Praise for *Ceramic Materials*

“The unprecedented completeness of this book makes it a bible on ceramic materials. It is a must read textbook for researchers, graduate students, and undergraduate students who are interested in ceramics.” —Zhong Lin Wang, Regents’ Professor, The Hightower Chair in Materials Science and Engineering, Georgia Institute of Technology

“...an outstanding introduction to the subject, clearly written, very detailed, and actually fun and quite easy to read for anyone with some basic scientific background. Each chapter contains several exercises, which this reviewer found to be very helpful. I also found extremely useful the shaded boxes on almost every page with short definitions plus “people in history.” After being exposed to many books on ceramic science during my 40-year career, I finally found a book with which I can restart my ceramic education again.” —Dr. Antoni Tomsia, Lawrence Berkeley National Laboratory

“...a valuable resource for the materials science and engineering community, both as a textbook and as a general reference to this important field ... recommended reading and a serious study source for anyone interested in ceramics....” —Professor Richard W. Siegel, Director, Rensselaer Nanotechnology Center, Rensselaer Polytechnic Institute

“The book is just wonderful, and one can only envy what the authors have done! It is the best book I have seen to date. Very clearly written with excellent examples and explanations [as well as] beautiful figures and photographs.” —Professor Safa Kasap, Canada Research Chair in Electronic and Optoelectronic Materials, University of Saskatchewan

“This new book...covers all important topics including history, microstructures, tools, defects, mechanical properties, and processing of ceramics for understanding and solving the problems of ceramic science and engineering,....” —Professor Yuichi Ikuhara, The University of Tokyo

“This is a comprehensive text covering, as the title suggests, both the science and engineering of ceramic materials. What I particularly like about the presentation of the material is that it is broken down into useful themed sections where related topics are grouped together.... This will be a very useful text for MSE undergraduate ceramic courses and for post graduates starting M.Sc. or Ph.D. work and who are new to the field of ceramic materials.” —Professor John Kilner, BCH Steele Chair in Energy Materials, Department of Materials, Imperial College London

“Ceramic Materials: Science and Engineering is a very thorough book.... Its uniqueness lies in the coverage of fundamentals...[as well as] properties and applications...at an unparalleled level, while also providing excellent sections on defects and processing.... Carter and Norton’s book is a must have in the ceramics field.” —Juan Claudio Nino, UFRF Professor, Department of Materials Science and Engineering, University of Florida, Gainesville

“It is no mean task to compete with Kingery et al.’s classic textbook on the subject, but the authors have managed to provide a fresh new perspective on the subject with their unique and student-friendly writing style coupled with spectacular graphics and

micrographs ... a truly remarkable text that is bound to become a benchmark in the field.” —Professor N. Ravishankar, Materials Research Centre, Indian Institute of Science

“...an excellent introductory textbook and basic reference for students and professionals interested in the field of technical ceramics.... There are two aspects which set this book apart from most specialty engineering textbooks. First, this book is replete with micrographs, photographs, and diagrams that complement the refreshingly easy-to-read text. Second, the authors discuss the field of technical ceramics in a societal context that will help novices understand why ceramics are important to our past and future. In summary, I highly recommend this text.” —Doreen Edwards, Dean and Professor of Materials Science, Inamori School of Engineering at Alfred University

“As a practitioner of ceramic science and technology over the last 25 years, I was truly amazed with the easy to understand and quite innovative presentation approach of various contents in the book.... This book provides a comprehensive look at various topics from the fundamental aspects of ceramics to the properties required for various applications.... I am sure this book will serve a key reference to students, technology developers, and end users all over the world.” —Dr. Mrityunjay (Jay) Singh, Chief Scientist, Ohio Aerospace Institute, NASA Glenn Research Center

*This text is dedicated to our wives
Bryony Carter and Christine Wall*

*Words still cannot explain, describe, or say enough
Thanks to you both*

About the Authors

C. Barry Carter joined the Department of Chemical, Materials, & Biomolecular Engineering at the University of Connecticut in Storrs in July 2007 and began a 5-year term as the Department Head. Before that he spent 12 years (1979–1991) on the Faculty at Cornell University in the Department of Materials Science and Engineering (MS&E) and 16 years as the 3M Heltzer Multidisciplinary Endowed Chair in the Department of Chemical Engineering and Materials Science (CEMS) at the University of Minnesota (1991–2007). He worked as a research assistant to Oxford University Professor H.M. (Tiny) Powell on inclusion compounds before going up to Cambridge in 1967. He obtained his BA (1970), MA (1974), and ScD (2001) from Cambridge University; his M.Sc. (1971) and DIC from Imperial College, London; and his D.Phil. (1976) from Oxford University. He was Sir Peter Williams’s first student at Imperial College, working with him on the intercalation of layer materials. After a postdoctoral interval in Oxford with his D.Phil. thesis advisor Sir Peter Hirsch, Barry moved to Cornell University in 1977, initially as a postdoctoral fellow, then becoming an Assistant Professor (1979), Associate Professor (1983), and Professor (1988) and directing the Electron Microscopy Facility (1987–1991). At Minnesota, he was the founding Director of the High-Resolution Microscopy Center and then the Associate Director of the Center for Interfacial Engineering; he created the Characterization Facility as a unified facility, including many forms of microscopy and diffraction in one physical location. He has held numerous visiting scientist positions: in the United States at the Sandia National Laboratories, Los Alamos National Laboratory, and Xerox PARC; in Sweden at Chalmers University (Gothenburg); in Germany at the Max Planck Institut für Metallforschung (Stuttgart), the Forschungszentrum Jülich, Hannover University, and IFW (Dresden); in France at ONERA (Chatillon); in the United Kingdom at Bristol University and Cambridge University (Peterhouse); and in Japan at the ICYS at NIMS (Tsukuba).

Dr. Carter is the co-author of two textbooks (the other is *Transmission Electron Microscopy: A Textbook for Materials Science* with David Williams) and the co-editor of six conference proceedings. He has published more than 290 refereed journal

papers and more than 400 extended abstracts/conference proceedings papers. Since 1990 he has given more than 120 invited presentations at universities, conferences, and research laboratories. Among numerous awards, he has received the Simon Guggenheim Award (1985–1986), the Berndt Matthias Scholar Award (1997–1998), and the Alexander von Humboldt Senior Award (1997). He organized the 16th International Symposium on the Reactivity of Solids (ISRS-16 in 2007). He was an Editor of the *Journal of Microscopy* (1995–1999) and of *Microscopy and Microanalysis* (2000–2004); he continues to serve on the Editorial Board of both journals. He became Editor-in-Chief of the *Journal of Materials Science* in 2004, sharing this task with Rees Rawlings until 2007; the journal's impact factor rose from 0.826 for 2003 to 2.015 for 2011.

Barry is a Fellow of the American Association for the Advancement of Science (AAAS), the Materials Research Society (MRS), the Microscopy Society of America (MSA), the American Ceramic Society (ACerS), and the Royal Microscopical Society (RMS). His research group has won the American Ceramics Society's Roland B. Snow Award six times, including the three consecutive years 2000–2002. He was the 1997 President of MSA and served on the Executive Board of the International Federation of Societies for Electron Microscopy (IFSEM) (1999–2002). He was elected General Secretary of the International Federation of Societies for Microscopy (IFSM) for the period 2003–2010 and was then elected President of IFSM for the period 2011–2014 in 2010. He was elected to the Connecticut Academy of Science and Engineering in 2010.

M. Grant Norton is Professor of Materials Science and Engineering in the School of Mechanical and Materials Engineering at Washington State University. From 2005 to 2011 he served as Associate Dean of Research and Graduate Programs in the College of Engineering and Architecture. Professor Norton obtained his Ph.D. in Materials from Imperial College, London in 1989 under the direction of Professor B.C.H. Steele and spent a 2-year postdoctoral interval at Cornell University with Professor C. Barry Carter before joining the Washington State University faculty in 1991. In 2003 and 2004 he was an Air Force Office of Scientific Research (AFOSR) Faculty Research Associate at Wright-Patterson Air Force Base in Ohio and spent the 1999–2000 academic year as a Visiting Professor in the Department of Materials at Oxford University. From 2000 to 2005 Professor Norton was Chair of Materials Science at Washington State University and from 2004 to 2007 he held the Herman and Brita Lindholm Endowed Chair in Materials Science. He is author or co-author of about 200 papers in the archival literature, several book chapters, and two textbooks. Professor Norton serves as Deputy Editor-in-Chief of the *Journal of Materials Science*, is on the Editorial Board of *Journal of Nanotechnology*, and is on the International Editorial Board of the *Journal of Materials Education*. Prior to entering academia, Norton worked for two major European multinational companies: Cookson Group PLC and Heraeus GmbH. He has consulted for a number of companies and organizations, including the United States Air Force and REC Silicon, the world's largest producer of silicon materials. In 2009, Governor Christine Gregoire appointed Professor Norton to the Board of Directors of the Washington Technology Center. In 2007, Norton co-founded GoNano Technologies, Inc., a university spin-off company focused on clean energy and life science applications of silica Nanosprings. Most recently, Dr. Norton co-founded Cataluna, Inc., which is commercializing a novel catalyst that has applications in fuel reforming and fuel-flexible fuel cells.

Preface to the First Edition

In today's materials science curriculum, there is often only time for one course on ceramic materials. Students will usually take courses on mechanical properties, thermodynamics and kinetics, and the structure of materials. Many will also have taken an introductory overview of materials science. In each of these courses, the students will have encountered ceramic materials. The present text assumes background knowledge at this introductory level but still provides a review of such critical topics as bonding, crystal structures, and lattice defects.

The text has been divided into seven parts and 37 chapters: we will explain the thinking behind these decisions. Part I examines the history and development of ceramic materials: how they have literally shaped civilization. We include this material in our introductory lectures and then make the two chapters assigned reading. Part II discusses the bonding, structure, and the relationship among phases. Students often find this part of the course to be the most difficult because structures are implicitly 3-dimensional. However, so many properties depend on the structure whether crystalline or amorphous. We have limited the number of structures to what we think the students can manage in one course, we give references to texts that the students can spend a lifetime studying and recommend our favorite software package. Part III consists of two chapters on our tools of the trade. Most ceramics are heated at some stage during processing. Unfortunately heat treatments are rarely exactly what we would like them to be; the heating rate is too slow, the furnace contaminates the sample, the environment is not what we want (or think it is), etc. Techniques for characterizing materials fill books and the students are familiar with many already from their studies on metals. So, the purpose of this chapter is, in part, to encourage the student to find out more about techniques that they might not have heard of or might not have thought of applying to ceramics; you could certainly skip Part III and make it assigned reading especially if the students are taking overlapping courses. Part IV discusses defects in ceramics and aims at providing a comprehensive overview while again not being a dedicated book on the subject. Part IV leads straight into Part V—a basic discussion of mechanical properties applied specifically to ceramics. The last two parts contain just over half the chapters. The two topics are Processing (Part VI) and Properties (Part VII) and are, of course, the reason we study ceramic materials. The warning is—these topics form the second half of the book because the student should understand the materials first, but it then becomes too easy to miss them in a one-semester course due to lack of time. We know, we have done this and the students miss the part that they would often appreciate most. Chapter 36 is probably the most fun for half the students and both the authors; Chapter 37 is the most important for all of us.

Many modern ceramists will acknowledge their debt to the late David Kingery. His pioneering 1960 text was one of the first to regard ceramics as a serious scientific subject. Both his book and his research papers have been referenced throughout the present text. Our definition of a ceramic material follows directly from Kingery's definition: a nonmetallic, inorganic solid. Nonmetallic refers to the bonding: in ceramics, it is predominantly covalent and/or ionic. Ceramics are always inorganic solids although they also may be major or minor components of composite materials.

Throughout the text we ask the question “what is special for ceramics?” The answer varies so much that it can be difficult to generalize, but that is what we are attempting where possible. Having said that, ceramics are always providing surprises. Indium tin oxide is a transparent conductor of electricity. Yttrium barium copper oxide is a superconductor at 90 K. Doped gallium nitride is revolutionizing home lighting and is becoming a critical component for all traffic lights. Neodymium-doped garnet is the basis of many solid-state lasers.

A feature of this text is that we keep in mind that many of today’s high-tech ceramic materials and processing routes have their origin in the potter’s craft or in the jeweler’s art, and materials that are new to the materials scientist may be old friends to the mineralogist and geologist. Throughout the text we will make connections to these related fields. The history of ceramics is as old as civilization, and our use of ceramics is a measure of the technological progress of a civilization.

The text covers ceramic materials from the fundamentals to industrial applications including a consideration of safety and their impact on the environment. We also include throughout the text links to economics and art. So many choices in ceramics have been determined by economics. We often think of ceramics as being inexpensive materials: bottles, bricks, and tiles certainly are. Ceramics are also the most valuable materials we have: per gram, emerald still holds the record.

No modern materials text can be complete without considering materials at the nanoscale. Nanoceramics appear throughout this text, but we decided not to create a special chapter on the topic. What we have done is to highlight some of these topics as they appear naturally in the text. It is worth noting that nanoscale ceramics have been used for centuries; it is just recently that we have had a name for them.

The figures generally contain much more information than is given in the text. We use this fact in some of the homework questions and hope that the extra detail will encourage the students to delve into the literature to learn more about the topic. One place to start this search is, of course, with the original citation if there is one. These citations are grouped together at the end of the text, in part for this purpose, but also to recognize the contributions of our colleagues.

On the website (www.ceramat.org), we are developing supplementary material including an extensive list of suggestions for filling any weak or missing areas in the student’s background and will update these suggestions periodically. We give annotated references to the original studies that have been quoted in the text. We also include further examples of images that supplement those in the text. The Web site will also house two sets of questions to complement those at the end of each chapter. One set consists of shorter questions that we use in pop quizzes but are also useful for students, especially those working alone, to assess their own progress. The second set includes questions, which we use for homework and take-home exams.

After reviewing some history, we consider bonding and structures (Chapters 3–8). Essentially, this set of chapters examines the science that underpins our definition of a ceramic material. The way atoms are connected together by covalent or ionic bonds is illustrated by considering simple and complex structures. We introduce glasses as a natural subsection of complex structures rather than as a separate branch of ceramics. Window glass is a ceramic material, just like lithium niobate, mica or silicon. The difference is that glasses are not crystalline: crystalline quartz has more in common with amorphous silica glass than it does with alumina. The final chapter in this sequence is important in most branches of materials science: which ceramics are compatible with other ceramics, which are not, and which of these materials react to form new compounds. We emphasize that these are equilibrium phase diagrams and that ceramics often need high temperatures and long times to attain equilibrium. (Geological times are needed in some cases.)

The next two topics (Chapters 9–10) examine two tools (in the broadest sense) that we will use: we need to prepare the ceramic material and this usually involves heating. Then we need to characterize it.

In Chapters 11 thru 15 we explore the whole topic of defects in ceramics, from point defects to voids, and elaborate on why they are important in the rest of the text. In Chapter 13 the combination of surfaces, nanoparticles and foams builds on the common theme of the surface as a defect but does not treat it in isolation from properties or real ceramic processing. The positioning of the next three chapters (Chapters 16–18) on mechanical properties was decided because of the authors' bias. This allows us to integrate mechanical behavior into processing, thin films, glass ceramics, and such in the immediately following chapters.

We begin the section on processing with a discussion of minerals and then consider the different forms and shapes of ceramic powders. The topic of glass is separated into Chapters 21 and 26 with the use of organic chemistry, the principles of shaping, and the processes that occur during shaping (sintering, grain growth and phase transformations) separating them. In this text we do not want to separate processing from the science; where we have separated them, this is only done to help the student absorb the concepts serially rather than in parallel! We discuss making films and growing crystals in Chapters 27–29. This group of chapters really gets to the heart of ceramic processing and mixes liquids (whether due to a solvent or to melting) in with the powders. We do not emphasize the mechanical aspects but make it clear that a full understanding requires that we think about them and not just for hot-pressing or for crystalline ceramics.

The remaining eight chapters cover the applications of ceramics with the emphasis on what property is being exploited, how we optimize it, and just how far we can still go with these materials; remember how the development of glass optical fibers has changed society forever in less than 40 years. Again our bias is clear. Ceramics are amazing materials and the underlying physics is fascinating but the subject of physics can easily obscure this excitement. Physicists are often not fully aware of the value of chemistry and all too often underestimate the *feel* a ceramist has for these materials. Before concluding the text with the most rapidly changing topic of industry and the environment in Chapter 37, we examine two groups of ceramics that affect us all even though we may not think about them—ceramics in biology/medicine and ceramics as gemstones. Whether as objects of beauty or symbols of something more lasting, polished natural single crystals of ceramics have inspired awe for centuries and challenged scientists for nearly as long.

We would like to thank our students and postdocs, past and present, who have helped us so much to appreciate and enjoy ceramic materials. The students include Katrien Ostyn, Karen Morrissey, Zvi Elgat, Bruno De Cooman, Yonn Rasmussen (formerly Simpson), David Susnitzky, Scott Summerfelt, Lisa Moore (formerly Tietz), Chris Scarfone, Ian Anderson, Mike Mallamaci, Paul Kotula, Sundar Ramamurthy, Jason Heffelfinger, Matt Johnson, Andrey Zagrebelny, Chris Blanford, Svetlana Yanina, Shelley Gilliss, Chris Perrey, Jeff Farrer, Arzu Altay, Jessica Riesterer, Jonathan Winterstein, Maxime Guinel, Dan Eakins, Joel LeBret, Aaron LaLonde, and Tyler Pounds. The postdocs include John Dodswoth, Monica Backhaus-Ricoult, Hermann Wendt, Werner Skrotski, Thomas Pfeiffer, Mike Bench, Carsten Korte, Joysurya Basu and Divakar Ramachandran and especially Ravi Ravishankar and Stuart McKernan. We thank Carolyn Swanson for carefully drawing so many diagrams for this text and Janet McKernan for her expert proofreading, continued patience, and rare common sense. Janet generated the index, negotiated hyphens, and tried to remove all our errors and typos; those that remain that should not or are missing that should be present are solely the responsibility of the authors. We thank our many colleagues for providing figures and understanding on some of the special topics. In particular, we thank Richard Hughes, Rosette Gault, Peter Ilsley, Liz Huffman, and Fred Ward.

We thank our colleagues and collaborators. David Kohlstedt who introduced CBC to ceramics. Herman Schmalzried who is not only our guru on solid-state reactions but the model of a truly wonderful Professor and mentor. Gisela Schmalzried who provided meals and company during many visits to Hannover, Gottingen and Buntentock. Paul Hlava has been our guide and guru on everything to do with gems

and minerals: he is one of the world's natural teachers. MGN thanks Brian Cantor for hosting his sabbatic at Oxford University where parts of this text were written. Likewise, CBC thanks Eva Olssen at Chalmer's University, Yoshio Bando at NIMS, and Paul Midgley, Colin Humphreys and the Master and Fellows of Peterhouse at Cambridge University.

C. Barry Carter
M. Grant Norton

Preface to the Second Edition

As nearly everything we said in the Preface to the first edition still holds, we suggest you read that first. The text is divided into seven parts. The first three parts discuss the fundamentals of ceramic materials. In the next two parts we consider defects and how they determine the mechanical behavior of ceramics. The sixth part is really critical to ceramics—how they are processed. In the final part, we relate all these earlier considerations to the properties, performance, and applications of ceramics.

Our definition of a ceramic material still follows directly from Dave Kingery's: A ceramic is a nonmetallic, inorganic solid. Nonmetallic refers to the bonding, where in ceramics it is predominantly covalent and/or ionic. The approach throughout the text is unchanged, as we repeatedly ask the question: "What is special about ceramics?" After all, those are the main messages that you should take from a textbook entitled *Ceramic Materials*.

We remind our students to think of the special cases that are not as unique as we once thought.

- ITO is a transparent conductor of electricity, but it is not the only oxide with this property.
- YBCO is a superconductor at 90 K, but other oxides are superconductors at much higher temperatures.
- GaN is in the home, your flashlight, and your traffic lights (or at least it will be when your town catches up).

As with many aspects of materials science, we always need to be willing to readjust our thinking. For example, some of yesterday's insulators are today's wide-band-gap semiconductors; and it is always important to be able to connect to the broader influences, such as the potter's craft and the jeweler's art, to understand that ceramic materials are the foundation of many businesses. Many people around the world make a living by making and using ceramics.

As you'll see, there is still no chapter devoted to "nano" ceramics. Nanoceramics have been with us for centuries. They are spread throughout the text, although sometimes they may be difficult to see. We have added a full chapter on energy production and storage and then enhanced our discussion of industry. The hope is that students will be able to read these chapters on their own and work on the questions when they have time. Most semester- or quarter-long courses will not reach Chapter 38!

Yes, we have tried to be a little provocative at times. The title to Chapter 12 asks a question. It could be rephrased as: "Are the Properties of Dislocations Unimportant?" Then you'd get a resounding "No!" but that is too obvious. We ask students to think about why we linked three topics in the title of Chapter 15. Why do we ask "Conducting Charge or Not" rather than state "Electrical Properties?" Because the latter would be wrong, of course. The titles may not be (aren't) perfect, but we hope the students will think about them before, during, and after reading the chapter.

We continue to work on the website (www.ceramicmaterials.org) to include supplementary material, and teachers should feel free to contact the authors directly (cbarrycarter@gmail.com and mgrantnorton@gmail.com). We thanked our students and postdocs, past and present, and several colleagues in the original Preface. None of

that gratitude is diminished. To this group, we would like to add (and apologize for earlier omissions) Eray Aydil, Bill Gerberich, Uwe Kortshagen, Joe Michael, Dave Williams (of course), Su Ha, Julia Nowak, Timothy Turba, Caleb Ellefson, and Jonathan Winterstein, who was an undergraduate with M.G.N. and a Ph.D. student with C.B.C. and survived! Timothy took classes with C.B.C. and then was a Ph.D. student with M.G.N.! We also thank Sanjit Bhowmick, Maria Josefina Arellano-Jimenez, and Uttara Sahaym, our recent postdocs.

We are pleased to thank our new colleagues and collaborators at the University of Connecticut (including Mark Aindow and Pamir Alpay—editors on the *Journal of Materials Science* with us) and in the EU-supported MACAN project (especially Mehmet A. Gülgün and Wayne Kaplan).

Finally, we would like to thank some of those who have helped us in so many other ways: Walter Dennis Carter and the late Mary Isabel Carter; Benjamin Carter; Emily, Robert, Oscar, and Vincent Hein; Adam and Aditya Carter; Mamta Tahiliani; Betty Gilbert and the late John Gilbert; and Ted Norton.

Foreword

Ceramics are both the oldest materials made by humans and among the most recent and most sophisticated today. Not so long ago, students used to be taught—much like the Greeks were taught that everything was made of earth, fire, and wind—that there are three types of material: metals, plastics, and ceramics. This division clearly doesn't even come close to classifying, let alone describing, the enormous variety of materials available to either the engineer or the artist today. Nor does it begin to give a feel for the untold wealth that has been generated from utilizing the properties of ceramics to create products that have enriched so many people's lives in recent years. Indeed, it is impossible to imagine anything in today's most advanced technology—including cellular networks, mobile devices, computers, airplanes, electrical systems, and cars—that doesn't depend on the properties of ceramics and the ability to manufacture them with exquisite control.

The processing of ceramic materials—by which we mean the selection of constituent powders and chemicals and their synthesis, forming, and shaping—was once a high-level craft practiced after years of apprenticeship, with practical knowledge passed down from one skilled person to the next. In many cases, the ingredients and the processing were secrets and little more than alchemy, as is wonderfully told in the delightful book, *The Arcanum*. The author, Janet Gleeson, recounts the trials and tribulations of Johann Frederick Bottger, a brilliant eighteenth-century apothecary and alchemist who worked in isolation in Meissen (under the penalty of death) to discover the secrets for making porcelain.

During the early decades of the last century, this craft began to change with the work of Norton, culminating in a series of books, most notably *Refractories* (McGraw-Hill, First Edition, 1931). Combining advances in other fields, *Refractories* brought together the central ideas of shaping, phase equilibria, sintering, and properties that are the cornerstones of much of ceramics today. That set the stage for a series of rapidly accumulating scientific breakthroughs in topics central to understanding the behavior of ceramics. The next seminal book was Kingery's *Introduction to Ceramics*, published in 1960 (Wiley), which was later expanded and extensively revised. For many years, it is probably the case that no course in ceramics at the college or university level around the world was complete unless it was based on this seminal text.

As new ceramic materials have been identified and characterized and new devices developed based on one or another of the exceptional properties of ceramics, the scientific and technical literature has exploded. This has generated new subfields of ceramics and has identified new intellectual problems, as well as producing many highly specialized texts. Concurrently, there have been staggering advances in characterization that enable us to see all the way from the atomic arrangement in crystals and their grain boundaries to the magnetic and electrical structure of ceramics and how they change with temperature or field.

How can all these advances be communicated and the knowledge passed on? In these times, when technical information, and in some cases even the detailed derivation of equations, can be readily accessed and downloaded from the World Wide Web, it is becoming apparent that there are two main types of undergraduate and introductory graduate textbook: one, a comprehensive but limited-in-scope text

using a consistent mathematical description together with full derivation of equations; and the other, a text that effectively introduces concepts and ideas. With technological advances in printing and the plummeting cost of high-quality images, these concept-based texts are becoming more affordable and suitable for publication in multiple forms.

This beautifully and profusely illustrated text, *Ceramic Materials*, belongs to the second category. It encompasses the intellectual breadth of ceramics as we know it today, introducing the field in its broadest sense to any interested student. It was thought that long gone are the days when a single book could cover the field of materials science in any detail, but this text with superbly crafted and clear illustrations does indeed cover the entire field of ceramics. Other, more specialized texts describe or reproduce the mathematical development of the phenomenon underlying the behavior and properties of ceramics. This text takes a different tack, introducing the key concepts through words, diagrams, images (black and white as well as color), and photographs. Only when it is necessary to explain an essential concept are equations presented—in many cases, just a few equations or even a single one, such as the Herring-Nabarro creep equation. Also, in contrast to the majority of texts, each of the photographs is of exceptional quality, sometimes stunning, and so there is little or no ambiguity as to what the photographs are illustrating or why they are being used. Many of the concepts in ceramic materials are, of course, common to other areas of materials science, such as crystal structures, crystal shapes, grain boundaries, defects, and diffusion, to mention a few. Thus, a substantial portion of this text can be profitable reading for students in other areas of materials science.

As in the first edition, the subject matter is grouped into seven major parts, as listed in the table of contents, but this new edition includes a chapter on the applications of ceramics in clean energy technology, including oxide fuel cells, lithium-ion batteries, ultra-capacitors, and ceramics as catalysts. It also has an expanded chapter on the role of ceramics in industry. The other notable change is that many of the diagrams and illustrations are now in color, adding vividness to the text and further emphasizing the important role they play in communicating the ideas and descriptions in the text. The only drawback of this second edition is that, like the original, it is rather heavy to carry around, so I look forward to the iPad edition!

1.8 Ceramics on the Internet	10
1.9 On Units	10
Chapter Summary	13
2 Some History	17
Chapter Preview	17
2.1 Earliest Ceramics: The Stone Age	17
2.2 Ceramics in Ancient Civilizations	19
2.3 Clay	19
2.4 Types of Pottery	21
2.5 Glazes	22
2.6 Development of a Ceramics Industry	23
2.7 Plaster and Cement	24
2.8 Brief History of Glass	25
2.9 Brief History of Refractories	27
2.10 Major Landmarks of the Twentieth Century	28
2.11 Museums	30
2.12 Societies	31
2.13 Ceramic Education	31
Chapter Summary	31

PART II MATERIALS

3	Background You Need to Know	37
	Chapter Preview	37
3.1	The Atom	37
3.2	Energy Levels	38
3.3	Electron Waves	39
3.4	Quantum Numbers	40
3.5	Assigning Quantum Numbers	41
3.6	Ions	42
3.7	Electronegativity	45
3.8	Thermodynamics: The Driving Force for Change	46
3.9	Kinetics: The Speed of Change	49
	Chapter Summary	50
4	Bonds and Energy Bands	53
	Chapter Preview	53
4.1	Types of Interatomic Bond	53
4.2	Young's Modulus	53
4.3	Ionic Bonding	55
4.4	Covalent Bonding	60
4.5	Metallic Bonding in Ceramics	65
4.6	Mixed Bonding	65
4.7	Secondary Bonding	66
4.8	Electron Energy Bands	68
	Chapter Summary	71
5	Models, Crystals, and Chemistry	73
	Chapter Preview	73
5.1	Terms and Definitions	73
5.2	Symmetry and Crystallography	75
5.3	Lattice Points, Directions and Planes	76
5.4	Importance of Crystallography	78
5.5	Pauling's Rules	78
5.6	Close-Packed Arrangements: Interstitial Sites	81
5.7	Notation for Crystal Structures	83
5.8	Structure, Composition, and Temperature	83
5.9	Crystals, Glass, Solids, and Liquid	84
5.10	Defects	85
5.11	Computer Modeling	85
	Chapter Summary	86
6	Binary Compounds	89
	Chapter Preview	89
6.1	Background	89
6.2	CsCl	90
6.3	NaCl (MgO, TiC, PbS)	90
6.4	GaAs (β -SiC)	91
6.5	AlN (BeO, ZnO)	92
6.6	CaF ₂	93
6.7	FeS ₂	94
6.8	Cu ₂ O	95
6.9	CuO	95
6.10	TiO ₂	95
6.11	Al ₂ O ₃	96
6.12	MoS ₂ and CdI ₂	97
6.13	Polymorphs, Polytypes, and Polytypoids	98
	Chapter Summary	100

7	Complex Crystal and Glass Structures	103
	Chapter Preview	103
7.1	Introduction	103
7.2	Spinel	104
7.3	Perovskite	105
7.4	The Silicates and Structures Based on SiO ₄	107
7.5	Silica	108
7.6	Olivine	108
7.7	Garnets	109
7.8	Ring Silicates	110
7.9	Micas and Other Layer Materials	111
7.10	Clay Minerals	111
7.11	Pyroxene	112
7.12	β-Aluminas and Related Materials	113
7.13	Calcium Aluminate and Related Materials	113
7.14	Mullite	114
7.15	Monazite	114
7.16	YBa ₂ Cu ₃ O ₇ and Related HTSCs	114
7.17	Si ₃ N ₄ , SiAlONs, and Related Materials	115
7.18	Fullerenes and Nanotubes	116
7.19	Zeolites and Microporous Compounds	117
7.20	Zachariasen's Rules for the Structure of Glass	118
7.21	Revisiting Glass Structures	119
	Chapter Summary	120
8	Equilibrium Phase Diagrams	123
	Chapter Preview	123
8.1	What's Special About Ceramics?	123
8.2	Determining Phase Diagrams	124
8.3	Phase Diagrams for Ceramists: The Books	126
8.4	Gibbs Phase Rule	127
8.5	One Component ($C = 1$)	128
8.6	Two Components ($C = 2$)	128
8.7	Three and More Components	130
8.8	Composition with Variable Oxygen Partial Pressure	131
8.9	Quaternary Diagrams and Temperature	134
8.10	Congruent and Incongruent Melting	135
8.11	Miscibility Gaps in Glass	136
	Chapter Summary	137
 PART III TOOLS		
9	Furnaces	143
	Chapter Preview	143
9.1	The Need for High Temperatures	143
9.2	Types of Furnace	143
9.3	Combustion Furnaces	144
9.4	Electrically Heated Furnaces	145
9.5	Batch or Continuous Operation	145
9.6	Indirect Heating	147
9.7	Heating Elements	148
9.8	Refractories	150
9.9	Furniture, Tubes, and Crucibles	151
9.10	Firing Process	151
9.11	Heat Transfer	152
9.12	Measuring Temperature	153
9.13	Safety	155
	Chapter Summary	156

10	Characterizing Structure, Defects, and Chemistry	159
	Chapter Preview	159
10.1	Characterizing Ceramics	159
10.2	Imaging Using Visible-Light, Infrared, and Ultraviolet Microscopy	160
10.3	Imaging Using X-rays and CT Scans	162
10.4	Imaging in the SEM	162
10.5	Imaging in the TEM	163
10.6	Scanning-Probe Microscopy	164
10.7	Scattering and Diffraction Techniques	166
10.8	Photon Scattering	167
10.9	Raman and IR Spectroscopy	167
10.10	NMR Spectroscopy and Spectrometry	170
10.11	Mössbauer Spectroscopy and Spectrometry	171
10.12	Diffraction in the EM	172
10.13	Ion Scattering (RBS)	173
10.14	X-ray Diffraction and Databases	174
10.15	Neutron Scattering	176
10.16	Mass Spectrometry	177
10.17	Spectrometry in the EM	177
10.18	Electron Spectroscopy	178
10.19	Neutron Activation Analysis	179
10.20	Thermal Analysis	180
	Chapter Summary	181

PART IV DEFECTS

11	Point Defects, Charge, and Diffusion	187
	Chapter Preview	187
11.1	Are Defects in Ceramics Different?	187
11.2	Types of Point Defects	188
11.3	What is Special for Ceramics?	189
11.4	What Type of Defects Form?	190
11.5	Equilibrium Defect Concentrations	190
11.6	Writing Equations for Point Defects	193
11.7	Solid Solutions	193
11.8	Association of Point Defects	196
11.9	Color Centers	197
11.10	Creation of Point Defects in Ceramics	198
11.11	Experimental Studies of Point Defects	198
11.12	Diffusion	199
11.13	Diffusion in Impure, or Doped, Ceramics	200
11.14	Movement of Defects	203
11.15	Diffusion and Ionic Conductivity	204
11.16	Computing	205
	Chapter Summary	206
12	Are Dislocations Unimportant?	209
	Chapter Preview	209
12.1	A Quick Review of Dislocations	210
12.2	Summary of Dislocation Properties	214
12.3	Observation of Dislocations	214
12.4	Dislocations in Ceramics	215
12.5	Structure of the Core	216
12.6	Detailed Geometry	218
12.7	Defects on Dislocations	220
12.8	Dislocations and Diffusion	222

12.9	Movement of Dislocations	222
12.10	Multiplication of Dislocations	223
12.11	Dislocation Interactions	225
12.12	At the Surface	225
12.13	Indentation, Scratching, and Cracks	225
12.14	Dislocations with Different Cores	226
	Chapter Summary	227
13	Surfaces, Nanoparticles, and Foams	231
	Chapter Preview	231
13.1	Background to Surfaces	231
13.2	Ceramic Surfaces	232
13.3	Surface Energy	232
13.4	Surface Structure	234
13.5	Curved Surfaces and Pressure	235
13.6	Capillarity	237
13.7	Wetting and Dewetting	238
13.8	Foams	239
13.9	Epitaxy and Film Growth	240
13.10	Film Growth in 2D: Nucleation	240
13.11	Film Growth in 2D: Mechanisms	241
13.12	Characterizing Surfaces	242
13.13	Steps	245
13.14	In Situ Condition	246
13.15	Surfaces and Nano	246
13.16	Computer Modeling	247
13.17	Introduction to Properties	249
	Chapter Summary	250
14	Interfaces in Polycrystals	253
	Chapter Preview	253
14.1	What are Grain Boundaries?	253
14.2	For Ceramics	255
14.3	GB Energy	256
14.4	Low-Angle GBs	258
14.5	High-Angle GBs	260
14.6	Twin Boundaries	262
14.7	General Boundaries	265
14.8	GB Films	265
14.9	Triple Junctions and GB Grooves	268
14.10	Characterizing GBs	269
14.11	GBs in Thin Films	271
14.12	Space Charge and Charged Boundaries	271
14.13	Modeling	272
14.14	Some Properties	272
	Chapter Summary	274
15	Phase Boundaries, Particles, and Pores	277
	Chapter Preview	277
15.1	The importance	277
15.2	Different types	278
15.3	Compare to Other Materials	278
15.4	Energy	279
15.5	The Structure of PBs	279
15.6	Particles	280
15.7	Use of Particles	281
15.8	Nucleation and growth of particles	282
15.9	Pores	284
15.10	Measuring porosity	286

15.11	Porous Ceramics	287
15.12	Glass/Crystal Phase Boundaries	288
15.13	Eutectics	289
15.14	Metal/Ceramic PBs	289
15.15	Forming PBs by Joining	290
	Chapter Summary	292

PART V MECHANICAL STRENGTH AND WEAKNESS

16	Mechanical Testing	297
	Chapter Preview	297
16.1	Philosophy	297
16.2	Types of Testing	299
16.3	Elastic Constants and Other ‘Constants’	299
16.4	Effect of Microstructure on Elastic Moduli	302
16.5	Test Temperature	302
16.6	Test Environment	303
16.7	Testing in Compression and Tension	304
16.8	Three-point and Four-point Bending	305
16.9	K_{IC} from Bend Test	306
16.10	Indentation	306
16.11	Fracture Toughness from Indentation	307
16.12	Nanoindentation	308
16.13	Ultrasonic Testing	309
16.14	Design and Statistics	309
16.15	SPT Diagrams	313
	Chapter Summary	313
17	Plasticity	317
	Chapter Preview	317
17.1	Plastic Deformation	317
17.2	Dislocation Glide	318
17.3	Slip in Alumina	319
17.4	Plastic Deformation in Single Crystals	319
17.5	Plastic Deformation in Polycrystals	322
17.6	Dislocation Velocity and Pinning	323
17.7	Creep	324
17.8	Dislocation Creep	325
17.9	Diffusion-Controlled Creep	325
17.10	Grain-Boundary Sliding	326
17.11	Tertiary Creep and Cavitation	327
17.12	Creep Deformation Maps	327
17.13	Viscous Flow	328
17.14	Superplasticity	329
	Chapter Summary	330
18	Fracturing: Brittleness	333
	Chapter Preview	333
18.1	Importance of Brittleness	333
18.2	Theoretical Strength: Orowan Equation	334
18.3	Effect of Flaws: Griffith Equation	335
18.4	Crack Tip: Inglis Equation	337
18.5	Stress Intensity Factor	337
18.6	R Curves	338
18.7	Fatigue and Stress Corrosion Cracking	339
18.8	Failure and Fractography	340
18.9	Toughening and Ceramic Matrix Composites	342

18.10	Machinable Glass-Ceramics	345
18.11	Wear	346
18.12	Grinding and polishing	347
	Chapter Summary	348

PART VI PROCESSING

19	Raw Materials	353
	Chapter Preview	353
19.1	Geology, Minerals, and Ores	353
19.2	Mineral Formation	354
19.3	Beneficiation	355
19.4	Weights and Measures	356
19.5	Silica	356
19.6	Silicates	356
19.7	Oxides	359
19.8	Nonoxides	363
	Chapter Summary	366
20	Powders, Fibers, Platelets, and Composites	369
	Chapter Preview	369
20.1	Making Powders	369
20.2	Types of powders	270
20.3	Mechanical Milling	270
20.4	Spray Drying	372
20.5	Powders by Sol-gel Processing	373
20.6	Powders by Precipitation	373
20.7	Chemical Routes to Nonoxide Powders	374
20.8	Platelets	375
20.9	Nanopowders by Vapor-Phase Reactions	375
20.10	Characterizing Powders	375
20.11	Characterizing Powders by Microscopy	376
20.12	Sieving	376
20.13	Sedimentation	377
20.14	Coulter Counter	378
20.15	Characterizing Powders by Light Scattering	378
20.16	Characterizing Powders by X-ray Diffraction	379
20.17	Measuring Surface Area (BET Method)	379
20.18	Determining Particle Composition and Purity	380
20.19	Making Fibers and Whiskers	381
20.20	Oxide and Carbide Fibers	381
20.21	Whiskers	382
20.22	Glass Fibers	382
20.23	Coating Fibers	383
20.24	Making CMCS	384
20.25	CMCs from Powders and Slurries	385
20.26	CMCs By Infiltration	385
20.27	In Situ Processes	386
	Chapter Summary	386
21	Glass and Glass-Ceramics	389
	Chapter Preview	389
21.1	Definitions	389
21.2	History	390
21.3	Viscosity, η	392
21.4	Glass: A Summary of Its Properties, or Not	394
21.5	Defects in Glass	395

21.6	Heterogeneous Glass	395
21.7	YA Glass	396
21.8	Coloring Glass	396
21.9	Glass Laser	397
21.10	Precipitates in Glass	397
21.11	Crystallizing Glass	398
21.12	Glass as Glaze and Enamel	399
21.13	Corrosion of Glass and Glaze	402
21.14	Types of Ceramic Glasses	402
21.15	Natural Glass	404
21.16	Physics of Glass	405
	Chapter Summary	406
22	Sols, Gels, and Organic Chemistry	411
	Chapter Preview	411
22.1	Sol–gel Processing	411
22.2	Structure and Synthesis of Alkoxides	412
22.3	Properties of Alkoxides	413
22.4	Sol–gel Process using Metal Alkoxides	414
22.5	Characterization of the Sol–gel Process	418
22.6	Powders, Coatings, Fibers, Crystalline, or Glass?	418
	Chapter Summary	421
23	Shaping and Forming	423
	Chapter Preview	423
23.1	The Words	423
23.2	Binders and Plasticizers	424
23.3	Slip and Slurry	424
23.4	Dry Pressing	425
23.5	Hot Pressing	425
23.6	Cold Isostatic Pressing	426
23.7	Hot Isostatic Pressing	427
23.8	Slip Casting	428
23.9	Extrusion	429
23.10	Injection Molding	430
23.11	Rapid Prototyping	431
23.12	Green Machining	431
23.13	Binder Burnout	432
23.14	Final Machining	432
23.15	Making Porous Ceramics	433
23.16	Shaping Pottery	433
23.17	Shaping Glass	434
	Chapter Summary	435
24	Sintering and Grain Growth	439
	Chapter Preview	439
24.1	Sintering Process	439
24.2	Terminology of Sintering	440
24.3	Capillary Forces and Surface Forces	441
24.4	Sintering Spheres and Wires	441
24.5	Grain Growth	443
24.6	Sintering and Diffusion	443
24.7	Liquid-Phase Sintering	445
24.8	Hot Pressing	446
24.9	Pinning Grain Boundaries	446
24.10	Grain Growth	447
24.11	Grain Boundaries, Surfaces, and Sintering	449
24.12	Exaggerated Grain Growth	449

24.13	Fabricating Complex Shapes	450
24.14	Pottery	451
24.15	Pores and Porous Ceramics	451
24.16	Sintering with Two and Three Phases	452
24.17	Examples of Sintering in Action	453
24.18	Computer Modeling	453
	Chapter Summary	454
25	Solid-State Phase Transformations and Reactions	457
	Chapter Preview	457
25.1	Transformations and Reactions: The Link	457
25.2	Terminology	458
25.3	Technology	458
25.4	Phase Transformations Without Changing Chemistry	460
25.5	Phase Transformations Changing Chemistry	461
25.6	Methods for Studying Kinetics	462
25.7	Diffusion Through a Layer: Slip Casting	463
25.8	Diffusion Through a Layer: Solid-State Reactions	464
25.9	Spinel-Forming Reaction	464
25.10	Inert Markers and Reaction Barriers	465
25.11	Simplified Darken Equation	466
25.12	Incubation Period	466
25.13	Particle Growth and the Effect of Misfit	467
25.14	Thin-Film Reactions	468
25.15	Reactions in an Electric Field	470
25.16	Phase Transformations Involving Glass	471
25.17	Pottery	472
25.18	Cement	472
25.19	Reactions Involving a Gas Phase	473
25.20	Curved Interfaces	474
	Chapter Summary	474
26	Processing Glass and Glass-Ceramics	477
	Chapter Preview	477
26.1	Market for Glass and Glass Products	477
26.2	Processing Bulk Glasses	477
26.3	Bubbles	480
26.4	Flat Glass	482
26.5	Float-Glass	483
26.6	Glass Blowing	484
26.7	Coating Glass	485
26.8	Safety Glass	486
26.9	Foam Glass	487
26.10	Sealing Glass	487
26.11	Enamel	487
26.12	Photochromic Glass	488
26.13	Ceramming: Changing Glass to Glass-Ceramics	488
26.14	Glass for Art and Sculpture	490
26.15	Glass for Science and Engineering	492
	Chapter Summary	493
27	Coatings and Thick Films	495
	Chapter Preview	495
27.1	Defining Thick Film	495
27.2	Tape Casting	495
27.3	Dip Coating	497
27.4	Spin Coating	498
27.5	Spraying	498

27.6	Electrophoretic Deposition	500
27.7	Thick Film Circuits	502
	Chapter Summary	506
28	Thin Films and Vapor Deposition	509
	Chapter Preview	509
28.1	Difference Between Thin Films and Thick Films	509
28.2	Acronyms, Adjectives, and Hyphens	509
28.3	Requirements for Thin Ceramic Films	510
28.4	Chemical Vapor Deposition	510
28.5	Thermodynamics of CVD	512
28.6	CVD of Ceramic Films for Semiconductor Devices	513
28.7	Types of CVD	514
28.8	CVD Safety	515
28.9	Evaporation	515
28.10	Sputtering	516
28.11	Molecular-Beam Epitaxy	517
28.12	Pulsed-Laser Deposition	518
28.13	Ion-Beam-Assisted Deposition	519
28.14	Substrates	519
	Chapter Summary	520
29	Growing Single Crystals	523
	Chapter Preview	523
29.1	Why Single Crystals?	523
29.2	Brief History of Growing Ceramic Single Crystals	523
29.3	Methods for Growing Single Crystals of Ceramics	524
29.4	Melt Technique: Verneuil (Flame-Fusion)	525
29.5	Melt Technique: Arc-Image Growth	527
29.6	Melt Technique: Czochralski	527
29.7	Melt Technique: Skull Melting	530
29.8	Melt Technique: Bridgman-Stockbarger	531
29.9	Melt Technique: HEM	532
29.10	Applying Phase Diagrams to Single-Crystal Growth	532
29.11	Solution Technique: Hydrothermal	533
29.12	Solution Technique: Hydrothermal Growth at Low Temperature	535
29.13	Solution Technique: Flux Growth	535
29.14	Solution Technique: Growing Diamonds	537
29.15	Vapor Technique: VLS	537
29.16	Vapor Technique: Sublimation	538
29.17	Preparing Substrates for Thin-Film Applications	538
29.18	Growing Nanowires and Nanotubes by VLS and Not	538
	Chapter Summary	539

PART VII PROPERTIES AND APPLICATIONS

30	Conducting Charge or Not	545
	Chapter Preview	545
30.1	Ceramics as Electrical Conductors	545
30.2	Conduction Mechanisms in Ceramics	547
30.3	Number of Conduction Electrons	548
30.4	Electron Mobility	549
30.5	Effect of Temperature	549
30.6	Ceramics with Metal-Like Conductivity	550
30.7	Applications for High- σ Ceramics	551
30.8	Semiconducting Ceramics	553
30.9	Examples of Extrinsic Semiconductors	554

30.10	Varistors	556
30.11	Thermistors	557
30.12	Wide-Band-Gap Semiconductors	558
30.13	Ion Conduction	558
30.14	Fast Ion Conductors	559
30.15	Batteries	559
30.16	Fuel Cells	560
30.17	Ceramic Insulators	562
30.18	Substrates and Packages for Integrated Circuits	564
30.19	Insulating Layers in Integrated Circuits	565
30.20	Superconductivity	566
30.21	Ceramic Superconductors	567
	Chapter Summary	569
31	Locally Redistributing Charge	573
	Chapter Preview	573
31.1	Background on Dielectrics	573
31.2	Ferroelectricity	578
31.3	BaTiO ₃ : The Prototypical Ferroelectric	579
31.4	Solid Solutions with BaTiO ₃	582
31.5	Other Ferroelectric Ceramics	582
31.6	Relaxor Dielectrics	583
31.7	Ceramic Capacitors	583
31.8	Ceramic Ferroelectrics for Memory Applications	586
31.9	Piezoelectricity	586
31.10	Lead Zirconate-Lead Titanate Solid Solutions	588

Part I

History and Introduction

Introduction

CHAPTER PREVIEW

In materials science we often divide materials into distinct classes. The primary classes of solid materials are ceramics, metals, and polymers. This classification is based on the types of atoms involved and the bonding between them. The other widely recognized classes are semiconductors and composites. Composites are combinations of more than one material and often involve ceramics, such as fiberglass. Semiconductors are materials with electrical conductivities that are very sensitive to minute amounts of impurities. As we'll see later, most materials that are semiconductors are actually ceramics. An example is gallium nitride, the blue-green laser diode material.

In this chapter we define what we mean by a “ceramic.” We also describe some of the general properties of ceramics. The difficulty when drawing generalizations, particularly in this case, is that it is always possible to find an exception to the rule. It is because of the wide range of properties exhibited by ceramics that they find application in such a variety of areas. A general theme throughout this textbook is the importance of the interrelationship between the way in which a ceramic is processed, its microstructure, and its properties. We give some examples of these interrelationships in this chapter to illustrate their importance.

1.1 DEFINITIONS

If you look in any introductory materials science book you find that one of the first sections describes the classification scheme. In classical materials science, materials are grouped into five categories:

1. Metals
2. Polymers
3. Ceramics
4. Semiconductors
5. Composites

The first three are based primarily on the nature of the interatomic bonding, the fourth on the materials conductivity, and the last on the materials structure—not a very consistent start.

Metals, both pure and alloyed, consist of atoms held together by delocalized electrons that overcome the mutual repulsion between the ion cores. Many main-group elements and all of the transition and inner transition elements are metals. They also include alloys—combinations of metallic elements or metallic and nonmetallic elements (such as those in steel, which is an alloy of primarily Fe and C). Some commercial steels, such as many tool steels, contain ceramics. These are the carbides (e.g., Fe_3C and W_6C) that produce hardening and enhance wear resistance, but they also make it more brittle. The delocalized electrons

give metals many of their characteristic properties (e.g., good thermal and electrical conductivity). It is because of their bonding that many metals have close packed structures and deform plastically at room temperature.

Polymers are macromolecules formed by covalent bonding of many simpler molecular units called mers. Most polymers are organic compounds based on carbon, hydrogen, and other nonmetals such as sulfur and chlorine. The bonding between the molecular chains determines many of their properties. Cross linking of the chains is key to the vulcanization process that turned rubber from an interesting but not very useful material into, for example, tires that made traveling by bicycle much more comfortable and were important in the production of the automobile. The terms “polymer” and “plastic” are often used interchangeably. However, many of the plastics that we are familiar with are actually combinations of polymers and often include fillers and other additives to give the desired properties and appearance.

Ceramics are usually associated with “mixed” bonding—a combination of covalent, ionic, and sometimes metallic. They consist of arrays of interconnected atoms; there are no discrete molecules. This characteristic distinguishes ceramics from molecular solids such as iodine crystals (composed of discrete I_2 molecules) and paraffin wax (composed of long-chain alkane molecules). It also excludes ice, which is composed of discrete H_2O molecules and often behaves just like many ceramics. The majority of ceramics are compounds of metals or

metalloids and nonmetals. Most frequently they are oxides, nitrides, and carbides. However, we also classify diamond and graphite as ceramics. These forms of carbon are inorganic in the most basic meaning of the term: they were not prepared from a living organism. Richerson (2000) says “most solid materials that aren’t metal, plastic, or derived from plants or animals are ceramics.”

Semiconductors comprise the only class of material based on a property. They are usually defined as having electrical conductivity between that of a good conductor and an insulator. The conductivity is strongly dependent upon the presence of small amounts of impurities—the key to making integrated circuits. Semiconductors with wide band gaps (greater than about 3 eV), such as silicon carbide and boron nitride, are becoming of increasing importance for high-temperature electronics; for example, SiC diodes are of interest for sensors in fuel cells. In the early days of semiconductor technology, such materials would have been regarded as insulators. Gallium nitride (GaN), a blue-green light-emitting diode (LED) material is another ceramic that has a wide band gap. Annual sales of GaN-based LEDs exceed \$7.5 billion, which is greater than the total sales of gallium arsenide (GaAs) devices.

Composites are combinations of more than one material or phase. Ceramics are used in many composites, often as the reinforcement. For example, one of the reasons a B-2 stealth bomber is stealthy is that it contains over 22 t of carbon/epoxy composite. In some composites the ceramic is acting as the matrix (ceramic matrix composites, or CMCs). An early example of a CMC—dating back over 9,000 years—is brick. These often consisted of a fired clay body reinforced with straw. Clay is an important ceramic and is the backbone of the traditional ceramic industry. In concrete, both the matrix (cement) and the reinforcement (aggregate) are ceramics.

The most widely accepted definition of a ceramic is given by Kingery (1976): *a ceramic is a nonmetallic, inorganic solid*. Thus, all inorganic semiconductors are ceramics. By definition, a material ceases to be a ceramic when it is melted. At the opposite extreme, if we cool some ceramics enough they become superconductors. All of the so-called high-temperature superconductors (HTSCs) (those that lose all electrical resistance at liquid-nitrogen temperatures) are ceramics. Trickier is glass, such as is used in windows and optical fibers. Glass fulfills the standard definition of a solid: it has its own fixed shape but is usually a supercooled liquid. This property becomes evident at high temperatures, when it undergoes viscous deformation. Glasses are clearly special ceramics. We may crystallize certain glasses to make glass-ceramics such as those found in Corningware[®]. This process is referred to as “ceramming” the glass (i.e., making it into a ceramic). We stand by Kingery’s definition and have to live with some confusion. We thus define ceramics in terms of what they are not.

It is also not possible to define ceramics, or indeed any class of material, in terms of specific properties.

- We can’t say “ceramics are brittle” because some can be superplastically deformed and some metals can be more brittle: a rubber hose or banana at 77 K shatters under a hammer.
- We can’t say “ceramics are insulators” unless we put a value on the band gap (E_g) where a material is not a semiconductor.
- We can’t say “ceramics are poor conductors of heat” because diamond has the highest thermal conductivity of any known material.

Before we leave this section, let’s consider a little history. The word ceramic is derived from the Greek *keramos*, which means “potter’s clay” or “pottery.” Its origin is a Sanskrit term meaning “to burn.” The early Greeks used the word *keramos* when describing products obtained by heating clay-containing materials. The term has long included all products made from fired clay, including:

- Bricks
- Fireclay refractories
- Sanitary-ware
- Tableware

Silica refractories were first made in 1822. Although they contained no clay, the traditional ceramic process of shaping, drying, and firing was used to make them. Therefore, the term “ceramic,” although retaining its original sense of a product made from clay, began to include other products made by the same manufacturing process. The field of ceramics (broader than the materials themselves) can be defined as the art and science of making and using solid articles that contain as their essential component a ceramic. This definition covers the purification of raw materials, the study and production of the chemical compounds concerned, their formation into components, and the study of structure, composition, and properties.

1.2 GENERAL PROPERTIES

Ceramics generally have specific properties associated with them, although as we just noted this can be a misleading approach to defining a class of material. However, we look at some properties and see how closely they match our expectations of what constitutes a ceramic.

Brittleness. This property is recognized from personal experience, such as dropping a glass beaker or a dinner plate. The reason that the majority of ceramics are brittle is the mixed ionic-covalent bonding that holds the constituent atoms together. At high temperatures (above the glass transition temperature), glass no longer behaves in a brittle manner; it behaves as a viscous liquid. That is why it is easy to form glass into intricate shapes. What we can say, then, is that most ceramics are brittle at room temperature but not necessarily at elevated temperatures.

Poor electrical and thermal conduction. The valence electrons are tied up in bonds and are not free as they are in metals. In metals, it is the free electrons—the electron gas—that determines many of their electrical and thermal properties. Diamond, which we classified as a ceramic in Section 1.1, has the highest thermal conductivity of any known material. The conduction mechanism is due to phonons, not electrons, as we describe in Chapter 34.

Ceramics can also have high electrical conductivity:

The oxide ceramic ReO_3 has an electrical conductivity at room temperature similar to that of Cu.

The mixed oxide $\text{YBa}_2\text{Cu}_3\text{O}_7$ is an HTSC; it has zero resistivity below 92 K.

These are two examples that contradict conventional wisdom when it comes to ceramics.

Compressive strength. Ceramics are stronger in compression than in tension, whereas metals have comparable tensile and compressive strengths. This difference is important when we use ceramic components for load-bearing applications. It is necessary to consider the stress distributions in the ceramic to ensure that they are compressive. An important example is in the design of concrete bridges, where the concrete, a CMC, must be kept in compression. Ceramics generally have a low degree of toughness, although combining them in composites can dramatically improve this property.

Chemical insensitivity. A large number of ceramics are stable in both harsh chemical and thermal environments. Pyrex glass is used widely in chemistry laboratories specifically because it is resistant to many corrosive chemicals, stable at high temperatures (it doesn't soften until 1,100 K), and resistant to thermal shock because of its low coefficient of thermal expansion ($33 \times 10^{-7} \text{ K}^{-1}$). It is also widely used in bakeware.

Transparent. Many ceramics are transparent because they have a large E_g . Examples include sapphire watch covers, precious stones, and optical fibers. Glass optical fibers have percent transmission $> 96\%/km$. Metals are transparent to visible light only when they are very thin, typically $< 0.1 \mu\text{m}$.

Although it is always possible to find at least one ceramic that shows atypical behavior, the properties we have mentioned here are in many cases different from those exhibited by metals and polymers.

1.3 TYPES OF CERAMIC AND THEIR APPLICATIONS

Using the definition given in Section 1.1, you can see that a large number of materials are ceramics. The applications for these materials are diverse, from bricks and tiles to electronic and magnetic components. These applications use the wide

range of properties exhibited by ceramics. Some of these properties are listed in Table 1.1 together with examples of specific ceramics and applications. Each of these areas is covered in more detail later. The functions of ceramic products are dependent on their chemical composition and microstructure, which determines their properties. The interrelationship between structure and properties is a key element of materials science and engineering.

You may find that, in addition to dividing ceramics according to their properties and applications, it is common to classify them as *traditional* or *advanced*.

- Traditional ceramics include high-volume items such as bricks and tiles, toilet bowls (whitewares), and pottery.
- Advanced ceramics are newer materials, such as laser host materials, piezoelectric ceramics, and ceramics for dynamic random access memories (DRAMs), among others, which are often produced in small quantities at higher prices.

There are other characteristics that separate these categories.

Traditional ceramics are usually based on clay and silica. There is sometimes a tendency to equate traditional ceramics with low technology, although advanced manufacturing techniques are often used. Competition among producers has caused processing to become more efficient and cost-effective. Complex tooling and machinery is often used and may be coupled with computer-assisted process control.

Advanced ceramics are also referred to as “special,” “technical,” or “engineering” ceramics. They exhibit superior mechanical properties, corrosion/oxidation resistance, or electrical, optical and/or magnetic properties. Whereas traditional clay-based ceramics have been used for over 25,000 years, advanced ceramics have generally been developed only within the last 100 years.

Figure 1.1 compares traditional and advanced ceramics in terms of the type of raw materials used, the forming and shaping processes, and the methods used for characterization.

1.4 MARKET

Ceramics is a multibillion-dollar industry. Worldwide sales are about \$100 billion ($\10^{11}) per year; the U.S. market alone is over \$35 billion ($\3.5×10^{10}) annually. (As with all economic data, there are variations from year to year).

The general distribution of industry sales is as follows.

55%	Glass
17%	Advanced ceramics
10%	Whiteware
9%	Porcelain enamel
7%	Refractories
2%	Structural clay

TABLE 1.1 Properties and Applications for Ceramics

<i>Property</i>	<i>Example</i>	<i>Application</i>
Electrical	Bi ₂ Ru ₂ O ₇	Conductive component in thick-film resistors
	Doped ZrO ₂	Electrolyte in solid-oxide fuel cells
	Indium tin oxide (ITO)	Transparent electrode
	SiC	Furnace elements for resistive heating
	YBaCuO ₇	Superconducting quantum interference devices (SQUIDS)
Dielectric	SnO ₂	Electrodes for electric glass melting furnaces
	α-Al ₂ O ₃	Spark plug insulator
	PbZr _{0.5} Ti _{0.5} O ₃ (PZT)	Micropumps
	SiO ₂	Furnace bricks
	(Ba,Sr)TiO ₃	Dynamic random access memories (DRAMs)
Magnetic	Lead magnesium niobate (PMN)	Chip capacitors
	γ-Fe ₂ O ₃	Recording tapes
	Mn _{0.4} Zn _{0.6} Fe ₂ O ₄	Transformer cores in touch tone telephones
	BaFe ₁₂ O ₁₉	Permanent magnets in loudspeakers
Optical	Y _{2.66} Gd _{0.34} Fe _{4.22} Al _{0.68} Mn _{0.09} O ₁₂	Radar phase shifters
	Doped SiO ₂	Optical fibers
	α-Al ₂ O ₃	Transparent envelopes in street lamps
	Doped ZrSiO ₄	Ceramic colors
	Doped (Zn,Cd)S	Fluorescent screens for electron microscopes
	Pb _{1-x} La _x (Zr _z Ti _{1-z}) _{1-x/4} O ₃ (PLZT)	Thin-film optical switches
Mechanical	Nd doped Y ₃ Al ₅ O ₁₂	Solid state lasers
	TiN	Wear-resistant coatings
	SiC	Abrasives for polishing
	Diamond	Cutting tools
	Si ₃ N ₄	Engine components
Thermal	Al ₂ O ₃	Hip implants
	SiO ₂	Space shuttle insulation tiles
	Al ₂ O ₃ and AlN	Packages for integrated circuits
	Lithium-alumino-silicate glass ceramics	Supports for telescope mirrors
	Pyrex glass	Laboratory glassware and cookware

In the United States, sales of structural clay in the form of bricks amount to \$160 million per month. Financially, however, the ceramics market is clearly dominated by glass. The major application for glass is windows. World demand for flat glass is about 40 billion square feet—worth over \$40 billion. Overall market distribution in the United States is:

32%	Flat glass
18%	Lighting
17%	Containers
17%	Fiberglass
9%	Television tubes, cathode ray tubes (CRTs)
5%	Consumer glassware
1%	Technical/laboratory
1%	Other

Advanced ceramics form the second largest sector of the industry. More than half of this sector is comprised

of electrical and electronic ceramics and ceramic packages.

36%	Capacitors/substrates/packages
23%	Other electrical/electronic ceramics
13%	Other
12%	Electrical porcelain
8%	Engineering ceramics
8%	Optical fibers

High-temperature ceramic superconductors, which would fall into the category of advanced ceramics, are not presently a major market area. They constitute less than 1% of the advanced ceramics market. Significant growth has been predicted because of their increased use in microwave filters and resonators with particular application in cell phones.

Engineering ceramics, also called structural ceramics, include wear-resistant components such as dies, nozzles,

FIGURE 1.1. Comparison of various aspects of traditional and advanced ceramics.

and bearings. Bioceramics (e.g., ceramic and glass-ceramic implants and dental crowns) account for about 20% of this market. Dental crowns are made of porcelain and over 30 million are made in the United States each year.

Whiteware sales, which include sanitary ware (e.g., toilet bowls, basins) and dinnerware (plates, cups), account for about 10% of the total market for ceramics. The largest segment of the whiteware market, accounting for about 40%, comprises floor and wall tiles. In the United States we use about 2.5 billion (2.5×10^9) square feet of ceramic tiles per year. Annual sales of sanitary ware in the United States total more than 30 million pieces.

Porcelain enamel is the ceramic coating applied to many steel appliances such as kitchen stoves, washers and dryers. Porcelain enamels have much wider applications as both interior and exterior paneling in buildings, for example in subway stations. Because of these widespread applications it is perhaps not surprising that the porcelain enameling industry accounts for more than \$3 billion per year.

More than 50% of refractories are consumed by the steel industry. The major steel-making countries are China, Japan, and the United States. Structural clay products include bricks, sewer pipes, and roofing tiles. These are high-volume, low-unit-cost items. Each year about eight billion bricks are produced in the United States with a market value of over \$1.5 billion.

1.5 CRITICAL ISSUES FOR THE FUTURE

Although glass dominates the global ceramics market, the most significant growth is in advanced ceramics. There are many key issues that need to be addressed to maintain this growth and expand the applications and uses of advanced ceramics. It is in these areas that there will be increasing employment opportunities for ceramic engineers and materials scientists.

