrase activity is based on the rate of CO_2 hydration by the enzyme. Such transformation was monitored by a procedure which consists in the measure of time necessary for the pH of an appropriate buffer to decrease from 8 to 7.5 in the presence of a constant CO_2 flow: such time period is dose-dependently reduced by the addition of the enzyme and further modified in the presence of carbonic anhydrase inhibitory compounds.

C.1.1.2 Patch clamp technique in kidney cells[2]

PURPOSE AND RATIONALE

In the different parts of the kidney (proximal tubules, distal tubules, collecting ducts) fluid is reabsorbed and substances may be transported either from the tubule lumen to the blood side (reabsorption) or vice versa (secretion). Besides active transport and coupled transport systems, ion channels play an important role in the function of kidney cells. The various modes of the patch clamp technique (cell-attached, cell-excised, whole-cell mode) (Neher and Sakmann 1976; Hamill et al. 1981) allow the investigation of ion channels. In addition, the investigation of other electrogenic transport mechanisms, such as the sodium-coupled alanine transport can be studied.

PROCEDURE

The patch clamp technique can be applied to cultured kidney cells (Merot et al. 1988), to freshly isolated kidney cells (Hoyer and Gögelein 1991) or to cells of isolated perfused kidney tubules (Gögelein and Greger 1984). The latter method shall be described in more detail.

Segments of late superficial proximal tubules of rabbit kidney are dissected and perfused from one end with a perfusion system (Burg et al. 1966; Greger and Hampel 1981). The non-cannulated end of the tubule is freely accessible to a patch pipette. Under optical control (differential interference contrast optics with 400× magnification) the patch pipette can be moved through the open end into the tubule lumen and is brought in contact with the brush border membrane. After slight suction of the patch electrode, gigaseals form instantaneously and single potassium or sodium channels can be recorded in the cell-attached or inside-out cell-excised mode (Gögelein and Greger 1984; Gögelein and Greger 1986a).

In order to obtain exposed lateral cell membranes suitable to the application of the patch clamp method, pieces of the tubule are torn off by means of a glass pipette (diameter about 40 µm). As to facilitate the tearing off, the tubules are incubated for about 5 min in 0.5 g/l collagenase (Sigma, C 2139) at room temperature. After tearing off part of the cannulated tubule, clean lateral cell membranes are exposed at the non-cannulated end. The patch pipette can be moved to the lateral cell membrane and gigaseals can be obtained. It was possible, to investigate potassium channels (Gögelein and Greger 1987) and nonselective cation channels (Gögelein and Greger 1986b) in these membranes.

As cells are still part of an epithelial layer and, therefore, are intracellularly coupled, the whole-cell technique is not appropriate in this preparation. On the other hand, cotransport systems can only be investigated by the whole-cell method because the transport rate of a single event is much too small to be resolved in a similar manner as single ion channel events. Consequently, cells of rabbit proximal tubules are isolated as described in detail elsewhere (Hoyer and Gögelein 1991; Heidrich and Dew 1977). After cervical dislocation the kidneys are rapidly excised and placed in ice-cold solution [mmol/l]: 150 K-cyclamate, 10 HEPES, 1 $CaCl_2$, 1 $MgCl_2$, pH 7.4. The following steps are performed on ice: After decapsulation, superficial cortical slices of about 0.5 mm thickness are dissected and minced with a scalpel. The tissue is homogenized in a Dounce homogenizer by three strokes with a loose-fitting pestle. The homogenate is then poured through graded sieves (250, 75 and 40 µm) to obtain a population of single cells. Since the predominant tubule section of the cortex of the rabbit kidney is the pars convoluta of the proximal tubule, it can be concluded that the majority of the isolated cells in the cell suspension are of proximal tubule origin. By light microscopy cells are identified by long microvilli distributed over the entire cell surface and can easily be discriminated from remaining erythrocytes, cell detritus and tubular fragments.

By application of the whole-cell mode of the patch clamp technique to freshly isolated cells of convoluted proximal tubules, the sodium-alanine cotransport system could be investigated in detail (Hoyer and Gögelein 1991).

EVALUATION

In isolated perfused renal tubules, concentration response curves of drugs which inhibit ion channels can be obtained with the patch clamp technique. In isolated cells of the proximal tubule, the whole-cell mode of the patch clamp technique enables the investigation of the sodium-alanine cotransport system. The apparent K_m values for sodium and L-alanine can be recorded.

MODIFICATIONS OF THE METHOD

Schlatter (1993) recorded membrane voltages of macula densa cells with the fast or slow whole-cell patch-clamp method. The effects of diuretics and the conductance properties of these cells were examined.

C.1.1.3 Perfusion of isolated kidney tubules[3]

PURPOSE AND RATIONALE

The various tubule segments: proximal tubule (PT, S1–S3); descending thin limb of the loop of Henle (DTL); ascending thin limb of the loop of Henle (ATL); thick ascending limb of the loop of Henle (TAL); distal convoluted tubule (DCT); connecting tubule (CNT); cortical collecting duct (CCD); medullary collecting duct (MCD); papillary collecting duct (PCD) have different functional properties. The *in vitro* perfusion of isolated tubule segments (Burg et al. 1966) is the method of choice if one has to identify the site and the mechanism of action of a pharmacological agent which has been shown to act on kidney function in clearance and micropuncture studies.

PROCEDURE

After its invention by Burg et al. (1966) this technique has been used successfully in the kidney tubule segments of several species: man; rabbit; rat; mouse; hamster; snake; birds etc. The tubule segments are dissected from thin kidney slices (<1 mm thickness). Usually dissection can be done using sharpened forceps or needles without the addition of proteases (collagenase). The segment is identified by its anatomical location and by its appearance. A 20–50× lens is used for dissection. Dark field illumination is helpful for the identification of the segment under study. PT, TAL, DCT, CNT, CCD, MCD can all be dissected quite easily. The dissection of DTL, ATL and PCD is much more difficult because these segments are damaged easily by the mechanical dissection. Dissection is usually performed at 4 °C in a Ringer type solution.

The dissected segment is transferred into the perfusion chamber by a transfer pipette. The perfusion chamber is mounted in the stage of an inverted microscope (20–400×). The chamber is usually kept at 37 °C, and the bath perfusate is also preheated to this temperature. The bath perfusate will depend on the tubule segment under study. In most instances it will contain HCO_3^- and will be bubbled with CO_2. The metabolic substrate will be acetate for PT and D-glucose for TAL, CCD etc. The actual perfusion is performed with two sets of concentric glass pipettes, one set at the perfusion end; and one at the collection end of the segment. These pipettes are manufactured with special glass forges. The most refined one has been designed by Hampel and Greger. The glass tube is rotated at approximately 1 rps, is moved in perpendicular direction by a remote control, and the heating filament is moved in xy direction also by a remote control. The shaping of the glass is observed continuously by a lens (5–50×). The pulling force is provided by weights fixed on the lower end of the glass tube. The pipettes are cut either by a diamond or by the pulling force of a small glass bead, fixed on the edge of a vertical platinum filament and melted sidewise on the pipette. When the heating current of the platinum filament is switched off the filament retracts and brakes the pipette a the desired site. Greger and Hampel (1981) have modified the original perfusion system of Burg and co-workers. Their device is optimized inasmuch as it guarantees concentric alignment of the various pipettes. The forward and backward movement is controlled by small electric motors. At the perfusion side they use 4 concentric pipettes. The outermost one contains sylgard and is driven over the perfused end of the tubule in order to seal this end. The tubule is held by a holding pipette with appropriate dimensions. The tubule is sucked into this pipette up to the constriction. Then the perfusion pipette with a tip diameter smaller than the inner diameter of the perfused segment is advanced into the segment held by the holding pipette. The perfusion pipette is put under hydrostatic pressure of a few to

[3] Contribution by R. Greger (first edition) and M. Bleich (second edition).

100 cm to achieve a perfusion rate of 1–20 nl/min. Usually the collapsed tubule lumen opens when the perfusion pipette is advanced. The pipette is advanced in the lumen until it reaches an area of the segment where it appears intact by inspection (200–400×). Within its lumen the perfusion pipette contains yet another pipette, the fluid exchange pipette. With this pipette the composition of the perfusate can be replaced very rapidly (Greger and Schlatter 1983). The collection end of the tubule segment is sucked into a holding pipette. A sylgard pipette is advanced to seal the collection site. The holding pipette at the collection site will contain mineral oil in flux measurements. Then a collection pipette is advanced through the oil to quantitatively collect the perfusate delivered by the tubule.

The **measured parameters** can be as follows:

Flux measurements (Schafer et al. 1974). The collection rate (V_c, nl/min) can be measured by the constant bore collection pipette by timed collections. Radioactive tracers can be added to the lumen or bath fluid. For instance, radioactively labelled inulin can be added to the perfusate (In_p) and can be used to measure volume absorption (ΔV = perfusion rate ($V_i - V_c$). Unidirectional fluxes, bath to lumen and lumen to bath, for any given substance can be quantified, and permeabilities (P_x) can be determined:

$$P_x = (V_i - V_c)\, L^{-1} [\ln (x_p In_c x_c^{-1} In_p) + 1]$$

where L is the length of the segment; x_p and x_c are the concentrations of x in the perfusate and in the collected fluid; and In_c is the inulin concentration in the collected fluid. Net fluxes of x can be determined as the difference of the unidirectional fluxes or by the chemical determination of Δx (perfusate – collected fluid). This requires very sensitive methods. Electron probe analysis of Na^+, K^+, Ca^{2+}, Mg^{2+} etc. has been used to determine the net transport of these ions in various tubule segments (Wittner et al. 1988). Flux studies are usually performed at low luminal perfusion rates of a few nl/min. Substances under study can be added to the luminal and bath perfusate, and paired data can be obtained under control and experimental conditions (Burg and Green 1973; Stoner et al. 1974; Burg 1980; Burg and Stoner 1976; Dillingham et al. 1993).

Transepithelial electrical measurements. The perfusion pipette can be connected to the high impedance input of an electrometer. The voltage is referenced to the grounded bath. The connections are usually made with agar bridges (80 g agar in 1 l Ringer's solution), and appropriate corrections for liquid junction voltages must be applied. With identical solutions in the bath and in the lumen and with high luminal perfusion rates (> 10 nl/min), any transepithelial voltage (V_{te}) must be caused by active transport = active transport potential (Frömter 1984). Hence, the effectiveness of putative inhibitors of active transport can also be examined by the measurement of V_{te}. According to Ohm's law the determination of the flux of ions also requires the measurement of transepithelial resistance. Greger (1981) has introduced a method which utilizes a dual channel perfusion pipette, made of Q-shaped glass. One channel is used for perfusion and the other for current (I_{te}) injection. The current is defined by a resistor chosen such that the deflection in V_{te} generated by this pulse is in the order of 10–20 mV. Transepithelial resistance (R_{te}) can now be calculated from ΔV_{te} and I_{te}. The ratio of V_{te} and R_{te} is called equivalent short circuit current. It is directly proportional to active transport (Greger 1985). The measurement of V_{te} and R_{te} is much more efficient than flux studies for pharmacological screening, provided that the process under study produces a transepithelial voltage. Several substances can be examined in one single tubule in strictly paired fashion (Schlatter et al. 1983; Wangemann et al. 1986). The time resolution of the measurements is on the order of 1 s, whereas that of flux studies is several minutes at best.

Intracellular electrical measurements. Greger and Schlatter (1983) have developed a method for the use of impalement techniques in the isolated perfused tubule. Very fine tip microelectrodes (Ø < 100 nm) are used to impale the tubule cell across the basolateral membrane. The actual impalement is performed by a piezo stepper which accelerates the microelectrode to high speed, which makes it possible to penetrate the rigid basal membrane. The simultaneous measurement of V_{te}, R_{te}, and basolateral membrane voltage (V_{bl}) allows for a complete analysis of voltages and resistances (Greger 1985; Ullrich and Greger 1985). Ion selective microelectrodes can also be used in impalement studies, and the cytosolic ion activities for e.g. Na^+, K^+, Cl^- can also be determined (Greger 1985). These methods are all rather difficult to perform. They are of high relevance for the understanding of the function of a given tubule segment and for the detailed description of the mechanism of action of a drug, which, in preceding studies has been shown to act in a given tubule segment.

Patch clamp studies. The combination of *in vitro* perfusion of renal tubules and patch clamp analysis of ion channels in the luminal and basolateral membranes is described in Sect. C.1.1.2.

Fluorescent dyes in the isolated perfused tubule. Several fluorescent dyes for the monitoring of Na^+, K^+,

Cl^-, Ca^{2+}, pH have become available during the past few years. These dyes can be used in the *in vitro* perfused tubule (Nitschke et al. 1991). The inverted microscope is equipped with an appropriate illumination and filter wheel for excitation. The emission is measured by photon counting or by a video camera. When compared with impalement methods, these techniques are probably easier for routine use.

EVALUATION

For each of the above protocols paired measurements of one or several given parameters of tubule transport are obtained under control conditions and in the presence of a substance under study. Also concentration response curves can be obtained in one single preparation (Schlatter et al. 1983; Wangemann et al. 1986; Wittner et al. 1987). Intracellular measurements are usually required to define the mechanism of action (Greger 1985). Especially the electrical and optical measurements have a very high reproducibility. For screening usually 3 preparations are sufficient. Approximately 10 preparations are required for concentration response curves.

C.1.1.4 Isolated perfused kidney

PURPOSE AND RATIONALE

Isolated kidney is a good tool for studying proximal tubule, but of limited value for distal tubule function. The kidney can be perfused *in situ* and isolated *in vitro*. The isolated kidney can be perfused by a pump using blood or plasma-like solutions. One specific problem of the blood-perfused dog kidney *in vitro* is its instability. After only 1 h of perfusion, glomerular filtration and renal blood flow decline markedly. It was reported that *in situ*-perfused isolated dog kidney seems to be more stable. In isolated perfused rat kidney plasma-like solutions are used for perfusion. This system, by inclusion of a dialyzing unit, provides optimal conditions for maintaining a constant electrolyte composition of the perfusate. However, function of distal tubule is also grossly impaired in this rat model. The isolated kidney does not acidify tubular fluid, and the concentrating ability is reduced.

PROCEDURE

Kidneys are obtained from anaesthetized male rats with a body weight of 300 to 400 g. The donor animals are fasted overnight prior to surgery, but have free access to water. After the abdominal cavity is exposed by a

ventricular incision, the right ureter is cannulated with PE-50 polyethylene tubing and heparin is injected into the vena cava (500 U/kg body weight). The venous cannula is introduced into the vena cava below the right renal vein. The right kidney is freed from the perirenal fat, not disrupting the renal capsule. The renal artery is cannulated via the superior mesenteric artery without interruption of flow. Thereafter, the kidney is continuously perfused with a perfusion solution fed from the gravity system situated 130 cm above the cannula. Ligatures around the renal artery and vena cava above the renal pedicle are tied. The kidney is then removed from the animal and placed in a Plexiglas chamber. A perfusion pressure of 80–90 mm Hg in the renal artery is maintained by adjusting the speed of the perfusion pump. For more details see references.

EVALUATION

After the equilibration period, clearance periods of 20 min are used. Urine samples are collected and perfusate is obtained at midpoint of the clearance period for the evaluation of overall kidney function. For determination of glomerular filtration rate (GFR) and fluid transport, ^{3}H-labelled polyethylene glycol is added to a modified Krebs-Henseleit bicarbonate buffer. Electrolytes are determined in urine by standard flame photometry. Fractional excretions of water, electrolytes and test compounds are calculated.

MODIFICATIONS OF THE METHOD

Tarako et al. (1991) evaluated oxygen supply and energy state in the isolated perfused rat kidney.

Metabolic activities of the isolated perfused rat kidney were described by Nishiitsutsuji-Uwo et al. (1967).

Cox et al. (1990) used the isolated perfused rat kidney as a tool in the investigation of renal handling and effects of nonsteroidal anti-inflammatory drugs.

C.1.2 *In vivo* methods

C.1.2.1 Diuretic activity in rats (LIPSCHITZ test)

PURPOSE AND RATIONALE

A method for testing diuretic activity in rats has been described by Lipschitz et al. (1943). The test is based on water and sodium excretion in test animals and compared to rats treated with a high dose of urea. The "Lipschitz-value" is the quotient between excretion by test animals and excretion by the urea control.

PROCEDURE

Male Wistar rats weighing 100–200 g are used. Three animals per group are placed in metabolic cages provided with a wire mesh bottom and a funnel to collect the urine. Stainless-steel sieves are placed in the funnel to retain feces and to allow the urine to pass. The rats are fed with standard diet (Altromin® pellets) and water ad libitum. Fifteen hours prior to the experiment food and water are withdrawn. Three animals are placed in one metabolic cage. For screening procedures two groups of three animals are used for one dose of the test compound. The test compound is applied orally at a dose of 50 mg/kg in 5.0 ml water/kg body weight. Two groups of 3 animals receive orally 1 g/kg urea. Additionally, 5 ml of 0.9% NaCl solution per 100 g body weight are given by gavage. Urine excretion is recorded after 5 and after 24 h. The sodium content of the urine is determined by flame photometry. Active compounds are tested again with lower doses.

EVALUATION

Urine volume excreted per 100 g body weight is calculated for each group. Results are expressed as the "Lipschitz-value", i.e., the ratio T/U, in which T is the response of the test compound, and U, that of urea treatment. Indices of 1.0 and more are regarded as a positive effect. With potent diuretics, Lipschitz values of 2.0 and more can be found. Calculating this index for the 24 h excretion period as well as for 5 h indicates the duration of the diuretic effect. Similar to urine volume, quotients can be calculated for sodium excretion.

Dose-response curves can be established using various doses. Loop diuretics are characterized by a steep dose-response curve. Saluretic drugs, like hydrochlorothiazide, show Lipschitz values around 1.8, whereas loop diuretics (or high ceiling diuretics) like furosemide, bumetanide or piretanide reach values of 4.0 and more.

CRITICAL ASSESSMENT OF THE METHOD

The Lipschitz test has been proven to be a standard method and a very useful tool for screening of potential diuretics.

MODIFICATIONS OF THE METHOD

The method has been modified in various ways by several authors. Cummings et al. (1960) recommended a sequential procedure with criteria for acceptance or rejection of test drugs. Kau et al. (1984) recommended a method for screening diuretic agents in the rat using normal saline (4% body weight) as hydrating fluid.

Homozygous Brattleboro rats exhibit symptoms of diabetes insipidus (Valtin et al. 1965). The condition is due to the failure of hypothalamic neurons to produce vasopressin, which is due to a single base point deletion in the vasopressin gene (Schmale and Richter 1984). The abnormal quinine drinking aversion in the Brattleboro rat with diabetes insipidus is reversed by a vasopressin agonist (Laycock et al. 1994).

These animals can be used to study vasopressin agonism and antagonism and the aquaretic effects of synthetic drugs.

Klatt et al. (1975) described a method of collecting urine excreted by cats. On the basis of urine funnel used in rats, an appropriate larger metabolism cage made out of transparent, rigid polyvinyl chloride was used. The cage was improved by a built-in sieve cone which assured good separation of urine and feces. A device to measure and record the time and amount of voided urine was attached. Urine was collected in a vessel with a hose connection from the bottom to a pressure sensor. An attached overflow tube could be occluded. The initial pressure of the sensor was fed into a linear recorder. Before the test, the recorder was calibrated with a sufficient amount of distilled water to adjust the number of division intervals for direct measurement of voided urine in milliliters. This allowed calculation of the time point of voiding from the chart speed.

C.1.2.2 Saluretic activity in rats

PURPOSE AND RATIONALE

Excretion of electrolytes is as important as the excretion of water for treatment of peripheral edema and ascites in congestive heart failure as well as for treatment of hypertension. Potassium loss has to be avoided. As a consequence, saluretic drugs and potassium-sparing diuretics were developed. The diuresis test in rats was modified in such a way that potassium and chloride as well as osmolality are determined in addition to water and sodium. Ratios between electrolytes can be calculated indicating carbonic anhydrase inhibition or a potassium sparing effect.

PROCEDURE

Male Wistar rats weighing 100–200 g fed with standard diet (Altromin® pellets) and water ad libitum are used. Fifteen hours prior to the test, food but not water is withdrawn. Test compounds are applied in a dose of

50 mg/kg orally in 0.5 ml/100 g body weight starch suspension. Three animals are placed in one metabolic cage provided with a wire mesh bottom and a funnel to collect the urine. Two groups of 3 animals are used for each dose of a test drug. Urine excretion is registered every hour up to 5 h. The 5-h urine is analyzed by flame photometry for sodium and potassium and argentometrically by potentiometrical end point titration (Chloride-Titrator Aminco) for chloride. To evaluate compounds with prolonged effects the 24 h urine is collected and analyzed. Furosemide (25 mg/kg p.o.), hydrochlorothiazide (25 mg/kg p.o.), triamterene (50 mg/kg p.o.), or amiloride (50 mg/kg p.o.) are used as standards.

EVALUATION

- The sum of Na^+ and Cl^- excretion is calculated as parameter for saluretic activity.
- The ratio Na^+/K^+ is calculated for natriuretic activity. Values greater than 2.0 indicate a favorable natriuretic effect. Ratios greater than 10.0 indicate a potassium-sparing effect.
- The ratio

$$\frac{Cl^-}{Na^+ + K^+}$$

(ion quotient) is calculated to estimate carbonic anhydrase inhibition.
- Carbonic anhydrase inhibition can be excluded at ratios between 1.0 and 0.8. With decreasing ratios slight to strong carbonic anhydrase inhibition can be assumed.

MODIFICATIONS OF THE METHOD

Adrenalectomized rats treated with DOCA or aldosterone can be utilized to test **aldosterone antagonists**. Spironolactone has no effect in the absence of a mineralocorticoid, but reverses in a dose-related manner the effect of DOCA on the Na^+/K^+ ratio in the urine (Kagawa et al. 1957; Bicking et al. 1965).

C.1.2.3 Diuretic and saluretic activity in dogs

PURPOSE AND RATIONALE

Dogs have been extensively used to study renal physiology and the action of diuretics. Renal physiology of the dog is claimed to be closer to man than that of rats. Oral absorbability of diuretic substances can appropriately be studied in dogs. Using catheters, interval collections of urine can be made with more reliability than in rats. Simultaneously, blood samples can be withdrawn to study pharmacokinetics.

PROCEDURE

Beagle dogs of either sex have to undergo intensive training to be accustomed to accept gavage feeding and hourly catheterization without any resistance. The dogs are placed in metabolic cages. At least 4 dogs are used as controls receiving water only, as standard controls (1 g/kg urea p.o. or 5 mg/kg furosemide p.o.) or the test drug group. Twenty-four hours prior to the experiment food but not water is withheld. On the morning of the experiment, the urine bladder is emptied with a plastic catheter. The dogs receive 20 ml/kg body weight water by gavage, followed by hourly doses of 4 ml/kg body weight drinking water. The bladder is catheterized twice in an interval of 1 h and the urine collected for analysis of initial values. Then, the test compound or the standard is applied either orally or intravenously. Hourly catheterization is repeated over the next 6 h. Without further water dosage the animals are placed in metabolic cages overnight. Twenty-four hours after dosage of the test compound, the dogs are catheterized once more and this urine together with the urine collected over night in the metabolic cage registered. All urine samples are analyzed by flame photometry for sodium and potassium and by argentometry (Chloride Titrator Aminco) for chloride content. Furthermore, osmolality is measured with an Osmometer.

EVALUATION

Urine volume, electrolyte concentrations and osmolality are averaged for each group. The values are plotted against time to allow comparison with pretreatment values as well as with water controls and standards. The non-parametric U-test is used for statistical analysis.

C.1.2.4 Clearance methods[4]

PURPOSE AND RATIONALE

Investigations of clearance represent indirect methods for the evaluation of renal function and provide information on the site of action of diuretics and other pharmacological agents within the nephron. The discovery of the countercurrent multiplier system as the mechanism responsible for the concentration and dilution of the urine has been the prerequisite for the identification of the site of action of diuretic drugs. A drug that acts solely in the proximal convoluted tubule, by causing the delivery of the increased amounts of filtrate to the loop of Henle and the distal convolution, would augment the clearance of solute-free water (C_{H_2O}) during water diuresis and the reabsorption of solute-free water (T_{CH_2O}) during water restriction. In contrast, drugs that inhibit sodium reabsorption in Henle's loop would impair both C_{H_2O} and T_{CH_2O}. On the other hand, drugs that act only in the distal tubule would reduce C_{H_2O} but not T_{CH_2O}.

PROCEDURE

Clearance experiments are performed either in conscious or anaesthetized beagle dogs under conditions of water diuresis and hydropenia. The status of water diuresis and hydropenia may be accomplished as described by Suki et al. (1965). Water diuresis is induced by oral administration of 50 ml of water per kg body weight and maintained by continuos infusion into jugular vein of 2.5% glucose solution and 0.58% NaCl solution at 0.5 ml/min per kg body weight. When water diuresis is well established, the glucose infusion is discontinued and control urine samples are collected by urethral catheter. Blood samples are obtained in the middle of each clearance period. After the control period, compounds to be tested are administered and further clearance tests are performed.

Hydropenia is induced by withdrawing the drinking water 48 h before experiment. On the day before the experiment 0.5 U/kg body weight of vasopressin in oil is injected intramuscularly. On the day of the experiment 20 mU/kg vasopressin is injected i.v., followed by infusion of 50 mU/kg per hour vasopressin. To accomplish constant urine flow 5% NaCl solution is infused at 1 ml/min per kg body weight up to i.v. administration of a compound to be tested, followed by i.v. infusion of 0.9% NaCl solution at a rate equal to the urine flow. Glomerular filtration rate (GFR) and renal plasma flow (RPF) are measured by the clearance of inulin and para-aminohippurate, respectively. Therefore, appropriate infusion of inulin (bolus of 0.08 g/kg followed by infusion of 1.5 mg/kg per min) and para-aminohippurate (bolus 0.04 g/kg followed by infusion of 0.3 mg/kg per min) are initiated. Inulin and para-aminohippurate are measured according to Walser et al. (1955) and Smith and al (1945), respectively.

EVALUATION

The following parameters may be determined: water and electrolyte excretion, GFR, RPF, C_{H2O}, T_{CH2O} and plasma renin activity. Results of test compound are compared statistically with control and standard drug treated animals.

MODIFICATIONS OF THE METHOD

Rönnhedh et al. (1996) described a simple method to perform serial renal clearance studies without urine collection in rats. This was applied to non-radiolabeled para-aminohippurate sodium and iothalamate sodium which were used respectively to estimate renal blood flow and glomerular filtration rate.

Gabel et al. (1996) described fast and accurate assays for measuring glomerular filtration rate and effective renal blood flow in conscious rats. An enzymatic method was developed for the determination of inulin and a colorimetric method was developed for determination of p-aminohippurate in the plasma and urine of rats.

Hropot et al. (1985) described clearance methods in monkeys. Chimpanzees weighing 30.7 ±10.6 kg were anesthetized with 1 mg/kg Sernylan i.m. Food was withdrawn 24 h prior to the experiment and the animals received only tap water ad libitum. In the morning before the experiment, the urinary bladder of the animals was emptied by catheterization. The urine was discarded. To determine the glomerular filtration rate (inulin clearance), a bolus injection of 50 mg/kg inulin i.v. was given and followed by a continuous infusion of 3 ml/min inulin dissolved in Ringer lactate solution. After an equilibrium of 60 min, urine and blood samples were collected for two control clear-

[4] Contribution by M. Hropot.

ance periods of 30 min each. The control periods were followed by intravenous administration of the test preparation in a dose of 20 mg/kg. Thereafter, urine and blood samples were collected during 6 clearance periods. The following parameters were determined: urine excretion, inulin clearance and urate clearance [ml/kg/min], fractional excretion of urate and plasma urate [mmol/l].