Structural ceramics include silicon nitride (Si_3N_4), silicon carbide (SiC), zirconia (ZrO_2), boron carbide (B_4C), and alumina (Al_2O_3). They are used in applications such as cutting tools, wear components, heat exchangers, and engine parts. The relevant properties of structural ceramics are high hardness, low density, high-temperature mechanical strength, creep resistance, corrosion resistance, and chemical inertness. Three key issues must be solved to expand the use of structural ceramics.

- Reducing the cost of the final product
- Improving reliability
- Improving reproducibility

Electronic ceramics include barium titanate (BaTiO_3), zinc oxide (ZnO), lead zirconate titanate [$\text{Pb}(\text{Zr}_x\text{Ti}_{1-x})\text{O}_3$], aluminum nitride (AlN), and HTSCs. They are used in applications as diverse as capacitor dielectrics, varistors, micro-electro-mechanical systems (MEMS), substrates, and packages for integrated circuits. There are many challenges for the future.

- Integrating with existing semiconductor technology
- Improving processing
- Enhancing compatibility with other materials

Bioceramics are used in the human body. The response of these materials varies from nearly inert to bioactive to resorbable. Nearly inert bioceramics include alumina (Al_2O_3) and zirconia (ZrO_2). Bioactive ceramics include hydroxyapatite and some special glass and glass-ceramic formulations. Tricalcium phosphate, which dissolves in the body, is an example of a resorbable bioceramic. Three issues will determine future progress.

- Matching mechanical properties to human tissues
- Increasing reliability
- Improving processing methods

Coatings and films are generally used to modify the surface properties of a material (e.g., a bioactive coating deposited on the surface of a bio-inert implant). They may also be used for economic reasons: we may want to apply a coating of an expensive material on a lower cost substrate rather than make the component entirely from the more expensive material. An example is applying a diamond coating on a cutting tool. In some cases, we use films or

coatings simply because the material performs better in this form. An example is the transport properties of thin films of HTSCs, which are improved over those of the material in bulk form. Some issues need to be addressed.

- Understanding film deposition and growth
- Improving film/substrate adhesion
- Increasing reproducibility

Composites may use ceramics as the matrix phase and/or the reinforcing phase. The purpose of a composite is to display a combination of the preferred characteristics of each of the components. In CMCs, one of the principal goals has been to increase fracture toughness through reinforcement with whiskers or fibers. When ceramics comprise the reinforcement phase in, for example, metal matrix composites, the result is usually an increase in strength, enhanced creep resistance, and greater wear resistance. Three issues must be solved.

- Reducing processing costs
- Developing compatible combinations of materials (e.g., matching coefficients of thermal expansion)
- Understanding interfaces

Nanoceramics can be either well established or at an early stage in their development. For example, they are widely used in cosmetic products (e.g., sunscreens), and they are critical in many catalytic applications. Their use in fuel cells, coatings, and other devices, in contrast, is often quite new. There are three main challenges.

- Making them
- Integrating them into devices through either top-down or bottom-up approaches
- Ensuring that they do not have a negative impact on society

1.6 RELATING MICROSTRUCTURE, PROCESSING, AND APPLICATIONS

The field of materials science and engineering is often defined by the interrelationships of four topics: synthesis and processing; structure and composition; properties; and performance. To understand the behavior and properties of any material, it is essential to understand its structure. Structure can be considered on several levels, all of which influence final behavior. At the finest level is the electron configuration, which affects such properties as color, electrical conductivity, and magnetic behavior. The arrangement of electrons in an atom influences how it will bond to another atom; and this, in turn, has an impact on the crystal structure.

The arrangement of the atoms or ions in the material also needs to be considered. Crystalline ceramics have a very regular atomic arrangement, whereas in noncrystalline

or amorphous ceramics (e.g., oxide glasses) there is no long-range order. Locally, though, we may identify similar polyhedra. Such materials often behave differently relative to their crystalline counterparts. It is not only perfect lattices and ideal structures that have to be considered but also the presence of structural defects, which are unavoidable in all materials, even amorphous ones. Examples of such defects include impurity atoms and dislocations.

Polycrystalline ceramics have a structure consisting of many grains. The size, shape, and orientation of the grains play a key role in many of the macroscopic properties of these materials (e.g., their mechanical strength). In most ceramics, more than one phase is present, with each phase having its own structure, composition, and properties. Control of the type, size, distribution, and amount of these phases within the material provides a means to control its properties. The microstructure of a ceramic is often a result of the way it was processed. For example, hot-pressed ceramics often have very few pores, whereas this may not be the case in sintered materials.

The interrelationship between the structure, processing, and properties are evident throughout this text. They are illustrated here by five examples.

1. The *strength* of polycrystalline ceramics depends on the grain size through the Hall–Petch equation. Figure 1.2 shows strength as a function of grain size for MgO. As the grain size decreases, the strength increases. The grain size is determined by the size of the initial powder particles and the way in which they were consolidated. The grain boundaries in a polycrystalline ceramic are also important. The strength then depends on whether the material is pure, contains a second phase or pores, or just contains glass at the grain boundaries. The relationship is not always obvious for nanoceramics.
2. *Transparent or translucent ceramics* require that we limit the scattering of light by pores and second-phase particles. Reduction in porosity may be achieved by hot-pressing to ensure a high-density product. This approach has been used to make transparent polarized lead-lanthanum-zirconate-titanate (PLZT) ceramics for electrooptical applications, such as in flash-blindness goggles, shown in Figure 1.3, which were developed during the 1970s by Sandia National Laboratories in the United States for use by combat pilots.
3. *Thermal conductivity* of commercially available polycrystalline AlN is usually lower than that predicted by theory because of the presence of impurities (mainly oxygen), which scatter phonons. Adding rare earth or alkaline metal oxides (e.g., Y_2O_3 and CaO, respectively) can reduce the oxygen content by acting as a getter. These oxides are mixed in with the AlN powder before it is shaped. The second phase, formed between the oxide additive and the oxide coating on the AlN grains, segregates to triple points, as shown in Figure 1.4.

FIGURE 1.2. Dependence of fracture strength of MgO (at 20°C) on grain size.

FIGURE 1.3. Pilot wearing the flash-blindness goggles (in the “off” position).

4. *Soft ferrites* (e.g., $Mn_{1-\delta}Zn_{\delta}Fe_2O_4$) are used in a range of devices, such as the yoke that moves the electron beam in an “old-fashioned” television tube. The permeability of soft ferrites is a function of grain size, as shown in Figure 1.5. Large, defect-free grains are preferred because we need to have very mobile domain walls. Defects and grain boundaries pin the domain walls and make it more difficult to achieve saturation magnetization.
5. *Alumina ceramics* are used as electrical insulators because of their high electrical resistivity and low

FIGURE 1.4. Transmission electron microscopy (TEM) image of grain boundaries in AlN showing an yttria-rich second-phase particle at the triple junction. The curved bands within the larger grain are planar defects that may accommodate impurity oxygen.

FIGURE 1.5. Variation of permeability with average grain diameter of manganese-zinc ferrite with uncontrolled porosity.

dielectric constant. For most applications, pure alumina is not used. Instead, we blend the alumina with silicates to reduce the sintering temperature. These materials are known as debased aluminas and contain a glassy silicate phase between alumina grains. Debased aluminas are generally more conductive (lower resistivity) than pure aluminas, as shown in Figure 1.6. Debased aluminas (containing 95% Al_2O_3) are used in spark plugs.

FIGURE 1.6. Dependence of resistivity on temperature for various compositions of alumina.

1.7 SAFETY

When working with any material, safety considerations should be uppermost. There are several important precautions to take when working with ceramics.

Toxicity of powders containing, for example, Pb, Cd, or fluorides should be known. When shipping the material, the manufacturer supplies information on the hazards associated with their product. It is important to read this information and keep it accessible. Some standard resources that give information about the toxicity of powders and their “acceptable” exposure levels are given in the References at the end of the chapter.

Small particles should not be inhaled. The effects have been well known, documented, and then often ignored since the 1860s. Proper ventilation, improved cleanliness, and protective clothing have significantly reduced many of the industrial risks. Care should be taken when handling any powders (both toxic and nontoxic materials). The most injurious response is believed to be when the particle size is $<1\ \mu\text{m}$; larger particles either do not remain suspended in the air sufficiently long to be inhaled or, if inhaled, cannot negotiate the tortuous passage of the upper respiratory tract. The toxicity and environmental impact of nanopowders has not been clearly addressed but is the subject of various studies, such as by the Royal Society (2004), and ongoing research at universities where a particular focus is on carbon nanotubes, which are often injected into mice.

High temperatures. Much of ceramic processing involves the use of high temperatures. The effects of high

TABLE 1.2 Color Scale of Temperature

Color	Corresponding $T\ (^{\circ}\text{C})$
Barely visible red	525
Dark red	700
Cherry red, just beginning to appear	800
Clear red	900
Bright red, beginning orange	1,000
Orange	1,100
Orange-white	1,200
Dull white	1,300
Bright white	1,400

temperatures on the human body are obvious. What is not so obvious is how hot something actually is. Table 1.2 gives the color scale for temperature. From this tabulation, you can see that an alumina tube at 400°C does not show a change in color, although it still burns skin. Other safety issues involved with furnaces are addressed in Chapter 9.

Organics are used as solvents and binders during processing. Traditionally, organic materials have played little role in ceramic processing. Nowadays, however, they are widely used in many forms of processing. Again, the manufacturer provides safety data sheets on any products it ships. This information is important and should always be read carefully.

As a rule, the material safety data sheets (MSDSs) should be readily accessible for all the materials you are using. In fact, many states require that they are kept in the laboratory.

1.8 CERAMICS ON THE INTERNET

There is a great deal of information about ceramics on the Internet. Here are just some of the many useful websites.

- www.acers.org American Ceramic Society. Membership information, meetings, books.
- www.acers.org/cic/propertiesdb.asp Ceramic Knowledge Center. This database has links to many other sources of property information including the National Institute of Standards and Technology (NIST) and National Aeronautics and Space Administration (NASA) materials databases.
- www.ceramics.com Links to many technical and industrial sites.
- www.ceramicforum.com Website for the ceramics professional.
- www.ecers.org European Ceramics Society.
- www.ceramicsindustry.com Source of industry data.
- www.porcelainenamel.com/ Porcelain Enamel Institute.

1.9 ON UNITS

We have attempted to present all data using the Système International d’Unités (SI). The basic units in this system are listed in Tables 1.3, 1.4, 1.5, and 1.6 together with

TABLE 1.3 SI Base Units

<i>Base quantity</i>	<i>Name</i>	<i>Symbol</i>
Length	Meter	m
Mass	Kilogram	kg
Time	Second	s
Electric current	Ampere	A
Thermodynamic temperature	Kelvin	K
Amount of substance	Mole	mol
Luminous intensity	Candela	cd

derived quantities. The primary exceptions where non-SI units are encountered is in the expression of small distances and wavelengths, where the Å (angstrom) is used by electron microscopists and X-ray crystallographers and the eV (electron volt) as a unit of energy for band gaps and atomic binding energies. We have not used the former but do use the latter for convenience. In the ceramics industry, customary U.S. units are commonly encountered. For example, temperature is often quoted in Fahrenheit (°F) and pressure in pounds per square inch (psi). Conversions for SI units and some of the special British and U.S. units are in Table 1.7 and 1.8.

TABLE 1.4 SI Derived Units

<i>Derived quantity</i>	<i>Name</i>	<i>Symbol</i>
Area	Square meter	m ²
Volume	Cubic meter	m ³

The SI base unit of temperature is the Kelvin (K). We use both K and °C in this text. The degree Celsius is equal in magnitude to the Kelvin, which implies that the numerical value of a temperature difference or temperature interval whose value is expressed in °C is equal to the numerical value of the same temperature difference or interval when its value is expressed in K.

Several of the figures that we have used were obtained from sources where the original data were not in SI units. In many cases, we have converted the units into SI units using conversions and rounding in accordance with ASTM Standard E 380. Any variations from this procedure are noted in the appropriate place.

The decade power notation is a convenient method of representing large and small values within the SI units. Examples that you will encounter in this book include nm (10^{-9} m) and pF (10^{-12} F). The full decade power notation scheme is given in Table 1.9.

TABLE 1.9 Decade Power Notation^a

CHAPTER SUMMARY

We adopted the definition of a ceramic as *a nonmetallic, inorganic solid*. This definition encompasses a wide range of materials, many of which are described as semiconductors elsewhere. The definition of ceramics we adopted is not quite complete in that glass—which behaves like a solid at room temperature and below but has the structure of a liquid—is actually a very important ceramic. More than half the ceramic industry is devoted to producing glass. The second largest segment of the ceramics market is advanced ceramics (also called special, engineering, or technical ceramics). This area is exciting and includes many of the newer materials, such as HTSCs, bioceramics, and nanoceramics. These areas are predicted to experience significant growth.

PEOPLE AND HISTORY

In most of the chapters we include a short section relating to the history of the topic, usually one-line biographies of our heroes in the field—some of whom have defined the subject. If the section is a little short in some chapters, the names/events may be listed in another chapter. The purpose of this section is to remind you that although our subject is old it is also quite young, and many of the innovators never thought of themselves as ceramists.

EXERCISES

- Which of the following materials could be classified as a ceramic. Justify your answer. (a) Solid argon (Ar); (b) molybdenum disilicide (MoSi_2); (c) NaCl; (d) crystalline sulfur (S); (e) ice; (f) boron carbide (B_4C).
- Is silicone rubber (widely used as a caulking material in bathrooms and kitchens) a ceramic or a polymer? Explain your reasoning.
- There are several phases in the Fe-C system. One phase is the γ -Fe (austenite), which can contain up to about 8 at. % C. Another phase is cementite, which contains 25 at.% C. Is either of these two phases a ceramic? Justify your answer.
- The following definition has been proposed: “All ceramics are transparent to visible light.” Is this a good way to define a ceramic? Explain your reasoning.
- In the distribution of industry sales of advanced ceramics (Section 1.4), 13% was listed as “Other.” Suggest applications that might be included in this group.
- Ceramic tile accounts for about 15% of the floor tile market. (a) What alternatives are available? (b) What advantages/disadvantages do ceramics have over the alternatives? (c) What factors do you think influence the total amount of ceramic floor tiles used?
- Gerber, the baby food manufacturer, is replacing most of its glass baby food jars with plastic. Miller Brewing Co. now sells some of its popular beers in plastic containers. Compare glass and plastics in terms of their application for packaging food and beverages.

- 1.8 The steel industry is the major consumer of refractories. What other industries might be users of this ceramic product?
- 1.9 Pearls and garnets are both examples of gems. We classify garnet as a ceramic. Would you classify pearl as a ceramic? Briefly justify your answer.
- 1.10 Some nuclear reactors use MOX fuel. What is MOX and is it a ceramic?
- 1.11 In Section 1.2 we identified ReO_3 as a ceramic with high electrical conductivity. Where in the periodic table of elements is Re? Do you think this position is related to its electrical conductivity? Briefly explain your answer to the second part of this question.
- 1.12 Pyrex[®] glass is highly resistant to strong acids such as HCl and HNO_3 . What company makes Pyrex[®]?
- 1.13 Aluminum nitride (AlN) has high thermal conductivity. What company or companies make AlN? Are any of these companies located in the United States?
- 1.14 In the text, we use the following acronyms: ASTM, NIST, and NASA. Define each of these acronyms and briefly describe why each of these organizations might have an interest in ceramics.
- 1.15 Convert the following values into nanometers: (a) 10 pm; (b) 0.3 mm; (c) 0.01 cm; (d) 2,000 am; (e) 0.02 m; (f) 0.2 dm.
- 1.16 Small particles were reviewed in a 2004 report by the Royal Society. Briefly summarize by referring to more recent reports how our understanding of toxicity has developed.
- 1.17 You are familiar with potter's clay. Explore the web or otherwise to help you to explain what jeweler's clay is. Also, how does potter's clay differ from brickmaker's clay? What is fireclay? Are any of these materials ceramics?
- 1.18 How do the materials hydroxyapatite and tricalcium phosphate relate to diet?
- 1.19 More difficult task: Explain Table 1.2 quantitatively.
- 1.20 Use your library to access the following journals: J Eur. Ceram. Soc., J Am. Ceram. Soc., J Mater. Res., and J Mater. Sci. Which ceramic material was most reported/published in January of this year? Why do you think that happened?

REFERENCES

In the reference sections throughout the book, we list general references on the overall theme of the chapter and specific references that are the source of information referenced in the chapter. If a general reference is referred to specifically in the chapter, we generally do not repeat it.

Some History

CHAPTER PREVIEW

In this chapter we present a brief history of ceramics and glasses. Because of the length of time over which they have been important to human existence it would be possible, indeed it has been done, to fill entire volumes on this one topic. In a one-semester course we don't have the luxury of spending so much time on any one topic, but history is important. In ceramics, it helps if we understand why certain events/developments occurred, and when and how they did. We're really interested in setting the scene for many of the subsequent chapters. The earliest ceramics that were used are flint and obsidian. They exhibit conchoidal fracture like many modern-day ceramics, such as cubic zirconia and glasses. This property enabled very sharp edges to be formed, which were necessary for tools and weapons. During the latter period of the Stone Age (the Neolithic period) pottery became important. Clay is relatively abundant. When mixed with water, it can be shaped and then hardened by heating. We describe the different types of pottery and how the ceramics industry developed in Europe. The Europeans were not responsible for many of the early inventions in pottery; they were mostly trying to copy Chinese and Near East ceramics. Europe's contribution was to industrialize the process. We also describe some of the major innovations in ceramics that occurred during the twentieth century, such as the float-glass process, bioceramics, and the discovery of high-temperature superconductivity. These developments are important in defining the present status of the field and give some indications of areas where future innovations may occur. We finish the chapter by giving information about museums that have major collections of ceramic materials, and we list the relevant professional societies.

2.1 EARLIEST CERAMICS: THE STONE AGE

Certain ancient periods of history are named after the material that was predominantly utilized at that time. The Stone Age, which began about 2.5 million years ago, is the earliest of these periods. Stone, more specifically flint, clearly satisfies our definition of a ceramic, given in Chapter 1.

Flint is a variety of chert, which is itself cryptocrystalline quartz. Cryptocrystalline quartz is simply quartz (a polymorph of SiO_2) that consists of microscopic crystals. It is formed from silica that has been removed from silicate minerals by chemical weathering and carried by water as ultrafine particles in suspension. Eventually, it settles out as amorphous silica gel containing a large amount of water. Over time, the water is lost and small crystals form, even at low temperatures. During settling, the chemical conditions are changing slowly. As they change, the color, rate of deposition, and texture of the precipitate can also change. As a result, cryptocrystalline quartz occurs in many varieties, which are named based on their color, opacity,

banding, and other visible features. Flint is a black variety of chert. Jasper is a red/brown variety.

Flint is easily chipped, and the fracture of flint is conchoidal (shell-like), so that sharp edges are formed. The earliest stone tools are remarkably simple, almost unrecognizable unless they are found together in groups or with other objects. They were made by a process called percussion flaking, which results in a piece (a flake) being removed from the parent cobble (a core) by a blow from another stone (a hammer-stone) or hard object. Both the flake and the core have fresh surfaces with sharp edges and can be used for cutting. Although pebble tools have a cutting edge, they are extremely simple and unwieldy. These basic tools changed, evolved, and improved through time as early hominids began to remove more flakes from the core, completely reshaping it and creating longer, straighter cutting edges. When a core assumes a distinctive teardrop shape, it is known as a hand ax, the hallmark of *Homo erectus* and early *Homo sapiens* technology. Figure 2.1 is an example of a stone tool made by percussion flaking and then finished by pressure flaking. It was found in Washington State.

Christian Thomsen first proposed the division of the ages of prehistory into the Stone Age, Bronze Age, and Iron Age for the organization of exhibits in the National Museum of Denmark in 1836. These basic divisions are still used in Europe, the United States, and in many other

areas of the world. In 1865, English naturalist John Lubbock further divided the Stone Age. He coined the terms Paleolithic for the Old Stone Age and Neolithic for the New Stone Age. Tools of flaked flint characterize the Paleolithic period, whereas the Neolithic period is represented by polished stone tools and pottery. Because of the age and complexity of the Paleolithic further divisions were needed. In 1872, the French prehistorian Gabriel de Mortillet proposed subdividing the Paleolithic into Lower, Middle, and Upper. Since then, an even earlier subdivision of the Paleolithic has been designated with the discovery of the earliest stone artifacts in Africa. The Basal Paleolithic includes the period from around 2.5 million years ago until the appearance and spread of hand axes. These different periods are compared in Figure 2.2.

FIGURE 2.1. Stone tool made by percussion flaking and finished by pressure flaking.

Stone tools that were characteristic of a particular period are often named after archeological sites that typified a particular technological stage.

Period	Years Before Present	Stone Industry	Archaeological Sites	Hominid Species	Major Events
Neolithic	10,000	Blade tools	Lascaux Pincevent	<i>Homo sapiens sapiens</i>	Farming
Upper Paleolithic			Dolni Vestonice		Art
Middle Paleolithic			Tabun Shanidar Klasies River		<i>Homo sapiens neanderthalensis</i>
Lower Paleolithic	100,000	Mousterian flake tools	Verteszöllös Kalambo Falls	Archaic <i>Homo sapiens</i>	Burial of dead Oldest dwellings
	200,000	Clactonian chopping tools	Torraiba	<i>Homo erectus</i>	Use of fire
	500,000		Terra Amata Olgorgesailie		Spread out of Africa
	1,000,000		Zhoukoudien Trinil		Handaxes
Basal Paleolithic	2,000,000	Acheulean handaxes	Koobi Fora	<i>Homo habilis</i>	Large brains First stone tools
		Oldowan pebble tools	Olduvai Swartkrans		
	3,000,000		Hadar Laetoli	<i>Australopithecus</i>	
	6,000,000			<i>Ardipithecus</i>	Oldest hominid fossils

FIGURE 2.2. Chronology of the Stone Age.

- Oldowan pebble tools were found in the lowest and oldest levels of Olduvai Gorge.
- Acheulean hand axes are named after the Paleolithic site of St. Acheul in France, which was discovered in the nineteenth century.
- Clactonian chopping tools are named after the British site of Clacton-on-Sea, where there is also the earliest definitive evidence for wood technology in the prehistoric record—the wood was shaped using flint tools.
- Mousterian flake tools are named after a site in France. The later blade tools are flakes that are at least twice as long as they are wide.

Another important ceramic during the Stone Age was obsidian, a dark gray natural glass precipitated from volcanic lava. Like other glasses, it exhibits conchoidal fracture and was used for tools and weapons back into the Paleolithic period.

2.2 CERAMICS IN ANCIENT CIVILIZATIONS

The oldest samples of baked clay include more than 10,000 fragments of statuettes found in 1920 near Dolní Vestonice, Moravia, in the Czech Republic. They portray wolves, horses, foxes, birds, cats, bears, and women. One of the prehistoric female figures, shown in Figure 2.3, had remained almost undamaged. It was named the “Venus of Vestonice” and is believed to have been a fertility charm. The absence of facial features on this and other “Venus” figures is causing many anthropologists to rethink the role

FIGURE 2.3. A 25000-year old baked clay Pavlovian figurine called the “Venus of Vestonice,” which was found in 1920 in Dolni Vestonice in the Czech Republic.

these figures might have played in prehistoric society. The statuette stands about 10 cm tall and has been dated as far back as 23,000 BCE. One of the most recent archeological finds was made in the caves of Tuc d’Audoubert in France, where beautifully preserved clay bison have been found that are estimated to be 12,000 years old.

The earliest archeological evidence of pottery production dates back to about 10,000 BCE and the discovery of fragments from a cave dwelling near Nagasaki, Japan. This type of pottery is called Jomon pottery because of the characteristic surface patterns, which were made with a twisted cord. Jomon means “cord pattern.” The pottery featured patterns made with sticks, bones, or fingernails. These vessels, like those produced in the Near East about 10,000 years ago, were fired at a low temperature compared to modern-day pottery production.

By 6,400 BCE, pottery-making was a well-developed craft. Subsequent developments in the history of ceramics are shown in Figure 2.4. We describe some of them in more detail later in the chapter.

2.3 CLAY

Silicate minerals make up the vast majority of the earth’s crust, which is not surprising if we consider:

- The abundance of Si and O (Figure 2.5)
- The high strength of the Si–O bond (Table 2.1)

Because silicate and aluminum silicate minerals are widely available, they are inexpensive and form the backbone of the traditional high-volume products of the ceramic industry. Their abundance also explains why earthenware products are found in nearly every part of the world. The situation is very different with regard to kaolinite, the essential ingredient, along with feldspar and quartz, needed to make porcelain, by far the finest and most highly prized form of ceramic. Kaolin deposits are more localized. There are excellent deposits, for example, in southwest England. In the United States, most kaolin comes from the Southeast, between central Georgia and the Savannah River area of South Carolina.

Clay minerals remain the most widely used raw materials for producing traditional ceramic products. The total U.S. production of clays is about 40 million tons per year, valued at \$1.5 billion.

The clay minerals are layered or sheet silicates with a grain size $<2 \mu\text{m}$. Chemically, they are aluminosilicates. In nature, mica (shown in Figure 2.6) is constructed by stacking layers together to form sheets. Kaolinite has a related structure but tends to have smaller “grains.” Rocks that contain large amount of kaolinite are known as kaolin. When the sheets are separated by films of water, the platelets slide over one another to give plasticity to the mixture. This plasticity is the basis for the use of clay for pottery. Moreover, when the clay–water mixture dries, it

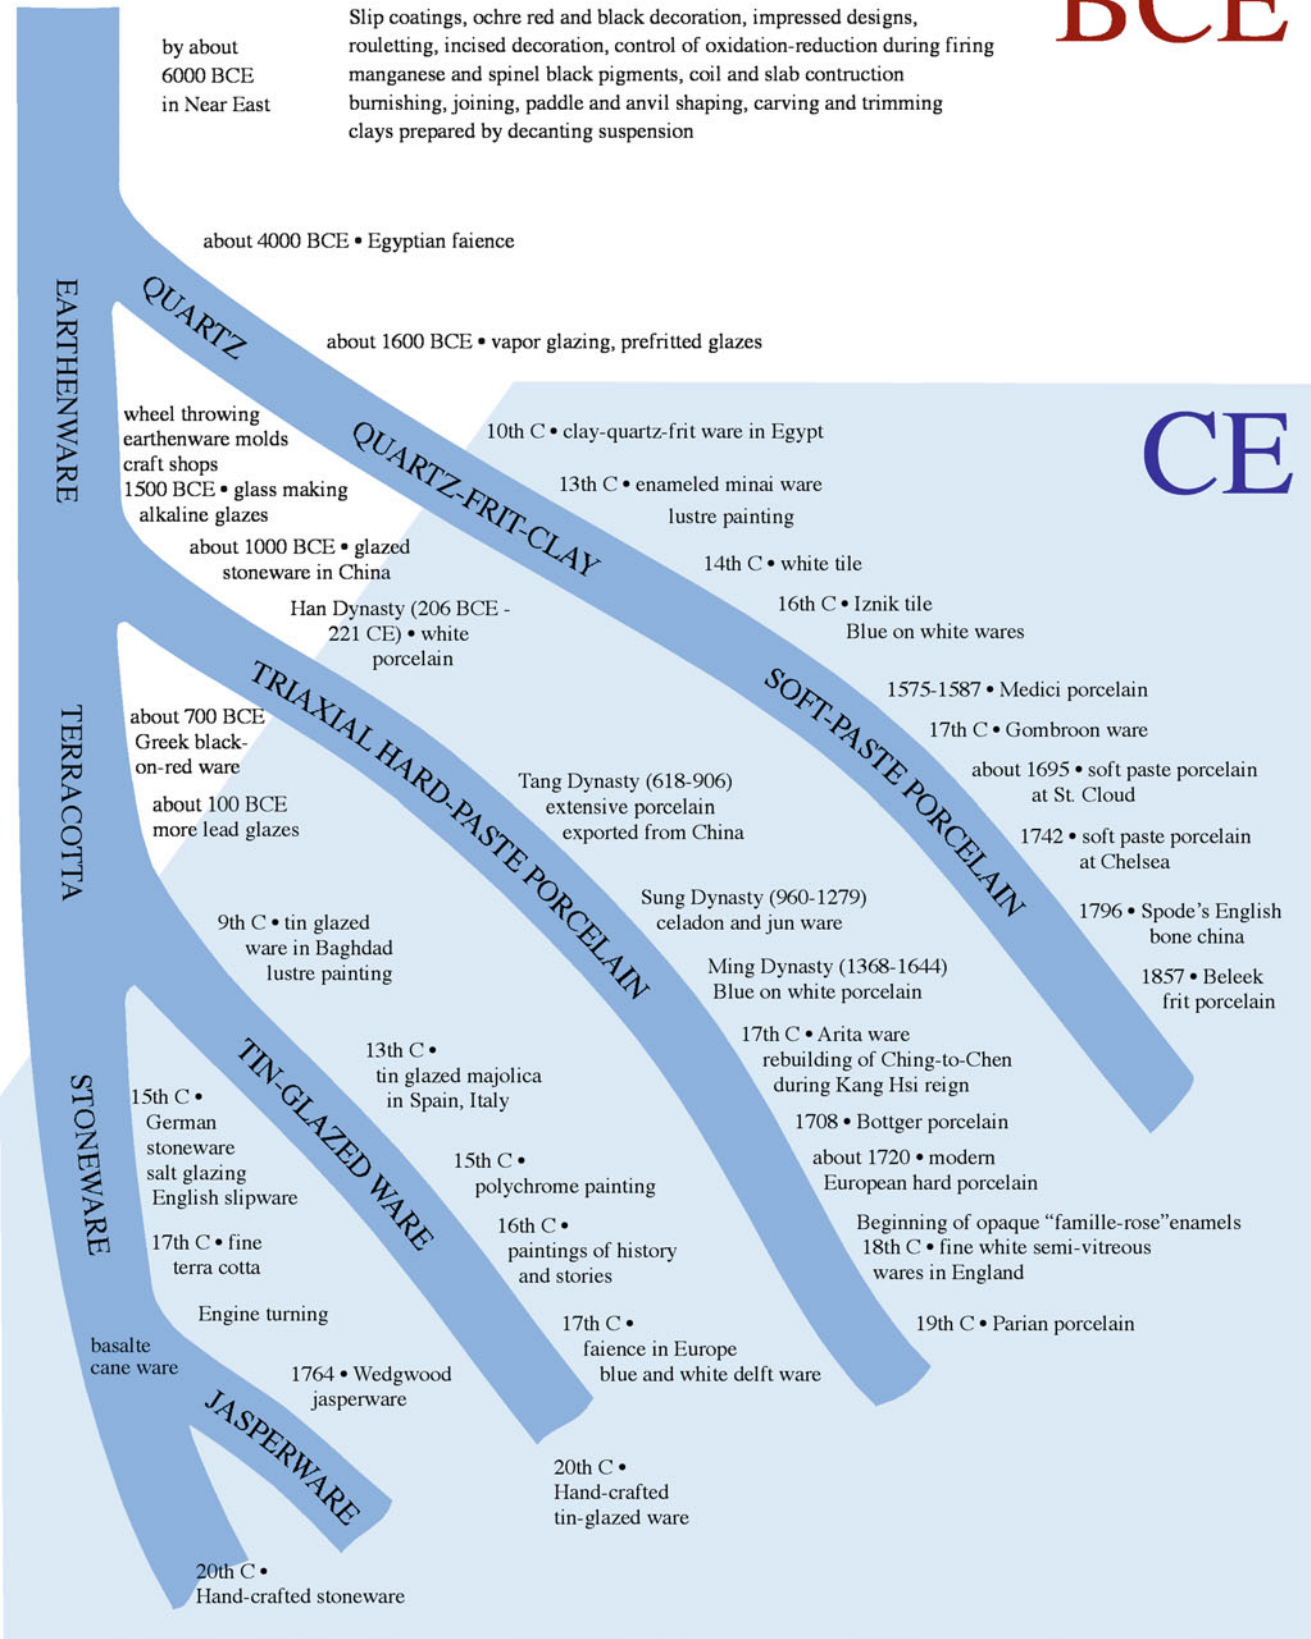

FIGURE 2.4. The “flow” of ceramic history illustrates the mainstreams of earthenware, terra cotta, and stoneware; of “triaxial” hard-paste porcelain; of quartz-based bodies; and of tin-glazed ware. Some important shaping and decorative techniques are illustrated, but the diagram is far from complete.

2.4 TYPES OF POTTERY

Pottery is broadly divided into

- Vitrified ware
- Nonvitrified ware

The classification depends upon whether the clay was melted during the firing process into a glassy (vitreous) substance. Within these divisions we have:

- *Earthenware*. Made from red “earthenware clay” and fired at fairly low temperatures, typically between 950°C and 1,050°C. It is porous when not glazed, relatively coarse, and red or buff-colored, even black, after firing. The term “pottery” is often used to signify earthenware. The major earthenware products are bricks, tiles, and terra cotta vessels. Earthenware dating back to between 7,000 and 8,000 BCE has been found, for example, in Catal Hüyük in Anatolia (today’s Turkey).
- *Stoneware*. Similar to earthenware but fired to a higher temperature (around 1,200–1,300°C). It is vitrified, or at least partially vitrified, and so it is nonporous and stronger. Traditional stoneware was gray or buff-colored, although the color can vary, ranging from black—through red, brown, and gray—to white. Fine white stoneware was made in China as early as 1,400 BCE (Shang Dynasty). Johann Friedrich Böttger and E.W. von Tschirnhaus produced the first European stoneware in Germany in 1707. It was red. Later Josiah Wedgwood, an Englishman, produced black stoneware called basalte and white stoneware colored by metal oxides, called jasper.
- *Porcelain*. Invented by the Chinese and produced during the T’ang Dynasty (618–907 CE). It is a white, thin, and translucent ceramic that possesses a metal-like ringing sound when tapped. Porcelain is made from kaolin (also known as china clay), quartz, and feldspar. Fired at 1,250–1,300°C, it is an example of vitreous ware. The microstructure of porcelain is quite complicated. Figure 2.7 shows a backscattered electron image, obtained using a scanning electron microscope (SEM), of the microstructure of a “Masters of Tabriz” tile (1436 CE). It shows that it contains many large grains of quartz immersed in a continuous glass phase.
- *Soft-paste porcelain*. Porcelain with low clay content that results in a low alumina (Al_2O_3) content. The most common form of soft-paste porcelain is formed of a paste of white clay and ground glass. This formulation allows a lower firing temperature but provides a less plastic body. Not being very tough, it is easily scratched and more rare than hard-paste porcelain.
- *Hard-paste porcelain*. Porcelain with a relatively high alumina content derived from clay and feldspar, which permits good plasticity and formability but requires a

becomes hard and brittle and retains its shape. On firing at temperatures about 950°C, the clay body becomes dense and strong. We describe the structures of some of the important clay minerals, including kaolin, in Chapter 7.

high firing temperature (1,300–1,400°C). Böttger produced the first successful European hard-paste porcelain in 1707–1708 consisting of a mixture of clay and gypsum. This work laid the foundation for the Meissen porcelain manufacture in Saxony (Germany) in 1710.

- *Bone china*. This has a recipe similar to that for hard-paste porcelain but with an addition of 50% animal bone ash (calcium phosphate). This formulation improves strength, translucency, and whiteness of the product and was perfected by Josiah Spode at the end of the eighteenth century. It was then known as “English China” or “Spode China.”

2.5 GLAZES

To hermetically seal the pores of goods made of earthenware, an additional processing step called glazing was introduced around or probably even before 3,000 BCE by the Egyptians. It involved coating the fired objects with an aqueous suspension consisting of finely ground quartz sand mixed with sodium salts (carbonate, bicarbonate, sulfate, chloride) or plant ash. The ware was then refired, usually at a lower temperature, during which the particles would fuse into a glassy layer.

Two other types of glaze, which also date back several millennia, have been applied to earthenware. They are the transparent lead glaze and the opaque white tin glaze.

FIGURE 2.7. Microstructure of a “Masters of Tabriz” tile showing many large grains of crystalline SiO_2 .

2.5.1 Lead Glaze

The addition of lead reduces the melting or fusion point of the glaze mixture, which allows the second firing to be at an even lower temperature. The first lead-rich glazes were probably introduced during the Warring States period (475–221 BCE). The lead oxide (PbO) content was about 20%. During the Han Dynasty (206 BCE to CE 200), higher lead oxide contents were typical, up to 50–60%. Lead glazing was subsequently widely used by many civilizations. However, lead from the glaze on tableware may be leached by food. Table 2.2 shows lead released from two glazes that were made to match those of two Eastern Han Dynasty lead glazes. The glaze formulations were remade and fired by CERAM (formerly the British Ceramic Research Association) in the United Kingdom. The amount of lead released in a standard leach test is determined by filling the glazed ceramic item with 4% acetic acid at 20°C for 24 h. The acid is then analyzed for Pb by flame atomic absorption spectrometry. The present U.S. Food and Drug Administration limit for Pb release from small hollowware is 2 ppm.

Some historians believe that lead release from glazes on pitchers and other food and beverage containers and utensils poisoned a large number of Roman nobility and thus contributed (together with lead from water pipes) to the fall of the Roman Empire (see, e.g., Lindsay 1968). Lead poisoning was responsible for high mortality rates in the pottery industry even during the nineteenth century. Many countries have now outlawed lead glazing unless fritted (pre-melted and powdered) glazes are utilized that prevent the lead from being easily leached. The possibility of leaching a heavy metal from a glass is a concern today in the nuclear-waste storage industry.

2.5.2 Tin Glaze

The Assyrians, who lived in Mesopotamia (today’s Northern Iraq), probably discovered tin glazing during the second millennium BCE. It was utilized for decorating bricks but eventually fell into disuse. It was reinvented again in the ninth century CE and spread into Europe via the Spanish island of Majorca, after which it was later named (*Majolica*). Centers of majolica manufacture developed in Faenza in Italy (*Faience*) and in 1584 at the famous production center at Delft in The Netherlands (*Delftware*). Tin glazing became of industrial importance at the end of the nineteenth century with the growth of the ceramic sanitary ware industry.

TABLE 2.2 Composition of Han Lead Glazes (wt%) and Lead Metal Release (ppm)

	PbO	SiO_2	Al_2O_3	Fe_2O_3	TiO_2	CaO	MgO	K_2O	Na_2O	BaO	CuO	SnO_2	Cl	S	Pb release

2.6 DEVELOPMENT OF A CERAMICS INDUSTRY

Quantity production of ceramics began during the fourth millennium BCE in the Near East. Transition to a large-scale manufacturing industry occurred in Europe during the eighteenth century. At the beginning of the century, potteries were craft institutions. But this situation was transformed at several important sites:

- Vincennes and Sèvres in France
- Meissen in Germany
- Staffordshire in England

By the end of the eighteenth century, the impact of greater scientific understanding (e.g., chemical analysis of raw materials) had changed the field of ceramics. At the same time, the ceramic industry played an influential role in the industrial revolution and the development of factory systems in England and across Europe. Ceramics became an important and growing export industry that attracted entrepreneurs and engineers to develop modern production and marketing methods. A leader in this revolution was Josiah Wedgwood.

In 1767 Wedgwood produced improved unglazed black stoneware, which he called “basalte.” The famous Wedgwood “jasperware” began production in 1775 and consisted of the following.

- One part flint
- Six parts barium sulfate
- Three parts potters’ clay
- One-quarter part gypsum

Wedgwood was so excited by this new ceramic body that he wrote to his partner: “The only difficulty I have is the mode of procuring and conveying incog (*sic*) the raw material . . . I must have some before I proceed, and I dare not have it in the nearest way nor undisguised.”

Jasper is white, but Wedgwood found that it could be colored an attractive blue by the addition of cobalt oxide. (The mechanism for color formation in transition metal oxides is described in Chapter 32.) The manufacturing process was soon changed (in part because of a sharp increase in the cost of the blue pigment), and the white jasper was coated with a layer of the colored jasper. Wedgwood jasper remains sought after and highly collectable.

Wedgwood also was instrumental in changing the way manufacturing was done. He divided the process into many separate parts and allowed each worker to become expert in only one phase of production. This approach was revolutionary at the time and was designed to increase the performance of each worker in a particular area and reduce the requirement for overall skill. He was also concerned with trade secrets; each workshop at his factory had a

separate entrance so workers would not be exposed to more than a limited number of valuable secrets.

In the increasingly competitive entrepreneurial economy of the eighteenth century, Wedgwood was one of the leading figures to have the foresight and the willingness to expend the necessary effort to promote the general interests of the ceramics industry. In the early days of the pottery industry in England, transport of raw materials in and product out was done with pack animals. It was clear that quantity production could not be achieved without better transportation. Wedgwood organized a potters’ association to lobby for better roads and, more importantly, a canal system. The opening of the Trent-Mersey Canal in 1760 ensured that Staffordshire would remain the center of English pottery production.

As with many industries, the first stage of the Industrial Revolution did not result in deterioration of working conditions. A partly rural craft-based skill such as pottery-making became an injurious occupation only as industrialization progressed, bringing poor workers from the countryside into overcrowded town centers. Occupational diseases were prevalent in the potteries. The main problem was diagnosed at an early date—lead poisoning. In 1949, British regulations forbade the use of raw lead in glaze compositions. Prior to this regulation there had been 400 cases of lead poisoning a year at the end of the nineteenth century. Although experiments with leadless glazes were recorded throughout the nineteenth century, lead was essential. The safe solution adopted and approved early in the twentieth century was a lead glaze of low solubility, produced by making the glaze suspension out of fritted lead.

Another serious health risk for potters was pneumoconiosis: flint dust particles when inhaled caused gradual and often fatal damage to the lungs. It was a lingering disease that took many decades to diagnose and control. Flint is still used as a component in the bodies of many traditional ceramic wares, but the risk of pneumoconiosis has been virtually eliminated through proper ventilation and cleanliness of workshops and the use of protective clothing.

In North America, the origin of pottery production occurred in regions where there were deposits of earthenware clay and the wood needed for the kilns. The abundance of these raw materials were factors in the English colonialists settling in Jamestown, Virginia in 1607. There is evidence that pottery production began in Jamestown around 1625 (see Guillard 1971). Similar supplies were available in the Northeast for the English potters accompanying the small band of farmers and tradesmen who arrived in Plymouth in the 1620s. In New England and Virginia, potters used a lead glaze brushed onto the inside of the earthenware vessel to make the porous clay watertight.

The important pottery centers in North America during the mid-nineteenth century were Bennington, VT, Trenton, NJ, and East Liverpool, OH. The geographical location of each center formed a right triangle located in the

Northeast. These locations had deposits of fine clay plus river transportation, which provided easy access to markets. By 1840, there were more than 50 stoneware potteries in Ohio, earning Akron the tag “Stoneware City.”

In the past, ceramic production was largely empirical. To maintain uniformity, producers always obtained their raw materials from the same supplier and avoided changing any details of their process. The reason was that they were dealing with very complex systems that they did not understand. Nowadays, thanks to the result of ~100 years of ceramics research, processing and manufacturing are optimized based on an understanding of basic scientific and engineering principles. Research in ceramics was spurred on by two main factors:

- Development of advanced characterization techniques such as X-ray diffraction and electron microscopy, which provided structural and chemical information
- Developments in ceramic processing technology

2.7 PLASTER AND CEMENT

A special ceramic is hydraulic (or water-cured) cement. World production of hydraulic cement is about 1.5 billion tons per year. The top three producers are China, Japan, and the United States. When mixed with sand and gravel, we obtain concrete, the most widely utilized construction material in industrialized nations. In essence, concrete is a ceramic matrix composite (CMC) in which not just the matrix but also the reinforcing material is ceramic.

Ancient Romans and Greeks, 2,000 years ago, pioneered the use of cement. Its unique chemical and physical properties produced a material so lasting that it stands today in magnificent structures such as the Pantheon in Rome. Roman cement consisted of a mixture of powdered lime (CaO) and volcanic ash (a mixture of mainly SiO₂, Al₂O₃, and iron oxide)—called *pozzolana*—from Mount Vesuvius, which buried the ancient city of Pompeii in 79 CE. This mixture hardens in the presence of water.

Contemporary hydraulic cement—for example Portland cement (invented by Joseph Aspdin and named after a natural stone from the island of Portland in England, which it resembles)—has a composition similar to that of pozzolanic cement. The chief ingredients of Portland cement are di- and tricalcium silicates and tricalcium aluminate. In the reduced nomenclature given in Table 2.3, these ingredients would be expressed as C₂S, C₃S, and C₃A, respectively. Portland cement is produced to have a specific surface area of ~300 m²/kg and grains between 20 and 30 μm. The average composition is given in Table 2.4. In Chapter 8 we show you on a ternary phase diagram the composition range of Portland cements.

TABLE 2.3 Reduced Nomenclature for Cement Chemistry

Lime	CaO = C
Alumina	Al ₂ O ₃ = A
Silica	SiO ₂ = S
Water	H ₂ O = H

The setting reactions for Portland cement are similar to those for the ancient pozzolanic cement. The first reaction is the hydration of C₃A. This reaction is rapid, occurring within the first 4 h. It causes the cement to set.

The C₃AH₆ phase, or ettringite, is in the form of rods and fibers that interlock. The second reaction, which causes the cement to harden, is slower. It starts after about 10 h and takes more than 100 days to complete. The product is tobermorite gel, a hydrated calcium silicate (Ca₃Si₂O₇·3H₂O), which bonds everything together.

Protuberances grow from the gel coating and form arrays of interpenetrating spines. Scanning electron microscopy (SEM) has been one tool that has been used to examine cement at various stages in the setting and hardening process. Figure 2.8 shows an SEM image recorded 8 days into the hardening process. The plate-like features are calcium hydroxide (CH); the cement (Ct) grains are already completely surrounded by the tobermorite gel (called CSH in the figure).

The development of strength with time for Portland cement is shown in Figure 2.9. The reactions give off a lot of heat (Figure 2.10). In very large concrete structures, such as the Hoover Dam at the Nevada–Arizona

border in the United States, heat is a potential problem. Cooling pipes must be embedded in the concrete to pump the heat out. These pipes are left in place as

a sort of reinforcement. In the case of the Hoover Dam, the construction consisted of a series of individual concrete columns rather than a single block of concrete. It is estimated that if the dam were built in a single continuous pour, it would have taken 125 years to cool to ambient temperatures. The resulting stresses would have caused the dam to crack and possibly fail.

Plaster of Paris is a hydrated calcium sulfate (2CaSO₄·H₂O). It is made by heating naturally occurring gypsum (CaSO₄·2H₂O) to drive off some of the water. When mixed with water, plaster of Paris sets within a few minutes by a

FIGURE 2.9. Increase in compressive strength of Portland cement with time.

cementation reaction involving the creation of interlocking crystals:

To increase the setting time, a retarding agent (the protein keratin) is added. Plaster of Paris is named after the French

city where it was made and where there are abundant gypsum deposits. Following the Great Fire of London, in 1666, the walls of all wooden houses in the city of Paris were covered with plaster to provide fire protection. The earliest use of plaster coating dates back 9,000 years and was found in Anatolia and Syria. The Egyptians used plaster made from dehydrated gypsum powder mixed with water as a joining compound in the magnificent pyramids.

2.8 BRIEF HISTORY OF GLASS

The history of glass dates back as far as the history of ceramics itself. We mentioned in Section 2.1 the use of obsidian during the Paleolithic period. It is not known for certain when the first glass objects were made. Around 3,000 BCE, Egyptian glassmakers systematically began making pieces of jewelry and small vessels from glass; pieces of glass jewelry have been found on excavated Egyptian mummies. By about 1,500 BCE, Egyptian glassmakers during the reign of Tuthmosis III had developed a technique to make the first useable hollowware.

The glass was made from readily available raw materials. In the clay tablet library of the Assyrian King Ashurbanipal (669–626 BCE) cuneiform texts give glass formulas. The oldest one calls for 60 parts sand, 180 parts ashes of sea plants, and 5 parts chalk. This recipe produces

FIGURE 2.11. Glass workers in Bohemia, from the *Travels of Sir John Mandeville* (ink and tempera on parchment, Flemish, early fifteenth century).

a $\text{Na}_2\text{O-CaO-SiO}_2$ glass. The ingredients are essentially the same as those used today but the proportions are somewhat different. Pliny the Elder (23–79 CE) described the composition and manufacture of glass in *Naturalis Historia*. During Roman times glass was a much-prized status symbol. High-quality glassware was valued as much as precious metals.

Figure 2.11 shows a Flemish drawing from the early fifteenth century depicting glass workers in Bohemia (from the *Travels of Sir John Mandeville*). It shows the legendary pit of Mynon with its inexhaustible supply of sand.

And beside Acre runs a little river, called the Belyon [Abellin], and near there is the Fosse of Mynon, all round, roughly a hundred cubits broad; and it is full of gravel. And however much be taken out in a day, on the morrow it is as full as ever it was, and that is a great marvel. And there is always a great wind in that pit, which stirs up all the gravel and makes it eddy about. And if any metal be put therein, immediately it turns to glass. This gravel is shiny, and men make good clear glass of it. The glass that is made of this gravel, if it be put back in the gravel, turns back into gravel, as it was at first. And some say it is an outlet of the Gravelly Sea. People come from far countries by sea with ships and by land with carts to get some of that gravel.

Sand is an important constituent of most oxide glasses. Early glassmakers would have made effective use of natural resources and set up their workshops near a source of raw materials. This practice was also adopted during the

time of Josiah Wedgwood and was the reason that the ceramic industry developed in the north of England—not in London, the capital. The illustration also shows the entire cycle of producing a glass object, from obtaining the raw materials to testing the final product.

One of the most common methods used to form glass is glassblowing. Although this technique was developed over 2,000 years ago in Syria, the glassblowing pipe has not changed much since then. The main developments are the automated processes used to produce glass containers and light bulbs in the thousands. We summarize the important milestones in glass formation and production in Chapter 21.

In this section we consider two specific aspects of the history of glass.

- Lead crystal glass
- Duty on glass

These events occurred between the very early experimentation with glasses in Egyptian and other ancient civilizations and more modern developments in glass such as optical fibers and glass-ceramics.

The Venetians used pyrolusite (a naturally occurring form of MnO_2) as a decolorizer to make a clear glass. This addition was essential because the presence of impurities, chiefly iron, in the raw materials caused the glass to have an undesirable greenish-brown color. The manganese oxidizes the iron and is itself reduced. The reduced form of manganese is colorless but when oxidized it is purple (Mn in the +7 oxidation state). Manganese was used until quite recently as a decolorizer; and some old windows may be seen, particularly in Belgium and The Netherlands, where a purple color has developed owing to long exposure to sunlight, which oxidized the manganese back to the purple form.

Lead-crystal glass is not crystalline, but the addition of large amounts of lead oxide to an aluminosilicate glass formulation produces a heavy glass with a high refractive index and excellent transparency. Suitable cutting, exploiting the relative ease with which lead glass can be cut and polished, enhances the brilliance. The lead content, in the form of PbO , in Ravenscroft's lead crystal glass has been determined to be about 15%. Nowadays, lead crystal glasses contain 18–38% PbO . For tableware to be sold as “lead crystal,” the PbO content must be about 25%.

Expansion of the British glass industry followed the success of lead crystal glass; and during the eighteenth century it achieved a leading position that it held for a 100 years. The beautiful drinking glasses of this period are collectors' items. English production was hindered only by a steady increase of taxation between 1745 and 1787 to pay for a war against France. The tax was levied on glass by weight, and as the tendency had been to add more lead oxide the production was checked. As a result, many glassmakers moved to Ireland where glass was free from duty, and glassworks were set up in Dublin and Waterford.

During the eighteenth and nineteenth centuries, the British government regarded the glass industry as an

inexhaustible fund to draw on in times of war and shortage. A glass duty was first imposed by statute in 1695 and made perpetual the following year, but it was so high it discouraged manufacturers and was soon reduced by half. The duties were repealed in 1698 because of reduced consumption of coal and the rise in unemployment. In 1746, duties were again levied, but they were also imposed on imported glassware. The Act of 1746 required a record to be kept of all furnaces, pots, pot chambers, and warehouses; and due notice had to be given when pots were to be changed. That same year the regulations were applied for the first time in Ireland, as a result of which many of the flourishing glassworks established there to avoid the excise duties began to decline. The duties seriously delayed technological innovation, and in 1845 they were repealed. The industry immediately entered a new period of growth.

The Industrial Revolution started in England during the latter part of the eighteenth century, but it did not radically affect the glass industry in its early stages because mechanical power was not required in the glassworks. The impact of mechanization is shown best by its development in the American glass industry. American workers were scarce and wages were much higher than in Europe, and so means were sought to increase productivity. One of the important developments at this time was a process for making pitchers by first pressing and then free-hand blowing, patented by Gillinder in 1865. This patent led to a period where American container production changed from a craft industry to a mechanized manufacturing industry.

To the early glassmakers, the nature of the structure of glass was a mystery. But they did know that the addition of certain components could modify properties. The most successful model used to describe the structure of oxide glasses is the random-network model devised by W.H. Zachariasen (1932). We describe this model in some detail in Chapter 21. Although the random-network model is over 60 years old, it is still extensively used to explain the behavior and properties of oxide glasses; and it is widely used in industry for developing and modifying glass formulations.

2.9 BRIEF HISTORY OF REFRACTORIES

The development of refractories was important for many industries, most notably for making iron and steel and for glass production. The iron and steel industry accounts for almost two-thirds of all refractories used. The discovery by Sidney Gilchrist Thomas and his cousin Percy Gilchrist in 1878 that phosphorus could be removed from steel melted in a dolomite-lined Bessemer converter (and subsequently on a dolomite hearth) was an important development. They solved a problem that had defeated the leading metallurgists of the day. What is even more remarkable is

that Thomas, who had originally wanted to be a doctor, was a magistrate's clerk at Thames police court in London. Out of interest, he attended evening classes in chemistry and later metallurgy at Birkbeck Mechanics Institute (now Birkbeck College, University of London), where he became aware of the phosphorus problem. It took three attempts (over a 1-year period) by Thomas and Gilchrist to report the successful outcome of their work to the Iron and Steel Institute. A lesson in perseverance! When their paper was finally presented (Thomas and Gilchrist 1879) the success of their process had become widely known, and they attracted an international audience.

Dolomite refractories are made from a calcined natural mineral of the composition $\text{CaCO}_3 \cdot \text{MgCO}_3$. The production of magnesite, a more slag-resistant refractory than dolomite, began in 1880. Magnesite refractories consist mainly of the mineral periclase (MgO), with a typical composition in a ratio of MgO 83–93%/ Fe_2O_3 2–7%. Historically, natural magnesite (MgCO_3) that was calcined provided the raw material for this refractory. With increased demands for higher temperatures and fewer process impurities, higher purity magnesia from seawater and brine has been used. This extraction process is described in Chapter 19.

In 1931, it was discovered that the tensile strength of mixtures of magnesite and chrome ore was higher than that of either material alone, which led to the first chrome–magnesite bricks. Chrome refractories are made from naturally occurring chrome ore, which has a typical composition in ratios of Cr_2O_3 30–45%/ Al_2O_3 15–33%/ SiO_2 11–17%/ FeO 3–6%. Chrome–magnesite refractories have a chrome/magnesia ratio of 70:30. Such bricks have a higher resistance to thermal shock and are less liable to change size at high temperatures than magnesite, which they replaced in open-hearth furnaces. The new refractories also replaced silica in the furnace roof, which allowed higher operating temperatures, with the benefits that these furnaces were faster and more economical than furnaces with silica roofs.

Finally, not the least important development in refractories was the introduction of carbon blocks to replace fireclay (composition similar to kaolinite) refractories in the hearths of blast furnaces making pig iron. Early experience was so successful that the “all carbon blast furnace” seemed a possibility. These hopes were not realized because later experience showed that there was sufficient oxygen in the upper regions of the furnace to oxidize the carbon and hence preclude its use there.

As in the history of other ceramics, the great progress in refractories was partly due to developments in scientific understanding and the use of new characterization methods. Development of phase equilibrium diagrams and the use of X-ray diffraction and light microscopy increased understanding of the action of slags and fluxes on refractories and also of the effect of composition on the properties of the refractories.

2.10 MAJOR LANDMARKS OF THE TWENTIETH CENTURY

Uranium dioxide nuclear fuel. In 1954 and 1955, it was decided to abandon metallic fuels and to concentrate on UO_2 (sometimes referred to as urania) as the fuel for power-producing nuclear reactors. The water-cooled, water-moderated nuclear reactor would not have been possible without urania. Its important properties are:

1. Resistance to corrosion by hot water
2. Reasonable thermal conductivity (about 0.2–0.1 times that of metals)
3. Fluorite crystal structure, which allows accommodation of fission products (see Section 6.5)

Reactor pellets are often cylinders that are about 1 cm high and 1 cm in diameter with a theoretical density of about 95%. Many pellets are loaded into a closely fitting zirconium alloy tube that is hermetically sealed before insertion into the reactor.

Following World War II (and the first use of nuclear weapons), there was a lot of research in the field of nuclear energy. Many of the people doing this research started with the wartime Manhattan project. Almost all worked in a few government-supported laboratories, such as those at Oak Ridge (in Tennessee) or Argonne (in Illinois) or at commercially operated laboratories that were fully government supported. In other countries, most of the work was also carried out in government laboratories (e.g., Chalk River in Canada and Harwell in England). The excitement in nuclear energy continued into the 1970s until the Three Mile Island incident. Much of the interest and research in nuclear energy and nuclear materials has waned in the United States. Work continues in several countries, though, including Japan, France, and Canada; and it may resume elsewhere as energy demands grow.

Float-glass process. Flat, distortion-free glass has long been valued for windows and mirrors. For centuries, the production of plate glass was a labor-intensive process involving casting, rolling, grinding, and polishing. The process required much handling of the glass and had high waste glass losses. As a result, plate glass was expensive and a premium product. Drawing processes were used extensively for window glass but were not suitable for producing distortion-free sheets for the more demanding applications. In 1959, Alastair Pilkington introduced the float-glass process to make large unblemished glass sheets at a reasonable cost. It took 7 years and more than \$11 million (>\$150 million today) to develop the process. We describe the technical details of the float-glass process in Chapter 21. Float-glass furnaces are among the largest glass-melting tank furnaces in use today and can produce 800–1,000 t of finished glass per day. A float-glass production line can be 700 ft long, with the tin path over 150 ft in length. It can produce a sheet with a width of 12 ft.

The float-glass process dramatically decreased the cost of glass and led to a tremendous increase in the use of glass in modern architecture. Each year the float-glass process produces billions of dollars worth of glass.

Pore-free ceramics. During and following World War II new ceramics became important because of their special properties. They were fabricated from single-phase powders by sintering. This process differed from the classic silicate ceramic processing in that no liquid phase was formed. In the early stages of their development, all such ceramics were porous after firing and hence opaque. Robert Coble found that addition of a small amount of MgO inhibited discontinuous grain growth in Al_2O_3 and permitted it to be sintered to a theoretical density to yield a translucent product. The first commercial product using this new property was called Lucalox (for transLUCent ALuminum OXide). It is used primarily to contain the Na vapor in the high-pressure Na-vapor lamps, which give nighttime streets their golden hue. Operating at high temperature, Na-vapor lamps have a luminous efficiency of $>100 \text{ lmW}^{-1}$, the highest of any light source (a 100 W tungsten-filament lamp has an efficiency of $\sim 18 \text{ lmW}^{-1}$). They have displaced almost all other light sources for outdoor lighting. Na-vapor lamps are produced at an estimated rate of 16 million per year. A new product, the ceramic-metal halide lamp, utilizes the same ceramic envelope. It has an intense white light and is just now being introduced. Lumex ceramic utilizes much of the same principles in its preparation. It is based on doped yttrium oxide and is used as a scintillation counter in the General Electric computed tomography X-ray scanner.

Nitrogen ceramics. Silicon nitride was first produced in 1857 (Deville and Wöhler 1857) but remained merely a chemical curiosity. It wasn't until much later that it was considered for engineering applications. During the period 1948–1952 the Carborundum Company in Niagara Falls, New York, applied for several patents for the manufacture and application of silicon nitride. By 1958, Haynes (Union Carbide) silicon nitride was in commercial production for thermocouple tubes, rocket nozzles, boats, and crucibles for handling molten metal. British work in silicon nitride, which began in 1953, was directed toward the ceramic gas turbine. It was supposed that sea and land transport would require turbines with material capabilities beyond those of the existing nickel-based superalloys. This work led to the development of reaction-bonded silicon nitride (RBSN) and hot-pressed silicon nitride (HPSN). In 1971, the Advanced Research Projects Agency (ARPA) of the U.S. Department of Defense placed a \$17 million contract with Ford and Westinghouse to produce two ceramic gas turbines, one a small truck engine and the other producing 30 MW of electrical power. The goal was to have ceramic engines in mass production by 1984. Despite considerable investment, there is still no commercial ceramic gas turbine. The feasibility of designing complex engineering components using ceramics has been demonstrated, and

there has been increasing use of ceramics in engineering applications. Unfortunately, there is not a viable commercial process for manufacturing complex silicon nitride shapes with the combination of strength, oxidation resistance, and creep resistance required for the gas turbine, together with the necessary reliability, life prediction, and reproducibility.

Magnetic ferrites. The development of ceramic magnetic materials for commercial applications really started in the early 1930s. In 1932, two Japanese researchers, Kato and Takei, filed a patent describing commercial applications of copper and cobalt ferrites. J.L. Snoeck of N.V. Philips Gloeilampenfabrieken in Holland performed a systematic and detailed study of ferrites in 1948. This work launched the modern age of ceramic magnets. The following year, Louis Néel, a French scientist, published his theory of ferromagnetism. This was an important step in the history of magnetic ceramics because most of the ceramics that have useful magnetic properties are ferrimagnetic. About one million tons of ceramic magnets are produced each year.

Ferroelectric titanates. These materials are used as capacitors, transducers, and thermistors, accounting for about one-half the sales of electroceramics. The historical roots leading to the discovery of ferroelectricity can be traced to the nineteenth century and the work of famous crystal physicists Weiss, Pasteur, Pockels, Hooke, Groth, Voigt, and the brothers Curie. Beginning with the work on Rochelle salt (1920–1930) and potassium dihydrogen phosphate (1930–1940), the study of ferroelectrics accelerated rapidly during World War II with the discovery of ferroelectricity in barium titanate. There then followed a period of rapid proliferation of ferroelectric materials, including lead zirconate titanate (PZT), the most widely used piezoelectric transducer. Together with the discovery of new materials, there was an increase in the understanding of their structure and behavior, which led to new applications for ferroelectric ceramics, including in micro-electro-mechanical systems (MEMS).

Optical fibers. In 1964, Charles K. Kao and George A. Hockman, at the now defunct Standard Telecommunications Laboratory (STL) in the United Kingdom, suggested sending telecommunications signals along glass fibers. These early fibers had very high losses—the difference in the amount of light that went in versus the light that came out—compared to the fibers produced today. Robert Maurer, Donald Keck, and Peter Schultz at the Corning Glass Works in New York State produced the first low-loss fibers in 1970. They were made by a process known as modified chemical vapor deposition (MCVD) and had losses of <20 dB/km. Today, losses typically are 0.2–2.0 dB/km. In 1988, the first transatlantic fiberoptic cable, TAT-8, began carrying telephone signals from America to Europe. The link is 6,500 km long and can carry 40,000 conversations per fiber. Glass fibers are also critical in today’s endoscopes.

Glass Ceramics. S. Donald Stookey made the first true glass-ceramic at Corning Glass Works in 1957. He accidentally overheated a piece of Fotoform glass—a photosensitive lithium silicate glass. The glass didn’t melt; instead, it was converted to a white polycrystalline ceramic that had much higher strength than the original glass. The conversion from the glass to the crystalline ceramic was accomplished without distortion of the articles and with only minor changes in dimensions. Small silver crystals in the glass acted as nucleation sites for crystallization. The development of this new Pyroceram composition launched Corning into the consumer products market. In 1958, Corningware® was launched. Stookey went on to develop a number of glass-ceramics, including one that was used as a smooth-top cooking surface for stoves. The invention of glass-ceramics is a good example of serendipity, but Stookey had to be aware of the significance of what he had made. There are many other examples of the role of luck in the invention and development of new materials, including Teflon, safety glass, and stainless steel.

Tough ceramics. Ceramics are inherently brittle with low toughness. In 1975, Garvie, Hannink, and Pascoe published a seminal article entitled “Ceramic Steel.” They were the first to realize the potential of zirconia (ZrO₂) for increasing the strength and toughness of ceramics by utilizing the tetragonal to monoclinic phase transformation induced by the presence of a stress field ahead of a crack.

A great deal of effort has been expended to devise theories and develop mathematical frameworks to explain the phenomenon. It is generally recognized that, apart from crack deflection, which can occur in two-phase ceramics, the t→m transformation can develop significantly improved properties via two different mechanisms: microcracking and stress-induced transformation toughening. We describe these mechanisms in Chapter 18. So far three classes of toughened ZrO₂-containing ceramics have been made.

- Partially stabilized zirconia (PSZ)
- Tetragonal zirconia polycrystals (TZPs)
- Zirconia-toughened ceramics (ZTCs)

Bioceramics. The first suggestion of the application of alumina (Al₂O₃) ceramics in medicine came in 1932, although the field of bioceramics really didn’t develop until the 1970s with the first hip implants using alumina balls and cups. Studies showed that a ceramic ball was more biocompatible than metals and provided a harder, smoother surface that decreased wear. In 1982, the U.S. Food and Drug Administration approved these materials for use. Each year, about 135,000 hips are replaced in the United States, with more than a million hip prostheses using alumina components having been performed to date. Alumina is an example of a nearly inert bioceramic. Bioactive ceramics and glasses—materials that form a

bond across the implant–tissue interface—were an important development. The first and most studied bioactive glass, known as Bioglass 45S5, was developed by Larry Hench and coworkers at the University of Florida. The first successful use of this material was as a replacement for the ossicles (small bones) in the middle ear. A range of bioactive glass-ceramics has also been developed.

Fuel cells. The British scientist Sir William Robert Grove (1839) discovered the principle on which fuel cells are based. Grove observed that after switching off the current that he had used to electrolyze water, a current started to flow in the reverse direction. The current was produced by the reaction of the electrolysis products, hydrogen and oxygen, which had been adsorbed onto the Pt electrodes. Grove's first fuel cell comprised two Pt electrodes, both half immersed in dilute H_2SO_4 : one electrode was fed with O_2 the other with H_2 . Grove realized that this arrangement was not a practical method for energy production. The first practical fuel cell was developed in the 1950s at Cambridge University in England. The cell used Ni electrodes (which are much cheaper than Pt) and an alkaline electrolyte. Pratt and Whitney further modified the alkaline fuel cell in the 1960s for NASA's Apollo program. The cells were used to provide on-board electrical power and drinking water for the astronauts. The alkaline fuel cell was successful but too expensive for terrestrial applications, and it required pure hydrogen and oxygen. There are many types of fuel cell, but the one most relevant to ceramics is the solid-oxide fuel cell (SOFC). The SOFC uses a solid zirconia electrolyte, which is an example of a fast-ion conductor. We discuss later how fuel cells convert chemical energy into electrical energy.

High-temperature superconductivity. In 1986, Bednorz and Müller discovered high-temperature superconductivity at the IBM Research Laboratory in Zurich, Switzerland. Art Sleight had shown earlier that oxides could be superconductors, but the required temperature was still very low. The discovery that certain ceramics lose their resistance to the flow of electrical current at temperatures higher than metal alloys may be as important as the discovery of superconductivity itself. Because of the significance of their discovery, Bednorz and Müller were awarded the Nobel Prize for Physics in 1987—only a year after their discovery. The impact of the discovery of high-temperature superconductivity launched an unprecedented research effort. The 2-year period after Bednorz and Müller's discovery was a frenzied time, with a host of new formulations being published. Paul Chu and colleagues at the University of Houston, Texas discovered the most significant of these new ceramics, $\text{YBa}_2\text{Cu}_3\text{O}_7$, in 1987. This YBCO, or 123 superconductor as it is known, is superconducting when cooled by the relatively inexpensive liquid nitrogen. This opened up enormous possibilities and led to expansive speculations on a future based on these materials. The original promises have not been fulfilled, but new applications are being developed, and the

field is still quite young. The current market is less than 1% of the advanced ceramics market. Predictions indicate that over the next 5 years annual growth rates of up to 20% might be achieved.

2.11 MUSEUMS

There are many museums around the world that house collections of ceramics. The list we give here is not exclusive, but it does include some of the major collections as well as sites that have important historical significance.

- Ashmolean Museum, Oxford, UK. A museum of the University of Oxford. Founded in 1683, it is one of the oldest public museums in the world. Important collections include early Chinese ceramics and Japanese export porcelain. www.ashmolean.org
- British Museum, London. One of the greatest museums in the world. Contains a large, outstanding collection of antiquities including numerous Stone Age artifacts. Currently, the museum is housing the Sir Percival David collection of Chinese ceramics, one of the finest collections (~1,700 pieces) of Chinese ceramics outside Asia. www.britishmuseum.org
- Corning Museum of Glass, Corning, NY, USA. One of the outstanding glass collections in the world. More than 33,000 objects representing the entire history of glass and glassmaking. www.cmog.org
- Metropolitan Museum of Art, New York, NY. Ceramic collections include Medici porcelain and Böttger porcelain. The museum also has one of the finest glass collections in the world. www.metmuseum.org
- Musée du Louvre, Paris. One of the greatest museums of the world. Contains extensive collections of antiquities, including many examples of ancient earthenware vessels, some dating from the Chalcolithic period. www.louvre.fr
- Musée National de Céramique, Sèvres, France. Collection includes examples of early European porcelains including a Medici porcelain bottle made in 1581; the first successful European effort to produce ware equivalent to Persian and Chinese porcelain. Also contains examples of French soft-paste porcelain as well as earlier ceramics. www.ceramique.com
- The Palace Museum, Beijing. Housed in the Forbidden City. Exhibits include a comprehensive history of the development of Chinese ceramics. www.dpm.org.cn
- Ross Coffin Purdy Museum of Ceramics at the American Ceramic Society headquarters, Westerville, Ohio. Houses a cross section of traditional and high-tech ceramics produced during the last 150 years. www.acers.org/acers/purdymuseum
- Smithsonian Institution, Washington, DC. The Freer Gallery of Art and the Arthur M. Sackler Gallery contain collections of ancient ceramics with

important examples from China and the Near East. www.asia.si.edu

- Victoria and Albert Museum, London. The world's largest museum of the decorative arts. Contains the National Collections of glass and ceramics. The extensive ceramic collection includes Medici porcelain and early Chinese and Near East ceramics. www.vam.ac.uk
- The World of Glass, St. Helens, UK. A museum and visitor center in the hometown of Pilkington glass. Pilkington plc originated in 1826 as the St. Helens Crown Glass Company. Contains the Pilkington glass collection. www.worldofglass.com

2.12 SOCIETIES

There are several professional ceramics societies in the world. In the United States, the American Ceramic Society (ACerS), founded in 1899, is the principal society for ceramists. The society, which is based in Westerville, Ohio, is divided into 10 divisions: Art, Basic Science, Cements, Electronics, Engineering Ceramics, Glass and Optical Materials, Nuclear and Environmental Technology, Refractory Ceramics, Structural Clay Products, Whitewares and Materials. The society organizes an annual meeting and publishes the *Journal of the American Ceramic Society*. The journal was created in 1918 and is one of the most important peer reviewed journals in the field. www.acers.org

Many other countries have professional societies for those working in the field of ceramics.

- Institute of Materials, Minerals and Mining (IoM³) www.iom3.org
- Deutsche Keramische Gesellschaft www.dkg.de
- European Ceramic Society (ECerS) <http://www.ecers.org>
- Swedish Ceramic Society <http://www.keram.se/sks>
- Ceramic Society of Japan www.ceramic.or.jp
- Canadian Ceramics Society www.ceramics.ca
- Chinese Ceramic Society www.ceramsoc.com
- Society of Glass Technology www.sgt.org

2.13 CERAMIC EDUCATION

The first formal ceramics program (Clay-Working and Ceramics) in the United States was established in 1894 at the Ohio State University in Columbus, Ohio. It marked a change from on-the-job training that was prevalent in the traditional North American art potteries and family establishments of earlier years toward formal university study. Ceramics was also taught at Alfred University in New York and many other schools across the nation. One of the most remarkable ceramists of the time was Adelaide Robineau who taught at Syracuse University in New York. Robineau was a studio ceramist who devised her own clay bodies, concocted her own glazes, threw the forms, and then decorated, glazed, and fired them herself. Few women at the time were involved in the technical aspects of ceramic production. It was considered proper for women to be decorators only, rather than be part of more technical pursuits or to throw on the wheel, a physically demanding job regarded as better left to men.

From 1894 to 1930 a number of universities formed their own ceramic engineering programs.

- New York State School of Clay-Working and Ceramics at Alfred University: 1900
- Rutgers University: 1902
- University of Illinois: 1905
- Iowa State College: 1906
- University of Washington: 1919
- West Virginia University: 1921
- North Carolina State University: 1923
- Pennsylvania State College: 1923
- Georgia Institute of Technology: 1924
- Missouri School of Mines (now Missouri University of Science and Technology): 1926
- University of Alabama: 1928
- Massachusetts Institute of Technology: 1930

The first materials science departments began to appear at universities in the 1960s. Many of them were based on existing metallurgy departments. At some of the universities that had specific ceramics programs, these activities were incorporated into the new materials departments. Now, ceramic science and engineering is mostly taught in Materials Science and Engineering (MS&E) programs in the United States.

CHAPTER SUMMARY

The history of ceramics is intertwined with human history. Society and technology have been affected by ceramics in many ways: from the first use of flint and obsidian during the Stone Age, to the formation of vessels from clay, to the use of refractories in the iron and steel industry, to the fabrication of optical fibers for high-speed communication ceramics. We mentioned many of the more recent developments in the field of ceramics. The science behind these materials is described in many of the later chapters.

PEOPLE AND HISTORY

Aspdin, Joseph. He was an English mason and invented Portland cement in 1824. It was so named because of its resemblance to white limestone from the island of Portland, England. The first Portland cement made in the United States was produced at Coploy, Pennsylvania in 1872.

Bednorz, Johannes Georg (born 1950) and *Karl Alexander Müller* (born 1927). Scientists at the IBM research laboratory in Zurich, Switzerland, they discovered the phenomenon of high-temperature superconductivity. They began working together in 1982 and were both awarded the Nobel Prize for Physics in 1987.

Böttger, Johann Friedrich. Born in 1682, the young Böttger was apprenticed as an apothecary in Berlin, where he claimed to have transformed mercury into gold, a feat he apparently demonstrated convincingly in 1701. When reports of this reached Frederick I, Böttger fled to Saxony, where in addition to his metallurgical research he began his work in ceramics. He used von Tschirnhaus' mirrors and lenses to produce a dense, red stoneware and a European equivalent to white Chinese porcelain. He died in 1719. Walcha (1981) wrote an authoritative history of Böttger and Meissen.

David, Sir Percival (1892–1964). An avid collector and researcher of Chinese ceramics, he presented his collection to the University of London, which was opened to the public in 1952. The most famous pieces in his collection are the pair of blue-and-white porcelain vases (called the David Vases) that he reunited in 1935. These vases have a date inscription that records that in AD 1351 a man called Zhang Wenjin from Yushan County presented them to a Daoist temple in Xingyuan (modern-day Wuyuan County).

Kingery, W. David. He played a key role in creating the field of ceramic science. He authored *Introduction to Ceramics*, first published in 1960, the “bible” for a generation of ceramists. Well known for his work in the field of sintering, in his later years he worked extensively on the history of ceramics. He died in June 2000.

Orton, Edward, Jr. Born in 1863 in Chester, NY, he studied mining engineering at Ohio State University (OSU). He was the founder of the ceramic engineering program at OSU in 1894 and a founder of the American Ceramic Society. He died in 1932.

Pilkington, Sir Alastair. Born in 1920, he served in World War II. In 1942, he was captured on the island of Crete and spent the rest of the war as a prisoner of war. After finishing his studies at Cambridge University, he joined the Pilkington Glass Company in 1947. By 1959, the float-glass process was a success and the production of flat-glass revolutionized. He died in 1995.

Ravenscroft, George. He developed lead crystal glass during the last quarter of the seventeenth century to rival the Venetian *crystallo* developed during the early sixteenth century. He was granted a patent in March 1674 for a “crystalline glass resembling rock-crystal.”

Seeger, Hermann A. He was the world's pioneer scientific ceramist. The English translation of Seeger's work, *The Collected Writings of Hermann Seeger*, was published in 1913 by the American Ceramic Society.

Simpson, Edward. Better known as “Flint Jack,” he was an Englishman and one of the earliest experimental stone toolmakers. Using nothing more than a steel hammer, he created replicas of ancient stone tools, which he sold during the late nineteenth century to museums and a Victorian public that was very interested in prehistoric times. He was able to make the tools appear old and worn by using chemicals and a lapidary tumbler. In 1867, he was sent to prison for theft.

von Tschirnhaus, Count Ehrenfried Walther. Born in 1651, he was a physicist famous for his experiments with high temperatures and mineral fusions achieved by focusing sunlight in a solar furnace. He was made a foreign member of the French Royal Academy in 1683. He died in 1708.

Wedgwood, Josiah. Born in 1730, the last child in a family of 12, he went into business for himself in 1759 in Staffordshire. One of the most remarkable innovators of the eighteenth century, he revolutionized the process of manufacturing. He was a member of the Royal Academy and a member of the Lunar Society of Birmingham, which included in its members many of the great innovators of that period, such as James Watt the inventor of the steam engine. Mankowitz (1980) gives a detailed account of the life of Wedgwood and his pottery.

Zachariasen, William Holder. Born in 1906, he was a Norwegian-American physicist who spent most of his career working in X-ray crystallography. His description of the glass structure during the early 1930s became a standard. He died in 1980.

EXERCISES

- 2.1 Gypsum, the raw material for Plaster of Paris, occurs in several varieties. The Greeks used a form of gypsum as windows for their temples. What particular property would be important for this application? What form of gypsum would be most suitable?
- 2.2 What do you think might be the role of CuO in the Han lead glaze (Table 2.2)?
- 2.3 Why do you think it was so important for the early ceramic industries to locate near the source of raw materials? Does a similar situation occur today?
- 2.4 The largest concrete construction project in the world is the Three Gorges Dam in China. How much concrete was used in this project?

- 2.5 Which company is the largest producer of glass optical fibers?
- 2.6 Corningware[®] is a glass-ceramic product that was once widely used for cookware but is rarely used now. What were some of the problems with Corningware[®]? Would these problems be inherent to all glass-ceramics?
- 2.7 Solid oxide fuel cells (SOFCs) are not used in transportation applications (such as automobiles and buses). What fuel cells are being used for these applications, and what are their advantages over the ceramic-based SOFCs?
- 2.8 The transition temperature (T_c) for the YBCO superconductor is 95 K. Higher T_c s are found with other ceramic high-temperature superconductors, but these materials are not being used commercially. What are some of the other materials, and what are some of the factors that are limiting their use?
- 2.9 The Hall of Mirrors (La Galerie des Glaces) at the Palace of Versailles in France was begun in 1678, well before the development of the float-glass process. What technology was available during the seventeenth century for producing flat plates of glass?
- 2.10 Concrete is a mixture of gravel (called aggregate) and cement. The spectacular 142-ft internal diameter dome of the Pantheon in Rome is made of concrete. What material did the Romans use for aggregate in the construction of the Pantheon? Could the material they used be classified as a ceramic?
- 2.11 Classify the oxides in Table 2.2 based on the location of the cation (metal ion) in the Periodic Table of Elements (e.g., one group would be all the transition metal oxides). Discuss any trends you notice in your classification scheme.
- 2.12 In Section 2.10 we highlighted the importance of pore-free ceramics. However, there are numerous applications for highly porous ceramics. Identify two applications for porous ceramics. (Hint: There are many examples in later chapters).
- 2.13 Make a list of companies that manufacture SOFCs. Are any of these companies publicly traded?
- 2.14 In industry, non-SI units are still widely used. In particular, temperature is often given in °F rather than °C. Calculate the firing temperatures for earthenware and stoneware in °F and compare them to the melting temperature of quartz in the same units.
- 2.15 Portland cement has a specific surface area (SSA) of $\sim 300 \text{ m}^2/\text{kg}$. How does this value compare to the SSA of ceramic nanopowders such as fumed silica?
- 2.16 Using the four journals in question 1.20, what is the most widely studied nitride ceramic today? Why is this so?
- 2.17 What material would have been used to make the stone tool in Figure 2.1? Speculate on how the availability of such material influenced the development of civilization. How do we use similar materials today?
- 2.18 Discuss what we mean by “bone china”. Why is this odd terminology?
- 2.19 Two other terms with interesting histories are majolica and faience. Explain.
- 2.20 In the eighteenth Century we might have named Sèvres, Meissen and Staffordshire as three related regions. Explain why. Using the internet or otherwise, explain which three towns or regions you would name today instead.

Part II

Materials

Background You Need to Know

CHAPTER PREVIEW

We summarize three concepts fundamental to all materials science in this chapter: atomic structure, thermodynamics, and kinetics. You should be familiar with these topics from introductory chemistry, physics, and materials science classes so we only give a brief review here. Books are written on each of these topics. In ceramics, you can often avoid such books, but the details become more critical as you delve deeper into the subject.

The properties of a material are determined, to a large extent, by how the constituent atoms bond together. The nature of this bonding is determined by the electron configuration of the atoms. The electron configuration of an atom also determines the properties of the atom and materials that contain it. For example, the ceramic magnetite (Fe_3O_4) is magnetic due to the presence of unpaired electrons in the 3d level of Fe; you need to know what the 3, the d, and “unpaired” denote. To understand why Mn ions can exist with many different charge states but we invariably only find Al ions with a 3+ charge, you must know the electron configuration of the respective atoms.

Knowledge of both thermodynamics and kinetics is necessary to understand how ceramic materials behave and what happens when they are processed. Thermodynamics tells us what is possible, and kinetics tells us how long we have to wait for the inevitable. Thus, thermodynamics tells us if a specific chemical or physical reaction can occur. In ceramics, these changes are often brought about because samples are routinely heated and cooled. Ceramics may be processed at temperatures $>1,800^\circ\text{C}$ and then cooled to 25°C . Some processes occur at $1,800^\circ\text{C}$ but may continue or change as we cool the sample. Conversely, some ceramics change their properties at quite low temperatures. For example, BaTiO_3 changes from the paraelectric cubic phase to the ferroelectric tetragonal phase at 120°C . Kinetics tells us how rapidly these reactions proceed. Diamond is thermodynamically unstable at room temperature and atmospheric pressure, but the phase change occurs much too slowly to worry jewelers.

3.1 THE ATOM

The bases for understanding the structure of the atom are quantum theory and wave mechanics, which were developed in the early 1900s. The important conclusions of these studies, particularly as they relate to materials, are:

- Electrons in atoms can only move in certain stable orbits (i.e., only certain energy values are possible). *We expand on this fact when we describe energy bands, which are used to explain electron conductivity.*
- Transition between orbits involves the emission or absorption of energy. *These transitions can be a source of color, and we use them to analyze chemistry by spectroscopy.*
- No two electrons in the same atom can have the same four quantum numbers. *This requirement led to*

introduction of the spin quantum number. Atoms containing electrons with unpaired spins have magnetic properties.

- It is impossible to know simultaneously the position and momentum of an electron with certainty. *We use this property in tunnel diodes.*
- Electrons have wavelike properties. *This means that they can be diffracted. Electron diffraction, like X-ray diffraction, gives us the crystal structure.*

In the following sections we summarize how these conclusions lead to our present view of the structure of the atom and, in particular, the nature and arrangement of the electrons in the atom. We are not attempting to summarize modern physics—only the concepts that we use in this text. You need to understand the main aspects of the nature of the chemical bond in ceramic materials: what is an ionic bond? what is a covalent bond? why do most

bonds show a mixture of the two? We use spectroscopy and microscopy to probe the electronic structure to determine the local chemistry of the ceramic.

3.2 ENERGY LEVELS

The quantization of energy levels is a key aspect in understanding atomic structure. Bohr's model involves electrons moving only in certain stable orbits. The angular momentum of the orbiting electrons is quantized so that only specific orbits are allowed and only certain energy values are possible.

These orbits are known as stationary states, and the one with the lowest energy is called the ground state.

Quantization of angular momentum is $nh/2\pi$, where n is the principal quantum number. As the principal quantum number increases:

1. The radius, r , of the electron orbit increases (i.e., the electron is further from the nucleus)
2. The energy, E , of that electron is also increased

The first five Bohr orbits (i.e., $n = 1-5$) are also referred to as shells. We define a shell as a group of states that have the same n . A letter is used to denote each shell.

Shell	K	L	M	N	O	...
n	1	2	3	4	5	...

Charles Barkla, an early X-ray spectroscopist, introduced this terminology for electron shells in 1911. We still use it today to designate characteristic X-rays for both X-ray diffraction and chemical analysis with electron microscopy. Barkla named the two types of characteristic X-ray emissions he observed as the K-series and L-series. He later predicted that an M-series and a J-series might exist. An M-series was subsequently discovered but no J-series. The K shell is hence the first shell.

The other aspect of Bohr's theory is that although an electron is in a stationary state the atom does not radiate. Electrons can be excited into higher energy orbits if the atom is stimulated (thermally, electrically, or by absorption of light). These orbits are the excited states and are

more distant from the nucleus. The residence time of an electron in the excited state may be very short (~1 ns) before it spontaneously descends to a lower energy state and eventually the ground state. During each transition, the excess energy is emitted in the form of a photon. Any transition between orbits involves either emission or absorption of energy. Understanding this concept is necessary in, for example, appreciating how a laser works. If the energy emitted is in the visible part of the electromagnetic spectrum (Table 3.1), we can observe the emission. The emission from the ruby laser (ruby is a ceramic) is

at 694 nm (in the red). A frequency-doubled Nd-doped yttrium aluminum garnet (YAG) laser (YAG is another ceramic) operates in the green part of the spectrum at 530 nm.

Bohr's model was quite popular at the time because an electron circling the nucleus is conceptually similar to the earth circling the sun. The idea that orbiting electrons did not radiate was less easy to accept, Bohr simply insisted they didn't and that was that!

Most importantly the model explained a number of physical phenomena. Bohr's assumption that electrons are particles with well-defined orbits was not consistent with the concept of "simultaneous indeterminacy" of position and momentum as propounded in the Heisenberg uncertainty principle.

What you should remember from this discussion is the origin of KLMNO and the terminology. We use this again in Chapter 10.

Electron energy levels and the Bohr model are important for understanding:

- Atomic radii—As we fill shells going down a particular period, the atoms get bigger (r increases).

THE BOHR ATOM

Quantization of angular momentum

$$m_e v r = n \frac{h}{2\pi} \quad (\text{Box 3.1})$$

Radius of possible electron orbits

$$r = \frac{\epsilon_0 n^2 h^2}{\pi m_e e^2} \quad (\text{Box 3.2})$$

Energy of the electron

$$E = \frac{m_e e^4}{8 \epsilon_0 n^2 h^2} \quad (\text{Box 3.3})$$

Energy, E (J)	Wavelength, λ (nm)	Color
2.84×10^{-19}	700	Red
3.20×10^{-19}	620	Orange
3.42×10^{-19}	580	Yellow
3.75×10^{-19}	530	Green
4.23×10^{-19}	470	Blue
4.73×10^{-19}	420	Violet

- Ionization energy—As we fill shells going down a particular period, it becomes progressively easier to remove the outer electron(s) (E increases with respect to the ground state).
- Covalent bond formation—Ionization energies must be high (E large).
- Magnetic ceramics—We need to have an M shell.
- X-ray spectroscopy—We use the Barkla notation: the energy of the characteristic X-rays depends on the electron energy levels involved.

3.3 ELECTRON WAVES

Demonstrating electron diffraction (a property associated with waves) was proof of their wave nature. In 1927, C.J. Davisson and L. Germer in the United States and, independently, G.P. Thomson and A. Reid in the United Kingdom showed that electrons could be diffracted in much the same way as X-rays. We care because we can't explain the properties of electrons and X-rays without this understanding.

The wavelike nature of electrons enables electron diffraction studies of materials. Most electron diffraction patterns are obtained with a transmission electron microscope, which allows us to get structural information from very small regions. This is of particular importance in many new ceramics, where we are often dealing with thin interface layers (e.g., at grain boundaries) and very small grains (nanopowders).

One of the most important consequences of the dual nature of electrons is Heisenberg's uncertainty principle, which states that it is impossible to know simultaneously both the momentum and position of a particle with certainty. If we are describing the motion of an electron of known energy or momentum, we can speak only in terms of a probability of finding that electron at a particular position. This leads to the electron-density or electron-cloud representation of electron orbitals.

The Schrödinger equation is as central to quantum mechanics as Newton's equations are to classical mechanics and relates the energy of an electron to its wave properties. The equation describes the likelihood that a single electron will be found in a specific region of space. The wave function, ψ , depends on E and V , the total energy and the potential energy of the electron, respectively.

The importance of the wave function has been expressed by Atkins (2009): "A wave function contains all there is to know about the outcome of experiments that can be done on a system." Thus, the Schrödinger wave equation includes information about the chemical behavior of all atoms and compounds and the answer to whether any proposed chemical reaction will take place.

Mathematically, ψ describes the motion of an electron in an orbital. The modulus of the wave function squared, $|\psi(r)|^2$, is a direct measure of the probability of finding the electron at a particular location. The Schrödinger wave equation can be solved exactly for hydrogen. To apply it, you must first transform it into polar coordinates (r, θ, ϕ) and then solve it using the method of separation of variables (described in, e.g., Kreyszig 2011).

Solution of these equations leads to three quantum numbers: n, l , and m_l .

The Schrödinger wave equation can be set for atoms with more than one electron, but it cannot be solved exactly in these cases. The second and subsequent electrons introduce the complicating feature of electron-electron repulsion. Nevertheless, the basic characteristics of the orbitals don't change, and the results obtained for hydrogen are applied to many-electron atoms.

Methods are becoming available that allow us to calculate the structure of some "bulk" materials. Generally, this calculation is done only rarely, by starting with the Schrödinger equation. The calculations are just too difficult or too time-consuming. Actually, it's worse than it looks because we also have to deal with charge.

THE DE BROGLIE HYPOTHESIS

All matter possesses wave properties. Every moving particle can be associated with a wavelength, λ , given by

$$\lambda = \frac{h}{mv} = \frac{h}{p}$$

SCHRÖDINGER WAVE EQUATION

The time independent form is

$$\nabla^2\psi + 8\pi^2m/h^2(E - V)\psi = 0 \quad (\text{Box 3.4})$$

∇^2 is the operator

$$\partial^2/\partial x^2 + \partial^2/\partial y^2 + \partial^2/\partial z^2 \quad (\text{Box 3.5})$$

In polar coordinates ψ has the form

$$\psi(r, \theta, \phi) = R(r)\Theta(\theta)\Phi(\phi) \quad (\text{Box 3.6})$$

$R(r), \Theta(\theta), \Phi(\phi)$ are each only functions of r, θ , and ϕ .

3.4 QUANTUM NUMBERS

Four quantum numbers are necessary to specify the state of any electron.

- n —principal quantum number
- l —orbital shape, or orbital angular momentum, quantum number
- m_l —orbital orientation, or orbital magnetic, quantum number
- m_s —spin, or spin magnetic, quantum number

A shell is a group of states that have the same n and corresponds to Bohr's n . A subshell is a smaller group of states having both the same values of n and l . An orbital is specified by n , l , and m_l and can contain a maximum of two electrons with opposite spins.

- n has integer values, 1, 2, 3, ... and determines the size
- l has integer values, 0, 1, 2, ..., $n-1$ (for any value of n) and determines shape
- m_l has integer values between $-l$ and $+l$ including 0 (for any value of l) and determines orientation
- m_s can have values of $\pm 1/2$ and specifies the direction of spin

The introduction of an external magnetic field provides the most convenient reference axis for m_l . The values of m_l are determined by the l quantum number.

For each value of l there are $(2l + 1)$ values of m_l . For historical reasons, the 0, 1, 2, and 3 values of the l quantum number are designated by the letters s, p, d, and f, respectively. (This choice is a relic of early spectroscopic studies when certain spectral series were designated “sharp,” “principal,” “diffuse,” or “fundamental”).

The s orbitals are spherical. The three 2p orbitals have directional properties as shown in Figure 3.1. For example, the $2p_z$ orbital has regions of greatest concentration or probability along the z -axis, and the probability of finding a $2p_z$ electron in the XY plane is zero. The shapes of the five 3d orbitals are more complicated (because there are more of them) (Figure 3.2), and we usually don't talk about f.

Are these numbers important for ceramics? The answer, of course, is yes.

- The color of a ceramic, such as ruby, derives directly from transitions between energy levels. The energy levels are the result of which orbitals are occupied and their relative energies.
- We use transitions for chemical analysis of ceramics—certain transitions are allowed (quantum mechanical selection rules).
- Magnetism relates directly to the spin of the electrons. If we have more spins up than down, we have magnetization.

QUANTUM NUMBERS

Li, Na, K and Cs have many common features because they all have a single electron in an outer s shell: 2s, 3s, 4s and 5s.

The main difference between MnO, FeO, CoO and NiO is due to the change in the d ($l = 3$) electrons on the transition-metal ion.

SUMMARY OF QUANTUM NUMBERS (QN)

Name	Symbol	Value
Principal QN	n	1, 2, 3, ...
Orbital-shape QN	l	0, 1, 2, ... ($n-1$)
Orbital-orientation QN	m_l	Integral values from $-l$ to $+l$ including zero
Spin QN	m_s	$\pm 1/2$

FIGURE 3.1. The $2p_x$, $2p_y$, and $2p_z$ orbitals. The nodal plane represents the area where the probability of finding the electron is zero.

FIGURE 3.2. The 3d atomic orbitals. The 4d, 5d, and 6d orbitals are essentially identical to the 3d orbitals except they are bigger. The sign of wavefunction changes from one lobe to the next in a given orbital, which is important when we consider the formation of molecular orbitals.

- Atomic arrangements in covalently bonded ceramics can be understood by considering hybridization of atomic orbitals. It is the sp^3 hybridization of atomic orbitals in carbon that allows the tetrahedral arrangement of atoms in diamond. The s and the p in sp^3 refer to the atomic orbitals.

3.5 ASSIGNING QUANTUM NUMBERS

A shorthand notation that expresses the quantum numbers for each electron represents the electron configuration. The importance of this step is that it allows us, for example, to calculate the magnetic moment of magnetite and determine what happens if we replace the Fe^{2+} ions with Ni^{2+} .

The key to the building process for many-electron atoms is the Pauli exclusion principle: no two electrons in an atom can have the same set of four quantum numbers.

For example, the two electrons in the ground

state of atomic He ($Z = 2$) must possess the following quantum numbers:

$$n = 1, \quad l = 0, \quad m_l = 0, \quad m_s = +1/2$$

$$n = 1, \quad l = 0, \quad m_l = 0, \quad m_s = -1/2$$

The two electrons in the He atom are placed in the 1s orbital with opposite spins, consistent with the Pauli's principle. The electron configuration of He is abbreviated as $1s^2$. The next row in the periodic table is similar; we are just filling the next shell ($n = 2$ and so on).

Lithium ($Z = 3$) has the electron configuration $1s^2 2s^1$. We fill the 2s orbital before the 2p because of shielding effects that lower the energy of the 2s orbital with respect to the 2p orbital. Both the 2s and 2p orbitals in the Li atom are shielded from the +3 nuclear charge by the 1s electrons. However, the 2s orbital has a larger probability density close to the nucleus and is not shielded as strongly as the 2p orbital.

For a C atom ($Z = 6$), there are a number of possible configurations for the second electron in the set of three 2p orbitals. We use Hund's rule to determine where the electron will go: for any set of orbitals of equal energy the electronic configuration with the maximum number of parallel spins results in the lowest electron-electron repulsion. Thus, the ground state for atomic carbon is $1s^2 2s^2 2p_x^1 2p_y^1$.

We can build the ground-state electron configuration of atoms of all elements by filling the orbitals in order of increasing energy, making sure that the Pauli exclusion principle and Hund's rule are obeyed. (Hund's rules are violated in predicting the correct ground state of an atom. There are occasional exceptions when the rules are used to discuss excited states that we encounter, for example, in spectroscopy). The total number of electrons that the orbitals can hold is given in Table 3.2.

There is no single ordering of orbital energies, but the following order is a useful guide:

$$1s < 2s < 2p < 3s < 3p < 4s < 3d < 4p < 5s < 4d < 5p < 6s < 4f \approx 5d < 6p < 7s < 5f \approx 6d.$$

Figure 3.3 is a mnemonic diagram that can be used for determining the filling order. You simply follow the arrows and numbers from one orbital to the next. Orbital energies depend on the atomic number and on the charge on the atom (ion).

In the sequence of orbital energies shown above, the 4s orbitals have a lower energy than the 3d orbitals and so they are filled first, in keeping with the minimum energy principle. For example, the electron configuration of the outer 10 electrons of calcium (atomic number $Z = 20$) is $3s^2 3p^6 3d^0 4s^2$.

IONIZATION

For ceramics, the important feature in all these models is which electrons can we move to make the ion and how easy is it going to be.

TABLE 3.2 The s, p, d, and f Orbital Sets

Type of orbital	Orbital quantum numbers	Total orbitals in set	Total number of electrons that can be accommodated
s	$l = 0, m_l = 0$	1	2
p	$l = 1, m_l = 1, 0, -1$	3	6
d	$l = 2, m_l = 2, 1, 0, -1, -2$	5	10
f	$l = 3, m_l = 3, 2, 1, 0, -1, -2, -3$	7	14

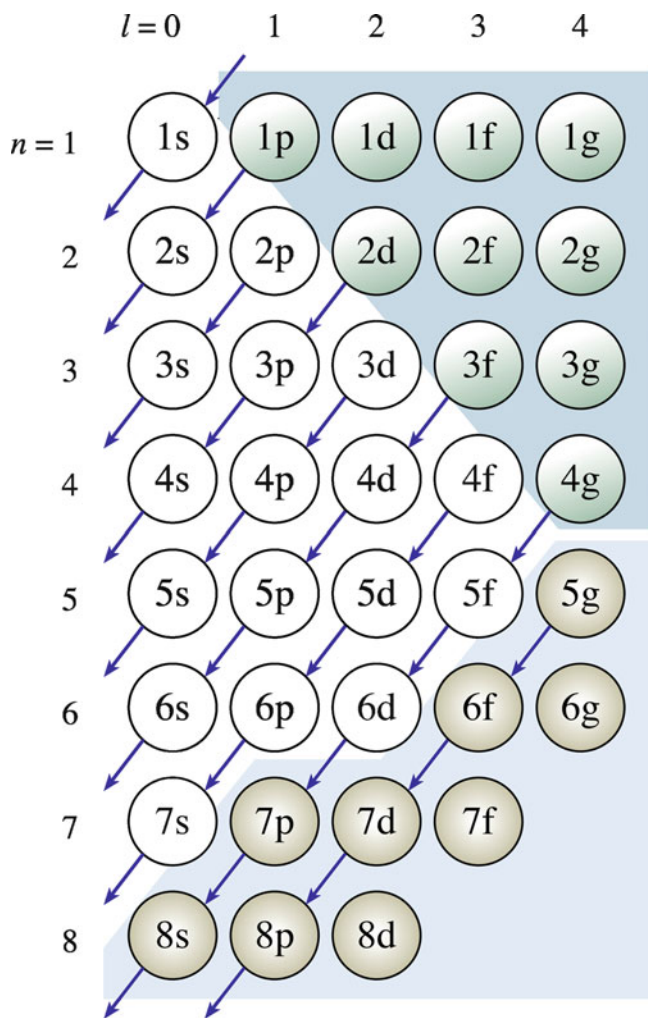

FIGURE 3.3. Mnemonic for predicting the filling order of the atomic orbitals. The upper colored block shows imaginary orbitals. Orbitals in the lower blue block are not filled in the known elements.

In the filling of the electron orbitals for elements 21–29, there are two irregularities: one at 24 (chromium) and one at 29 (copper). Each of these elements contains one 4s electron instead of two. The reason for this apparent anomaly is that exactly filled and half-filled 3d orbitals are particularly stable (they have lower energy) compared to the neighboring occupancies of four and nine, respectively. The electron configurations of the first row transition

TABLE 3.3 Arrangement of Electrons for the First Row Transition Elements ($Z = 21\text{--}29$)

Z	Element	Electron configuration
21	Sc	$1s^2 2s^2 2p^6 3s^2 3p^6 3d^1 4s^2$
22	Ti	$1s^2 2s^2 2p^6 3s^2 3p^6 3d^2 4s^2$
23	V	$1s^2 2s^2 2p^6 3s^2 3p^6 3d^3 4s^2$
24	Cr	$1s^2 2s^2 2p^6 3s^2 3p^6 3d^5 4s^1$
25	Mn	$1s^2 2s^2 2p^6 3s^2 3p^6 3d^5 4s^2$
26	Fe	$1s^2 2s^2 2p^6 3s^2 3p^6 3d^6 4s^2$
27	Co	$1s^2 2s^2 2p^6 3s^2 3p^6 3d^7 4s^2$
28	Ni	$1s^2 2s^2 2p^6 3s^2 3p^6 3d^8 4s^2$
29	Cu	$1s^2 2s^2 2p^6 3s^2 3p^6 3d^{10} 4s^1$

elements are given in Table 3.3. The electron configurations of the first row transition metals are of importance when we discuss electrical conduction and magnetic behavior of ceramics that contain these elements.

The electron configurations of all the elements in the periodic table are shown in Table 3.4, where we used the shorthand representation for the electron configurations (start with the nearest filled noble gas).

Examination of the electron configuration of the elements shows clearly the basis for their periodic behavior. Elements with atomic numbers 2, 10, and 18 are the noble gases. These elements are stable and chemically inert. Inertness is equated with completely filled shells of electrons. Elements with similar outer shell configurations possess many similar properties. Figure 3.4 shows the periodic table of elements. It is clearly a good idea to know where the atoms lie in the periodic table as it determines whether they lose or gain electrons more easily and thus how the ion is charged, as we'll now discuss.

3.6 IONS

In ceramics we are usually dealing with materials that have a significant fraction of ionic character in their bonding. The requirements for ionic bonding are simple.

- One element must be able to lose 1, 2, or 3 electrons.
- The other element must be able to accept 1, 2, or 3 electrons.

54	Xe	[Kr]4d ¹⁰ 5s ² 5p ⁶			
55	Cs	[Xe]6s			

In both cases the “3” is rare, and it must not involve too much energy exchange. The ionization energy (IE) is the energy required to remove an electron from the gaseous atom. The first ionization energy (IE₁) is the energy required to remove one electron from the neutral gaseous atom to produce a gaseous ion with a charge of +1.

FIGURE 3.4. Periodic table of elements as viewed by a ceramist showing atomic numbers and electronegativity. Different colors show the groupings of some of the most important components of traditional ceramics (*blue*) and advanced ceramics (*orange*). Elements that are becoming increasingly important in a number of emerging applications for ceramics are shown in *green*. Other elements, such as Pb (as in PZT), deserve color today but we hope not in the future.

The noble gases, which have a complete shell of outer electrons, have very high ionization energies; whereas the elements in group I (e.g., Na and K), which have an outer ns^1 orbital, have much lower ionization energies. Second ionization energies—the energy required to remove an electron from a gaseous ion with charge +1—are significantly higher than first ionization energies because when an electron is lost the effective nuclear charge, Z_{eff} , increases. As a result, the effective radius of an atom or ion decreases, and the net attraction between the electrons and the nucleus increases (Table 3.5).

The electron affinity (EA) of an atom is the energy change accompanying the addition of one electron to a neutral gaseous atom to produce a negative ion. Values of EA are shown in Table 3.6. A positive value indicates that the reaction

is exothermic.

The values of EA also show a periodic behavior that can be explained by examining the electron

IONIZATION ENERGY

This reaction is always endothermic ($\text{IE}_1 > 0$). The sign is a convention of thermodynamics; some fields use the opposite convention.

ELECTRON AFFINITY

Note: The sign convention used for EA is in contradiction to that usually found in thermodynamics, an unfortunate historical artifact.

configurations of the elements. The electron affinity is high for elements in group VII (e.g., F and Cl). The addition of one electron to these atoms forms negative ions with a noble gas electron configuration—a stable arrangement. Atoms that already have full orbitals (e.g., He, Ne) or half-full orbitals (e.g., Be, N) often have negative electron affinities. Full and half-full orbitals are more stable.

As we'll see in Chapter 4, ionic

compounds generally form only between very reactive metallic elements and very reactive nonmetals. Two requisites are that the ionization energy to form the cation and the electron affinity to form the anion must be energetically favorable. The overall reaction costs some, but not too much, energy.

Recap:

- Ionization energy (IE): the energy required to remove an electron from the neutral gaseous atom
- Electron affinity (EA): the change in energy when one electron is added to a neutral gaseous atom

3.7 ELECTRONEGATIVITY

Electronegativity is a measure of the strength with which an atom in a molecule attracts electrons. Like IE and EA, the dependence of electronegativity on Z can be explained by examining electron configurations. Atoms with almost completely filled outer energy levels (e.g., F and Cl) are strongly electronegative and readily accept electrons. However, atoms with nearly empty outer shells (e.g., Li and Na) readily give up electrons and are strongly electropositive. Higher Z elements also have low electronegativity; because the outer electrons are at a greater distance from the positive nucleus, electrons are not as strongly attracted to the atom.

The electronegativity scale of the elements is included in Figure 3.4 using Pauling's classification. F is assigned the largest electronegativity; four and the other elements are then based on this value. The differences in the

electronegativities of two atoms in a molecule can be used to estimate bond strengths and bond ionicities (i.e., the percentage of ionic characters in the bond—the extent of “mixed” bonding) (see Section 4.6 for numerical examples).

3.8 THERMODYNAMICS: DRIVING FORCE FOR CHANGE

Thermodynamic principles are important in all aspects of materials science. In this section, we introduce some of the fundamentals, but thermodynamics is discussed in several other chapters, such as in regard to point defects in Chapter 11 and to surfaces in Chapter 13. The primary role of thermodynamics in ceramics is to tell us whether a system is stable and what conditions (usually changes in temperature or pressure) can cause it to change. Our system may be a crystal structure, a phase, a grain boundary, an aggregate of powder particles, or a concentration of defects. Table 3.7 lists some of the important thermodynamic parameters we meet in ceramics together with their units.

GIBBS FREE ENERGY

The change in free energy is defined by

$$\Delta G = \Delta H - T\Delta S \quad (\text{Box 3.7})$$

The change in enthalpy is given by

$$\Delta H = \Delta E + P\Delta V \quad (\text{Box 3.8})$$

When the process involves no volume change, i.e., $P\Delta V = 0$, so $\Delta H = \Delta E$ we can write

$$\Delta G = \Delta E - T\Delta S \quad (\text{Box 3.9})$$

TABLE 3.7 Important Thermodynamic Parameters

Parameter	Definition	Units
C_p	Heat capacity at constant pressure	J/K
c_p	Molar heat capacity at constant pressure	J/K.mol
C_v	Heat capacity at constant volume	J/K
c_v	Molar heat capacity at constant volume	J/K.mol
E	Energy	J
G	Gibbs free energy	J
H	Enthalpy	J
μ_i	Chemical potential	J
P	Pressure	Pa
S	Entropy	J/K
T	Temperature	K

3.8.1 Thermodynamic Stability

Gibbs free energy (G) is a property that provides a convenient measure of the driving force of a reaction, and it may be used to define thermodynamic stability. When we want to know whether a process is energetically favorable, we have to determine the change in free energy (ΔG) associated with that process. For the change

which may be an oxidation reaction or a phase transformation, the change in free energy is

$$\Delta G = G_B - G_A$$

where G_B is the free energy of the final state, and G_A is the free energy of the initial state.

- $\Delta G < 0$ for a favorable process. There's a natural tendency to move spontaneously from A to B.
- $\Delta G > 0$ for an unfavorable process. The reaction as written does not proceed spontaneously; the reverse reaction is the spontaneous one.
- $\Delta G = 0$ for a process at equilibrium.

CONVENIENT FORMS OF ΔG

Mixing A and B to form a solution (important in constructing phase diagrams)

$$\Delta G = RT(X_A \ln a_A + X_B \ln a_B)$$

Oxidation of a metal to form a ceramic

$$\Delta G = RT \ln p_{O_2}$$

Electrochemical process (such as in a fuel cell)

$$\Delta G = -zFE = RT \ln p_{O_2}$$

In many processes, particularly those that occur in ceramics, there is little if any volume change, so $P\Delta V = 0$. Because the sign of ΔG is dependent on temperature and pressure, a particular system, such as a crystal structure, can be stable only within a certain range of P and T . By varying P and/or T , ΔG eventually becomes negative relative to some other structure and a phase transition occurs. This may be a transition from one crystal structure to another (e.g., phase transformation in quartz), or it may be a transition from one aggregate state to another state (e.g., during sintering when we get grain growth and a reduction in the total grain boundary area), or it could be when we melt a solid to form a liquid.

Gibbs free energy is a function of temperature, pressure, and the number of moles of all the species present in the system.

3.8.2 Effect of Temperature

Many of the processes of interest in ceramics occur at high temperature. At absolute zero ($T = 0\text{ K}$), the term containing the entropy change, $T\Delta S$, is zero and ΔG depends only on ΔE . However, as T increases, the $T\Delta S$ term becomes increasingly important; and at some temperature a process can occur spontaneously even though ΔE is positive. The values of ΔE and ΔS depend on temperature, and we can rewrite Box 3.9 to account for this.

$$\Delta G_T = \Delta E_T - T\Delta S_T \quad (3.1)$$

The subscript indicates that the values are given at temperature T . To obtain values of ΔE_T and ΔS_T , we need to use the heat capacities of the material.

The molar heat capacities are:

$$c_p = dH/dT \quad (3.2)$$

$$c_v = dE/dT \quad (3.3)$$

In many solids, particularly ceramics, with low coefficients of expansion $c_p \sim c_v$, it is easier to obtain values of c_p , and the variation with temperature is normally fitted to an analytical expression of the form:

$$c_p = a + bT + cT^{-2} \quad (3.4)$$

We use equation 3.4 in Chapter 34 to determine the c_p value for various ceramics.

Using c_p we can obtain expressions for ΔE_T and ΔS_T .

$$\Delta H_T = \Delta H_{298} + \int_{298}^T \Delta c_p dT \quad (3.5)$$

$$S_T = S_0 + \int_0^T \frac{c_p}{T} dT \quad (3.6)$$

If the external work of expansion due to heating is zero (as it is when a material is heated at constant volume) or if it is negligible (as it is when solids are heated at atmospheric pressure), all of the heat supplied goes into internal energy; and we can approximate ΔH_T by ΔE_T . Values of ΔH_{298} are already tabulated. The variation of ΔG with temperature is illustrated in Figure 3.5.

When the signs of ΔE_T and ΔS_T are the same, some reactions that are not favorable at one temperature become favorable at another, and vice versa. It is often useful to know the temperature at which a reaction becomes favorable. This is the temperature at which a positive ΔG_T switches to a negative ΔG_T due to the $-T\Delta S_T$ term. We find this crossover temperature by setting ΔG_T in equation 3.1 equal to 0 and solving for T .

FIGURE 3.5. Variation in Gibbs free energy as a function of temperature. The vertical segments are associated with phase transformations.

FIGURE 3.6. Effect of temperature on reaction spontaneity. The two lines cross when the energy contribution becomes less than the entropy contribution.

$$T = \frac{\Delta E_T}{\Delta S_T} \quad (3.7)$$

Figure 3.6 shows the effect of temperature on reaction favorability. The slopes of the two lines and the crossover temperature depend on the specific system.

FIGURE 3.7. Pressure dependence of Gibbs free energies of carbon in graphite and diamond. Diamond becomes more stable at high pressures.

3.8.3 Effect of Pressure

Higher pressures favor structures that have a higher density. Their formation involves a decrease in volume (negative ΔV). For instance, diamond ($\rho = 3.51 \text{ g cm}^{-3}$) is more stable than graphite ($\rho = 2.26 \text{ g cm}^{-3}$) at very high pressures. At room temperature, graphite transforms to diamond at pressures greater than about 1.5 GPa (14,400 atm.), as shown in Figure 3.7. Graphite is the stable phase at room temperature and pressure. The influence of pressure, at constant T , on the Gibbs free energies of two phases, α and β , is given by

$$\left(\frac{\partial G_{(\alpha \rightarrow \beta)}}{\partial P}\right)_T = \Delta V_{(\alpha \rightarrow \beta)} \quad (3.8)$$

3.8.4 Effect of Composition

In ceramics we are often dealing with multicomponent systems such as the ternary quartz, clay, and feldspar used in the formation of porcelains or the binary NiO and Al_2O_3 that react to form a spinel. Equilibrium, at constant T and P , is reached in these systems when the chemical potential, μ_i , of a component is the same in all of the phases in which it is present. The chemical potential, or the partial molar free energy of a component in a given phase, is defined as

$$\mu_i = \left(\frac{\partial G}{\partial n_i}\right)_{T,P,n_j} \quad (3.9)$$

where n_i is the number of moles of component i , and n_j is the number of moles of component j .

Deduction of the phase rule (Chapter 8), which defines the conditions of equilibrium in terms of the number of phases and the components of a system, follows directly from the requirement that μ_i of each constituent i be the same in every phase at equilibrium. If μ_i is different, we get a reaction, the rate of which is determined by kinetics.

We can combine equation 3.9 with our definition of Gibbs free energy and produce a differential form of the Gibbs equation.

$$\partial G = V\partial P - S\partial T + \sum \mu_i \partial n_i \quad (3.10)$$

The importance of equation 3.10 is that it links the free energy of the system to our usual experimental variables (T and P) and the observable properties (V and concentration).

3.9 KINETICS: SPEED OF CHANGE

Thermodynamics tells us whether a process can happen. Kinetics tells us whether that process will happen at a reasonable, or measurable, rate. The rates of chemical reactions have been found to depend very strongly on the temperature. A useful rule of thumb is that the rate doubles for every 10 K increase in temperature. The rate, k , of many reactions follows the Arrhenius rate law

$$k = A \exp - (E_a/RT) \quad (3.11)$$

where R is the gas constant ($8.314 \text{ JK}^{-1} \text{ mol}^{-1}$); A is a temperature-independent preexponential constant; and E_a is the activation energy. A plot of k versus T gives a curve that increases exponentially. The activation energy represents the minimum energy required for a reaction to happen. The value of E_a may be determined from the logarithmic form of the Arrhenius equation.

$$\ln k = \frac{E_a}{RT} + \ln A \quad (3.12)$$

A plot of $\ln k$ against $1/T$ yields a straight line with slope $-E_a/R$, as shown in Figure 3.8. This type of plot is called an Arrhenius plot, and a reaction giving such a straight line is said to show Arrhenius behavior.

Most reactions that proceed at a moderate rate (i.e., occur appreciably in minutes or hours) have values of E_a between 50 and 100 kJ. For such reactions, you can use equation 3.11 to verify the photographer's guide that reactions go two or three times as fast when the temperature increases by 10°C .

An important example of a process that exhibits Arrhenius behavior is diffusion. The diffusion coefficient D (units of cm^2/s) is a strong function of temperature.

$$D = D_0 \exp(-E_a/RT) \quad (3.13)$$

For ceramics, the value of E_a varies over quite a wide range, from about 50 to 800 kJ/mol ($\sim 0.5\text{--}8 \text{ eV}$ per atom).

FIGURE 3.8. Arrhenius plot. The slope of the line indicates the activation energy for the process.

The activation energy represents the energy necessary for an atom to jump from one atomic position to another.

The diffusion coefficient also depends on chemical potential and time. These changes are represented in Fick's laws, which we describe in Chapter 11.

At sufficiently low temperatures, any structure can be stabilized kinetically. Kinetic stability is not a well-defined term because the limit below which a conversion rate is considered to be negligible is arbitrary. There are many examples of kinetically stabilized materials. Two examples in ceramics are:

- Glasses. At room temperature, a glass is a kinetically stabilized material. Given enough time, all glasses transform to their crystalline counterpart.
- Tridymite (a high-temperature polymorph of SiO_2). Transformation of quartz at 867°C should lead to the formation of tridymite. However, the transformation is very slow (it involves complete alteration of the crystal structure), and direct conversion by heating alone has not been proved. All natural tridymite contains other oxides, which it is believed stabilize the structure. Pure tridymite cannot be obtained at room temperature.

Notice that we have not considered the environment of the combining atoms/ions, so we have not actually used the crystal/amorphous nature of the ceramic.

CHAPTER SUMMARY

We reviewed some of the fundamentals that underpin all aspects of materials science. Knowing the electron configuration of an atom allows us to understand some of the properties of materials that contain that atom. It also helps us determine the type of bonding that occurs between different atoms. In ceramics, the bonding is important because it is not straightforward. It often involves ionic and covalent contributions and sometimes also a metallic component.

Thermodynamics and kinetics enable us to explain why and how chemical reactions take place. This information is important in many areas of ceramics but particularly in ceramic processing. Traditional processing of ceramic components is carried out at high temperatures because the kinetics would be too slow otherwise. Kinetics is often closely linked with economics. Processes that are slow are usually expensive.

PEOPLE AND HISTORY

Arrhenius, Svante August. He won the 1903 Nobel Prize in Chemistry for his work on the electrical conductivity of salt solutions (he was also nominated for the Physics Prize). He is often hailed as a pioneer of modern environmentalism for his work on the greenhouse effect. One of his predictions was that the United States might pump its last barrel of oil in 1935. Fortunately, he was proved wrong, but his concern about the world's natural mineral resources and the need for alternative sources of energy was prescient. He died in 1927 aged 68.

Barkla, Charles Glover (1877–1944). He was born in Widnes, Lancashire, England. After obtaining his master's degree in physics he went to work in the Cavendish Laboratory with J.J. Thomson. In 1913, he accepted the position of Chair in Natural Philosophy in the University of Edinburgh in Scotland; and he remained there until he died. He was awarded the 1917 Nobel Prize in Physics for his discovery of the characteristic röntgen radiation of the elements.

Bohr, Neils (Denmark): In 1913, he proposed an atomic model where electrons could only move in certain stable orbits. He won the Nobel Prize in Physics in 1922 and died in 1962 at age 77.

Boltzmann, Ludwig Eduard. He was born in Vienna in 1844 and died aged 62. His “constant” is inscribed on his tomb in Vienna. Many argued strongly against his ideas, and he committed suicide shortly before experiments justified them.

Davisson, Clinton Davis and Germer, Lester Halbert. They were working at Bell Labs at the time of their discovery of electron diffraction. Davisson died in 1958 aged 76. Germer died in 1971 at age 75.

de Broglie, Louis. In 1924, he hypothesized that all matter possesses wave properties. A French Duke, he won the Nobel Prize in Physics in 1929. He died in 1987 at age 94.

Heisenberg, Werner (1901–1976). He was born in Würzburg, Germany. He obtained his Ph.D. in 1923 at the University of Munich. His theory of quantum mechanics was published at age 23, and he was awarded the 1932 Nobel Prize in Physics for this theory. At the end of World War II he was taken prisoner by American troops and sent to England. He returned to Germany in 1946. He was Director of the famous Max Planck Institute for Physics and in 1953 became President of the Alexander von Humboldt Foundation. He died in 1976 aged 74.

Pauli, Wolfgang (1900–1958). Born in Vienna, Austria, he obtained his doctoral degree in 1921 from the University of Munich. After that he worked with Max Born and then with Neils Bohr. He held various appointments in the United States during World War II, including at the Institute of Advanced Study in Princeton. After the war he returned to the Federal Institute of Technology in Zurich as professor of theoretical physics. He won the 1945 Nobel Prize in Physics for developing the eponymous exclusion principle.

Pauling, Linus Carl. Pauling won the Noble Prize for Chemistry in 1954 and for Peace in 1962. He died in 1994 at age 93.

Schrödinger, Erwin. He was born in Vienna, Austria in 1887. His great discovery, Schrödinger's wave equation, was made in 1926. He won the Nobel Prize in Physics in 1933 for that work. When Hitler came to power in Germany (1933), he moved to England. He moved back to Austria but had to escape when his native country became annexed in 1938. He eventually moved to the Institute for Advanced Studies in Dublin where he remained until he retired. He died in 1961 at age 73.

Thomson, Joseph John and Thomson, George Paget. These men were father and son. Rutherford was J.J.'s student at Cambridge. The elder Thomson discovered the electron in 1897 and won the Nobel Prize in Physics in 1906. His son, G.P. Thomson, won the same Nobel Prize in 1937 together with Davisson. He died in 1976 (born 1892). Thus, the father “proved” that electrons were particles, and the son “proved” they were waves.

EXERCISES

- 3.1 Explain the trend in the first ionization energies of elements in the second row (Na to Cl) of the periodic table.
- 3.2 Explain the trend in ionization energies of singly charged ions of the halogens.
- 3.3 Explain the trend in electron affinities of elements in the second row (Na to Cl) of the periodic table.
- 3.4 What is the ionization energy of F? Would you expect the process of ionization to be endothermic or exothermic?
- 3.5 Calculate the energy of the Na $3s^1$ electron. The value of the first ionization energy for Na is 0.50 MJ/mol. Explain the difference, if any, between these two numbers.
- 3.6 Explain the trend in Pauling electronegativities of elements in the second row (Na to Cl) of the periodic table.
- 3.7 An electron has the principal quantum number four. What are the possible values of l , m_l , and m_s for this electron?
- 3.8 Determine the activation energy for the reaction shown in Figure 3.8.
- 3.9 Even though glasses are not thermodynamically stable, we know they exist at room temperature. Explain this phenomenon and describe briefly how you could increase the rate at which a glass would crystallize.
- 3.10 Show that the volume change for the transformation graphite \rightarrow diamond is negative.
- 3.11 In Table 3.3 we highlighted the electron configurations of Cr and Cu. What is special about the electron configurations of these particular elements?
- 3.12 As you go down a column in the periodic table, you generally find that the electronegativity decreases for the main group elements. In contrast, as you go down a column of transition metal atoms, there is no consistent trend in electronegativity values. Why?
- 3.13 The Gibbs free energy of formation of Ag_2O at room temperature is -11 kJ and for Cu_2O the corresponding value is -142 kJ. What do these numbers imply about these two oxides?
- 3.14 Why is temperature so important in ceramics?
- 3.15 The activation energy for migration of gold nanoparticles on gallium nitride has been determined to be 27 kJ/mol. (1) Convert this number to eV. (2) Would you expect the activation energy to be the same for gold nanoparticles on all ceramics? Briefly justify your answer.
- 3.16 Discuss the sign used for E that says the reaction is exothermic when EA is positive.
- 3.17 Using the four journals in question 1.20, give 10 exceptions to the “shading rule” in Figure 3.4.
- 3.18 Is the crossover in Figure 3.7 what and where you would expect?
- 3.19 When is 50 kJ/mol approximately equal to 0.5 eV/atom?
- 3.20 We say that “a useful rule of thumb is that the rate doubles for every 10 K increase in temperature.” Discuss this statement.

Bonds and Energy Bands

CHAPTER PREVIEW

Bonding in ceramic materials may be quite complicated. It is primarily covalent and/or ionic, but it may also have a metallic component, a van der Waals component, and so on. In this chapter we review the basic types of primary and secondary bonds and see how they apply to ceramics. We also review the concept of energy bands, which is used when we discuss electrical properties later. The purpose of this chapter is to review the concepts that we use throughout the text. If it is not a review for you, suggestions are given for suitable texts that can give you the details. Important topics include the type of bonding, the origin of hybridization, mixed bonding, and energy bands.

4.1 TYPES OF INTERATOMIC BOND

We can divide interatomic bonds into two categories.

- Primary (strong) bonds
- Secondary (weak) bonds

The types of primary and secondary bonds and their energy ranges are given in Table 4.1. In the next few sections we briefly review the general characteristics of these bonds.

All interatomic forces are electrostatic in origin. The simplest expression for the bond energy is:

$$E = -\frac{A}{r^n} + \frac{B}{r^m} \quad (4.1)$$

where r is the interatomic distance; and A , B , n , and m are constants characteristic of the type of bonding. The first term is the attractive component, and the second is due to repulsion. Only when $m > n$ is a minimum (equilibrium) value of E possible. Equation 4.1 says that attractive forces predominate when atoms are far apart and repulsive interactions predominate when the atoms are close together. The bond–energy curve can be plotted as shown in Figure 4.1A. When the energy is a minimum, the atoms are at their equilibrium separation ($r = r_0$); the lowest energy state defines the equilibrium condition. When discussing ceramics, we usually think of the material in terms of ions; ions with the same sign always repel one another due to the Coulomb force.

If we differentiate equation 4.1 with respect to r , we obtain an equation that describes the resultant force F between a pair of atoms

$$F = \frac{dE}{dr} = \frac{nA}{r^{n+1}} - \frac{mB}{r^{m+1}} \quad (4.2)$$

The force is zero at the equilibrium separation.

Sign conventions for force: In Figure 4.1A the force is attractive when F is positive. This is the usual convention in materials science (and in Newton’s law of universal gravitation). The force is attractive if $A > 0$ and negative if $A < 0$. Beware: in electrostatics, the convention is that a negative force is attractive.

4.2 YOUNG’S MODULUS

We can change the equilibrium spacing (r_0) of the atoms in a solid by applying a force. We can push the atoms closer together (compression), $r < r_0$, or pull them farther apart (tension), $r > r_0$. Young’s modulus (E) is a measure of the resistance to small changes in the separation of adjacent atoms (*modulus* is Latin for “a small measure”). It is the same for both tension and compression.

Young’s modulus is related to the interatomic bonding forces; and, as you might expect, its magnitude depends on the slope of the force–distance curve at r_0 .

Close to r_0 the force–distance curve approximates a tangent; when the applied forces are small, the displacement of the atoms is small and proportional to the force. We can define the stiffness of the bond, S_0 , as the slope of this line.

$$S_0 = \left(\frac{dF}{dr} \right)_{r=r_0} = \left(\frac{d^2E}{dr^2} \right)_{r=r_0} \quad (4.3)$$

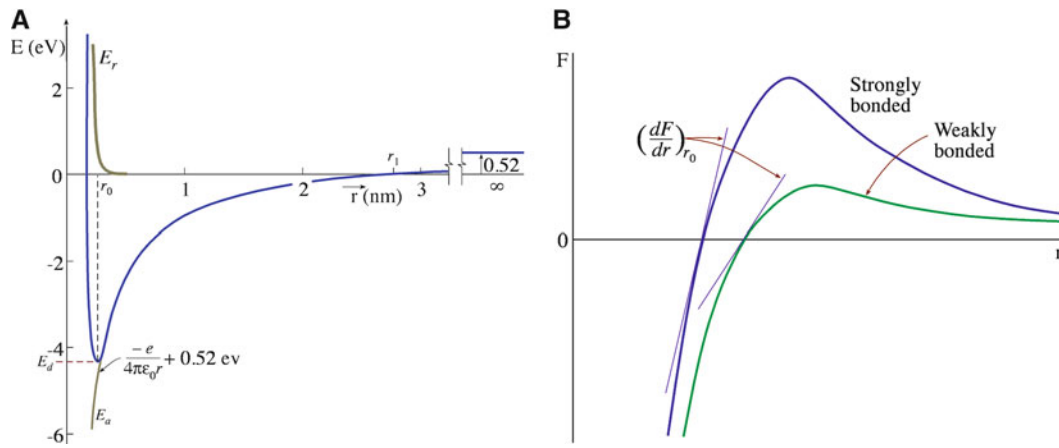

FIGURE 4.1. (A) Bond–energy curve for KCl. At infinite separation, the energy is that required to form K^+ and Cl^- from the corresponding atoms. (B) Force–distance curves for two materials: one where the bonding is strong and one where it is weak.