Tanaka et al. (1990) evaluated uricosuric and diuretic properties of diuretic agents using clearance studies in urate-loaded dogs and urate-loaded rabbits.

C.1.2.5 Micropuncture techniques in the rat[5]

PURPOSE AND RATIONALE

Micropuncture techniques have been applied to the direct investigation of the effect of diuretics on single nephron function. The observed changes in tubular fluid reabsorptive rates and electrolyte concentrations can be used to asses the mechanism of action. The rat is the model of choice since proximal and distal tubules as well as collecting ducts are accessible for micropuncture.

[5] Contribution by M. Hropot.

PROCEDURE

Clearance and free-flow micropuncture studies are performed in rats with a body weight of about 250 g, anaesthetized by the intraperitoneal injection of thiopentone (Trapanal® 50 mg/kg). The animals are fasted for 16 h before the beginning of the experiment, but have free access to tap water. After anesthesia the animals are placed on a thermostatically heated table. Thereafter rats are tracheotomized and carotid artery and jugular vein are cannulated for blood pressure recording, blood sampling, and for infusion of compounds, respectively. The left kidney is carefully exposed by a flank incision, embedded in a small plastic vessel with cotton wool, and bathed with paraffin oil at 37 °C. The ureter is cannulated and rectal temperature monitored continuously. A bolus injection of 75 µCi inulin ^{3}H in 0.7 ml NaCl solution is given, followed by 0.85% NaCl solution at a rate of 2.5 ml/min per 100 g body weight. The sustained infusion delivers 75 µCi inulin ^{3}H per hour. The control puncture of tubules is performed 45 min after beginning of the intravenous infusion. The direct collection of tubular fluid samples from proximal and distal tubules is carried out with glass capillaries of 8 to10 µm external diameter using a micromanipulator and microscopic observation. Distal tubules are identified by intravenous injection of lissamine green. The control period is followed by the test period. After an equilibration period of 30 min with the compound to be tested, micropuncture is performed again and tubular fluid is collected. The uretral urine is collected and blood sampling is performed in the middle of each clearance period.

EVALUATION

The following parameters may be determined: inulin clearance (GFR), single nephron GFR, fractional delivery of water, sodium and potassium in proximal and distal tubules and in urine. All data are expressed as mean values ±SEM. Comparison of the effects of compounds to be tested with controls is performed by one way analysis of variance and by Student's *t*-test for paired and unpaired data.

C.1.2.6 Stop-flow technique[6]

PURPOSE AND RATIONALE

This procedure is of considerable value in the localization of transport processes along the length of the nephron. During clamping of the ureter, glomerular filtration is grossly reduced. The contact time for the tubular fluid in the respective nephron segments increases, and the concentration of the constituents of tubular fluid should approximate the static-head situation. After release of the clamp, the rapid passage of the tubular fluid should modify the composition of the fluid only slightly. The first samples should correspond to the distal nephron segment, the latest to glomerular fluid. However, with introduction of the micropuncture technique, the stop-flow method appears less attractive.

PROCEDURE

This method can be performed in different animals during anesthesia and was originally described by Malvin et al. (1958). The ureter of an animal undergoing intense osmotic diuresis is clamped for several minutes allowing a relatively static column of urine to remain in contact with the various tubular segments for longer than the usual periods of time. Thus, the operation of each segment on the tubular fluid is exaggerated. Then the clamp is released, and the urine is sampled sequentially. Small serial samples are collected rapidly, the earliest sample representing fluid which had been in contact with the most distal nephron segment. Substances examined are administered along with inulin before the application of uretral occlusion. However, tubular segments downstream from the proximal segments may modify the tubular fluid during its egress.

EVALUATION

In each sample the concentration of a glomerular marker, such as inulin, and the concentration of the substance under study are measured. Fractional excretion of the substance and the glomerular marker are plotted versus the cumulative urinary volume.

MODIFICATIONS OF THE METHOD

Shinosaki and Yonetani (1989), Shinosaki et al. (1994) performed stop-flow studies on tubular transport of uric acid in rats treated with pyrazinoic acid, an inhibitor of tubular urate secretion.

Tanaka et al. (1990) used stop-flow experiments to test uricosuric and diuretic activities of new compounds in dogs.

C.2 Impaired renal function

C.2.1 Chronic renal failure in the rat

PURPOSE AND RATIONALE

Chronic renal failure is a frequent pathological condition in man. An animal model as described by Acott et al. (1987) is of value to test new diuretics under these conditions.

PROCEDURE

Sprague-Dawley rats weighing 150–200 are anesthetized by i.m. injection of ketamine (40 mg/kg) and droperidol/fentanyl (Inovar) 0.25 mg/kg. Through a 6-cm midline incision in the abdominal wall the small bowel and cecum are lifted and placed on saline-soaked gauze sponges. The exposed right kidney is dissected from the retroperitoneal area and the vascular and ureteric pedicles are ligated with 2–0 silk sutures, transected, and the kidney is removed. The renal artery of the left kidney is dissected into the hilum to expose the three main segmental renal arteries. The kidney is not dissected out of the peritoneum. The anterior caudal branch of the artery is then temporarily ligated to establish the volume of renal tissue supplied. The area of ischemia becomes demarcated within 10–15 s. If this approximates 1/4 to 1/3 of the kidney, a permanent ligature is placed. The viscera are then carefully replaced in the abdomen and peritoneum and linea alba are closed with a continuous suture. The skin is closed with stainless-steel clips.

Blood for serum creatinine is collected by retro-orbital puncture under anesthesia at various time intervals up to 12 months. In association with this, 24-hour urines are collected for measurement of creatinine, protein, and specific gravity.

EVALUATION

Serum creatinine increases up to 500 µM/l after 12 months, whereas creatinine clearance decreases. Significantly increased urine volumes are accompanied by decreased urine specific gravity indicating a decreased concentrating ability. Proteinuria is significantly increased. Terminal uremia occurs after 14–15 months.

CRITICAL ASSESSMENT OF THE METHOD

The method may be used for special pharmacological studies as well as for evaluation of renal toxicity of new chemicals.

MODIFICATIONS OF THE METHOD

Sancho et al. (1989) used a similar procedure in rats ligating two of the three terminal branches of the left renal artery, followed by right nephrectomy.

Freeman (1971) induced azotemia combined with hypothermia in rats by ligation of the urinary bladder at the base.

William et al. (1997) described renal ischemia-reperfusion injury in rats. The animals were anesthetized and subjected to 45 min of bilateral renal occlusion using atraumatic vascular clamps before renal perfusion was reestablished. After various time interval (up to 1 week) blood urea nitrogen, creatinine and myeloperoxidase activity in the kidney were determined. The protective effects of an intracellular adhesion molecule monoclonal antibody were tested.

Ishidoya et al. (1995), Klahr and Morrissey (1997) induced interstitial renal fibrosis by unilateral ureteral obstruction in Sprague Dawley rats and tested the effect of ACE inhibitors and angiotensin II receptor antagonists.

Hartenbower and Coburn (1972) described a method for producing chronic renal insufficiency in the *chick*. By urethral ligation, the function of one kidney was completely eliminated, and the functional mass of the other was reduced by two-thirds. The method resulted in elevation of plasma concentration of uric acid, the major product of protein catabolism in avian plasma, to levels 2–4 times normal for periods as long as 3 weeks.

Two to 3 weeks old White Leghorn cockerels are anesthetized with ether, and the abdominal feathers are clipped. The chick is placed supine on a small operating board with hips flexed and legs extended over the head. An incision is made along the left side of the abdomen extending into the peritoneal cavity. Self-retaining retractors are used to maintain exposure. The right ureter is identified and ligated just proximal to its junction with the cloaca. The left ureter and renal vein are ligated with a single suture near the middle of the left kidney.

The degree of azotemia is assessed by measuring uric acid levels in blood samples 0.2–0.3 ml, obtained by cardiac puncture at intervals of 2–6 days after surgery.

Uric acid blood levels are compared between operated and sham-operated animals. Histological examination is performed after sacrifice of the animals.

C.2.2 Chronic renal failure after subtotal (five-sixths) nephrectomy in rats

PURPOSE AND RATIONALE

Subtotal (five-sixths) nephrectomy in rats has been used by many authors as model for chronic renal failure. Levine et al. (1997) used this model to evaluate the hypothesis that under these conditions endogenous angiotensin II modulates *in vivo* bicarbonate reabsorption (J_{tCO_2}) in distal tubules via H^+-adenosinetriphosphatase and Na^+/H^+-exchange. Bicarbonate reabsorption (J_{tCO_2}) in distal tubules is significantly increased in five-sixths nephrectomized rats.

PROCEDURE

Surgical procedure

Male Sprague-Dawley rats weighing 230–280 g are anesthetized with halothane via a face mask. Prior to the first incision, the animal is given 20 ml/kg normal saline subcutaneously. On a heated table, a midline laparatomy is performed 2 cm below the xiphoid bone cartilage and the abdomen is opened. The right kidney is isolated and brought out of the abdomen by grasp-

ing the fat at the lower pole of the kidney. This fat is blunt dissected (sparing the adrenal gland), and three silk 4-0 ligatures are passed under the ureter, renal artery, and renal vein, tying one distally and two proximally. The ureter, renal artery and renal vein are then cut between the ligatures, the proximal ties are cut short, and the distal tie is pulled out, removing the kidney. After the area is checked for bleeding, the left kidney is the similarly isolated and brought out of the abdomen. The fat around the kidney is blunt dissected, avoiding excessive handling of the kidney or damage to the ureter, and the left and right renal poles are removed (two-thirds nephrectomy). The left remnant kidney is then returned to the abdomen and moistened with 5 ml of normal saline. The abdomen is closed with sutures and the skin with autoclips. Sham rats undergo the same procedure, except that the kidneys are only touched by the instruments. All rats are allowed 13–16 days recovery prior to microperfusion.

Microperfusion experiments

The rats are anesthetized with 100 mg/kg thiobutabarbital sodium and placed on a heated operating table. After tracheostomy, using a PE-240 tubing, the left carotid artery is cannulated for continuous blood pressure measurement and collection of blood for acid-base and electrolyte analyses while the left jugular vein is cannulated with three lines for infusion of fluid, pentobarbital sodium anesthetic and 10% Lissamine green (Levine et al. 1996). The left kidney is exposed by flank incision, carefully dissected from the adrenal gland, and immobilized in a stainless steel cup covered with mineral oil. The ureter is catheterized with PE-50 tubing to ensure proper urine flow.

To replace surgical fluid losses, the rats are infused at 1% body wt/h for 30 min via the jugular vein with donor plasma from control rats. The animals are then maintained on 0.9% saline at 1% body wt/h for the remainder of the experiment.

Two-loop perfusable surface distal tubules are identified by injecting a bolus of 1% Lissamine green into surface proximal loops and observing its passage through the nephron. The distal tubules are perfused at 15 nl/min with a hypotonic solution containing (in mM) 28 HCO_3, 26 Cl, 56 Na, 2 K, 1.8 Ca, 22 urea, and 4 gluconate, as well as 0.05% FD and C green dye no. 3 (Keystone, Chicago, IL) and 0.1% albumin. The perfused bicarbonate load, higher than in free flow, is chosen to more easily reveal the effect of inhibitors. Sample collections are quantitative and timed. A 10-min preperfusion period precedes all collections.

Groups of five-sixths nephrectomized rats are treated with various agents, e.g., angiotensin II, angiotensin$_1$ receptor antagonists, or Na^+/H^+ antiporter inhibitors.

Analyses

Whole blood and urine pH and P_{CO2} are measured quantitatively by an electrode blood-gas system and HCO_3 concentrations are calculated. Plasma and urine Na^+ and K^+ concentrations are measured by flame photometry and Cl^- concentrations by electrotitration. Plasma total protein concentrations and urine specific gravity are measured by refractometry, and hematocrits are determined by a microcapillary reader. Urine osmolalities are determined by freezing-point osmometry. Plasma creatinine concentrations are determined by the Jaffé method without deproteinization.

Perfusate and sample total CO_2 concentrations are measured by microcalorimetry (Levine et al. 1996). A standard curve is run before sample analysis, and standard samples bracket the determination of sample and perfusate CO_2 determination.

EVALUATION

The perfusion rate (R_P) is calculated as the product of the measured collection rate (R_C) and the ratio of inulin concentration in collected tubular fluid and perfusate. Water absorption (J_V) is calculated as the difference between the calculated perfusion rate and the measured collection rate (R_P minus R_C). J_{tCO_2} is calculated as

$$J_{tCO_2} = [(R_P C_P) - (R_C C_C) / L$$

whereby C_P and C_C are the measured CO_2 concentrations in perfusate and collected fluid, respectively, and L is the tubular length in millimeters, measured by dissection after latex injection.

Data are expressed as the means ±SE. Statistical significance is assessed by two-tailed unpaired Student's *t*-test or one way analysis of variance (ANOVA) followed by either Dunnett's test for multiple comparisons vs. control or the Newman-Keuls test for all pairwise comparisons. Tests indicating a value of $P < 0.05$ indicate a statistically significant difference between groups.

MODIFICATIONS OF THE METHOD

Function of the remnant kidney after subtotal (5/6) nephrectomy in **rats** has been used for many purposes:

to test the potential benefit of calcium antagonists (Tolins and Raij 1990; Jarusiripipat et al. 1992; Van den Branden et al. 1997) or antioxidants (Vaziri et al. 1998),

to verify the effect of ACE-inhibitors (Pelayo et al. 1990; Kakinuma et al. 1992; Ashab et al. 1995; Liu et al. 1996; Ali et al. 1998; Cohen et al. 1998; MacLaughlin et al. 1998), angiotensin antagonists (Kohzuki et al. 1994, 1995; Brooks et al. 1995; Barreto-Chaves and Mello-Aires 1996; Noda et al. 1997; Lariviere et al.

1998; Roczniak et al. 1999) and endothelin receptor antagonists (Nabokov et al. 1996; Potter et al. 1997; Wolf et al. 1999; Brochu et al. 1999; Shimuzu et al. 1999), or Na^+/H^+ antiporter inhibitors (Fernandez et al. 1994),

to study the influence of hormones, such as parathyroid hormone (Fukagawa et al. 1991; Urena et al. 1994; Yi et al. 1995; Schaefer et al. 1996), growth hormone (Santo et al. 1992; Garcia de Boto et al. 1996), insulin-like growth factor I (Hazel et al. 1994; Mak and Pak 1996; Tonshoff et al. 1997), vasopressin (Bardoux et al. 1999), atrial natriuretic factor (Wong and Wong 1991, 1992), Luk et al. 1995) or erythropoietin (Poux et al. 1995; Zhou et al. 1997), during development of chronic renal failure.

Kimura et al. (1999) reported a model of progressive chronic renal failure in *rats*, produced by a single injection of microspheres (20 to 30 µm in diameter) into the left renal artery after right nephrectomy.

Cowley et al. (1996) described the **Han:SRPD rat** strain which develops autosomal dominant polycystic kidney disease with chronic renal failure that resembles human autosomal dominant polycystic kidney disease.

Chronic renal failure can be induced by feeding a lithium containing diet (40–50 mmol/kg) to newborn *rats* until an age of 55–65 weeks (Christensen et al. 1992, 1997; Nyengaard et al. 1994).

Stockelman et al. (1998) described chronic renal failure in a **mouse** model of human adenine phosphoribo-syltransferase deficiency. Hamilton and Cotes (1994) used a partial nephrectomy model in *mice* with two-thirds of total renal mass excised to evaluate erythropoiesis and erythropoietin production from extrarenal sources such as the submandibulary salivary gland. Koumegawa et al. (1991) suggested the DBA/2FG-pcy *mouse*, which develops numerous cysts in kidney cortex and medulla, a progressive anemia and an elevation of blood urea nitrogen, as useful spontaneous model of progressive renal failure.

Brown et al. (1990) studied the metabolism of erythropoietin in normal and uremic **rabbits** with 5/6 nephrectomy. Bonilla-Felix used *rabbits* after 75% nephrectomy to study the response of cortical collecting ducts from remnant kidneys to arginine vasopressin.

Fine et al. (1990), Vaneerdeweg et al. (1992) described surgical techniques for kidney resection to produce chronic renal failure in **dogs**.

C.2.3 Experimental nephritis

C.2.3.1 General considerations

Various experimental procedures were described as models for glomerulonephritis in human beings. Most of them were developed in rats and rabbits. They involve the reactions of antibodies against renal components, such as Masugi nephritis (Masugi and Sato 1934), Heymann nephritis (Heymann 1959), nephrotoxic serum nephritis (Unanue and Dixon 1967), crescentic type anti-glomerular membrane nephritis (Nagoe et al. 1994, 1998), anti-Thy1 nephritis (Chen et al. 1999).

Moreover, MRL Mpf lpr/lpr (MRL/lpr)-mice were described which spontaneously develop a severe disease with many symptoms very similar to human systemic lupus erythematodes, i.e. hypergammaglobulinemia, and glomerulonephritis (Theofilopoulos and Dixon 1981; see also I.2.2.16).

C.2.3.2 Nephrotoxic serum nephritis

PURPOSE AND RATIONALE

Nephrotoxic serum nephritis is produced in animals by administration of heterologous antibody against glomerular basement membrane. This is regarded as an experimental model of human glomerular immune injury resulting in glomerulonephritis (Unanue and Dixon 1967). The glomerular lesions induced by nephrotoxic serum nephritis vary with species. The Wistar-Kyoto rat is susceptible to the induction of a crescentic glomerulonephritis following small doses of nephrotoxic serum (Kushiro et al. 1998; Suzuki et al. 1998).

PROCEDURE

Preparation of nephrotoxic serum

Normal Wistar rat kidneys are fully perfused with physiologic saline through a catheter placed in the aorta. Renal cortical tissue is removed, homogenized and diluted with physiological saline at about 20% suspension. Two ml of renal cortical homogenate are emulsified with an equal volume of Freund's complete adjuvant. This emulsion is injected subcutaneously into rabbits twice a month for two months. Seven days after the last injection, the rabbits are bled from the carotid artery under anesthesia. The sera are decomplemented for 30 min at 56 °C and absorbed with freshly harvested rat erythrocytes.

Experimental protocol

Male Wistar-Kyoto rats weighing 150 g receive either continuous administration of the test drug by an osmotic pump (ALZA Co., Palo Alto, USA) or saline. Twenty-four hours later, the rats are injected with 1 ml of nephrotoxic serum. At 9, 12, and 14 days, urine samples are collected and urinary protein levels are measured using the Lowry method. At 14 days the rats are sacrificed under ether anesthesia, and both kidneys are removed. Portions of these tissues are processed for light microscopy, immunofluorescence staining and immunoperoxidase staining.

For light microscopy, tissues are fixed and embedded in paraffin. Sections are stained with hematoxylin and eosin, and periodic acid Schiff's reagent. Twenty glomeruli are examined per rat and number of glomeruli which forms crescent is counted.

Indirect immunofluorescence studies are performed on 3 μm-thick cryostat sections which are air dried and incubated with anti-rat intercellular adhesion molecule-1 (ICAM-1) antibody (Tamatani and Miyasaka 1990) for 60 min at room temperature. After washing the

antibody binding is visualized by incubating the sections for 30 min with fluorescein isothiocyanate-labeled goat anti-mouse IgG.

Direct immunofluorescence studies are performed on 4 µm thick cryostat sections, which are incubated with fluorescein isothiocyanate-labeled goat anti-rat IgG, goat anti-rat C3, goat anti-rat fibrinogen and goat anti-rabbit IgG.

The staining intensity of 20 glomeruli per rat is semiquantitatively assessed into 4 grades.

For **immunoperoxidase staining** the distribution of leukocytes is examined using an immunoperoxidase ABC kit (Vector Lab, Burlingame, USA). Nonspecific protein binding is blocked by incubating the cryostat sections with 10% bovine serum in Tris-buffered saline for 20 min. Nonspecific staining is blocked by 15 min incubation with avidin and then biotin using the avidin-biotin blocking kit (Vector Lab). Endogenous peroxidase activity is inhibited by incubating the sections in methanol containing 0.3% H_2O_2 for 20 min. Sections are first incubated for 60 min with primary antibodies at room temperature, incubating monoclonal antibodies against rat monocytes/macrophages (ED-1), rat CD4 and rat CD8. Then the sections are incubated with biotinylated donkey anti-mouse IgG for 30 min at room temperature. Biotinylated horseradish peroxidase is applied for 30 min at room temperature. Peroxidase activity is developed in 3,3-diaminobenzidine and hydrogen peroxide. The sections are then counterstained with Mayer's hemato-xylin. The number of ED-1 positive cells, CD4 positive cells and CD8 positive cells per glomerular cross-section is counted in 20 glomeruli per rat.

EVALUATION

All data are expressed as mean ±SEM. Significance of differences between groups is determined using Wilcoxon's test.

MODIFICATIONS OF THE METHOD

Masugi and Sato (1934), Krakower and Greenspon (1951), Heyman et al. (1959, 1965), Eddington et al. (1968) already described experimental allergic glomerulonephritis in rats.

Ito et al. (1983), Nagao et al. (1994, 1998) induced crescentic type antiglomerular basement membrane nephritis in male Sprague Dawley rats by injecting 6.5 mg rabbit gamma-globulin in 0.25 ml Freund's complete adjuvant into the hind foot pads, following the injection of 0.6 ml of rabbit anti-rat glomerular basement membrane serum into the tail vein.

Couser et al. (1978) studied the development of immune deposits on the subepithelial surface of the glomerular capillary wall in isolated rat kidneys perfused at controlled perfusion pressure, pH, temperature, and flow rates with recirculating oxygenated perfusate containing bovine serum albumin in buffer and sheep antibody to rat proximal tubular epithelial cell brush border antigen.

Hayashi et al. (1996) tested the effects of a flavonoid in original-type anti-glomerular basement membrane antibody associated glomerulonephritis in male Sprague Dawley rats on upregulation of intracellular adhesion molecule expression and on increase in leukocyte function-associated antigen positive cells in nephritic glomeruli.

Nagamatsu et al. (1999) found beneficial effects of an angiotensin II type I receptor antagonist in anti-glomerular basement membrane antibody-associated nephritis in rats.

Sanaka et al. (1997) evaluated the effects of a free radical scavenger on the progression of nephrotoxic serum nephritis in male Sprague Dawley rats. The rat glomerular basement membrane was prepared according to the method of Krakower and Greenspon (1951) who localized the nephrotoxic antigen within the isolated renal glomerulus.

Kawasaki et al. (1992) induced crescentic glomerulonephritis with a small dose of nephrotoxic serum in WKY rats, which was characterized by the early infiltration of CD8 positive cells in glomeruli. *In vivo* depletion of CD8 positive cells completely prevented proteinuria and crescent formation.

Okuda et al. (1990) provided evidence of an elevated expression of transforming growth factor-β, proteoglycans and fibronectin in glomerulonephritis induced in rats by injection of anti-thymocyte serum.

Hamada and Nagase (1996), Chen et al. (1999) induced anti-Thy1 nephritis with the antibody to the Thy-1 antigen which is present in the mesangial cells of the glomeruli. The early pathobiological cellular events are characterized by invasion of platelets, polymorphonuclear leukocytes, and monocytes into the glomerulus which occurs within hours after induction of nephritis. Complement-dependent mesangiolysis then ensues between day 1 and 3.

Passive Heymann nephritis (Heymann 1959) was used a model by Hara et al. (1991), Nagao et al. (1996), Heise et al. (1998). The disease is induced in rats by heterologous antibody to crude renal border antigen Fx1A. The model is characterized by granular deposition of heterologous and homologous antibody and complement along the glomerular capillary wall and as a counterpart, extensive electron-dense subepithelial deposits are seen at the ultrastructural level. Massive proteinuria develops after a latent period of 2 to 4 days in the absence of glomerular hypercellularity.

Kawasaki et al. (1995) studied the therapeutic effect of combined treatment with monoclonal antibodies against intercellular adhesion molecule 1 (ICAM-1) and lymphocyte-function-associated antigen 1 (LFA-1) in **Masugi nephritis** of Wistar-Kyoto rats.

Thaiss et al. (1989) evaluated the effect of the immunosuppressant cyclosporin A on an active model of *in situ* immune complex glomerulonephritis. Wistar rats were preimmunized with human IgG and 2 weeksafter the last antigen injection, the left kidney was perfused with cationized human IgG in order to induce unilateral *in situ* immune complex glomerulonephritis.

Okubo et al. (1990) studied the immunosuppressive effects of FK506 on active Heymann's nephritis and the autologous phase of Masugi nephritis.

Rennke et al. (1994) developed a model system of acute nephritis in the rat whereby a chemically reactive form of the hapten azobenzenearsonate is introduced directly in to the left kidney of pre-immunized Brown Norway rats.

C.2.4 Experimental nephrosis

PURPOSE AND RATIONALE

Some compounds used in antineoplastic therapy induce nephrosis in animals, like the antibiotic adriamycin (= doxorubicin) (Milner et al. 1991, 1994; Chagnac et al. 1994; Wapstra et al. 1996; De Boer et al. 1999; Mutti et al. 1999) or daunomycin (Kimura et al(1993), the aminonucleoside puromycin (Yayama et al. 1993; Guoji et al. 1994; Magil 1996; Ebihara et al. 1997; Nosaka et al. 1997; Park et al. 1998; Asami et al. 1999; Pedraza-Chaverri et al. 1999) or cisplatin (Abdel-Gayoum et al. 1999).

These models allow to test the protective effects of drugs even after the renal disease in established, i.e. mimic the clinical situation (Wapstra et al. 1996).

PROCEDURE

Male Wistar rats with an initial weight of about 300 g receive a single intravenous dose of 2 mg/kg adriamycin. Twice a week during a 12-weeks period, the animals are weighed, 24-h urine is collected and blood pressure is measured by the tail-cuff method.

During the first 5 weeks, all animals are kept on a low sodium diet with tap water ad libitum. After stabilization of proteinuria (5 weeks), animals are divided into 2 groups receiving either low sodium or normal sodium diet. After a week stabilization on these diets, animal receive different doses of treatment in their drinking water. These regimen is continued until the end of the study (week 12), at which time all animals are sacrificed and blood samples and kidney tissue are obtained.

During each blood pressure measurement session, five measurements are recorded for each animal. The blood pressure is taken as the mean of the last 3 recordings. Urinary protein is determined by the Pyrogallol Red-molybdate method (RA-1000 Technicon). Urinary sodium, creatinine and urea and serum electrolytes, creatinine, albumin, cholesterol and triacylgly-cerols are measured by a standard autoanalyser technique. Kidney samples are fixed in paraformaldehyde and embedded in paraffin. Sections are stained with the periodic acid/Schiff technique. Focal glomerular sclerosis is scored semiquantitatively by light microscopy.

EVALUATION

Analysis of co-variance is used to compare the experimental groups (defined by diet or dose of drug) after 2 weeks of treatment (week 8) and the end of the study (week 12) with the baseline value (week 6) as a co-variable. Tuckey's method is used for comparison of groups receiving different doses of drug. The other statistical comparisons are performed using Student's *t*-test.

MODIFICATIONS OF THE METHOD

Fawn-Hooded rats develop systemic hypertension and spontaneous age-dependent glomerulosclerosis with proteinuria (Mackenzie et al. 1997).

Spontaneous nephrosis with proteinuria occurs in Dahl salt-sensitive rats fed on a normal sodium diet (Yoneda et al. 1998).