TABLE 4.1 Typical Bond Strengths

Type of bond	Bond energy (kJ/mol)
Ionic	50–1,000
Covalent	200–1,000
Metallic	50–1,000
van der Waals	0.1–10
Hydrogen	10–40

The stiffness is analogous to the spring constant or elastic force constant of a spring and is the physical origin of Hooke’s law. Close to r_0 we can assume that the force between two atoms that have been stretched apart a small distance r is

$$F = S_0(r - r_0) \quad (4.4)$$

If we consider pulling two planes of atoms apart then the total force per unit area can be obtained by dividing F by r_0^2

$$\frac{F}{r_0^2} = \sigma = \frac{S_0(r - r_0)}{r_0^2} = \frac{S_0}{r_0} \left(\frac{r - r_0}{r_0} \right) = \mathcal{E}\epsilon \quad (4.5)$$

where σ and ϵ should be familiar to you already—they are stress and strain, respectively. Moduli obtained from this approach are approximate because they relate to two atoms only, ignoring the effects of neighboring atoms. (Although we only discussed Young’s modulus here, the conclusions are applicable to the other elastic moduli we describe in Chapter 16). As the interatomic spacing, and in some cases the bonding, varies with direction in a single crystal, Young’s modulus is dependent on the direction of stress in relation to the crystal axes. Single crystals are elastically anisotropic.

Figure 4.1B shows force–distance plots for two materials: one that has weakly bonded atoms and the

TABLE 4.2 Young’s Modulus as a Function of Melting Temperature

Compound	Average young’s modulus (GPa)	Melting temperature ($^{\circ}C$)
Titanium carbide	310	3,180
Tungsten	414	2,996
Silicon carbide	345	Sublimes > 2,800
Periclase (MgO)	207	2,800
Beryllia (BeO)	310	2,585
Spinel (MgAl ₂ O ₄)	241	2,160
Corundum (Al ₂ O ₃)	366	2,050

Copper	110	1,083
Halite (NaCl)	34	801
Aluminum	69	660
Magnesium	41	650
Polystyrene	2.8	<300
Nylon	2.8	<300
Rubber	0.07	<300

other strongly bonded atoms. With reference to bond–energy curves, a material with a high modulus has a narrow, steep potential energy well; a broad, shallow energy well is characteristic of a low modulus. Table 4.2 lists values of Young’s moduli for different materials as a function of melting temperature. You can see the general trend: the higher the melting temperature, the higher the modulus. Melting temperatures are also indicative of bond strengths, which are determined mainly by the depth of the energy well. The modulus is determined by the curvature at the bottom of the well. It is this difference that accounts for deviations from the general trend.

As the temperature of a material increases, Young’s modulus generally slowly decreases, as shown for single-crystal aluminum oxide (corundum) in Figure 4.2. As the temperature approaches absolute zero, the slope of the curve approaches zero as required by the third law of thermodynamics. (The entropy of any pure substance in

FIGURE 4.2. Temperature dependence of Young's modulus for corundum.

complete internal equilibrium is zero). An empirical relationship that fits the data for several ceramics is

$$E = E_0 - bT \exp\left(\frac{-T_0}{T}\right) \quad (4.6)$$

where E_0 is Young's modulus at absolute zero; b and T_0 are empirical constants; and T_0 is about half the Debye temperature. (The Debye temperature is that at which the elastic vibration frequency of the atoms in a solid is maximum.) As the temperature increases, the separation between the atoms is increased and the force necessary for further increases is slightly decreased.

For polycrystalline ceramics there is an additional effect due to grain boundaries. At high temperatures there is a rapid decrease in the measured values of Young's moduli, as shown in Figure 4.3. This has been attributed to non-elastic effects such as grain boundary sliding and grain boundary softening. Young's modulus of a bulk ceramic continues to change as described by equation 4.6 but we are measuring changes due to the grain boundaries. The importance of grain boundaries in the mechanical behavior of ceramics will become apparent in later chapters.

4.3 IONIC BONDING

In a pure ionic bond there is complete transfer of electrons from one atom to another. Pure ionic compounds do not exist. Although compounds such as NaCl and LiF are often thought of as being ionic, in general all such "ionic" solids have a covalent component.

The requirement for ionic bonding is that the ionization energy to form the cation and the electron affinity to form the anion must both favor it energetically. The formation of isolated ions from isolated atoms requires energy; and thus the formation of the pair of ions would not give a

FIGURE 4.3. Temperature dependence of Young's modulus for several polycrystalline ceramics.

stable situation. However, the pair of ions have a strong mutual attraction that leads to strong binding in the molecule. Because the Coulomb force is strong and long range, many ionic compounds have high melting and high boiling temperatures. Ionic bonds do not favor particular directions. This is very different from covalent bonding.

4.3.1 Energy of an Ion Pair

Before considering a lattice of ions, we consider a single pair of oppositely charged ions separated by a distance r . The electrostatic attractive energy E is

$$E = - \frac{|Z_M||Z_X|e^2}{(4\pi\epsilon_0 r)} \quad (4.7)$$

where Z_m and Z_x are the charges on the cation and anion, respectively. The negative sign in equation 4.7 means that as r becomes smaller the energy becomes increasingly more negative. To obtain equilibrium separation, there must be repulsion to balance the attraction.

TABLE 4.3 Values of the Born Exponent

Ion configuration	No.
He	5
Ne	7
Ar, Cu ⁺	9
Kr, Ag ⁺	10
Xe, Au ⁺	12

Strong repulsive forces arise when the full electron orbitals of both ions overlap because some electrons then must go into higher energy states in accordance with the Pauli exclusion principle. The repulsion energy rises rapidly with decreasing distance between the ions.

The repulsive energy is often given by an equation of the form

$$E_r = \frac{B}{r^n} \quad (4.8)$$

where B is a constant, and n is known as the Born exponent. Information about the Born exponent may be obtained from compressibility data because we are measuring the resistance of the ions to be closer together than r_0 . The Born exponent depends on the type of ion involved. Larger ions have higher electron densities and hence larger values of n (Table 4.3).

The total energy of the ion pair is given by summing equations 4.7 and 4.8

$$E = -\frac{|Z_M||Z_X|e^2}{(4\pi\epsilon_0 r)} + \frac{B}{r^n} \quad (4.9)$$

The inset in Figure 4.1A shows how when r is large the bond energy is >0 because of the net energy involved in forming the ion pair.

4.3.2 Madelung Constant

In a crystal lattice, all of the ions interact. The interaction between ions with opposite charge is attractive and is repulsive between ions of like charge. The summation of all these interactions is known as the Madelung constant, \mathcal{A} (Madelung 1918). The energy per ion pair in the crystal is then

$$E = -\frac{\mathcal{A}|Z_M||Z_X|e^2}{(4\pi\epsilon_0 r_0)} \quad (4.10)$$

The Madelung constant is defined as the ratio of the Coulomb energy of an ion pair in a crystal to the Coulomb energy of an isolated ion pair at the same separation (the equilibrium separation of the ions in the crystal not in an isolated pair).

$$\mathcal{A} = \sum_i -\frac{Z_i Z_j}{|Z_1||Z_2|r_{ij}} \quad (4.11)$$

MADELUNG CONSTANT FOR LINEAR ARRAY

For the infinite linear array of ions shown in Figure 4.4 we obtain

$$\mathcal{A} = 2[1 - 1/2 + 1/3 - 1/4 + \dots]$$

The factor 2 occurs because there are two ions, one to the right and one to the left of our reference ion, at equal distances r_{ij} . We sum this series using the expansion

$$\ln(1+x) = x - x^2/2 + x^3/3 - x^4/4 + \dots$$

Thus the linear Madelung constant

$$\mathcal{A} = 2 \ln 2.$$

FIGURE 4.4. Linear array of ions of alternate signs separated by r_0 .

FIGURE 4.5. NaCl structure showing distances between ions in multiples of r_0 .

The distance r_{ij} is the separation between ions at equilibrium in multiples of r_0 .

In three dimensions, the series presents greater difficulty than the linear example. It is not possible to write down the successive terms by quick inspection. More importantly, the series only converges slowly and keeps reversing in sign so you have to consider the whole infinite crystal. An approach we can use to obtain \mathcal{A} for a three-dimensional crystal structure is illustrated for NaCl (Figure 4.5). Let us consider the interactions between the

TABLE 4.4 Madelung Constants of Some Common Crystal Structures

Structure	Coordination number	Geometrical factor \mathcal{A}
Sodium chloride	6:6	1.74756
Cesium chloride	8:8	1.76267
Zinc blende	4:4	1.63806
Wurtzite	4:4	1.64132
Fluorite	8:4	2.51939
Rutile	6:3	2.408 ^a
Corundum	6:4	4.1719 ^a

^aValue of \mathcal{A} depends on details of the structure

central cation and all of the other ions in the cell. Due to electroneutrality requirements in the unit cell, ions located on the cube faces count 1/2, those on the cell edges count 1/4, and the corner ions count 1/8. (This is the same approach that you use when determining the number of atoms per cell).

Using equation 4.11, we obtain

$$\mathcal{A} = -(6/2)(-1)/1 - (12/4)(1)/\sqrt{2} - (8/8)(-1)/\sqrt{3}$$

Hence

$$\mathcal{A} = 3 - 2.1212 + 0.5774 = 1.456$$

If we consider a larger cell size, the value we obtain for the Madelung constant is closer to that determined for the NaCl structure using computer calculations. Doubling the length of the cell edge gives $\mathcal{A} = 1.75$. These simple calculations are a little misleading because the sum is really infinite. There are two important points.

- \mathcal{A} is well defined for a particular crystal structure; it is usually ~ 2 .
- \mathcal{A} is unique for a particular crystal structure; that is, it is the same for NaCl and MgO.

Table 4.4 lists Madelung constants for some common crystal structures. The value of the Madelung constant is determined only by the geometry of the lattice and is independent of the ionic radius and charge. Unfortunately, some tables incorporate ionic charge, so care is necessary when looking up and comparing values. For example, the Madelung constant for fluorite may be given as 5.038 and that of Al_2O_3 as 25.031; the constant for MgO may then be given as different to that for NaCl.

Table 4.4 confirms that the value of the Madelung constant for all of these different crystal structures is > 1 . The implication is that the crystal is more stable than an isolated ion pair. The fact that the Madelung constant for the NaCl structure, which has six nearest neighbors, is close to the Madelung constant of the CsCl structure, which has eight nearest neighbors, indicates that

- The number of neighbors does not significantly influence the lattice energy.

- The Coulomb energy does not depend on the type of crystal structure.

In Chapter 5 we'll see that packing is the most important consideration in determining the structure adopted by predominantly ionically bonded crystals. The difference in \mathcal{A} between some crystal structures is very small. In such cases (e.g., the zinc blende and wurtzite structures—named after the two crystalline forms of ZnS), the difference in the resulting electrostatic energy is small. For zinc blende and wurtzite, it is $\sim 0.2\%$. When the energy difference between structure types of the same stoichiometry is small, we often encounter polymorphism: the compound can form with more than one structure. We examine this useful complication in Chapter 7.

4.3.3 Lattice Energy

With knowledge of the Madelung constant, we can write the total energy for one mole of the crystal lattice containing an Avogadro's number (N) of ion pairs

$$E = -\frac{\mathcal{A}N|Z_M||Z_X|e^2}{(4\pi\epsilon_0 r)} + \frac{NB}{r^n} \quad (4.12)$$

The minimum energy, E_0 , at r_0 is obtained by differentiating equation 4.12 with respect to r .

$$\frac{dE}{dr} = 0 = \frac{\mathcal{A}N|Z_M||Z_X|e^2}{(4\pi\epsilon_0 r_0^2)} - \frac{nBN}{r_0^{n+1}}$$

The constant B is then

$$B = \frac{\mathcal{A}N|Z_M||Z_X|e^2 r_0^{n-1}}{4\pi\epsilon_0}$$

Rewriting equation 4.12 gives the Born-Landé equation, which is quite successful in predicting accurate values of the lattice energy of an ionic compound.

$$E_0 = -\frac{\mathcal{A}N|Z_M||Z_X|e^2}{4\pi\epsilon_0 r_0} \left(1 - \frac{1}{n}\right) \quad (4.13)$$

It requires only knowledge of the crystal structure (to choose \mathcal{A} correctly) and r_0 . Both parameters are readily available from X-ray diffraction data.

As an example of using equation 4.13, let us calculate the value of E_0 for MgO. We need to substitute the following values:

$$\begin{aligned} \mathcal{A} &= 1.748 \text{ (from Table 4.4)} \\ n &= 8 \text{ (an average value based on Table 4.3)} \\ r_0 &= 210 \text{ pm (from X-ray diffraction data)} \end{aligned}$$

This gives $E_0 = -4,046.8 \text{ kJ/mol}$.

The terms in equation 4.1 are modified in other models because it would be surprising for one value of n to fit all atoms when we have no physical justification for any particular number. For example, the repulsion term may be represented by

$$E_r = be^{-(r/\rho)} \quad (4.14)$$

where b and ρ are constants determined from compressibility measurements. This gives the Born–Mayer equation (Born and Mayer 1932) for lattice energy.

$$E_0 = -\frac{\mathcal{A}N|Z_M||Z_X|e^2}{4\pi\epsilon_0r_0} \left(1 - \frac{\rho}{r_0}\right) \quad (4.15)$$

The Born–Mayer equation emphasizes the fact that equation 4.1 is designed purely to match the observed phenomenon. It is not a fundamental “truth” like the Coulomb interaction.

4.3.4 Born-Haber Cycle

The Born-Haber (Born 1919; Haber 1919) cycle shows the relationship between lattice energy and other thermodynamic quantities. It also allows the lattice energy to be calculated. The background to the Born-Haber cycle is Hess’s law, which states that the enthalpy of a reaction is the same whether the reaction proceeds in one or several steps. The Born-Haber cycle for the formation of an ionic compound is shown in Figure 4.6. It is a necessary condition that

$$\Delta H_f = \Delta H_{AM} + \Delta H_{AX} + \Delta H_{IE} + \Delta H_{EA} + E \quad (4.16)$$

or in terms of the lattice energy

$$E = \Delta H_f - \Delta H_{AM} - \Delta H_{AX} - \Delta H_{IE} - \Delta H_{EA} \quad (4.17)$$

where ΔH_{AM} and ΔH_{AX} are the enthalpies of atomization of the metal and the nonmetal, respectively. For gaseous diatomic molecules, ΔH_A is the enthalpy of dissociation (bond energy plus RT) of the diatomic molecule.

FIGURE 4.6. Born-Haber cycle.

For metals that vaporize to form monatomic gases, ΔH_A is identical to the enthalpy of sublimation. If a diatomic molecule M_2 sublimes, the dissociation enthalpy of the reaction ($M_2 \rightarrow 2M$) must also be included. As defined earlier, E is the lattice energy of the crystal and represents the heat of formation per mole of a crystal MX from $M_{(g)}^+$ and $X_{(g)}^-$.

As an example of using the Born-Haber cycle, we calculate the lattice energy of MgO . The values of the various thermodynamic parameters can be found in Kubaschewski et al. (1993), Johnson (1982), and the NIST-JANAF tables (Chase 1998).

For MgO :

ΔH_f	−601.7 kJ/mol
ΔH_{AM}	147.7 kJ/mol
ΔH_{AX}	249 kJ/mol [The actual value for the dissociation enthalpy is 498 kJ/mol, but we need to take half of this value because we are considering the reaction $1/2O_2(g) \rightarrow O(g)$.]
ΔH_{IE}	2,188 kJ/mol
ΔH_{EA}	−638 kJ/mol

By substitution into equation 4.17, we get $E = -2,548.4$ kJ/mol.

If we compare this value with that calculated using the Born-Landé equation, we see that they are quite different. The Born-Haber cycle gives a lattice energy about 60% higher than the Born-Landé value. The reason for this difference is that although we often regard MgO as essentially an ionic ceramic it has an appreciable covalent character. If similar calculations, using the Born-Landé equation and the Born-Haber cycle, are performed for $NaCl$ or one of the other alkali halides, the values obtained using the two methods agree to within 1–2% as shown in Table 4.5. The differences in the above calculations are sometimes used as a means of defining an ionic compound—if the results are similar, it must be ionic. Although this definition is not very useful within the context of ceramics, it does serve as an illustration that the bonding in most ceramics is not simply ionic.

TABLE 4.5 Lattice Energies of Some Alkali and Alkaline Earth Metal Halides at 0 K

Compound	Born-Haber cycle	Born-Landé equation
NaF	−910	−904
NaCl	−772	−757
NaBr	−736	−720
NaI	−701	−674

KI	−646	−623
CsF	−741	−724
CsCl	−652	−623
CsI	−611	−569
MgF_2	−2,922	−2,883
CaF_2	−2,597	−2,594

4.3.5 Ionic Radii

We know from quantum mechanics that atoms and ions do not have precisely defined radii. However, the concept of an ion as a hard sphere with a fixed radius is useful when predicting crystal structures. Experimental evidence shows that such a model has some justification: the model often “works.” Nevertheless, always bear in mind that atoms and ions are not rigid spheres, and their size is affected by their local environment.

We cannot measure ionic radii directly. What we can measure rather easily, and with high accuracy using X-ray crystallography, in most crystals is r_0

$$r_0 = r_M + r_X \quad (4.18)$$

where r_M is the radius of the cation (usually a metal), and r_X is the radius of the anion.

To obtain ionic radii, it is necessary to fix the radius of one of the ions in equation 4.18. Historically, the radius of the I^- ion was fixed, and the other radii were calculated with respect to it (Landé 1920). Later, Pauling (1960) produced a consistent set of ionic radii that have been used widely for many years. Many mineralogists use

Goldschmidt’s values. The most comprehensive set of ionic radii is that compiled by Shannon and Prewitt (1969) and revised by Shannon (1976). Table 4.6 lists Shannon’s ionic radii. Although there are several different tabulations, they are for the most part internally consistent. It is important, though, to use radii from only one data set. Never mix values from different tabulations.

There are several important trends in the sizes of ions.

- The radii of ions within a group in the periodic table increase with increasing Z (this is for main group elements; the transition metals often behave differently).
- The radius of a cation is smaller than the corresponding atom.
- The radius of an anion is larger than the corresponding atom.
- In a particular row of the periodic table, the anions are bigger than the cations.

Using X-ray methods, it is possible to obtain accurate electron density maps for ionic crystals. Those for NaCl and LiF are shown in Figure 4.7. It has been suggested that

the minimum in the electron density contours between the nuclei could be taken as the radius position for each ion. The ionic radii values obtained by this method differ somewhat from those obtained by other methods and tend to make the anions smaller and the cations larger. Notice that the electron density does not go to zero in the region between nuclei, even for “ionic” crystals.

4.4 COVALENT BONDING

A pure covalent bond forms when atoms that have the same electronegativity combine; the electrons are shared equally. Such a bond occurs only between identical atoms. Examples of pure covalent bonds are the C–C bond in diamond and the Si–Si bond in silicon. If the atoms have similar electronegativities, a bond can form that has a large covalent component. The most important such bonds for ceramics are the Si–O bond found in silicates and the Al–O bond in alumina.

The bond–energy curve for a covalent bond has the same general shape as that shown in Figure 4.1A. The main difference is that we don’t have the additional energy term associated with the formation of ions. The forces involved are still electrostatic.

- Attractive forces: between the electrons of one atom and the nucleus of the neighboring atom
- Repulsive forces: between electrons on neighboring atoms

4.4.1 Molecular Orbitals

One way to consider covalent bond formation is to look at what happens to the individual atomic orbitals (AOs) on adjacent atoms as they overlap at short distances to form molecular orbitals (MOs). The simplest case is that of two 1s orbitals. At relatively large separations (≥ 1 nm), the electron orbital on one atom is not influenced significantly by the presence of the other atom. As the two atoms approach each other, the orbitals overlap and the electron density between the nuclei increases. At r_0 , the individual AOs become a single MO—called a bonding MO—with the electron density concentrated between the nuclei.

A bonding MO can be described as the sum of the wave functions of the contributing AOs

$$\psi_{\text{Bond}} = \psi_A + \psi_B \quad (4.19)$$

The probability of finding an electron at a given point in the MO is proportional to ψ_{Bond}^2

$$(\psi_{\text{Bond}})^2 = (\psi_A + \psi_B)^2 \quad (4.20)$$

Equation 4.20 is shown as a function of internuclear distance in Figure 4.8.

We can represent an MO pictorially, similar to the way we do for AOs—by outlining a shape that encloses most of the electron density and consequently is given by the molecular wave function. Figure 4.9 represents the bonding MO formed by the combination of two 1s AOs. Because regions of high electron density lie between the atoms, covalent bonds are directional. The directional

FIGURE 4.8. Distribution shows the probability of finding an electron at a given point in a molecular orbital (MO) as a function of distance.

FIGURE 4.9. Representation of a bonding MO obtained by summing two atomic orbitals (AOs). In this case the example is H_2 .

ON THE CONVENTION OF ASSIGNING COORDINATE AXES

The line that connects the nuclei in a diatomic molecule is designated the z axis and is thus common to both nuclei. The two sets of corresponding x and y axes are parallel.

nature greatly influences the atomic arrangements in covalently bonded solids and their mechanical properties. Diamond, a purely covalently bonded ceramic, is the hardest known material.

We can also form an MO—called an antibonding MO—by subtracting the wave functions of the contributing orbitals.

$$\psi_* = \psi_A - \psi_B \quad (4.21)$$

In the antibonding MO, illustrated in Figure 4.10, the electron density is greatly reduced in the overlap region and is zero midway between the nuclei. The antibonding MO is less stable than the isolated AOs from which it is derived and consequently higher in energy.

The MOs that are symmetrical when rotated around a line joining the nuclei are called sigma (σ) MOs. The bonding and antibonding MOs are referred to as σ^b and σ^* , respectively. Figure 4.11 shows the relative energies of

FIGURE 4.10. Representation of the formation of an antibonding MO. An appropriate example is again H_2 .

FIGURE 4.11. Energy level diagram for the H_2 MOs and the corresponding AOs.

these MOs at r_0 . We can construct two MOs from two $1s$ AOs that have the same energy. The bonding MO has lower energy than the AOs, and the antibonding MO has higher energy.

We can also form MOs from the overlap of p orbitals. There are three p orbitals that are equivalent in shape and volume but point along different coordinate axes. Figure 4.12 shows six kinds of MO formed from overlap of the p_x , p_y , and p_z orbitals.

The overlap of the p_z orbitals is qualitatively similar to the overlap of s orbitals; and the bonding MO is designated σ_z^b . The two p_x orbitals and the two p_y orbitals do not overlap along the z axis; rather, they overlap above and below it. This type of MO is called a π orbital. The π MOs that concentrate electron density in the region between the two nuclei are known as π bonding MOs. The combination of p_x orbitals produce a bonding MO π_x^b , whereas the combination of p_y orbitals produces a bonding MO π_y^b . These two MOs have the same shape and energy but are orthogonal.

Following the convention used for the antibonding σ MOs, the π antibonding MOs are denoted π_x^* and π_y^* . Assuming no mixing of the s and p orbitals, the relative energies of the MOs are

$$\sigma_s^b < \sigma_s^* < \sigma_z^b < \pi_x^b = \pi_y^b < \pi_x^* = \pi_y^* < \sigma_z^*$$

FIGURE 4.12. MOs formed from p_z (top) and p_x (bottom) AOs. The original AOs are shown at the upper right of each MO.

A diagram of these energy levels is shown in Figure 4.13. It was constructed by allowing interactions only between the orbitals on atom A and atom B, which have the same energy. Actually, interactions can occur between AOs on the *same* atom provided that the energy between the orbitals is not too large. This new arrangement of the electrons is called hybridization.

4.4.2 Hybridization of Atomic Orbitals

In atoms containing AOs that are close in energy, different orbitals can mix to give so-called hybrid orbitals. Mixing between 1s and 2s orbitals does not occur. For example, in Na the energy difference between these orbitals is 9 MJ/mol. The energy difference between the 2s and 2p orbitals is less and varies with Z . In F, the energy difference between the s and p orbitals is large enough that we neglect mixing. However, in the case of elements to the left of F in the periodic table, mixing between the 2s and 2p AOs is important and results in a change in the order of the levels, as shown in Figure 4.14.

An sp hybrid orbital formed from one s orbital and a single p orbital is illustrated in Figure 4.15. Combining s and p orbitals causes reinforcement in the region in which the sign of the wave function is the same and cancellation where the signs are opposite.

We can represent these situations mathematically:

$$\psi_{sp1} = \psi_s + \psi_p \quad (4.22)$$

$$\psi_{sp2} = \psi_s - \psi_p \quad (4.23)$$

FIGURE 4.13. Energy-level diagram for a homonuclear diatomic molecule where there is negligible sp hybridization.

FIGURE 4.14. Energy-level diagram for a homonuclear diatomic molecule where sp hybridization has occurred.

FIGURE 4.16. Formation of sp^3 hybrid orbitals.

two or more orbitals on the same atom to form a new set of hybrid AOs.

FIGURE 4.15. Two sp hybrid orbitals formed by adding and subtracting the corresponding wave functions.

where ψ_s and ψ_p are the wave functions of an s and p orbital, and ψ_{sp1} and ψ_{sp2} represent the new sp orbitals. This process is similar to the formation of MOs. Keep in mind, however, that in the present case we are combining

4.4.3 Hybridized Orbitals in Ceramics

A very important example of hybridization is that occurring between one s orbital and three p orbitals to form sp^3 hybrid orbitals. In carbon, the ground state electron configuration is $1s^2 2s^2 2p_x^1 2p_y^1$; in this state, carbon would be divalent because only the unpaired electrons in the p_x and p_y orbitals are available for bonding. To form four bonds, carbon must be raised to its valence state. This requires promotion of one of the s electrons from the $2s$ orbital to the formerly empty $2p_z$ orbital. The electron configuration now becomes $1s^2 2s^1 2p_x^1 2p_y^1 2p_z^1$. This promotion costs 406 kJ/mol but is more than compensated for by the formation of two extra C–C bonds. The C–C bond energy is 348 kJ/mol.

Hybridization between the $2s$, $2p_x$, $2p_y$, and $2p_z$ orbitals forms four equivalent sp^3 hybrid orbitals, as shown for carbon in Figure 4.16. Each sp^3 hybrid orbital has one-fourth s character and three-fourths p character. The four sp^3 orbitals are directed toward the corners of a regular tetrahedron. Thus, in diamond each carbon atom has four localized tetrahedral sp^3 hybrid orbitals. A C–C MO is formed when orbitals from neighboring carbon atoms combine. The angle between three carbon bonds is $109^\circ 28'$. For covalently bonded materials that show tetrahedral coordination, sp^3 hybridization must occur.

Points to note:

- Promotion of electrons to form an excited state can occur independently of hybridization.

FIGURE 4.17. Energy level diagram for diamond and graphite.

- Hybridization prohibits certain configurations and allows others (C hybridizes sp^3 in diamond and sp^2 in graphite).
- The local atomic order depends upon mutual repulsion of the valence electrons and space requirements.
- The structure a material adopts is the one that has the lowest energy.

In diamond, for each tetrahedral group there are four sp^3 orbitals associated with the central carbon and one from each neighboring carbon, forming four bonds. The four electrons from the central carbon and one from each neighboring carbon are just sufficient to fill the bonding MOs. The four antibonding orbitals are empty. In diamond, the bonding and antibonding MOs are separated by a large energy gap, as shown in Figure 4.17. This energy gap is the reason diamond is an electrical insulator at room temperature. (We discuss the energy gap again in Section 4.8 and in Chapter 30).

Several other important ceramic materials in which the bonding is predominantly covalent have tetrahedral coordination of nearest-neighbor atoms [e.g., silicon carbide (SiC) and aluminum nitride (AlN)]. In these materials, sp^3 hybridization has occurred; but because of the different electronegativities of the constituent atoms, the electron density is not symmetrical in a plane drawn between the atoms. The crystal structure of these materials is described in Chapter 6.

In graphite, the carbon atoms are in a trigonal planar arrangement, with each carbon bonded to three nearest neighbors. The carbon is sp^2 hybridized. Hybridization occurs between the C 2s orbital and the $2p_x$ and $2p_y$ orbitals, producing three hybrid orbitals lying in a plane at 120° to each other. Overlap of the sp^2 hybrid orbitals to produce localized bonds between carbon atoms gives a hexagonal network.

The strong bonding between carbon atoms causes overlap of adjacent $2p_z$ orbitals, which are aligned perpendicular to the plane of the hybrid orbitals. This overlap is termed π -type overlap. Because the $2p_z$ orbital is half-

TABLE 4.7 Orbital Geometries for Hybridization: Equivalent Valence Orbitals

No. of bonds	Representation	Shape	Example
2	sp	Linear	BeH_2 , HgCl_2
3	sp^2	Trigonal	B_2O_3 , BN, graphite

	d^4sp^3	Dodecahedral	—
	d^5p^3	Square antiprism	—

filled, the π band is only half full, as shown in Figure 4.17. This half-filled band is why graphite has high electrical conductivity.

In hexagonal boron nitride (h-BN), which has a structure similar to graphite, the bonding between the B and N atoms is predominantly covalent, and the trigonal planar structure in the layers is a result of sp^2 hybridization of the atomic orbitals of the B and N atoms. The ground-state electronic configuration of B is $1s^2 2s^2 2p_x^1$; one 2s electron is promoted to the $2p_y$ orbital, giving the electron configuration $1s^2 2s^1 2p_x^1 2p_y^1$. The unfilled 2s and 2p orbitals hybridize to form three equivalent sp^2 hybrid orbitals. Nitrogen has the electronic configuration $1s^2 2s^2 2p_x p_y p_z$. Promotion of one of the 2s electrons gives the following electron configuration to the atom $1s^2 2s 2p_x 2p_y 2p_z^2$. The three half-filled orbitals combine to give three sp^2 -hybrids in the xy plane.

The spatial arrangement of atoms around each N atom is the same as that around each B atom. Structurally, there are many similarities between h-BN and graphite; and both can be converted under high temperature and pressure into a cubic form. The crystal structures of cubic boron nitride (c-BN) and diamond are similar. However, unlike graphite, h-BN is an electrical insulator. The reason for this difference is that the p_z orbitals in h-BN, which lie perpendicular to the plane of the network, are either empty in the case of B or filled in the case of N. Because the energies of the p orbitals on B and N are quite different, there is little interaction, with no delocalization, as was the case in graphite.

- h-BN is a white or colorless insulator.
- Graphite is a shiny black or gray electrical conductor.

Hybridization can also involve d orbitals (for atoms with $Z > 21$). The shapes produced are more complicated than those for hybridization only between s and p orbitals. Table 4.7 lists some hybrid orbitals containing s, p, and d orbitals, which are illustrated in Figure 4.18. Hybridization

FIGURE 4.18. Geometrical arrangements of some hybrid orbitals involving s, p, and d AOs.

involving s, p, and d orbitals occurs in MoS₂. Mo ($Z = 42$) has the electron configuration [Kr] 4d⁵ 5s¹. One of the 4d electrons is promoted into the empty p_x orbital to give the electron configuration [Kr] 4d⁴ 5s¹ 5p_x¹. Hybridization occurs to produce d⁴sp hybrid orbitals on each Mo atom, resulting in trigonal prismatic coordination, with each Mo being surrounded by six sulfur atoms.

For most ceramic materials we do not need to consider hybridization involving d orbitals. However, even when they are not involved in bonding, the d orbitals can be extremely important in determining the properties of materials (particularly magnetism).

4.5 METALLIC BONDING IN CERAMICS

Metallic bonding is the primary bond in metals and can be thought of as an electrostatic interaction between the delocalized valence electrons and the positively charged ion cores. It is the delocalized electron gas that gives rise to many of the characteristic properties of metals, such as high electrical and high thermal conductivities. Metallic bonds don't require a balanced electric charge between the elements; the electrostatic equilibrium is between the metal ions and the electron gas. For this reason, different elements can mix in metallic alloys in arbitrary ratios.

Metallic bonding is traditionally neglected because of the definition of a ceramic. However, some compounds that are thought of as ceramics can, under certain conditions, show metallic behavior. Others can even be superconducting. (Superconductivity is a property

associated with both metals and ceramics.) Therefore, it helps to keep a more open view of ceramics.

In addition to bonds showing mixed covalent and ionic character, the bonding in some ceramics shows partial metallic character. Transition metal carbides (e.g., TiC, Mo₂C) and nitrides (e.g., TiN, NbN) have properties that suggest both metallic and covalent bonding occur in the crystal.

- TiN is gold in color and is an electrical conductor.
- TiN has a very high MPt (2,949°C) and is brittle at 25°C.

The high MPt suggests that TiN is a metal; the brittleness is associated with ceramics. Neither property is exclusive to metals or ceramics. The bonding in transition metal carbides and nitrides is complex. It consists of a combination of metal-to-metal and metal-to-nonmetal interactions and involves simultaneous contributions of metallic, covalent, and ionic bonding.

The exact details of the bonding mechanisms in these ceramics are still controversial, and several approaches to explain the wide range of observed properties have been suggested. One common feature to all the proposed mechanisms is that of orbital hybridization. Hybridization of the s, p, and d orbitals in the transition metal and of the s and p orbitals in the nonmetal has been proposed.

The transition metal borides also show characteristics of covalent and metallic materials. The bonding in the borides is complicated by the fact that there are interactions between the B atoms to form chains, layers, or three-dimensional networks. In the carbides and nitrides, there are no C–C or N–N interactions. Despite these complexities, we can still use some of the same

approaches that we use for simple oxides (Chapter 6) to predict the crystal structure of these ceramics. The point to remember is that the bonding in ceramics is usually mixed and is occasionally very complex. Many of the new ceramics are interesting because of their special properties, which often occur because the bonding is mixed.

4.6 MIXED BONDING

From the preceding sections, it should be clear that in ceramics we don't usually have pure ionic bonds or pure covalent bonds but, rather, a mixture of two or more different types of bonding. Even so, it is still often convenient and frequent practice to call predominantly ionic bonded ceramics "ionic ceramics" and predominantly covalently bonded ceramics "covalent ceramics."

We can form some general rules about bonding based on the series of electronegativity values.

- Two atoms of similar electronegativity form either a metallic bond or a covalent bond according to whether they can release or accept electrons, respectively.
- When the electronegativities differ, the bond is partially ionic.

The ionic character of a bond increases with the difference in electronegativity of the two atoms, as shown by equation 4.24.

$$\begin{aligned} \text{Fraction of ionic character} \\ = 1 - \exp\left[-0.25(X_M - X_X)^2\right] \end{aligned} \quad (4.24)$$

where X_M and X_X represent the electronegativities of M and X (keeping the cation/anion labeling). Using equation 4.26 and electronegativity values in Table 3.6, we can see that B_4C , SiC, and BN are highly covalent (6%, 12%, and 22% ionic character, respectively). Oxides of the alkali metals and alkaline earth metals are predominantly ionic. The metal–oxygen bond has 73% ionic character in MgO and 82% in BaO. Some important ceramics fall between these limits: for example, GaN (38% ionic character), SiO_2 (51% ionic character), ZnO (59% ionic character), and Al_2O_3 (63% ionic character). With bonding that shows mixed ionic-covalent characteristics, the electrons are located closer to the electronegative atom (compare the electron densities around the Li^+ and F^- ions in Figure 4.19).

Because the covalent bond is directional and the ionic bond is not, the degree of directionality changes with bond character. Such changes can have a marked influence on crystal structure. Both ionic and covalent bonds can be very strong; but because covalent bonds are directional, covalent materials respond differently to deformation. The fraction of covalent character present can thus influence the mechanical properties of the ceramic.

FIGURE 4.19. Contours of constant electron density in the first-row hydrides.

4.7 SECONDARY BONDING

Secondary bonds are so called because the compound involved invariably also has ionic or covalent bonding. Secondary bonds are generally much weaker than primary bonds, although they can be critical in determining both the existence of a particular crystal structure and the properties of a material.

4.7.1 van der Waals bonding

The origin of van der Waals bonding (known also as the London interaction) is weak electrostatic attraction between closely spaced neutral atoms and molecules. The explanation for this universally attractive force is that even a neutral atom has a charge distribution that fluctuates rapidly. When two atoms are brought together, the fluctuations in one can induce a field around the other, and this coupling results in the attractive force. Although van der Waals bonding is present in all crystalline solids, it is only important when it is not overwhelmed by strong bonding forces.

FIGURE 4.20. Interaction energies for macroscopic geometries. The key is the Hamaker constant, \mathcal{A} .

The energy of a crystal bound by van der Waals forces can be expressed by the Lennard-Jones potential with two constants, A_{LJ} and B_{LJ}

$$E = -\frac{A_{LJ}}{r^6} + \frac{B_{LJ}}{r^{12}} \quad (4.25)$$

The potential is empirical: it provides a good fit to the experimental data. Both the repulsive and attractive terms decrease rapidly with increasing r . The attractive van der Waals forces are proportional to $1/r^7$ and are therefore of much shorter range than the ionic (Coulombic) forces, which are proportional to $1/r^2$.

In ceramics, van der Waals bonding is important in layered structures. In pyrophyllite, a layered silicate, van der Waals bonds between the oxygen ions in adjacent layers allow easy slip parallel to the layers. In the mineral talc, van der Waals bonds between the layers are even weaker than in pyrophyllite. You can cleave talc with your fingernail.

In graphite and hexagonal boron nitride, there is strong covalent bonding within each layer. Between the layers the bonding is van der Waals. These materials show highly anisotropic properties (e.g., in their mechanical strength). Little effort is required to separate the sheets, but much more effort is required to break them.

MoS₂ has a structure built of MoS₆ units, where each Mo is surrounded by six S atoms. The layers are joined by

van der Waals bonds between the S atoms and can slip over one another easily. Thus, MoS₂ has mechanical properties that are similar to those of graphite.

4.7.2 Hamaker Constant

Van der Waals interactions are just as important at the macroscopic level—where they influence behavior such as wetting and fracture—as they are at the atomic and molecular level. The interaction energies between different macroscopic geometries can be described in terms of the Hamaker constant, \mathcal{A} , as shown in Figure 4.20.

$$\mathcal{A} = \pi^2 A_{LJ} \rho_1 \rho_2 \quad (4.26)$$

TYPICAL VALUES IN CALCULATING \mathcal{A}

$A_{LJ} \sim 10^{-77} \text{Jm}^6$

$\rho \sim 3 \times 10^{28} \text{m}^{-3}$ (for $r \sim 0.2\text{nm}$)

where A_{LJ} is the coefficient in equation 4.25 and ρ_1 and ρ_2 are the number of atoms per unit volume in the two bodies. Typical values for Hamaker constants are about 10^{-19} J for interactions across a vacuum (or air).

The values for some ceramics are listed in Table 4.8. We can use these values to estimate the strength of the van der Waals interactions between, for example, two spherical particles using the equations in Figure 4.20. Remember that the forces are obtained by differentiating the energies with respect to distance.

As you might expect, things are actually a little more complicated than equation 4.26 implies. We need,

TABLE 4.8 Hamaker Constant, A

Material	A (zJ)
Al ₂ O ₃	140
Fe ₃ O ₄	210
ZrO ₂	270
TiO ₂	430
SiC	440
Fused quartz	63
Mica	100
CaF ₂	70

TABLE 4.9 Hamaker Constants for Fused Quartz Interacting with Air Across Another Medium

Medium	A (zJ)
Water	-8.7
Octane	-7.0
Tetradecane	-4.0

as when calculating the Madelung constant, to consider the influence of neighboring atoms on the interaction between any pair of atoms. An alternative method developed by Lifshitz (1956) for determining A uses bulk properties of a material such as dielectric constants and refractive indices. The values given in Table 4.8 were calculated using this approach. In general, materials with high dielectric constants and refractive indices have higher values of A . If the interactions occur across a medium, the value and sign of A may change, as shown in Table 4.9.

4.7.3 Hydrogen Bonding

Hydrogen bonds are usually stronger than van der Waals bonds but are still considerably weaker than primary bonds. Hydrogen bonds occur when a hydrogen atom that is in an ordinary covalent bond joins to another, usually highly electronegative atom. The classic example where such bonds are important is, of course, water. The H–O bonds in the H₂O molecule are fully saturated, yet the bonds between the molecules can be so strong that ice forms with a well-defined crystal lattice.

In kaolinite, hydrogen bonds can form between basal oxygen atoms of one plane and the upper hydroxyl groups of the next. The weak hydrogen bonding between each octahedral-tetrahedral double layer makes the materials very anisotropic. Layers easily slip over one another, giving the material a greasy feel and making it excellent for molding, particularly when water is present.

4.8 ELECTRON ENERGY BANDS

The energy levels for electrons in a single isolated atom are highly discrete and are given by Box 3.3 in Chapter 3. When a number of atoms are brought together to form a

FIGURE 4.21. Formation of electron “bands” as interatomic spacing is reduced.

solid, the Pauli exclusion principle does not allow any two electrons to have the same set of four quantum numbers. The energies that were identical in the isolated atoms shift relative to one another in the formation of a molecule and subsequently a solid. The sharply defined electronic energy levels broaden into an allowed band of energies when a large number of atoms are brought together to form a solid. We illustrated how this happens in diamond and graphite in Figure 4.17.

If we think of a solid as just a very large molecule, we can view the formation of electron energy bands as arising from a combination of a large number of MOs. As the molecule becomes larger, the number of MOs increases; and they become more closely spaced in energy. In a solid, the number of MOs is so large that we can regard them simply as a continuous band of energy levels.

If we consider the case of diamond, the highest occupied band, referred to by chemists as the highest occupied molecular orbital (HOMO), is σ^b . The lowest unoccupied band, referred to as the lowest unoccupied molecular orbital (LUMO), is the σ^* . Although the bands themselves are important, the most significant aspect of these diagrams is the energy gap between bands. Knowledge of the band gap energy, which is related to chemical bonding, allows us to draw important conclusions about the electrical conductivity of a material.

The effect of distance on the formation of energy bands is illustrated in Figure 4.21. The closer the atoms are together,

the more marked is the shift in available energy states. The higher energy states broaden first. Broadening of the lower energy states, which are closer to the nucleus, is less marked.

In materials science, we usually define the highest filled electron energy band when the material is in its ground state as the valence band. The lowest energy band containing unoccupied states when the material is in its ground state is the conduction band. At absolute zero, the electrons occupy the lowest available energy states; the energy of the highest occupied state is Fermi energy, E_F . This energy level separates the occupied from the unoccupied electron levels only when the electron configuration is in its ground state (i.e., at 0 K).

A solid behaves as an insulator if the allowed energy bands are either filled or empty because no electrons can move in an electric field. Metals always have a partially filled valence band; the Fermi energy is in the middle of the band, which makes the metals electrical conductors. In semiconductors and insulators, we always have completely filled or completely empty electron bands; and the Fermi energy lies between the bands. Consequently, they are not good electrical conductors at ambient temperatures.

Classically, the valence and conduction bands in ceramics are well separated, so they are insulators. In perfect insulators the gap between bands is so large that thermal excitation is insufficient to change the electron energy states, and at all temperatures the conduction band contains essentially zero electrons and the next lower band of energy is completely full, with no vacant states.

In models of electrons in solids we usually introduce two functions.

- Density of states, $N(E)$, which defines the number of energy states available to electrons. There are no available energy states in the band gap, and so $N(E)$ is zero in this region.
- Fermi function, $P(E)$, which defines the probability of finding an electron at a particular energy state.

These functions are shown graphically in Figure 4.22 together with the electron distribution function $F(E)$.

$$F(E) = 2N(E)P(E) \quad (4.27)$$

In this book, we primarily represent the energy levels of a solid as the familiar and simple block diagrams showing the band gaps. This approach is straightforward, but the question that is often asked is what we are plotting on the x -axis. A more satisfactory form is illustrated in

DENSITY OF STATES

$$N(E) = \frac{\pi}{4} \left(\frac{8m}{h^2} \right)^{3/2} E^{1/2}$$

Fermi-Dirac distribution:

$$P(E) = \frac{1}{\exp[(E - E_F)/kT] + 1}$$

Figure 4.23, where we plot the density of states versus energy. Either description allows the prediction of the electrical properties of a material based on the size of E_g . Hence, we can say whether a material will behave as a conductor or an insulator.

It is possible to convert an insulator to a metal

under very high pressures as a result of the broadening of

FIGURE 4.22. Electron distribution functions. See the text for N , P , and E .

FIGURE 4.23. Plot of the density of states function and Fermi function versus energy.

FIGURE 4.24. Plot of energy versus pressure illustrating how an insulator-to-metal transition can occur at high pressures.

TABLE 4.10 Critical Pressure for Metal-Insulator Transformation at 300 K

Material	P (GPa)
C	168
BN	211
SiC	64
AlN	90
GaN	87

the energy bands that occur when the atomic cores are moved closer together, as shown in Figure 4.24. If we make the assumption that the Fermi level does not change, the material undergoes a transition from insulator to metal at the point when the valence and conduction bands begin to overlap. Very high pressures are required to cause this transition. For example, germanium is usually a semiconductor with a band gap of 0.7 eV. It becomes a metal under a pressure of 12 GPa. Examples of critical pressures for insulator-metal transitions at 300 K in some ceramics are given in Table 4.10.

To understand some of the optical properties of ceramics and why certain materials may be favored for

solar cell or laser applications, we need to know whether the band gap is direct or indirect. The two situations are illustrated in Figure 4.25. The electrons in a band have both energy and momentum (they are not bound) expressed as a wave vector, \mathbf{k} , with units of reciprocal length (usually cm^{-1}). Energy diagrams can be plotted for various wave vectors.

In direct band gap materials, the top of the valence band and the bottom of the conduction band are located at the same point in \mathbf{k} space. This is not the case for an indirect band gap. It is direct band gap materials that are of most interest for optoelectronic applications.

The probability of electronic transitions across the band gap is higher in materials with a direct band gap, which results in higher efficiency in devices such as lasers and LEDs.

Before we leave this chapter, let's have a word about nanomaterials. The value of E_g for nano-sized crystals is often significantly larger than for the bulk form of the material. This is associated with how the bands broaden as the number of atoms in the solid increases, as illustrated in Figure 4.26.

As an example, bulk silicon has $E_g = 1.1$ eV. For nanocrystalline silicon E_g varies with the size of the crystals and for sizes < 2 nm $E_g > 2$ eV.

FIGURE 4.26. How the energy band gap arises in a nanoparticle.

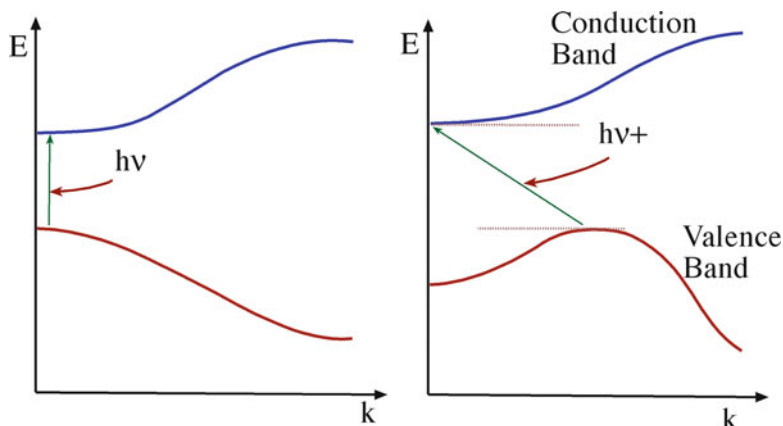

FIGURE 4.25. Direct and indirect band gap transitions. Energy is plotted versus wave vector.

CHAPTER SUMMARY

This chapter was a review of things that you already knew. There are three types of primary bond that are used to hold atoms together. In introductory materials science classes, we tend to think of each type of bond as being a distinct form, with materials adopting one type or another. At a qualitative level, this approach might work; and for many metals, semiconductors, and polymers it's usually quite close to the actual situation we encounter. However, in ceramics almost every bond has a mixture of covalent, ionic, and in some cases metallic characteristics. The type of interatomic bond affects the crystal structure that a material adopts. The influence of mixed bonding can mean that the type of structure predicted, based on either purely ionic or purely covalent bonding, is incorrect. The role of hybridization, or mixing, of atomic orbitals is very important in ceramics, which are predominantly covalently bonded. For example, the tetrahedral coordination of carbon atoms in diamond requires sp^3 hybridization.

We discussed the concept of energy bands here, both in terms of the broadening of electron energy states and from the MO approach. Knowledge of electron energy band diagrams is essential for understanding the electrical properties of materials. The most important feature of the energy band diagram is the band gap. There are no available states in this region.

Secondary bonding is also important in many ceramics. The most familiar properties of graphite, hexagonal-BN, and clay minerals are determined by the presence of weak secondary bonds.

PEOPLE AND HISTORY

Born, Max. Born in Breslau in 1882, Born graduated from the University of Göttingen in 1907, where he studied the stability of elastic wires and tapes. During World War I he had to join the German Armed Forces, where he worked in a scientific office on the theory of sound range. After the war he was appointed Professor at the University of Frankfurt-on-Main. In 1933, he was forced to emigrate from Germany and came first to Cambridge University in England, then to the Indian Institute of Science in Bangalore, and finally to the University of Edinburgh in Scotland, where he worked until his retirement in 1953. He won the 1954 Nobel Prize in Physics and died in 1970.

Haber, Fritz. He was born in Breslau, Germany in 1868. He completed studies at the University of Heidelberg, the University of Berlin, and the Technical School at Charlottenberg. The Haber process for the synthesis of ammonia was patented in 1908, and by 1914 the process was into quantity production. Ammonia was important in Germany's war efforts as a source of nitric acid, which was essential for the manufacture of explosives. It is clear that this prolonged the war. Haber was given the 1918 Nobel Prize in Chemistry (actually awarded in 1919) for his work on nitrogen fixation. In 1933, Haber resigned from his post as Director of the Institute for Physical and Electrochemistry at Berlin-Dahlem. He died in exile in Switzerland in 1934.

Madelung, Erwin. He was born in 1881 in Bonn, Germany. From 1921 to 1949 he was Professor of Theoretical Physics at Frankfurt University. He died in 1972.

van der Waals, Johannes Diderik. A Dutch physicist, he was born in Leyde in 1837 and died in Amsterdam in 1923. He was awarded the Nobel Prize for Physics in 1910 for his work on the equation of the state for gases and liquids

Young, Thomas. He was born in 1773. His accomplishments include introduction of the modulus of elasticity. Young is best known for his work in optics. He died in 1829.

EXERCISES

- 4.1 By considering the hybridization of orbitals in diamond, explain why it is (a) an electrical insulator at room temperature and (b) extremely hard.
- 4.2 Why are covalently bonded materials generally less dense than metallically or ionically bonded ones?
- 4.3 Calculate the force of attraction between an Na^+ ion and a Cl^- ion, the centers of which are separated by 1.5 nm.
- 4.4 Calculate Born-Landé lattice energies of the following compounds: NaCl, KCl, and CsCl. Compare the values you obtain to those given in Table 4.5 and discuss any differences.
- 4.5 Sketch bond–energy curves for two ceramics, one with a high Young's modulus and one with a low Young's modulus.
- 4.6 Rank the following ceramics in terms of the increasing fraction of ionic character in their bonds: SiC, AlN, Si_3N_4 , B_4C , GaN, Al_2O_3 , and SiO_2 .

- 4.7 Sketch a bond–energy curve for two atoms held together by van der Waals forces. Describe how this curve differs from the one shown in Figure 4.1, which is for ionic bonding.
- 4.8 What do we mean by the term “insulator–metal transition.” Are there any practical applications for such a transition?
- 4.9 Estimate the force of adhesion between two spherical Al_2O_3 particles of radius 1 μm separated by a distance of 10 nm. How does the force change as the separation increases?
- 4.10 Estimate the surface energy of Al_2O_3 . Assume that for two surfaces in contact D is ~ 0.2 nm.
- 4.11 “All ceramics are mixed bonded.” Is this statement correct? If not, why not?
- 4.12 Briefly describe the terms “hybrid orbitals” and “mixed bonding.” Can these terms be used interchangeably? If not, why not?
- 4.13 In Figure 4.3, Young’s modulus drops significantly at very high temperatures. Why?
- 4.14 Draw approximate electron density maps for the ceramics listed in question 4.6.
- 4.15 A bulk ceramic has been fabricated that absorbs light at 400 nm. The same ceramic is now produced in the form of 3 nm diameter nanoparticles. Do you expect the absorption wavelength to increase or decrease? Briefly explain your answer.
- 4.16 Diamond can be converted to a metal under a pressure of 12 GPa. What load would you apply to a cube of diamond, 1 mm long on each side, to make this happen?
- 4.17 Explore the literature to find three other examples of the band gap varying with the size of a nanoparticle.
- 4.18 The Hamaker constant of air is about 10^{-19} J. Explain to the nonceramist why this very small number is still important and why it is so small. Without looking at earlier chapters, how many zJ is this?
- 4.19 The value of the Hamaker constant in Table 4.9 is negative. Discuss this.
- 4.20 Draw a square pyramid and a trigonal pyramid to show the different hybridizations.

Models, Crystals, and Chemistry

CHAPTER PREVIEW

Most ceramics are crystalline. The exception is glass, which we usually discuss separately. Not only do the properties of ceramic crystals depend on how the atoms or ions are arranged, but the type and nature of defects also depend on crystal structure. You probably first encountered crystallography when discussing metals. In all, 65 (almost 90%) of the metallic elements are either cubic or hexagonal. In ceramics, many of the most important materials are neither cubic nor hexagonal, so we need to be more familiar with the rest of the subject. It is recommended that you learn by heart the main structures described in Chapters 6 and 7. In this chapter, we provide the means to make this study more systematic.

To understand why ceramics have particular structures and why certain defects form in these structures, it is really important to understand Pauling's rules. These rules require that you can visualize a tetrahedron and an octahedron and see how they fit together. To understand properties such as piezoelectricity or the mechanisms of phase transformations, you must be able to visualize the crystal structure of the material. This requirement is especially true when we want to predict the properties of single crystals. We summarize the features of crystallography that we use throughout the text and give references to more specialized resources for rigorous proof of theorems and more detailed discussion.

An important point to keep in mind is that the term "ceramic" generally refers to materials that have been processed in the laboratory or the factory plant, but these materials often exist in nature. Sometimes the natural minerals are rare, such as moissanite, which is now being manufactured as a gemstone. There are far more materials and structures in nature than are used in technology. Understanding the basic principles and knowing where to learn more about minerals may help you find the next monazite or at least to know why it might be useful. A great source for further reading is the mineralogical literature.

5.1 TERMS AND DEFINITIONS

We begin by defining the vocabulary of the subject. Most of this section should be familiar to you from other courses.

Crystal lattice: A three-dimensional array of points related by translational symmetry. The translation can occur in three independent directions, giving three independent base vectors. We can fully describe such a lattice by three vectors **a**, **b**, **c**, and three angles, α , β , γ . The special property of a crystal lattice is that the lattice points are identical: if we have an atom at or near one point, there must be an identical atom at the same position relative to every other lattice point.

Unit cell: The vectors **a**, **b**, **c** define a cell. There is, in principle, an infinite number of ways to define a unit cell in any crystal lattice. However, as in many areas of crystallography, there is a convention:

1. The unit cell should have the same symmetry as the crystal—the base vectors are parallel to symmetry axes or perpendicular to symmetry planes.
2. The origin of the unit cell is usually a center of symmetry.
3. The base vectors should be as short as possible—the cell volume should be as small as possible. The exceptions arise when choosing a longer vector, and a larger cell makes the symmetry more obvious.
4. The angles between the axes should be as close as possible to 90° or, if not, then $>90^\circ$.
5. A unit cell having the smallest possible volume is called a primitive cell.

Lattice parameters: The vectors **a**, **b**, **c** and the angles, α , β , γ are called the lattice parameters of the unit cell. Tabulated lattice parameters are, unless otherwise stated, values at room temperature and pressure. They vary with changes in temperature or pressure.

TABLE 5.1 The Seven Crystal Systems

System	Relationship between lattice parameters	Example
Triclinic	$a \neq b \neq c$ $\alpha \neq \beta \neq \gamma \neq 90^\circ$	Turquoise Kyanite Albite feldspar
Monoclinic	$a \neq b \neq c$ $\alpha = \gamma = 90^\circ; \beta \neq 90^\circ$	Monazite Titanite Orthoclase
Orthorhombic	$a \neq b \neq c$ $\alpha = \beta = \gamma = 90^\circ$	Olivine Brookite Stibnite
Tetragonal	$a = b \neq c$ $\alpha = \beta = \gamma = 90^\circ$	Zircon Rutile Hausmannite
Hexagonal	$a = b \neq c$ $\alpha = \beta = 90^\circ; \gamma = 120^\circ$	High quartz Wurtzite Beryl
Rhombohedral (or trigonal)	$a = b = c$ $\alpha = \beta = \gamma \neq 90^\circ$	Ilmenite Calcite Corundum
Cubic	$a = b = c$ $\alpha = \beta = \gamma = 90^\circ$	Halite Magnetite Garnet

Crystal system: There are seven unique shapes that can each be used to fill three-dimensional space. These are the seven crystal systems into which all crystals are classified. They are listed in order of increasing symmetry in Table 5.1.

Bravais lattices: There are 14 different ways to arrange lattice points. These are constructed as three separate types.

- Primitive (P) lattices—one lattice point per unit cell
- Body-centered (I) lattices—a lattice point at the corners and one in the center of the cell
- A-, B-, C- or F-centered lattices—a lattice point at the corners and others at one (A, B, C) or all three (F) of the faces

The 14 Bravais lattices are shown in Figure 5.1. For reasons of symmetry (Rule 1, above) we don't always choose a primitive cell. The face-centered cubic cell may be referred to the rhombohedral cell (which is primitive), but the cubic cell reflects the higher symmetry of the lattice.

Lattice points per cell: Primitive cells have only one lattice point per cell, whereas nonprimitive cells have more than one. A lattice point in the interior of a cell (N_i) can be thought of as belonging entirely to that cell; one in a cell face (N_f) is shared by two cells; and a corner one (N_c) is shared by eight. The number of lattice points (N) per cell is given by

$$N = N_i + \frac{N_f}{2} + \frac{N_c}{8} \quad (5.1)$$

Basis: Group of atoms associated with each and every lattice point. We can describe crystal structures in terms of a Bravais lattice and a Basis

$$\text{Bravais Lattice} + \text{Basis} = \text{Crystal Structure} \quad (5.2)$$

This approach is often used by solid-state physicists and is particularly useful when we want to determine the structure factor of a crystal. Crystal structures are formed by placing a basis of atoms either on the points of a Bravais lattice or in some fixed relation to those points. There may be no atoms actually located on the lattice points.

Coordination number (CN): Number of nearest neighbors.

Symmetry elements: These symmetry elements are easy to understand because you can see them by handling real crystals or crystal shapes. For example, crystals of MgO are cubic, and calcite (CaCO_3) is trigonal, as shown in Figure 5.2. They apply to macroscopic shapes but we limit our choice by ignoring those where the shape could not correspond to the unit cell of a crystal.

- *Rotation axis.* Clockwise rotation of $360^\circ/n$ about axis. Crystals may have twofold (diad), threefold (triad), fourfold (tetrad), or sixfold (hexad) rotation axes; the onefold axis is always present. Any other rotation, such as a fivefold axis, is not consistent with the definition that a crystal lattice must have translational symmetry.
- *Mirror plane.* When a plane can be chosen such that all features on one side of the plane appear, as if in a mirror, on the other side of the plane, the crystal has a mirror plane (also known as a plane of symmetry). We call this an m plane.
- *Center of symmetry.* If every feature in or on the object can be joined to an identical feature by an imaginary line through the center of the object, we say the object has a center of symmetry.
- *Inversion axis.* If when any point is rotated about an axis and then moved through the center of symmetry it arrives at an identical point, the object has an inversion axis. We refer to such axes as $\bar{1}$, $\bar{2}$, $\bar{3}$, $\bar{4}$, or $\bar{6}$ axes. Notice that the $\bar{1}$ axis is, in fact, describing a center of symmetry. The $\bar{2}$ axis is an alternative description of an m plane.

There are other symmetry elements, such as screw axes, that are meaningful for crystals but not to our macroscopic crystal shapes. Figure 5.3 illustrates some of the symmetry elements for a cube. The most important are the four threefold axes along the $\langle 111 \rangle$ diagonals.

CRYSTAL SYSTEMS
All crystals belong to one of the seven crystal systems

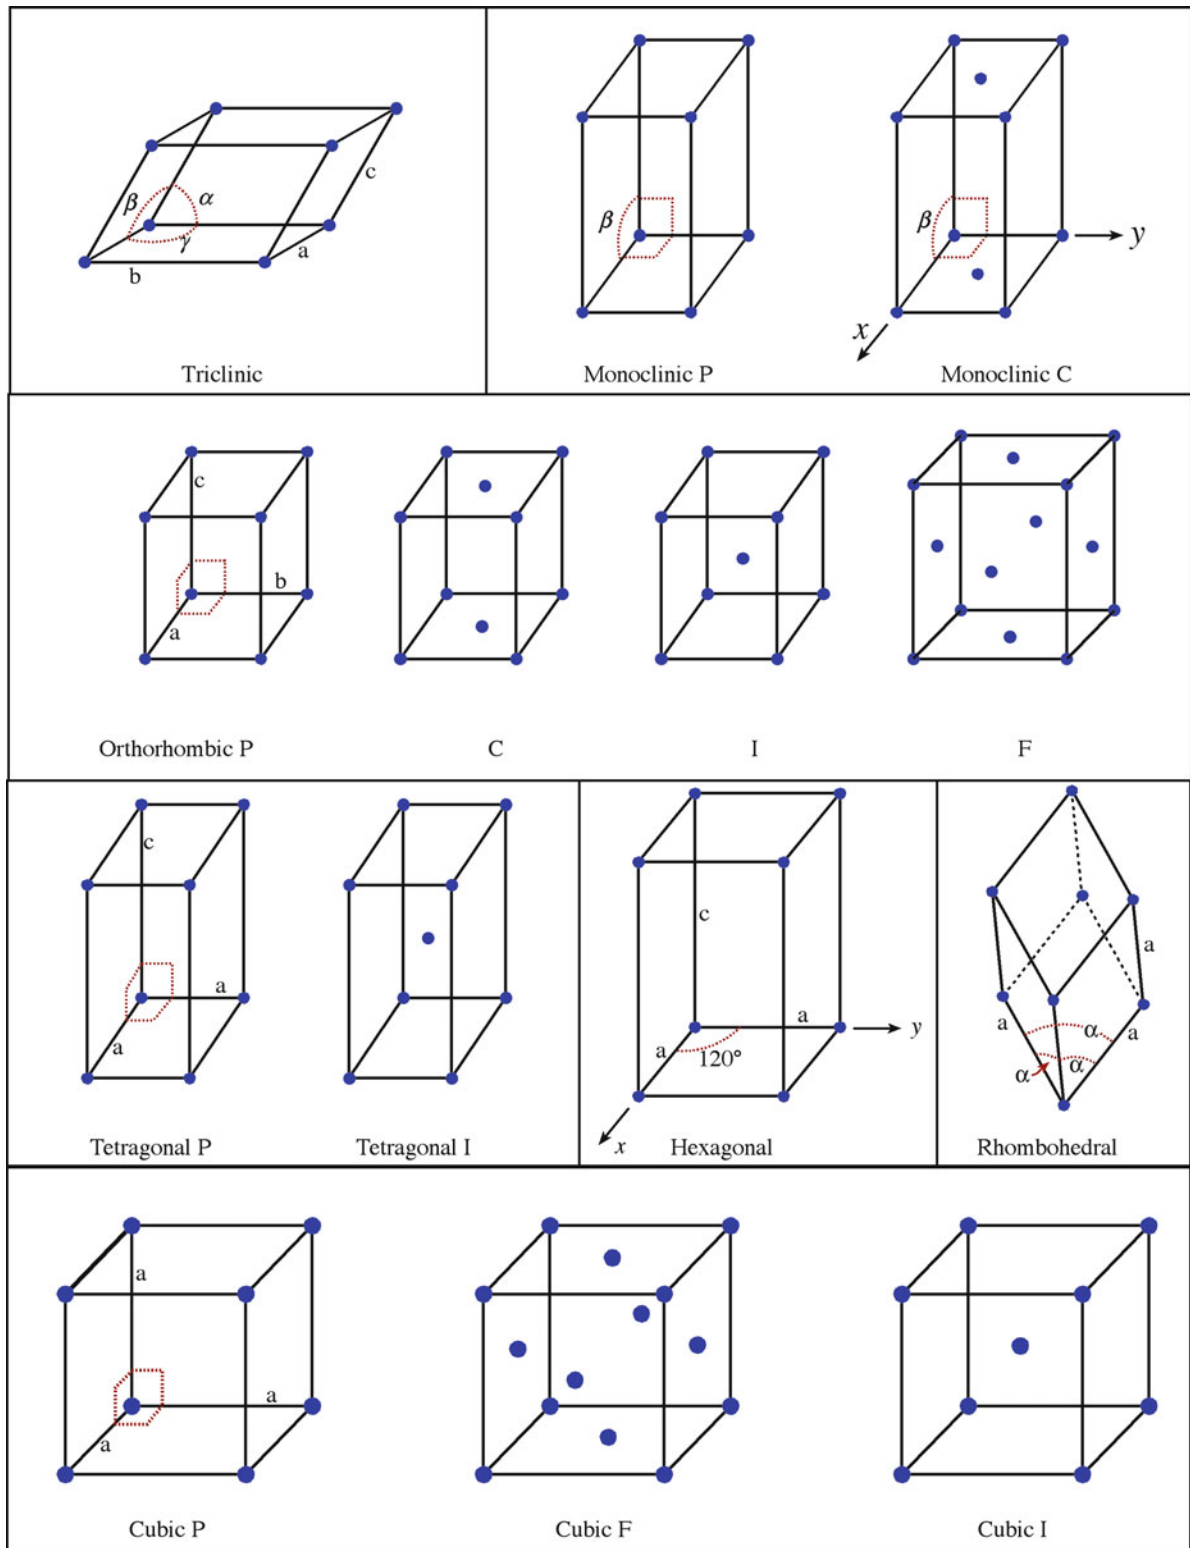

FIGURE 5.1. The 14 Bravais lattices.

5.2 SYMMETRY AND CRYSTALLOGRAPHY

Describing the symmetry of crystals is often more complicated than that of solid shapes such as the cube in Figure 5.3. For example, the crystal may have a cubic

shape and belong to the cubic crystal system but not have the maximum internal symmetry.

Table 5.2 lists the Hermann-Mauguin notation for expressing the symmetry operators. Some combinations of symmetry elements produce the same answer. For

FIGURE 5.2. Crystals with faceted surfaces, illustrating macroscopic symmetry elements. (A) MgO. (B) Calcite.

FIGURE 5.3. Symmetry elements for a simple cube.

TABLE 5.2 Symmetry Operators (Hermann-Mauguin Notation)

X	Rotation axis alone
\bar{X}	Inversion axis alone
X/m	Rotation axis with a symmetry plane <i>normal</i> to it
Xm	Rotation axis with a symmetry plane that is not normal to it (usually a vertical symmetry plane)
$\bar{X}m$	Inversion axis with a symmetry plane not normal to it
X2	Rotation axis with a diad normal to it
X/mm	Rotation axis with a symmetry plane normal to it and another not so

In writing the symbol, the principal symmetry axis is placed first. For cubic, 3 is always second

example, m is the same as $\bar{2}$ and $\bar{2}3$ and $2m3$ are both the same as $2/m3$, which is written as $m3$. Therefore, as with any convention, the only way to get it right is to memorize it. Table 5.3 lists the symmetry operations associated with each of the seven crystal systems. The final column in Table 5.3 has the maximum possible symmetry and is called the holosymmetric point group. For example, NaCl is $m3m$, and FeS_2 is $m3$. Both crystals are cubic, but they have different symmetries; we show the reasons in Chapter 6. The notation is not always the same as indicated at the top of the column. The symbols given here are known as the international convention. Actually, we could write them out fully, but the reduced description contains the essentials; for example, $m3m$ is actually $\bar{4}/m3m$, and 43 is actually 432 .

You can find the full details of the international convention in the *International Tables for Crystallography* (1983). These symmetry operations or elements can be combined to provide 32 crystal classes. The crystal classes are often called the crystal point groups. They are the point groups that are consistent with the translational symmetry of a crystal.

5.3 LATTICE POINTS, DIRECTIONS, AND PLANES

The notation used for identifying planes and faces of crystals is that of W.H. Miller and is referred to as the Miller Indices of a plane. The lengths of the unit cell are a , b , and c . A family of planes cuts these axes at the origin and at $\frac{a}{h}$, $\frac{b}{k}$, $\frac{c}{l}$. The plane is then defined by the indices h , k , and l . If these indices are not all integers we multiply by the quotient to make them integers. Thus, the intercepts $\frac{3}{2}a$, $4b$, $1c$ give h,k,l values of $\frac{2}{3}$, $\frac{1}{4}$, and 1; and this hkl is 8.3.12. We only use periods to separate the numbers if one of them is >9 . If the intercept is negative, we write \bar{h} (bar h , sometimes read as h bar).

TABLE 5.3 The 7 Crystal Systems and the 32 Crystal Point Groups

Crystal system	Essential symmetry	X	\bar{X}	X/m	Xm	$\bar{X}m$	X2	X/mm
Triclinic	1-fold axis	1	$\bar{1}$	—	—	—	—	—
Monoclinic	2-fold axis (parallel to y)	2	m	2/m	—	—	—	—

FIGURE 5.4. Miller indices of some lattice planes. The lattice-plane spacing is given by d_{hkl} .

Figure 5.4 illustrates some of low-index planes in the orthorhombic crystal system. Because there may be different combinations of hkl that give symmetry-equivalent planes, we use (hkl) to denote a particular plane and $\{hkl\}$ to denote an equivalent set of planes. The faces of the cube form the set of $\{100\}$ planes.

Directions are easier to define. The vector $U\mathbf{a} + V\mathbf{b} + W\mathbf{c}$ is simply written as $[UVW]$. We can then write $\langle UVW \rangle$ to denote all the equivalent directions formed by permuting U , V , and W . The vector $U\mathbf{a} - V\mathbf{b} + W\mathbf{c}$ is denoted by $[UV\bar{W}]$. Some low-index directions in the orthorhombic system are illustrated in Figure 5.5.

A special direction, known as the zone axis, is the one that is common to two planes $h_1k_1l_1$ and $h_2k_2l_2$. The directions $[h_1k_1l_1]$ and $[h_2k_2l_2]$ are the normals to the two planes, and the

FIGURE 5.5. Indices of directions in an orthorhombic unit cell with examples of vectors included.

MILLER INDICES

Low-index planes have small values h , k and l (and i). All are integers.

FINDING THE ZONE AXIS

$$[UVW] = [h_1k_1l_1] \times [h_2k_2l_2]$$

$$U = k_1 l_2 - l_1 k_2$$

$$V = l_1 h_2 - h_1 l_2$$

$$W = h_1 k_2 - k_1 h_2$$

zone axis $[UVW]$ is then given by the vector cross product. The zone axis has particular significance in electron microscopy because it represents the direction of the incident electron beam with respect to the sample.

When discussing crystals with hexagonal symmetry, it is helpful to use Miller-Bravais indices because they clarify the symmetrically equivalent planes. In this scheme, a fourth index, i , is introduced such that $i =$

$-(h + k)$. Figure 5.6 shows some planes and directions in the hexagonal system. The advantage of the four index Miller-Bravais system, and the main reason for its use, is that similar planes have similar indices (as we saw in the case of the Miller system). For example, the planes $(10\bar{1}0)$, $(01\bar{1}0)$, $(\bar{1}100)$, $(\bar{1}010)$, $(0\bar{1}10)$, (1100) are the six side

planes (called prism planes) of the hexagonal lattice; they clearly are of similar type. In the Miller system, however, they are (100), (010), ($\bar{1}10$), ($\bar{1}00$), (0 $\bar{1}0$), and (1 $\bar{1}0$); and they are definitely not of a similar type.

CONVERTING NOTATION: MILLER AND MILLER-BRAVAIS

$$\begin{aligned} U = u - t & & u = (2U - V)/3 \\ V = v - t & & v = (2V - U)/3 \\ W = w & & t = -(u + v) \\ & & = -(U + V)/3 \\ & & w = W \end{aligned}$$

To transform directions, it is helpful to remember from Figure 5.6 that the vector [1 1 1 0] is a null vector: it has no length! Thus, we can change the three-index direction [1 1 0] in Figure 5.6 to its four-index form as follows [1 1 0] \rightarrow [1 1 0 0] \rightarrow [1+f 1+f f 0], so our four-index notation for directions is the same as for planes (i.e., $U + V + W = 0$), we want $2 + 3f$ to be zero. Thus, $f = -\frac{2}{3}$, and the direction is $[\frac{1}{3} \frac{1}{3} -\frac{2}{3} 0]$ or [1 $\bar{2}$ 0].

The two notations are related, and it is straightforward to convert between them. The Miller-Bravais system is widely used in ceramics because alumina (sapphire) often

behaves as if it were hexagonal although it's actually trigonal.

5.4 IMPORTANCE OF CRYSTALLOGRAPHY

Understanding the crystalline structure of ceramics is critical to understanding many of their properties.

- *Diffusion.* Often depends on size and number of interstitial sites; both functions of the crystal structure.
- *Deformation by slip or twinning.* In ceramics there are both crystallographic and electrostatic considerations. The slip direction is usually along a close-packed direction. The slip plane is usually a closely packed plane or one that does not put like charges in juxtaposition. Twin planes are usually special low-index planes.
- *Piezoelectricity.* Crystals must be noncentrosymmetric.
- *Thermal conductivity.* Phonon conductivity is most efficient in simple crystal structures formed by small atoms.
- *Fracture.* Often crystallographic but not always (e.g., glass and cubic zirconia).
- *Cleavage.* Always crystallographic. Cleavage planes have high atomic density, but we also need to consider charge.
- *Ferrimagnetism.* In ferrimagnets the coordination number of the magnetic cation (usually a Fe ion) determines its behavior in an applied magnetic field.

To really appreciate the importance, and complexities, of the relationships between crystallography and properties, see Nye (1985).

5.5 PAULING'S RULES

Ceramic materials are often thought of as being ionically bonded, and ions are thought of as being charged spheres. Many important ceramics are oxides, where the oxygen anion is much larger than the cation. The crystal structure adopted by the material is based on a balance between the attractive and repulsive forces in the crystal. The electrostatic attractive force between ions of unlike charge implies that an ion with a high CN would be more stable than an ion with a low CN (i.e., the electrostatic attraction is maximized). However, if too many ions of the same charge are clustered around an individual ion of the opposite charge, they begin to interfere with one another (i.e., the electrostatic repulsion is maximized). There exists a CN where the attraction is maximized and the repulsion is minimized. This number is determined by the ratio of the radii of the two ions. Questions then arise as to why certain oxides have the structure they do and how does this affect mixing or doping of oxides.

FIGURE 5.6. Indices of planes (using Miller-Bravais notation) and directions (using three-index Miller notation) in the hexagonal unit cell.

Pauling proposed a set of rules to use when discussing such topics. These rules work so well that they are sometimes regarded as laws, which they are not. We discuss the origin of the rules and then the rules themselves.

The idea is simply that ions of opposite sign pack together in such a way as to keep ions of like sign apart.

- *Rule 1:* A coordinated polyhedron of anions is formed about each cation. The cation–anion distance is determined by the sum of the two radii, and the CN is determined by the radius ratio.
- *Rule 2:* In a stable structure, the total strength of the bonds that reach an anion in a coordination polyhedron from all neighboring cations should be equal to the charge of the anion.
- *Rule 3:* The polyhedra in a structure tend not to share edges or faces. If the edges are shared, the shared edges are shortened. Shared faces are the least favorable.
- *Rule 4:* Crystals containing different cations of high valence and a small CN tend not to share polyhedron elements with each other.
- *Rule 5:* The number of essentially different kinds of constituents in a crystal tends to be small.

When reading the discussion of these rules, keep in mind the following questions and remember that all rules have exceptions.

- Why do CsCl and NaCl have different structures?
- Why do Mg²⁺ ions tend to occupy tetrahedral sites whereas Al³⁺ ions occupy octahedral sites in spinel, when both ions occupy octahedral sites in MgO and Al₂O₃?
- Why do zinc blende and wurzite have different structures when both are ZnS? Why does GaAs have one structure and AlN have the other?
- What determines the structure of silicates? Are any other structures like this?
- Is the structure of BaTiO₃ important regarding its properties?

On Rule 1: A coordinated polyhedron of anions is formed about each cation. The cation–anion distance is determined by the sum of the two radii. CN is determined by the radius ratio:

$$\text{Radius ratio} = \frac{r_M}{r_X} \quad (5.3)$$

A MNEMONIC

Ca²⁺ is a cation.

MX

M is the cation and is often a metal.

X is the anion and is never a metal.

You'll sometimes see CA or + – instead of MX.

A given CN is stable only when the ratio of cation to anion radius is greater than some critical value. These limits are given in Table 5.4. The derivation of these limits is strictly geometrical, as shown in Figure 5.7.

Why are the radius ratio and CN related? Coulomb interactions

mean that like signs should be as far apart as possible and opposite signs as close together as possible. Crystal structures are thus at their most stable when the cations have the maximum CN allowed by r_X . In many well-known ceramics, the cation coordination polyhedron is the basic building block.

On Rule 2: In a stable structure, the total electrostatic strength of the bonds, S , reaching an anion in a coordination polyhedron from all neighboring cations should be equal to the charge of the anion

$$S = \frac{Z_M}{CN} \quad (5.4)$$

where CN is the coordination number, and Z_M = the charge on the cation. The fundamental idea is that the crystal must be electrically neutral.

We can illustrate this idea for the oxygen anion. Each O²⁻ might bond to a combination of cations.

- Si⁴⁺ ions, $S = 4/4 = 1$. Two bonds of strength 1 reach the shared oxygen ion from the surrounding silicon ions. This is the case in, for example, cristobalite (a polymorph of SiO₂). The Si⁴⁺ are surrounded by four O²⁻ ions in a tetrahedral arrangement.
- Al³⁺ ions, $S = 3/6 = 1/2$. Each O²⁻ ion is surrounded by four Al³⁺, each with a bond strength of 1/2. The Al³⁺ is surrounded by six O²⁻ ions in an octahedral arrangement. This is the case in, for example, corundum.
- In the mineral kyanite, Al₂SiO₅, we have one Si⁴⁺ plus two Al³⁺ ions surrounding each O²⁻ ion. There are six O²⁻ around each octahedral Al³⁺ ion.

TABLE 5.4 Pauling's Critical Radius Ratios

Polyhedron	CN	Minimum (= r_M/r_X)
Cube	8	0.732
Octahedron	6	0.414
Tetrahedron	4	0.225
Triangle	3	0.155

FIGURE 5.7. Geometric method for calculating limiting radius ratios.

- In forsterite, Mg_2SiO_4 , we have one Si^{4+} ion plus three octahedral Mg^{2+} ions ($S = 2/6$). We need three Mg^{2+} ions to balance the charge.

In silicates, the Si atoms are each surrounded by four O^{2-} anions, so each O ion has an additional charge of -1 that must be used to bond to another ion. Thus, for an aluminosilicate, we need a large cation with a charge of $+1$ or $+2$ so it can be surrounded by eight or more oxygen ions. Calcium (with $\text{CN} = 8$) fits this requirement to give calcium aluminosilicate. Table 5.5 shows predicted CN and S values for various cations.

On Rule 3: Polyhedra in a structure prefer not to share edges or faces. Clearly, if the faces are shared, at least three edges are also shared.

TABLE 5.5 Predicted Coordination and Strength of the Bond			
Ion	r_M/r_X	Predicted coordination	Strength of bond
Si^{+4}	0.37	4	1
Al^{+3}	0.41	4 or 6	$3/4$ or $1/2$ ($3/4$ or $3/6$)
Mg^{+2}	0.47	6	$1/3$ ($2/6$)
Ti^{+4}	0.55	6	$2/3$ ($4/6$)
K^{+1}	0.75	8	$1/8$

This effect is large for cations with high valence and a small CN. In the first case, the charge on the cation is large, increasing the Coulomb repulsion. It is especially large when the radius approaches the lower limit of stability of the polyhedron. Thus, if two anion polyhedra have an edge or face in common, the cations are being brought too close together. We can give an alternative statement of the rule. The existence of edges, and particularly faces, common to two anion polyhedra in a coordinated structure decreases its stability.

Examples

CsCl: The anions sit at the corners of cube and share faces.
 NaCl: The anions sit at the corners of octahedra and share edges.
 ZnS: The anions sit at corners of tetrahedra and share vertices.

If polyhedra share edges, these edges tend to be shortened. We can think of this shortening as concentrating more “anion” between cations, which are too close together! The converse of the rule is that if you find an apparent violation it is likely that the bonding is not ionic. However, many materials with the ZnS structure, which does the best job of separating like ions, have predominantly covalent bonding. Determination of the fraction of ionic character in a bond can be made using Equation 4.24.

Some Examples In FeS_2 (iron pyrites, fool's gold, and a ceramic), the $[\text{FeS}_6]$ octahedra are linked by shared edges that are longer than expected.

Silicates contain $[\text{SiO}_4]^{4-}$ tetrahedra; in all cases, they only share corners due to strong mutual repulsion between Si^{4+} . Again, there is actually a large covalent component to the bonding.

It is thus a geometric rule again but is nonetheless important. For example, the edges of the occupied octahedra in Al_2O_3 are 0.25 nm long, not 0.28 nm long.

On Rule 4: Crystals containing different cations of high valence and a small CN tend not to share polyhedron elements with each other. Sharing parts of polyhedra decreases the stability of the structure, so this rule is really a corollary to rule 3.

As an example, in CaTiO_3 , $[\text{CaO}_{12}]$ polyhedra share edges, and $[\text{TiO}_6]$ polyhedra share corners. The Ti^{4+} cation is more highly charged than the Ca^{2+} cation, so the CN is smaller; the Coulombic repulsion between cations is proportional to the product of the charges.

On Rule 5: The number of essentially different kinds of constituents in a crystal tends to be small. As far as possible, the environments of chemically similar atoms are similar (and Pauling's analysis assumes that the bonding is all ionic.)

If all types of bonding are possible, it is a bit difficult to predict what will happen; but if every oxygen has the same environment, there is only one possibility. The result is actually found in garnet. This rule only requires the ions to be *similarly coordinated*. Their actual geometric positions need *not* be equivalent. They are *not* structurally indistinguishable. The rule actually has limited value because in a majority of silicates the oxygen ions do not have like environments.

5.6 CLOSE-PACKED ARRANGEMENTS: INTERSTITIAL SITES

A close-packed structure is one that has the maximum volume of the unit cell occupied by atoms. The occupied fraction of the unit cell can be determined by calculating the atomic packing factor (APF)

$$\text{APF} = \frac{\text{number of atoms per cell} \times \text{volume of one atom}}{\text{volume of unit cell}} \quad (5.5)$$

The *maximum* possible APF for packing of spheres all having the same size is 0.74. This arrangement is the one

GARNET

$\text{Ca}_3\text{Al}_2\text{Si}_3\text{O}_{12}$, is not only a gemstone but also a ceramic. Other garnets such as yttrium aluminum garnet (YAG) and gallium gadolinium garnet (GGG) are technologically much more important materials.

Ion:	Ca^{2+}	Al^{3+}	Si^{4+}
O^{2-} coordination	8	6	4
O bond strength, S	$2/8 = 1/4$	$3/6 = 1/2$	$4/4 = 1$

seen in grocery stores in which oranges in adjacent layers sit off-center, resting within the pocket created by the oranges sitting side-by-side below. Materials scientists and crystallographers (as well as greengrocers) have known that this is the most efficient way to

stack a bunch of round objects but mathematicians took a long time to be convinced (see the interesting book on this topic and other mathematical riddles by Singh 1997). A mathematical proof for what is known as the Kepler Conjecture was announced in 1998 and the manuscript published 7 years later (Hales 2005).

Crystal structures having an APF of 0.74 are called close-packed structures. There are only two close-packed structures

- Face-centered cubic (fcc)
- Hexagonal close-packed (hcp)

We consider the fcc and hcp structures in some detail because they are so common. For the fcc structure, all the points are actually lattice points. In the hcp structure, this is not the case. Thus, we should never say the "hcp lattice," but we do. The hcp structure describes a particular arrangement of similar atoms, but it is not a lattice of identical points.

The relationship between the fcc and hcp structures is illustrated in Figure 5.8A. The atoms on the (111) planes of the fcc structure are arranged in a hexagonal pattern just like the atoms on the (0002) planes of the hcp structure. The only difference between the two structures is the way in which these hexagonal sheets of atoms are arranged above one another. In the hcp structure, the atoms in the second layer are above the hollows in the first layer, and the atoms in the third layer are above the atoms in the first layer, so the stacking sequence can be summarized as A B A B A B The stacking in the hcp structure is illustrated in Figure 5.8B. The first two atom layers in the fcc structure are put down in the same way, but the atoms of the third layer are placed in the hollows of the second layer; not until the fourth layer does a position repeat. The stacking sequence for fcc is therefore A B C A B C A This sequence is illustrated in Figure 5.8C.

In predominantly ionically bonded oxide ceramics, the O^{2-} ion approximates to a sphere. Therefore, we can view these structures as based on a close-packed arrangement of spheres and then filling the remaining space. We must remember that the anions are not necessarily touching but are merely arranged in a way that is the same as that in close-packed structures.

FIGURE 5.8. (A) Comparison of fcc and hcp structures using the stacking of close-packed rafts of atoms (spheres). (B) Stacking sequence in hcp. (C) Stacking sequence in fcc.

The questions we need to answer now are:

- Where are the interstitial sites?
- What is their CN?
- How many sites are there?

The fcc and hcp arrangements offer both octahedral and tetrahedral interstices, making them good hosts for cations because two size ranges can be incorporated. Both fcc and hcp arrangements can be stabilized by filling just the tetrahedral sites or just the octahedral sites. The fcc lattice can be stabilized by filling a combination of tetrahedral and octahedral sites. In the fcc arrangement, there are eight tetrahedral sites and four octahedral sites per cell. The locations of these sites are shown in Figure 5.9A. There are four tetrahedral sites and two octahedral sites per cell in the hcp arrangement. The locations of these sites are shown in Figure 5.9B.

In ceramics, the APF is always < 0.74 , even though we have increased the number of atoms per cell. As an example, if we fill all the octahedral sites in an fcc arrangement of O^{2-} with cations (e.g., Mg^{2+}) as we'll see in Chapter 6, the APF is 0.69. In other words, 69% of the cell volume is occupied by ions.

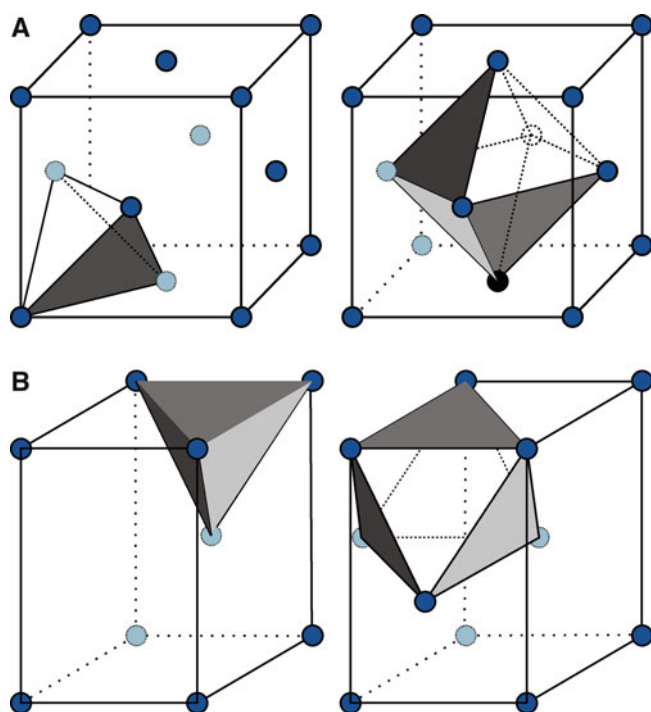

FIGURE 5.9. (A) Interstitial sites in the fcc structure, (B) Interstitial sites in the hcp structure.

5.7 NOTATION FOR CRYSTAL STRUCTURES

One of the things you'll notice is that many crystal structures are named after particular materials (often a naturally occurring mineral) that exhibits the structure. There are no systematic names for crystal structures, as there are, for example, for organic compounds, which are named using a system recommended by the International Union of Pure and Applied Chemistry (IUPAC). This system provides us with a systematic way of naming many organic compounds on sight, and the name indicates the structure of the compound. A similar system is not used for naming crystal structures. However, there are several notations for specifying crystal structures that can be very useful.

- *Strukturbericht*. The symbol consists of a letter that characterizes the type of structure and a number designating a specific type within a letter category. The rules are given in Table 5.6.
- *Pearson*. The symbols give, successively, the crystal system, the Bravais lattice symbol, and the number of atoms per unit cell. The notation is summarized in Table 5.7. Even though you can find out the crystal system, the Bravais lattice, and the number of atoms from this notation, you can't differentiate among different structures with similar notations. For example, cF8 refers to sodium chloride, diamond cubic, and zinc blende structures, which are different from one another.

TABLE 5.6 The Strukturbericht Notation

Symbol	Definition	Symbol	Definition
A	Element	E-K	Complex
B	AB compounds	L	Alloys
C	AB ₂	O	Organic
D	A _m B _n	S	Silicates

Examples of Strukturbericht and Pearson symbols are given in Table 5.8.

5.8 STRUCTURE, COMPOSITION, AND TEMPERATURE

Many ceramics exist in different structures at different temperatures. These structures are known as polymorphs, and we give some examples in Chapter 6. The most stable structure at any particular temperature is governed by its free energy, G . The polymorph with the lowest free energy is the most stable. Expressions for the free energy and internal energy were given in Chapter 3. Both the internal energy, E , and the entropy, S , depend on crystal structure.

The following rules can be given for the temperature and pressure dependence of thermodynamically stable structures.

- At $T = 0$, $G = E$ (i.e., the free energy is fixed by the internal energy).

FIGURE 5.10. Relationship between internal energy E and free energy G of three polymorphic forms: $E_3 > E_2 > E_1$ and $S_3 > S_2 > S_1$. The form with the lowest G is the one usually found at a specific temperature.

- At $T > 0$, the TS term becomes increasingly important, and structures with a low degree of order are favored.
- At a sufficiently high temperature, a polymorph with a larger S may achieve a lower G despite its larger E , as illustrated in Figure 5.10. The increased values of E and S of the high-temperature forms correspond to more open structures (larger specific volumes) with higher symmetry.
- There are two components to entropy (both increase as T increases): thermal entropy and configurational entropy.
- In the liquid state, the order is even lower; and it is the lowest in the gaseous state. Raising the temperature leads to melting and finally to evaporation.
- Higher pressures favor structures that occupy a lower volume (i.e., that have a higher density).

The crystal structure of a ceramic also depends on composition. As an example, consider three oxides of iron.

1. Wüstite (FeO): Cubic rock salt structure. Iron is in the 2+ oxidation state.
2. Hematite (Fe_2O_3): Rhombohedral corundum structure. Iron is in the 3+ oxidation state.
3. Magnetite (Fe_3O_4): Cubic spinel structure. Iron is in the 3+ and 2+ oxidation states.

The reasons for these differences are explained by Pauling's rules.

There is another factor that can influence the equilibrium structure of a material, and that is surface energy. The effect of surface energy has become of increasing importance with the interest in nano-sized particles of ceramics. When particle size is very small, the fraction of atoms on the surface is

FIGURE 5.11. Calculated enthalpy of alumina (γ - and α -) polymorphs as it varies with the surface area. The calculation is a molecular dynamic (MD) simulation using data for small surface areas. Large surface area per gram implies small particles.

very large. Surface energy effects can then dominate, as illustrated in Figure 5.11, which shows that $\gamma\text{-Al}_2\text{O}_3$, rather than $\alpha\text{-Al}_2\text{O}_3$, can become the thermodynamically stable phase of aluminum oxide when the surface area exceeds $\sim 175 \text{ m}^2/\text{g}$. The key thing to remember is that nanomaterials don't always behave the same as the bulk material.

5.9 CRYSTALS, GLASS, SOLIDS, AND LIQUID

Classically, there are three distinct states of matter: gas, liquid, and solid. (The newer two, plasma and Bose-Einstein condensates, are not applicable to our discussion so we omit them here.) In the previous section we noted how as temperature increases it is thermodynamically favorable for transitions to occur, from a more ordered form to a less ordered one. The atoms or molecules that make up a gas are randomly arranged (E and S are high) and widely separated. A gas fills all the available space inside a container. The atoms or molecules that make up a liquid are also randomly arranged, but they are closer together than those in a gas; and they move relative to one another. The characteristic of a liquid is that it fill a container to the extent of its own volume. The third state of matter is solid, which can be defined as having a fixed shape. Solids can be classified as either *crystalline* or *noncrystalline*.

When we discuss crystals, we are concerned with interatomic bonding, interatomic distances, the environment of the ions, and long-range ordering. All of these

concepts, except for long-range ordering, are relevant to noncrystalline materials such as glass. In fact, when we discuss silica-based glasses, the main point is how we do or do not link SiO₄ tetrahedra together. The concept of order that is important is separating the different classes of condensed matter. The basic differences are summarized below:

Crystal	Ordering on lattice: long-range order
Glass	Short-range order
Liquid	No order to short-range order

There are many amorphous ceramics (glasses). There are fewer amorphous semiconductors and some amorphous metal alloys. The main consideration, as you'll see in Chapter 21, is the rate of cooling necessary to avoid crystallization. In many oxides, the critical rate of cooling is very easy to achieve because the number of components is large and we have directional (covalent) bonding. The latter consideration also holds for semiconductors, but for metal alloys we usually can rely only on frustrating crystallization using complex compositions and rapid quenching.

5.10 DEFECTS

One reason we need to understand the structure of perfect crystals is so we can begin to understand imperfect crystals. The topic is not specific just to ceramics. The interaction of defects is often most important to us. For ceramics, a special example of such interactions occurs in grain growth. Grain-boundary movement in ceramics usually involves the movement of point defects.

Understanding atomic bonding helps us understand the structures of crystals and glass. When we think of crystals, we think of atoms arranged in a perfect way. We traditionally think in terms of crystal defects, but we also consider how these ideas apply to defects in glass.

One question we must keep in mind is: "How is this feature different from metals?" The answer is not always as obvious as it might seem because we often compare ceramic materials to particularly simple (usually fcc) metals. Apart from carbon and the elemental semiconductors Si and Ge, all ceramics contain two or more different atoms so we should at least compare them with metal alloys, not pure metals. The next question is: "How do defects influence the properties of the ceramic?" For that we first need to understand defects.

We classify defects as having zero, one, two, or three dimensions, as shown in Table 5.9. Actually, all of the defects we discuss are three-dimensional. Ceramics usually have mixed bonding (i.e., a combination of ionic and covalent bonding). Hence, when we introduce defects, we usually change the local distribution of charge or break bonds, depending on which type of bond predominates.

TABLE 5.9 Hierarchy of Crystal Lattice Defects

"Dimension"	Defect	Some topics
0	Point defects	Geometry, strain energy, charge
1	Line defects	Geometry, energy
2	Surfaces	Thermodynamics
	Grain boundaries	Structure, chemistry, wetting
	Phase boundaries	Phase distribution
3	Volume defects	Precipitates, particles, and voids

Any change in charge distribution can produce long-range effects. A broken covalent bond is known as a dangling (unpaired electron) bond that also behaves like a localized charge.

We've discussed the packing of ions in terms of coordination polyhedra. When we create defects in a crystal, we can create new polyhedra that are not found in the perfect crystal. Pauling's rules were developed for perfect crystals, but the principles still apply when we examine defects. One complication is that as we introduce grain boundaries, for example, new sites are produced that depend on the detailed nature of the grain boundary. Amorphous materials present a new challenge when describing point defects. Two amorphous materials can have different structures that depend on the processing history even if the chemistry is the same.

5.11 COMPUTER MODELING

Computer modeling of oxide structures and of defects in oxides is becoming more important, in part because the code is improving but mainly because faster computers can make more realistic calculations. The problems for ceramic materials are those discussed in Chapters 3 and 4. If the bonding is ionic, the ion-ion interactions are both strong and long range. If there is a covalent component to the bonding, the bonds have a directional character. (Glasses exist in a metastable state, so their structure is by definition not the equilibrium one.) The problem is twofold. We need computer code that can handle the long-range interactions. Even simple ceramics can have large unit cells, which means that the computer must also be able to handle a large number of atoms.

We summarize the approaches being used by different researchers to calculate properties of ceramics. This discussion is very brief and incomplete, but it should give an idea of how the subject is developing. One encouraging feature is that software packages suitable for the knowledgeable researcher who is not an expert programmer are becoming available commercially. These packages fall into two categories that can be linked. In one, the atomic structure of a ceramic crystal can be displayed after inputting the appropriate crystal parameters. Such programs are simply using the rules of crystallography to generate the structures. The other, and far more complex, programs also

use the interatomic potentials to deduce features of the structure and are performed using molecular dynamic (MD) approaches.

5.11.1 Terms Used in Modeling

We begin by listing some of the terms you will encounter.

Pseudo-potential: This is an expression that is used to represent a real crystal potential. An equation such as Equation 4.1 is chosen, and the parameters are changed until a calculated value is obtained that agrees well with the known value of a physical parameter. This process is carried out simultaneously for several parameters that are chosen to have some relevance to what you would like to calculate.

Electronic structure calculation: Although ceramics are thought of as insulators, the electrons are important in understanding optical properties, for example.

5.11.2 Computer Modeling of Structures: The Need for Potentials

Most ceramics cannot be modeled from first principles simply because we don't know the potentials well enough. Therefore, the challenge with modeling crystals is that we have to use a model for the potential. These are available for Si and are quite good for Al_2O_3 and MgO. We can summarize the problems for modeling ceramics as follows.

- Ceramics usually contain charged species. This means that the interionic forces extend over very large distances (remember the Madelung constant). To model such materials we need large unit cells. This problem becomes more difficult when we model defects.

- When the ceramic is covalent or has a large covalent component to the bonding, directions are important. Si is the classic example of a covalent material. It can be modeled but only because enormous effort can be justified by its commercial importance. Modeling silicates, which also have a large covalent component, is less developed.

Ceramics lag behind metals for two reasons. Firstly, most ceramics contain more than one component, so we need to have potentials for each ion. (FeO contains three ions for this purpose.) Secondly, the potentials have to be used to predict known quantities, and these are not usually as well known as they are for metals.

A number of software packages are now available as shareware or commercially. One such program is GULP: the acronym stands for Generalized Utility Lattice Program. GULP can be used to perform different types of simulation on 3D periodic solids and on isolated defects in such materials. GULP simulates structures of ionically bonded materials using a shell model and uses the crystal symmetry to accelerate the calculations and to simplify the input. These two factors can make it faster and more efficient than other programs. If you use GULP, for example, you have access to at least 23 different potentials or models, including Buckingham, Morse, Coulomb, and Stilingier-Weber. Examples of the uses of GULP are modeling Al_2O_3 , defects in garnets, zeolites, and molecular sieves, and the structure of Al_2SiO_5 polymorphs. CeriusTM, another software package for simulating structures, also includes diffraction modules. The state-of-the-art approach is to use first principles computations. Three widely used packages are Siesta, VASP, and FHI-aims. All are being used for ceramic materials. Exploring takes time—or a career.

CHAPTER SUMMARY

This is the chapter where we introduced crystallography. Some students object to having to learn this material. Our view is that you cannot understand point defects, piezoelectricity, grain boundaries, elasticity of noncubic crystalline materials, and so on unless you understand the differences between crystal structures; and for this you must understand the principles of crystallography. Pauling's rules for ionic ceramics give us a set of tools that allow us to predict the coordination of ions and even to guess the structure of a crystal that may be new to us. The exceptions to these rules often result from the presence of a covalent component to the bonding, which itself gives clues to the coordination. Once we know the crystal structure, we can predict what point defects might occur and even guess at the energies involved—just from counting broken bonds, for example. The best-known examples of such point defect sites are the octahedra and tetrahedra in close-packed (fcc or hcp) lattices, but we find these polyhedra in many different crystal structures although they may be more difficult to recognize elsewhere. Therefore, just by considering Pauling's rules, we are introduced to one of the most useful concepts of solid-state chemistry—the concept of crystals being constructed by arranging polyhedra. The polyhedra are clusters of atoms that behave in quite systematic ways. As we'll see in the following chapters, the most important of these polyhedra is the tetrahedron, formed by four oxygen ions with a Si ion at the center. However, it is certainly not the only polyhedron of interest to us.

PEOPLE AND HISTORY

Bravais, Auguste (1811–1863) presented his ideas on crystallography to the French Academy of Sciences in 1849. He was interested in a number of fields including botany, astronomy, and physics. It is for his work in crystallography that he is best remembered.

Goldschmidt, Victor Moritz was born in Zurich but spent his scientific career in Norway (1888–1947). Like Pauling, he derived rules for ionic radii.

Haüy, René-Just (1743–1822) published his essay in 1784 on a theory of the structure of crystals. The story is that his interest in crystals began when he examined a specimen of calcite that he had accidentally just dropped.

Hooke, Robert (1635–1703) published *Micrographica* in 1665 showing images taken with his microscope. A genius.

Miller, William Hallows (1801–1880) was born in South Wales and was Professor of Mineralogy at Cambridge University from 1832 until he died. He wrote the book that explained the notation developed by William Whewell. Although he gave full credit to the pioneering work of his mentor, Whewell, we still refer to Miller indices.

Whewell, William (1794–1866) (see Miller above). One-time President of the Geological Society (hence the indices), he is now remembered as a philosopher. He also invented the word scientist for Coleridge; and anode, cathode, and ion for Faraday! He was sometimes called a polymath—read about him and be impressed.

Wulff, Georgii (Yurii) Viktorovich was a Russian crystallographer born in 1863. The initial “G” was used in translations of his papers rather than “Y”. He died in 1925 in Moscow.

Wyckoff, Ralph Walter Graystone was born in 1897 and died in 1994. He authored the classic book, *The Structure of Crystals* (1931).

EXERCISES

- 5.1 Calculate the percentage of free space in an fcc stacking of spheres and a simple cubic stacking of spheres. Relate the result to two important ceramic structures.
- 5.2 How do you expect the lattice parameters of Si and SiO₂ (high cristobalite) to compare? How does this fit with the experiment? Discuss.
- 5.3 When the {111} planes of SiC stack with the sequence ABABAB, the SiC has hexagonal symmetry. When they stack with the sequence ABCABC, it has cubic symmetry. What symmetry does it have when it stacks ABCBABCBA? Explain your reasoning.
- 5.4 The face-centered cubic cell may be referred to the rhombohedral cell. Using a sketch, show the relationship between the two cells.
- 5.5 Are there any interstices in hcp that are not present in fcc?
- 5.6 Why is there no Bravais lattice called orthorhombic A, monoclinic B, or tetragonal C?
- 5.7 If a sapphire crystal showed only one type of rhombohedral plane and the two basal planes, what would the shape of the crystal be?
- 5.8 FeS is a more complicated structure than FeO. Why would you not be surprised at this result?
- 5.9 In calcite (CaCO₃) the Ca²⁺ ion has a CN 6. Using the appropriate Pauling rule determine the ion environment around each O²⁻ ion.
- 5.10 From the ionic radii given, estimate the coordination numbers for the following oxides: (a) MgO. (b) Al₂O₃. (c) Li₂O, Li⁺ 76 pm; O²⁻ 140 pm; Mg²⁺ 72 pm; Al³⁺ 54 pm.
- 5.11 From the literature (reference your sources): What are the lattice parameters of calcite and aragonite? Why and when do each occur? How are they related?
- 5.12 Without looking at the chapter, write down three examples for each of the seven crystal systems. Then, write down two more examples by looking through the literature (reference your sources).
- 5.13 Look at Table 5.3 and replace all the dashed symmetry elements with one that is already in the table.
- 5.14 What is the zone axis for the following pairs of planes: (a) (111) and (112), (b) (001) and (123), (c) (135) and (853)? How do these answers change if the crystal is orthorhombic instead of cubic?
- 5.15 What are the [1234], [2345], and [8642] directions better known as?
- 5.16 Why do ceramists use the Pauling rules and not the Goldschmidt rules? Why do many now use the Shannon-Prewitt values for ionic radii? Give any references that you use when probing the literature to answer the question.

- 5.17 Use the literature to make a list of as many different garnets as you can find. Which of these are already commercially important? Do you expect Pauling's rules to apply to all of them?
- 5.18 "Crystals are more difficult to understand than glasses because they can have many different structures." Justify your criticism of this claim.
- 5.19 Assuming all the particles are the same size and almost equiaxed. What are the dimensions of the particles at the crossover point in Figure 5.11?
- 5.20 We normally draw the unit cell of fluorite one way, but Pauling says we should draw it differently. Explain this sentence and draw the two different unit cells.

REFERENCES

There are many books on crystals and crystallography—which is best for you depends on your background and interests. A great source for further reading is the mineralogical literature. The books by Putnis (1992) and Deer, Howie, and Zussman (1992), among others, provide great insight, as does the literature from solid-state chemistry, such as the books of Wells (1970), Hyde and Anderson (1989), and others. These references are given in Chapters 6 and 7.

Binary Compounds

CHAPTER PREVIEW

In this and the following chapter, we describe the most important simple (binary) crystal structures found in ceramic materials. You need to know the structures we've chosen because many other important materials have the same structures and because much of our discussion of point defects, interfaces, and processing use these materials as illustrations. Some (i.e., FeS_2 , CuO , Cu_2O) are less important materials, and you would not be the only ceramist not to know their structure. We include these oxides in this discussion because each one illustrates a special feature that we find in oxides. These structures are just the tip of the iceberg for the topic known as crystal chemistry (or solid-state chemistry). The mineralogist would have to learn these, those in Chapter 7, and many more. In most examples, we mention some applications of the chosen material.

In traditional ceramic oxides, the anion is usually the larger ion, so we often think of a ceramic crystal structure as a three-dimensional array of anions with cations inserted in the interstices. Whether a particular structure is stable depends on Pauling's rules. We first review some of the important lattices, paying particular attention to the polyhedra that are formed by groups of anions. As the variety of ceramics being used in today's high-technology environment increases, some of the above assumptions cease to be valid. In certain oxides, the cation is bigger than the anion, and covalently bonded oxides and nonoxides can't be treated as arrays of hard spheres. Therefore, we learn the rules and try to understand the exceptions. The concept of crystals being arrays of polyhedra still works whether the bonding is ionic or covalent and whether the anion or the cation is larger.

In this and the following chapter, the xyz axes of cubic crystal structures lie along the cube edges; the length of the cube edge is the lattice parameter.

6.1 BACKGROUND

Using Pauling's rules, we can think of all crystal structures in terms of filling polyhedra—those we discussed in Chapter 5. Particularly simple cases are the simple cubic (sc), hexagonal close-packed (hcp), and face-centered cubic (fcc) lattices. In oxides such as Al_2O_3 and MgO , the anion is the larger ion, which we believe forms a scaffold, with the cations then filling the interstices between the anions. This thinking has a historical bias to it. It comes from the days when ceramics were light-element oxides. Such compounds automatically have smallish cations.

With the growing importance of ternary and tertiary oxides and the nonoxide ceramics, we have to be careful when making such assumptions. You must also remember that Pauling's rules apply to compounds in which the bonding is primarily ionic. In some compounds, the structure is the one predicted by Pauling's rules, but the reason may not be the one we gave when deriving the rules! In other words, if the bonding has a large covalent component, beware. Similarly, if the cation is large (e.g., in UO_2),

we should not (though we sometimes do) consider the structure a close-packed stacking of anions even if they do appear to lie on an fcc lattice.

Although we examine only a few materials here, each has the same structure as other important materials. We list a few of these isomorphous materials. The examples chosen are also important because other crystal structures can be related to them with only a small distortion added to change the symmetry.

The format of this chapter is summarized as follows.

CsCl	sc lattice with a two-atom basis
NaCl, GaAs	fcc lattice with a two-atom basis
CaF_2 , FeS_2	fcc lattice with a three-atom basis
AlN	Hexagonal "close-packed" lattice with a two-atom basis
Cu_2O	More complex but still cubic
TiO_2 , CuO	Much more complex
Al_2O_3 , CdI_2	"hcp" anions but not hcp structures
MoS_2	Layered material

6.2 CsCl

We start with the CsCl structure because it is the simplest possible, not because of its importance. The Bravais lattice of the CsCl structure is sc. We can view this structure in two ways:

- Two interpenetrating sc lattices, one of Cs^+ and one of Cl^- . The two sublattices are displaced by $\frac{1}{2}\langle 111 \rangle$.
- One sc lattice with a two-atom basis (Cs^+ at $0,0,0$ and Cl^- at $\frac{1}{2}, \frac{1}{2}, \frac{1}{2}$).

The concept of a sublattice is helpful when visualizing structures, but the phrase is sometimes used when the atoms do not really lie on a lattice. In this example, the lattice could be based on the positions of either the Cs^+ ions or the Cl^- ions.

We can check this structure against Pauling's rules. The ratio of the ionic radii (in pm) is

$$r_{\text{Cs}^+}/r_{\text{Cl}^-} = 170/181 = 0.94$$

As the ratio is >0.732 , the Cs^+ should be eightfold coordinated. It is clear from Figure 6.1 that the coordination number (CN) is 8. This structure does not appear to occur for oxides because the (divalent) cation radius would need to be >102.5 pm (O^{2-} is 140 pm). It is not directional bonding that causes the structure to be adopted, just the packing requirements. This structure is the model B2 structure found in some important intermetallics such as NiAl. It is also adopted by a number of halides having useful optical properties. As shown in Figure 6.2, CsBr, CsI, TlCl, and TlBr transmit in part of the ultraviolet (UV) spectrum, all of the visible (shaded region) range, and the near-infrared (IR) spectrum.

6.3 NaCl (MgO, TiC, PbS)

The NaCl (rock salt or halite) structure is quite simple and is found for sulfides and carbides and some oxides, including MgO, CaO, SrO, BaO, CdO, FeO, and NiO. The anions

FIGURE 6.1. CsCl crystal structure. The polyhedron is the cube.

FIGURE 6.2. Range of transmittance for halide samples grouped by structure. (Each sample is 2 mm thick; 10% cutoff.) The vertical band shows the visible range.

are in an fcc arrangement, and all the octahedral interstices are occupied by cations, as shown by Figure 6.3. The CN is 6 for both anions and cations.

The NaCl structure can be represented as:

- Two interpenetrating fcc lattices: one of anions and the other of cations displaced by $\frac{1}{2}\langle 001 \rangle$ or by $\frac{1}{2}\langle 111 \rangle$.
- An fcc lattice with a two-atom (Na-Cl) basis. (Cl^- at $0,0,0$ and Na^+ at $\frac{1}{2}, 0, 0$ or alternatively Cl^- at $0,0,0$ and Na^+ at $\frac{1}{2}, \frac{1}{2}, \frac{1}{2}$).

Of course, this structure is actually not close-packed even though we have an fcc arrangement of anions. In the fcc metals each atom has 12 nearest neighbors (CN is 12); in NaCl each ion has six nearest neighbors (CN is 6) so the packing of the anions must be less dense than fcc. (By Pauling's rules, the octahedral interstice between the Cl^- ions must be larger than the minimum or the structure will be unstable).

For MgO (magnesia or periclase), $r_{\text{Mg}^{2+}}/r_{\text{O}^{2-}} = 0.6$ so the Mg must be surrounded by oxygen ions in an octahedral configuration. The bond strength (valence/coordination) is $S_{\text{Mg}} = +2/6 = +1/3$, so each O^{2-} must also be surrounded by 6 Mg ions. There is not a lot of choice on how to join them up. Note that $r_{\text{Na}^+}/r_{\text{Cl}^{2-}} = 0.56$, which is also >0.414 but <0.732 .

FIGURE 6.3. The NaCl crystal structure with Cl at 000. (Top) Ion positions. (Bottom) Edge-sharing Cl octahedron.

FeO, CoO, MnO, and NiO are similar. NiO has the NaCl structure above its Néel temperature (523 K). Below this temperature, magnetic ordering makes it rhombohedral. MnO and FeO behave similarly, but CoO undergoes a tetragonal distortion when the spins align; the Néel temperatures are 122, 198, and 293 K, respectively. Stoichiometric NiO is pale green. When heated in air, it oxidizes and becomes a semiconductor.

Many of the oxides, carbides, and nitrides with the NaCl structure tend to be nonstoichiometric. Titanium monoxide exists over the range $Ti_{0.85}O$ to TiO . FeO never occurs; it is always nonstoichiometric with a composition ranging from $Fe_{0.90}O$ to $Fe_{0.96}O$. As a consequence of these vacancies, the transition metal exists in two valence states, causing the oxide to exhibit semiconductor properties (as for NiO).

In the transition metal carbides and nitrides, think of the metal as being in the close-packed arrangement with carbon or nitrogen atoms located in the interstices. The coordination number can again be determined by the radius ratio, which in this case is given by r_x/r_m , where r_x is the radius of the interstitial atom, and r_m is the radius of the metal atom. Some values of atomic radius and radius ratios for transition metal carbides and nitrides are given in Table 6.1. The radius–ratio values given in Table 6.1 are consistent with a CN of

TABLE 6.1 Atomic Radius and Radius Ratios for Some Carbides and Nitrides

Metal	Ti	Zr
Atomic radius (nm)	0.147	0.160
C/M ratio	0.525	0.482
N/M ratio	0.511	0.470

6 based on the critical radius ratios given earlier in Table 5.4. The interstitial atoms are located at either an octahedral site or the center of a trigonal prism. For the transition metals, the tetrahedral interstices in the close-packed structures are too small for C or N.

All of the octahedral interstitial sites are occupied in the NaCl structure. In general, when the radius ratio is <0.59 the metal atoms form very simple structures. The interstitial atom and its nearest metal neighbors comprise a structural unit. We can consider the structure of these materials as that of a metal with occupied interstitial sites. There are no C–C or N–N interactions in carbides and nitrides.

Some of the nitrides and carbides (e.g., NbC, TaC, ZrN), which adopt the NaCl structure, are low-temperature superconductors. Although there is no direct evidence that this property is a direct consequence of the crystal structure, the crystal structure may play an important role.

Carbides with the NaCl structure have high hardness, are chemically inert, and have high melting temperature. The best-known example is TiC. It melts at $3,147^\circ\text{C}$, has a Knoop hardness of 2,470, and a Young’s modulus of 310 GPa. It is resistant to oxidation up to $1,200^\circ\text{C}$. (There is more discussion in Chapters 16–18.)

6.4 GaAs (β -SiC)

We can represent this structure as:

- Two interpenetrating fcc lattices: one of anions and the other of cations displaced by $\frac{1}{4}\langle 111 \rangle$
- An fcc lattice with a two-atom basis (one atom at 0,0,0 and the other at $\frac{1}{4}, \frac{1}{4}, \frac{1}{4}$)

This structure is rather open: the atomic packing factor (APF) for GaAs is only 0.41. In the GaAs structure, each atom has only four nearest neighbors; the CN is 4 for both Ga and As. The structure is shown in Figure 6.4 in three-dimensional form for the (110) projection. The projection is important because it clearly shows the tunnels along the $\langle 110 \rangle$ direction (remember that there are six equivalent $\langle 110 \rangle$ directions). You will

II–VI, III–V AND IV–IV

The classical name for this structure is zinc blende or sphalerite (ZnS)
GaAs, InP, InSb, etc. are not minerals
Cubic SiC is known as carborundum or moissanite

FIGURE 6.4. Zinc blende crystal structure. (Top) Ion positions. (Bottom) Corner-sharing tetrahedra.

FIGURE 6.5. HRTEM image of GaAs showing the Ga-As 0.14-nm dumbbell.

also see that many high-resolution transmission electron microscopy (TEM) images are recorded with this sample orientation because it optimizes the details seen in the image. An example is shown in Figure 6.5.

We can form the structure by stacking the anions in an fcc sequence and then filling half the tetrahedral interstices with cations. We could have chosen to stack the cations and then fill the interstices with anions, but the anions are usually larger. Other isomorphous materials include InP, InSb, GaP (known collectively as the III–Vs) and cubic SiC.

Materials with the GaAs structure are usually

TABLE 6.2 Relationship Between Band Gap Energies and Bonding in III–V Semiconductors

Compound	E_g (eV)	% Ionic character in bond
AlP	3.0	9
GaP	2.35	6
AlAs	2.1	6
AlSb	1.55	4
GaAs	1.35	4
InP	1.30	4
GaSb	0.70	2
InAs	0.33	2
InSb	0.17	1

Note: % ionic character was calculated using Equation 4.24

semiconductors; this property is a direct consequence of the covalent bonding. In the III–Vs, the band gap increases as the ionic component to the bonding increases, as shown in Table 6.2. If we replace all of the Ga and all of the As by C, Si, or Ge, we have the diamond-cubic (dc) structure of diamond, Si and Ge. Now the bonding is entirely covalent (and Pauling’s rules would not work). We next consider the GaAs structure in comparison to AlN.

6.5 AlN (BeO, ZnO)

A second polymorph of ZnS is wurtzite (würzite in German). Many AB compounds, such as AlN, GaN, BeO, and ZnO, form in the wurtzite and zinc blende structures under different conditions. We can form the wurtzite structure by arranging the anions with hcp stacking and then filling half the tetrahedral interstices with cations. The structure is illustrated in Figure 6.6. The CN is 4 for both anions and cations. The first nearest-neighbor environment in AlN is identical to that in GaAs; but in GaAs there are four identical $\langle 111 \rangle$ directions, whereas AlN only has one $[0001]$ direction. Consider BeO: the bond strength is $S_{\text{Be}^{2+}} = +2/4 = +1/2$. Each O^{2-} must be surrounded by 4 Be^{2+} . Hence, the structure has to be created by stacking tetrahedra.

- For wurtzite, we stack the tetrahedra ABABAB.
- For zinc blende, we stack the tetrahedra ABCABC.

Although the theory clearly works beautifully, the catch is that the bonding between the Be^{2+} ions and the O^{2-} ions, or the Zn^{2+} ions and the S^{2-} ions, has a large covalent component. Sulfides in particular tend to be covalently bonded. Therefore, it is not really correct to apply Pauling’s rules, which were developed for ionic materials.

Another material that can be grown in either the wurtzite or zinc blende form is SiC. The bonding

APPLY PAULING’S RULES

$$\text{BeO} \quad r_{\text{Be}^{2+}}/r_{\text{O}^{2-}} = 0.25$$

$$\text{ZnS} \quad r_{\text{Zn}^{2+}}/r_{\text{S}^{2-}} = 0.34$$

FIGURE 6.6. Wurtzite crystal structure viewed along $[11\bar{2}0]$. (Top) Ion positions showing $A\alpha B\beta$ stacking. (Bottom) Two interpenetrating arrays of corner-sharing tetrahedra. (Only one set is needed to construct the crystal).

here is mainly covalent (~88%) as both Si and C are group IV elements. SiC is special in that it is very difficult to produce in a single structure. It always has the chemical composition SiC, but it tends to be a mixture of the two stacking sequences. These structures are two of the polytypes of SiC. The cubic form of SiC is being produced as a diamond simulant known as moissanite.

BeO and AlN have both been used for electronic packaging because of their high thermal conductivity. BeO has the higher thermal conductivity, but its powder is highly toxic.

ZnO is a semiconductor in which the conductivity depends on excess zinc atoms; its use in varistors relies

on the properties of its grain boundaries (see Chapter 14). GaN is of great interest for manufacturing blue–green laser diodes and blue and green light-emitting diodes (LEDs). It is ubiquitous in solid-state white lighting for energy-efficient domestic use. In fact, all of Singapore and much of China have LED traffic lights.

6.6 CaF₂

The mineral CaF₂ is known as fluorite, flourspar, and Blue John. The ionic radii are $r_{\text{Ca}^{2+}} = 100$ pm and $r_{\text{F}^-} = 130$ pm. Therefore, $r_{\text{Ca}^{2+}}/r_{\text{F}^-}$ is ~0.8. By Pauling's rules, Ca²⁺ ions should have a CN of 8 and F⁻ ions a CN of 4. Because the fluoride ions are larger, we should think of the structure as simple cubic stacking of the F⁻ ions with the Ca²⁺ ions filling every other cube interstice. However, you may remember the structure better by arranging the Ca²⁺ ions on an fcc lattice and then placing the F⁻ anions on the $\frac{1}{4}, \frac{1}{4}, \frac{1}{4}$ sites. These are the sites occupied by the Ga in GaAs, but now all such sites are occupied, not just half of them. There is a large unoccupied cube interstice in the middle of the cell at $\frac{1}{2}, \frac{1}{2}, \frac{1}{2}$ (the unoccupied site in the other description). The fluorite structure is shown in Figure 6.7.

Cubic zirconia (CZ) is stable only at high temperatures or when stabilized by addition of a dopant. CZ is a well-known diamond simulant in jewelry. Ceria and urania are both stable in the fluorite structure. In UO₂, our alternate description of the structure is now clearly the better one: the U⁴⁺ ion is large. The unoccupied cube interstice at $\frac{1}{2}, \frac{1}{2}, \frac{1}{2}$ (in the center of the cell) in UO₂ is very important; it can accommodate nuclear fission products (e.g.,

He) without straining the lattice. The oxides Li₂O, Na₂O, and K₂O are said to have the antifluorite structure because the location of the anions and cations is reversed relative to fluorite.

There is a great deal of interest in fluorides with the CaF₂ structure for optical applications. State-of-the-art production processes for semi-

conductor devices use deep-UV lasers to produce circuits with features as small as 130 nm. CaF₂ is then the material of choice for semiconductor lithography. It is one of only a few materials that are transparent at the shorter wavelengths of deep-UV light (refer to Figure 6.2: CaF₂ is transparent down to 0.13 μm). The next major steps for lithography are expected to be systems using even

PACKING IN ZnS

We have hcp packing of S²⁻ ions for wurtzite, fcc packing of S²⁻ for zinc blende. In both structures Zn²⁺ ions are located in half the tetrahedral interstices to maximize their separation.

FLUORITE-STRUCTURE OXIDES

c-ZrO₂, CeO₂, UO₂

FIGURE 6.7. Fluorite crystal structure. The fluoride ions occupy the eight tetrahedral sites (or the Ca ions occupy half the cube sites, with an empty one at the center of the unit cell).

FIGURE 6.8. FeS₂ crystal structures. The Fe ions occupy the fcc positions. The cubic cell also contains four S–S dumbbells.

shorter-wavelength light, ultimately achieving feature sizes down to 70 nm, where even CaF₂ does not suffice. You can also see top-of-the-line cameras using fluorite lenses, so optical-quality CaF₂ will retain its value.

6.7 FeS₂

The structure of pyrite (fool’s gold) is complicated but interesting. The Fe cations sit inside a sulfur octahedron. Three such octahedra then share a common vertex, and there is no edge sharing. The S–S bond length within the octahedron is 0.307 or 0.332 nm, but the S–S bond that joins the octahedra together is only 0.218 nm long. The space group is Pa $\bar{3}$ with $a = 0.542$ nm. It’s instructive to compare pyrite and NaCl. The pyrite structure is shown in Figure 6.8. Both appear to have an fcc cell, with the Cl being replaced by an S₂ dumbbell; but the dumbbells point along different directions for each of the edges. The result is that NaCl belongs to the m3m class, whereas pyrite belongs to the m3 class (still cubic but with a lower symmetry). Hence, NaCl has a fourfold axis along [001]; FeS₂ does not, but you can find large (>4 cm on the side) single-crystal cubes of pyrite. Many binary metal chalcogenides (compounds containing S, Se, or Te) have the FeS₂ structure, as do a few oxides (CdO₂, α -K₂O, β -Na₂O). Note that S is below O in the periodic table, so we might ask what the charge is on Fe in FeS₂.

Some of the relationships between the NaCl structure and materials with related structures such as pyrite are shown in Figure 6.9. This schematic is an illustration of how a simple structure can be systematically distorted to produce a host of new crystal structures.

FIGURE 6.9. How two simple structures (NaCl and FeS₂) can be related to more complicated crystal structures.

6.8 Cu₂O

There are two main oxides of copper, Cu₂O and CuO. Cuprite, Cu₂O, is cubic with the m3m crystal group. It takes a little effort to imagine the structure. Start with the Si structure (dc) and replace all of the Si atoms with O²⁻ anions. Each anion is now surrounded by four other anions. Place a Cu⁺ cation between every pair of anions. Then, where there is no tetrahedron in the dc structure, insert a new filled tetrahedron. Alternatively, we could have just created the tetrahedra of anions with cations between each one and then stacked the maximum number (without changing their rotation) into the cube. This structure is difficult to visualize.

A simpler way to remember the structure is shown in Figure 6.10. Four Cu ions form an fcc unit cell, and two O ions occupy two of the tetrahedral sites. The O²⁻ ions are much larger than the Cu⁺ ions. (Remember how we think about the fluorite structure).

This structure is particularly interesting because it consists of two linkages of tetrahedra that are rotated 90° to one another. The upper tetrahedron in Figure 6.10 is linked to another along the [1 $\bar{1}$ 0] direction at the top and along the [110] direction at the bottom (A connects to B). The second tetrahedron has the reverse arrangement.

Ag₂O and Pb₂O are isomorphous oxides. Cu₂O and Ag₂O are p-type semiconductors because they contain

FIGURE 6.10. Cu₂O crystal structures. (Top) ion positions. (Bottom) Two “occupied” tetrahedra. Cu ions sit at the fcc sites. Two O ions “occupy” tetrahedral sites.

excess oxygen atoms. The energy gap in Cu₂O is ~1.5 eV, and the impurity levels (acceptors) are about 0.3–0.6 eV above the valence band edge. Cuprite occurs naturally as a transparent red mineral.

6.9 CuO

You might think CuO would have a simple structure (following CoO, NiO, ZnO). Actually, tenorite (also known as melaconite) is monoclinic with the 2/m crystal class. The Cu atoms lie approximately in the middle of a square plane of four anions. Each anion is surrounded by four cations in what resembles a distorted tetrahedron. Square-plane coordination is the special feature of the cupric ion, Cu²⁺. Knowing the complex structure of these oxides can help understand the oxidation mechanisms of Cu. The square-plane coordination seen in this binary oxide is relevant when we later think about complex copper-based oxides, such as YBCO.

6.10 TiO₂

TiO₂ exists as rutile, anatase, and brookite. These structures are different, and we cannot think in terms of simply packing oxygen anions and filling the interstices. Each of the TiO₂ structures consists of Ti⁴⁺ cations in the center of oxygen octahedra. In rutile, which has tetragonal symmetry, the structure is constructed by linking octahedra. An octahedron is placed at each of the eight corners such that two are actually sharing an apex (e.g., at T). The six points on these octahedra are then connected by one rotated octahedron sitting in the center of the unit cell. The edges of the octahedra link together to give chains along the z axis, as shown in Figure 6.11. Each Ti⁴⁺ is thus surrounded by six O²⁻ ions, and each O²⁻ anion is surrounded by three Ti⁴⁺ ions. The structure is primitive tetragonal, with $a = 0.459$ nm, $c = 0.296$ nm, and two formula units per unit cell. The easiest projection is (001), where we are looking along the fourfold axis.