Mizuno et al. (1999) studied the ICGN mouse strain as a unique model for naturally occurring nephrotic syndrome.

Focal segmental glomerulosclerosis with heavy proteinuria has been found in mice in which the Mpv17 gene was inactivated (Mpv17 –/– mice). Binder et al. (1999) recommended these animals as model of steroid-resistant nephrosis sensitive to radical scavenger therapy.

Kimura et al. (1993) described strain specificity in the susceptibility of mice to daunomycin-induced nephrosis.

Klahr and Morrissey (1997) described the effects of ACE inhibitors and angiotensin II receptor antagonists on various parameters associated with renal interstitial fibrosis induced by unilateral ureteral obstruction in rats.

C.3
Uricosuric and hypo-uricemic activity

C.3.1
In vitro methods

C.3.1.1
Inhibition of xanthine oxidase *in vitro* indicating hypouricemic activity

PURPOSE AND RATIONALE

Xanthine oxidase catalyzes the oxidation of hypoxanthine and xanthine to uric acid. Xanthine oxidase is a complex metalloflavoprotein containing one molybdenum, one FAD and two iron-sulfur centers of the ferredoxine type in each of its two independent subunits. Usually, the enzyme is isolated from cow's milk. The enzyme is inhibited by allopurinol and related compounds. The production of uric acid from the substrate (xanthine) can be determined by measuring the change in optical density in the UV range.

PROCEDURE

The test compound is incubated with xanthine oxidase (usually derived from milk, sometimes derived from rat liver or small intestine), EDTA and phosphate buffer solution (pH 7.8) at 37 °C. Control solutions without test compound are incubated under identical conditions. Following addition of xanthine, the change in absorbance is determined.

Assay conditions:
- wavelength: 293 nm
- line path: 10 mm
- final volume: 1.0 ml

EVALUATION

The percent inhibition of xanthine oxidase is determined relative to control solutions.

IC_{50} values of test compounds are calculated.

Standard data:
- Allopurinol: IC_{50}: ca 10^{-8} mol/l

C.3.1.2
Urate uptake in brush border membrane vesicles

PURPOSE AND RATIONALE

The urate-anion exchanger system in brush border membrane vesicle, which mediates hydroxyl ion gradient-dependent urate uptake, is the most likely route for the mediation of urate transport in the first step of urate reabsorption in the proximal tubules. Luminal drugs which inhibit urate reabsorption are inhibiting the transport of urate by blocking the urate/anion exchanger.

PROCEDURE

Male Sprague Dawley rats weighing 320–380 g are sacrificed by decapitation and the kidneys are removed immediately. All steps for the preparation of brush border membrane vesicles are carried out at 4 °C. Renal

cortex is homogenized for 2 min in a medium containing 250 mmol/l mannitol, 10 mmol/l Tris, 16 mmol/l HEPES buffer (pH 7.5) using a Physcotron homogenizer. The homogenate is centrifuged at 2 400 *g* for 10 min and the supernatant is centrifuged at 2 800 *g* for 20 min. Subsequently, the supernatant is discarded and the loosely packed membrane-rich layer is flushed off from the bottom densely packed brown pellet. The membrane-rich layer is resuspended manually in 250 mmol/l mannitol containing 10 mmol/l Tris-HEPES (pH 7.5) using a Dounce homogenizer and $MgSO_4$ is added to a final concentration of 10 mmol/l. After standing for 20 min, the suspension is centrifuged at 2 400 *g* for 20 min and the supernatant containing brush border membranes is recentrifuged two more times at 2 400 *g* for 20 min. The final supernatant is centrifuged at 28 000 *g* for 20 min and the pellet is suspended in a small amount of medium containing 150 mmol/l mannitol, 50 mmol/l potassium phosphate buffer (pH 7.5) and 2 mmol/l $MgSO_4$ to a final protein concentration of 4–8 mg/ml. The brush border membrane vesicle preparation is frozen and stored at –80 °C until use.

After preincubation of the brush border membrane vesicle preparation for 2 h, [2-^{14}C]urate uptake is initiated by adding 200 µl of incubation medium to 20 µl of the membrane suspension. The incubation medium has the following composition (mmol/l): 150 mannitol, 2 $MgSO_4$, 50 potassium phosphate buffer, pH 6.0 or 7.5, 0.02 [2-^{14}C]urate, and various concentrations of the inhibitor. At 10 s after the addition of the incubation medium, 200 µl portions of the suspension are pipetted onto the center of prewetted cellulose acetate filters kept under suction. The vesicles retaining on the filter are washed immediately with 5 ml of an ice-cold solution containing 150 mmol/l mannitol and 50 mmol/l potassium phosphate buffer, pH 6.0 or 7.5, which is used at the same pH as the incubation medium. Preincubations and incubations are performed at 23 ±1 °C. Each experiment is performed in triplicate. Corrections are made for the radioactivity bound to the filters in the absence of membrane vesicles. The term of the OH^- gradient-dependent urate uptake is defined as the difference between the uptakes in the incubation medium at pH 6.0 and that at pH 7.5. The OH^- gradient-dependent urate uptake at 10 s is assumed to present an initial velocity.

EVALUATION

From a concentration-response curve relating log concentration of drug to the logit activity of the OH^- gradient-dependent urate uptake for 10 s, IC_{50} (concentration producing 50% of inhibition) is determined by least-squares regression analysis.

C.3.2 *In vivo* methods

C.3.2.1 Diuretic and uricosuric activity in mice

PURPOSE AND RATIONALE

Renal excretion of uric acid consists of three components: complete filterability of uric acid in the glomerulus, subsequent tubular reabsorption, and tubular secretion (Gutman and Yü 1961). Pronounced species differences have been described in uric acid metabolism including man. Mice were recommended for primary screening of uricosuric drugs.

PROCEDURE

Male NMRI mice weighing 25–30 g are used. On the evening prior to the experiment, food but not water is withheld. In the morning, the mice are orally loaded with 50 ml/kg 0.9% NaCl-solution. Together with the sodium load the test compound is applied by gavage in 2% starch suspension. Controls receive saline and starch suspension only. Groups of 5 mice are placed into metabolism cages. Urine is collected over 4 h. In the urine sodium and potassium are determined by flame photometry, chloride by argentometrically with potentiometrical end point titration (Chloride titrator, Aminco®), uric acid by the Uriquant®-method, creatinine by the Jaffé-reaction, as well as pH and osmolality.

EVALUATION

Urine excretion is calculated in ml/kg. Uric acid-, creatinine- and ion- excretions are calculated in mmol/kg and expressed as percent changes versus controls. The changes are evaluated statistically using Student's *t*-test.

CRITICAL ASSESSMENT OF THE METHOD

Some saluretic-diuretic agents, like ethacrynic acid, are inactive in the rat, when given orally. Moreover,

uricosuric activity in mice is less reliable than that in primates.

C.3.2.2 Hypouricemic activity after allantoxanamide treatment in rats

PURPOSE AND RATIONALE

Most species used for pharmacological experiments have rather low blood levels of uric acid. Experimental hyperuricemia can by induced by inhibition of the enzyme uricase. In most species uricase metabolizes uric acid to allantoin. Allantoxanamide blocks uricase and increases endogenously synthesized uric acid. This increase is blocked by compounds like allopurinol.

PROCEDURE

Non fasted male Sprague Dawley rats weighing 230–280 g are treated by intraperitoneal injection of 250 mg/kg allantoxanamide suspended in 5 ml/kg sesame oil. The test compound is applied orally in a dose of 50 mg/kg in 40 ml/kg water. Likewise, the standard compound allopurinol is given in a dose of 50 mg/kg. Eight rats are used for the each dose of test drugs and standard. The animals are placed individually into metabolism cages with free access to food and water. Urine is collected during the periods of 1 to 6 and 7 to 24 h. Blood is withdrawn by retroorbital puncture prior and 2, 6 and 24 h after compound administration. Uric acid is determined with the Uric-aquant®-method in plasma [mmol/l] and urine [mmol/l].

EVALUATION

Mean values of uric acid concentrations in plasma at the different time intervals and mean values of uric acid excretion after 6 and 24 h of the test group are compared with the control group (allantoxanamide treated only) using Student's *t*-test.

C.3.2.3 Hypouricemic and uricosuric activity after potassium oxonate treatment in rats

PURPOSE AND RATIONALE

Increase of uric acid in serum of rats is induced by a special diet and the uricase inhibitor potassium oxonate. Uric acid concentration in serum and uric acid excretion in urine prior and after three experimental days are determined.

PROCEDURE

Male Wistar rats weighing 250 g are placed individually in metabolic cages. They are offered a special diet containing 5% fructose, 3% uric acid, 2% potassium oxonate (2,4-dihydroxy-1,3-triazine-6-carbonic acid) and 0.001% artificial sweetener. Drinking water consists of a 0.5% solution of potassium oxonate. The animals are treated orally with 50 or 100 mg/kg of the test compound or the standard (allopurinol) dissolved in 5 ml/100 g body weight of 0.5% potassium oxonate solution. The treatment is repeated on the second day. On the third day 24 h urine is collected and the animals are sacrificed by exsanguination. Concentrations of uric acid and electrolytes (Na^+, K^+, Cl^-) are determined in blood and urine.

EVALUATION

Concentrations of uric acid and electrolytes in blood and urine of animals treated with the test compound are compared statistically with control and standard drug treated animals.

MODIFICATIONS OF THE METHOD

Clearance techniques in oxonate-treated rats were used by Yonetani et al. (1987), Shinosaki et al. (1991), Dan et al. (1994).

Sugino and Shimada (1995) tested uricosuric effects in oxonate-loaded rats, in the pyrazinoic acid suppression test and in the phenolsulfonphthalein test.

C.3.2.4 Phenol red excretion in rats

PURPOSE AND RATIONALE

Phenol red (= phenolsulfonphthalein) excretion is an indirect test for uricosuric activity. After intravenous injection phenol red is mainly eliminated by active secretion in the proximal tubulus of the kidney. Treatment with uricosuric agents decreases the secretory activity of tubulus cells resulting in a delayed excretion of phenol red. Plasma values of phenol red are increased in treated animals as compared to controls.

PROCEDURE

Male Wistar rats weighing 120–150 g are treated orally with the test compound or the standard 30 min prior to intravenous injection via the tail vein with 2.5 ml/kg of a 3% aqueous solution of phenolsulfonphthalein. For intravenous application, 5.0 ml/kg of the test drug solution are injected immediately after the phenolsulfonphthalein injection followed by flushing with 2.5 ml/kg saline. By retro-orbital puncture blood samples are with-drawn after 30, 60 and 180 min. Blood (0.2 ml) is diluted with 2 ml 0.9% NaCl-solution and centrifuged. To 1 ml of the supernatant 1 ml of 1% sodium carbonate solution and 8 ml of saline are added. Using a spectrophotometer (Eppendorf, Hamburg) extinction at 546 nm is determined.

EVALUATION

Extinction values are calculated for total blood. At each time interval the values in treated rats are compared statistically with those of controls.

C.3.2.5 Uricosuric activity in Dalmatian dogs

PURPOSE AND RATIONALE

Most species have low plasma levels and low renal excretion of uric acid. The Dalmatian dog is an exception with excessive uric acid excretion, but with relatively high plasma levels. Explanations are a genetically determined defect in tubular reabsorption of the filtered urate (Friedman and Byers 1948; Kessler et al. 1959) and a defective hepatic uricase activity (Yü et al. 1971). The Dalmatian dog is being used for studies of uricosuric agents.

PROCEDURE

Conscious male Dalmatian dogs with a body weight of about 20 kg are used. Food but not water is withheld 24 h prior to the experiment. The animals are placed individually in metabolic cages. The urinary bladder is emptied by catheterization. Twenty ml/kg drinking water is applied by gavage. Every 2 h the animals are catheterized again, blood is withdrawn from a jugular

vein and additional 8 ml/kg drinking water is applied by gavage. The urine and blood values obtained after the first 2 h serve as control. Then, the test compound is applied either i.v. or orally. Up to 8 h blood and urine samples are collected every 2 h. No water is given after the last sampling. The dogs stay over night in the metabolic cages. Twenty-four hours after beginning of the experiment, venous puncture and catheterization is performed once more. Blood and urine samples are analyzed for uric acid (Uricaquant®-method), creatinine (Jaffé reaction), sodium and potassium (flame photometry), calcium and magnesium (atom absorption method), and chloride (argentometry) as well as for osmolality.

EVALUATION

The values after application of the drug are compared with predrug values.

CRITICAL ASSESSMENT OF THE METHOD

Dalmatian dogs bred by commercial breeders are not always homozygous. Therefore, not every dog is suitable for experiments on uric acid excretion.

C.3.2.6 Uricosuric activity in Cebus monkeys

PURPOSE AND RATIONALE

The Cebus monkey is described not to possess uricase (Simkin 1971) and to have different metabolic conditions for uric acid than other experimental animals. This species is chosen for special studies of anti-uricopathic drugs since it resembles more closely human uric acid metabolism.

PROCEDURE

Cebus monkeys (*Cebus albifrons*) of either sex weighing 3.0 to 5.0 kg are used. Twenty-four h prior to the test, food is withheld, but water is available ad libitum. On the morning of the experiment, the animals receive 20 ml/kg drinking water by gavage, followed by oral application of the test compound. Control animals receive water only. The animals are placed in individual metabolism cages and the spontaneously voided urine is collected after 2, 6, and 24 h. After 2 and 6 h, additional 4 ml/kg water is given by gavage. From a cubital vein blood is withdrawn prior to the experiment and 2, 6 and 24 h after application. Urine and serum samples are analyzed for uric acid (Uricaquant®-method), creatinine (Jaffé reaction), sodium and potassium (flame photometry), calcium and magnesium (atom absorption method), and chloride (argentometry) as well as for osmolality.

EVALUATION

Allopurinol and probenicide are used as standard drugs and are compared with test compounds.

CRITICAL ASSESSMENT OF THE METHOD

The use of the Cebus monkey as animal model has been proven to be the most valuable method to test putative hypouricemic compounds (Hropot 1988).

MODIFICATIONS OF THE METHOD

Onuma et al. (1988) used Cebus monkeys for evaluation of uricosuric effects of an aryloxyacetic derivative.

Yonetani et al. (1987) performed clearance experiments with uricosuric drugs in anesthetized chimpanzees.

Dan et al. (1989) tested the activity of AA-193, an uricosuric agent in rats, mice and Cebus monkeys.

C.4 Influence on lower urinary tract

C.4.1 *In vivo* studies

C.4.1.1 Micturition studies

PURPOSE AND RATIONALE

Urinary incontinence is a major psychosocial, medical, and economic problem. The most common condition to be treated pharmacologically is incontinence due to detrusor instability. The response of the urinary bladder to filling with increasing volumes of fluid (cystometrogram) is a common procedure for evaluating bladder function in both animals and humans. The response of the vesico-urethral complex can be arbitrarily divided into the collection and expulsion phases. The nervous control of the detrusor, the internal and the external sphincter has been reviewed by Kuru (1965). A detailed description of the nervous control of the urinary bladder of the cat has been given by De Groat (1975). The pharmacology of lower urinary tract muscles and penile erectile tissues has been reviewed by Anderson (1993). Ferguson and Christopher (1996) reviewed urine bladder function and drug development. Urine storage and timely expulsion of bladder content are produced through the coordinated activation of a series of reflexes involving cholinergic, sympathetic, and, possibly, purinergic, serotonergic, and peptidergic innervation. In view of this complexity, *in vivo* models were developed for the quantitative analysis of the effects of drugs on the function of the vesico-urethral complex (Maggi et al. 1983, 1985, 1986, 1987a,b, 1992).

PROCEDURE

Male Wistar rats weighing 340–360 g are anesthetized by subcutaneous injection of 1.2 g/kg urethane. The left jugular vein is cannulated for drug injection. Body temperature is kept constant by means of a heating pad maintained at 37 °C. Through a midline incision of the abdomen, the urinary bladder is exposed and emptied of urine by application of a slight manual pressure. A 20-gauge needle is inserted through the apex of the bladder dome for 3–4 mm into its lumen. The needle is connected to a pressure transducer by means of a polyethylene tubing (1.5 mm OD and 1.0 mm ID) and the whole system filled with saline. The tubing is provided with an internal coaxial polyethylene tubing (0.6 mm OD and 0.3 mm ID) inserted through a side hole and sealed by a drop of epoxy resin. The second tubing serves for intravesical infusion of fluid and is connected, through a peristaltic pump, to a saline reservoir.

Intraluminal pressure signals are delivered to an amplifier and displayed on a four channel polygraph. Warm saline-soaked cotton wool swabs are laid around the exteriorized organ to maintain its temperature and to keep it moist in experiments involving the topical application of substances on the bladder dome.

After a 15-min equilibration period at zero volume, variations in intraluminal pressure are recorded in response to continuous infusion of saline at a rate of 2.8 ml/h at 37 °C for 30–40 min by means of a peristaltic pump connected to the polyethylene tubing inserted into the bladder. This infusion rate simulates the maximal hourly diuresis within the physiological range. In each preparation the infusion is continued until micturition occurs. Micturition is referred as the emission of several drops of fluid during a sustained phasic contraction of the detrusor muscle which is followed by return to zero or, in any case, to a value lower than that recorded just before micturition.

For both intravenous and topical administration, substances are dissolved in saline.

EVALUATION

In each experiment, the following parameters are evaluated:

1. pressure threshold = intraluminal pressure value recorded just before micturition
2. volume threshold = the volume of infused saline required to obtain micturition
3. maximal amplitude of micturition contraction
4. residual volume after micturition

The effect of substances on the compliance of the bladder wall is evaluated by comparing the volume-pressure-relationship of treated animals with that of controls.

Statistical analysis of the data is performed by means of the Student's *t*-test for paired or unpaired data, or by means of analysis of variance followed by the Tukey test. Statistical analysis of nonparametric data is made by the chi square test.

MODIFICATIONS OF THE METHOD

Either chemical (6-hydroxydopamine, reserpine) or surgical (section of hypogastric nerves) sympathectomy produces a picture of detrusor hyperreflexia and urine dropping, mimicking cystometric finding in human disease (Maggi et al. 1987a).

Postius and Szelenyi (1983) described a model for *in vivo* screening of spasmolytic compounds using the rat bladder.

Dray (1985) used the spontaneous, volume-induced contractions of the urinary bladder in the anesthetized rat to assess the central activity of substances with opioid properties.

Pietra et al. (1990) studied the effects of some antidepressants on the volume-induced reflex contractions of the rat urinary bladder. The urinary bladder of anesthetized rats was filled via the recording catheter by incremental volumes of warmed saline until bladder contractions occurred as a result of central activity. Volume-induced contractions were then recorded and occurred rhythmically and reproducibly for 2–3 h. Drug activity was assessed in each animal against the background frequency of bladder contractions, for a 15-min time period following intravenous administration of different doses.

Harada et al. (1992) proposed a method for rapid evaluation of the efficacy of pharmacologic agents and their analogs in enhancing bladder capacity and reducing the voiding frequency. Conscious rats were placed in a restrainer over a urine collector. The collector was secured to an Statham UC3 strain transducer, the output of which was amplified by a Gould bridge amplifier. Data were monitored on a polygraph.

Conte et al. (1991) proposed a method for simultaneous recording of vesical and the external urethral sphincter pressure in urethane-anesthetized rats.

Angelico et al. (1992) reported *in vivo* effects of different antispasmodic drugs on the rat bladder contractions induced by topically applied KCl.

Oyasu et al. (1994) measured spontaneous bladder contractions caused by raising the intravesical volume in anesthetized rats.

Yaksh et al. (1986) described a chronic model for study of micturition in unanesthetized rats. A bladder catheter was implanted chronically through laparatomy and externalized percutaneously.

Horváth et al. (1994) reported an ultrasonic method to study the influence of drugs on micturition in intact rats.

Tillig and Constantinou (1996) described videomicroscopic imaging of urethral peristaltic function in anesthetized rats. Cystometrograms were performed by recording continuously the bladder pressures while detecting micturition using a sensor placed at the orifice of the urethra. Renal pelvic pressure was measured during continuous perfusion using a nephrostomy inserted through the parenchyma. A catheter was placed in the femoral vein for intravenous drug administration. The left pyelo-ureteric junction and the upper part of the ureter were visualized using a stereomicroscope equipped with a video camera and a tape recorder. One syringe pump was used for filling the bladder to perform continuous cystometrograms. An other syringe pump was used for infusion of indigo carmine to assist the visualization of the bladder pressure.

Conte et al. (1988) developed a cystometric technique for quantitative studies on physiopharmacology of micturition in conscious, freely moving rats.

Peterson et al. (1989), Noronha-Blob et al. (1991) described *in vivo* cystometrogram studies in urethane-anesthetized and conscious **guinea pigs**.

Moreau et al. (1983) described simultaneous cystometry and uroflowmetry for evaluation of the caudal part of the urinary tract in **dogs**.

Imagawa et al. (1989) reported an *in vivo* procedure for functional evaluation of sympathetically mediated responses in lower urinary tract of dogs.

Häbler et al. (1990, 1992) examined the functional properties of unmyelinated and myelinated primary afferent neurons innervating the pelvic viscera in anesthetized **cats**. The axons were isolated from the intact dorsal root and the intact or chronically de-efferented ventral root of segment S2. The responses of the neurons were studied with natural stimulation of the urinary bladder using innocuous or noxious increases of intravesical pressure.

C.4.2
Studies in isolated organs

C.4.2.1
Studies on renal pelvis

PURPOSE AND RATIONALE

The isolated renal pelvis of the guinea pig has been used as pharmacological tool mainly by the group of Maggi (Maggi and Giuliani 1991, 1992; Maggi et al. 1992a,b, 1992c, 1994, 1995; Giuliani and Maggi 1996; Santicioli et al. 1995, 1997; Patachini et al. 1998; Bigoni et al. 1999).

PROCEDURE

Male albino guinea pigs weighing 250–300 g are stunned and bled. The whole kidney and attached ureter are removed and placed in oxygenated Krebs solution. The renal pelvis is carefully dissected from the renal parenchyma, separated from the ureter, cut and connected to threads to record motility along the circular axis. The preparation is suspended in a 5 ml organ bath and mechanical activity recorded by means of an isotonic transducer (load 1 mN). Transmural electrical field stimulation is made by means of platinum wire electrodes placed at the top and the bottom of the organ bath and connected to a GRASS S 88 stimulator. Square wave pulses (pulse width 0.5 ms, 60 V) are delivered in trains of 10 s duration at frequencies of 5 to 10 Hz.

Experiments commence after a 60 to 90 min equilibrium period after which amplitude and frequency of spontaneous activity has reached a steady state. *In vitro* capsaicin desensitization is made by exposure of the preparation to 10 µM for 15 min, followed by washing out and further equilibration for 30–60 min.

Concentration response curves to noradrenaline and acetylcholine are performed by non-cumulative addition to the bath at 20 min intervals. Contact time of drugs is 15 min.

EVALUATION

All values are expressed as mean ±SEM Statistical analysis is performed by means of Student's *t*-test for paired or unpaired data or by analysis of variance.

MODIFICATIONS OF THE METHOD

Zhang and Lang (1994), Lang et al. (1995), Lang and Zhang (1996) Teele and Lang (1998) recommended circumferentially cut strips from the proximal renal pelvis of guinea pigs since these strips contract more frequently than strips cut from the mid region.

Kimoto and Constantinou (1990, 1991) studied contractility of smooth muscle strips from the pace-

maker regions and pelviureteric junction of renal pelvis from **rabbits**.

Kondo et al. (1992) determined the effects of dobutamine and terbutaline on adenylate cyclase activity and cyclic AMP content in the renal pelvis of rabbits.

Seki and Suzuki (1990) made intracellular recordings to study the electrical properties of smooth muscle cells in the rabbit renal pelvis.

Zwergel et al. (1991) developed an intact **canine** model to measure renal pelvic pressure after complete ureteral obstruction with a balloon catheter inflated in the distal ureter.

C.4.2.2 Studies on urinary bladder and internal urethral sphincter

PURPOSE AND RATIONALE

Several authors investigated the influence of drugs on isolated parts of the lower urinary tract. Ueda et al. (1984) studied the effects on smooth muscle of the rabbit bladder dome, trigone and proximal urethra.

PROCEDURE

Male New Zealand rabbits weighing 2–3 kg are sacrificed and the abdomen is opened to remove the bladder and the urethra. After excess fat and connective tissue is removed, the bladder and the urethra are dissected into dome, trigone and proximal urethral preparations. All strips are cut transversely being approximately 2×6 mm unstretched. Ligatures are placed on both ends of the strips and one end is attached to a tissue holder and the other to a strain gauge force-displacement transducer connected to a polygraph on which isometric tension changes are recorded. Each of the strips is then placed into a 20 ml tissue bath containing Krebs-Ringer solution bubbled with 95% O_2 + 5% CO_2 at 37 °C. Resting tension is adjusted

to 1 g during an equilibrium period of at least 2 h. The contractile and relaxant responses are measured as increases or decreases from the resting tension. Doses-response curves are performed in a cumulative matter. Tissues are pretreated with an antagonist 20 min before the addition of an agonist.

EVALUATION

The values are expressed or plotted as the means ±SE and pA_2 values are calculated according to Arunlakshana and Schild (1959). Data are analyzed using the *t*-test, analysis of variance, Dunnett's test and regression analysis.

MODIFICATIONS OF THE METHOD

Pietra et al. (1990) studied the effects of some antidepressants by the *in vitro* inhibition of carbachol-induced contractions of rat detrusor strip preparations. The detrusor muscle tissue (bladder dome) was cut in a semicircular direction and further dissected into strip preparations measuring approximately 2×20 mm.

The preparation of the isolated, innervated urinary bladder of the rat was reported by Hukovic et al. (1965). Electrical stimulation was performed by a bipolar electrode from the nerves running close to the ureter.

Mapp et al. (1990) used the isolated rat urinary bladder to study the pharmacological modulation of the contractile response to toluene diisocyanate.

Maggi et al. (1985) used isolated detrusor strips of rat bladder connected to an isometric strain gauge and stimulated by field stimulation.

Anderson (1978) recommended the **rabbit** detrusor muscle a an unique in-vitro smooth muscle preparation. Rabbit detrusor muscles are thin and devoid of underlying submucosal tissue with parallel fiber orientation. The tissue exhibits autorhythmicity, characteristic of most single unit type smooth muscle preparations and can be employed in either isometric or isotonic organ bath recording systems.

Honda and Nakagawa (1986) studied the effects of the optical isomers of an alpha-1 adrenoceptor antagonist in rabbit lower urinary tract and prostate.

Khanna et al. (1977, 1981) evaluated the *in vitro* responses of three segments of rabbit lower urinary tract, e.g., the bladder body, the bladder base and the proximal urethra.

Ferguson and Marchant (1995) studied the inhibitory actions of GABA on rabbit urinary bladder muscle strips.

Andersson et al. (1983) studied the electrically induced relaxation of the noradrenaline contracted isolated urethra from rabbit and man. In rabbits, two circular transverse sections, each 4 mm long, were taken from the middle and upper parts of the urethra. Human urethral preparations were obtained from male patients undergoing cysto-urethrectomy en bloc because of bladder cancer. Rings of tissue were taken from the membranous and supra- and infra-collicular parts of the prostatic urethra.

Andersson et al. (1992) used transversal strips from the middle and upper part of rabbit urethra to study the involvement of nitric oxide in the electrically-induced, nerve-mediated relaxation.

Weetman (1972) described the preparation of the isolated, innervated urinary bladder in **guinea pigs**. Contractions of the tissue induced by nerve stimulation could be blocked by local anesthetics and by tetrodotoxin.