In anatase, the arrangement of the anions and cations is similar, and the crystal is again tetragonal; but now each octahedron is somewhat distorted, and shares four of its edges with other octahedra. In brookite, the structure is even more complicated, with octahedra sharing both edges and corners. So the trend for rutile–anatase–brookite is toward ever-decreasing symmetry.

Rutile is the simplest compound of a family of titanates that have high dielectric constants. They range from $\kappa \sim 100$ for rutile to several thousand for BaTiO₃. Of the other oxides that share the rutile structure, CrO₂ is ferromagnetic with a Curie temperature of 389 K; and VO₂ and MnO₂ are antiferromagnetic with Néel temperatures of 343 and 84 K, respectively. SnO₂ (cassiterite) and several binary

FIGURE 6.11. Rutile crystal structure viewed nearly parallel to the z axis. Each of the pairs of overlapping octahedra (e.g., P_1/P_2) shares an edge. The two octahedra in the lower right thus have point T in common. The central octahedron touches each of the eight at the corners.

fluorides such as MgF_2 are isomorphous. A lesser-known isomorphous compound is stishovite, which is a high-pressure form of SiO_2 .

6.11 Al_2O_3

Alumina (the ceramic) or corundum (the mineral) refers to $\alpha-Al_2O_3$. When it is doped with Cr^{3+} , the mineral is called ruby; when doped with Ti ions, we call it sapphire. Natural sapphire actually contains a combination of Ti^{4+} and Fe^{2+} , which compensate the charge difference. Some of the Fe^{2+} can be replaced by Ti^{2+} , so the Fe:Ti ratio can vary. (We may also have Ti^{3+} present).

Hematite, Fe_2O_3 , is isomorphous with alumina; it actually has almost exactly the same c/a ratio. Ilmenite is closely related but with Fe + Ti instead of Al + Al. Cr_2O_3 and Ga_2O_3 have a related structure. (In_2O_3 is completely different).

The crystal structure of Al_2O_3 is trigonal with the $\bar{3}m$ crystal class, and it has a pseudo-hexagonal oxygen sublattice (which is why we usually use a hexagonal cell

FIGURE 6.12. Sapphire crystal structure. (Top) $[11\bar{2}0]$ view. (Bottom) $[0001]$ view. (Left) Atomic models. (Right) Stacking octahedra. P_1 and P_2 are two unoccupied octahedra. S is a triangle of more closely spaced O^{2-} ions. Open circles (lower left) show AB stacking of the anions. The unit cell is outlined for both projections.

and four-index Miller-Bravais notation), but the symmetry really is threefold, not sixfold. In Al_2O_3 , the oxygen ions have what can be thought of as hcp stacking, with the Al^{3+} ions occupying two-thirds of the octahedral interstices (balancing the charge). The corundum structure is shown from two directions in Figure 6.12. Six parallel (0001) planes of oxygen ions are required to build the Al_2O_3 rhombohedral cell because the stacking is $AxB\beta A\gamma B\alpha A\beta B\gamma$; the Al^{3+} ions always sit in the C positions (think of the ABC fcc stacking), which is why we see the Al^{3+} ions when looking down the c -axis.

It is instructive to consider this structure in some detail. We can build it by stacking occupied octahedra (shown on the right). Each octahedron shares a face with the one above and the one below, but these are not regular octahedra. Pauling's rules say that it is not favorable to share faces of polyhedra. To compensate, the Al^{3+} cations move away from each other and toward the unoccupied octahedron (e.g., P_1 and P_2), as you can see in Figure 6.12. The oxygen anions move close together (e.g., the boxed group labeled S) to shield the nearby positive charges.

The result is that the (0001) “plane” of Al^{3+} cations actually lies on two distinct (0001) planes. This also means that there are two different oxygen–oxygen ion distances in the octahedra. We saw a similar effect in Section 6.7.

Specific letters are used to designate several of the common crystallographic planes in corundum (Table 6.3, Figure 6.13). It is useful to know this convention, especially if you want to order or use single-crystal sapphire substrates.

Aluminum oxide is by far the most widely used compound with this structure. As a single crystal, it is used in watch bearings and pressure-resistant windows. Hot-pressed powders are employed as electrical insulators, windows or radomes transparent to microwaves, envelopes

TABLE 6.3 Common Crystallographic Planes in Sapphire

Plane “name”	Miller-Bravais index	<i>d</i> spacing (nm)
a	(11 $\bar{2}$ 0)	0.2379
c or basal plane	(0001)	0.2165
m	(10 $\bar{1}$ 0)	0.1375
n	(11 $\bar{2}$ 3)	0.1147
r	(1 $\bar{1}$ 02)	0.1740

FIGURE 6.13. Location of important planes in sapphire.

for lamps, and electrical devices. In polycrystalline form it is also the basis of refractory bricks, crucibles, and spark-plug insulators.

6.12 MoS_2 AND CdI_2

MoS_2 and CdI_2 are based on the hcp structure. In molybdenite, the Mo atoms are located in positions corresponding to the unit cell of the hcp structure. An S–S pair is centered along the *c*-direction directly opposite the Mo atoms, giving the structure shown in Figure 6.14. The stacking sequence can be written as AbABaB, where the capital letters denote the S atoms and the lowercase letters the Mo atoms. The metal atom has a CN of 6, as it is in the TiO_2 and CdI_2 structures. Thus, we would expect that phases with r_M/r_X between 0.41 and 0.73 would form any of these structures. However, the more ionic compounds form the rutile structure, and the more covalent compounds have the CdI_2 structure. Those in which the bonding is intermediate adopt the MoS_2 structure.

Several of the Mo and W chalcogenides adopt the molybdenite structure, but MoS_2 is the most interesting phase and is an excellent (dry) lubricant. It is instructive to compare the MoS_2 structure to the structure of graphite, which is shown for comparison in Figure 6.15. The unit cell of graphite is clearly hexagonal and has lattice parameters $a = 0.2456$ nm and $c = 0.6696$ nm. The C–C

FIGURE 6.14. Crystal structure of molybdenite. S ions stack ABB, whereas Mo ions occupy half the trigonal prisms in each S “sandwich”.

bond length is 0.142 nm in the sheets and 0.335 nm between sheets. The six-membered rings are stacked to give an ABAB sequence. It is the long bond distance in the *c*-direction that gives graphite similar properties as a solid lubricant. (Actually, it is the weak bonds between pairs of basal planes that cause the bonds to be long).

FIGURE 6.15. Crystal structure of graphite. C atoms form hexagonal rings, but the unit cell is a rhombus (e.g., MoS₂). See also Figure 29.19A. Viewed along the *c* axis, the *upper* figure shows just one layer (e.g., A); and the lower shows A stacked on B.

As expected, graphite has highly anisotropic properties. The properties of graphite within the sheets are similar to those of a metal, whereas the properties perpendicular to the sheets are more like those of semiconductors.

Because interlayer (van der Waals) bonding is very weak in MoS₂ and graphite, the structures can also exist in a rhombohedral form with a stacking sequence AbABaBCcC. Other layer materials naturally adopt this structure. (Graphite can also stack ABC).

The crystal structure of hexagonal BN is closely related to that of graphite except that the atoms in one layer lie directly above those in the next, and the six-membered rings are made up of alternating B and N atoms, which also alternate along the *c* direction. BN also exists with the sphalerite and wurtzite structures (which are nearly as hard as diamond; see Chapter 16).

This structure can also be derived from the hcp structure by replacing the metal atoms in the unit cell by I atoms and by adding Cd atoms at the corners of the unit cell. Thus, the I⁻ ions sit in an hcp arrangement with the Cd²⁺ ions between them. The more covalent AB₂ phases tend to form the CdI₂ structure. Thus, the larger polarizable iodides and bromides form this structure with highly polarizing cations, whereas the fluorides favor the rutile structure.

6.13 POLYMORPHS, POLYTYPES, AND POLYTYPIDS

Polymorphs are materials that have the same chemical composition but different crystal structures. Many ceramic materials show this behavior, including SiO₂, BN, BaTiO₃, ZrO₂, and BeO. Transitions between different polymorphs may occur as a result of changes in temperature or pressure. The relationships between the polymorphic forms of silica are shown in Figure 6.16 with the corresponding temperatures needed for transformation. These are not the only known phases of SiO₂. At pressures around 2 GPa,

FIGURE 6.16. How polymeric forms of silica can be converted into one another by displacive or reconstructive structural transformations.

FIGURE 6.17. Stacking sequences for five SiC polytypes.

FIGURE 6.18. Relating the cubic and rhombohedral unit cells for zinc blende.

quartz transforms into coesite. At even higher pressures, around 7.5 GPa, coesite transforms to stishovite. The high-pressure forms have been prepared experimentally and also found at the famous Cañon Diablo Meteor site in Arizona. (We examine these structures further in Chapter 7).

When an element exists in different solid phases we refer to the phases as allotropes. Graphite and diamond are two allotropes of carbon.

Polytypism is a special, one-dimensional type of polymorphism in which the different crystal structures assumed by a compound differ only in the order in which a two-dimensional layer is stacked. The effect is common in layer structures (e.g., MoS₂, graphite, layer silicates). Silicon carbide (SiC), a ceramic material of considerable importance, displays the richest collection of polytypic forms. More than 200 SiC polytypes have been determined. Figure 6.18 shows

TABLE 6.4 Relationships Between Polytypes in Silicon Carbide

Structure	Strukturbericht	Stacking sequence	Lattice parameters		Ramsdell notation
			a (nm)	c (nm)	
Wurtzite	B4	AB	0.3076	0.5048	2H
Zinc blende	B3	ABC	0.308	0.755	3C
Carborundum III	B5	ABAC	0.3076	1.004	4H
Carborundum II	B6	ABCACB	0.3080	1.509	6H
Carborundum I	B7	ABACBCACBABCAC	0.3080	3.781	15R

the structural relationship between five polytypes. Table 6.4 gives the stacking sequence and lattice parameters for the polytypes.

You can see in Figure 6.17 that we have translated the usual cubic representation of the zinc blende cell into a rhombohedral one, which can be compared directly with the unit cells of the other SiC polytypes. A way of viewing the cubic (3C) cell as a rhombohedral cell is shown in Figure 6.18. The former cubic-cell diagonal has become now the *c*-axis of the corresponding rhombohedral cell. Of course, the arrangement of the atoms remains unchanged.

You can also see that we introduced a new notation scheme in Table 6.4. The Ramsdell notation is frequently used when referring to different polytypic forms and describes the stacking sequence in these complex structures. The notation consists of a number and a letter. The number indicates the number of layers in the sequence. The letter indicates the structure type (C = cubic, H = hexagonal, R = rhombohedral). At one extreme we have the zinc blende SiC (3C), with pure cubic stacking in the [111] direction. At the other extreme we have wurtzite SiC (2H), with pure hexagonal stacking in the [0001] direction. The other polytypes have either H or R stacking sequences. For example, the carborundum III (B5) structure in Figure 6.17 has

the Ramsdell symbol 4H: the sequence consists of four layers and then repeats, and the structure is hexagonal.

In this chapter we have discussed the structure of a series of binary compounds that are also used as models for other compounds. All ceramics students must learn some of these structures by heart, but it is equally important to know the reason we chose these structures and how they relate to Pauling's rules (Chapter 5). Also, remember that Pauling's rules were developed for ionic materials, so any covalent component may compromise the predictions. The polyhedra found in these simple structures reappear in much more complex structures, as we'll see in Chapter 7. Each of the compounds has an application as illustrated here, but we concentrate more on those applications in later chapters. As an example, CaF₂ used to be known as an interesting structure and a semiprecious stone. That it would today be grown as 200 mm diameter crystals for 135 μm UV lithography would not have been imagined a few years ago. Although it is used for its optical properties, the orientation of the crystal must be controlled because the optical properties depend on the crystal orientation. The best large sapphire windows (with minimum birefringence) are cut from (0001) crystals. The crystal structure of crystalline materials controls most of the properties of these materials.

CHAPTER SUMMARY

To really understand ceramic materials, you must know the basic crystal structures. Then you can picture the polyhedra—such as the tetrahedron and the octahedron—and know what we mean when we talk about linking them, distorting them, substituting them, and so on. Always keep Pauling's rules in mind. We've discussed the most important of the structures of the binary compounds, and you must know CsCl, NaCl, GaAs, AlN, CaF₂, MoS₂ and Al₂O₃ by heart. We have also included FeS₂, Cu₂O, CuO, and CdI₂ and TiO₂ in part because these materials are becoming more important in their own right but also because they provide insight into many related binary compounds. Throughout this chapter and in Chapter 7 many of the diagrams were drawn using CrystalMaker. This is an affordable program for the Mac and PC and should be available to every student taking any ceramics or mineralogy course. It is today's equivalent of the real (wooden) ball and (steel) stick models that used to be passed around the class but rarely were taken to your dorm room. It allows you to switch from ball-and-stick to polyhedra at the click of the mouse.

PEOPLE AND HISTORY

Bragg, W.H. and Bragg, W.L. (father and son). They did not discover X-ray diffraction, but they realized that it could be used to determine the structure of crystals. The first structure they solved was that of NaCl. They won the 1915 Nobel Prize in Physics “for their services in the analysis of crystal structure by means of X-rays.” In addition to the Braggs, the other fathers and sons with tandem Nobel laureates are the Thomsons (Sir Joseph Thomson for Physics 1906 and his son George Paget Thomson for Physics 1937) and the Siegbahns (Karl Manne Siegbahn for Physics 1924 and his son Kai Siegbahn for Physics 1981).

Coes, Loring. A high-pressure scientist, he gave his name to the high-pressure form of quartz. He first synthesized coesite in 1953 at Norton Laboratories.

Moissan, Ferdinand Frédéric-Henri. He began researching diamond synthesis in 1889. His idea was to produce diamonds by passing an electrical current through a sample of iron and sugar charcoal followed rapidly by quenching it in cold water. After one experiment Moissan isolated very small diamond octahedral crystals. After his death in 1907, it was revealed that one of Moissan’s assistants had planted natural diamonds to make Moissan feel better. Moissan did actually make SiC, which was later given the name Moissanite.

IUCr (International Union of Crystallography). This Society publishes the journal *Acta Crystallographica*. IUCr recorded: “the very first specialized X-ray diffraction meeting with international representation was an informal one and was held at Ewald’s mother’s house on the Ammersee, Germany, in 1925. In addition to Ewald, the small group included W.L. Bragg, L. Brillouin, C.G. Darwin, P.J.W. Debye, R.W. James, M. von Laue, I. Waller, and R.W.G. Wyckoff.”

EXERCISES

- 6.1 Draw and label (the ions and at least three directions) the [100], [111], and [110] projections for rock salt, GaAs, CsCl, and fluorite.
- 6.2 Draw and label (the ions and at least three directions) the [0001], [1 $\bar{1}$ 00], and [11 $\bar{2}$ 0] projections for hematite.
- 6.3 Draw and label (the ions and at least three directions) the [0001], [1 $\bar{1}$ 00], and [11 $\bar{2}$ 0] projections for ZnO.
- 6.4 Estimate the radius of the cubic interstice in UO₂. Discuss this result using Pauling’s rules.
- 6.5 You know the crystal class of FeS₂ and its space group. Explain the relationship.
- 6.6 Prove that the atomic packing factor for GaAs is 0.41. The atomic radii for Ga and As are 0.135 and 0.125 nm, respectively. The lattice parameter is 0.565 nm.
- 6.7 The coordination number (CN) for silver and copper ions in Ag₂O and Cu₂O is 4. This is quite unusual for these ions. What would you expect the CN to be based on the sizes of the ions? How might you explain the observed differences, if any? The ionic radii of the ions are given in Table 4.6.
- 6.8 Does rutile obey Pauling’s rules?
- 6.9 How do the densities of high cristobalite and silica glass compare? You will need to dig for the data on this one—in the library or on the Internet.
- 6.10 NaCl, TiC, and PbS have the same structure. Are they all good examples of Pauling’s rules in action?
- 6.11 Imagine that NaCl could exist in the rock salt, CsCl, and zinc blende structure with an Na-Cl bond length of 0.1 nm. What would be the lattice parameters of the crystal in each case? If the Cl[−] ion has its usual (Pauling) radius, what would you deduce about the size of the Na⁺ ion in each case?
- 6.12 If the lattice parameters of MgO are $a = b = c = 0.2$ nm and $\alpha = \beta = \gamma = 90^\circ$, what is the lattice parameter of the primitive rhombohedral unit cell?
- 6.13 What is the orientation of the crystal that is imaged in Figure 6.5? Label three different planes that are edge on in this orientation.
- 6.14 Nanoparticles of ZnO are among the hottest materials for high-tech (money-making) applications because of their electronic properties. Explore the literature and make a list of 10 possible applications and the form of ZnO in each case (e.g., particle, rod, film).
- 6.15 Why did Ramsdell create his notation? (Reference your source.)
- 6.16 Explain how the 4H structure (in Ramsdell notation) can be hexagonal.
- 6.17 You know the structure of graphite is 2H but can be 3R. In this context, discuss the meaning of the phrases a) two layers of graphene, b) three layers of graphene, c) four layers of graphene, and d) five layers of graphene.

- 6.18 Remembering exercise 6.17, speculate on the structure and properties of the imaginary molybdenite.
- 6.19 Why can SiC exist in so many different polytypes? Explore the literature to find the largest lattice parameter that has been reported for a SiC polytype (c in Figure 6.17). (Report your source).
- 6.20 Molybdenite is used as a solid lubricant and may have applications for batteries. How are these two applications related?

Complex Crystal and Glass Structures

CHAPTER PREVIEW

This chapter is separated from the previous one just to make it less overwhelming! We've demonstrated the principles in Chapter 5 and considered some of the simpler ceramic structures in Chapter 6. Now we are considering structures that have more than two chemically different atoms in the unit cell (such as $\text{YBa}_2\text{Cu}_3\text{O}_7$) although some still have only two components. We include materials (such as SiO_2) where covalent bonds are particularly important and encounter materials involving secondary bonds such as van der Waals interactions (especially in the clay minerals).

It is a little difficult to learn these structures by heart, but some, such as cristobalite and perovskite, you should know. For others, you may survive by just knowing the basic ideas involved. This emphasizes the reason for this chapter (and Chapter 6)—if you understand the building blocks, you can better appreciate the properties of more complex structures that are composed of combinations of such building blocks. The logic behind the order in which these are discussed is first cubic, then the silicates (starting with silica), then the complicated ones, and finally some new materials that challenge our perception of what is a ceramic.

Glass has often been treated separately from ceramics, but today few programs in materials science have the time for a specialized course on glass. We include a discussion of glass structures in this chapter because they link so closely with the crystal structure of crystalline silicates and the general concept of coordination polyhedra. We discuss the properties of glass later. Remember that the structure of glass is *not* random; it just lacks long-range order. We have point defects and other defects in glass just as we do in crystals; the challenge is to define the nondefective structure that we can relate them to. What makes a point defect in glass a defect and not just part of the glass?

A common mantra throughout this chapter is “diagrams are essential.” A difficulty is that you generally need more than one diagram (view) to appreciate a three-dimensional (3D) structure. Computer programs can make the 3D aspects much more apparent.

In this and the previous chapter, the xyz axes in the schematics of cubic crystal structures lie along the cube edges. The length of the cube edge is the lattice parameter.

7.1 INTRODUCTION

In most simple metal–oxide structures, $r_M \ll r_X$ and the structures can be built up by considering a nearly close-packed arrangement of oxygen ions with cations located in interstices. The ionic radius ratios given earlier are useful and provide a means of predicting the coordination number (CN) of a particular compound, and often the predictions are in good agreement with observed values. In cases where the observed CN differs greatly from the expected value, such as 12 for K^+ in mica, $\text{KAl}_3\text{Si}_3\text{O}_{10}(\text{OH})_2$, it is probable that the other ions present play the most important part in determining the arrangement.

The ions that are close to the transition values of the radius ratio can show variations in CN. An example is the

Al^{3+} ion ($r_{\text{Al}}/r_{\text{O}} = 0.38$), which sits inside oxygen tetrahedra in many aluminosilicates but inside octahedra in others (as is the case for Al_2O_3). The Al^{3+} ion has CNs of both 4 and 6 in sillimanite, both 5 and 6 in andalusite, but only 6 in kyanite even though all three are stable minerals, and all have the composition Al_2SiO_5 . Another example is the Zr^{4+} ion ($r_{\text{Zr}}/r_{\text{O}} = 0.51$), which is octahedrally coordinated in several crystals, e.g., CaZrO_3 (isomorphous with perovskite), but has a CN of 8 in zircon, ZrSiO_4 . As Pauling said, the size of the ion depends on the site that it occupies.

Table 7.1 lists some deviations from the CN predicted by radius ratios. Where the observed CN is larger than predicted, there is a gain in electrostatic energy by increasing the number of nearest neighbors. This gain is larger

TABLE 7.1 CN and Bond Strength, S, of Various Cations with Oxygen

<i>Ion</i>	<i>r_M</i> (pm)	<i>CN_{theory}</i>	<i>CN_{obs}</i>	<i>S</i>
B ³⁺	16	3	3, 4	1 or 3/4
Li ⁺	53	6	4	1/4
Si ⁴⁺	29	4	4, 6	1
Al ³⁺	38	4	4, 5, 6	3/4 or 1/2
Ge ⁴⁺	39	4	4, 6	1 or 2/3
Na ⁺	73	6	4, 6, 8	1/6
Zr ⁴⁺	51	6	6, 8	2/3 or 1/2
Ca ²⁺	71	6, 8	6, 7, 8, 9	1/4
Ce ⁴⁺	57	6	8	1/2
K ⁺	99	8, 12	6, 7, 8, 9, 10, 12	1/9

than the energy expended in deforming the surrounding ions. Remember that the ions are not rigid spheres. Where the observed CN is smaller than predicted, there is often an appreciable amount of covalent character to the bonding. Covalent bonds are strongly directional.

Why so much about silicates? We spend effort on silicates not just because they are the main constituents of the earth's upper mantle (and therefore the geological materials we most readily see) but because they are really ubiquitous (even when you don't at first realize it) and therefore provide many of our raw materials. We suspect that silicates also have an enormous range of unexplored applications. Silicates also link in with the second unusual topic for such a chapter, namely glass: many glasses are silicates that lack long-range order.

7.2 SPINEL

The mineral spinel is MgAl₂O₄. Spinel has the general formula AB₂O₄, although later we also write it as AO.*n*B₂O₃, where *n* describes the nonequimolarity. Bragg and Nishikawa actually solved the spinel structure independently in 1915. The spinel structure is so important because the magnetic ferrites are spinels. For the ferrites, we express the chemical formula as MO.Fe₂O₃, where M is a divalent metal ion, such as Mn, Ni, Fe, or Co (or a mixture of such ions).

Although structurally quite simple, spinel has a large number of atoms or ions associated with each lattice point in its Bravais lattice. The Bravais lattice is fcc, and the unit cell contains a total of 56 ions (32 oxygen ions). There are four lattice points per fcc unit cell and thus 14 ions associated (two formula units) with each lattice point.

In spinel we often think of the O²⁻ ions as sitting on

the fcc lattice sites. Actually, they are generally slightly displaced from these exact positions. Considering the cations and thinking of MgAl₂O₄, the Al³⁺ ions now occupy some of the octahedral sites, with the Mg²⁺ ions being located on tetrahedral sites. This arrangement is the "normal" as opposed to "inverse" spinel structure; most spinels are not exactly normal! Note that the arrangement of the oxygen ions is essentially the same as in MgO, but now some of the octahedral and some of the tetrahedral interstices are occupied instead of only the octahedral ones.

- *Normal spinel*: The A²⁺ ions occupy only tetrahedral sites, and the B³⁺ ions occupy only octahedral sites.
- *Inverse spinel*: All the A²⁺ ions and half the B³⁺ ions sit on the octahedral sites; the tetrahedral sites are occupied now by the other half of the B³⁺ ions.

The arrangement of the cations is such that the lattice parameter of the spinel MgAl₂O₄ is close to twice that of the corresponding MgO. If we think of the spinel cubic unit cell as divided into eight cubes, these smaller cubes would be almost exactly the size of the MgO unit cell. This means that six parallel {111} planes of oxygen ions are required to construct the rhombohedral cell, rather than three.

Looking at some ionic radii, we can understand why the same structure can be formed with Ni or Co substituting for Mg. Similarly, Fe or Cr can substitute for Al.

O²⁻ : 140 pm, Mg²⁺ : 72 pm, Ni²⁺ : 69 pm, Co²⁺ : 74 pm

O²⁻ : 140 pm, Al³⁺ : 53 pm, Fe³⁺ : 65 pm, Cr³⁺ : 62 pm

If we look at this structure along a [110] direction (Figure 7.1A, B), we can see the tetrahedra and octahedra. Remember that the anions are in an fcc stacking sequence, so this is a close-packed direction for the O ions. Spinel thus shows particularly clearly how a structure can be built up by systematically filling some of the octahedral (O) sites and some of the tetrahedral (T) sites. The apparently touching tetrahedra are actually at different heights in this projection, so they do not share an edge. The lines P₁ and P₂ remind you where the edge-on {111} planes lie. If we rotate the structure through 90° about the horizontal [110] axis, we reach the [001] projection shown in Figure 7.1C.

We can look at the structure in several ways. In Figure 7.1B, the cell has been divided into eight distinct layers of ions. This sequence is PqRsTuVw, where the upper case refers to mixed O²⁻ plus

SOME IMPORTANT SPINELS

γ-Fe ₂ O ₃	Maghemite
MgAl ₂ O ₄	'Real' spinel
NiFe ₂ O ₄	A classic ferrite
Fe ₃ O ₄	Magnetite

FIGURE 7.1. Spinel crystal structure. The 32 anions in the unit cell form eight slightly distorted fcc oxygen lattices. The cations are then distributed with one tetrahedron occupied in each “sub-cell” (rather like Cu_2O). The 16 octahedral sites are then distributed in rows along one $\langle 110 \rangle$ direction or the orthogonal one depending on the layer (V,R or T, P in “b”).

octahedral cation layers, and the lower case refers to the tetrahedral cations. This method of building the structure emphasizes that there are only two different “planes” of ions to stack! The row of octahedral sites actually rotates 90° every $1/4$ cell (i.e., every two layers). Hence, layers P and T are shifted relative to one another but are rotated 90° relative to R and V.

BaTiO₃ AND KNbO₃

A	B	O
$R_{\text{Ba}^{2+}} = 136 \text{ pm}$	$R_{\text{Ti}^{4+}} = 61$	$R_{\text{O}^{2-}} = 140 \text{ pm}$
$R_{\text{K}^+} = 138 \text{ pm}$	$R_{\text{Nb}^{5+}} = 64$	$R_{\text{O}^{2-}} = 140 \text{ pm}$

CaCO₃ AND CaTiO₃

The carbonate is an inorganic salt. The anion is CO_3^{2-} , which is quite like a sphere although it actually has 3-fold symmetry and is shown as a triangle in Figure 7.3. This anion and the Ca^{2+} are arranged in similar way to NaCl but with a threefold distortion.

The structure is effectively shifted by $1/4 [1\bar{1}0]$ every four layers (half way up the cell). (We return to this stacking in Chapter 14).

How did Bragg determine the spinel structure, and how can you distinguish normal and inverse? X-ray diffraction measures the distribution of electrons and hence allows us to deduce atom position by measuring the structure factor. The positions $x_n, y_n,$ and z_n are fractional coordinates of atoms in the unit cell. Because the structure factor, F , depends on $x_n, y_n,$ and z_n , the value of $F_{\text{normal}} \neq F_{\text{inverse}}$.

In $\gamma\text{-Fe}_2\text{O}_3$, the other cation is a “vacancy”; maghemite is known as a defect spinel and is related to the other important defect spinel $\gamma\text{-Al}_2\text{O}_3$ (although there may be other complications involving H^+ ions in this case). The Fe ions in magnetite occupy both tetrahedral and octahedral sites so it is FeFe_2O_4 but we haven’t specified which ion (Fe^{2+} or Fe^{3+}) sits where. Spinel is notorious for being nonequimolar ($n \neq 1$, which does not mean the same as nonstoichiometric). When the formula is written as $\text{AO}.n\text{B}_2\text{O}_3$, the value of n can vary from 1 to 3.5 depending on A, B, and T.

7.3 PEROVSKITE

With a general formula ABO_3 , the A cation and the anions effectively form an fcc array with a large octahedron in the center of the cell but no available tetrahedra (because of the charge). The ideal perovskite structure is simple cubic, and this is what we generally imply when we refer to the perovskite structure. The mineral perovskite is CaTiO_3 and is actually orthorhombic at room temperature, only becoming cubic at temperatures above 900°C . Other ceramics with the perovskite structure include BaTiO_3 , SrTiO_3 , and KNbO_3 , each being written in the general form ABO_3 . Don’t confuse the structure with that of ilmenite, FeTiO_3 , which is related to the alumina structure.

The perovskite structure is shown in Figure 7.2A. Looking at the ionic radii, we can see a trend. The O^{2-} anion and the larger cation (A^{2+}) have similar radii so that the structure is not just determined by O^{2-} . The larger cation and the anion combine to form a “close-packed” arrangement, with the smaller cation, B^{4+} , sitting in the oxygen octahedral interstices. The octahedra then link together by sharing corners, as shown in Figure 7.2B.

FIGURE 7.2. Perovskite crystal structure. The lattice is simple cubic, with several cations able to occupy the central octahedron. (A) Atomic model. (B) Polyhedron.

The bond strength is given as

$$\text{Ti} - \text{O} = +4/6 = 2/3; \quad \text{Ca} - \text{O} = +2/12 = 1/6$$

Each O^{2-} anion coordinates with two Ti^{4+} and four Ca^{2+} cations so that the total bond strength is

$$2 \times 2/3 + 4 \times 1/6 = +2$$

Barium titanate (BaTiO_3) is the prototype ferroelectric material. It has the ideal perovskite structure above 120°C . At temperatures below 120°C , the small cation (Ti^{4+}) shifts off its ideal symmetrical position at the center of each octahedral interstice. This shift creates an electric dipole; it polarizes the structure electrically, which in turn causes the material to become noncubic; it changes the cell dimensions. Spontaneous electrical polarization in the absence of an applied electric field is termed *ferroelectricity*. The link between electric field and mechanical deformation of the unit cell is known as the *piezoelectric effect*: it allows us to convert an electrical signal to a mechanical one and vice versa. This shift actually has the same origin as the flexibility of this structure: many ions can fit in the central octahedron.

The perovskite structure is particularly important for several reasons:

- Many perovskites are ferroelectric.
- Many perovskites are piezoelectric.
- Many perovskites have a high dielectric constant.

FIGURE 7.3. Crystal structure of calcite. The Ca^{2+} cations sit in the octahedral site; the CO_3^{2-} ions are represented as a triangle that each links six octahedra. The octahedra each has one of two orientations and “stacks” in an ApBqCr sequence giving the $\bar{3}$ symmetry and producing the c lattice parameter of 1.71 nm (a is 0.50 nm).

The perovskite structure is also of interest to mineralogists. A mineral with the perovskite structure of composition close to MgSiO_3 is believed to be the predominant mineral in the lower mantle (depths of about 600 km) of the Earth. The perovskite structure of MgSiO_3 is stable only at very high pressures.

Perovskites have also received much attention since 1986 because the superconducting oxide YBCO contains perovskite structural elements. The importance of this structure was again realized in 1993 when the phenomenon of colossal magnetoresistance (CMR) was discovered in a range of manganate ceramics with a layered perovskite structure similar to that found in YBCO and other high-temperature superconductors.

7.4 THE SILICATES AND STRUCTURES BASED ON SiO_4

We can start by considering ionic radii and Pauling's rules.

$$r_{\text{Si}^{4+}}/r_{\text{O}^{2-}} = 0.40/1.40 = 0.29 < 0.41$$

Thus, tetrahedral coordination is expected, and the bond strength, S , is +1 ($= +4/4$). The $(\text{SiO}_4)^{4-}$ units are the building blocks for all silicates; each O^{2-} ion is coordinated with two Si^{4+} ions, so the tetrahedra join at corners. Actually, there is a very large covalent component too so that the Si–O bond is very strong (it is only ~40% ionic). Thus, Pauling's rules don't really apply, and we just talk

about the SiO_4 unit and take account of the charge separately.

Some possible linkages of SiO_4 tetrahedra are illustrated in Figure 7.4. This is a key idea in understanding silicates. We can either keep the SiO_4 tetrahedra separate or link them to one another. If we link them, then we can form chains or rings. Then we can join rings to make sheets or join chains to make double chains. Units formed by these combinations are listed in Table 7.2.

To give you an idea of the variety of structures that are then possible, a discussion of just the structures (not properties—just structures) of rock-forming minerals consisting of isolated SiO_4 tetrahedra is the subject of a 900-page text. Table 7.3 lists some examples of the classes of silicates with special structures. Table 7.4 gives an idea of the complex crystallography involved. Clearly, we can't go through all the ideas of silicates as this is an enormous field.

TABLE 7.2 Linking SiO_4 Tetrahedra to Make Silicates

#	Structure unit	Structure formula
0	$[\text{SiO}_4]^{4-}$	Orthosilicates
1	$[\text{Si}_2\text{O}_7]_n^{6-}$	Pyrosilicates
2	$[\text{SiO}_3]_n^{2n-}$	Pyroxene chain
2.5	$[\text{Si}_4\text{O}_{11}]_n^{6n-}$	Amphibole
		Note difference between this and infinite-sheet clays (Si_2O_5)
3	$[\text{Si}_2\text{O}_5]_n^{2n-}$	
4	$[\text{SiO}_2]_n^0$	3D network

#Number of shared vertices

Albite		C $\bar{1}$	Triclinic	Framework silicate
Anorthite		P $\bar{1}$	Triclinic	Framework silicate

You should know the general principles, the bonding, etc., and the language!

A special feature of the silicates is that it is often quite easy to replace the cations that are outside the SiO₄ tetrahedra. This leads to the idea of *isomorphous replacement*. We can even replace the Si⁴⁺ in the SiO₄ tetrahedron with other similar-size ions (such as Al³⁺) having the same oxygen coordination. The idea is that $r_{\text{Al}^{3+}}/r_{\text{O}^{2-}} = 0.36$, which is close to 0.41. Al³⁺ can have 6 or 4 coordination. To balance the charge, we also need to replace some Na⁺ (say) by Ca²⁺. The following are two well-known examples:

- Forsterite and fayalite are structurally almost identical and thus form a continuous solid solution, with Mg²⁺ gradually being replaced by Fe²⁺ across the series (as we go to fayalite).
- The feldspar minerals fall into two main series: the alkali (K-Na) feldspars, where we gradually replace Na⁺ by K⁺ across the series, and the plagioclase (Ca-Na) feldspars, where there is a continuous variation in composition by substituting Ca²⁺ + Al³⁺ for Na⁺ + Si⁴⁺.

TABLE 7.5 Some Densities

Oxide	a (nm)	c (nm)	Density in g/cm ³
High quartz	0.501	0.547	2.65
High tridymite	0.503	0.822	2.26
High cristobalite	0.713		2.32
MgO			3.59
Al ₂ O ₃			3.96

7.5 SILICA

Silica has many different polymorphic forms (see Section 6.13). We discuss three forms of SiO₂, namely quartz, tridymite and cristobalite (note the spelling). For each form, at low temperatures (the α phase) we find a structure that is a distortion of the high-temperature form (the β phase). In each case, changing from the α to β structure involves a displacive phase transformation; the atoms need to move only slightly relative to one another. However, to change from one form to another requires breaking bonds. This process is much more difficult and is known as a reconstructive phase transformation.

The Si–O–Si arrangement of ions does not always lie exactly on a straight line, especially for the low-temperature forms. If the bonding were purely ionic, the line would be straight and the O^{2−} should lie exactly in the middle: the reason in each case is that we want to maximize the electrostatic attractive forces and minimize the electrostatic repulsion. However, the Si–O bond is ~60% covalent, so there is a strong tendency toward directional bonding. The different forms of silica have different densities, each being much less dense than the more ionic oxides, as shown in Table 7.5.

The structure of high cristobalite, showing the highest symmetry, is illustrated in Figure 7.5 as arrangements of atoms and as a stacking of tetrahedra. The Si⁴⁺ cations sit in the same positions as the Si atoms in the dc Si structure. An O^{2−} anion is located between each and every pair of Si⁴⁺ cations! In high tridymite, the Si⁴⁺ cations sit on wurtzite sites instead of zinc blende, and the O^{2−} anion again sits between the cations! You can appreciate the movement that is needed to transform tridymite to cristobalite. When tridymite is found, it always contains small amounts of impurities. It is possible that these impurities are necessary to stabilize the structure.

7.6 OLIVINE

The olivine minerals are orthosilicates: the SiO₄ tetrahedra are isolated from one another, meaning that the tetrahedra do not share oxygen ions. The structure is seen from two directions in Figure 7.6, which shows that the structure can be envisioned in a way that relates it to spinel and alumina. The hexagonal ABAB stacking of the anions seen in “A” is

FIGURE 7.5. Crystal structure of cristobalite. The most symmetrical for SiO_2 having cubic symmetry ($m\bar{3}m$) and a lattice parameter of 0.72 nm.

just like alumina, as is the view from normal to these close-packed layers shown in “B.” Unlike alumina, some of the cations are in tetrahedral sites, and others are in octahedral sites, like spinel. But unlike spinel, the two types of site are present between every close-packed layer of anions. Like spinel, the pairs of tetrahedra are not actually sharing edges, as appears to be the case in “A.” The result of this distribution of cations is that the crystal structure is orthorhombic, with the b lattice parameter by far the longest, at 1.02 nm; the a and c lattice parameters are 0.48 and 0.60 nm, respectively. The O^{2-} anions at the corners of the tetrahedra are linked by O-A-O bonds (A being Mg or similar); some tetrahedra point up, others point down. In forsterite, this Mg^{2+} ion is located at the center of an octahedron just as it is in MgO.

The best-known composition of olivine, the light green gemstone peridot, is $(\text{Mg}_{0.9}\text{Fe}_{0.1})_2\text{SiO}_4$. The olivines are a group of minerals showing isomorphous replacement.

- Forsterite, Mg_2SiO_4 ; with up to 10% Fe replacing Mg
- Fayalite, Fe_2SiO_4 ; with up to 10% Mg replacing Fe
- Monticellite, $\text{Ca}(\text{Mg,Fe})\text{SiO}_4$; the Ca and Mg/Fe give an ordered stacking
- Tephroite, Mn_2SiO_4 ; a rare mineral that may contain Zn, Fe, or Mg substituting for Mn

FIGURE 7.6. Crystal structure of olivine, an orthosilicate. (A) View along [001]. (B) View along [100]. Examples of octahedra and tetrahedra are outlined in both figures. Typified by forsterite, Mg_2SiO_4 .

Olivine is one of the most important materials in the earth sciences. The structure has been rediscovered recently because of its importance for cathode materials in lithium-ion batteries (see Chapter 37).

7.7 GARNETS

Garnet refers to both the garnet group of silicates and the garnet structure, which is also adopted by nonsilicates. Some names and chemical compositions of garnets are summarized in Table 7.6. The garnets have the general formula $\text{A}_3\text{B}_2(\text{DO}_4)_3$, where A and B refer to divalent and trivalent cations; D is Si in the case of silicates. In the nonsilicates, the structure is interesting because the same trivalent ion can sit in two very different sites, the A site and the B site. Important nonsilicate garnets include YAG (a laser host material) and YIG (a magnetic garnet).

It may help to remember the composition of YAG, say, by remembering that it is $4(\text{X}_2\text{O}_3)$ where X is a combination of trivalent cations. The structure is formed

TABLE 7.6 Examples of Garnets

Garnet	Formula	Alternate	a (nm)
Pyrope	Mg ₃ Al ₂ Si ₃ O ₁₂	Mg ₃ Al ₂ (SiO ₄) ₃	1.146
Almandine	Fe(II) ₃ Al ₂ Si ₃ O ₁₂	Fe(II) ₃ Al ₂ (SiO ₄) ₃	1.153
Spessartine	Mn ₃ Al ₂ Si ₃ O ₁₂	Mn ₃ Al ₂ (SiO ₄) ₃	1.162
Grossular	Ca ₃ Al ₂ Si ₃ O ₁₂	Ca ₃ Al ₂ (SiO ₄) ₃	1.185
Andradite	Ca ₃ (Fe(II),Ti) ₂ Si ₃ O ₁₂	Ca ₃ Fe(III) ₂ (SiO ₄) ₃	1.205
Uvarovite	Ca ₃ Cr ₂ Si ₃ O ₁₂	Ca ₃ Cr ₂ (SiO ₄) ₃	1.202
Hydrogrossular	Ca ₃ Al ₂ Si ₂ O ₈ (SiO ₄) _{1-m} (OH) _{4m}		
YAG	Al ₃ Al ₂ Y ₃ O ₁₂	Al ₅ Y ₃ O ₁₂	
YIG (I: iron)	Fe ₃ Fe ₂ Y ₃ O ₁₂	Fe ₅ Y ₃ O ₁₂	
GGG	Ga ₃ Ga ₂ Gd ₃ O ₁₂	Ga ₅ Gd ₃ O ₁₂	

by combining DO₄ tetrahedra and BO₆ octahedra (at the corners). The 3D framework thus formed contains cavities that can be viewed as distorted cubes of a triangular dodecahedron, as shown in Figure 7.7. The A cation sits in the large dodecahedral site (CN = 8). This is a very flexible crystal structure that has certainly not been fully exploited due to its complexity. However, many new garnets are now being produced, such as erbium-doped yttrium scandium gallium garnet [(Y,Er)₃Sc₂Ga₃O₁₂, or Er:YSGG] single crystals. These materials are being used for diode-pumped solid-state lasers that radiate in the 3-μm range.

7.8 RING SILICATES

The ring silicates are also known as the metasilicates. Well-known ring silicates are beryl, tourmaline, and cordierite. The first two are mainly thought of as gemstones, all have interesting properties; and cordierite has already found a special application. Its low coefficient of thermal expansion means that it does not fracture easily during rapid heating or cooling and thus finds use in refractories. In fact, it is the material used to form the honeycomb structure of catalytic converters.

The structures of beryl and cordierite are closely related. To change from one to the other, replace 3Be²⁺ + 2Al³⁺(=12+) with 3Al³⁺ + 2Mg²⁺(=13+). Then maintain overall neutrality by replacing one Si⁴⁺ ion with an Al³⁺ ion.

Tourmaline is quite complex, with one end member having the formula NaAl₃Al₆B₃Si₆O₃₀(OH). The structure shown in Figure 7.8 is interesting because it exhibits trigonal, not hexagonal, symmetry. Because it

FIGURE 7.7. Crystal structure of garnet. The general formula is A₃B₃(CO₄)₃ where C is Si for the silicates. The B cation sits in an octahedral site, and the largest cation A is located in a dodecahedron. The bcc unit cell has a lattice parameter of ~1.1 nm. With 20 atoms in the chemical formula, there are 160 atoms in the unit cell.

RING SILICATES

Beryl	Be ₃ Al ₂ Si ₆ O ₁₈
Cordierite	Al ₃ Mg ₂ (Si ₅ Al)O ₁₈
Tourmaline	XY ₃ Z ₆ B ₃ Si ₆ (O,OH) ₃₀ (OH,F)

is piezoelectric, tourmaline was used in the 1940s as a pressure-sensing component in the A-bomb. It is now used by some to “attract inspiration and to promote understanding.”

FIGURE 7.8. Crystal structure of tourmaline. The threefold axis can be seen. The lattice parameters are $a = 1.58$ and $c = 0.71$ nm. Most of the nominal 140 atoms in the cell sit in tetrahedral or octahedral sites, but the important boron ion sits at the center of three planar anions.

7.9 MICAS AND OTHER LAYER MATERIALS

Micas have very special properties: they are very rigid but cleave very easily along one plane. The crystal structure is well defined. The bonds within the layers are very strong, but those between the layers are weak; hence, they are known as layer materials. Before window glass was available, mica sheets were used as window material. We can easily cleave the sheets to produce a thin transparent ceramic.

Figure 7.9 shows the structure of mica. The van der Waals bonding between the sheets is not usually shown because it is so weak. Mica comes in several forms including muscovite, biotite, and the lesser-known phlogopite variety. Micas are used to provide easy paths for crack propagation in some commercial machinable ceramics.

FIGURE 7.9. Crystal structure of mica showing the large K^+ ions forming a sheet of octahedral sites. The c lattice parameter normal to this sheet is 2.0 nm, with a and b being much smaller (0.52 and 0.90, respectively). The polyhedron model emphasizes the layer nature of the structure.

7.10 CLAY MINERALS

Clay minerals are among the most important materials we know or have ever known as they form the basis of pottery and building bricks. The properties of clays are determined by the fact that they are layer materials. They are a subgroup of the layer silicates. In general, the clay minerals are hydrated aluminum silicates based on $(Si_2O_5)_n$ sheets.

Kaolinite $[Al_2Si_2O_5(OH)_4]$ is the most common clay mineral. It is a 1:1 layer silicate, meaning that the structure

FIGURE 7.10. In the crystal structure of kaolinite, the SiO_4 tetrahedra form one side of the sheet, and the octahedra contain OH^- on the outer layer attached to the Al^{3+} ions. The sheets are held together only by van der Waals bonds.

consists of alternating layers of $[\text{SiO}_4]^{4-}$ tetrahedra combined with octahedrally coordinated aluminum ions, as shown schematically in Figure 7.10.

- In the tetrahedral sheet, each $[\text{SiO}_4]^{4-}$ tetrahedron shares three corners, forming a continuous sheet with the general formula $(\text{Si}_2\text{O}_5)_n^{2n-}$.
- The nonbonded tetrahedral apices of the sheet all point in the same direction.
- These apices connect the tetrahedral sheet to the octahedral sheet.
- The O atoms at the apex of each tetrahedron are shared with an octahedral sheet.
- The octahedral sheet is made up of an array of edge-sharing octahedra with either (OH) groups or O atoms at the corners.

CLAY MINERAL GROUP

Kaolinites	Illites
Smectites	Vermiculites

Because the charge must be balanced, Al^{3+} ions occupy only two-thirds of the octahedral sites in kaolinite. The linkage between the tetrahedral and the octahedral sheets imposes restrictions on their relative sizes. If the fit between the sheets is not ideal, the resultant misfit leads to the formation of small crystals, as the strain imposed by any misfit increases with the area of the layer.

There is strong primary (covalent/ionic) bonding within each of the layers. However, the bonding between the layers is the weaker van der Waals type. Because the bonding is weak between the sheets, these silicates exhibit perfect one-directional cleavage.

Another member of the illite group is hydrous mica, where the principal interlayer cation is K. A smectite you might encounter is montmorillonite. Smectites can expand by incorporating water or organics between the structural layers. Vermiculite is derived from the Latin *vermiculare*, which means to breed worms and describes what appears to happen when the material is heated rapidly. Otherwise, it is very similar to phlogopite mica. As you would guess, most of these minerals have chemical compositions that are complex.

7.11 PYROXENE

The pyroxene group of minerals is a group of ferromagnesium silicates that occur in almost all types of igneous rock, so they are very important in mineralogy. Names you might encounter include enstatite, diopside, augite, jadeite, and spodumene; there are 20 accepted names of minerals in the group. The Si–O tetrahedra are linked at two corners and form an infinite chain parallel to the z axis. The base of each tetrahedron is nearly parallel to the (001) plane. The chains are then linked laterally by layers of octahedra, which contain six or eight coordinated cations such as Ca, Mg, Fe, or Na. The octahedra share edges and thus form continuous sheets on the (100) plane. A projection of the pyroxene structure is given in Figure 7.11.

Diopside	Monoclinic	$\text{Ca}(\text{Mg,Fe})\text{Si}_2\text{O}_6$ ($a = 0.975$ nm, $b = 0.892$ nm, $c = 0.525$ nm, $\beta = 105.83^\circ$)
Enstatite	Orthorhombic	$(\text{Mg,Fe})_2\text{Si}_2\text{O}_6$ ($a = 1.822$ nm, $b = 0.881$ nm, $c = 0.517$ nm)
Jadeite	Monoclinic	$\text{NaAlSi}_2\text{O}_6$
Spodumene	Monoclinic	$\text{LiAlSi}_2\text{O}_6$

You can guess the complexity of the structure from the lattice parameters! Although these materials are extremely important in mineralogy, they are not yet exploited much in ceramics.

FIGURE 7.11. Crystal structure of a pyroxene (spodumene) shows layers of Li^+ (larger) and Al^{3+} (smaller) ions in octahedra alternating with layers of Si^{4+} in tetrahedra, giving a nominal formula of $\text{LiAlSi}_2\text{O}_6$.

7.12 β -ALUMINAS AND RELATED MATERIALS

The β -aluminas are a family of nonstoichiometric aluminates, the most important of which have the approximate formulae $\text{Na}_2\text{O} \cdot 11\text{Al}_2\text{O}_3$ (β -alumina), $\text{Na}_2\text{O} \cdot 8\text{Al}_2\text{O}_3$ (β' -alumina), and $\text{Na}_2\text{O} \cdot 5\text{Al}_2\text{O}_3$ (β'' -alumina).

There are actually quite a few important ceramics that can be thought of as being constructed with layers of spinel separated by less-dense arrays of cations. These include not only the β -aluminas but also the magnetoplumbites and $\text{CaAl}_{12}\text{O}_{19}$ (CA_6 ; see Section 7.13). The model of the β -alumina structure is shown in Figure 7.12. We can think of this structure as being two twin-related blocks of spinel separated by a plane containing the large Na^+ ions. The result is that this “twin” plane is an open structure and that the c lattice parameter is large (2.12 nm for CA_6): it is a very anisotropic structure.

The Na^+ ions can move quite freely within the “twin” plane between the spinel layers; as a result the cation conductivity is high within these planes but negligible in the perpendicular direction. The high ion conductivity makes these ceramics of interest for battery applications, and this has been exploited in the Na-S cell. This cell was developed in ~1965 by Ford Motor Co. but has not been used in production. The main difficulty is that the cell must be kept at an operating temperature of 350°C to keep the electrode molten.

The mineral barium magnetoplumbite has the chemical formula $\text{BaFe}_{12}\text{O}_{19}$ or $\text{BaO} \cdot 6\text{Fe}_2\text{O}_3$ and is perhaps the most important of the hexagonal ferrites because it is a hard magnet with the spins all aligned along the c axis. This oxide is used in the magnetic stripe on credit cards.

FIGURE 7.12. Crystal structure of β -alumina. The main features are the large value of c , the twinned spinel blocks, and the mirror plane containing the Na^+ (or K^+ or Ca^+) ion.

7.13 CALCIUM ALUMINATE AND RELATED MATERIALS

In Chapter 2 we mentioned cement and the reactions that occur during the setting and hardening of this material. There is a class of cements known as calcium aluminate cements (CACs) or high-alumina cements (HACs). These ceramics are not used as widely as Portland cement, but their attraction is the rapid hardening reactions. In 1 day CAC achieves the same strength as Portland cement achieves in a month.

The principal component present in CAC is calcium monoaluminate (CA in cement chemistry nomenclature; see Table 2.2). Its structure resembles that of β -tridymite, one of the polymorphs of SiO_2 . Rather than having $[\text{SiO}_4]^{4-}$ tetrahedral sharing corners in CA, we have $[\text{AlO}_4]^{5-}$ tetrahedra. The large Ca^{2+} ion distorts the tridymite network, and the structure is monoclinic.

The $[\text{AlO}_4]^{5-}$ tetrahedron is about the same size as the $[\text{SiO}_4]^{4-}$ tetrahedron and can form rings, chains, two-dimensional sheets, or three-dimensional networks in the same way by sharing oxygen corners. Other related calcium aluminates are also important in the chemistry of high alumina cements. The common feature of the structures of grossite (CA_2) and mayenite (C_{12}A_7) is that they too contain corner-sharing AlO_4 tetrahedra.

- Grossite, calcium dialuminate, is monoclinic. It is less reactive than CA.
- Mayenite, dodecacalcium hepta-aluminate, is cubic. It is the most reactive species in HACs.
- Hibonite, CA_6 , is found in Ca-rich aluminas and has the magnetoplumbite structure (see Section 7.12).

7.14 MULLITE

Mullite is thought by some to be the most important ceramic although (like spinel) the name now refers to a group of ceramic materials. It is an orthorhombic silicate made up of chains of AlO_6 octahedra running parallel to the z axis and cross linked by tetrahedra containing Si and Al. In Figure 7.13 these chains of octahedra (Oc) are seen at the corners and center of the unit cell and run into the paper; the two parallel chains are rotated relative to one another. The polyhedron labeled C is not a tetrahedron, although it looks like one in this projection; T is a tetrahedron though. Sometimes the structure is rather different (it's a derivative), but the material is still called mullite (or a mullite). Mullite, the mineral, was originally from the Isle of Mull in Scotland and is $3Al_2O_3 \cdot 2SiO_2$ or simply $3/2$ -mullite. The composition actually varies over a wide range corresponding to $Al_2[Al_{2+2x}Si_{2-2x}]O_{10-x}$, quite a solid-solution range. The crystal structure can be related to that of sillimanite (Al_2SiO_5 , i.e., $x = 0$ in the general formula or $Al_2O_3 \cdot SiO_2$) but is much more complicated! This causes problems when determining Burgers vectors of dislocations—the details of the crystal structure can be

FIGURE 7.13. Crystal structure of mullite viewed along the short z axis ($a = 0.76$ nm, $b = 0.77$ nm, $c = 0.29$ nm). The sites Oc and T are never fully occupied, so this is an idealized schematic of this orthorhombic orthosilicate. The chains of octahedra at the corners and center lie along z .

different in different mullites. $2Al_2O_3 \cdot 2SiO_2$ has been produced synthetically. Fe^{3+} and Ti^{3+} can replace Al^{3+} —it's a very accommodating structure.

Mullite has many important high-tech applications. We use mullite for coatings and for fibers. One use of mullite is in ceramic-matrix composites or CMCs; it has useful mechanical strength and has promise as the matrix for oxide reinforcing fibers. Above all, when we heat a clay containing Al_2O_3 and SiO_2 , we form mullite—hence the claim that mullite is the most important ceramic and certainly the most important silicate for the ceramist.

7.15 MONAZITE

The mineral monazite has the composition $LnPO_4$; the anion is effectively $(PO_4)^{3-}$. In nature, the mineral actually consists of a mixture of several slightly different minerals because Ln (representing a lanthanide) can easily be replaced by one or more rare earths (Ce, La, Nd, etc.) and usually also contains thorium. There is some disagreement on the lattice parameters for monazite in the literature, which may in part depend on its purity. There are also two unit cells in use:

1. Monoclinic, $P2_1/n$, with $a = 0.6782$ nm, $b = 0.7057$ nm, $c = 0.6482$ nm, and $\beta = 103.21^\circ$
2. Monoclinic, $P2_1/c$, with $a =$ same, $b =$ same, but $c = 0.6269$ nm ($a + c$ of “1”) and $\beta = 126.53^\circ$

The latter is correct by today's crystallographic conventions, but the former is found to be useful in describing defects such as twin boundaries. You may encounter both. Monazite is the primary ore for Th, Ce, and La; the first of these means that it is often radioactive. Mineral engineers have long known it as a principal source of Ce, but even then it often contains significant concentrations of ThO_2 . Until the mid-1990s, few ceramists had heard of it. Then it was found to be a potential coating material for fibers to be used in ceramic composites. In this application, the composition chosen is usually $LaPO_4$.

7.16 $YBa_2Cu_3O_7$ AND RELATED HTSCs

$YBa_2Cu_3O_7$ (YBCO) has an orthorhombic layered-perovskite structure, with $c \sim 3a$ and $a \sim b$, as shown in Figure 7.14A. The Cu and O ions are arranged as chains along the b -direction between the Ba–O layers and as planes between the Ba–O and Y layers. Figure 7.14B shows how the YBCO structure is related to the perovskite structure. The structure consists of a sequence of oxide layers perpendicular to the c -axis as follows:

1. A Cu–O layer has two oxygen vacancies as compared with the “fully oxidized” YBCO perovskite. The Cu(1)

FIGURE 7.14. Models for YBCO. (A) Unit cell for the fully oxygenated compound (with ...O₇); the shaded region shows the perovskite unit with Y in the center and Cu at the corners. (B, C) The structure is more readily appreciated from (B) [100] and (C) [110] views, each showing six unit cells. Note how the perovskite “unit cell” is rotated 45° relative to the unit cell of the YBCO.

site in this oxygen layer has CN = 4 and is surrounded by four oxygen ions in a square arrangement (as found in CuO). In YBa₂Cu₃O₇ this is the plane made by the CuO “chains.”

2. A Ba–O layer.
3. A Cu–O layer in which the Cu(2) has a CN = 5 and is surrounded by five oxygen ions that form a square-based pyramid. This is the plane we call the CuO₂ plane.
4. A Y layer that has four oxygen vacancies as compared with the fully oxidized perovskite.

You can see in the literature that the chemical formula of YBCO is alternatively written as YBa₂Cu₃O_{6+x} or YBa₂Cu₃O_{7-δ}. The reason is that the material is almost always oxygen-deficient. So which form is correct? YBa₂Cu₃O₆ is an insulator. It has to be doped to gradually become a metallic-like conductor and a superconductor below *T_c*. The doping is achieved by adding additional oxygen-forming CuO “chains.” These oxygen ions attract electrons from the CuO₂ planes that then become metallic. Thus, the “correct” formula for YBCO is YBa₂Cu₃O_{6+x} where *x* corresponds to partial oxygen content:

For 0.0 < *x* < 0.4, YBa₂Cu₃O_{6+x} is an insulator
 For ~0.4 < *x* < 1.0, YBa₂Cu₃O_{6+x} is a superconductor.

The oxygen content can be changed reversibly from 6.0 to 7.0 simply by pumping oxygen in and out of the parallel chains of CuO running along the *b* axis. Careful studies indicate that the maximum *T_c* is reached for *x* ~ 0.93

(*T_c* = 94 K) and that for *x* = 1.0 *T_c* = 92 K. (The important point is that liquid N₂ boils at 77 K).

It is thought that superconductivity essentially takes place within the quasi two-dimensional CuO₂ planes. The Cu–O chains can be considered as a “charge-reservoir” that is needed to transfer charge into the CuO₂ planes. This means we can consider this high-temperature superconductor (HTSC) as CuO₂ planes separated by a charge reservoir. Charge carriers are added by doping: adding oxygen to YBa₂Cu₃O₆, which enters the compound as O²⁻ and forms CuO chains. To maintain charge balance, electrons are removed from the copper oxide planes, and the remaining holes are mobile (hence conduction). The properties are anisotropic (i.e., different along different directions). Therefore, orientation of the individual grains is essential in the fabrication of polycrystals or epitaxial thin films.

The other HTSCs—bismuthates and thallates—are all layered structures with Cu–O planes present. The different phases are formed by stacking the same building-block layers in different sequences, as shown in Figure 7.15, producing, for example, Bi₂Sr₂CaCu₂O₈ (known as the Bi 2212 phase).

7.17 Si₃N₄, SiALONS, AND RELATED MATERIALS

Most of the materials discussed so far in this chapter have been oxides; and, in general, ceramists have neglected nonoxides. Part of the reason is that we often process

materials in a partial pressure of O₂. In what follows, we briefly introduce some of the exceptions that have not been mentioned previously.

Silicon nitride, Si₃N₄, exists in two forms, designated α and β . The structures and lattice parameters of these forms were determined by X-ray diffraction data.

α -Si₃N₄; hexagonal : $a = 0.7748$ nm; $c = 0.5617$ nm.

Space group P6₃/m

β -Si₃N₄; hexagonal : $a = 0.7608$ nm; $c = 0.29107$ nm.

Space group P31c

Each Si is at the center of a slightly irregular tetrahedron of nitrogen atoms. The SiN₄ units then share corners; each N is common to three tetrahedra. The structures differ in the arrangement of the tetrahedral units. Planes of atoms in the β form are linked along the [001] direction in a sequence ABAB..., whereas in the α form the sequence is ABCDABCD....

The SiN₄ and SiO₄ tetrahedra are similar, except that whereas each oxygen atom in SiO₄ is common to two tetrahedra, each nitrogen atom in SiN₄ is common to three tetrahedra.

By substituting O²⁻ for N³⁻ and Al³⁺ for Si⁴⁺ we can form a family of compounds known as “SiAlONs.” They can be produced by high-temperature reactions between, for example, Si₃N₄ and Al₂O₃. The general formula for the SiAlONs is (Si,Al)₃(O,N)₄. Other metal atoms can be incorporated into the structure giving (Si,M)(O,N)₄; possibilities for M include Mg + Al, Li + Al, and Y.

Other nitrides. The interest in β -C₃N₄ is that it is predicted to have a bulk elastic modulus comparable to

diamond. Several attempts have been made, with varying degrees of success, to produce it in bulk and as a thin film. The structure of β -C₃N₄ is related to the β -Si₃N₄ structure. The CN₄ tetrahedra link by sharing N atoms. Each C atom has four nearest neighbors, forming an almost regular tetrahedron; and each N has three nearest-neighbor C atoms, forming 120° bond angles.

7.18 FULLERENES AND NANOTUBES

In Chapter 6, we discussed the structure of diamond and graphite—allotropes of carbon. The discovery of the C₆₀ molecule in 1985 introduced a new, third, ordered form of carbon—the fullerenes. The special new feature of C₆₀ (shown in Figure 7.16A) is the regular incorporation of five-sided rings of C atoms that allow the formation of curved sheets of carbon atoms. C₆₀ has 12 pentagonal (five-sided) and 20 hexagonal (six-sided) faces symmetrically arrayed to form a molecular ball; in fact, a soccer ball uses the same geometric configuration as fullerene.

In the solid state, the C₆₀ molecules bind with each other through weak van der Waals forces and can self-assemble to form an fcc arrangement. At room temperature, the size of the cubic unit cell is 1.4 nm, and the nearest-neighbor C₆₀–C₆₀ distance is 1.0 nm. At lower temperatures, the arrangement of the fullerenes may become simple cubic with a larger unit cell. In the fcc arrangements there are, of course, interstices with either octahedral or tetrahedral character. Alkali metal atoms such as K or Rb can be incorporated into the interstitial sites to give a molecular formula of K₃C₆₀ or Rb₃C₆₀. The interest in these doped fullerenes is that they are superconductors. The highest T_c in the series of alkali metal doped C₆₀ is 33 K for Cs₂RbC₆₀.

A wide variety of fullerene structures have been produced with the general formula C_n, where n can take on small (70) or very large (240 and 540) values. In each case, the structure consists of 12 uniformly distributed pentagons connecting an array of hexagons.

Although pentagons are necessary to give an approximately spherical shape, by simply rolling a hexagonal graphite sheet we can produce carbon nanotubes. These objects can be considered a new source of mesoporous ceramics. They are dimensionally confined in two directions. If the ends are closed, as shown in Figure 7.16B, we again need to incorporate the pentagon. Just as graphite grows as sheets, the single-walled nanotube (SWNT) can grow as a multi-walled nanotube as you can see in Figure 7.16C. The “layer” spacing of the walls is usually what we expect from graphite except at the closed ends. It is an interesting exercise to take a single sheet of graphite (drawn on paper), roll it, and rejoin the bonds; you immediately realize that you can introduce a shear or chirality

FIGURE 7.16. The structure of (a) C_{60} and (b) carbon nanotubes. (c) Image of the end of a six-layer carbon nanotube.

(like a screw dislocation along the tube). The chirality determines the electrical conduction along the nanotube.

Many variations on the C nanotube can be produced using other layer materials such as MoS_2 . Tubes built from other oxides that are not layer materials might sometimes be better described as pipes.

7.19 ZEOLITES AND MICROPOROUS COMPOUNDS

Zeolites are aluminosilicates that have a framework structure with large cavities built in. The general formula of the zeolites is $(Na_2, K_2, Ca, Ba)[(Al, Si)O_2]_n \cdot xH_2O$, which means that they are chemically related to the feldspars. They are found in nature as crystals with large mineral specimens coming from Pune (near Mumbai in India). They are becoming much more important as synthetic minerals when they are used as molecular sieves or catalyst supports. The atlas of zeolite types lists 98 tetrahedral

FIGURE 7.17. Structure of sodalite, a zeolite. The tetrahedra shown in “a” link together to form large “cages.” The most important features are the channels between the cages, which are seen in “b.” In “a” the corner and body centering ions are Cl^- ; the others are Na^+ ions. The tetrahedra contain either Si^+ or Al^+ .

frameworks that are structurally distinct and are known as the TO4 frameworks, where T (at the center of the O tetrahedron) is usually either Si or Al but could be P, Ga, B, or other components. The International Zeolite Association (IZA) has compiled the different structural types and given each one a three-letter code, which they call the Structural Type Code. The 3D frameworks are then assembled using secondary building units (SBUs) that consist of 4, 5, and 6-rings. You can appreciate the idea by examining the example shown in Figure 7.17. This figure represents sodalite, which is actually cubic with a lattice parameter of 0.887 nm.

Microporous ceramics are being designed to extend the concept of zeolites by building structures that do not necessarily have the well-defined walls of a zeolite crystal but still have the large cavities; an ordered alignment of the cavities can make it appear that the material is crystalline. The IUPAC definition is that a microporous material contains micropores (free diameter < 2 nm); mesoporous materials contain mesopores (free diameter 2–50 nm).

7.20 ZACHARIASEN'S RULES FOR THE STRUCTURE OF GLASS

Many compounds can form glasses. Silicate glasses are what we usually think of as “glass.” However, the topic actually includes many other materials that are thought of as amorphous; but even that terminology can be misleading. In this section, we just discuss the aspects of structure as they relate to the theme of polyhedra. We leave the question of “what is a glass?” to Chapter 21.

In 1932, W.H. Zachariasen proposed a set of rules that are usually satisfied when an oxide forms a glass. His analysis was based on the following considerations:

1. The interatomic bonding forces in glasses and crystals must be similar given the similar elastic modulus of the two types of solids.
2. Like crystals, glasses consist of an extended 3D network, but the network does not have translational periodicity.

Studying the structure of glass is difficult because of the lack of translational symmetry. X-ray diffraction spectra from glasses show diffuse maxima, not sharp spots or even sharp rings. These diffuse rings can be interpreted in terms of a radial distribution function (RDF is the acronym; the quantity is $\rho(r)$).

$\rho(r)$ = atom density in a spherical shell of radius r from the center of any selected atom.

An illustration of such a function is shown in Figure 7.18. The peaks in this figure correspond to the broad bands seen in the diffraction pattern. The corresponding plot for the crystalline material is also shown. The function is equally applicable for a crystal, but the peaks are then delta functions. What is less clear is whether or not a particular (or any) glass is truly amorphous or if “crystallites” at the nanometer scale are present.

The structure of an oxide glass can be modeled in terms of coordination polyhedra of cations surrounded by a variable number of oxygen ions. In crystalline oxides, the polyhedra

FIGURE 7.18. Radial distribution function of a glass showing a sharp first-neighbor peak, a broader second-neighbor peak, and then a gradual increase with increasing r .

can share not only corners but also edges and/or faces; in glasses the polyhedra can share only corners. Silica glass is then pictured as a disordered version of the crystal with all oxygen ions bridging tetrahedra, as shown in Figure 7.19.

Zachariasen summarized his findings as four rules and emphasized how the structure of SiO_2 glass differs from the crystalline form shown here as the (111) plane of cristobalite.

1. An oxygen ion links to two or fewer glass-forming atoms.
2. CN of the glass-forming atoms is small.
3. Oxygen polyhedra share only corners.
4. Polyhedra form a 3D network.

These rules have been used since the 1930s and have become almost folklore. You should remember that they were proposed when the main glasses studied were silicates, although borate and phosphate glasses were known.

Further tendencies for glass formers have been listed.

1. The valence of the cation is ≥ 3 .
2. As the size of the cation decreases, so does its glass-forming tendency.
3. The cation's electronegativity is between 1.5 and 2.5.

In a general way, the role of the cations depends on the valence, CN, and the related values of the single-bond strength. Cations of higher valence and lower coordination than the alkalis and alkaline earth oxides may also

FIGURE 7.19. Comparing the structures of (a) crystalline silica and (b) glass.

				Hg	2
				Ga	3
				Sn	4
		Pb	2	Pb	4

contribute in part to the network structure. We can list the cations in three groups. The different types of ion present in oxide glasses are summarized in Table 7.7.

1. Network formers are those cations that form coordination polyhedra in glass (e.g., Si).
2. Network modifiers are those oxides that do not participate directly in the network (e.g., Na).
3. Intermediate ions can sometimes act in either role (e.g., Al).

In practice, in oxide glasses the polyhedra are triangles and tetrahedra. When a network modifier such as Na₂O is added to silica glass (SiO₂), a specific number of Si–O bonds are broken. This process is represented schematically in Figure 7.20. Si–O bonds are broken, and the added oxygen saturates the unsatisfied bond of one Si; and two Si–O[−] bonds are formed. The excess negative charge on the oxygen is compensated by the nearby Na⁺ cations (adding an ionic character to the glass). The Si–O–Si bridge-rupture mechanism leads to a loosened network structure with two types of oxygen:

1. Bridging oxygens are bonded to two Si.
2. Nonbridging oxygens (NBOs) are bonded to one Si.

To summarize, Zachariasen’s model has dominated glass science for several decades and is still extremely useful. However, diffraction methods do not actually provide definitive proof for such a model; they can only confirm that the results do not contradict this hypothesis. Remember also that the model was developed specifically for oxide glasses and is not necessarily applicable to other types of glasses.

FIGURE 7.20. How network modifiers in glass cause nonbridging O ions.

7.21 REVISITING GLASS STRUCTURES

The Zachariasen model began to be reexamined in the 1990s. The important point is that silicate glass is, in many ways, just like the other silicates that *do* have long-range order. Most especially they are all 3D solids. Figure 7.21 shows the same information as in Figure 7.19B, but it is redrawn to show different ways of looking at this structure. A crystal composed of corner-sharing SiO₄ tetrahedra (Figure 7.21A) has orientational and translational symmetry. We can then call such a network “topologically ordered.” A silica glass is then topologically disordered—we can’t describe it by symmetry operations, but it looks very similar to the crystalline form otherwise. The tetrahedron is an example of a rigid structuring element called a polytope (i.e., our polyhedra). The connectivity of a 3D structure can be described by the parameter {*V*, *C*}, where *V* is the number of vertices per polytope, and *C* is the number of polytopes sharing a vertex. Incidentally, the polytope for the glass former B₂O₃ is the BO₃ triangle, so the tetrahedron is not the essential polytope. A network of triangles on a plane joining at the vertices is a {3,2} arrangement.

For our (SiO₄) tetrahedron *V* is 4, but the diagram shown in Figure 7.19B is actually a two-dimensional continuous random network of triangular polytopes, with *V* = 3 and *C* = 2 (so it’s {3,2}). The Si atoms

FIGURE 7.21. Different ways of representing the same array of ions in a silica glass.

define a point (which can be called a node) in each triangle. If we join these nodes as in Figure 7.21A, then we have an array of primitive rings; now this network of nodes is a $\{2,3\}$ set because we're just joining lines, and three join at each junction. This new network is said to tile or tessellate the two-dimensional

space. The set of tetrahedra associated with this ring is then called a local cluster and can be compared to the unit cell in a crystal. Alternative tiling schemes are shown in Figure 7.21B, C. The challenge is to describe the 3D structure. Our usual way of looking at it is shown in Figure 7.21D.

CHAPTER SUMMARY

This chapter examined some crystal structures that students must learn, including spinel and perovskite. Students should also know the different arrangements of the SiO_4 tetrahedra. Most of the other structures are looked up as needed, but the idea of how to build micas and clays really should be known. The structures of materials such as the β -aluminas, YBCO, the SiAlONs, and the fullerenes all use concepts that we examined in Chapter 6 but in a more complicated form. The special feature in the fullerenes is the five-sided ring; in Chapters 12 and 14 we'll see five-sided rings in dislocation cores and grain boundaries in Si and Ge, where they have been known since before 1960. These structural features were well known years before they were discovered. You can look up the complex structures, but you should be able to recognize the special features of each one and how they are constructed from simple atomic groupings. Zeolites are endlessly fascinating and are like enormous 3D crossword puzzles. These materials are often left to inorganic chemists to synthesize or chemical engineers to use, which is unfortunate because their applications in materials science and engineering are far-reaching. Two pages on glass is not adequate treatment but hopefully shows you some of the potential for discovery in these noncrystalline solids.

PEOPLE AND HISTORY

Curl, Robert F. Jr. (1933–), *Richard E. Smalley* (1943–2005), and *Sir Harold W. Kroto* (1939–). These men shared the 1996 Nobel Prize in Chemistry for their discovery of fullerenes. In 1999, buckyballs were found to exist naturally in a meteor.

Fuller, Richard Buckminster (1895–1983). He was an architect and inventor of the geodesic dome that resembles the structure of C_{60} , shown in Figure 7.16A. C_{60} is often referred to as the buckyball.

Megaw, Helen Dick. She died in 2002 at age 94. She reported the crystal structure of $BaTiO_3$ in *Nature* (155:484, 1945). She spent most of her academic career in Cambridge.

Zachariasen, William Houlder (1906–1980). This Norwegian-American physicist spent most of his career working in X-ray crystallography, but he is best remembered for his description of the glass structure in the early 1930s. He wrote only one paper on glass and was surprised to see it become the work that he is remembered for (information courtesy Jim Philips).

EXERCISES

- 7.1 Compare the ionic sizes in $CaZrO_4$ and $CaSiO_4$ and discuss how well they fit Pauling's rules and if they should.
- 7.2 Discuss for Mg_2TiO_4 and Mn-Zn ferrite, which is preferred, normal or inverse spinel, on the basis of Pauling's rules.
- 7.3 In spinel, other than $\langle 110 \rangle$, is there a low-index direction where only like cations project on one another?
- 7.4 How many ions do you expect to find in a unit cell of grossular?
- 7.5 Discuss whether we should write the formula for superconducting YBCO as $YBa_2Cu_3O_{7-\delta}$ or $YBa_2Cu_3O_{6+x}$.
- 7.6 We often say that the structure of YBCO is related to the perovskite structure. Draw diagrams of the two crystal structures and then explain this relation.
- 7.7 By delving into the literature, explain which three ceramic materials you think are the next (after those discussed in the chapter) most important in each of these categories: silicates, oxides, nonoxides. Then summarize how they are processed.
- 7.8 In silicon oxynitride, Si_2N_2O , we have SiN_3O tetrahedra. Sketch the possible structure of this ceramic.
- 7.9 Consider the fcc arrangement of doped solid C_{60} that we described in Section 7.18. Explain why we get only Cs_1C_{60} when we dope with Cs and why for sodium doping we can get Na_6C_{60} and $Na_{10}C_{60}$.
- 7.10 By examining the literature, discuss how niobates and titanates can be combined and how the perovskite structure facilitates it.
- 7.11 Using Table 7.1, comment on r_M for the following groups of ions: (a) Li^+ , Na^+ , K^+ ; (b) Si^{4+} , Ge^{4+} , Ce^{4+} , Zr^{4+} ; (c) B^{3+} , Al^{3+} .
- 7.12 If maghemite and magnetite both have the spinel structure, how can this be if spinel is AB_2O_4 ?
- 7.13 Label three planes for both Figure 7.1B and C.
- 7.14 Knowing the structure and lattice parameters of $BaTiO_3$, deduce the lattice parameters of $CaTiO_3$.
- 7.15 $CaTiO_3$ is the mineral perovskite. Why is $BaTiO_3$ much more important (explain the effect of Ba rather than Ca)? How does $SrTiO_3$ fit into your scheme?
- 7.16 Add another two silicates to each of the columns in Figure 7.4. Reference your sources.
- 7.17 The silicates in Table 7.3 are not just catalog items for mineralogists. Use the literature to find one commercial use for each one listed.
- 7.18 In Table 7.7 Al is listed as a former and an intermediate and Pb as an intermediate and a modifier. Under what conditions do you think Pb might be an intermediate and under what conditions do you think Pb might act as a modifier? Do you think the location of the Pb would affect lead release from Pb-containing glasses?
- 7.19 Tourmaline was very important in the period 1945–1955. What has replaced it, and why did it “work” so well when it was used.
- 7.20 The β -aluminas have potential applications for batteries. Discuss the different structures of the β -aluminas, how you would measure their conductivity, and what you would use to store the charge.

Equilibrium Phase Diagrams

CHAPTER PREVIEW

Most ceramics are multicomponent materials, and the most stable phase at any temperature is the one with the lowest free energy, G . One use of phase diagrams is to represent which phase or phases we might expect to be present as a function of temperature. There are a large number of books concerned with just this one topic. Lots of work was carried out in the 1950s and 1960s, but many systems have remained almost completely unexplored; and it's not a well-funded topic in the United States now. The lack of effort is in spite of the demonstration that new complex ceramics such as the high-temperature superconductors YBCO and BiSCCO and the magnetic manganates possess extraordinary, and potentially very useful, properties.

Much of the classical work on phase equilibria has actually been concerned with processing metals. Thus, the Fe–O phase diagram is perhaps the most thoroughly characterized because of its importance to the iron and steel industry.

A word to keep in mind throughout our discussion is equilibrium: we are talking about equilibrium phase diagrams. Often we use a phase diagram as a guide to processing. If the process is in progress, then it is not in equilibrium. Also, by definition, a chemical reaction is not an equilibrium process. If a reaction is exothermic, then a rise in temperature favors the reactants. Although most of the phase diagrams we use in ceramics are for a pressure of 1 atm, in one-component systems such as carbon pressure is a very important variable. It tells us what pressure we need for direct synthesis of diamond. In metal–oxygen diagrams, the partial pressure of oxygen determines what is the stable form of the oxide.

8.1 WHAT'S SPECIAL ABOUT CERAMICS?

As many ceramics are oxides, the oxygen partial pressure, pO_2 , is an important variable. There is a lot of information about many metal–oxygen systems. In part, this is due to interest in how to obtain metals by direct reduction from their oxides. A frequent way of representing free energies of formation of oxides as a function of pO_2 and T is the Ellingham diagram (Ellingham 1944) that was popularized by Richardson and Jeffes for iron and steel production (Richardson and Jeffes 1948). Much less is known about nitrides and oxynitrides or even carbides.

Many ceramics are multicomponent materials, and hence many of the important phase diagrams involve three or more components. Here are some examples of where phase diagrams have very practical applications in the use of ceramics.

Refractory silica brick. It was used for the roof of

the open-hearth furnace, which was once an important method for steel production. Now silica refractories are used in coke ovens and as roofs in glass tanks. Typical operating temperatures are 1,625–1,650°C. The phase diagram tells us that the SiO_2 needs to be quite pure (only 0.2–1.0 wt.% Al_2O_3) or it melts.

Fire-clay brick. This is a classic clay product with a composition close to kaolinite. Although it is used at temperatures below 1,587°C, the phase diagram tells us that some liquid is often present because these ceramics contain 22–33 wt.% Al_2O_3 . Why is this material so important? It performs the task very well and is cheap to produce.

Barium titanate. Pure cubic $BaTiO_3$ single crystals cannot be grown from a melt of that composition because the hexagonal phase is in equilibrium with the liquid at the solidification temperature (1,618°C). Although the hexagonal phase transforms to the cubic phase at 1,460°C,

DALTON'S LAW OF PARTIAL PRESSURES:

$$p_A = X_A P$$

p_A	partial pressure of A
X_A	mole fraction of A
P	total pressure of gas mixture

the phase change is sluggish and thus the hexagonal phase can exist at room temperature. The hexagonal form of BaTiO_3 is not ferroelectric, which is the property we are most often interested in. In Chapter 28 we describe how single crystals of cubic BaTiO_3 can be grown.

Adhesion of metals in integrated circuits. Aluminum has been used for over 30 years as interconnect and top-level metallization in integrated circuits. One of the reasons Al is so good is that it reduces SiO_2 to form interfacial metal-oxide bonds that promote adhesion and stability. One of the problems with copper metallizations is that SiO_2 is more stable than Cu_2O . Despite this difficulty, Cu has several significant advantages over Al and is now used in many commercial devices such as IBM's processor for the Apple G5, Intel's Pentium IV, and AMD's Athlon. The relative oxidizing powers of metals are represented frequently on Ellingham diagrams. In Chapter 15 we show how these diagrams can be useful in developing brazes for ceramics.

8.2 DETERMINING PHASE DIAGRAMS

We refer you to basic thermodynamics texts for the details on the origin of phase diagrams and the phase equilibria book by Bergeron and Risbud. In this section we just summarize some key points. First is some thermodynamic background to phase diagrams.

- The phase with the lowest free energy, G , is thermodynamically stable.
- The chemical potential, μ_i , of a component is the same in all of the phases in which it is present. This requirement is used in the derivation of Gibbs Phase Rule.
- At equilibrium, the temperatures and pressures of all phases are equal.

Determining a phase diagram requires measuring which phases are in equilibrium under well-defined conditions.

An especially critical factor for ceramics is being sure that we have equilibrium. In ceramics we have two challenges.

- We need to make measurements at high temperature, where direct determination of phases is difficult.
- The valence of the cations may change as the temperature or pressure changes. If the cation is polyvalent, then the valence depends on the oxygen activity, which as we'll see later depends on the partial pressure of oxygen, $p\text{O}_2$.

To ensure that we have equilibrium, the two bulk phases should really be in intimate contact, separated by a flat (planar) interphase boundary.

The number of techniques we can use for direct determination of phase diagrams of ceramic systems is quite limited because of the requirement for high temperatures.

- High-temperature X-ray diffraction. Maximum operating temperatures are up to $2,500^\circ\text{C}$ in high vacuum, $2,400^\circ\text{C}$ in inert atmospheres, and $1,700^\circ\text{C}$ in air.
- Transmission electron microscopy with hot-stage. Maximum temperature $1,300^\circ\text{C}$; working in vacuum, typically $\sim 10^{-4}$ Pa, so no control of $p\text{O}_2$.

Most techniques that are used to determine phase diagrams experimentally use an indirect approach. Note that often we are not trying to determine an entire diagram but, rather, the specific parts that may be of interest, such as the solvus lines, the liquidus, or the eutectic temperature. Figure 8.1 is an example of using cooling curves to determine the liquidus and eutectic for a binary system. Heating curves produce similar results and are often easier to achieve experimentally. Phase changes produce the deviations in time-temperature curves. These measurements would be made using differential thermal analysis (DTA) or differential scanning calorimetry (DSC). Maximum temperatures for these instruments are about $1,700^\circ\text{C}$. At this temperature, many of the important

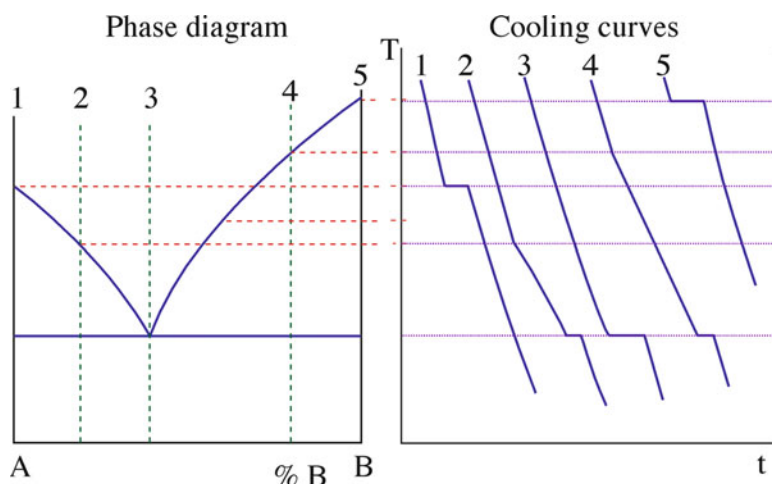

FIGURE 8.1. The use of cooling curves for determining the liquidus and eutectic in a binary phase diagram.

FIGURE 8.2. Parametric method for determining the solvus lines in a binary phase diagram.

ceramics such as Al_2O_3 (melts at $2,054^\circ\text{C}$), SiO_2 (melts at $1,710^\circ\text{C}$), and ZrO_2 (melts at $2,677^\circ\text{C}$) are still solid. Another problem with ceramic melts, especially those containing SiO_2 , is their high viscosity. Most oxide glasses are silicates. Crystallization from these melts is often difficult, and reaching equilibrium can take a very long time (years!).

A frequently used method for studying phase equilibria in ceramics is X-ray diffraction on samples that have been equilibrated at high temperature and then quenched. This technique is particularly useful for the solid-state portions of the phase diagram, such as determining the position of the solvus lines. In each single solid solution region of a binary phase diagram there is a change in lattice parameter with composition. In the phase field where both solid solutions exist, the lattice parameter of each solid solution remains constant, with composition as shown in Figure 8.2. The position of the solvus line, at a particular temperature, corresponds to the change in slope. It is important that the conditions are sufficient for the system to reach equilibrium and that high-purity powders are used.

We can calculate phase diagrams using the requirement that the

lowest free energy state is the equilibrium one. If calculations are performed for a range of temperatures, then the phase boundaries can be determined. Because we often don't know the absolute values for thermodynamic quantities, but changes in these, we use the expression:

$$\Delta G = \Delta H - T\Delta S \quad (8.1)$$

ΔH and ΔS can be determined at any temperature using the heat capacity, c_p

$$\Delta H_{T_2} - \Delta H_{T_1} = \int_{T_1}^{T_2} \Delta c_p dT \quad (8.2)$$

and

$$\Delta S_{T_2} - \Delta S_{T_1} = \int_{T_1}^{T_2} \frac{\Delta c_p}{T} dT \quad (8.3)$$

The problem is that heat capacities are not known for many compounds. As a result, we often make assumptions that allow us to determine a part of the phase diagram that is important to us.

8.2.1 Estimation of Liquidus and Eutectic Temperature for a Binary System

We can estimate the position of the liquidus assuming that our mixture forms an ideal solution; hence it obeys Raoult's law. From the Clausius-Clapeyron equation with some integration and algebraic manipulation we can obtain

$$\ln X_A = -\frac{\Delta H_f}{R} \left(\frac{T_M - T}{T_M T} \right) \quad (8.4)$$

where X_A is the mole fraction of component A and ΔH_f is the enthalpy of fusion. Values of T are plotted against composition. At the intersection of these lines is the eutectic point. This approach works well for many alkali halide systems (e.g., the NaF-KF system) but not so well for many oxides. For example, the $\text{PbO-B}_2\text{O}_3$ system shows dissociation on melting.

An alternative method for calculating the liquidus is to calculate differences in free energy of the solid (G_s) and liquid (G_l) phases as a function of temperature.

CLAUSIUS-CLAPEYRON EQUATION

Change in vapor pressure (P) of a solid with a change in T

$$\frac{dP}{dT} = \frac{\Delta H_S}{T(V_V - V_S)}$$

ΔH_S = enthalpy of sublimation of solid
 V_V = molar volume of vapor
 V_S = molar volume of solid

SOME USEFUL DATA

NiO $T_M = 2,257$ K; $\Delta H_f = 50.6$ kJ/mol
 MgO $T_M = 3,073$ K; $\Delta H_f = 77.4$ kJ/mol
 BeO $T_M = 2,830$ K; $\Delta H_f = 71.1$ kJ/mol
 UO₂ $T_M = 3,150$ K; $\Delta H_f = 54.0$ kJ/mol

$$G_s - G_l = -\Delta H_f \ln \frac{T_M}{T} \quad (8.5)$$

We need to know the enthalpy of fusion, ΔH_f and the melting temperature, T_M .

Figure 8.3 shows how this method has been used to construct the phase diagram for the UO₂-BeO system. The agreement with the published diagram is quite good.

8.2.2 Estimation of Liquidus and Solidus for Systems with Complete Solid Solubility

Figure 8.4 shows free energy versus composition plots at 2,700°C for the NiO-MgO system and the corresponding phase diagram. This system is one where the components are mutually soluble in both the solid and liquid states. Determination of the free energy curves uses equation 8.5

and the free energy change associated with mixing liquid NiO and liquid MgO, which can be calculated using

$$\Delta G = RT[X \ln X + (1 - X)\ln(1 - X)] \quad (8.6)$$

The use of computer methods for calculating phase diagrams is becoming increasingly important. The results of many of these studies are available in CALPHAD: Computer Coupling of Phase Diagrams and Thermochemistry (Saunders 1998 and online). Figure 8.5 illustrates such computed phase diagrams.

8.3 PHASE DIAGRAMS FOR CERAMISTS: THE BOOKS

The books are really important for ceramics, so we emphasize them here rather than just at the end of the chapter. All ceramicists must be familiar with “the books.” The first volume of the series “Phase Diagrams for Ceramists” was published in 1964 and is in daily use. The series currently contains 12 volumes. The companion volume by Bergeron and Risbud is entitled *Introduction to Phase Equilibria in Ceramics* and should always sit on the same shelf. The books are unique in that the later volumes contain both new and updated diagrams, but the old diagrams found in the

FIGURE 8.3. UO₂-BeO phase diagram determined using free energy calculations.

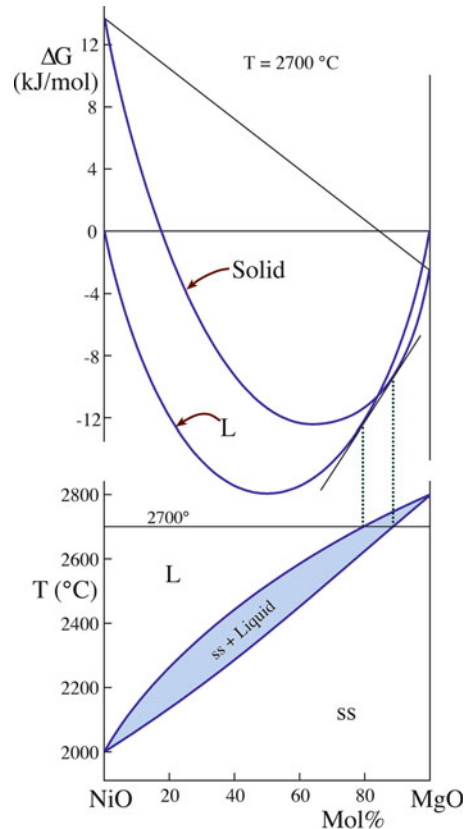

FIGURE 8.4. NiO-MgO phase diagram and free energy curves at $T = 2,700^\circ\text{C}$.

8.4 GIBBS PHASE RULE

We derive the Gibbs Phase Rule in three steps.

Step 1. Consider the situation where we have C components that exist in X phases. If Fe and O are the components, Fe and FeO would be examples of phases. Thus, there are XC composition variables. Adding the two important external variables in ceramics, P (pressure) and T , gives $XC + 2$ variables.

Start with $XC + 2$

Step 2. If we described the composition of a phase in terms of the mole fraction of its components, then when we have described all but one of the mole fractions; the last one must be known because together the mole fractions all add up to unity. This happens for each of the X phases, so X of the variables are actually fixed.

Deduct X

Step 3. In equilibrium, the chemical potential of a component must be the same in all the phases (otherwise it won't be equilibrium). If the concentration is fixed in one phase, then the chemical potential is fixed in that phase. The chemical potential must then be fixed in all the phases because it's the same in all phases. Thus, if the concentration is known in one phase, then $X-1$ variables (the concentrations in the other phases) are automatically fixed (even though they are not necessarily the same, their chemical potential is the same). Because this is true for all C of the components, $(X-1)C$ variables are fixed (they are not independent variables).

Deduct $(X-1)C$

Hence the number of independent variables is given by

$$F = (XC + 2) - X - (X - 1)C$$

Rearranging gives us Gibbs Phase Rule.

$$F + X = C + 2 \quad (8.7)$$

Note that many texts use P for the number of phases and V for the degree of freedom. We use F for (degrees of) freedom. Our P is an important variable—the pressure; and V is our volume. We use X for the number of phases.

Most of the time we just examine different systems with up to three components ($C = 1, 2, \text{ or } 3$). The

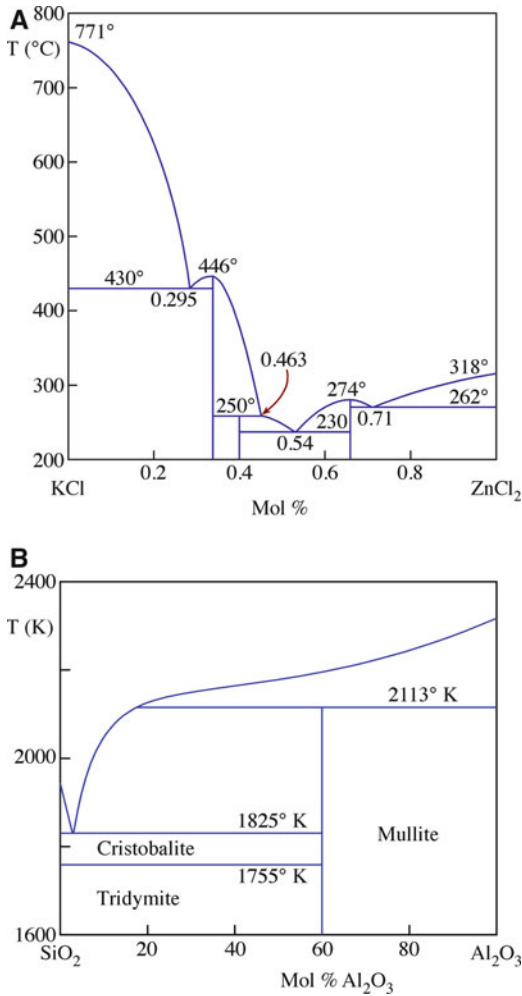

FIGURE 8.5. (a) CALPHAD phase diagram for KCl–ZnCl₂. (b) CALPHAD phase diagram for SiO₂–Al₂O₃.

earlier volumes are still often quoted. Many of these diagrams resulted from research in the 1950s and 1960s, but there are many going back to 1915. The first diagram in the book (Figure 1) was produced in 1951 and is for the system Al–Al₂O₃. It shows the gaseous species over liquid Al₂O₃ as a function of T and P . One of the earliest is for the AgNO₃–NaNO₃ system, which was devised in 1900 (Figure 1040). Unfortunately, this field is not currently well supported. In our brief discussion in this chapter, we take the approach of “learn by example.”

A warning on units is necessary. As many of the data were collected before the establishment of SI units, the plots contain combinations of weight percent, mole fraction, and mole %; kbars and atm for pressure; but fortunately only °C (not °F) for temperature.

GIBBS C, F, AND X

C for component
 F for freedom
 X for phase

FIGURE 8.6. H₂O phase diagram (1,000 atm. is ~100 MPa).

difficulty sometimes is in counting the components. There are also four and five component diagrams in ceramics. We always have to be aware that the sample might contain nonequilibrium phases.

8.5 ONE COMPONENT (C = 1)

In each of these examples, we have one component, meaning that the chemical composition of the material does not vary. From the phase rule, we have P and T as two variables, which is what we plot in each case. Using $F + X = C + 2$ for a one-phase region, we can vary both P and T . For a two-phase region (the line), if we vary P then T is determined. For a three-phase region in a one-component system there are no variables.

Example 1 Water: one component (Figure 8.6). X takes its maximum value of three when $F = 0$. The three coexisting phases are then solid, liquid, and gas at point A, or the liquid and two solid phases at point D. Points A and D occur at unique combinations of temperature and pressure. Lines correspond to locations where two phases are in equilibrium ($X = 2$ and $F = 1$). If we vary T , then P must vary so we stay on the line. This diagram is a simplification of what we know now because there are many (11 or 12) other known crystalline forms of ice. The form that occurs in nature is called ice Ih (a hexagonal form) and has a density of 0.931 g/cm^3 (water is 1.00 g/cm^3 ; hence the iceberg phenomenon). The other forms exist at either lower values of T or higher values of P than shown in Figure 8.6. (We've kept this pressure in atmospheres because the most important equilibrium occurs at 1 atm).

Example 2 Carbon: one component (Figure 8.7). This is a classic example of an element with three solid phases. We often remind owners that diamonds are only metastable, but fortunately the kinetics of the phase transformation are very slow. Notice where we live—in a dot at the bottom left corner.

Example 3 SiO₂: one component (Figure 8.8). Silica is not only one of the most important ceramics but its phase diagram is also very interesting. Remember, the composition is constant. This schematic diagram emphasizes both

FIGURE 8.7. C phase diagram.

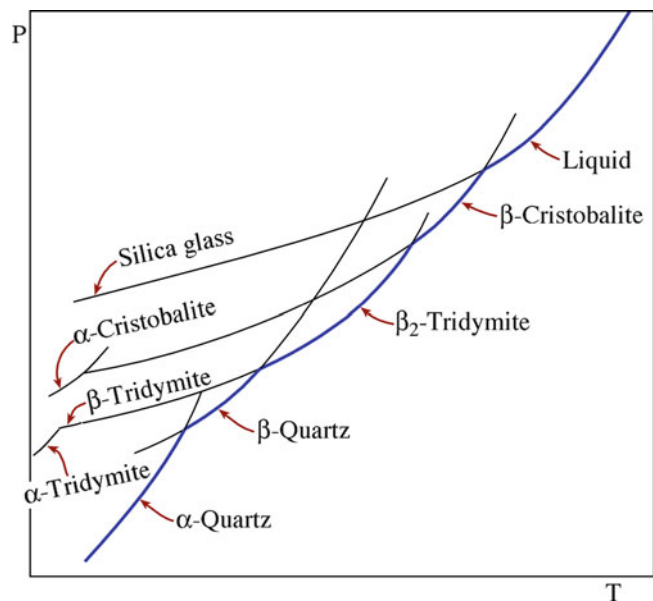

FIGURE 8.8. SiO₂ phase diagram.

the relationship between the glass and the liquid and the fact that the glass is the high-pressure phase; the glass is denser than any of the crystalline forms (similar to ice). The phase rules always apply.

8.6 TWO COMPONENTS (C = 2)

Binary phase diagrams are very important for ceramics. The two most important cases for ceramics are the combination of a metal plus oxygen and the combination of two oxides. A model two-component system is shown in Figure 8.9, where you can see we are now using the third dimension to display the data.

If there is one phase ($X = 1$), as at B, then the three variables are pressure, temperature, and one other—for example, the composition (x/y ratio).

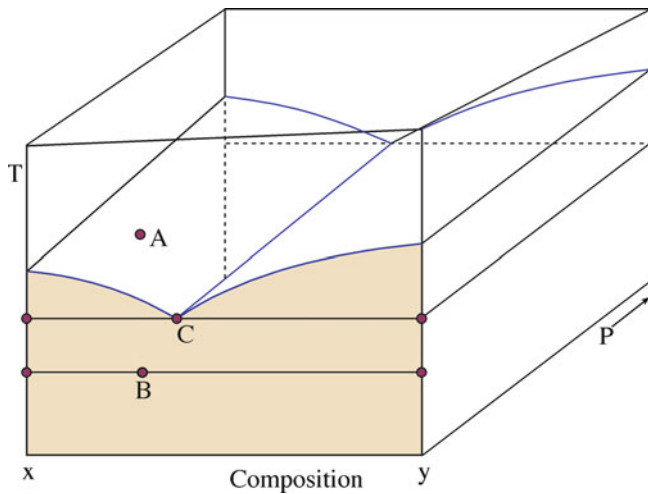

FIGURE 8.9. Model binary phase diagram showing T , P , and composition as variables.

If there are two phases present ($X = 2$), such as the liquid and one solid phase at A, then $F = 2$. If, for example, we fix P , we are free to vary T and move along the liquid/solid phase boundary (a surface).

The special feature is that we have introduced surfaces into the phase diagram. In ceramic materials, the gas phase may be very important. This is where ceramics are particularly different from metals: oxygen (or nitrogen or water vapor and hence hydrogen) may be a component of the system. The gas phase is not important if the valence of the cations is fixed and the total pressure, P , is fixed at 1 atm. We consider materials with variable valence in Section 8.8.

Example 1 NiO/CoO: Two components and P fixed (Figure 8.10). The special feature about this diagram is that both oxides have the rock salt structure. Pauling's rules tell us not to be surprised that they are fully interchangeable. However, it's reported that there is a two-phase region at low temperatures. Notice three points:

- At the high temperatures, the diagram contains only dashed lines—intelligent guesses.
- The two-phase region occurs where kinetics are quite slow.
- The composition is given as a mole fraction.

This is a case where you start with “the book” and then go back to the original reference to learn how the pO_2 was controlled, how the two phases were identified, and so on.

Example 2 MgO/CaO: Two components and P fixed (Figure 8.11). This diagram is a classic eutectic even though CaO and MgO both adopt the rock salt structure. Because the sizes of the two cations differ by more than 15%, solid solubility is limited.

Example 3 MgO/MgAl₂O₄/Al₂O₃: Two components and P fixed (Figure 8.12). This is a particularly important, but

FIGURE 8.10. NiO–CoO phase diagram.

FIGURE 8.11. The MgO–CaO phase diagram.

relatively simple, system in ceramics. It involves three widely used materials, which are also archetypal structures. We can choose the two components to be MgO and Al₂O₃. Then, in the one-phase region we have two variables in addition to P and T . In the two-phase region (along the boundaries) we can vary T and the Mg:Al ratio. Notice that the composition is given in weight percent, which is not too bad for this system but really

FIGURE 8.12. MgO–Al₂O₃ phase diagram.

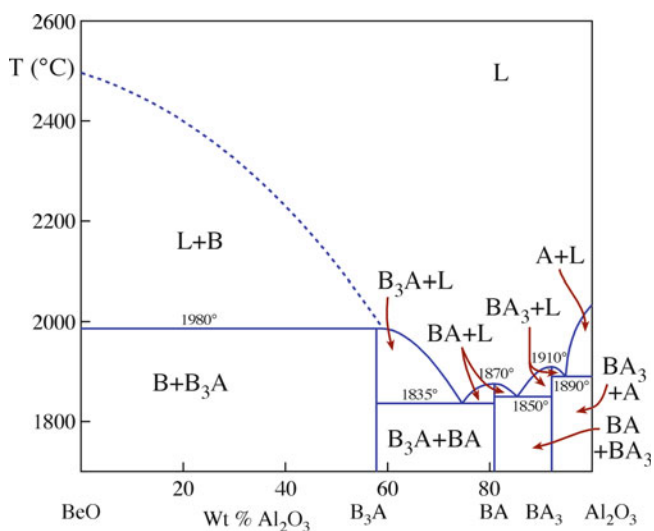

FIGURE 8.13. BeO–Al₂O₃ phase diagram.

distorts the related MgO/Cr₂O₃ and NiO/Al₂O₃ systems. The spinel phase field is already quite wide at 1,600°C and becomes wider at high temperatures, especially toward the Al₂O₃-rich side. We can grow two eutectic structures; one essentially contains pure Al₂O₃.

Example 4 BeO/Al₂O₃: Two components and *P* fixed (Figure 8.13). Notice that all the phases can be regarded as combinations of BeO and Al₂O₃, so we can denote them as B₃A, BA, and BA₃. From the chemical point of view, the system looks quite similar to MgO/Al₂O₃, but clearly it is very different: three separate eutectics are shown; and none of the compounds has the spinel structure. BeAl₂O₄ is the mineral chrysoberyl and has a structure similar to olivine, which is not unrelated to spinel.

Example 5 MgO/TiO₂: Two components and *P* fixed (Figure 8.14). This system is interesting because of the occurrence of four different eutectics. Such eutectics in

FIGURE 8.14. MgO–TiO₂ phase diagram.

this and other systems have been used to prepare some interesting two-phase materials. For example, when a liquid with composition in the MgO-rich region is cooled from the eutectic temperature at 1,707°C, it produces a material that consists of alternating lamellae of nearly pure MgO and Mg₂TiO₄. Other systems show different structures, which are determined in part by the interfacial energies. Of course, interfacial energies are usually not considered in the analysis of phase diagrams.

HUME-ROTHERY RULES FOR COMPLETE SOLID SOLUBILITY

- Same crystal structure
- Equal valence
- Ionic radius within ±15%
- No chemical reactivity

If we have two oxides we need only consider the sizes and valences of the cations.

8.7 THREE AND MORE COMPONENTS

When three components (ternary systems; *C* = 3) are present, the phase diagrams become more difficult to draw because we then have *F* + *X* = 5. If the pressure is fixed, then we have four variables. We need one axis for each component and one for the temperature, for example, so we draw the compositions on a triangle and plot *T* as the vertical coordinate, as shown in Figure 8.15A. The base triangle is called the Gibbs triangle. The example shown in Figure 8.15A corresponds to the case where three oxides form solid solutions (extending the NiO/CoO example).

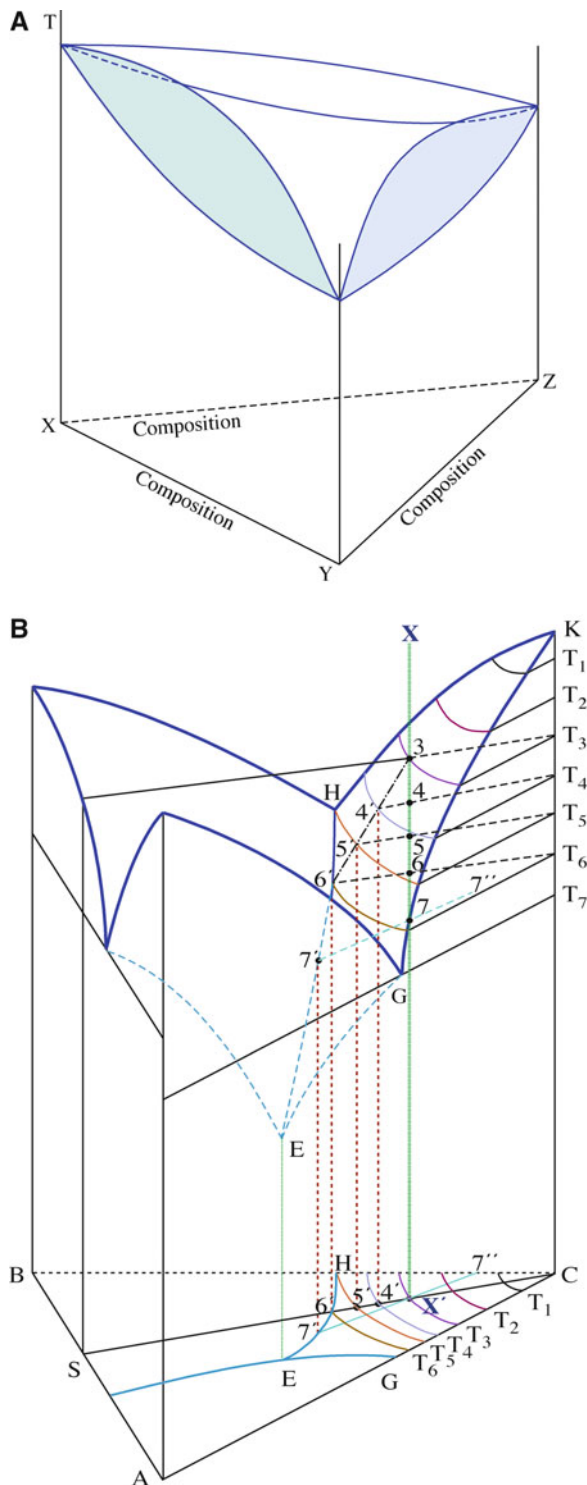

FIGURE 8.15. (A) A model ternary phase diagram for a system showing three solid solutions. (B) A model ternary phase diagram for a system showing three eutectics.

The example shown in Figure 8.15B is the case of three simple binaries, each with a single eutectic (extending the MgO/CaO example). Figure 8.15B is worth some effort to understand. The lines of constant temperature at the solid/liquid phase boundary are projected onto the base of the Gibbs triangle. The location

of each of the three eutectics is also projected and correspond to an abrupt change in the curvature of the constant-temperature contour. The three eutectics then meet at a “grand eutectic” at E. For sufficiently slow cooling, E corresponds to the ultimate eutectic temperature—below T_E the sample is solid.

In the materials that are often most important, the diagrams are more complicated. The phase diagram books then often show them as projected triangles as in Figures 8.16, 8.17, and 8.18.

Example 1 MgO/Al₂O₃/SiO₂: Three components and P fixed (Figure 8.16). Notice that there are perhaps three locations for E. This diagram contains several really important ceramics. We have already examined one of the binary diagrams included here (MgO/Al₂O₃) and will examine another below (MgO/SiO₂). Diagrams such as this have difficulty showing what is happening at temperatures other than the liquidus.

Example 2 CaO/Al₂O₃/SiO₂: Three components and P fixed (Figure 8.17). This figure illustrates the extension of the use of abbreviations to three components. It also illustrates how you can combine the eutectics with a set of tie lines. The CA_{*n*} ceramics are found in high-alumina cements. The phases are all shown as being crystalline. Notice that CS is close to the midpoint, but AS and CA are closer to Al₂O₃.

Example 3 Na₂O/CaO/SiO₂: Three components and P fixed (Figure 8.18). This system is particularly interesting because of its relevance to soda-lime glass formation. Because of this interest, the diagram has been limited to the silica-rich corner of the Gibbs triangle.

Each of these diagrams shows the contours of the solid/liquid boundary. It is now a little more difficult to envision what occurs as we lower the temperature of the liquid phase. The basic ideas are the same as for the two-component systems, as shown in Figure 8.19. The cooling path follows the steepest descent on the liquidus—in this case it reaches T_E —at which point the whole sample is solid and kinetics become the controlling factor.

8.8 COMPOSITION WITH VARIABLE OXYGEN PARTIAL PRESSURE

The gas phase, particularly the oxygen partial pressure, p_{O_2} , is important when the valence of the cation can change.

In ceramics, we usually run experiments at 1 atm., but geologists are interested in much higher pressures, and hot pressing is an established commercial method for processing ceramics.

There are two ways to control the p_{O_2} . Usually, we don't try to change or control the total pressure—we avoid

FIGURE 8.16. The MgO–Al₂O₃–SiO₂ phase diagram.

FIGURE 8.17. CaO–SiO₂–Al₂O₃ phase diagram.

FIGURE 8.18. Na₂O–CaO–SiO₂ phase diagram.

FIGURE 8.19. Cooling path in a ternary system.

vacuum systems whenever possible because they greatly increase the expense. The approach used is to fix the p_{O_2} using one of the following reactions

If there is no solid present, then we have just one phase; namely, the gas and $X + F = C + 2$ gives $F = 3$. So we can vary T , P_{total} and the composition (CO_2/CO ratio or H_2/H_2O ratio).

If there is a solid present (e.g., graphite or Ni), then we have just two variables (because we have two phases, $X = 2$), which fixes the system. If Ni is present, for example, then essentially the Ni/NiO equilibrium sets the p_{O_2} . The same occurs if Fe is present.

We spend some time now discussing the Fe-O diagram shown in Figure 8.20. Here, gas is important. In the Fe-O phase diagram, we have two components. We can call them Fe and O or

FeO and Fe_2O_3 as we wish. The special feature in Figure 8.20 is the fact that usually the lines of constant p_{O_2} are horizontal, whereas in two-phase fields they are inclined to the horizontal. They are inclined when the phase field contains a single phase (wüstite or magnetite).

In the two condensed phases region (region W+M): There are two condensed phases plus the gas (O_2), so $X = 3$. There are two components ($C = 2$; Fe and O), so we have only one degree of freedom: we can vary T or p_{O_2} . Therefore, the oxygen isobars (lines of constant p_{O_2}) on the phase diagram must be horizontal.

In the wüstite phase (region W): There is one condensed phase plus the gas (O_2), so $X = 2$. There are two components ($C = 2$; Fe and O), so we have 2° of freedom ($F = 2$). The reason the isobars have the particular slope is that they must connect the appropriate isobars at each side of their phase field.

This is the special feature for ceramics, especially when processing ceramics with a variable-valence cation in air: p_{O_2} is important.

Figure 8.20A shows the Fe-O diagram as a function of oxygen activity, which is essentially the p_{O_2} . This diagram shows what condensed phase is stable at each combination of temperature and p_{O_2} . Although this diagram does not give as much information as Figure 8.19 (because it doesn't show the composition of the condensed phase), it does emphasize one special feature: if we increase the temperature while keeping the p_{O_2} constant, the oxidation state of the Fe ion decreases. In this figure, the areas show situations where only one phase is present, and all of the lines represent two-phase regions. If we look back at Figure 8.19, the areas represented conditions where one or two phases are in equilibrium with a gas phase.

Figure 8.20B and C shows the related diagrams for the H-O and C-O systems. These diagrams can be very useful in the laboratory because this is how we try to reach the pressures indicated in Figure 8.19A: notice that neither system easily takes us below 10^{-23} atm. In each case, the temperature is plotted against a gas partial-pressure ratio, with the curves showing the contours for constant p_{O_2} . The curves are for the situation where the total pressure is fixed at 1 atm, so we don't need a vacuum system. The gray area in the C-O

system is instructive—we can't reach this in equilibrium because then carbon would form and the solid curve would represent equilibrium. In the gas phase, we have two components ($C = 2$) but only one phase (the gas), so $F = 3$. We can

PRESSURE CONVERSION

- 1 Pa = 1 N/m² = 1 m⁻¹·kg·s⁻²
- 1 N = 1 m·kg·s⁻²
- 1 bar = 0.1 MPa
- 1 kbar = 100 MPa
- 1 atm = 1.013 Pa
- 1 mmHg = 1 Torr = 0.1333 MPa

FIGURE 8.20. (a, b) The FeO–Fe₂O₃ phase diagram; (c) the H–O system; (d) the C–O system.

fix T and the total pressure and still vary p_{CO} , p_{CO_2} , p_{O_2} , or a ratio of any two. If we precipitate out carbon, then we have two phases (gas plus carbon), and $F = 2$. If we fix T and the total pressure (or any of the partial pressures), there is no remaining variable.

8.9 QUATERNARY DIAGRAMS AND TEMPERATURE

The diagrams are now becoming really difficult! Figure 8.21 illustrates an Si–Al–N–O tetrahedron that clearly has difficulty showing temperature effects.

FIGURE 8.21. (a) The Si-Al-N-O phase diagram represented as a tetrahedron. (b) The Si_3N_4 - SiO_2 - Al_2O_3 - AlN phase diagram.

The rectangle cut from it represents the SiO_2 - Al_2O_3 - AlN - Si_3N_4 quaternary system. Now we can plot the different true quaternary compounds, as shown in Figure 8.21B. The ceramics located in this system are then known collectively as the SiAlONs. We discussed the structures of these compounds in Chapter 7.

Notice the use of the Ramsdell notation. This example is more complicated than in Section 6.13 because the chemistry is also changing.

GIBBS FREE ENERGY OF MIXING

For an ideal solution ΔG_M is

$$\Delta G_M = RT(X_A \ln X_A + X_B \ln X_B)$$

and $\Delta H_M = 0$.
For non-ideal solutions, $\Delta H_M \neq 0$

FIGURE 8.22. MnO - Al_2O_3 phase diagram.

FIGURE 8.23. BaTiO_3 phase diagram.

8.10 CONGRUENT AND INCONGRUENT MELTING

Figure 8.22 shows the MnO - Al_2O_3 phase diagram. The equimolar composition melts congruently; that is, there is a direct transformation between the solid and liquid states without a change in the number of phases (in this case $X = 1$). BaO - TiO_2 is another example of a two-component system (Figure 8.23). This diagram

illustrates the concept of incongruent melting: there are actually three incongruently melting compounds. The diagram also shows that we cannot produce pure cubic BaTiO_3 by solidifying a liquid of that composition, which is important when we discuss crystal growth later. Notice that all the compounds on this phase diagram are BT_n (BT , BT_4 , etc.).

8.11 MISCIBILITY GAPS IN GLASS

Can glass be described by equilibrium phase diagrams? This question refers to the fact that glass is not itself in equilibrium. We can, however, describe some aspects of glass microstructure in terms of phase diagrams, especially that of liquid immiscibility, which leads to the phenomenon of phase separation, as illustrated in Figure 8.24.

The random-network model considers glasses as homogeneous. However, microscopic features on the scale of 3 nm to hundreds of nanometers can exist. These small features exist in a range of glasses and can result from a process of phase separation, in which a liquid that is homogeneous at high temperatures separates into two of more liquid phases on cooling.

Figure 8.25 shows the phase diagram for the BaO-SiO_2 system, which exhibits phase separation. The dome, shown by dashed lines because the system is metastable, is the key feature in a phase diagram where phase separation occurs (a similar dome occurs for $\text{Al}_2\text{O}_3/\text{Cr}_2\text{O}_3$, so this dome is not peculiar to glass).

The microstructure of glasses in the system BaO-SiO_2 can be determined using transmission electron microscopy (TEM). What we find is:

FIGURE 8.24. Image of small droplets of glass in a glass matrix. The composition of the glass is 16 wt.% CaO , 10 wt.% MgO , 14 wt.% Al_2O_3 , 60 wt.% SiO_2 .

FIGURE 8.25. Silica-rich end of the BaO-SiO_2 phase diagram.

- At the silica-rich side of the miscibility gap there are discrete spherical particles of a BaO -rich phase embedded in a continuous matrix of an SiO_2 -rich phase.
- Near the center of the miscibility gap there is a three-dimensionally interconnected mixture of BaO and SiO_2 phases.
- At the BaO -rich side of the miscibility gap there are discrete spherical particles of a SiO_2 -rich phase embedded in a continuous matrix of a BaO -rich phase.

The $\text{B}_2\text{O}_3\text{-PbO}$ system is another glass-forming system that shows a miscibility gap and phase separation.

The reason for phase separation of a liquid into two phases may be found by considering the thermodynamics of mixing. Figure 8.26 shows the three thermodynamic functions, ΔG , ΔH , and ΔS plotted at temperature T as a function of composition.

The common tangent to the minima in the free-energy curve determines the composition of the two phases in the glass, and the proportions of each are determined by the lever rule.

Phase separation is important for some commercial glass formulations.

Vycor Process. Glass containing 75 wt.% SiO_2 , 20 wt.% B_2O_3 , and 5 wt.% Na_2O melts at relatively low

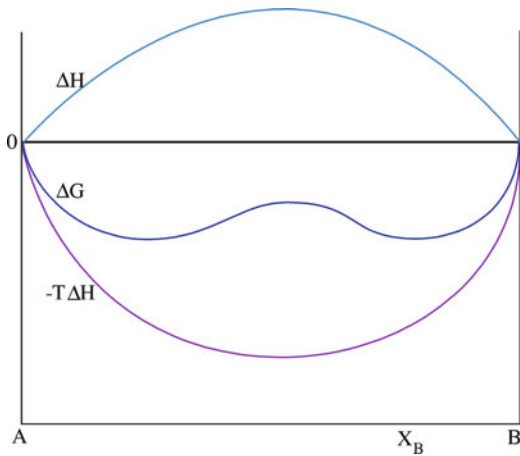

FIGURE 8.26. Energy diagram for a hypothetical system in which unmixing occurs.

temperatures due to high B_2O_3 content. It can then be formed into desired shapes and heat-treated in the range

$500\text{--}600^\circ\text{C}$ so the glass separates into two distinct phases, one consisting of almost pure SiO_2 and another rich in Na_2O and B_2O_3 . If this product is exposed to a suitable solvent at modest temperature, the sodium borate phase is leached out, leaving a SiO_2 -rich framework with a network of pores that are $\sim 4\text{--}15$ nm in diameter. This porous glass can be subsequently compacted at $\sim 1,000^\circ\text{C}$ to yield a transparent glass containing about 96 wt.% SiO_2 . The advantage of this process is that we can form the silica-rich glass at relatively low temperature. It would not be feasible to shape 96% silica glass by conventional methods because of the very high temperatures required to decrease the viscosity of a high-silica glass.

Pyrex. Pyrex glass belongs to the $Na_2O\text{--}B_2O_3\text{--}SiO_2$ system also. It exhibits phase separation on a very fine scale, typically <5 nm. By controlling the cooling process, we develop a glass with a special microstructure and very useful properties. It is the inclusion of a soluble phase within an insoluble one that explains the chemical durability of Pyrex.

CHAPTER SUMMARY

Phase diagrams are key to understanding many aspects of ceramic processing. Whether we are interested in forming a material by a solid-state reaction or growing a single crystal by solidification of a melt, the first approach is to look up the appropriate phase diagram. Knowing where to find these diagrams (in the “books”) is almost as important as being able to interpret them. The basic principles are the same for ceramics as they are for metals, so our approach was to highlight some important aspects of phase diagrams as they relate to ceramics.

PEOPLE AND HISTORY

We’ve mentioned *Boltzmann* and *Kelvin* in other chapters. Kelvin (as *William Thomson*) invented the word thermo-dynamics (now no hyphen) in 1849 when discussing Carnot’s work.

Carnot, Sadi Nicolas Léonard (1796–1832) was born in Paris and was known for his engine and cycle. His book *Reflections on the Motive Power of the Fire* was published in 1824! Clapeyron discovered the work, and Kelvin and Clausius later put his theory on the correct footing.

Clapeyron, Benoît Paul Émile (1799–1864) was born in Paris and wrote the *Driving Force of Heat*. His name is closely associated with Clausius, who published *Über die bewegende Kraft der Wärme* in 1850. (See his Googlebook if your German is good.)

Clausius, Rudolf Julius Emanuel (1822–1888) was born in Köslin Germany, which is now Koszalin in Poland and gave us entropy in 1865.

Gibbs, Josiah Willard (1839–1903) was born in New Haven, Connecticut. He was educated at Yale University and was awarded his doctorate in 1863—the first doctorate of engineering to be conferred in the United States. He was appointed professor of mathematical physics in 1871 prior to having any publications. He published the first part of his very famous work *On the Equilibrium of Heterogeneous Substances* in 1876 and the second part in 1878. He published many other important papers in thermodynamics as well as in other areas of physical science.

Hume-Rothery, William (1899–1968) founded the Department of Metallurgy (now the Department of Materials) at Oxford University in the mid-1950s. H.R., as he was known at Oxford, was the author of many books on metallurgy. One of his books *Electrons, Atoms, Metals, and Alloys* is a dialogue between an older metallurgist and a younger scientist.

Le Chatelier, Henry (1850–1936) is known for his principle and for inventing the optical pyrometer in 1892

EXERCISES

- 8.1 The iron–iron carbide phase diagram is probably the most important of all binary phase diagrams. Why is the diagram not a true equilibrium diagram? Does it matter?
- 8.2 Explain what we mean by the set of equations $\mu_1^a = \mu_1^b = \dots = \mu_1^c$. What is the significance of this expression?
- 8.3 The maximum operating temperature of high-temperature X-ray diffraction is 2,500°C in vacuum but only 1,700°C in air. Why the big difference? What, if any, effect would the lower operating temperature in air have on the determination of phase diagrams?
- 8.4 The UO_2 –BeO system shown in Figure 8.3 does not show any solid solution formation. Would you expect it to?
- 8.5 With reference to the phase diagram for water (Figure 8.6), explain (a) how the boiling point of water would change if you were to climb to the top of a mountain and (b) why ice-skating is possible.
- 8.6 Using Figure 8.7, determine the necessary conditions for direct conversion of graphite to diamond.
- 8.7 Using Figure 8.8, indicate all the triple points in the SiO_2 system.
- 8.8 Describe fully what happens when you cool down a melt of 40 mol% NiO–60 mol% MgO. Give the compositions of the phases and their relative amounts for at least three temperatures in the two-phase field.
- 8.9 Describe the phases that you expect to form as a liquid of composition BaTiO_3 is cooled down to room temperature. Given the statement we make in Section 8.10 about the growth of single crystals of cubic BaTiO_3 , what factors besides thermodynamics determine our ability to grow single crystals?
- 8.10 You have a sample containing 20 wt.% of Fe oxide in a $p\text{O}_2$ of 10^{-12} . What is the temperature of the sample. What happens to the sample if you slowly reduce the temperature?
- 8.11 Choosing a $p\text{O}_2$ of 10^{-12} , show how Figure 8.20A and B are related.
- 8.12 Consider the 10^{-12} curve in Figure 8.20C. What has this got to do with the 10^{-12} line in Figure 8.20A?
- 8.13 The three solid oxides in Figure 8.12 have very different phase fields. Discuss why this may be the case and what implications it may have.
- 8.14 Vonnegut's ice-nine is fictional even though Langmuir was reputedly the inspiration for it. What has this got to do with Figure 8.6?
- 8.15 CaO and MgO have the same crystal structure, but the 50:50 composition exists as two distinct phases. Explain why this is so and why we ask the question.
- 8.16 Explore the phase diagram in Figure 8.23 to show why we have difficulty growing crystals of BaTiO_3 . Draw the diagram in detail.
- 8.17 More difficult: explore the literature to suggest why Ba_2A and BaA_2 are not found.
- 8.18 Apply equation 8.7 to regions W, M, and M + H in Figure 8.20A and 15R in Figure 8.21.
- 8.19 Imagine you have 1 g of iron oxide. What phases would you expect to have if it were in thermodynamic equilibrium? Is this what you would have expected before consulting the phase diagram? (Explain.) How might the situation change if the particles were 1-nm cubes?
- 8.20 Are there any examples of hot stages for TEMs that do not require a vacuum? Is the same true for SEMs?

Tools

Furnaces

CHAPTER PREVIEW

Furnaces are the essential equipment in any ceramics laboratory. They can range in size from small electrically heated box furnaces, often called muffle furnaces, which can fit on a bench to the enormous gas-fired furnaces used to melt glass. In between these extremes there are furnaces of many shapes and sizes, designed to run at a range of temperatures and in a range of atmospheres. In addition to obtaining a high temperature, it is necessary to have furnace components that can withstand these temperatures without degradation. These materials are known as refractories. Much of our knowledge of refractory ceramics has come from early developments in the iron and steel industries. Whenever temperatures are high, vapor pressures may also be high, so be aware that the furnace material may contaminate the material you are processing. We also describe methods for measuring high temperatures and some of the important safety considerations that you must know when using furnaces and working at high temperatures.

9.1 THE NEED FOR HIGH TEMPERATURES

There are many areas in ceramics where we need high temperatures.

- Sintering—Most bulk ceramic components are made by sintering a powder compact. We need to use high temperatures ($>1,200^{\circ}\text{C}$) because of the low self-diffusion coefficients in the solid state. Even for liquid phase sintering, temperatures are still often $>1,200^{\circ}\text{C}$.
- Reactions—Forming mixed metal oxides such as BaTiO_3 and NiAl_2O_4 by solid-state reaction of the component oxides requires the use of elevated temperatures.
- Phase Transformations—An important phase transformation is that involving crystallization of a glass to form a glass-ceramic. Although the temperatures involved are not as high as those needed for glass melting, the phase transformation is typically carried out at around 800°C . Control of temperature is often necessary to ensure that the desired crystalline phase is formed and in the optimum particle size.
- Glass Melting—Glass products form the largest single segment of the ceramics industry. Glass production frequently requires melting of a batch consisting of a mixture of powdered metal oxides and metal carbonates. The temperature necessary to form a homogeneous liquid melt varies with batch composition but is typically in the range $1,300\text{--}1,600^{\circ}\text{C}$.

The melt is also very corrosive, which provides additional considerations in the choice of refractories.

- Crystal Growth—Most of the methods used to form single crystals, whether in the laboratory or in industry, require the use of high temperatures. Many single crystals are produced from the melt or by using suitable fluxes, and particular attention has to be paid to avoiding contamination of the melt and controlling the temperature during growth.