Isolated innervated, rat and guinea pig hemi-urinary bladder preparations were described by Dhattiwala and Dave (1975).

Burnstock et al. (1978) used recorded isometric tension of mucosal-free strips of the detrusor of the bladder from guinea pigs *in vitro* after electrical field stimulation.

Von Heyden et al. (1997) tested urethral relaxation after electrostimulation in guinea pigs. Male Hartley guinea pigs weighing 350–450 g were sacrificed and bladder, urethra and penis were dissected out. From each animal 4–6 urethral rings 1–2 mm thick were cut. The urethral rings were mounted according to their anatomical order: in channel 1 the most proximal ring (near the bladder neck) and in channel 6 the most distal ring (near the penile crura). The urethral rings were stretched by two spring-wire clips (Harvard Apparatus, South Natick, MA) whose tips closed in the urethral lumen. The manner in which the urethral rings were cut and mounted ensured that only the circularly oriented, mostly striated fibers contributed to the tension measured. Detrusor muscle was cut as a horizontal ring proximal to the trigone and mounted in the same way. The clips were connected with 4-O silk to a glass tissue support hook on one side and to an isometric force transducer (Föhr Medical Instruments GmbH, D-64342 Seeheim, Germany) on the other. A double-chambered bath (Föhr Medical Instruments GmbH, D-64342 Seeheim, Germany) was used in which the working chamber was connected to a second chamber, in which the gas (95% O_2 and 5% CO_2) was fed. The gas flow induced fluid circulation. Forces lower than 0.1 g could be measured without bubble artifacts in the working chamber. The transducer signals were fed into a thermal array recorder (Dash 10, Astro-Med, 63110 Rodgau, Germany). For tissue stimulation, vertical, L-shaped custom-made platinum electrodes (20 mm long, 0.3 mm diameter) 10 mm apart were used with a custom-made stimulator. The

tissue was mounted parallel with the electrodes. Bipolar, monophasic balance-charged rectangular pulses of 0.8-ms duration and 75 mA current were used.

Kunisawa et al. (1985) performed a pharmacological study of alpha adrenergic receptor subtypes in smooth muscle of **human** urinary bladder base and prostatic urethra.

Thornbury et al. (1992) reported on the mediation of nitric oxide of neurogenic relaxation of the urinary bladder neck muscle in **sheep**. Urinary bladders of sheep of either sex were obtained approximately 15 min after slaughter. Circularly oriented rings were cut from the region of the bladder just above the trigone. These were opened and the mucosa removed by sharp dissection to give strips with approximate dimensions of $10 \times 4 \times 4$ mm. The strips were mounted in organ baths and perfused with Krebs solution. Tension was measured with isometric transducers after field stimulation via platinum ring electrodes.

Hills et al. (1984) used isolated strips of the bladder from female **pigs**. Bladder neck strips were cut longitudinally and horizontally from the region of the bladder just below the trigone. The preparations were stripped of mucosa and trimmed to give a muscle strip of about 2×15 mm.

Klarskov (1987) studied the non-cholinergic, non-adrenergic inhibitory nerve responses of bladder outlet smooth muscle from female Danish Landrace pigs *in vitro*. Trigone strips were taken in an oblique direction from the internal urethral orifice and medially to one of the ureteric orifices, bladder neck strips transversal from the posterior half of the borderline between bladder and urethra, and urethral strips longitudinal from the proximal posterior part.

Teramoto et al. (1997) examined the membrane potential in the proximal urethra of pigs by use of the microelectrode technique.

C.4.2.3 Effects on external urethral sphincter

PURPOSE AND RATIONALE

In contrast to the smooth musculature of the internal urethral sphincter, the external urethral sphincter is a striate muscle and a part of the urogenital diaphragm (Kuru 1965). Judged from electromyographic studies it is generally accepted that the preponderance of continence depends on the external urethral sphincter. The external urethral sphincter shows a steady tonic discharge under resting conditions. As the bladder fills, there is initially an increase in this activity. When the rise in tension in the bladder wall leads to reflex contraction, the activity in the external urethra sphincter ceases and in remains quiescent during voiding. Parlani et al. (1992) used the external urethral sphincter of the rat as an *in vitro* model to evaluate the activity of drugs on the smooth and striated components of the urinary bladder outlet.

PROCEDURE

Male Wistar rats weighing 360–400 g are sacrificed by decapitation and exsanguination. Through a midline incision of the lower abdomen, the external urethral sphincter (Watanabe and Yamamoto 1979) is isolated from the perineal muscles and surrounding connective tissue and removed in toto. The preparation is placed in oxygenated Krebs solution, and a ring is taken from its middle region. In this area the urethra is encircled by bundles of striated muscle fibers partly interlaced with urethral smooth muscle. The rings are cut to obtain strips that are suspended in a 5-ml organ bath containing Krebs solution at 37 °C. A mixture of 96% O_2 and 4% CO_2 is bubbled into the organ bath. The preparations are connected by means of a silk thread to an isometric strain gauge under a constant load of 1 g. The contractile activity is recorded on a polygraph. Field stimulation is carried out by means of two platinum wire electrodes placed at the top and the bottom of the organ bath and connected to a Grass S11 stimulator. The preparations are allowed to equilibrate for at least 60 min. Square wave pulses are delivered at an intensity between 10 and 60 V, a frequency between 0.1 and 3 Hz, and a duration between 0.1 and 1 s; trains are of 5 s every 5 min. After three consecutive reproducible responses are obtained, drugs are added to the organ bath. The effect of drugs is expressed as the percent of inhibition of contractile response before exposure to drugs and is evaluated as soon as the maximum effect is reached.

EVALUATION

Means ±standard error of the mean are calculated. Statistical evaluation is performed by using Student's *t*-test for paired or unpaired data.

MODIFICATIONS OF THE METHOD

In some studies, denervation of the external urethral sphincter was performed (Somma et al. 1989; Parlani et al. 1992). Rats were anesthetized with 30 mg/kg penthotal i.p., then the major pelvic ganglia, known to provide both sympathetic and parasympathetic innervation to the urinary bladder and the external urethral sphincter (Hulsebosh and Goggeshall 1982; Purinton et al. 1973; Watanabe and Yamamoto 1979) are isolated and bilaterally removed through a small incision of the lower abdomen.

In the same preparations, somatic denervation of the external urethral sphincter was obtained by cutting the pudendal nerves. The paravertebral muscles were carefully dissected through an incision of the skin to exteriorize the sacral plexus. The pudendal nerves were isolated, and 2–3 mm of the nerve were removed. An absorbable sponge soaked with amikain solution was left in place to prevent bleeding and infection. The muscles and the skin were sutured with cat gut. The rats were allowed to recover for 10 to 15 days in individual cages with free access to water and food.

C.4.2.4 Propagation of impulses in the guinea pig ureter

PURPOSE AND RATIONALE

The mammalian ureter provides one of the most clear examples of electromechanical coupling in smooth muscle. The ureter smooth muscles are electrically and mechanically quiescent but, when depolarized to threshold, they fire an action potential characterized by an unusually long-lasting potential and generate a phasic contraction (Shuba 1977; Brading et al. 1983; Meini et al. 1995). Both the action potential and the accom-

panying contraction critically depend upon the influx of extracellular calcium through voltage-sensitive L-type channels, which are enhanced and blocked by dihydropyridine drugs, Bay K 8644 and nifedipine, respectively. The model predicts that suppression of action potentials at any site of the ureter will suppress the propagation of contraction and peristalsis. (Weiss 1992).

PROCEDURE

Male albino guinea pigs weighing 25–300 g are stunned and bled. The whole kidney and ureter are excised and placed in a Petri dish containing oxygenated Krebs solution for dissection. A 4–5 cm long piece of ureter is dissected from the inferior renal pole and placed in a three-compartment organ bath which enables a separate superfusion of different parts of the organs. Two Perspex partitions are used to separate the renal-, middle- and bladder-sites. They include a window covered with condom rubber: a small hole (about 300 µm) is made in the rubber to enable the passage of the ureter. Proximal to each partition, the renal and bladder ends are pinned to a Sylgard support. The distal portions of the renal and bladder ends are connected via a pulley to isotonic transducers (Basile 7006, load 2 mN) for recording of mechanical activity on a two-channel polygraph. Each compartment is perfused by means of a peristaltic pump at a rate of 1 ml/min with oxygenated Krebs solution at 34 °C.

Electrical field stimulation is applied to either compartment by means of two wire platinum electrodes positioned in parallel with the two sides of the ureter. Square wave pulses (5–25 ms pulse width, 20 V) are automatically delivered every 100 s by means of a GRASS S88 stimulator.

Drugs are applied by superfusion at the middle site. Amplitudes of contraction are recorded.

EVALUATION

Values are calculated as mean ±SEM. Statistical analysis is performed by means of Student's *t*-test or by means of analysis of variance.

Chapter D
Respiratory activity

D.1 *In vitro* tests

D.1.0.1 Histamine (H_1) receptor binding

PURPOSE AND RATIONALE

Histamine is considered to play a major role in asthmatic attacks. H_1-antagonists have been used since decades as therapeutic agents. This assay is used to determine the affinity of test compounds to the histamine H_1 receptor by measuring their inhibitory activities on the binding of the H_1 antagonist ^{3}H-pyrilamine to a plasma membrane preparation from guinea pig brain.

PROCEDURE

Brains from guinea-pigs are homogenized in ice-cold Tris buffer (pH 7.5) in a Potter homogenizer (1 g brain in 30 ml buffer). The homogenate is centrifuged at 4 °C for 10 min at 50 000 *g*. The supernatant is discarded, the pellet resuspended in buffer, centrifuged as before, and the final pellets resuspended in Tris buffer (1 g fresh weight/5 ml). Aliquots of 1 ml are frozen at –70 °C.

In the competition experiment, 50 µl ^{3}H-pyrilamine (one constant concentration of 2×10^{-9} M), 50 µl test compound (>10 concentrations, 10^{-5}–10^{-10} M) and 100 µl membrane suspension from guinea pig whole brain (approx. 10 mg wet weight/ml) per sample are incubated in a shaking bath at 25 °C for 30 min. Incubation buffer: 50 mM Tris-HCl buffer, pH 7.5.

Saturation experiments are performed with 11 concentrations of ^{3}H-pyrilamine ($0.1–50 \times 10^{-9}$ M). Total binding is determined in the presence of incubation

buffer, non-specific binding is determined in the presence of mepyramine or doxepin (10^{-5} M).

The reaction is stopped by rapid vacuum filtration through glass fibre filters. Thereby the membrane-bound is separated from the free radioactivity. The retained membrane-bound radioactivity on the filter is measured after addition of 3 ml liquid scintillation cocktail per sample in a liquid scintillation counter.

EVALUATION OF RESULTS

The following parameters are calculated:

- total binding of ^{3}H-pyrilamine
- non-specific binding: binding of ^{3}H-pyrilamine in the presence of mepyramine or doxepin
- specific binding = total binding – non-specific binding
- % inhibition of ^{3}H-pyrilamine binding: 100 – specific binding as percentage of control value

The dissociation constant (K_i) and the IC_{50} value of the test drug are determined from the competition experiment of ^{3}H-pyrilamine versus non-labeled drug by a computer-supported analysis of the binding data.

D.2
Effects on air ways

D.2.1
Tests in isolated organs

D.2.1.1
Spasmolytic activity in isolated guinea pig lung strips

PURPOSE AND RATIONALE

Several autacoids such as histamine and leukotrienes, induce bronchoconstriction. Histamine is an important mediator of immediate allergic and inflammatory reactions. It causes bronchoconstriction by activating H_1-receptors. Calcium ionophores induce the release of leukotrienes via the 5-lipoxygenase pathway. Leukotrienes are powerful bronchoconstrictors that appear to act on smooth muscles via specific receptors. In this method, drugs are tested for their capability of inhibiting bronchospasm induced by histamine or calcium ionophore. It is used to detect H_1- and leukotriene receptor blocking properties of test compounds.

PROCEDURE

Albino guinea-pigs of either sex weighing 300–450 g are sacrificed with an overdose of ether. The chest cavity is opened and the lungs are removed. They are cut into strips of 5 cm and placed into a physiological saline solution. Thereafter, the lung strips are mounted in an organ bath containing a nutritive solution. The bath is bubbled with carbogen and maintained at 37 °C. Under a pre-load of 0.5 g–3 g, the tissue is left to equilibrate for 30–60 min. Prior to testing, carbachol is added to the bath to test the lung strips' ability of contraction. Twenty min later, two prevalues are obtained by adding the spasmogen

- histamine dihydrochloride 10^{-6} g/ml for 5 min, or
- Ca – ionophore 5×10^{-6} g/ml for 5 min, or
- Leukotriene LTC_4 10^{-9}–10^{-8} g/ml for 10 min, or
- Leukotriene LTD_4 10^{-9}–10^{-8} g/ml for 10 min

to the bath and recording the contractile force at its maximal level. Following a 20 min equilibration period, the spasmogen is administered again. Five minutes thereafter, the test compound is added in cumulative doses from 10^{-8} to 10^{-4} g/ml at 5 or 10 min intervals. The contractile response is determined isometrically.

Test modification:
Inhibition of prostaglandin synthesis

This procedure is identical to the test described above with the exception that the prostaglandin synthesis is inhibited by addition of indomethacin at 10^{-6} g/ml prior to spasmogen administration.

EVALUATION

The percent inhibition of spasmogen induced contraction is calculated.

MODIFICATIONS OF THE METHOD

Lung parenchyma strips from various species were used to measure bronchoactivity by Kleinstiver and Eyre (1979).

A descriptive model of the events occurring during an inflation-deflation cycle using excised rat lungs was proposed by Frazer et al. (1985).

Barrow (1986) measured volume-pressure cycles in air-filled or liquid-filled rabbit lungs ranging from intact lungs with the rib cage immobilized to isolated lungs.

D.2.1.2 Spasmolytic activity in isolated trachea

PURPOSE AND RATIONALE

The isolated tracheal chain of guinea pigs can be used to test for β-blocking activity (see Sect. A.1.2.7). In addition, this model can be used to test compounds which inhibit bronchospasms. It is used to detect β-sympathomimetic, H_1-receptor blocking and leuko-triene receptor blocking properties of test drugs.

Carbachol is a cholinergic agonist that produces contraction of bronchial smooth muscle by muscarinic stimulation.

Histamine is an important mediator of immediate allergic (type 1) and inflammatory reactions. It causes bronchoconstriction by activating H_1-receptors.

Calcium ionophores induce the release of leukotrienes via the 5-lipoxygenase pathway. Leukotrienes are powerful bronchoconstrictors that appear to act on smooth muscle via specific receptors.

To asses a compound's ability to inhibit carbachol induced bronchospasm via β-receptor activation, a β-receptor blocking agent (for example propranolol) must be added. If relaxation of bronchial smooth muscle is brought about by β-receptor activation, the spasmolytic effect will decrease following propranolol administration.

The effect of bradykinin can be abolished by bradykinin antagonists (Hock et al. 1991).

The effects of potassium channel openers can also be studied in this test (Englert et al. 1992).

PROCEDURE

Albino guinea pigs of either sex weighing 300–550 g are sacrificed by CO_2 narcosis. The entire trachea is dissected out and cut into individual rings (2–3 cartilaginous rings wide). Twelve–fifeteen rings are tied together with silk threads and mounted in the organ bath containing Krebs-Henseleit solution. The tissue is maintained at 37 °C under a tension of 0.5 g and gassed with carbogen. Isometric contractions are recorded via a strain-gauge transduced on a polygraph. Forty-five minutes are allowed for equilibration before the addition of the spasmogen.

The following spasmogens are used:

- carbachol (2×10^{-7} g/ml)
- histamine (10^{-7} g/ml)
- Ca – ionophore for release of leukotrienes
- leukotriene LTC_4 (10^{-9}–10^{-8} g/ml)
- leukotriene LTD_4 (10^{-9}–10^{-8} g/ml)

When the contraction has reached its maximum (initial spasm) after 10–12 min, the standard drug, e.g., isoprenaline (1 ng/ml) or aminophylline (10 ng/ml) is administered. The bronchial responses are allowed to plateau and are recorded. The tissue is rinsed thoroughly and control contractions are induced again by adding spasmogen. After obtaining the initial spasm again, the test drug is added and the contractile force is recorded at its maximal level.

Determination of mechanism of action (testing for β-sympathomimetic effect). After obtaining the initial carbachol induced spasm, propranolol is administered 5 min before the addition of the test drug. Three minutes later, the tissue is challenged by carbachol administration.

EVALUATION

The percent inhibition of carbachol or other spasmogen induced contractions is calculated. From dose-response curves ED_{50} values can be calculated.

CRITICAL ASSESSMENT OF THE METHOD

The isolated guinea pig trachea has been proven to be an useful tool for several purposes, e.g., screening procedures and studies on mode of action, e.g., of potassium channel openers.

MODIFICATIONS OF THE METHOD

The molecular mechanisms of β-adrenergic relaxation of airway smooth muscle were described by Kotlikoff and Kamm (1996).

Farmer et al. (1986) studied the effects of epithelium removal on the sensitivity of **guinea-pig** isolated trachealis to bronchodilator drugs.

Wilkens et al. (1992) described a bioassay system for a tracheal smooth muscle-constricting factor using

an isolated guinea pig trachea which was cannulated from both sides, mounted in an organ bath and monitored by a TV camera attached to a microscope. The picture was digitized continuously, and the diameter of the trachea calculated and displayed on a monitor throughout the experiment.

Coleman and Nials (1989) described a versatile, eight-chamber superfusion system for the evaluation of spasmogenic and spasmolytic agents using guinea pig isolated tracheal smooth muscle.

Goldie et al. (1986a) studied the influence of the epithelium on responsiveness of guinea pig isolated trachea to contractile and relaxant agonists.

Lee et al. (1997) studied the effects of bupivacaine and its isomers on guinea pig tracheal smooth muscle. The trachea from the larynx to the carina was removed and cut into single rings. Seven tracheal rings were tied together with the circular muscle running on the same side of the chain, placed into an organ bath containing Krebs Ringer's solution and connected to a force placement transducer for measurement of isometric tension.

Wong et al. (1997) tested the effects of tyrosine kinase inhibitors on antigen challenge of guinea pig lung *in vitro*. Guinea pigs were passively sensitized by a single i.p. injection of 1 mg/kg rabbit IgG antibody against ovalbumin. Bronchial rings, 3 mm in length, were obtained from the hilar bronchi of sacrificed animals and suspended isometrically in an organ bath in Krebs bicarbonate buffer with a resting load of 2 g. To determine maximum antigen-induced contractions, bronchial rings were exposed to increasing concentrations of ovalbumin. To evaluate the role of protein tyrosine kinase in mediating smooth muscle anaphylactic contraction, protein tyrosine kinase inhibitors were preincubated with bronchial rings 30 min before addition of ovalbumin.

Eltze and Galvan (1994) compared the inhibition of preganglionic and postganglionic contraction of the **rabbit** isolated bronchus/trachea by antagonists with selectivity for different muscarinic receptor subtypes with their affinities at M_1, M_2, M_3, and M_4 receptors (Barnes 1993).

For **experiments with vagus nerve stimulation**, the vagi were isolated with rings of the proximal main stem bronchi and a small portion of the distal trachea. The tissues were hung on stainless steel hooks, which passed through the lumen, and were placed in a water-jacketed organ bath filled with Krebs solution plus 2×10^{-5} M choline chloride to promote resynthesis of acetylcholine, 10^{-5} M indomethacin to prevent generation of cyclo-oxygenase products, and 10^{-6} M DL-propranolol to block possible β-adrenoceptor-mediated effects. The preparation was fixed under a resting tension of 1 g for isometric contraction measurement using a force transducer. The vagi were passed around bipolar platinum electrodes held at the surface of the bath. Electrical stimulation was performed with trains (20 Hz, 0.3 ms at 20 V) elicited every 20 min.

For experiments with **field stimulation**, two-ring preparations from the distal trachea of the rabbit were suspended in organ bath in Krebs solution with the above mentioned additions under a resting tension of 1 g. Isometric contractions were elicited at 1 h intervals by continuous electrical field stimulation via platinum electrodes (20 Hz, 0.3 ms at 20 V) for an average 3–7 min to reach a stable plateau.

Vaali et al. (1996) studied in isolated tracheal rings of **rats** and guinea pigs the bronchorelaxing effects of nitric oxide donors. The epithelium of some rings was removed by gentle rubbing. Rat mesenteric rings were cut from the same animals as the bronchi and similarly prepared by removing the endothelium by gently rubbing of the intimate surface.

Farmer et al. (1994) used the isolated trachea from male **ferrets** weighing 1.5–2.5 kg to study the effects of bradykinin receptor agonists.

Toews et al. (1997) assessed the effects of the phospholipid mediator lysophosphatidic acid on the contractile responsiveness of isolated tracheal rings from **rabbits** and **cats**.

Tamaoki et al. (1993) used isolated rings of segmental bronchi from *dogs* to study atypical β-adrenoceptor-(β_3-adrenoceptor)mediated relaxation.

The preparation of **bovine** tracheal smooth muscle for measuring airway responsiveness *in vitro* was described by Hashjin et al. (1995).

Lulich and Paterson (1980) used **human** isolated bronchial muscle preparations and compared the effects of histamine and other drugs with the effects observed on the central and peripheral airways of the rat.

Goldie et al. (1986b) measured the responses of human bronchial strip preparations to contractile and relaxant agonists in preparations from non-diseased and from asthmatic lung obtained 3–15 h post mortem.

Hulsman and de Jongste (1993) reviewed the methods to study human airways *in vitro*.

D.2.1.3 Reactivity of the isolated perfused trachea

PURPOSE AND RATIONALE

The mechanism by which the epithelium affects the reactivity of tracheal musculature can be studied using the isolated perfused trachea preparation. Contractile agonists can be added either to the serosal (extraluminal) or to the mucosal (intraluminal) surface (Fedan and Frazer 1992).

PROCEDURE

A 4-cm segment of the trachea of male guinea pigs is removed after sacrifice of the animal and placed for cleaning in modified Krebs-Henseleit solution at 37 °C containing (millimolar) NaCl 113.0, KCl 4.8, $CaCl_2$ 2.5, KH_2PO_4 1.2, $MgSO_4$ 1.2, $NaHCO_3$ 25.0, and glucose 5.7 (pH 7.4) being gassed with 95% O_2/5% CO_2. The trachea is then attached to a stainless-steel perfusion holder (Munakata et al. 1988), extended to its *in situ* length and placed in an organ chamber (the serosal compartment) at 37 °C containing 25 ml of gassed modified Krebs-Henseleit solution. This solution is also pumped at a constant rate of 30 ml/min through the lumen (mucosal compartment). Responses of the tracheal musculature are obtained by measuring changes in inlet-outlet ΔP between the side holes of indwelling catheters, while the trachea as perfused at a constant rate of modified Krebs-Henseleit solution. The inlet and outlet catheters are connected to the positive and negative sides, respectively, of a differential pressure transducer.

Agonists are added in step-wise increasing, cumulative concentrations. Two consecutive dose-response cur-ves are obtained after the addition either to the serosal or mucosal compartment. The second dose-response curve is obtained 1.5 h after the end of the first, the preparation being washed every 15 min during the intervening period.

EVALUATION

Responses are quantified as ΔP in centimeters of H_2O. Geometric EC_{50} values are determined from least-square analysis of a logit model and are presented along with 95% confidence intervals.

MODIFICATIONS OF THE METHOD

Baersch and Frölich (1996) measured continuously the changes of the diameter of isolated guinea pig tracheal tubes by a newly developed imaging bioassay system. The tracheal tube between larynx and bifurcation was prepared to a length of 1.8–2.5 cm, cannulated at both ends and mounted in a 15 ml organ bath filled and perfused with oxygenated Krebs solution at 37 °C. The lumen of the trachea was perfused with warm (37 °C) Krebs solution from a reservoir that was isolated from the tissue bath. Changes in diameter of the trachea were assessed by computerized video microscopy. The tracheal diameter was used as marker for airway size, thus allowing calculation of muscle contractions under experimental conditions. Following a 30-min equilibrium period, a contraction was induced by intraluminal application of methacholine (0.1 mmol/l) as reference contraction. After washout and return to a stable baseline, cumulative concentration-response curves were obtained by luminal or extraluminal drug application.

Yang et al. (1991) studied the role of epithelium in airway smooth muscle responses to relaxant agents. The results suggested that the epithelium is a relatively weak barrier for lipophilic agents but has a major role as a diffusion barrier to hydrophilic substances.

Munataka et al. (1988, 1989) developed an *in vitro* system to assess the role of epithelium in regulating airway tone using the intact **guinea pig** trachea. The responses to histamine, acetylcholine and hypertonic KCl when stimulated from the epithelial or serosal site were first examined in tracheae with intact epithelium. Then the responses to these agonists were registered after epithelial denudation.

Pavlovic et al. (1989) studied the role of airway epithelium in the modulation of bronchomotor tone in the isolated trachea of **rats**. An organ bath was constructed that permitted independent circulation of fluid within the lumen or around the exterior of the tracheal segment. In one-half of the preparations the epithelium was mechanically removed.

Fernandes et al. (1989) described a co-axial bioassay system, whereby rat cross-cut aorta strip preparations were set up in co-axial assemblies under 500 mg resting tension within a guinea pig tracheal segment serving as donor of the smooth muscle relaxant factor from guinea-pig tracheal epithelium.

Lewis and Broadley (1995) investigated the influence of spasmogen inhalation by guinea pigs upon subsequent demonstration of ovalbumin-induced hyperreactivity in isolated airway tissues. Guinea pigs were sensitized with ovalbumin (i.p.) 14 days before use. *In vitro* airway hyperreactivity induced by ovalbumin inhalation was determined by challenging with aerosolized spasmogen (5-HT, methacholine, the thromboxane-mimetic U-46619, or adenosine) 24 h before and again 18–24 h after the ovalbumin inhalation. One h later, the animals were sacrificed and isolated airways perfused lung halves and tracheal spirals were set up for determination of tissue sensitivity to carbachol, histamine, and adenosine.

Sparrow and Mitchell (1991) used bronchial segments obtained from the lungs of Large-white-/Landrace-cross **pigs** to study the modulation by the epithelium of the extent of bronchial narrowing produced by substances perfused through the lumen.

Mitchell et al. (1989) compared the reactions of perfused bronchial segments and bronchial strips of *pigs* to histamine and carbachol.

Hulsman et al. (1992) recommended the perfused **human** bronchiolar tube as a suitable model.

Omari et al. (1993) studied the responsiveness of human isolated bronchial segments and its relationship to epithelial loss.

D.2.1.4 Bronchial perfusion of isolated lung

PURPOSE AND RATIONALE

Bronchial perfusion of the isolated lung was described by Sollmann and von Oettingen (1928) as a simple method for studying pharmacological reactions of bronchiolar muscle. The method consists in perfusing fluid down the trachea through the bronchi, and allowing it to escape from the alveoli through scratches on the surface of the lungs. Bronchoconstriction results in a reduced rate of flow, bronchodilatation is indicated by an increased flow. The method has been used to evaluate sympathomimetic drugs by Tainter et al. (1934) and by Luduena et al. (1957).

PROCEDURE

Guinea pigs weighing about 200 g are sacrificed by a head blow. The chest is opened, the trachea cut at the upper end and removed with the lung. The trachea is attached to the cannula of an perfusion apparatus. Only one lung is perfused, the other being tied off. The lower part of the lower lobe is cut off and the rest of the lung surface is scratched deeply assuring maximal pre-medication flow.

The perfusion fluid has the following composition in percentage of anhydrous salts: NaCl 0.659, $NaHCO_3$ 0.252, KCl 0.046, $CaCl_2$ 0.005, $MgCl_2$ 0.0135, NaH_2PO_4 0.01, Na_2HPO_4 0.008, glucose 5%, pH 8.0. The temperature of the perfusion medium is 37.5 °C and the lung is enclosed in a glass cylinder to be protected from variations in the environmental temperature.

The trachea is attached to the cannula of a perfusion apparatus which pumps the solution at a constant rate into a manometric tube connected with the perfused organ. Resistance to the flow (bronchoconstriction) results in an increase in the height of the column of fluid in the manometer. The intensity of bronchodilator effect is measured by the fall of the column in the manometer.

After the lung is attached to a T-shaped cannula, the pump is set in motion and the fluid, after filling the lung, flows out of the system through the third opening of the cannula. By gentle pressure air bubbles are forced out of the lung into the overflow. The lung is then treated in the aforesaid manner, and the upper outlet of the cannula closed. Histamine HCl is added in a concentration of 1 : 2 500 000 as soon as the perfusion starts and the flow is adjusted to obtain a constant progressive increase in pressure.

The drugs are injected near the cannula when the perfusion pressure reaches a level of 500–650 ml of water. The volume injected is always 0.1 ml.

Each drug is tested for bronchodilating activity against the bronchoconstriction induced by histamine in parallel with l-arterenol following a Latin square, including three doses of each drug and three doses of l-arterenol graded at 0.5 log intervals.

EVALUATION

Activity ratios of bronchodilating agents versus the standard can be calculated with a 3 + 3 point assay including confidence limits.

D.2.1.5 Vascular and airway responses in the isolated lung

PURPOSE AND RATIONALE

The isolated perfused rat lung allows the simultaneous registration of pulmonary vascular and airway responses to various drugs.

PROCEDURE

Male Sprague-Dawley rats weighing 300–350 g are intraperitoneally anesthetized with pentobarbital sodium (50 mg/kg). The trachea is cannulated with a short section of polyethylene tubing, connected to a rodent ventilator, and ventilated with room air enriched with 95% O_2/5% CO_2, with a tidal volume of 4–5 ml/kg and 2 cm H_2O positive end-respiratory pressure. The rats are heparinized with 1 000 units of intravenous heparin and are rapidly exsanguinated by withdrawing blood from the carotid artery.

The lung is exposed by median sternotomy, and a ligature is placed around the aorta to prevent systemic loss of blood. The main pulmonary artery is catheterized, and the lung is removed en block and suspended in a warmed (39 °C), humidified (100%) water-jacketed chamber. An external heat exchanger is used to maintain the temperature of the perfusate and the isolated lung chamber constant throughout the experiment. The perfusate solution (15 ml of heparinized blood and 5 ml modified Krebs-Henseleit solution) is placed in a reservoir and mixed constantly by a mag-

netic stirrer. The lungs are perfused with a peristaltic roller pump at a flow rate of 8–14 ml/min to maintain a physiological baseline pulmonary arterial perfusion pressure of 15 ±0.5 mm Hg. Pulmonary arterial perfusion pressure, airway pressure, and reservoir blood level are continuously monitored, electronically averaged and recorded with a polygraph.

EVALUATION

Changes (increase or decrease) in pulmonary arterial pressure and in airway pressure after injection of test compounds are measured in mm Hg and compared with baseline values.

MODIFICATIONS OF THE METHOD

Bernard et al. (1997) described an isolated perfused lung model with real time data collection and analysis of lung function. Male Sprague Dawley rats were anesthetized with 130 mg/kg pentobarbital i.p. The trachea was cannulated and then ventilated with 5% CO_2 and 95% air at e rate of 60 breath/min and a tidal volume of 2.5 ml. An injection of 650–700 units/kg of heparin was made into the right ventricle. A cannula was placed into the main pulmonary artery. The left ventricle was incised and the lungs were washed free of blood with warmed Krebs-Henseleit bicarbonate buffer with 4.5% BSA and 0.1% glucose. The left atrium was then cannulated to allow outflow of the perfusate. The lung was then removed and suspended in a chamber for perfusion. The flow rate of the perfusate was adjusted to 8–10 ml/min/kg. Ventilation was maintained at 60 breaths/min with humidified and warmed gas. The lung was allowed to recover for 15 min at which time the lung mechanic parameters of flow, volume, transpulmonary pressure, pulmonary artery pressure, weight, resistance, elastance, and positive enddiastolic pressure were measured.

Hauge (1968) studied the conditions governing the pressor responses to ventilation hypoxia in isolated perfused rat lungs.

Uhlig and Heiny (1995) measured the weight of the isolated perfused rat lung during negative pressure ventilation for quantitating edema formation in the isolated lung.

Uhlig and Wollin (1994) described an improved setup for the isolated perfused rat lung. Breathing mechanic, such as tidal volume, pulmonary compliance, and pulmonary resistance, as well as perfusate characteristics, such as pulmonary vascular resistance, pulmonary pre- and postcapillary resistance, perfusate pH, P_{O2}, and P_{CO2}, and the capillary filtration coefficient were determined.

Byron et al. (1986) used the isolated perfused rat lung preparation for the study of aerosolized drug deposition and absorption.

Hendriks et al. (1999) published a modified technique of isolated left lung perfusion in the rat.

Riley et al. (1981) determined the tissue elastic properties of saline-filled isolated hamster lungs by measuring the pressure-volume relationships and studied the prevention of bleomycin-induced pulmonary fibrosis by *cis*-4-hydroxy-L-proline.

Lewis and Broadley (1995) tested the influence of spasmogen inhalation by **guinea pigs** upon subsequent demonstration of albumin-induced hyperreactivity in isolated airway tissues, such as perfused lung halves and tracheal spirals.

Anglade et al. (1998) measured the pulmonary capillary filtration coefficient in isolated **rabbit** lungs which were suspended by a string tied around the tracheal cannula from a counter-balanced force transducer to perform continuous weight measurement. To measure the pulmonary capillary filtration coefficient, pulmonary venous pressure was raised stepwise which results in an initial large weight gain for a few seconds followed by a slower rate of weight gain. The pulmonary capillary filtration coefficient was calculated on the slow phase of the weight curve by a time zero extrapolation or from the slope of the curve.

Nakamura et al. (1987) studied neurogenic pulmonary edema in lung perfusion preparations *in situ* in the **dog**.

Allen et al. (1993) studied the cardiovascular effects of a continuous prostacycline administration into an isolated *in situ* lung preparation in the dog.

Pogrebniak et al. (1994) investigated the influence of tumor necrosis factor in an isolated lung perfusion model in **pigs**.

The fluid filtration coefficient before and after infusion of *Escherichia coli* endotoxin was measured in excised **goat** lungs by Winn et al. (1988).

D.2.2 *In vivo* tests

D.2.2.1 Bronchospasmolytic activity in anesthetized guinea pigs (Konzett-Rössler method)

PURPOSE AND RATIONALE

The principle war first described by Kiese (1935). Konzett and Rössler (1940) published a method suitable for screening procedures which found worldwide acceptance. A survey on the history and further modifications was given by Döring and Dehnert (1997).

The method is based on registration of air volume changes of a living animal in a closed system consisting of the respiration pump, of the trachea and the bronchi as well as of a reservoir permitting measurement of volume or pressure of excess air. Bronchospasm decreases the volume of inspired air and increases the volume of excess air. Thus, the degree of bronchospasm can be quantified by recording the volume of excess air. Administration of spasmogens like acetylcholine, histamine, bradykinin, serotonin, ovalbumin, PAF, substance P, methacholine or leukotrienes, results in contraction of bronchial smooth muscle.

The method permits the evaluation of a drug's bronchospasmolytic effect by measuring the volume of air, which is not taken up by the lungs after bronchospasm.

PROCEDURE

Guinea-pigs of either sex weighing 250–500 g are anaesthetized with 1.25 g/kg i.p. urethane. Pentobarbital (60 mg/kg s.c.) and alcuronium chloride (1 mg/kg s.c.) are to be preferred when the bronchospasm is elicited by PAF or substance P. Anesthesia has to be deep enough in order to prevent influence of spontaneous respiration. The trachea is cannulated by means of a two way cannula, one arm of which is connected to the respiratory pump and the other to a Statham P23 Db transducer. The animal is artificially respired using a Starling pump with an inspiratory pressure set at 90–120 mm of water, an adequate tidal volume of 3 ml/100 g body weight and a frequency of 60 strokes per minute. Excess air, not taken up by the lungs, is measured and recorded on a polygraph. The internal jugular vein is cannulated for the administration of spasmogens and test compounds. The carotid artery is cannulated for measuring blood pressure.

Testing

Guinea-pigs receive the following spasmogens by i.v. administration:

- acetylcholine hydrochloride (20–40 µg/kg), or
- methacholine (20–40 µg/kg), or
- histamine dihydrochloride (5–20 µg/kg), or
- bradykinin triacetate (10–20 µg/kg), or
- ovalbumin (1 mg/kg), or
- PAF (25–50 ng/ml), or
- leukotrienes LTC_4, LTD_4 (about 1 µg/kg), or
- substance P (0.5 µg/kg).

After obtaining two bronchospasms of equal intensity, test compounds are administered i.v., p.o., s.c. or intraduodenally.

The spasmogen is given again at the following time intervals:

- 5, 15 and 30 min after i.v. administration of the drug
- 15, 30 and 60 min after intraduodenal administration of the drug
- 30 and 60 (sometimes also 120) min after p.o. administration of the drug.

The following standard compounds are used:

- atropine sulfate (0.01 mg/kg, i.v.) to inhibit acetylcholine or methacholine induced spasms
- aminophylline (6 mg/kg, i.v.) to inhibit bradykinin induced spasms
- tolpropamine-HCl (0.2 mg/kg) to inhibit histamine induced spasms
- imipramine-HCl (3–5 mg/kg) to inhibit serotonin-kreatinin-sulphate induced spasms.

EVALUATION

Results are expressed as percent inhibition of induced bronchospasm over the control agonistic responses. The ED_{50} value is calculated.

CRITICAL ASSESSMENT OF THE METHOD

The "Konzett-Roessler"-method has been proven to be a standard procedure in respiratory pharmacology being modified by several authors (Rosenthale and Dervinis 1968).

MODIFICATIONS OF THE METHOD

Forced insufflation was proposed as a simple but accurate inhalation procedure for investigating the activity of anti-asthmatic drugs in guinea pigs by Schiantarelli et al. (1982).

Lundberg et al. (1983), Belvisi et al. (1989), Miura et al. (1994) determined airway opening pressure (P_{ao}) as an index for tracheobronchial resistance to air flow.

Orr and Blair (1969) and Riley et al. (1987) sensitized rats intravenously with a potent antiserum to ovalbumin, obtained by infecting ovalbumin-sensitized donor rats with the parasitic nematode *Nippostrongylus brasiliensis* in order to boost IgE antibody production. The anesthetized animals were challenged with ovalbumin 48 h after sensitization and the subsequent increase in tracheal pressure was recorded.

Collier et al. (1993), Collier and James (1967) published a modification of the Konzett-Rössler-method using the forced re-inflation to overcome the severe bronchoconstriction occurring in sensitized guinea pigs.

Further modifications are by Schliep et al. (1986), Marano and Doria (1993).

Groeben and Brown (1996) measured changes in the cross-sectional area of conducting airways by cumulative doses of ipratropium with and without gallamine, a selective M_2 muscarinic receptor blocker, and after metaproterenol in anesthetized **dogs** using high-resolution computed tomography. Using a Somatom Plus scanner (Siemens), 50 to 55 contiguous scans were obtained, starting approximately 5 mm above the origin of the right upper lobe bronchus from the trachea and proceeding caudally using 1-mm table feed and 2-mm slice thickness. The dogs were anesthetized with thiopental. After paralysis was induced by succinylcholine, the trachea was intubated and the lungs ventilated with a volume-cycled ventilator with 100% oxygen. During the scans, the dogs were apneic at function residual capacity (approximately 2 min). Images were reconstructed using a high-spatial frequency algorithm.

D.2.2.2 Effect of arachidonic acid or PAF on respiratory function *in vivo*

PURPOSE AND RATIONALE

Based on the classical method of Konzett and Rössler (1940), Lefort and Vargafting (1978), Vargafting et al. (1979) studied the effects of arachidonic acid and PAF on respiratory function of guinea pigs *in vivo*.

Arachidonic acid is metabolized into thromboxane (TXA_2) and prostacyclin (PGI_2). TXA_2 produced in the lung leads to bronchoconstriction, which is independent from circulating platelets and leukotrienes; TXA_2 produced intracellularly in platelets induces a reversible thrombocytopenia. PGI_2 produced in the vessel wall leads to the reduction of systolic and diastolic blood pressure. All three effects are inhibited by drugs which block cyclo-oxygenase. In contrast, agents which block thromboxane synthetase inhibit bronchoconstriction and thrombocytopenia, but lead to a potentiation of blood pressure reduction.

In contrast to arachidonic acid, PAF as inducer leads to bronchoconstriction, which is platelet-dependent. In addition, PAF induces thrombocytopenia, leukocytopenia, reduction of blood pressure and increase of hematocrit. These effects are also reversible, but more persistent than those induced by arachidonic acid, and quickly result in tachyphylaxis. The test allows to evaluate the sites of action of drugs, which interfere with the mechanisms of broncho-constriction and thrombocytopenia; in an *in vivo*-model guinea pigs are challenged with the spasmogens and platelet-aggregating substances arachidonic acid or PAF (platelet activating factor).

PROCEDURE

Male guinea pigs (Pirbright White) weighing 300–600 g are anesthetized with 60 mg/kg pentobarbital sodium (i.p.). One of the jugular veins is cannulated for the administration of spasmogen and test compound. Both external carotid arteries are cannulated; one is connected to a pressure transducer to register blood pressure, the other is used for blood withdrawal. The trachea is connected to a Starling pump with an inspiratory pressure set of 80 mm H_2O, an adequate tidal volume of approx. 10 ml/kg body weight and a frequency of 70–75 strokes/min. Spontaneous respiration is inhibited by intravenous injection of pancuronium (4 mg/kg) or gallamine (2 mg/kg) on time.

In some experiments, pulmonal ß-receptors are blocked by intraperitoneal administration of propranolol (2 mg/kg).

Excess air, not taken up by the lungs, is conducted to a transducer with bronchotimer (Rhema, Germany) which translates changes in air flow to an electrical signal. Changes in air flow and arterial blood pressure are recorded continuously.

Animals receive multiple intravenous injections of the same dose of arachidonic acid (Sigma, 250–600 µg/kg prepared from a stock solution 10 mg/ml ethanol, 1 : 20 dilution with Na_2CO_3) until two bronchospasms of equal intensity are obtained. The test compound is administered intravenously and the spasmogen is given again at the following intervals: 2, 10, 20 and, if necessary, 30 min after administration of the drug.

Ordinarily, the lung has to be passively dilated (bronchotimer) after each of the bronchoconstrictions. Immediately before and 30–45 s after each of the arachidonic acid applications, approx. 50 µl blood are collected into Na-EDTA-coated tubes. The number of thrombocytes is determined with a platelet analyzer (Becton Dickinson Ultra-Flo-100 or Baker 810) in 10 µl samples of whole blood.

PAF (Paf-acether C16, Bachem, 0.03–0.04 µg/kg in 0.9% saline + 0.1% human serum albumin) as inducer is injected intravenously 60 min before, 5 min and, if necessary, 60 min after intravenous drug administration. Blood samples are collected 30 s before and 15 s after each of the PAF applications. The number of leuko-cytes and hematocrit values are determined automatically (TOA-microcell counter CC 108, Colora Meßtechnik).

Standard compounds:

- dazoxiben HCl (inhibitor of thromboxane synthetase, TSI)
- acetylsalicylic acid- (inhibitor of cyclo-oxygenase, COI)

EVALUATION

Percent inhibition or increase of bronchospasm, reduction of blood pressure, thrombocytopenia, leukocytopenia and hematocrit following test drug administration are calculated in comparison to control values before drug treatment. For the reduction of blood pressure, both the magnitude [mm Hg, systolic and diastolic] and the duration [min] are determined. Even a sole increase in duration of blood pressure reduction is considered as an increase of the effect. From the pattern profile of the influence on bronchoconstriction, thrombocytopenia and blood pressure reduction, the mechanism of action of a test drug is concluded:

- inhibitor of thromboxane synthetase
- inhibitor of cyclo-oxygenase
- other effect = no profile

In addition, the inherent action of the test substance on blood pressure is determined before arachidonic acid- or PAF-administration.

MODIFICATIONS OF THE METHODS

Kagoshima et al. (1997) used a modification of the Konzett-Rössler-method to test the suppressive effects of a PAF-antagonist on asthmatic responses in guinea pigs actively sensitized with ovalbumin. The immediate and the late asthmatic response were measured by the oscillation method according to Mead (1960).

D.2.2.3 Bronchial hyperreactivity

PURPOSE AND RATIONALE

Symptoms like asphyctic convulsions resembling bronchial asthma in patients can be induced by inhalation of histamine or other bronchospasm inducing agents in guinea pigs. The challenging agents are applied as aerosols produced by an ultra-sound nebulizer. The first symptoms are increased breathing frequency, forced inspiration, and finally asphyctic convulsions. The occurrence of these symptoms can be delayed by antagonistic drugs. Pre-convulsion time, i.e. time until asphyctic convulsions, can be measured.

PROCEDURE

Ten male albino guinea pigs weighing 300–400 g per group are used. The inhalation cages consist of 3 boxes each ventilated with an air flow of 1.5 l/min. The animal is placed into box A to which the test drug or the standard is applied using an ultra-sound nebulizer LKB NB108 which provides an aerosol of 0.2 ml solution of the test drug injected by an infusion pump within 1 min. Alternatively, the animal is treated orally or subcutaneously with the test drug or the standard. Box B serves as a sluice through which the animal is passed into box C. There, the guinea pig is exposed to an aerosol of a 0.1% solution of histamine hydrochloride provided by an ultra-sound nebulizer (De Vilbiss, Model 35 A). Time until appearance of asphyctic convulsions is measured. Then, the animal is immediately withdrawn from the inhalation box. The aerosols are removed from the back wall of the boxes by applying low pressure.

EVALUATION

Percent of increase of pre-convulsion time is calculated versus controls. ED_{50} values can be found, i.e. 50% of increase of pre-convulsion time.

CRITICAL ASSESSMENT OF THE METHOD

The "guinea pig asthma" has been applied as useful method in various modifications by many laboratories.

MODIFICATIONS OF THE METHODS

Simple methods to test bronchospasmolytic activity in conscious animals, called "thoracography" were described by Herxheimer (1956) Olsson (1971), Beume et al. (1985). A silicon tube with a diameter of 1 mm is filled with mercury and serves as strain gauge applied as belt around the thorax of conscious guinea pigs. Changes in electrical resistance due to breathing movements of the thorax are registered. The animals are exposed in a Plexiglas chamber to acetylcholine nebulized by an ultrasonic device. Time until onset of coughing indicated by an increase of signal amplitude and of severe asthmatic dyspnoea is registered.

Immunological factors are involved in bronchial hyperreactivity (Reynolds 1991).

Harris et al. (1976) immunized rabbits with thermophilic actinomyces antigen (Micropolyspora faeni). Lesions resembling hypersensitivity in man were found, characterized by a mononuclear cell interstitial reaction and a marked increase in the number of intra-alveolar cells.

Ufkes et al. (1983) induced bronchial and cardiovascular anaphylaxis in Brown-Norway rats, sensitized with trinitrophenyl haptenized ovalbumin and $AlPO_4$ as adjuvant 12 days prior to challenge with trinitrophenyl haptenized bovine serum albumin intravenously.

Raeburn et al. (1992) gave a survey on techniques for drug delivery to the airways and the assessment of lung functions in animal models including parameters such as lung compliance and airway resistance.

Elwood et al. (1992) studied the effects of dexamethasone and cyclosporin A on the airway hyperresponsiveness and the influx of inflammatory cells into bronchoalveolar lavage fluid seen 18 to 24 h after exposure to aerosolized ovalbumin in actively ovalbumin-sensitized Brown-Norway rats.

A model of bronchial hyperreactivity after active anaphylactic shock in conscious guinea pigs has been described by Tarayre et al. (1990). The guinea pigs were sensitized by an intramuscular injection of a large dose of ovalbumin in Freund's adjuvant. The adminis-

tration of ovalbumin to induce anaphylactic shock was by aerosol. Bronchial hyperreactivity to histamine was observed 3–6 h after the anaphylactic shock.

The importance of eosinophil activation for the development of allergen-induced bronchial hyperreactivity was underlined by Santing et al. (1994). A significant increase in bronchoreactivity to histamine was observed at 6 h after allergen exposure, which was associated with an increase of eosinophils in the bronchoalveolar lavage and an increase in the eosinophil peroxidase activity

The increased pulmonary vascular permeability may be related to the adult respiratory distress syndrome in man (Snapper and Christman 1989).

The infusion of small amounts of *Escherichia coli* endotoxin into chronically instrumented awake **sheep** results in well-characterized pulmonary dysfunction (Brigham and Meyrick 1986).

One animal model associated with both increased airway responsiveness and pulmonary inflammation is endotoxemia in sheep (Hutchinson et al. 1983).

The effect of a platelet activating factor receptor antagonist on the sheep's response to endotoxin was studied by Christman et al. (1987).

Chiba and Misawa (1995) characterized muscarinic cholinoceptors in airways of antigen-induced airway hyperresponsive rats. The animals were sensitized with 2,4-dinitrophenylated *Ascaris suum* extract together with *Bordetella pertussis* (2×10^6) as an adjuvant and were boosted with 2,4-dinitrophenylated *Ascaris suum* extract 5 days later. Isometric contractions of the circular muscle of isolated bronchial rings after addition of increasing doses of acetylcholine were measured with a force-displacement transducer.

Laboratory infection of **primates** with *Ascaris suum* may provide a model of allergic bronchoconstriction (Patterson et al. 1983; Pritchard et al. 1983; Eady 1986).

Richards et al. (1986) used various models of airway hypersensitivity, such as inhalation of *Ascaris suum* antigen in monkeys and dogs.

Rylander and Marchat (1988) studied the effect of a corticosteroid on an acute inflammation in the lungs of guinea pigs exposed to an aerosol of bacterial endotoxin. The subsequent inflammatory response was evaluated counting the number of cells obtained from airway lavage and in the lung interstitium as well as the chemotactic effect of alveolar macrophages.

Hatzelmann et al. (1996) reported on automatic leukocyte differentiation in broncho-alveolar lavage fluids of guinea pigs and Brown-Norway rats using an automatic cell analyzing system (Cobas Helios 5Diff; Hoffmann-La Roche; Grenzach-Wyhlen, Germany).

Minshall et al. (1993) demonstrated that neonatal immunization of **rabbits** with *Alternia tenuis* can lead to the development of persistent airway hyperresponsiveness.

Okada et al. (1995) studied late asthmatic reactions in **guinea pigs** sensitized with *Ascaris* antigen. They evaluated interleukin-1 production by immunostaining with anti-IL-1β antibody and elucidated the action of IL-1 in late asthmatic reactions with recombinant IL-1 receptor antagonist.

Folkerts et al. (1995) found that intratracheal inoculation of *parainfluenza type 3 virus* to guinea pigs induces a marked increase of airway responsiveness to increasing doses of intravenous histamine. In spontaneously anesthetized breathing guinea pigs, inhalation of an aerosol containing the nitric oxide precursor L-arginine completely prevented the virus-induced hyperresponsiveness to histamine.

Fryer et al. (1994, 1997) measured M_2 muscarinic receptor function in anesthetized and paralyzed guinea pigs by electrical stimulation of both vagus nerves producing bronchoconstriction (measured as pulmonary inflation pressure) and bradycardia.

D.2.2.4
Body plethysmography and respiratory parameters after histamine-induced bronchoconstriction in anesthetized guinea pigs

PURPOSE AND RATIONALE

Guinea pigs can be placed in a plethysmograph for measurement of respiratory parameters. Respiratory frequency and respiratory amplitude are recorded. The decrease of respiratory amplitude (diminished respiratory volume due to bronchoconstriction) and the reflectory increase of respiratory frequency after histamine inhalation are attenuated by bronchodilatatory drugs. Additional respiratory parameters can be recorded using a Fleisch tube and a catheter inserted into the pleural cavity (Englert et al. 1992). The method can be used for various purposes, e.g., to evaluate the antagonism against bradykinin-induced bronchoconstriction (Wirth et al. 1991, 1993) or the bronchodilator effects of potassium channel openers (Englert et al. 1992) or to measure the effect of morphine on respiration in rats (Kokka et al. 1965).

PROCEDURE

Guinea pigs of either sex weighing 400–600 g are anesthetized with 70 mg/kg pentobarbital i.p. The trachea, pleural cavity, jugular vein, and carotid artery are prepared and cannulated. The animals are mechanically ventilated with a Starling respiratory pump which delivers an inspiration volume that represents a tracheal pressure of 8 cm water at a rate of 60 strokes/min. Succinylcholine chloride at a dose of 1 mg/kg is given i.v. to prevent interference from spontaneous respiration. The guinea pigs are placed inside a whole body plethysmograph and tracheal, pleural, venous and arterial catheters are connected to onset ports in the wall of the plethysmograph box. The tracheal port is then connected with the respiration pump. **Airflow rate** into and out of the plethysmograph are measured as pressure difference with a No. 000 Fleisch tube and a differential pressure transducer (Fa. Hellige, PM 97 TC). Airflow is calibrated by passing compressed air through a rotameter. The **tidal volume (V_T)** is calculated from the flow signal. **Transpulmonary pressure (P_{TP})** is measured with a differential pressure transducer (Hellige, PM 97 TC), with one side attached to a catheter inserted into the right pleural cavity and the other side connected to a side port of the tracheal cannula. P_{TP} is calibrated with a water manometer. Signals from airflow, tidal volume and transpulmonary pressure are fed into an on-line computer system (PO-NE-MAH®, Model PF-1, Storrs) for calculation of **pulmonary resistance (R_L)** and **dynamic lung compliance (C_{DYN})**.

These parameters are calculated for each breath with a sampling rate of 100 s^{-1} for each circle. Flow and pressure signals for computation are obtained from a PLUGYS measuring system (Fa. Hugo Sachs Elektronik, Freiburg, Germany). Systemic arterial pressure is measured using a Statham pressure transducer (P 23 Db). Heart rate is computed from pressure pulses (Döring and Dehnert 1997).

Three doses of test compound or standard are injected intravenously. Saline injections serve as controls. Intravenous injections of histamine (0.5–2 μg/kg) lead to a short decrease in C_{DYN} and to a short increase in R_L by approximately 200% compared with baseline. Challenges are repeated at 5-min intervals, yielding the same increase in R_L during the whole 1-h experimental period. After 3 reproducible responses the test agent is administered intravenously 1 min before the histamine injection.

To evaluate test compounds for inhalation route, aerosols are generated with an ultrasonic nebulizer (LKB, model NB 108) and are administered to the animals through a shunt in the afferent limb of the respiratory pump, allowing the inspired air to pass through the nebulizer chamber before entering the animals lungs.

EVALUATION

Inhibition of histamine induced bronchoconstriction by various doses of test compound and standard is recorded. ED_{50} values for inhibition in R_L are calculated. Furthermore, the time course of histamine antagonism can be evaluated. Compounds can be tested either after iv. injection of histamine (prevention) or during intravenous infusion of histamine (intervention).

CRITICAL ASSESSMENT OF THE METHOD

Whole body plethysmography has been proven to be a useful tool in respiratory pharmacology for studies on the antagonism against various bronchoconstrictors, such as histamine and bradykinin, as well as for airway pharmacology of potassium channel openers.

MODIFICATIONS OF THE METHOD

Several authors use body plethysmography to study respiratory functions in animals (Amdur and Mead 1958; Blümcke et al. 1967), Pennock et al. 1979; Agarwal (1981), James and Infiesto (1983), Kisagawa et al. (1984), Griffith-Johnson (1988), Danko and Chapman (1988), Ball et al. (1991), Chand et al. (1993).

The effect of β-blockers on pulmonary function and bronchoconstrictor responsiveness in **guinea pigs** and rats has been studied by Chapman et al. (1985).

Finney and Forsberg (1994) developed a technique for quantification of nasal involvement in a guinea pig plethysmograph. Nasal and lower respiratory system conductance could be measured simultaneously in anesthetized animals.

A whole body plethysmograph for conscious animals has been described by Elliott et al. (1991) and improvements by Linton (1991).

Studies of bronchospasmolytic agents with aerosol challenge in conscious guinea pigs using a double chamber plethysmograph box have been reported by Schlegelmilch (1991).

Ball et al. (1991) described a method for the evaluation of bronchoactive agents in the conscious guinea pig. The method involves the use of "head out" whole body plethysmographs from which respiratory rate can be recorded by monitoring respiration-related changes in pressure within the body chamber.

Hey et al. (1995) used a head-out, whole body plethysmograph to examine the effects of $GABA_B$ receptor agonists on minute ventilation, tidal volume and respiratory rate due to room air and carbon dioxide-enriches gas hyperventilation in conscious guinea pigs.

Murphy et al. (1998) developed a method for chronic measurement of pleural pressure in conscious *rats*. Pleural pressures were measured by surgically implanting a fluid-filled polyurethane catheter attached to a pressure-sensitive radiotelemetry transmitter (Model TA11PA-C40, Data Sciences Int., St. Paul, MN) beneath the pleural surface. A compatible receiver (Model RLA0120) and a data acquisition and analysis software system (LabPRO, Version 3) sampling at a rate of 500 Hz were used to analyze the telemetric signals.

Sinnett et al. (1981) described a fast integrated flow plethysmograph for small animals (**mice**).

Simple methods to determine respiratory parameters in small animals were described by Schütz (1960), Höbel et al. (1971).

Schlenker (1984) and Schlenker and Metz (1989) evaluated ventilatatory parameters in dystrophic **Syrian hamsters**.

Wasserman and Griffin (1977) studied bronchoactivity in the intact anesthetized **dog**.

Paré et al. (1976) determined pulmonary resistance and dynamic lung compliance in **rhesus monkeys**.

Wegner et al. (1984) measured dynamic respiratory mechanics in monkeys by forced oscillations generated by a loudspeaker in an airtight chamber.

D.2.2.5 Pneumotachography in anesthetized guinea pigs

PURPOSE AND RATIONALE

The use of a pneumotachograph based on the principle of the Fleisch-tube and of additional pressure transducers allows simultaneous measurements of several respiratory and circulatory parameters in anesthetized guinea pigs (de la Motta 1991).

PROCEDURE

Guinea pigs (Pirbright white) weighing 300–400 g are anesthetized with 1.5 g/kg urethane i.p. The animals are shaved ventrally at the neck, placed on a heated operating table, and fixed at the upper extremities. A metal cannula with a blunted tip is inserted into the trachea and secured with a loop within the caudal section of the trachea. A thin plastic catheter is inserted into the esophagus and the tip located inside the thorax in order to register intrathoracic pressure. Furthermore, the cephalic vein at one side and the carotid artery on the opposite side are cannulated. The tracheal cannula is connected with pieces of tubing to a Fleisch

tube (pneumotachograph), size 0000. In order to avoid water condensation, the Fleisch tube is heated. The Fleisch tube is connected with a sensitive differential pressure transducer with a range of 2 cm H_2O (Validyne, model MP 45 -xx-871). One side of another pressure differential transducer with a range of 20 ml H_2O is connected with the esophageal catheter, the other side remaining open to room air. Both Validyne pressure transducers are connected to a separate preamplifier. For recording of the arterial blood pressure a Gould pressure transducer, Type P23Gb, is used. The signals for airflow and esophageal pressure are monitored at the output of the preamplifier with a digital 2-channel oscilloscope. To obtain various respiratory and circulatory parameters from the three primary signals they are calculated by certain formulae by an analogue computer (Buxco Pulmonary Mechanics Analyzer, Model 6). The following parameters are presented at the output of the instrument as analogue electrical signals:

Circulation

Systolic blood pressure, diastolic blood pressure, mean blood pressure

Respiration

Tidal volume, respiratory volume per minute, respiratory rate

Pulmonary mechanics

Airway resistance, dynamic compliance, end-respiratory work.

A multi-channel recorder (Graphtec Linearcorder Mark VII) serves a functional check on the Buxco Analyzer and as analogue presentation of the calculated parameters. Data processing is performed by a 12-channel A/D converter (Buxco Data Logger, Model D/C-12 F/V) which digitizes the analogue output signals of the Buxco Analyzer and sends them through a serial interface (RS232) to an IBM PC. A special software program (Lomask 1987; Hastings 1990a,b) provides a flexible facility for data reduction and statistical evaluation.

EVALUATION

For each individual experiment the data of the last 5 min before the first substance application are averaged and used as controls. The response values after substance application are then expressed as percentages of the controls. In this way each animal serves as its own control. For an analysis of the results the response values are averaged over certain time intervals.

CRITICAL ASSESSMENT OF THE METHOD

The method described in great detail by de la Motta (1991) may be modified using different equipment according to individual needs.

MODIFICATIONS OF THE METHOD

Measurement of respiratory parameters is based on earlier studies to be mentioned for historical reasons (Gad 1880; Pflüger 1882; Zwaardemaker and Ouwehand 1904; Jaquet 1908; Rohrer 1915; Gildemeister 1922; Fleisch 1925; v. Neergaard and Wirz 1927; survey by Döring HJ 1991).

Lorino et al. (1988) assessed respiratory mechanics of histamine bronchopulmonary reactivity in guinea pigs.

O'Neil et al. (1981) published a comparative study of respiratory responses to bronchoactive agents in rhesus and cynomolgus monkeys.

Rayburn et al. (1989) described a computer-controlled pulmonary function system for studies in large animals.

Five methods of analyzing respiratory pressure-volume curves have been compared by Lai and Diamond (1986).

A specially designed pneumotachograph that is placed inside the trachea of guinea pigs was described by Santing et al. (1992) allowing the evaluation of airway functions in conscious, unstressed animals.

Lorino et al. (1993) estimated the changes in end-respiratory lung volume accompanied histamine-induced bronchoconstriction in anesthetized, paralyzed, and mechanically ventilated guinea pigs from measurements of thoracic cross-sectional area, assessed from the voltage induced by an external uniform magnetical field in a pickup coil encircling the rib cage.

Gozzard et al. (1996) evaluated the effects of PDE-inhibitors in **New Zealand White rabbits** which were immunized within 24 h of birth with *Alternaria tenuis* antigen. Spontaneously breathing rabbits were intubated in neuroleptanalgesia with a cuffed endotracheal tube connected to a thermoregulated Fleisch pneumotachograph to allow measurement of tidal air flow. An oesophageal balloon catheter was inserted to provide a measure of intra-pleural pressure and transpulmonary pressure. Antigen challenge was performed with inhaled *Alternaria tenuis* extract.

An excellent survey on various methods and equipment to measure air flow is given by Döring and Dehnert (1997).

D.2.2.6 Airway microvascular leakage

PURPOSE AND RATIONALE

Plasma exudation in guinea-pig airways *in vivo* can be determined by Evans Blue dye and is fairly correlated with radiolabelled albumin (Rogers et al. 1989). This method can be used to study the antagonism against bradykinin- and platelet-activating factor-induced airway microvascular leakage and vagal stimulation-induced airway responses (Sakamoto et al. 1992, 1994).

PROCEDURE

Female Dunkin-Hartley guinea pigs weighing 380–600 g are anesthetized with an initial dose of 1.5 g/kg urethane injected i.p. Additional urethane is given i.v. 30 min later to achieve an appropriate level of anesthesia. A tracheal cannula is inserted into the lumen of the cervical trachea, a polyethylene catheter into the left carotid artery to monitor blood pressure and heart rate and another polyethylene catheter into the external jugular vein for administration of drugs. The animals are connected to a constant volume mechanical ventilator and then given an injection of 1.0–1.5 mg/kg suxamethonium i.v. to prevent interference with spontaneous respiration. A tidal volume of 10 ml/kg and a frequency of 60 strokes/min are used.

Lung resistance is measured as an index of airway function and monitored throughout the experiment. Transpulmonary pressure is measured with a pressure transducer with one side attached to a catheter inserted into the right pleural cavity and the other side attached to the side port of the intratracheal cannula. Airflow is measured by a pneumotachograph connected to a pressure transducer. The signals of the transducers are used for instantaneous calculation of lung resistance by an appropriate computer program.

The test compound (bradykinin receptor antagonist) is given intravenously. Ten min later, Evans Blue dye (20 mg/ml) is injected i.v. for 1 min. After 1 min, bronchoconstriction and microvascular leakage is induced by injection of bradykinin or by inhalation of bradykinin or PAF or vagal stimulation.

Six min after induction of leakage, the thoracic cavity is opened, and a cannula is inserted into the aorta through a ventriculotomy. Perfusion is performed with 100–150 ml 0.9% saline at a pressure of 100–120 mm Hg in order to remove the intravascular dye from the systematic circulation. Blood and perfusion liquid are expelled through an incision in the right and left atrium. Subsequently, the right ventricle is opened, and the

pulmonary circulation is perfused with 30 ml of 0.9% saline. The lungs are then removed, and the connective tissue, vasculature, and parenchyma are gently scraped. The airways are divided into 4 components: lower part of the trachea, main bronchi, the proximal 5 mm portion, and the distal intrapulmonary airways. The tissues are blotted dry, and then weighed. Evans Blue dye is extracted in 2 ml of formamide at 40 °C for 24 h, and measured in a spectrophotometer at 620 nm.

EVALUATION

Evans Blue dye concentration, expressed as ng/mg tissue, as well as lung resistance are compared by statistical means (unpaired Student's *t*-test or Mann-Whitney U test) between treated groups and controls receiving the challenge only.

MODIFICATIONS OF THE METHOD

Boschetto et al. (1989) tested the effect of antiasthma drugs on microvascular leakage in guinea pig airways. Microvascular leakage was induced by intravenous injection of platelet-activating factor (50 ng/kg) which acts directly on venular endothelial cells, and measured by quantifying extravasation of Evans blue dye.

Xu et al. (1998) induced pulmonary edema in rats by injection of 20 µg/kg angiotensin I and studied the suppression by ACE-inhibitors, ATII antagonists and α-adrenergic receptor blockers.

Rapidly developing pulmonary edema was induced by intravenous injection of 1.2 mg/kg of the GABA agonist bicuculline in rats and the role of endogenous endothelin was examined by Herbst et al. (1995).

D.2.2.7 Isolated larynx *in situ*

PURPOSE AND RATIONALE

The *in situ* isolated larynx of rats has been recommended by Willette et al. (1987) for evaluation peripheral opiate receptor antagonists. Peripheral opioid-induced laryngospasm and central opioid-induced respiratory depression can be measured simultaneously. Fentanyl citrate stimulates both peripheral and central opiate receptors, whereas [D-Ala^2-Met^5]-enkephalinamide stimulates only peripheral opiate receptors. Compounds that inhibit both laryngeal and respiratory effects of fentanyl, e.g., naloxone HCl, can be considered both central and peripheral opiate antagonists. Compounds that inhibit only the peripheral effects of fentanyl, e.g., naltrexone methylbromide, can be considered peripheral opiate receptor antagonists.

PROCEDURE

Laryngeal resistance experiments are carried out in male Sprague Dawley rats weighing 340–360 g and anesthetized with urethane (900 mg/kg, i.p.) The animals are secured in supine position and the left femoral artery and the left and right femoral veins are cannulated for recording of arterial blood pressure and administration of drugs. A right-angle polyethylene cannula (ID 1.67 mm, OD 2.42 mm) is inserted into the caudal trachea at the level of the manubrium for measuring tracheal flow via a small animal pneumotachograph. Care has to be taken to avoid damaging surrounding blood vessels or adjacent bilateral laryngeal nerves. Tracheal air flow is continually sampled (300 ml/min) for the breath to breath analysis of end tidal carbon dioxide with an infrared gas analyzer.

Laryngeal resistance in the rat is determined using a modification of the methods described by Stransky et al. (1973), Bartlett et al. (1973), and Willette et al. 1982b). The rostral portion of the trachea is cannulated with a right-angle polyethylene tube (ID 1.67 mm, OD 2.42 mm). This cannula is carefully advanced towards the larynx and secured with a suture (4-0 silk). A constant flow ($V = 30$ ml/min) of compressed air, maintained with a flow meter, is delivered through a cannula. Pre-laryngeal pressure is measured with a needle tipped pressure transducer inserted into the lumen of the flow cannula. A 1.75-cm segment of polyethylene tubing (OD 8.4 mm, ID 4.6 mm) is placed into the mouth to retract resistive components in the nasopharyngeal region.

Laryngeal resistance (*LR*) is calculated by the following equation:

$$LR = (P_L P_i - P_L P_0) / V$$

where $P_L P_i$ is the laryngeal pressure in the cannula directing a constant flow (V) through the larynx. $P_L P_0$ is the pressure in the cannula when it is removed from the trachea.

The agonist fentanyl is administered through the left femoral vein at a dose of 12 µg/kg which is equivalent to 1.5 times the ED_{99} in the conscious rat tail flick assay. The enkephaline analogue [D-Ala^2-Met^5]-enkephalinamide is injected at a dose of 250 µg/kg which acts peripherally and increases laryngeal resistance (Willette 1982a). The opiate receptor antagonists are administered similarly into the right femoral vein.

At the conclusion of the experiment, the pulmonary afferent stimulant, phenyldiguanide (25 µg/kg, i.v.) is injected into the right femoral vein to elicit laryngospasm and to determine the viability of the preparation.

EVALUATION

All summary values are expressed as the mean plus or minus the standard error of the mean (SEM) Comparisons are made with independent and paired two-tailed *t*-tests.

MODIFICATIONS OF THE METHOD

Inagi et al. (1998) assessed the effect of botulin toxin in the rat larynx be measurement of the optical density of PAS-stained laryngeal muscle after electrical stimulation, spontaneous laryngeal muscle activity, and laryngeal movement.

O'Halloran et al. (1994) studied the effects of upper airway cooling and CO_2 on breathing and on laryngeal and supraglottic resistance in anesthetized rats.

González-Barón et al. (1989) studied the modifications of larynx resistance changing bronchial tone in cats evoked by intravenous administration of 10 µg/kg carbachol as bronchoconstrictor and by fenterol (10 µg/kg) or isoproterenol (0.1 mg/kg) as bronchodilators.

Wang et al. (1999) developed an isolated, luminally perfused laryngeal preparation in anesthetized paralyzed cats in order to compare the effects of solutions with varying levels of pH and pCO_2 on pressure-sensitive laryngeal receptor sensitivity.

D.2.2.8 Safety pharmacology of the respiratory system

PURPOSE AND RATIONALE

Regulatory agencies (EMA 1997, 2000) have pointed out the necessity to perform safety pharmacology studies before application of a new drug to human beings and to assess most carefully any potential side effects. Organs or systems acutely necessary for life, i.e., the cardiovascular, respiratory and central nervous systems, are considered to be the most important to assess in safety pharmacology studies.

Murphy (1994) described techniques and study design for safety pharmacology of the respiratory system. The potential for drugs to cause secondary or toxicologic effects that influence respiratory function were evaluated. Changes in respiratory function can result either from alterations in the pumping apparatus that controls the pattern of pulmonary ventilation or from changes in the mechanical properties of the lung that determine the transpulmonary pressures (work) required for lung inflation and deflation. Defects in the pumping apparatus are classified as hypo- or hyperventilation. The ventilatory parameters include respiratory rate, tidal volume, minute volume, peak (or mean) inspiratory flow, peak (or mean) expiratory flow, and fractional inspiratory time. Defects in mechanical properties of the lung are classified as obstructive or restrictive disorders and can be evaluated in animal models by performing flow-volume and pressure-volume maneuvers. The parameters to detect airway obstruction include peak expiratory flow, forced expira-

tory flow at 25 and 75% of forced vital capacity, and a timed forced expiratory volume, while the parameters used to detect lung restriction include total lung capacity, inspiratory capacity, functional residual capacity, and compliance. Measurement of dynamic lung resistance and compliance, obtained continuously during tidal breathing, is an alternative method for evaluating obstructive and restrictive disorders, respectively, and is used when the response to drug treatment is expected to be immediate (within minutes post-dose). The species used in studies of safety pharmacology are the same as those used in toxicology studies (mostly rats and dogs) since usually phamacokinetic data are available from these species.

Several methods useful to determine safety pharmacology on respiratory system in small animals are described in the literature.

Amdur and Mead (1958) developed a technique by which tidal volume, intrapleural pressure and rate of flow of gas in and out of the respiratory system can be measured simultaneously in unanesthetized guinea pigs for periods of several hours.

King (1966) used a nitrogen closed-circuit method for the determination of functional residual capacity in anesthetized and tracheostomized rats.

Palecek (1969) developed a method for measurement of the following ventilatory parameters in the rat: tidal volume, frequency, functional residual lung capacity, and lung resistance and compliance.

D.2.2.8.1 Effects of respiratory depressant drugs in conscious rats

PURPOSE AND RATIONALE

Murphy et al. (1995) published a non-invasive method for distinguishing central from peripheral nervous system effects of respiratory depressant drugs in conscious rats using gas and sodium cyanide exposures and carotid body denervation.

PROCEDURE

Male Sprague Dawley rats weighing 270–490 g are used. For gas and sodium cyanide exposures the rats are exposed to gas mixtures using a two chambered plethysmograph. The body of the animal is enclosed in one chamber that is used to measure ventilatory parameters, while the head is enclosed in a cylindrical plastic headpiece attached to the body chamber. A rubber collar around the neck of the animal separated the two chambers. Specified gas mixtures are delivered from compressed gas tanks to the head chamber at a rate of 2 l/min. The type of gas mixture is controlled by a multi-port stainless steel manifold with individual valve controls.

The gas mixture contains either normal breathing air (21% O_2, 79% N_2) or elevated CO_2 (8% CO_2, 21% O_2, 71% N_2). The animals are first exposed to the normal air mixture for 5–10 min and then to the elevated CO_2 mixture for 5 min. The mean value for the 5 min CO_2 exposure is calculated for each ventilatory parameter. Following CO_2 exposure, rats are exposed to normal air mixture for a period of 5 in or until the ventilatory parameters return to normal before sodium cyanide is injected. Sodium cyanide (300 µg/kg) is administered as a bolus i.v. injection using a catheter implanted into a tail vein. The peak change in each ventilatory parameter is measured during the 1–2 min period of ventilatory stimulation following sodium cyanide injection.

For carotid body denervation, the rats are anesthetized with a cocktail containing ketamine (26.9 mg/kg), xylazine (2.9 mg/kg) and acepromazine (0.3 mg/kg). A midline incision in the neck is made and the glossopharyngeal nerve on each side of the neck is isolated. Using a dissecting microscope, the glossopharyngeal nerve is cut cranial to the carotid sinus nerve. The rats are allowed to recover 4–7 days prior to use.

Changes in ventilatory parameters are measured in conscious restrained rats using a body plethysmograph chamber with an internal volume of 2.2 l that seals around the neck of the animal and encloses the body within the chamber. Airflow rates within the chamber are measured using a pneumotach port and a differential pressure transducer attached to the plethysmograph chamber. The pressure signal is analyzed using an Upper Airway Monitor (Buxco Electronics. Inc., Sharon, CT) and values for tidal volume, respiratory rate, minute volume, peak expiratory flow, inspiratory time and expiratory time are determined for each breath. Average values of these parameters are calculated and expressed as digital output every 0.1 min using an analog-digital convertor. Mean inspiratory flow (respiratory drive) is calculated by dividing tidal volume by inspiratory time,

while fractional inspiratory time is calculated by dividing inspiratory time by the sum of inspiratory and expiratory times. Continuous tracings of flow and volume changes are also recorded to evaluate qualitative changes in ventilatory patterns.

EVALUATION

Group means and standard errors of the means (SEM) are presented for all quantitative data. Mean values of treated groups are considered to be statistically different from the control group if the calculated P value is < 0.05.

MODIFICATIONS OF THE METHOD

Drazen (1984) discussed the physiological basis and interpretation of indices of pulmonary mechanics and the rationale upon which effects of an intervention on the lung periphery can be distinguished from those of more central airways.

O'Neil and Raub (1984) described in detail pulmonary function testing in small laboratory animals.

Murphy et al. (1993) investigated the effects of intravenous injections of adenosine agonists and antagonists on pulmonary ventilation in conscious male Sprague Dawley rats.

D.2.2.8.2 Pulmonary function in unanesthetized dogs

PURPOSE AND RATIONALE

Mauderly (1974) described analysis of pulmonary function in the unanesthetized Beagle dog.

PROCEDURE

Purebred male or female Beagle dogs at an age between 12 months and 4 years are used. The dogs are fitted with a face mask and esophageal balloon catheter (Dubin and Morrison 1969) and placed in restraining stocks (Mauderly et al. 1971) which hold them in a standing position but do not place pressure on the thorax or abdomen. This allows the inhalation of a choice of gas mixtures, collection of various fractions of the expirate, and analysis of gas samples. Airflow signals from a pneumotachograph and transpulmonary pressure signals from the esophageal catheter transducer are relayed through a preamplifier to a resistance/compliance computer containing an integrator for obtaining tidal volumes from airflow signals, an oscilloscope output for displaying breathing loops, and two subtract circuits which allow the measurement of dynamic pulmonary resistance and compliance by the hysteresis loop closing technique. The dogs are then switched at end expiration to breathing oxygen and the open circuit nitrogen washout method is used for measuring functional residual capacity. The nitrogen clearance equivalent is calculated by dividing the liters of oxygen expired during the washout by the functional residual capacity in liters. Specific compliance is calculated by dividing compliance by the functional residual capacity. The respiratory frequency, tidal volume, and minute volume during oxygen breathing are also calculated from the washout data. The dogs are then breathed 500 ppm carbon monoxide in air, and the steady state, end tidal method (Mauderly 1972) is used for measuring CO diffusing capacity and fractional uptake of CO.

For a second series of experiments, the dogs are fitted with the breathing mask, manually restrained in supine position on a contoured table, and connected to the test apparatus. Breath-by breath tensions of O_2 and CO_2 are continuously monitored at the breathing valve and recorded. When the dogs are relaxed and their breathing traces stabilized, a timed collection of the expirate is made, and a sample of arterial blood is drawn from the femoral artery. Analysis of blood samples yields arterial P_{O_2}, P_{CO_2}, pH, and hemoglobin content. The breathing traces allow calculations of the respiratory frequency and alveolar (end tidal) P_{O_2} and P_{CO_2}. Expired volume and gas tension allow calculation of the minute volume, tidal volume, O_2 uptake, CO_2 output, and respiratory exchange ratio. The percentage of alveolar, effective, and alveolar deadspace ventilation are calculated from the CO_2 output, alveolar P_{CO_2}, and arterial P_{CO_2} (Luft and Finkelstein 1968). Specific ventilation is calculated by dividing the minute volume by the O_2 uptake.

Gas samples are analyzed for N_2, O_2 and CO_2 by a mass spectrometer, and CO tensions are determined by an infrared analyzer.

EVALUATION

Student's t-test is applied to determine the statistical significance of differences between mean values of the groups.

D.3 Antitussive activity

D.3.0.1 Antitussive activity after irritant inhalation in guinea pigs

PURPOSE AND RATIONALE

Cough is thought to be caused by a reflex. The sensitive receptors are located in the bronchial tree, particularly in the bifurcation of the trachea. These receptors can be stimulated mechanically or chemically, e.g., by inhalation of various irritants. Nerve impulses then activate the cough center in the brain. Several animals species and several irritants have been used, most frequently the citric acid induced cough in guinea pigs (Charlier et al. 1961; Karlsson et al. 1989 Braga et al. 1993).

PROCEDURE

Guinea pigs of either sex weighing 300–400 g are used. The animal is placed in a cylindrical glass vessel, with 2 tubes at either ends. One serves as the entrance of the aerosol, the other for its efflux. The latter tube has a side-arm connecting to a tambour, from which changes in pressure can be registered. A pinch-clamp with a variable screw is placed on the efflux tube beyond the side arm, permitting the regulation of the sensitivity of the system, so that the normal respiration is not registered, while the displacement of air in the enclosure caused by coughing of the animal is registered. The guinea pig is exposed to the aerosol of 7.5% citric acid in water for 10 min. Each animal is tested first to obtain the control response. The number of tussive responses is registered. One hour later, the test substance is applied either s.c. or orally, and 30 min later the guinea pig is subjected to the aerosol again. The number of coughs during 10 min is recorded.

EVALUATION

The number of coughs after treatment is expressed as percentage of the control period. Using various doses, ED_{50} values can be calculated.

CRITICAL ASSESSMENT OF THE METHOD

The citric acid induced coughing in guinea pigs has been proven to be an effective method to test antitussive agents.

MODIFICATIONS OF THE METHOD

Püschmann and Engelhorn (1978) studied the inhibition of the coughing reflex induced by inhalation of a citric acid spray in *rats*.

Other irritants have been used to induce cough, e.g. ammonia in dogs, guinea pigs, and cats (Rosiere et al. 1956; Källqvist and Melander 1957; Chen et al. 1960; Sallé and Brunaud 1960; Ellis et al. 1963), or nebulized sulfuric acid or sulfur dioxide in guinea pigs, rats, cats or dogs (Eichler and Smiatek 1940; May and Widdi-combe 1954; Winter and Flakater 1952, 1954; Friebel et al. 1955; Reichle and Friebel 1955; Wiedemeijer et al. 1960; Chermat et al. 1966; Karttunen et al. 1982). Capsaicin aerosol was used by Forsberg and Karlsson (1986), Gallico et al. (1997).

Winter and Flakater (1955) exposed sensitized guinea pigs to aerosol of a specific antigen.

Kamei et al. (1989) induced cough in rats by a nebulized solution of capsaicin. The cough reflex was measured as airflow into or out of the chamber of a body plethysmograph by a pneumotachometer head.

Carotis sinus excitation in dogs induced by injection of lobeline resulting in coughing could be suppressed by codeine (Gross 1957).

Sanzari et al. (1968) induced cough in cats anesthetized with α-chloralose by intravenous injection of 1,1-dimethyl-4-phenylpiperazinium iodide (DMPP), a ganglionic stimulant which is more potent than lobeline and possesses only marginal ganglionic blocking properties. The number of coughs was found to be a linear function of the dose of the irritant. Coughs were recorded as spikes superimposed on the respiratory pattern. The method is suitable for quantitative evaluation of antitussive activity.

D.3.0.2
Cough induced by mechanical stimulation

PURPOSE AND RATIONALE

Cough can be induced by mechanical stimulation of the trachea in anesthetized guinea pigs (Takagi et al. 1960; Gallico et al. 1994).

PROCEDURE

Male guinea pigs weighing 350–400 g are maintained in conditioned quarters (temperature 21 ±2 °C, relative humidity 55 ±10%, 12 h on-12 h off light cycle) with food and water ad libitum for at least 1 week before use.

After overnight fasting with water ad libitum, the guinea pigs are lightly anesthetized with 25% urethane (4 ml/kg i.p.) which induces surgical levels of analgesia without depressant effects on respiratory function. Analgesia is monitored throughout the experiment as the disappearance of head shaking in response to ear pinch. The animals are maintained at a constant body temperature of 37 °C by means of a heated plate. A thin steel wire is gently inserted into the trachea through a small incision near the cricoid cartilage. Coughs are evoked by pushing the steel wire to reach the bifurcation of the trachea 35 and 5 min before oral drug administration and 30, 60 and 120 min after treatment. One violent cough occurs upon each stimulation. Only those animals that respond to both mechanical stimulations before dosing are selected and then randomly assigned to receive the test drug at various doses or the standard (codeine 15, 30 and 60 mg/kg). Ten animals per dose are used.

EVALUATION

Evaluation of the statistical significance of the results is performed with Student's *t*-test for paired data. ED_{50} values are determined by logit transformation.

MODIFICATIONS OF THE METHOD

Several other ways of mechanical stimulation have been used, e.g., by a nylon-bristled stimulator thrust into the trachea in **dogs** (Kasé 1952, 1954), or by a silver thread in **decerebrated guinea pigs** (Lemeignan et al. 1966), or by vibration of an iron slung in the trachea of a dog induced by an electromagnet (Tedeschi et al. 1959) or electrical stimulation of the trachea via a bronchoscope (Gross et al. (1958) or through implanted copper elec-

trodes (Stefko and Benson 1953; Benson et al. 1953; Granier-Doyeux et al. 1959; Stefko et al. 1961).

Hara and Yanaura (1959), Yanaura et al. (1974, 1982) induced cough in unrestrained animals after implantation of electrodes in the trachea.

Combined mechanical and chemical stimulation has been applied by Kroepfli (1950).

Kasé et al. (1976) studied the antitussive activity of d-3-methyl-N-methylmorphinan in conscious mongrel **dogs**. Coughing was induced by mechanical stimulation with a stimulator consisting of 5 hog bristles on the mucosa of tracheal bifurcation through a chronically-built tracheal fistula and in lightly anesthetized cats with a stimulator consisting of 5 whiskers of a rabbit.

D.3.0.3 Cough induced by stimulation of the nervus laryngicus superior

PURPOSE AND RATIONALE

The probable pathways in the cough reflex arc are receptors in the area of the trachea and the large bronchi, afferent nerves mainly in the branches of the vagus nerve, a "cough center" located in the medulla oblongata, and efferent nerves closing the glottis and reinforcing the expiratory thrust. Stimulation of the Nervus laryngicus superior induces coughing. Antitussive agents with predominantly central action suppress the coughing reflex.

PROCEDURE

Cats of either sex weighing 2–3 kg are anesthetized with 40 mg/kg i.p. pentobarbital, placed on a heated operating table and their extremities secured. Since deep anesthesia suppresses coughing the dose of pentobarbital has to be adjusted. The fur is shaved ventrally at the neck. Small incisions are made at both sides of the larynx. The superior laryngeal nerves (forming a loop) are prepared carefully. After a median skin incision, the trachea is exposed and cannulated. The cannula is connected with a Fleisch-tube (size 00). One femoral artery is cannulated for registration of blood pressure via a Statham pressure transducer. One femoral vein is cannulated for intravenous application of test substances. Small hook electrodes are attached to each laryngeal nerve. At the end of an inspiration square wave impulses with a frequency of 50 Hz, an impulse width of 0.5 ms, an amplitude of 0.2–1.0 Volt, and a duration of 1–10 s are applied every 5 min. The intensity of the forced expiration is measured by the Fleisch pneumotachograph and recorded simultaneously with blood pressure on a polygraph. Prior to the intravenous application of the test compound, the response to three stimuli is recorded serving as control. After injection of the test compound or the standard the stimuli are repeated every 5 min. Suppression or diminution of the forced expiration is recorded over 1 h. Then, the next dose or the standard (codeine phosphate 1–2 mg/kg i.v.) is applied.

EVALUATION

Total or partial suppression of the forced expiration are recorded over time and expressed as percentage of control. Intensity and duration of the effect are compared with the standard.

CRITICAL ASSESSMENT OF THE METHOD

The method described by Domenjoz (1952) is very useful to detect centrally active antitussive agents like

codeine, but by definition can not determine compounds which act on cough receptors in the bronchial area. Moreover, even light anesthesia influences the cough reflex.

MODIFICATIONS OF THE METHOD

Several other assays have been described which elicit the cough reflex by central or nerve stimulation. Toner and Macko (1952) also stimulated the superior laryngeal nerve in anesthetized cats to induce a definite cough as indicated by rapid contractions of the abdominal musculature.

Mattalana and Borison (1955), Chakravarty et al. (1956) used decerebrated cats to study the central effects of antitussive drugs on cough and respiration. Cough responses were obtained by electrical stimulation of the dorsolateral region of the medulla with bipolar needle electrodes oriented by means of a stereotactic instrument.

Lindner and Stein (1959) evaluated derivatives of diphenyl-piperidono-propan, a series of antitussive drugs using a modification of the method originally described by Domenjoz (1952).

Schröder (1951) and Bobb and Ellis (1951) elicited cough in **conscious dogs** by stimulation of the vagus nerve in a surgically prepared skin loop. In anesthetized cats, coughs were elicited by electrical stimulation of the dorsolateral region in the upper medulla (Kasé et al. 1970).

D.4
Effects on tracheal cells and bronchial mucus secretion and transport

D.4.0.1
In vitro studies of mucus secretion

PURPOSE AND RATIONALE

Mucus secretion has been studied in isolated tracheas from ferrets and dogs (Borson et al. 1980; Kyle et al. 1987).

PROCEDURE

Ferrets of either sex weighing 0.6 to 1.5 kg are anesthetized with sodium barbital intraperitoneally. The trachea is exposed and cannulated with a special Perspex cannula about 5 mm below the larynx. The animal is then sacrificed with an overdose of the anesthetic and the chest is opened along the midline. The trachea is exposed to the carina, cleared of adjacent tissue, removed from the animal and cannulated just above the carina. The trachea, with its laryngeal end down, is then mounted in a water-jacketed organ bath and bathed on its submucosal site with Krebs-Henseleit solution plus 0.1% glucose at 37 °C and bubbled with 95% O_2 and 5% CO_2. The lumen of the trachea remains air-filled. A plastic catheter is inserted into the lower cannula to form an airtight seal into which secretions can periodically be withdrawn and collected. Volumes of secretions are estimated by the weight difference of catheter lengths with and without secretions.

Simultaneous measurements of both mucus secretion and changes in tissue volume *in vitro* are achieved by mounting portions of ferret trachea cut longitudinally along the posterior wall, flattened out and pinned to a Perspex chamber. Krebs-Henseleit solution at 37 °C and gassed with 95% O_2 and 5% CO_2, is circulated on the submucosal side of the tissue, while the luminal side is exposed to the atmosphere. The surface area of the exposed tissue is about 50 mm^2. Mucus secretion is promoted by electrical field stimulation at 50–100 V, 20 Hz, 1–2 ms duration, applied through the pins holding the tissue. Before the start of each experiment, surface fluid is gently wiped off from the luminal surface with a tissue pledglet. The epithelium is coated with a layer of powdered tantalum dust; as mucus secretion from submucosal glands occurs through gland ducts, the layer of tantalum effectively traps the secreted mucus above the duct and under the tantalum layer. Nearly hemispherical hillocks are formed. The surface is photographed at intervals through a dissecting microscope and hillock diameters

are measured. Assuming the hillocks to be hemispheres, the secretion volume per unit area is calculated. Drugs are added to the submucosal bath.

EVALUATION
Secretory response after electrical stimulation in the presence or absence of drugs is recorded after 45, 90, and 135 min.

MODIFICATIONS OF THE METHOD
Quinton (1979) used isolated tracheae from cats. A segment of the trachea was mounted in a chamber such that the serosal side was constantly bathed in Ringer solution, whereas the epithelial surface was coated with water-saturated paraffin oil. Secretion was stimulated by adding appropriate drug concentrations to the bath. Under a dissecting microscope, small droplets of secretory fluid were observed to form on the tracheal epithelial surface shortly after stimulation. Timed collection of droplets secreted from three to four glands were taken up between oil blocks in constant-bore capillaries (78 µm inner diameter), and droplet volumes were measured for rate determinations usually over a period of 5 min.

CRITICAL ASSESSMENT OF THE METHODS
Both modifications of the *in vitro* methods need at least as many animals and are as time consuming as the *in vivo* methods.

D.4.0.2 Acute studies of mucus secretion

PURPOSE AND RATIONALE
Many diseases of the respiratory tract cause both qualitative and quantitative changes in the mucus that covers and protects the airway epithelium. To study the influence of drugs, methods of collecting bronchial mucus are necessary (Braga 1988). Perry and Boyd (1941) described a method for collecting bronchial mucus from the rabbit.

PROCEDURE
Rabbits weighing 2.5 to 3.5 kg are anesthetized by intraperitoneal injection of 1.1 to 1.4 g/kg urethane. The trachea is exposed by blunt dissection and half opened, 2 cm below the cricoid cartilage. One arm of a T cannula with a large enough diameter to slightly distend the trachea is inserted into the trachea. The perpendicular arm is connected to an air outlet of a humidifier (temperature 35–38 °C, relative humidity 80%). The other arm is connected to a collection tube. The rabbit is restrained in the supine position on a 60-degree inclined board with his head downward. Respiratory tract fluids are collected in centrifuge tubes at one hour intervals. Mucus secretion can be stimulated by vagal stimulation or by ammonium chloride given by stomach tube or by pilocarpine given i.p.

EVALUATION
Time response curves after stimulants of mucus secretion are compared with data from untreated animals.

MODIFICATIONS OF THE METHOD
A method for collecting mucus from cats, using a segment of cervical trachea about 5 cm long isolated *in situ*, with nerve and blood supplies intact and a glass cannula inserted to each end, has been described by Gallagher et al. (1975).

A method to collect mucus from the upper tract trachea and the nasopharynx in dogs in acute experiments has been proposed by Proctor et al. (1973).

Engler and Szelenyi (1984) described a new method for screening mucosecretolytic compounds using tracheal phenol red secretion in **mice**. Phenol red at a dose of 500 mg/kg was injected intraperitoneally to male mice. Thirty min later, the animals were sacrificed by carbon dioxide. The whole trachea was dissected free from surrounding tissue and excised. Each trachea was washed for 30 min in 1 ml physiological saline. Afterwards, 0.1 ml 1 M NaOH was added to the washing to stabilize the pH of the lavage fluid. The concentration of phenol red was measured photometrically. Agonists were administered subcutaneously 15 min or intragastrally 30 min before phenol red was injected. Antagonists were given 5 min prior to the administration of agonists.

Other dyes, such as Evans blue or sodium fluorescein also are reported to be eliminated in the respiratory tract fluid of mice (Graziani and Cazzulani 1981).

Dye methods reported for mice can also be used for rats (Quevauviller and Vu-Ngoc-Huyen 1966). Alcian blue was used to stain the normal bronchial tree. After chronic treatment with sulfur dioxide, there were changes in bronchial coloration. Administration of drugs protected against the effects of sulfur dioxide.

Secretion from tracheal submucosal glands can be studied in **dogs** (Davis et al. 1982; Johnson and McNee 1983, 1985). In anesthetized dogs the epithelial surface of the upper trachea is exposed and coated with powdered tantalum. Secretions from the submucosal gland ducts form elevations (hillocks) in the tantalum layer. The number of hillocks that appear in a 1.2 cm^2 field is counted.

A micropipette method for obtaining secretions from single submucosal gland ducts *in vivo* in **cat** tracheas has been described (Ueki et al. 1979, 1980; Leikauf et al. 1984). In anesthetized cats an endotracheal tube was inserted into the lower trachea and connected to a constant volume respirator. The remainder of the trachea above the endotracheal tube was then dissected open by a midline incision. Paraffin oil equilibrated with HEPES buffer was then placed on the exposed mucosa to prevent drying and to aid visualization of the gland duct openings. The secretions from the gland duct openings were collected with constant-bore (99 µm ID) glass micropipettes. The volume and the viscosity of the secreted mucus were determined.

CRITICAL ASSESSMENT OF THE METHODS

For the methods of mucus collection in rabbits, cats or dogs a rather high number of animals is necessary to achieve data suitable for statistical analysis. For screening procedures the methods using dye elimination into the trachea of mice or rats seem to be preferable.

D.4.0.3 Studies of mucus secretion with chronic cannulation

PURPOSE AND RATIONALE

Several techniques have been developed for chronic collection of mucus (Wardell et al. 1970; Yankell et al. 1970; Scuri et al. 1980).

PROCEDURE

Beagle dogs weighing 9–11 kg are anesthetized by intravenous injection of 35–40 mg/kg pentobarbital sodium. The cervical trachea is exposed by a midline skin incision and blunt dissection of the muscles. A segment approximately 10 rings in length, with an intact blood and nerve supply, is transected. The cephalic and caudal parts of the trachea are anastomosed end-to-end with interrupted gut sutures to reestablish a patent airway. The isolated segment is loosened slightly from the surrounding tissue and turned 180° to reverse cilia movement. A funnel-shaped silicone cannula is attached to the outer surface of the proximal end of the tracheal segment with surgical mesh and sutured in place. With cannulation completed, the tracheal segment is placed in a pocket below the sternohyoid muscle and the cannula brought to the surface and exteriorized through a stab wound. Alternatively, the isolated segment is closed at its caudal end with interrupted gut sutures. The mucosal surface of the cervical end of the isolated tracheal segment is sutured with interrupted silk sutures to the overlying subcutaneous tissue through a small incision in the cervical skin. Muscles and skin are sutured normally. In two or three weeks the skin heals over the small stoma resulting in

a subcutaneous pouch of functioning tracheal tissue. Mucus samples can be collected for months. In this modification, a balloon can be placed into the pouch. Pressure changes in the balloon due to contraction of the smooth tracheal muscles after physostigmine injection or vagal stimulation or relaxation after atropine injection are recorded demonstrating parasympathetic innervation.

EVALUATION

Parasympathomimetic stimulation (0.5 mg/kg pilocarpine s.c.) increases the flow rate of tracheal fluids. Pressure changes in the balloon after injection of parasympathomimetic or sympathomimetic drugs are compared with baseline values.

MODIFICATIONS OF THE METHOD

Scuri et al. (1980) inserted a T-shaped cannula into the trachea of anesthetized rabbits. The wound was sutured, the third arm was connected with a collecting tube, and after 3 days of antibiotic administration, the mucus was collected at different times to establish basal production. For the experiments, mucus was collected during a 4 h control period, then drugs were given intravenously, orally or as aerosol inhalation. Mucus was further collected during the periods of 0 to 4 and 4 to 24 h and analyzed for sialic acid, fucose, and protein content.

A tracheal pouch method in ferrets has been described by Barber and Small (1974).

Several authors published methods to determine **viscoelastic properties and rheological behavior of tracheal and bronchial mucus**: Philippoff et al. (1970), Lopez-Vidriero and Das (1977), Martin et al. (1980) Kim et al. (1982), Braga (1988), King (1988), Majima et al. (1990).

CRITICAL ASSESSMENT OF THE METHODS

The methods using pouches in dogs may be useful for physiological studies, but for pharmacological purposes the rabbit method of Scuri et al. (1980) seems preferable.

D.4.0.4 Bronchoalveolar lavage

PURPOSE AND RATIONALE

Isolation of bronchial cells from bronchoalveolar lavage was described by Myrvik et al. (1961), Bassett et al. (1988), Fryer et al. (1994, 1997), Wang et al. (1997).

PROCEDURE

After determination of mechanical respiratory parameters in anaesthetized guinea pigs, bronchoalveolar lavage is performed via the tracheal cannula. The lungs are lavaged with 5 aliquots of 10 ml phosphate-buffered saline containing 3 mM EDTA and 100 µM isoproterenol (pH 7.2–7.4). The recovered lavage fluid (40–45 ml) is centrifuged, the cells are resuspended in 20 ml of phosphate-buffered saline, and total cells are counted using a hemacytometer. The remaining aliquot is centrifuged again and cells are stained to determine cell differentials

EVALUATION

The differences in cells recovered from bronchoalveolar lavage between treatment groups are tested by use of a one-factor analysis of variance. $P < 0.05$ is considered significant.

MODIFICATIONS OF THE METHOD

Gossart et al. (1996) determined TNF-α activity in the supernatant of bronchoalveolar lavage by the cytotoxicity against TNF-α-sensitive L929 murine fibroblasts.

D.4.0.5 Ciliary activity

PURPOSE AND RATIONALE

Ciliary activity is a natural defense mechanism of the mucosa in the respiratory tract against harmful extraneous agents resulting in a continuous transportation of secreted mucus. Many attempts have been made to visualize and to quantify this phenomenon. Several authors used the light beam reflex method which can be used for *in vivo* as well as for *in vitro* experiments (Dalhamn 1956, 1964; Dalhamn and Rylander 1962; Hakansson and Toremalm 1963; Mercke et al. 1974; Baldetorp et al. 1976; Lopez-Vidriero et al. 1985).

PROCEDURE

Rats are anesthetized by intraperitoneal injection of tribromo-ethanol (Avertin®). The trachea is exposed and its soft parts are incised by electrocoagulation so that bleeding is avoided. The cartilaginous rings are opened sufficiently to permit microscopy. The rat is immediately placed in a moist chamber. The trachea opening is linked to a microscope (Leitz Ultropak) by means of a rubber bellows which is fitted around the lens of the microscope and is made to embrace the trachea by means of a piece of rubber tubing that is slit along its length and secured to the bellows. The beam of an illuminating lamp is concentrated to a surface of about one mm^2. By placing a heat-reflecting filter in the path of the beam the rise in temperature can be reduced. For registration of the reflected light high speed cameras with a speed of 220 exposures are used. Alternatively, the reflected light from the microscope is directed to a TV camera and amplified to be displayed on a TV screen. The frequency of ciliar beats is recorded over one hour.

EVALUATION

The beat frequency of treated animals is compared with that of controls.

MODIFICATIONS OF THE METHOD

Mercke et al. (1974) described a stroboscopic method for standardized studies of mucociliary activity in rabbit tracheal mucosa.

Lierle and Moore (1935) inserted windows into anesthetized rabbits for observation of the ciliary activity in the maxillary sinus of living animals.

With modern equipment, a similar technique has been used by Hybbinette and Mercke (1982a–c), Lindberg and Mercke (1986), Lindberg et al. (1986), Mercke et al. (1987) to study the role of several pharmacologic agents in the mucociliary defense of the rabbit maxillary sinus.

Corssen and Allen (1958) compared the toxic effects of various local anesthetic drugs on human ciliated epithelium *in vitro* by observation of rotating globes of human tracheal epithelium in tissue culture.

Cheung (1976) performed high speed cinemicrographic studies on rabbit tracheal (ciliated) epithelia.

Iravani (1967, 1971, 1975) studied the ciliary activity in the intrapulmonary airways of rats by incident light microscopy.

Lee and Verdugo (1976), Verdugo et al. (1980) recommended laser light-scattering spectroscopy for the study of ciliary activity.

Rutland and Cole (1980) and Hesse et al. (1981) used a non-invasive method for obtaining nasal ciliated epithelium which is suitable for measurement of ciliary beat frequency.

Van de Donk et al. (1980) used isolated chicken embryo tracheas to measure the effects of preservatives on ciliary beat frequency. Maurer et al. (1982) studied the role of ciliary motility in acute allergic mucociliary dysfunction in cultivated ciliated cells from sheep.

Lopez-Vidriero et al. (1985) studied the effect of isoprenaline on the ciliary activity of an *in vitro* preparation of rat trachea.

Braga et al. (1986) described a simple and precise method for counting ciliary beats directly from the TV monitor screen using specimens of human ciliated epithelium obtained by brushing the nasal mucosa.

Curtis and Carson (1992) used pieces of human nasal epithelium for computer-assisted video measurement of ciliary beat frequency *in vitro*. Ciliary beat frequency was viewed with a microscope equipped with a phase contrast objective. The microscopic image was recorded by a camera and data stored by a videorecorder. For measuring ciliary beating, tapes were displayed with amplification on a monitor. A photoelectric transducer was positioned over the video image of the cilia. Movement of the cilia interrupting the light path caused changes in light intensity recorded by the photocell transducer.

D.4.0.6 Studies of mucociliary transport

PURPOSE AND RATIONALE

Mucus flow has been studied in *in vitro* and *in vivo* experiments (Iravani 1971; Ahmed et al. 1979). The rate of mucus flow can be estimated by measuring the time needed for certain particles to travel a known distance in the trachea. Numerous substances have been used such as charcoal particles (Dalhamn 1956), Teflon discs (Ahmed et al. 1979), and other pulverized materials (Deitmer 1989). The effect of local radioactivity on tracheal mucous velocity of sheep has been studied *in vitro* and *in vivo* by Ahmed et al. (1979).

PROCEDURE

For *in vitro* experiments, sheep are sacrificed during anesthesia, the trachea is exposed, clamped, and resected just below the cricoid cartilage. The chest is opened and the trachea is resected at the level of the carina. Then the trachea is slit open along the posterior membranous wall, pinned with gentle stretching on a board, and slanted upward at an angle of 25°. A metric ruler is placed along the board as a measuring reference. The board is then placed in a Plexiglas® chamber with a constant temperature of 37 °C and 100% humidity. Teflon discs are spread on the mucous layer. Tracheal mucus velocity is estimated by filming the movements of the radioopaque Teflon discs visualized on a television monitor connected to a camera. Disc motion is recorded for 1–2 min on a videotape, and the distance measured during the elapsed time is obtained from the videomonitor.

For *in vivo* measurements of tracheal mucus velocity, the roentgenographic method of Friedman et al. (1977), Sackner et al. (1977) is used. The sheep are restrained, and their heads are immobilized with a sling. The nasal mucosa is sprayed with a 2% lidocaine solution for topical anesthesia. A bronchofiberscope is inserted transnasally, and its tip is placed just below the vocal cords. Radioopaque Teflon discs 1.0 mm in diameter, 0.8 mm thick, and weighing 1,76 mg are blown through the inner channel of the bronchofiberscope onto the tracheal mucosa in a circumferential distribution. The cervical trachea containing the discs is visualized in the lateral projection with a television monitor. Disc motion is recorded on a videotape while the time is displayed on a digital clock. The disc image is marked to obtain the distance traveled. This distance is measured with a ruler, and the linear velocity of the disc is computed by dividing the distance by the elapsed time. This procedure is repeated for all discs in the field of view. To compute a mean tracheal mucus velocity, data from 10–15 discs are obtained in each filmed run.

EVALUATION

Disc velocities measured *in vitro* or *in vitro* are compared before and after treatment.

MODIFICATIONS OF THE METHOD

Mucociliary transport has been studied on the hard palate of decapitated frogs measuring the transport velocity of small particles, e.g., pieces of cork or charcoal (Kochmann 1930; Sadé et al. 1970).

Suzuki (1966) measured the movement of a standard object (1 mm^2 aluminum foil) on the ciliated surface of the palate of frogs.

Mucociliary clearance by the *in vitro* frog method was used by Leitch et al. (1985) to study the effects of ethanol.

Movement of poppy seeds in rabbit tracheal preparations was studied by Kensler and Battista (1966).

In chicken nasal mucosa the interaction between mucociliary transport and the ciliary beat was studied by Ukai et al. (1985).

Mucus transport in the respiratory tract of anesthetized cats was measured with uniform particles of lycopodium spores triturated with lamp black (Carson et al. 1966).

Mucociliary clearance velocities were determined by a radioisotopic method in dogs (Giordano et al. 1977, 1978).

D.4.0.7 Culture of tracheal epithelial cells

PURPOSE AND RATIONALE

Marked morphological changes of the airway epithelium, up to severe damage, are frequently observed in inflammatory airway diseases and appear to play an important role in the pathogenesis of the broncho-obstructive symptoms (Webber and Corfield 1993; Hay et al. 1994). Freitag et al. (1996) studied the effects of lipopolysaccharides (LPS) and TNF-α on cultured rat tracheal epithelial cells and determined NO synthase activity.

PROCEDURE

Trachea of newborn rats, cut into small pieces, are explanted with the epithelial surface downwards onto 60 mm culture dishes (Lechner et al. 1985) and cultured in low-calcium (60–80 µmol/l) RPMI-1640 medium at 37 °C and 5% CO_2. The medium containing 16% fetal calf serum is supplemented with epidermal growth factor and other growth promoting factors, such as 80 ng/ml cholera toxin, 2.6 ng/ml estradiol, 180 ng/ml hydrocortisone, 2.5 µg/ml insulin, 12.5 µg/ml transferrin, and 100 U/ml penicillin, 100 µg/ml streptomycin and 3.5 µg/ml amphotericin B to allow a selective outgrow of epithelial cells (Emura et al. 1990). Confluent epithelial layers are obtained after about 6–10 weeks at which time all cells show a positive staining with a pan-cytokeratin-antibody. Confluent cells of fol-lowing passages are treated for four subsequent days with LPS (10 µg/ml) or TNF-α (500 U/ml).

The **morphology** of the cells is evaluated is evaluated by daily inspection using a phase contrast microscope with photographical documentation. Cell density in the culture is determined in each culture dish by counting daily the number of cells in four marked areas (each 2 000 μm^2). For immunocytochemical staining, the cells are fixed by incubation in 100% methanol at –20 °C for 20 min. The cells are washed with Ca/Mg-free phosphate buffered saline and several areas are marked of by nail-varnish. A solution of the anti-cytokeratin(pan)-antibody (monoclonal mouse IgG, Boehringer Mannheim) is added, incubated for 2 h at room temperature and after washing incubated for 30 min with a secondary antibody (FITC coupled, polyclonal rabbit anti-mouse IgG, Sigma). After washing, fluorescence microscopy is performed using a microscope with a FITC-specific filter combination. Unspecific fluorescence is excluded by performing the staining procedure in a different area of the same culture, but without the addition of the primary antibody.

For **determination of NO synthase activity**, confluent cultures are washed with oxygenated and prewarmed (37 °C) Krebs-HEPES medium. Then the cells are incubated for 1 h in the same medium containing 37 kBq ^{3}H-L-arginine (100 nmol/l). After collection of the supernatants the cells are extracted in 1 ml of 0.4 mol/l $HClO_4$ for 2 h at 0–4 °C.

By **HPLC analysis** ^{3}H-compounds (^{3}H-L-citrulline, ^{3}H-L-ornithine and ^{3}H-L-arginine) in incubation media and cell extracts are separated on a reverse phase column (length 250 mm, inner diameter 4.6 mm, prepacked with Shadon ODS-Hypersil, 5 mm) using as mobile phase 0.1 mmol/l sodium phosphate buffer (adjusted to pH 1.8) which contains octane sulphonic acid sodium salt (400 mg/l), Na_2EDTA (0.3 mmol/l) and methanol (6.25% v/v) with a flow rate of 1 ml/min (Hey et al. 1995). The eluate is collected in 1 min fractions into counting vials. After addition of a commercial scintillation cocktail the radioactivity is determined by liquid scintillation spectrophotometry. External standardization is used to correct for counting efficiency. The retention time is determined by the use of ^{14}C-labelled (L-citrulline or L-ornithine) or ^{3}H-labelled (L-arginine) standards. Protein content in cells is determined by a commercially available assay.

EVALUATION

The amounts of ^{3}H-L-citrulline in supernatants or cell extracts are expressed as DPM/µg protein. Changes in cell density are expressed as % of the density observed in each culture dish at the start of the experiment. Mean values are given ±SEM. The significance of difference is evaluated by Student's *t*-test.

Chapter E
Psychotropic and neurotropic activity[1]

[1] Reviewed by W. H. Vogel, contribution of biochemical methods in the first edition by F. P. Huger.

E.1 Effects on behavior and muscle coordination

E.1.1 Spontaneous behavior

E.1.1.1 General considerations

The effects of drugs on the central and peripheral nervous systems can be easily recognized in normal animals. This does not necessarily mean that these effects can be used in therapy. Observing the global effects of drugs during LD_{50}-determinations, pharmacologists can detect psychotropic activity. Only, if these effects occur also in doses considerably below the LD_{50}, are further evaluations justified. This basic experience resulted in the development of a variety of observational tests and activity measurements.

E.1.1.2 Observational assessment

PURPOSE AND RATIONALE

A systematic, quantitative procedure assessing the behavioral state of mice for the evaluation of drugs has been described by Irwin (1964, 1968). The method is applied in the beginning of pharmacological screening to detect psychotropic activities. It allows to identify and differentiate the profile pattern of various classes of pharmacological agents. Furthermore, observational assessment allows into the safety and potential toxicity profile of a new drug.

PROCEDURE

Mice of either sex (NMRI-strain) with a weight between 18 and 22 g are kept under standard laboratory conditions 5 days before the experiment. Animals tested for oral administration have water ad libitum but are deprived of food 16 h before the test. Animals for intravenous or intraperitoneal administration have access to food and water ad libitum until the test. For unknown substances the following doses are given:

- i.v. administration: 100, 200, 400 mg/kg
- i.p. administration: 300, 600, 1 200 mg/kg
- oral administration: 500, 1 000, 2 000 mg/kg

Three animals are used for each dose. One group of 3 animals receiving the vehicle only, serves as control group.

Immediately after drug administration, the animals are closely observed for 2 h (following i.v. or i.p. administration) and for 5 h (following oral administration) by a "blind" observer. The following parameters are checked and compared to the vehicle control group:

Effects on CNS	Effects after manipulations
spontaneous motor activity	auditory stimulus response
restlessness	escape after touch
grooming behavior	righting reflex
squatting	paresis of hind limbs
staggering	paresis of forepaws
ataxic gait	catalepsy in induced positions
lying flat on the belly	
lying flat on the side	**Effects on reflexes**
lying flat on the back	
sleeping	pinna reflex
narcosis	corneal reflex
bizarre behavior	pain following stimulation
timidity	
Straub´s phenomenon	**Effects on autonomic nervous system**
writhing	
tremors	pupil diameter (constriction or dilatation)
twitches	eyelids (closure or exophthalmus)
opisthotonus	secretion of sweat
clonic convulsions	salivation
tonic convulsions	lacrimation
rolling and jumping convulsions	cyanosis
	piloerection
	defecation
	urination

Depending on the route of administration, the observations are performed at different time intervals: after intravenous and after intraperitoneal administration during the first 30 min, and after 1 and 2 h; after oral administration during the first 60 min, and after 2 and 6 h. The number of deaths is counted during the first 24 h and after 7 days in order to evaluate acute and late toxicity. Arbitrary scores are chosen for each symptom. If positive effects are seen with the lowest dose, the experiment is repeated with lower doses being decreased by a factor of 3.

CRITICAL ASSESSMENT OF THE TEST

The test has been used by almost every laboratory in the world involved in screening of potential new drugs. Almost every laboratory has introduced its own modifications. In particular, the scores and the calculations differ from one laboratory to the other. Additional tests, such as grip strength or rotarod, described below, have been included into the primary screen. Graph-bar profiles have been established for known drugs in order to rate new substances accordingly. The test is definitively an useful tool for primary screening resulting in

hints on psychotropic activity but also for actions on other systems. Nevertheless, this test can not substitute for more sophisticated tests for the evaluation of psychotropic activity.

MODIFICATIONS OF THE METHOD

Based on the guidelines of the United States Environmental Protection Agency (USEPA) (1991) Mattsson et al. (1996) described a performance standard for clinical and functional observational battery (FOB) for examinations of rats. The performance standard was an idealized composite of FOB data from experienced laboratory personnel, each person tested on a separate set of four groups of rats. The rats were examined in random order and treatments were either (a) saline, (b) chlorpromazine, (c) atropine, followed by physostigmine or (d) amphetamine.

Testing of neurotoxicity with new pharmaceuticals was reported by Haggerty (1991). He proposed a primary screen for rodents, consisting of a functional observation battery and an automated test for motor activity. In addition, a functional observation battery for dogs was developed. The rat tier I screen assesses such functions as home cage and open field activity, stimulus reactivity, and neuromuscular function. The dog tier I screen emphasizes evaluation of gait, postural reactions, and reflex function.

Rambert (2000) underlined the importance of some general conditions for general pharmacology of the CNS, such as choice of the animal species, administration route and controls of the experimental context (surroundings, temperature, schedules of the trials, interference with food-intake episodes, influence of noises and smells, expertise of the experimental staff).

Crawley and Paylor (1997), Crawley (2000) proposed a test battery and behavioral paradigms to investigate the behavioral phenotypes of transgenic and knockout mice. Several neurological and neuropsychological tests are described which can be used as first screen for behavioral abnormalities in mutant mice. Multiple behavioral paradigms are included for several categories, such as neurological reflexes, sensory abilities, motor functions, learning and memory, feeding, sexual behavior, analgesia, aggression, anxiety, depression, schizophrenia, and drug abuse.

E.1.1.3 Safety pharmacology core battery

PURPOSE AND RATIONALE

Regulatory agencies (EMA 1997, 2000) have pointed out the necessity to perform safety pharmacology studies before application of a new drug to human beings and to assess most carefully any potential side effects. Organs or systems acutely necessary for life, i.e., the cardiovascular, respiratory and central nervous systems, are considered to be the most important to assess in safety pharmacology studies. The following parameters of CNS activity should be assessed appropriately: motor activity, behavioral changes, coordination, sensory/motor reflexes and body temperature.

Detailed descriptions of tests are found for

Observation tests:

E.1.1.2 Observational assessment

Motor activity and behavior:

E.1.2.2 Method of intermittent observations
E.1.2.3 Open field test
E.1.2.4 Hole-board test
E.1.2.5 Combined open field test

Coordination:

E.1.3.1 Inclined plane
E.1.3.2 Chimney test
E.1.3.3 Grip strength
E.1.3.4 Rotarod method

Sensory/motor reflexes:

E.1.3.5 Influence on polysynaptic reflexes

E.1.3.6 Masticatory muscle reflexes

Follow-up studies for CNS safety pharmacology are recommended, such as behavioral pharmacology, learning and memory, specific ligand binding, neurochemistry, visual, auditory and/or electrophysiology examinations. Detailed descriptions of these tests are found in the respective chapters, e.g.,

E.1.2.6 EEG analysis from rat brain by telemetry.

E.1.2 Effects on motility (sedative or stimulatory activity)

E.1.2.1 General considerations

A survey on methods to evaluate depressants of the central nervous system has been published by Turner (1965). Many of these tests are still valid in spite of the fact that new classes of drugs have been introduced since that time which have not only augmented the therapeutic armamentarium but also changed the battery of pharmacological tests.

Sedative properties of drugs are tested mostly in mice or rats. Their spontaneous motor activity depends on various factors, such as the social situation (one or more animals), familiarity with the test environment, light and temperature. The term spontaneous motor activity includes different types of movements, such as locomotion, rearing, sniffing, grooming, eating and drinking. These phenomena can be well recognized by a skilled observer, but are difficult to record over long periods of time and to quantitate. Therefore, besides procedures based on observation many methods for automatic registration have been developed. Almost every pharmacologist working in this field has designed his/her own apparatus. Several attempts have been made to measure not only simple locomotion, but also rearing and other types of movement. The conditions to characterize drug effects by measuring locomotor activity have been surveyed by Kinnard and Watzman (1966), Geyer (1990).

A special phenomenon, called "thigmotaxis" which means that rats have the tendency to remain close to the walls of the cage, has been described by Barnett (1963). Moreover, methods to measure curiosity have been recommended. Only a few examples of prototypic methods and equipment can be given.

E.1.2.2 Method of intermittent observations

PURPOSE AND RATIONALE

The method described by Ther (1953) was designed to study stimulant and sedative drugs. The use of 3 mice per group implied a special social situation of the animals. For testing sedative activity, the mice are additionally treated with a stimulant, and for testing stimulant activity with a sedative drug. Each group of mice is observed repeatedly only for a short period of time during one hour and compared to a control group by a "blind" observer.

PROCEDURE

Mice of either sex with an average weight of 25 g are deprived of food and water for 24 h before the test. To avoid any influence of the circadian rhythm the experiment is performed only between 8:00 and 12:00 A.M. Twelve animals are divided into groups of 3 mice. One group of 3 mice serves as control group, the other groups receive different doses of the test drug intraperitoneally. For testing sedative activity, the mice are injected after 10 min subcutaneously with 0.5 mg/kg methamphetamine. For testing stimulant activity, the mice are treated with 800 mg/kg paraldehyde. Ten minutes afterwards, each group is placed into a glass jar of 12 cm diameter and 20 cm height which in turn are

placed in a wooden box of 130 × 50 × 30 cm. The glass jars are illuminated from above. Ten minutes after administration of methamphetamine or paraldehyde the observation is started.

EVALUATION

During 1 h the observer looks every minute for 1 s to each jar and registers if none, one, two or all three mice show any characteristic change in locomotion, rearing, grooming or sniffing. The maximum count in 1 h would be 180. Generally, activity decreases within 1 h. Nevertheless, methamphetamine treated animals have a total count between 120 and 150. Groups treated with an effective sedative drug show a dose dependent decrease of total counts. The number of counts in the treated groups is calculated as percentage of controls. From dose-response curves ED_{50}-values can be calculated.

CRITICAL ASSESSMENT OF THE METHOD

The method gives reliable results for sedative drugs and for compounds with central depressant activity, such as antihistaminics, neuroleptics and hypnotics. The disadvantage of the method lies in the fact that a skilled and trained observer is needed in order to get reproducible results. Therefore, several attempts have been made to automatize the method of intermittent observation.

MODIFICATIONS OF THE METHOD

Schaumann and Stoepel (1961) followed the principle of intermittent observation using a camera mounted above small wire cages (10 × 10 cm). The mice in the cages were photographed with an exposure time of 3 s every 7,5 min over a period of 2,5 h. Mice without movements give clear pictures, calculated as zero. Slight movements induce blurred contours, calculated as 1 point, and major movements give completely blurred pictures, calculated as 2 points. Normal mice show 20 or less points during 20 observations. Mice with more than 20 points are considered to be stimulated, mice with less than 5 points to be sedated. In this way ED_{50}-values can be calculated.

Vogel and Ther (1963) published an apparatus with automatic registration of intermittent observations. 18 cages are used which have a freely movable bottom with minimal weight which is supported by springs. A small permanent magnet attached below the floor induces an electrical current in a coil if the bottom is moved. Two mice are brought into each cage. The control device registers during a variable period between 0.5 and 3 s if the bottom of one cage is moved or not. Within one minute, all 18 cages are registered successively. The number of movements within one hour is recorded for each cage. The sensitivity of the electric induction system is variable. A calibration is possible which picks up every movement of the animal, however, does not register the movements due to breathing. Dose-response curves can be established for stimulant and sedative drugs.

Meyer (1962) measured the time until the exploration motility decreased to one third of the initial value.

Koek et al. (1987) used the principle of intermittent observations for various activities of rats such as locomotion, rearing, sniffing, licking, gnawing, grooming, loss of righting, Straub tail, ect. in order to compare the behavioral effects of drugs.

E.1.2.3 Open field test

PURPOSE AND RATIONALE

Interruption of light beams as a measure of movements of rats or mice in a cage ("open field") has been used by many authors such as Dews (1953), Saelens et al. (1968) Nakatsu and Owen, (1980). Recently developed devices allow to register not only general motor activity but also locomotion, rearing and the speed of locomotion (Barros et al. 1991; Ericson et al. 1991).

PROCEDURE

The rats are observed in a square open field arena (68 × 68 × 45 cm) equipped with 2 rows of 8 photocells, sensitive to infrared light, placed 40 and 125 mm above the floor, respectively. The photocells are spaced 90 mm apart and the last photocell in a row is spaced 25 mm from the wall. Measurements are made in the dark in a ventilated, sound-attenuating box. Interruptions of photocell beams can be collected by a microcomputer and the following variables can be evaluated:

- Motor activity: All interruptions of photo beams in the lower rows.
- Peripheral motor activity: Activation of photo beams in the lower rows, provided that the photo-beams spaced 25 mm from the wall were also activated.
- Rearing: All interruption of the photo beams in the upper rows.
- Peripheral rearing: Interruption of photo beams in the upper rows, provided that the photo beams spaced 25 mm from the wall were also activated.
- Locomotion: Successive interruptions of photocells in the lower rows when the animal is moving in the same direction.
- Speed: The time between successive photo beam interruptions during locomotion collected in 0.1 s categories.

Adult male Sprague-Dawley rats with a weight between 280 and 320 g are used. Drugs are injected subcutaneously 10 to 40 min. before test. The rats are observed for 15 min whereby counts per min. are averaged for 3 min intervals.

EVALUATION

Dose-response curves can be obtained for sedative and stimulant drugs, whereby the various parameters show different results. The effects of various doses are compared statistically with the values of controls and among themselves.

CRITICAL ASSESSMENT OF THE METHOD

Measurement of several parameters in an open field device allows to differentiate between various types of sedative or stimulant drugs, but these differences can only be detected if dose-response curves are obtained for each parameter.

MODIFICATIONS OF THE METHOD

Besides interruption of light beams, devices based on capacitance systems such as Animex® (Columbus Instruments, Ohio, USA) and Varimex®, have been developed and are widely used (Crunelli and Bernasconi 1979; Liu et al. 1985; Laviola G and Alleva E 1990; Honma et al. 1990; Magnus-Ellenbroek et al. 1993; Dauge et al. 1995; Petkov et al. 1995; Surmann et al. 1995; Gillies et al. 1996; Irifune et al. 1997; Ghelardini et al. 1998).

Nikodijevic et al. (1991) studied the behavioral effects of A_1- and A_2-selective adenosine agonists and antagonists in mice using a Digiscan activity monitor (Omnitech Electronics Inc., Columbus, OH) equipped with an IBM-compatible computer. The monitor included multiple activity monitor cages ($40 \times 40 \times 30.5$ cm), each of which was surrounded by horizontal and vertical sensors not detectable by the rodent.

Steiner et al. (1997) found that D_3 receptor deficient mice enter the center of an open field significantly more than their littermates suggesting an anxiolytic-like effect of the D_3 receptor mutation.

Vorhees et al. (1992) described a locomotor activity system for rodents. The system consists of a black, ventilated test chamber, internally lighted with a ceiling mounted video camera. The camera's image is transmitted to a contrast-sensitive tracker which maps the point of highest contrast and relays the digitalized coordinates to a PC. Dedicated software stores the information and simultaneously displays a map of the tracked subject.

Rex et al. (1996, 1998) described a modified open field test sensitive to anxiolytic drugs. Food-deprived rats were placed in one corner of the open field containing food in the center. The number of rats beginning to eat within the first 5 min was increased by known anxiolytic drugs.

Several computerized systems, based on interruptions of infrared light beams, on magnetic field or on video-analysis have been developed by Technical and Scientific Equipment GmbH, D-61348 Bad Homburg, Germany, or by Bilaney Consultants Ltd., St Julians, Sevenoaks, Kent, UK.

A novel method for counting spontaneous motor activity in rats was proposed by Masuo et al. (1997). In the "Supermex" system, a sensor detects the radiand body heat of an animal.

E.1.2.4 Hole-board test

PURPOSE AND RATIONALE

The evaluation of certain components of behavior of mice such as curiosity or exploration has been attempted by Boissier et al. (1964) and Boissier and Simon (1964). They used an open field with holes on the bottom into which the animals could poke their noses. The "planche à trous" or "hole-board" test has become very well recognized and has been modified and automatized by many authors.

PROCEDURE
Mice of either sex (NMRI strain) with a weight between 18 and 22 g are used. The hole-board has a size of 40 × 40 cm. Sixteen holes with a diameter of 3 cm each are distributed evenly on the floor. The board is elevated so that the mouse poking its nose into the hole does not see the bottom. Nose-poking is thought to indicate curiosity and is measured by visual observation in the earliest description and counted by electronic devices in more recent modifications. Moreover, in the newer modifications motility is measured in addition by counting interruption of light beams. Usually, 6 animals are used for each dose and for controls. Thirty minutes after administration of the test compound the first animal is placed on the hole-board and tested for 5 min.

CALCULATION
The number of counts for nose-poking of treated animals is calculated as percentage of control animals.

CRITICAL ASSESSMENT OF THE METHOD
Poking the nose into a hole is a typical behavior of mice indicating a certain degree of curiosity. Evaluation of this component of behavior has been proven to be quite useful. Benzodiazepines tend to suppress nose-pocking at relatively low doses.

MODIFICATIONS OF THE METHOD
A hole-poke measuring system is commercially available from Technical and Scientific Equipment GmbH, D-61348 Bad Homburg, Germany.

Clark G, Koester AG, Pearson DW (1971) Exploratory behavior in chronic disulfoton poisoning in mice. Psychopharmacologia (Berl.) 20:169–171

E.1.2.5 Combined open field test

PURPOSE AND RATIONALE
The simultaneous determination of locomotion and curiosity by using a modification of the hole-board test and a photo-beam system has been proposed as a relatively simple test (Weischer et al. 1976). Several types of such equipment are commercially available.

PROCEDURE
Male mice (NMRI-strain) with an average weight of 30 g are used. Each animal is tested individually in an automated open-field box which consists of a black Plexiglas cage (35 × 35 × 20 cm) with a post (8 × 8 × 20 cm) in the center of the cage. Two evenly spaced photo cell beams perpendicular to the wall and 2 cm above the floor divide the box into 4 compartments. Every photo cell beam interruption is registered automatically as an activity count. Each wall of the cage contains 4 evenly spaced 2 cm diameter holes in a horizontal array 7 cm above the floor. A row of 4 photocell beams is mounted 1 cm outside of the holes and automatically records every exploratory nose-poke. Thirty min. after intraperitoneal and 60 min. after oral administration of the test compound the animal is placed into the cage and the behavior recorded for a period of 5 min. Ten mice are used for each dose as well as for controls.

EVALUATION
Counts for motility (interruption of photo cell beams inside the cage) and for curiosity (interruption of photo cell beams outside the cage due to nose-poking) are recorded individually. The mean values of the treated groups are expressed as percentage of the control group. Using different doses, dose-response curves can be obtained.

CRITICAL ASSESSMENT OF THE METHOD
A dissociation between exploratory behavior and locomotion has been found with several drugs. Even well known stimulants can reduce exploratory behavior with a concomitant increase in locomotion. Depending on the dose, tranquilizers can reduce exploration without affecting locomotion. Due to the modifications of the equipment the results of different authors are often difficult to compare.

The limitations of photocell activity cages for assessing effects of drugs were discussed by Krsiak et al. (1970).

MODIFICATIONS OF THE TEST
Geyer (1982) described a similar device and reported different effects of amphetamine, caffeine, apomorphine and scopolamine. Adams and Geyer (1982) used this device to study the LSD-induced alterations of locomotor patterns and exploration in rats.

Geyer et al. (1986) described a behavioral monitor which was designed to assess the spatial and temporal sequences of locomotor movements in rats.

Other authors, e.g. Wolffgramm et al. (1988) used video recording of the movements of mice in the evening hours at low illumination and counted the locomotor activity as the number of field crossings and the exploratory activity as the number of rearings.

Ljungberg and Ungerstedt (1977) designed a testbox for the automatic recording of eight components of behavior in rats including compulsive gnawing induced by apomorphine.

Matsumoto et al. (1990) described a system to detect and analyze motor activity in mice consisting of a doughnut-shaped cage with 36 units of detectors radially arranged from the center of the cage. Each detector unit consisted of 4 pairs of photosensors (higher-, lower-, inner-, and outer-position sensors).

Schwarting et al. (1993) described a video image analyzing system for open-field behavior which measures turning behavior, thigmotactic scanning and locomotion in rats.

E.1.2.6 EEG analysis from rat brain by telemetry

PURPOSE AND RATIONALE

Field potential analysis of freely moving rats by radioelectroencephalography from different brain areas has been developed as a sensitive method in pharmacology (Dimpfel et al. 1986, 1989, 1990, 1992; Kropf et al. 1991).

PROCEDURE

Male adult rats are implanted with four stainless steel electrodes, mounted on a base plate, into the frontal cortex, striatum, thalamus, and reticular formation. The plate carries a microplug for a four-channel radiotransmitter. During the experimental sessions, which start 2 weeks after surgery, the transmitted field potentials are analyzed in real time using Fast Fourier Transformations. The resulting power density spectra are segmented into six frequency bands, each representing the integrated power over a certain frequency band.

EVALUATION

The data from three pre-drug periods of 15 min each are compared with those from continuously monitored 15-min postdrug periods.

MODIFICATIONS OF THE METHOD

De Simoni et al. (1990) developed a miniaturized optoelectronic system of telemetry for data obtained in freely moving animals by *in vivo* voltammetry, an electrochemical technique that uses carbon fiber microelectrodes to monitor monoamine metabolism and release continuously (Justice 1987).

E.1.3 Tests for muscle coordination

E.1.3.1 Inclined plane

PURPOSE AND RATIONALE

The method of Allmark and Bachinski (1949) using an inclined screen was originally developed for testing curare-like agents. Later on, it has been used by many authors (e.g. Randall et al. 1961) for testing compounds for muscle relaxant activity. The principle of an inclined plane has been used by Ther, Vogel and Werner (1959) for differentiating neuroleptics from other centrally active drugs. Rivlin and Tator (1977) also used an inclined plane to assess skeletal muscle relaxation.

PROCEDURE

The plane consists of two rectangular plywood boards connected at one end by a hinge. One board is the base, the other is the movable inclined plane. Two plywood side panels with degrees marked on their surface are fixed on the base. A rubber mat with ridges 0.2 cm in height is fixed to the inclined plane which is set at 65 degrees. Male mice (Charles River strain) with a body weight between 20 and 30 g are used. The test compound or the standard are administered to groups of 10 mice either i.p. or s.c. or orally. Thirty, 60 and 90 min thereafter, the mice are placed at the upper part of the inclined plane and are given 30 s to hang on or to fall off.

EVALUATION

The peak time is determined as the time at which a compound produces the maximum performance deficit. At this time interval, a range of doses is tested using 10 animals per group. ED_{50} values are calculated.

CRITICAL ASSESSMENT OF THE METHOD

The method has been proven to be a simple assay for muscle relaxant activity. Although the muscle relaxant tests satisfy the criteria of sensitivity and relative potency compared with clinically effective doses, the effects of anxiolytics are not clearly differentiated from neuroleptics and even from neurotoxic compounds.

MODIFICATIONS OF THE METHOD

Instead of an inclined wooden board, an inclined screen has been used by Randall et al. (1961) and Simiand et al. (1989).

E.1.3.2 Chimney test

PURPOSE AND RATIONALE

The "test de la cheminée" has been introduced by Boissier et al. (1960) as a simple test for tranquilizing and muscle relaxant activity.

PROCEDURE

Male mice (CD1, Charles River) weighing between 16 and 22 g are used in groups of 10 animals per dose. Pyrex-glass cylinders 30 cm long are required. The internal diameter varies with the animal's weight: for mice weighing 16 to 18 g, the diameter is 22 mm, for mice weighing 18 to 20 g, 25 mm; for mice weighing 20 to 22 g, 28 mm. Each tube has a mark 20 cm from its base. Initially, the tube is held in a horizontal position. At the end of the tube, near the mark, a mouse is introduced with the head forward. When the mouse reaches the other end of the tube, toward which it is pushed if necessary with a rod, the tube is moved to a vertical position. Immediately, the mouse tries to climb backwards and performs coordinated movements similar to an alpinist to pass a chimney in the mountains. This gave the name for the test. The time required by the mouse to climb backwards out at the top of the cylinder is noted.

EVALUATION

The ED_{50} (with 95% confidence limits), the dose for which 50% of the animals fail to climb backwards out of the tube within 30 s, is calculated by log-probit analysis.

CRITICAL ASSESSMENT OF THE METHOD

The chimney test can be used as an additional test with other tests determining muscle relaxant activity.

E.1.3.3 Grip strength

PURPOSE AND RATIONALE

The test is being used to assess muscular strength or neuromuscular function in rodents which can be influenced not only by sedative drugs and muscle relaxant compounds but also by toxic agents.

PROCEDURE

The method was described as 'test de l'agrippement' by Boissier and Simon (1960). Male or female mice with an average weight of 22 g are used. In a preliminary experiment the animals are tested for their normal reactivity. The animals are exposed to a horizontal thin threat or metallic wire suspended about 30 cm into the air which they immediately grasp with the forepaws. The mouse is released to hang on with its forelimbs. Normal animals are able to catch the threat with the hind limbs and to climb up within 5 s. Only animals who fulfill this criterion are included into the experiment. Ten mice are used in the control group and in the experimental groups. After oral or subcutaneous administration the animals are tested every 15 min. Animals which are not able to touch the threat with the hind limbs within 5 s or fall off from the threat are considered to be impaired. The test is continued for 2 h. The animals are observed for their behavior in the cages. Only if their behavior and their motility in the cage seem to be normal the disturbance of the grasping reflex can be considered as caused by central relaxation.

EVALUATION

The percentage of animals loosing the catching reflex is calculated. By use of different doses, ED_{50}-values are calculated. Likewise, time-response curves can be established.

CRITICAL ASSESSMENT OF THE METHOD

Only simultaneous observation of the animals under normal conditions gives the possibility to distinguish between central relaxation and toxic effects on neuromuscular function.

MODIFICATIONS OF THE METHOD

Kondziella (1964) described a method for the measurement of muscular relaxation in mice based on the capacity of hanging from a horizontal griddle.

Meyer et al. (1979) described a technique to measure the fore- and hind limb grip strength of rats and mice. The apparatus consists of an adjustable trough and a push-pull strain gauge with a triangular brass ring which is grasped by the animal with its forelimbs. The animal is pulled on the tail until the grip is broken. The animal continues to be pulled along the trough until the hind limbs grasp a T-shaped bar being also attached to push-pull strain gauge. The trial is completed when the grip of the hind limbs is also broken. Fore- and hind limb strength are measured. Dose-response curves could be established with various doses of chlordiazepoxide and phenobarbital.

Barcley et al. (1981) described the tight rope test for testing performance in mice.

Simiand et al. (1989) used a test originally described by Fleury (1957). A mouse held by the tail is placed on a small metallic grid which the animal gripped with its forepaws. The grid is than loaded with weights until the mouse could not longer support the weight of the grid. The endpoint is the maximal weight supported by the animal at least for 2 s. ED_{50}-values can be calculated for various centrally active skeletal muscle relaxants such as the benzodiazepines.

Deacon and Gardner (1984) described the pull-up test in rats. A rat is held by its hind legs in an inverted position. The time taken by the rat to pull itself up and grasp the hand of the experimenter is used as the test parameter.

Novack and Zwolshen (1983) tested muscle relaxants in various models, such as morphine-induced rigidity in rats, decerebrate rigidity in cats and the polysynaptic linguomandibular reflex in cats.