9.2 TYPES OF FURNACE

We can categorize the furnaces used to fire and sinter ceramic components in several ways. One way is based on the type of heat source used:

- Combustion
- Resistive
- Microwave, radiofrequency (RF), or infrared (IR)/visible light

Alternatively we could group them as:

- Periodic or batch furnaces
- Continuous furnaces

Electrical furnaces can produce direct (resistive) or indirect (induction or microwave) heating. We look at the

characteristics of each group of furnaces, keeping in mind that there is overlap. For example, we can have continuous gas-fired furnaces or continuous electrically fired furnaces. Historically, continuous furnaces and gas-fired furnaces are usually found in industry. Batch and electrically fired furnaces are used widely in university laboratories and in many small to medium-sized industrial applications. The current trend toward more environmental controls and demand for higher quality continues to expand the applications for electrically powered furnaces. Electric furnaces account for about 60% of the total industrial heating equipment market (about \$3 billion in total). There is still growth in the use of combustion furnaces, in particular for applications in the metal and cement industries.

This chapter is called furnaces, but it could have been called kilns or ovens as these terms are used to describe many of the same types of equipment. “Kiln” is widely used in the traditional ceramics industry and the pronunciation is sometimes “kil.” In the Potteries in England, for example, you may encounter the alternative pronunciation. “Furnace” is used interchangeably with kiln. “Oven” is more often used for either equipment used for drying ceramics (typically using lower temperatures) or for small furnaces.

9.3 COMBUSTION FURNACES

The most common combustion furnaces used in ceramic processing are gas-fired and use gaseous hydrocarbons as fuel. The large amount of energy produced heats the furnace and the parts inside. Gas-fired furnaces are used mainly in large industrial applications such as glass melting, the production of ceramic colors, and firing of traditional ceramic articles (e.g., tiles and whiteware). Figure 9.1 shows an example of a commercial glass-melting furnace.

FIGURE 9.1. Gas-fired batch furnace used in a commercial glass-blowing operation.

Combustion is an oxidative process; for the case where methane is the fuel:

The standard molar enthalpy, or heat, of combustion (ΔH_c°) may be calculated using equation 9.2.

$$\Delta H_c^\circ = \sum \Delta H_f^\circ(\text{products}) - \sum \Delta H_f^\circ(\text{reactants}) \quad (9.2)$$

For the reaction given in equation 9.1 we can write

$$\Delta H_c^\circ = \Delta H_f^\circ(\text{CO}_2) + \Delta H_f^\circ(2\text{H}_2\text{O}) - [\Delta H_f^\circ(\text{CH}_4) + \Delta H_f^\circ(2\text{O}_2)]$$

where ΔH_f° refers to the enthalpy of formation. These values are tabulated for many substances. One source is the thermochemical tables (e.g., Barin 1997). Making the appropriate substitutions, we get

$$\begin{aligned} \Delta H_c^\circ &= -393.51 + 2(-285.83) - (-74.81) \\ &= -890.36 \text{ kJ/mol} \end{aligned}$$

(Note that ΔH_f° for a material in its standard state is zero).

The simple idea is that the amount of energy released during combustion depends on the strength of the bond in the gas. Fuels with many weak (less stable) bonds, such as C–C and C–H, yield more energy than fuels with fewer such bonds or fuels that contain large numbers of strong bonds (e.g., C–O and O–H). Table 9.1 lists the standard molar enthalpies of combustion for a range of hydrocarbons.

For many combustion reactions, the standard enthalpy changes are listed as a function of temperature. If this information is not available, then it is necessary to calculate the enthalpy change at the temperature of interest, $\Delta H_c^\circ(T)$, using equation 9.3.

$$\Delta H_c^\circ(T) = \Delta H_c^\circ(298) + \int_{298}^T \Delta c_p dT \quad (9.3)$$

C ₂ H ₂	2,657	2,384	3,737	3,464

where c_p is the molar heat capacity at constant pressure, which can be expressed in the form

$$c_p(T) = a + bT + cT^{-2} \quad (9.4)$$

The temperature-independent coefficients a , b , and c are listed for several species in Table 9.2. It is important to remember that a , b , and c are only valid over certain temperature ranges.

Thermodynamics determines the maximum amount of energy that can be produced by a combustion reaction. This can be quantified by what is known as the adiabatic flame temperature, which is shown for several possible gas mixtures in Table 9.3. These values, and those for other gas mixtures, can be calculated by solving the enthalpy balance (Kirchhoff's law)

$$\Delta H_c^\circ(298\text{K}) + \int_{298\text{K}}^T \Sigma c_p dT = 0 \quad (9.5)$$

The maximum temperature that can be achieved in a gas-fired furnace is well below the adiabatic flame temperature because of heat loss caused by incomplete combustion and dissociation of the combustion gases (an endothermic process) at high temperature. Heat is also lost by conduction through the refractories and imperfect insulation.

9.4 ELECTRICALLY HEATED FURNACES

Most electrically heated furnaces use the principle of Joule, or resistance, heating where current flowing through a resistor produces heat. The starting point is Ohm's law:

$$V = IR \quad (9.6)$$

relating the current, I , through a resistance, R , to the applied potential, V . As current flows, power (P) is dissipated.

$$P = VI = I^2R \quad (9.7)$$

What we are often most interested in is the amount of energy converted into heat, Q , which is obtained simply by multiplying P by time, t .

$$Q = RI^2t = \rho \frac{l}{A} I^2t \quad (9.8)$$

The units of Q are joules but are often given as kWh (kilowatt hour), the familiar unit used by power utility companies to determine electricity usage.

The heat source in the earliest electric furnaces was direct current (dc) arcs formed between carbon electrodes, so the heating element really was an element. Carbon (in the form of graphite) is still used as a heating element, but most heating elements are now made from compounds. There are several types of heating element. We describe some of the important ones in Section 9.7. The choice of heating element depends on the maximum temperature that is required and the environment that the element will be exposed to.

There are several advantages to electric heating:

- It's easy to measure power input
- It's easy to control heating rates and temperature
- The furnace can operate in an atmosphere independent of the heating source

The main disadvantage of electric heating is that it usually costs more per energy unit than gas heating. However, the total energy usage for electric furnaces may often be lower than for gas-fired furnaces. The cost issue is not normally a problem in a university laboratory, but it can be a major concern for industrial applications. Two other types of furnace that use electricity are induction furnaces and microwave furnaces.

9.5 BATCH OR CONTINUOUS OPERATION

Batch operation. Figure 9.2 shows an example of a small electrically heated batch furnace. These types of furnace are used for temperatures up to 1,800°C and are designed

FIGURE 9.2. Small electrically heated box furnace.

FIGURE 9.4. Large batch furnace used in the production of traditional ceramic products.

FIGURE 9.3. Electrically heated tube furnace.

FIGURE 9.5. Large continuous furnace used in industry to produce traditional ceramic products and advanced ceramics, such as multilayer chip capacitors.

to be used in air. Figure 9.3 shows another example of a batch furnace. This particular furnace is known as a tube furnace. By flowing gases along a tube placed inside the furnace, the heating environment can be controlled. The usual operation of a batch furnace involves inserting the ceramic parts into the furnace at room temperature, heating to the desired temperature, then cooling back to room temperature. In some cases,

the parts may be inserted and removed while the furnace is at high temperature. For powders, this approach does not usually produce any problems, but for large consolidated parts the problem of cracking due to thermal shock is an important consideration. Batch furnaces are mainly used for small-scale heating experiments and for process development and evaluation; but they can also be found in large industrial applications, as shown in Figure 9.4. The advantages of batch furnaces are that they are simple to operate and flexible.

Continuous operation. Figure 9.5 shows an example of a large industrial continuous furnace. The classic use is for firing bricks, pottery, tiles, and whitewares. Similar furnaces are used in the production of advanced ceramics such as multilayer ceramic chip capacitors.

In a continuous furnace, the temperature at each location in the furnace is constant with time. The parts are moved through the furnace at a velocity giving the desired time–temperature profile. Continuous furnaces are best for mass production, where large quantities of material are subjected to the same conditions. The disadvantages of continuous furnaces are that the furnace temperature must be maintained throughout the process and there is a lack of flexibility.

9.6 INDIRECT HEATING

Induction furnaces. Induction heating provides a means for precise heating of electrically conducting objects. The object is immersed in an alternating magnetic field, which is usually produced by an external coil energized by an alternating current (ac) source. The magnetic field induces voltages in the conductive material, and these voltages produce circulating currents (called eddy currents). The magnitude of the induced voltage and the impedance of the material determine the size of the induced currents. It is the flow of induced currents that produces Joule heating of the material. A piece of metal may be introduced to begin the heating process—we must be able to couple the applied field to the ceramic. If the material we want to heat is an insulator, we can place it

FIGURE 9.6. Induction furnace. The sample is mounted within the coils, which are usually water-cooled copper.

inside a conductive crucible, such as graphite. A typical induction furnace is shown in Figure 9.6.

Induction heating gives many advantages:

- It is clean and fast.
- The process is easily reproducible.
- It can be automated.
- Localized heating is possible (actually, it's essential).

Induction furnaces operate at frequencies of 60–1,000 Hz and are thus often referred to as radio-frequency (RF) furnaces. They can be used for obtaining temperatures up to 3,000°C. Because the coil currents may be as high as 15 kA, the Cu coil conductors are usually hollow to permit water circulation for cooling.

Induction furnaces are generally used for melting and surface hardening. They are sometimes used for sintering in conjunction with hot pressing. These are the furnaces used in the skull-melting process, which is used to produce cubic zirconia.

Microwave furnaces. Microwave heating is an application of induction heating using higher frequencies. In many ways microwave furnaces are just expensive microwave ovens.

Heat is generated in nonconducting materials when microwave radiation excites the molecules in the material. The high-frequency radiation causes molecular polarization, and the ability of the molecules to follow the rapid reversal of the electric field results in the conversion of electromagnetic energy into heat within the irradiated material. The two predominant frequencies are 915 and 2,450 MHz (the microwave region extends from about 1 GHz up to about 300 GHz). Household microwave ovens operate typically at 2,450 MHz. The main difference between the microwave oven you use at home and those used in industrial applications is the power. The maximum power of a domestic appliance is about 700 W; industrial versions have powers up to 5 kW.

Microwave furnaces currently are used for research and small-scale production because the available power sources are limited in size. Microwave processing is an area where considerable research is being performed. The main direction for this research, and the possibility for future commercial applications, is reduction of production times and lowering the amount of energy consumption required for part processing.

The term “microwave safe” is used for various ceramic, glass, and plastic food and beverage containers. All glass and glass-ceramic cookware is microwave safe because it can withstand the high temperatures that can occur when cooking foods that are high in fat or sugar. Many plastics don't satisfy this requirement.

Arc-image furnaces. This usage is comparable to heating with electric-light bulbs. The light is focused on the sample using ellipsoidal mirrors. The heat is clean, and the sample can be held in an inert or oxidizing atmosphere. An important application of arc-image furnaces is in the growth of single crystals of ceramics with high melting temperatures (Chapter 29).

Lasers and electron beams. These can be used to provide local heating or for heating small quantities. The temperature control is not great, but these techniques are very versatile. Electron beams are used to vaporize silicon for thin-film deposition using molecular-beam epitaxy. A focused laser beam is the basis of the pulsed-laser deposition (PLD) thin-film growth technique (Chapter 28).

9.7 HEATING ELEMENTS

Never use a furnace like a black box. The heating elements will go to certain temperatures, but even then you may not want that type of material close to your sample to minimize contamination. Table 9.4 lists the materials used for electrical resistance heating.

- Furnaces operating in air at temperatures up to 1,300°C usually use wire-wound Cr alloys.
- For higher temperatures in air, either precious metals or SiC rods are used.
- For very high temperatures requiring an oxidizing environment, ceramic elements, most commonly ZrO₂, are used.
- In cases where reducing atmospheres can be tolerated, graphite or refractory metals such as Mo and W can be used.

We now look, in a little more detail, at some of the ceramic materials that are used as heating elements in furnaces. We also mention one other type of resistance element, SnO₂, which is used in electrically heated glass-melting furnaces.

TABLE 9.4 Electrical Resistance Heating Element Materials

Material	Maximum useful temperature (°C)	Usable atmosphere
<i>Chromium alloys</i>		
Chromel C, Nichrome, Kanthal DT	1,100	ONR
Kanthal A, Chromel A	1,300	ONR
<i>Metals</i>		
Pt	1,400	ONR
Pt-Rh alloys	1,500–1,700	ONR
Mo	1,800	NR
W	2,800	NR
<i>Ceramics</i>		
SiC	1,500	ON
MoSi ₂	1,700	ON
Lanthanum chromite	1,800	O
Thoria, stabilized	2,000	ONR, shock
Zirconia, stabilized	2,800	ONR, shock
Graphite	3,000	NR

O oxidizing, N neutral, R reducing, Shock particularly poor resistance to thermal shock

9.7.1 Silicon Carbide

Silicon carbide is the most widely used nonoxide ceramic for heating elements in high-temperature furnaces. SiC heating elements can be used up to 1,500°C in air because of the formation of a protective oxide layer. At temperatures in the range 1,500–1,600°C, SiC decomposes.

There are three main methods used to produce SiC heating elements:

- In situ reaction
- Reaction bonding
- Sintering

In the first method, a carbon tube is heated to about 1,900°C in a bed of sand (SiO₂) and coke (C). The tube may be directly resistance heated or heated indirectly by a sacrificial tube of smaller diameter. Silicon monoxide is generated from reaction 9.9 and infiltrates the carbon tube transforming it to SiC. The SiC tube is then removed and the residual carbon burned out. The tube has a porosity of about 30% and a large internal surface area. To prevent internal oxidation during use, the outer surfaces of the tube are coated with a thin layer of a calcium aluminosilicate glass and then fired at about 1,450°C. In this form, the tubes have uniform resistance along their length. A higher-resistance heating section is made by diamond sawing a spiral through the tube wall, as shown in Figure 9.7. Adjusting the pitch of the cut varies the resistance.

In the second method, a mix of SiC and carbon powders and a polymer binder is extruded to a rod. The “green” form is then brought in contact with molten silicon. The liquid penetrates the pores, reacting with the carbon to form silicon carbide and bonding the grains together. The resulting ceramic has low porosity and consequently a long service life. The resistance of the hot section of the rod is adjusted to the required value by spiraling, which is easier to do when the ceramic is in the “green” state.

In the third method, SiC powder is mixed with a polymer binder and extruded. The rod is then sintered in a carbon furnace at approximately 2,300°C. To give the rod low-resistance terminations, the ends are dipped into molten silicon, which is allowed to infiltrate along a predetermined length. In all cases, the ends of the elements are coated with aluminum to make electrical contacts.

The main disadvantage of silicon carbide heating elements is that they are extremely brittle and must be handled carefully, especially when being installed and wired.

9.7.2 Molybdenum Disilicide

Many metals form conductive silicides that, like SiC, are resistant to oxidation through the formation of stable layers

FIGURE 9.7. Examples of SiC furnace elements.

of silicates or silica on their surfaces at high temperatures. Molybdenum disilicide (MoSi_2) has been developed as a heating element for use in air at temperatures $>1,500^\circ\text{C}$. The resistivity of MoSi_2 behaves in the same way as for a metal—it increases with increasing temperature. The room-temperature resistivity of MoSi_2 is $2.5 \times 10^{-7} \Omega\text{-m}$; it increases to about $4 \times 10^{-6} \Omega\text{-m}$ at $1,800^\circ\text{C}$.

A commercial MoSi_2 heating element, known as Kanthal Super, comprises a mixture of MoSi_2 particles bonded together with an aluminosilicate glass phase, which forms 20% of the total volume. The elements are fabricated by extruding a mixture of fine MoSi_2 powder with clay. The rods are dried, sintered, and cut to various lengths. The heating zones are bent to the required shape at high temperature and are then welded to the larger-diameter terminal sections. The best-grade MoSi_2 element is capable of operating up to $1,800^\circ\text{C}$.

9.7.3 Zirconia

Cubic stabilized zirconia (ZrO_2) is used as a furnace element, allowing temperatures $>2,000^\circ\text{C}$ to be achieved. Because of the low conductivity of ZrO_2 at room temperature, they require preheating by gas or conventional resistance elements to reduce the resistance to a level at which Joule heating is effective. At temperatures $>1,000^\circ\text{C}$, the ceramic becomes sufficiently conductive to be self-heating. Zirconia can also be used as a susceptor for induction heating.

9.7.4 Tin Oxide

SnO_2 is frequently used as electrodes in glass melting furnaces, particularly those used for making glasses for optical components and lead “crystal” tableware.

The requirements for the electrode material are very specific:

- Electrical conductivity must be high at glass-melting temperatures.
- Resistance to corrosion by the molten glass must be high.
- It should not discolor the glass.

The electrodes are formed by mixing SnO_2 powder with small amounts of sintering aids such as ZnO and CuO and additives such as Sb and As , which make the material semiconducting. Typical electrode compositions contain more than 98 wt% SnO_2 . The oxide powders, together with binders, are pressed or slip cast into cylinders and fired in oxidizing conditions at temperatures of approximately $1,400^\circ\text{C}$. The largest electrodes made in this way are in the form of cylinders 600 mm long and 150 mm in diameter weighing about 60 kg. Cooling from the sintering temperature is carried out, in part, in a nitrogen atmosphere with the object of creating oxygen vacancies and so increasing room-temperature conductivity, which is typically about 0.1 S/m. High conductivity minimizes Joule heating in the electrode region outside the molten glass.

In electrically heated glass-melting furnaces, the batch is preheated, using oil or gas, to about $1,000^\circ\text{C}$, when it has sufficient conductivity to be directly heated to the “glass-finishing” temperature ($1,300\text{--}1,600^\circ\text{C}$) by power dissipated internally. By supplying the heat from within the body of the glass melt rather than from the outside, the free surface temperature is kept relatively low, and loss of volatile elements, particularly lead, is avoided. The process is economic because the heat is generated where it is required (i.e., in the glass). The elements are resistant to attack by glass and last about 2 years before being replaced.

9.7.5 Graphite

Graphite is a good choice as a heating element for resistive heating because it has a high melting temperature and a very low vapor pressure, even at temperatures above 3,000°C. These characteristics led to the use of graphite filaments in early incandescent lamps (They were eventually replaced by tungsten, which came into general use as a filament for incandescent lamps in 1911). The major disadvantages of using graphite furnace elements are:

- Reactivity with oxide ceramics
- Susceptibility to oxidation

All metal oxides are reduced when in direct contact with graphite at high temperatures. Even the most refractory oxides are reduced if the temperature is high enough.

9.7.6 Molybdenum and Tungsten

Both molybdenum and tungsten are refractory metals and are used as heating elements. Molybdenum reacts with oxygen at >700°C to form molybdenum trioxide (MoO₃). For applications above this temperature, it is necessary to have a reducing environment or vacuum. The maximum usable temperature for molybdenum heating elements is about 1,500°C. Above this temperature, creep is a problem. Tungsten can be used for temperature up to 3,000°C in inert atmospheres.

Figure 9.8 illustrates a problem that can occur with any furnace element—sample contamination. The sample is α-SiC that was heated in a tungsten furnace for 12 h at 1,300°C. The dark features are tungsten particles evaporated onto the surface during heat treatment.

FIGURE 9.8. A TEM image showing small particles of tungsten contamination formed on SiC.

9.8 REFRACTORIES

Refractories are materials capable of withstanding high temperatures and not degrading in a furnace environment when in contact with corrosive liquids and gases. Refractory insulators are used in high-temperature applications to reduce heat losses and to save fuel. Table 9.5 lists some of the important furnace insulation materials together with their maximum usable temperature and thermal conductivity, *k*. The lower the value of *k*, the better is the thermal insulating effect for equal thickness.

Figure 9.9 shows the arrangement of refractory bricks in a typical glass-melting furnace. Approximately 70% of all refractories used by industry are in the form of preformed bricks that come in a variety of shapes. There are several different types of refractory brick, and the choice depends mainly on the maximum operating temperature of the furnace and on the size of the furnace.

- Silica brick. Made from naturally occurring sources of silica and bonded by adding 3.0–3.5% CaO to promote liquid phase sintering.
- Semisilica brick. A silica brick containing 18–25% Al₂O₃.
- Fireclay brick. Made from kaolinite (Al₂O₃·2SiO₂·2H₂O) with 25–45% Al₂O₃.

TABLE 9.5 Refractories for Thermal Insulators

Material	<i>T</i> _{max} (°C)	<i>k</i> (Wm ⁻¹ K ⁻¹)
Glass, fiber	600	0.05
SiO ₂ , fiber	1,000	0.17
Firebrick, insulating	1,200–1,500	0.52
Fiberfrax	1,650	0.12
Al ₂ O ₃ , bubble	1,800	1.04
MgO, powder	2,200	0.52
MgO, solid	2,300	2.94
Carbon or graphite, powder	3,000	0.09
Radiation shields, Mo	2,100	0.69

FIGURE 9.9. Layout of refractories in an industrial glass melting furnace.

- High-alumina brick. Alumina content in the range 45–100 wt.%.
- Dolomite brick. Made from dolomite ($\text{CaCO}_3 \cdot \text{MgCO}_3$).
- Magnesia brick. Contains mainly MgO (typically >90% MgO).
- Chrome brick. Made from naturally occurring chrome ore. Contains 34% Al_2O_3 and 30% Cr_2O_3 . Often MgO is added to produce chrome-magnesia brick.
- Zircon refractory brick. Zircon is $\text{ZrO}_2 \cdot \text{SiO}_2$. Bricks may contain 4% CaO.

The schematic diagram of a blast furnace in Figure 9.10 shows how different types of refractories are used within the furnace. The maximum temperature (>1,700°C) is reached toward the base of the furnace, where the air “blast” comes in and where the slag is formed. Slag is a glassy waste product made up of limestone and silica (impurities in the iron ore), ash, and oxides. It is lighter than the molten iron and so forms a layer above it.

Refractories are one example of where a high-density ceramic product is not desirable—the space-shuttle tiles being the extreme example. The thermal conductivity, k_p , of air is only $0.026 \text{ Wm}^{-1} \text{ K}^{-1}$, significantly less than that of most crystalline ceramics. The thermal conductivity of a porous ceramic can be calculated using equation 9.10.

$$k_m = k_c \left(\frac{1 + \{2V_p[1 - (k_c/k_p)]/[2k_c/k_p + 1]\}}{1 - \{V_p[1 - (k_c/k_p)]/[k_c/k_p + 1]\}} \right) \quad (9.10)$$

where k_c is the thermal conductivity of the ceramic; k_p is the thermal conductivity of air; and V_p is the volume fraction of porosity.

FIGURE 9.10. Diagram of a blast furnace indicating the type of refractories used in each region.

When $k_c > k_p$, the resultant thermal conductivity is

$$k_m \sim k_c [(1 - V_p)/(1 + V_p)] \quad (9.11)$$

As an illustration, we can use equation 9.11 to estimate the thermal conductivity of a silica firebrick containing 30 vol% porosity (i.e., $V_p = 0.3$). The values of k_c and k_p are 1.4 and $0.026 \text{ Wm}^{-1} \text{ K}^{-1}$, respectively, giving a value of $k_m = 0.75 \text{ Wm}^{-1} \text{ K}^{-1}$.

Consequently, ceramics containing a high volume fraction of porosity have low values of k . The ceramic provides the high strength and high melting point requirements of the insulating material, and the porous microstructure ensures a very low k . We discuss other factors that affect thermal conductivity in Chapter 34.

In addition to their use in furnaces for ceramics processing, refractories are a very important sector of the ceramics industry because they are widely used in most high-temperature manufacturing processes.

- Iron and steel making (accounting for almost two-thirds of all refractories used)
- Copper and aluminum smelting
- Cement and ore processing
- Petroleum refining
- Petrochemical manufacturing

9.9 FURNITURE, TUBES, AND CRUCIBLES

Table 9.6 lists some of the important crucible materials. Crucibles and other furnace equipment, such as boats and setter plates, must meet the same requirements as refractory materials used for furnace insulation; that is, they must be able to withstand high temperatures and also contact with any corrosive liquids or gases used. Items such as crucibles and boats should also possess good thermal shock resistance as they may be heated and cooled rapidly. Figure 9.11 shows an example of a kiln furniture used for the production of dinnerware. Any component in contact with a crucible or other piece of furnace equipment at high temperature can be contaminated. SiO_2 is a major contaminant unless you are very careful.

9.10 FIRING PROCESS

A furnace is fired up in three stages.

- Heating-up stage
- Soaking period
- Cooling stage

The variations in the heating-up rate are chosen so that the changes of state to which the product is subject and the stresses that arise from the thermal expansion of the

product and the combustion of binders do not cause damage (e.g., cracks, pores). A common phase transformation that occurs during firing of silica-containing ceramics (e.g., whitewares) is that between α and β quartz at 537°C.

Furnace design and the heating mechanism determine the maximum heating rate of a furnace. It is important to always check the operating manual that came with a furnace before setting the controller.

The degree of sintering is a function of time and temperature. Different processes use different soaking

FIGURE 9.12. Firing curves for clay-bearing ceramic compositions. The soaking periods are in hours.

periods (the time at the desired firing temperature). For example, in the firing of thick-film inks, the typical soaking period is relatively short, only 6–10 min. Figure 9.12 shows examples of a much longer soaking periods used in the firing of clay-bearing ceramics.

Crystallization and other phase transformations that may occur in a product as well as thermal contraction must be taken into account in the cooling stage. At the beginning of the cooling process, the material is generally still rather plastic. It can be cooled fairly quickly at this stage because the thermal contraction does not cause the stresses to increase very much. Below a certain temperature, the plastic characteristics disappear. For many clay-based ceramics this is between 800°C and 600°C. In this range, a higher cooling rate accompanied by a steep temperature gradient can cause stresses to form in the product. In temperature ranges in which phase transformations accompanied by volume changes take place, too high a cooling rate can produce cracks. Especially when using raw materials rich in quartz, the specification of the cooling rate requires special care. One of the goals in processing both traditional and advanced ceramics is to decrease the product throughput time. Fast firing seeks to reduce total costs because of lower energy consumption and improved efficiency.

9.11 HEAT TRANSFER

The liberation of heat energy is only the first stage of the heating operation. This energy has to be transferred to the material to be heated. There are three fundamental types of heat transfer: conduction, convection, and radiation. All modes of heat transfer

- Require the existence of a temperature difference
- Are from the high-temperature medium to a lower-temperature one

A detailed study of heat transfer is best left to a specific course on this topic, or you can consult one of the standard

texts, for example Chapman (1984). Below we give a very brief description of each mode.

- Conduction is the transfer of heat from one part of a body to another part of the same body, or from one body to another that is in physical contact with it.
- Convection is the transfer of heat from one point to another within a fluid, gas, or liquid by mixing one portion of the fluid with another. In natural convection, the motion of the fluid is entirely the result of differences in density resulting from temperature.
- Radiation is the transfer of heat from one body to another not in contact with it, by means of wave motion through space.

Any, or all, of these mechanisms may be important in a particular heating application. Usually, they operate simultaneously but often with one predominating. At very high temperatures, such as those encountered in ceramic sintering, radiation is often the most important. At lower temperatures, convection is most likely to predominate.

9.12 MEASURING TEMPERATURE

In this section we describe some of the approaches used to determine the high temperatures employed in the processing of ceramics. More detailed information on temperature measurement can be found in McGee (1988).

9.12.1 Thermocouples

The most common and convenient means of measuring temperature is to use a thermocouple. The principle behind

the operation of a thermocouple is the Seebeck effect, discovered in 1821 by Thomas Seebeck. If two wires of different metallic composition are connected at their ends, forming a closed circuit, an electric current flows if one of the connections is heated. Measuring the potential (electromotive force, or emf) causing this current allows the determination of temperature. In Seebeck's original research, the two metals were bismuth and copper.

There are many different types of thermocouple available to cover temperatures ranging from -273°C to $2,000^{\circ}\text{C}$, and the most important ones are given in Table 9.7. The type of thermocouple you would use depends mainly on the temperature range over which you require information and the desired accuracy of the temperature reading. The most commonly used thermocouples for ceramic applications are types K, R, and C. These are used for temperatures up to $1,250^{\circ}\text{C}$, $1,450^{\circ}\text{C}$, and $2,300^{\circ}\text{C}$, respectively. At lower temperatures it is preferable to use a base metal combination, such as chromel-alumel, which gives greater accuracy.

In furnaces, the leads of the thermocouple are usually isolated from each other and other parts of the furnace by placing them either in thin alumina sheaths or by threading alumina beads along their length. The thermocouple is ideally placed directly into the furnace cavity close to the object being heated. The external circuitry that measures temperature and, through an associated electrical circuit, controls the power to the heating elements is kept outside the furnace.

A thermocouple is a very accurate means of measuring temperature, but you should always bear in mind that the temperature being measured is that at the thermocouple tip. Unless the thermocouple is in intimate contact with the ceramic parts being heated, they may actually be at a different temperature than that measured by the

TABLE 9.7 Characteristics of Thermocouples

Type	Combination of metals or alloys	Output at 900°C (mV)	Temperature limit $^{\circ}\text{C}$	Applications
T	Copper-constantan	20.9 ^a	400	Mild oxidizing, reducing, vacuum, or inert. Good where moisture is present. Low temperature and cryogenic applications
J	Iron-constantan	21.9 ^a	760	Reducing, vacuum, inert. Limited use in oxidizing at high temperatures. Not recommended for low temperatures
E	Chromel-constantan	68.8	900	Oxidizing or inert. Limited use in vacuum or reducing. Highest emf change per degree
K	Chromel-alumel	37.3	1,250	Clean, oxidizing, and inert. Limited use in vacuum or reducing. Wide temperature range. Most popular calibration
S	Pt-Pt 10%Rh	8.4	1,450	Alternative to Type K. More stable at high temps. Oxidizing or inert. Do not insert into metal tubes. Beware of contamination. High temperature
R	Pt-Pt 13%Rh	9.2	1,450	Same as type S
B	Pt 6%Rh-Pt 30%Rh	4.0	1,700	Oxidizing or inert. Do not insert into metal tubes. Beware of contamination. High temperature. Common use in glass industry
G (W)	W-W 26%Re	12.3	2,300	Vacuum, inert, hydrogen. Beware of embrittlement. Not practical below 750°C . Not for oxidizing atmosphere
C (W5)	W 5%Re-W 26%Re	16.4	2,300	Same as type G. Nonoxidizing atmosphere only
D (W3)	W 3%Re-W 25%Re	15.1	2,300	Same as type G. Nonoxidizing atmosphere only

The higher the output voltage, the simpler is the associated circuitry and/or the more accurate the temperature reading

^aOutput at 400°C

thermocouple. A good illustration of this point is that thermocouples are often used to give substrate temperatures during thin film growth. The thermocouple is frequently attached to be substrate support but is not in direct contact with the substrate itself. In controlled tests, it has been found that the measured thermocouple temperature and the actual surface temperature of the substrate can be off by as much as 100°C or in some cases even more.

9.12.2 Pyrometers

At any temperature above 0 K, all objects emit electromagnetic radiation in accordance with the Stefan-Boltzmann law:

$$E = \sigma T^4 \quad (9.12)$$

where σ is the Stefan-Boltzmann constant, which has a value of $5.6718 \times 10^{-8} \text{ JK}^{-4} \text{ m}^{-2} \text{ s}^{-1}$. The total energy (E) emitted at all wavelengths is proportional to T^4 . It is possible to estimate the temperature of a hot object by its color. In 1557, in his work on Renaissance pottery, Cipriano Piccolpasso described how the furnace operator was able to use color variations to judge furnace temperatures. As the temperature of an object increases, the range of wavelengths that it emits increases and shifts to shorter values. At temperatures above about 500°C there is red coloration that becomes increasingly orange as the temperature increases >1,000°C. At 1,400°C, the object appears bright white. Be careful when looking at hot objects, and remember that an object can still be too hot to handle even if it is not glowing red.

Optical pyrometers allow direct measurement of the temperature of an object. The disappearing filament optical pyrometer works by matching the intensity of radiant energy coming from an incandescent source to the intensity of a calibrated filament when both the source and the filament are viewed through a red filter. When the filament and the source intensities are the same, the image of the filament disappears as it is superimposed on the image of the source. An obvious requirement of this technique is that it can only be used to measure temperatures that produce visible incandescence, above about 750°C.

The advantages of the disappearing filament pyrometer are:

- The distance from the target to the source is not important (it is only necessary to have a clear image to compare with the filament image).
- Various places on a target can be examined for temperature distribution.
- Very high temperatures can be measured.

- The visible image ensures that the instrument is measuring the temperature of the desired portion of the target.
- Reasonable accuracy (at best, $\pm 0.2^\circ\text{C}$ at 775°C reduced to $\pm 1^\circ\text{C}$ at $1,225^\circ\text{C}$).

The disadvantages are:

- The instrument either must be sighted under blackbody conditions or the reading corrected for emittance.
- Absorption by dust, windows, flame, and other optical interference can produce errors.
- The disappearing filament optical pyrometer is slow and manual. However, other pyrometers such as the photoelectric optical pyrometer can be automated.

9.12.3 Pyrometric Cones

Pyrometric cones are small triangular ceramic prisms that, when set at a slight angle (known as self-supporting cones), bend over in an arc so that the tip reaches the level of the base at a particular temperature if heated at a particular rate, as shown in Figure 9.13. The bending of the cones is caused by the formation of a viscous liquid within the cone body, so that the cone bends as a result of viscous flow. The endpoint temperature when the tip of the cone touches the supporting plate is calibrated for each cone composition when heated at a standard rate. Values of endpoint temperatures for Orton cones (the U.S. name) are listed in Table 9.8 for the higher temperatures; the series actually runs from Cone 022 at 600°C, through cone 06 at 999°C to Cone 42 at the top of the scale. Because pyrometric cones are sensitive to both time and temperature, the actual temperatures associated with each

FIGURE 9.13. Orton cones: self-supporting type. The cones shown are 6 cm tall in their initial state.

TABLE 9.8 End Points of Orton Pyrometric Cones

Cone #	Endpoint (°C)	Cone #	Endpoint (°C)
12	1,337	31	1,679
13	1,349	31 ¹ / ₂	1,699
14	1,398	32	1,717
15	1,430	32 ¹ / ₂	1,730
16	1,491	33	1,741
17	1,512	34	1,759
18	1,522	35	1,784
19	1,541	36	1,796
20	1,564	37	1,830
23	1,590	38	1,850
26	1,605	39	1,865
27	1,627	40	1,885
28	1,638	41	1,970
29	1,645	42	2,015
30	1,654		

cone can vary, but this is also one of the reasons why they are very useful for ceramic processing. Sintering, for example, depends on both time and temperature.

9.13 SAFETY

The safety issues associated with the use of furnaces can be divided into three categories.

- *High-temperature hazards.* Working with high temperatures is the obvious safety hazard when using furnaces. Protective goggles or safety glasses should be used in all situations. As the temperature increases, the intensity of the emitted light rises, and the maximum shifts to shorter frequencies. This is apparent to an observer. At 1,000°C, the color of a furnace enclosure is a pleasing red. At 1,600°C, it is a brilliant, painful white; and goggles or glasses with green lenses should be used. Handling objects that have come from a furnace should be done using specially designed tongs and furnace tools; and hands should be protected with insulating gloves. Even if an object is not glowing red, it can still be at a temperature of >500°C.
- *Electrical hazards.* Electrical dangers should never be underestimated. All electrical equipment operating at mains voltages can be lethal. A current >100 mA (ac or dc) would almost invariably be fatal if passed through the body. Most electrical accidents are caused by worn-out equipment or faulty wiring, both of which can be avoided. All potentials in excess of a few tens of volts must be properly insulated and physically isolated before maintenance. A typical laboratory box furnace uses 240 or 208 V single phase at 50 or

60 Hz to generate 10 kW of power. This requires a current of about 40 A. All electrical equipment not fully insulated must be properly earthed in the interests of safety.

- *Chemical hazards.* Some of the chemicals used in ceramic processing are toxic. One important example is lead and its oxides, which are widely used in the production of certain types of glasses and pigments. Care should be taken to read safety data sheets that accompany any chemicals and take the necessary preventative action. Other safety issues can arise from unwanted reactions that occur within the furnace. Carbon monoxide (CO) is a deadly gas that can form from a reaction between trapped moisture (e.g., in the furnace insulation) and carbon. The source of carbon may be the graphite used in some furnaces for heating elements or in graphite-felt insulation. Problems can be avoided by ensuring that the furnace is kept dry. Domestic CO alarms can be installed in the laboratory area as an added precaution.

The importance of nitrogen ceramics, such as silicon nitride, means that furnaces are often operated using nitrogen gas. At high temperatures, it is possible to form cyanide complexes such as cyanogen (CN) and hydrogen cyanide (HCN). In graphite furnaces, the following reaction can occur

Above temperatures of 2,200°C, the CN concentration exceeds the lethal concentration guidelines. Fortunately, the gas is unstable and can be destroyed by passing it through an oxidizing flame. Hydrogen cyanide can form in graphite furnaces that contain mixtures of H₂/N₂ (called forming gas).

Forming gas is used in metal sintering furnaces and in some metallization processes to avoid oxidation of the metal. HCN can also form when water vapor, graphite, and nitrogen react.

It is essential to maintain dry conditions in these furnaces, as the reaction is thermodynamically favored at all temperatures. In cases that can involve the build-up of deadly gases, it is essential that the laboratory is well ventilated, and the discharge is vented away from the immediate work area.

CHAPTER SUMMARY

Furnaces are ubiquitous in all aspects of ceramics research, development, and production. High temperatures may be obtained through harnessing the heat generated by combustion reactions, but more often it is resistance heating that is used. Ceramic materials, most notably SiC, are widely used as resistive elements in electrically heated furnaces. Ceramic materials are also used to provide thermal insulation in all types of furnace. These materials are known by the collective term refractories because of their stability at high temperatures and their resistance to corrosive environments. Refractories are a major sector of the ceramics industry, with the largest consumers being the iron and steel companies.

PEOPLE AND HISTORY

Joule, James Prescott (1818–1889) was an English physicist born in Salford near Manchester. He showed that heat is produced by motion and thus helped end the caloric theory.

Kirchhoff, Gustav Robert (1824–1887) was born in Prussia (now part of Russia) and died in Berlin. He introduced the term black-body radiation, the laws of electrical networks, and much more.

Morse, E.F. patented the disappearing filament optical pyrometer in 1899. He lived in Trumansburg, NY, up Cayuga Lake from Ithaca. Samuel Morse was connected but apparently not closely. The invention was built on Edison's 1879 idea.

Norton, Frederick Harwood formed the Ceramics Division at MIT and wrote two classic texts on ceramics.

Orton Jr., Edward J. established the first ceramic engineering program at The Ohio State University (OSU) in 1894 and founded the American Ceramic Society in 1899. He created the Standard Pyrometric Cone Company, to make pyrometric cones, in a basement at OSU; these cones became the standards for monitoring firings and are known as Orton cones (<http://www.ortonceramic.com/>). Similar cones may have been used in China in the Northern Song Period (before 1127 CE), although Josiah Wedgwood used pyrometric beads instead. Outside the United States similar cones may be called Seger cones (after Hermann Seger) or the Staffordshire Cones in the United Kingdom.

Seebeck, Thomas Johann (1770–1831) was born in Estonia. He showed that a current flowed when you join two metals that are at different temperatures (the thermoelectric effect). This led to the invention of the thermocouple.

EXERCISES

- Table 9.4 lists materials used as furnace elements for ceramic processing. Find the costs of each type of element.
- Small electrically heated box furnaces are probably the most widely used furnaces in university ceramics laboratories. What are the characteristics of these furnaces that make them so useful?
- Why is a muffle furnace so named?
- (a) Explain briefly why the standard molar enthalpy of combustion for ethane (C_2H_6) is greater than that for methane. (b) Which is more useful as a fuel—methane or methanol? Briefly explain how you arrived at your answer. (c) Calculate the standard molar enthalpy of combustion of methane at 1,000 K.
- Explain why most refractory materials such as firebricks and fiber board insulation have high volume fractions of porosity.
- Is a high thermal expansion coefficient an advantageous or deleterious property of a refractory brick? Explain briefly the reasoning behind your answer.
- Briefly explain how a thermocouple works.
- The most widely used thermocouples for ceramic processing are types K, R, and C. Explain what alloys are used for each type and under what conditions each would be most appropriate.
- Pyrometric cones are widely used in industry for temperature measurement, yet they are rarely used in university ceramics laboratories. Why does this discrepancy exist?
- Pyrex and Vycor are glasses that are used as crucibles. Why is the maximum useful temperature of Pyrex less than half that of Vycor?
- Using Table 1.2, estimate the temperature of the furnace in Figure 9.1.

- 9.12 What type of thermocouple would be the most appropriate to measure the temperature of the furnace shown in Figure 9.1
- 9.13 You want a furnace that can operate at temperatures up to 1,800°C in air. Is molybdenum (Mo) a good choice for an electrical heating element for such a furnace? If not, what type of heating element would you recommend?
- 9.14 Name two crucible materials suitable for operation at 1,600°C in air. Compare your two choices in terms of cost.
- 9.15 How much does an optical pyrometer cost?
- 9.16 Suggest a physical reason for the changes in b in Table 9.2 and justify your answer.
- 9.17 Describe the current market for microwave ovens in ceramic processing, including furnaces combining microwave with other forms of heating. Document your sources and carefully critique them.
- 9.18 Some ceramic cups are not microwave-safe. Explain why this is so.
- 9.19 How do the space shuttle tiles achieve their insulation properties? Suggest how this property might be improved.
- 9.20 Using the library and other sources, discuss the use of a micro-electro-mechanical systems (MEMS) furnace.

WWW

<http://intarch.ac.uk/journal/issue1/peacey/toc.html> introduces furnaces in archeology. It gives the definition of a muffle from *Searle, A B 1930 The Encyclopedia of the Ceramic Industries, London* as *A chamber, case or box of refractory material, which is built in a furnace, and used to heat articles out of direct contact with flames or other products of combustion. It serves a purpose similar to a saggar, but being larger, is more suitable for some purposes.* The muffle is actually the enclosed section that protects the material from the combustion products of the furnace. The heat is conducted to the sample through the walls of the muffle. www.claygirl.com/glossary.html gives other definitions for the potter

Characterizing Structure, Defects, and Chemistry

CHAPTER PREVIEW

In this chapter we discuss techniques that can produce useful information about the structure, chemistry, and bonding in ceramics. There are so many characterization methods available that books are written on each one. Because we can't cover all the details or even all the techniques, we give examples and aim at making you aware of the key ones and their applications.

We can group the techniques into six categories.

- Imaging using visible (or nearly visible) light
- Imaging using electrons (mainly scanning and transmission electron microscopy—SEM and TEM, respectively)
- Imaging using sensing [atomic-force microscopy (AFM) and other scanned probes that “sense” a force or field]
- Scattering and diffraction (using X-rays, neutrons, α -particles, electrons)
- Spectroscopy and spectrometry [using X-rays for energy- and wavelength-dispersive spectrometry (EDS and WDS, respectively) Raman, IR, etc.]
- Thermal analysis [measuring changes (e.g., enthalpy) as a function of temperature]

Most of the techniques we describe can be used to study other classes of materials, but our examples are all related to ceramics.

The suitability of a characterization technique depends on the type of information we hope to obtain. It may also be dictated by the size of our sample, what part of the sample is important, and whether we can destroy the sample. Some of the limitations are:

- Reflection techniques examine only surfaces.
- Techniques using electrons require the sample to be in a vacuum.
- Techniques using transmitted electrons generally require the sample to be thin.
- For nanomaterials we need high resolution.

Two questions that we always ask are:

- How much material is required for the analysis?
- Is it destructive or nondestructive?

For example, TEM is invariably destructive, but you need a very small amount of material for the analysis.

10.1 CHARACTERIZING CERAMICS

In characterizing a ceramic—whether it is a single crystal, polycrystalline, or a glass—there are certain types of information that we are interested in obtaining.

- Chemistry. What is the composition, how does it vary within the sample, etc.?
- Structure. Is the ceramic crystalline or glass or a mixture of the two? What polymorph is present?
- Microstructure. Is the structure the same throughout the sample? Polycrystalline ceramics can't be uniform. Even glass can be structurally inhomogeneous.
- Surface. Whether the sample is crystalline or not, the nature of the surface is often particularly important. If the sample is crystalline, then surface orientation may

TABLE 10.1 Summary of Tools for Ceramics Using Chemical Characteristics

<i>Chemical characteristic</i>	<i>Characterization tool</i>
Composition	X-ray diffraction (XRD) X-ray fluorescence (XRF) Neutron activation analysis (NAA) Mass spectrometry (Mass Spec)

be critical. Even the surface of a glass is different chemically and structurally from the bulk. In nanomaterials, the surface is the most important feature because most of the atoms are there.

- Defects. In crystals we often want to determine dislocation density. In both crystals and glass we may be interested in the nature, concentration, and distribution of point defects. Techniques for characterizing defects are dealt with mainly in their respective chapters.

What we want to know determines which technique we should use. In the following sections our approach is to illustrate the type of information that can be obtained. Most of these methods are applicable not only to ceramics but to other classes of material. However, there are certain special features associated with ceramics.

- Techniques using electrons can be complicated because many ceramics charge locally, thus deflecting an electron beam.
- We are often interested in what happens while ceramics are being processed. Because of the environment or the high temperatures involved, such in situ studies may not be possible with the desired resolution.
- Ceramics are often multicomponent systems; knowing the average composition may not be too useful.

Therefore we may need local compositional analysis on a scale that may be in the nanometer range.

- Many ceramics contain light elements (e.g., B, C, N, O), which can be difficult to quantify.
- If we are interested in interfaces, for example, the interface may facet over short (<100 nm) distances; and it may contain steps that are only nanometers high. In studying such interfaces, it is essential that both grains be observed, so techniques requiring the sample to be broken along the interface would not be ideal (though they may be necessary).

Tables 10.1 and 10.2 lists some of the techniques that you might consider to obtain specific information about your material. In most cases, the use of a particular technique depends in part on its availability, and often a combination of techniques is necessary to get the complete picture.

10.2 IMAGING USING VISIBLE-LIGHT, INFRARED, AND ULTRAVIOLET MICROSCOPY

Light interacts with the specimen in many ways; we then study the resulting image contrast. Contrast is produced by reflection, absorption, refraction, polarization, fluorescence, or diffraction. This contrast can be modified by

physically changing the optical components and illumination mode of the microscope. The final image can also be processed, now mainly using computer techniques.

Visible-light microscopy (VLM) is used routinely for all ceramics. VLM is often referred to as optical microscopy, but essentially all microscopy is optical. The magnification of a VLM can range from $10 \times$ (a magnifying glass) to $50 \text{ k} \times$ using a liquid between the specimen and the lens. Modern VLMs are equipped with digital cameras (video or still) and feed straight into the computer. Ceramics are often transparent, especially (but not necessarily) if they are glass, so we can then use reflected or transmitted light. The sample can be viewed supported on a table or inverted. The inverted microscope has some advantages; in particular, you can attach contacts to, indent into, or support liquids on the free surface. You also have more flexibility with the lighting.

The lateral resolution using VLM is about 250 nm, and the depth of field has a similar value. Because of the poor depth of field of the VLM, we often examine polished surfaces (as in metallography). Vertical resolution can be $<1 \text{ nm}$ using interference contrast, and this is bettered only by the scanned probe techniques.

VLM is usually available in every laboratory. Although a conventional VLM may cost only \$2,000, the best metallographic microscopes can cost $> \$100,000$. There are numerous imaging methods used in VLM, so we list only a few here.

Dark-field. The image is formed using only scattered light (if there is no specimen present, then the image is dark). It is widely used in mineralogy, where multiphase materials are common.

Polarized light. Polarized VLM distinguishes between isotropic and anisotropic materials and provides information on

FIGURE 10.1. Slightly misoriented grains in a laser element imaged using polarized visible light microscopy (VLM). The crystal is yttrium orthovanadate with 0.27% Nd.

absorption color and boundaries between minerals of differing refractive indices. The technique provides local information on the structure and composition of materials, as shown in Figure 10.1, which is an image of a neodymium-doped yttrium orthovanadate laser crystal. Individual grains, separated by low-angle grain boundaries, are clearly revealed by polarized VLM.

Nomarski (differential interference contrast). The idea here is that we use interference. Contrast is generated by phase differences between two rays (a sample ray and a reference ray). In the Nomarski microscope, the two rays are created after the light has passed through the sample, where path differences occur because of regions having different refractive indices. The ray is split by a prism (called a Wollaston prism); and after passing through a polarizing filter the rays are recombined using a second prism at the image plane. By using a rotating stage, the image contrast can be varied. Using this technique it is possible to create very attractive images because of the enhanced contrast. Nomarski microscopes are more expensive than conventional VLMs because of the cost of the Wollaston prisms.

NSOM (near-field scanning optical microscopy, also known as SNOM). This is a broad and growing topic. The idea is that the resolution in VLM is limited by λ . If the light source is a fiber with an aperture in the end and we detect the reflected/scattered light with the same fiber, then the spatial resolution is determined by the diameter of the fiber. The limitation is that because the aperture diameter is smaller than λ (Figure 10.2) the emerging wave is evanescent, so the signal strength is small. The use of a

laser provides the necessary intensity and defines λ . The usefulness of the technique relies on the ceramics sample having suitable features to scatter the light.

NSOM PARAMETERS	
Aperture size	25–100 nm
Tip/sample gap	5–50 nm

FIGURE 10.2. End of the fiber and the sample, seen by near-field scanning optical microscopy (NSOM).

The technique can be used for other wavelengths and other signals (e.g., Raman). The latter technique is still being developed.

Infrared (IR) and Ultraviolet (UV) microscopy. Because semiconductors are transparent to IR radiation, defects in these materials can be examined with IR microscopy. A detector sensitive to IR is required. With IR and UV light, a converter or detector is also required. An advantage of UV microscopy is that because the wavelength of UV light is smaller than visible light the resolution of these microscopes is higher than VLMs. UV microscopy is widely used in the biological sciences to study subcellular structures. Using intense vacuum UV sources (available at national laboratories), it is possible to obtain results on, for example, electronic states.

10.3 IMAGING USING X-RAYS AND CT SCANS

X-ray topography can be used to obtain images of individual lattice defects in single crystals. This technique has been widely used to study crystal growth, in particular of silicon. It can be used in:

- Reflection (Berg-Barrett method)
- Transmission (Lang method or Borrmann method)

In either method, it is the intensity variation within the diffraction spot that is recorded. It is not usually the defects themselves that are imaged but, rather, the strain fields around them. These strains cause variations in plane spacing from their equilibrium value, thereby modifying the X-ray scattering process. Figure 10.3 shows a Lang topographic image of dislocations in KDP, or potassium dihydrogen phosphate (KH_2PO_4). KDP has a relatively large electro-optic effect and can be grown as large strain-free crystals. X-ray topography has several advantages for characterizing defects in single crystals. It is nondestructive, does not require ultra-thin samples (as we do in TEM), and can be used to observe very low dislocation densities (limit in TEM $>10^4 \text{ m/m}^2$).

Computed tomography (CT) is used to determine inhomogeneities arising from local differences in density. It is applicable to a range of ceramics and minerals and is particularly useful for identifying defects in single crystals. The sample is placed on an automated stage that rotates as a series of X-ray images (radiographs) are captured (much like a medical CT scan except that details as small as a few tens of microns can be resolved even in dense samples). A computer then processes the X-ray images and creates a three-dimensional (3D) reconstruction of the sample. Areas of lower density, such as cracks and voids, appear as darker contrast against a lighter background. Figure 10.4 shows density variations in the core of an Nd-doped YVO_4 sample.

FIGURE 10.3. X-ray topography image showing dislocations in potassium dihydrogen phosphate (KDP) imaged using a 022 reflection.

FIGURE 10.4. High-resolution X-ray computed tomography images from the top and side of the same sample.

10.4 IMAGING IN THE SEM

The basic layout of the SEM is shown in Figure 10.5. The SEM can have two imaging detectors: one for secondary electrons (SEs) and one for higher-energy backscattered electrons (BSEs). The SEM typically has a resolution in secondary-electron (SE) mode of 0.7 nm (at 25 kV) and 2.5 nm in BSE mode at 5 kV. In addition to the excellent spatial resolution, the other great advantage of the SEM is that it has a much greater depth of field than the VLM (the depth of field is several millimeters), so the images appear more three-dimensional. The physical reason for this is that the electron beam is very narrow.

The SEs are low-energy electrons, so they are very sensitive to surface topology. Figure 10.6 shows an example of an SE image, illustrating the excellent depth of field. BSEs are higher-energy electrons and are sensitive to the atomic number of the scattering atom. Hence, the intensity of the BSE signal depends on a combination of the average atomic number and density of the ceramic. As the kilovoltage is reduced, the scattering volume becomes more localized close to the surface of the sample. (The

FIGURE 10.5. Schematic of an SEM showing examples of pressures used.

FIGURE 10.6. Secondary electron (SE) image shows steps on an alumina surface.

FIGURE 10.7. Backscattered electron (BSE) microscopy shows different contrast from different materials in an MgO/In₂O₃ reaction couple.

BSE electrons penetrate farther into the sample and have farther to come out after being scattered.) Hence, the BSE image can give excellent mass-discrimination even at low voltages. In Figure 10.7 the three regions correspond to three different layers in a reaction couple. The MgO substrate is darkest, In₂O₃ is lightest, and the spinel, MgIn₂O₄, is intermediate. The very bright regions are Pt nanoparticles.

Charging in the SEM is usually avoided by coating the specimen (e.g., with a 1-nm layer of Pt). Working at lower accelerating voltages can also reduce charging effects, but then you compromise on the resolution; electron lenses work better at higher resolutions. In low-voltage SEM imaging, you are trying to balance the electrons emitted as the specimen is irradiated, with the charge building up on the specimen. Another way to avoid applying a conductive coating is to use an environmental or low-vacuum SEM. Then, the charging of the specimen is essential, grounded by the gas in the chamber. Variations in the SEM are summarized in Table 10.3.

Environmental SEMs allow operation at pressures of several Torr (0.1–20 Torr) in the sample chamber and at temperatures >1,000°C. In addition to being able to examine insulators, it is also possible to follow dynamic processes such as drying of cement and crystallization.

10.5 IMAGING IN THE TEM

Figure 10.8 shows a state-of-the-art TEM with a field emission source. The key requirement for using TEM is that we require the sample to be very thin (usually ≤200 nm), so the technique is destructive and specimen preparation can be time consuming. The benefits, however, are significant. Because of the large range of signals generated by the incident electron beam (Figure 10.9), a TEM allows full characterization of a sample at high resolution. The conventional imaging modes in a TEM

TABLE 10.3 Comparison Summary of Signals Used in SEM

Signal	Energy	Source	Use
Secondary electrons	~5 eV	Loosely bound electrons scattered from surface	Main signal for image formation
Backscattered electrons	Energies up to incident beam energy	Beam electrons scattered back after collision	Atomic number contrast, channeling patterns, magnetic contrast
Characteristic X-rays	Discrete values for each element	Interband transitions usually involving K and L	Chemical analysis
Light (cathodoluminescence)	UV, visible, IR	Interband transitions between higher energy levels	Imaging dislocations in semiconductors

FIGURE 10.8. A TEM with key features labeled.

are bright-field (BF) and dark-field (DF) imaging. In BF imaging, the image is formed using only the direct beam. An aperture (the objective aperture) is used to exclude all the diffracted electrons from contributing to the image. In DF imaging, the image is formed from one of the elastically scattered beams, and the objective aperture blocks the direct beam and all the other scattered electrons. The BF image in Figure 10.10a shows a thick particle of NiO sitting on a thin film of Al₂O₃; the different gray levels in the films correspond to different thicknesses in the Al₂O₃ film. The DF image in Figure 10.10b shows the same region after reacting the two oxides at high temperature;

FIGURE 10.9. Signals produced in a TEM.

by using a reflection that is excited only by the spinel product, we can see exactly where the spinel has formed.

The resolution of a TEM is determined by the energy of the electrons (controlled by the accelerating voltage), the thickness of the specimen (we want to avoid multiple scattering within the sample), the distance between the sample and the objective lens, and the inherent quality of the lens (defined by its spherical aberration coefficient). Figure 10.11, an image of SrTiO₃, shows variations in the oxygen occupancy. In 2012, the best high-resolution TEM has a resolution of 0.05nm. For nanotechnology, high-resolution (HR) TEM is an essential tool. An example is its use in studying

crystals of KI grown in a boron nitride nanotube, as shown in Figure 10.12.

RESOLUTION

The higher the resolution the smaller the features we can resolve.

10.6 SCANNING-PROBE MICROSCOPY

The topic of scanned probe microscopy includes several techniques that grew out of the development of scanning tunneling microscopy (STM) (which shared the Nobel Prize in 1986). The basic principle is that the tip of the probe determines the resolution of the image, as shown in Figure 10.13. STM has been used to study the atomic

FIGURE 10.10. Bright-field (A) and dark-field (B) microscopy (using a spinel reflection) of a particle of NiO on a film of Al₂O₃ before and after reaction.

FIGURE 10.11. High-resolution (HR) TEM image of the structure of SrTiO₃.

structure of ceramic surfaces. Figure 10.14 shows the reconstructed (110) surface of TiO₂. In addition to STM, there are now several other types of scanned probe microscopy. The most widely used is atomic-force microscopy (AFM), illustrated in Figure 10.15. AFM is extensively used to study the surfaces of nonconducting oxides. AFM images at low and high magnification, respectively, are shown in Figure 10.16. The lines are straight single steps (0.4 nm high) on the surface of

FIGURE 10.12. HRTEM image of a BN nanotube partly loaded with a crystal of KI.

FIGURE 10.13. Tip-sample interaction seen by scanning tunneling microscopy (STM). The tip does not make physical contact with the sample.

(111) spinel; the high-magnification image shows that the origins of the steps are a pair of dislocations emerging at the surface. A nano-scale indenter can be attached to the AFM, making it into an indenter with integrated imaging. Table 10.4 summarizes the common operating modes of the AFM.

AFM AND STM 'IMAGE' ATOMS
Both AFM and STM provide atomic resolution, meaning we can resolve individual atoms.

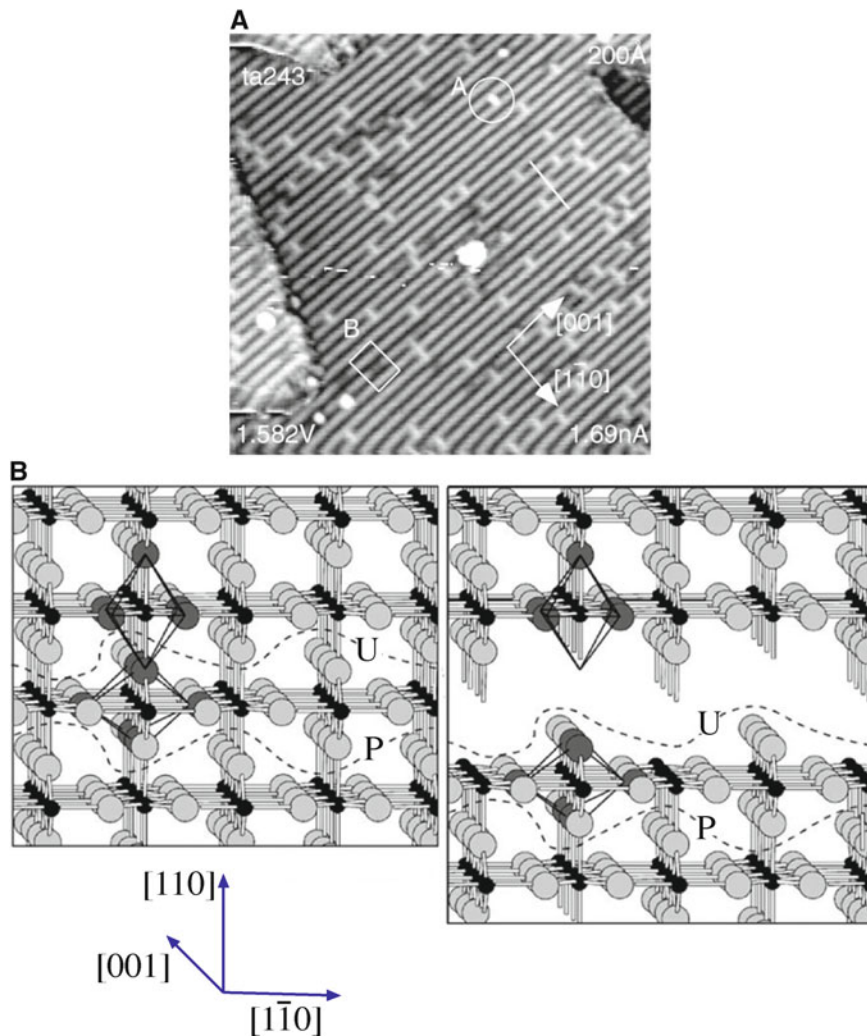

FIGURE 10.14. STM image of the (110) surface of TiO_2 . The features labeled “A” have been assigned as oxygen vacancies; the features labeled “B” have not been identified. The model shows how such a surface can be formed. The dashed lines indicate where the ‘break’ can occur. Large spheres are the O anions.

FIGURE 10.15. Tip–sample interaction shown by atomic-force microscopy (AFM) using a cantilever system.

10.7 SCATTERING AND DIFFRACTION TECHNIQUES

The fundamental idea is that we scatter particles or waves from the constituent atoms in the sample. If the waves interfere constructively, we have diffraction, which

implies that the sample is at least partly crystalline. If the sample is not crystalline, we may still learn about the distribution of the atoms from the radial distribution function (RDF). The process of scattering generally implies particles; diffraction generally suggests Bragg diffraction or constructive interference of waves.

We can summarize some techniques in diffraction and scattering (of photons, electrons, neutrons, for example).

Photon scattering	Raman and Fourier transform infrared (FTIR) are well known techniques for the chemist and increasingly important in ceramics
Electron diffraction	Selected-area diffraction (SAD) in the TEM Convergent-beam electron diffraction (CBED) in the TEM Electron-beam backscattering diffraction (EBSD) in the SEM Reflection high-energy electron diffraction (RHEED) in UHV for surfaces
Ion scattering	Rutherford backscattering spectrometry (RBS)

(continued)

X-ray diffraction	Powder diffraction for statistical determination of lattice spacings Laue back-reflection for orienting single crystals
Neutron scattering	Small-angle scattering in a range of environments

TABLE 10.4 Modes of Operating the Atomic-Force Microscope

Mode of operation	Force of interaction
Contact mode	Strong (repulsive); constant force or constant distance
Noncontact mode	Weak (attractive); vibrating probe
Intermittent contact mode	Strong (repulsive); vibrating probe
Lateral force mode	Frictional forces exert a torque on the scanning cantilever
Magnetic force	Magnetic field of the surface is imaged
Thermal scanning	Variation in thermal conductivity is imaged

Electrons interact most strongly with the sample, so for transmission the specimen must be thin and in a vacuum. Neutrons are at the other extreme but can be used only in dedicated (usually national) facilities because they require radioactive sources.

We use diffraction in the TEM to study the crystallography of the interfaces and characterize other crystal defects. Bragg made the first direct determination of a crystal structure using X-ray diffraction (XRD). XRD is still generally the most accurate method for characterizing crystal symmetry, provided the sample is large enough and can be isolated. However, XRD does not provide a high spatial resolution because the beam diameter is typically 1 mm, although with a rotating anode generator it may be 0.1 mm; and with a synchrotron $\leq 1 \mu\text{m}$ is possible.

10.8 PHOTON SCATTERING

Electromagnetic spectroscopy involves the interaction of electromagnetic waves and matter. We can use all regions of the electromagnetic spectrum, and each gives specific information about a material. Table 10.5 provides a summary, and succeeding sections deal with each of the methods in a little more detail with specific application to ceramics. Once again, to really understand each of the methods you need to read a specialist text.

10.9 RAMAN AND IR SPECTROSCOPY

Raman and IR spectroscopy both involve the scattering of light. In IR spectroscopy, the light is polychromatic and couples to vibrational modes in the solid through dipole moments, which are associated with the vibration. These vibrational modes cause a dip in the transmission spectra or a peak in the absorption spectra. The IR range is 0.78–1,000 μm ($12,820\text{--}10 \text{ cm}^{-1}$). The region where most fundamental vibrational modes occur, which is the most useful for materials characterization, is 2.5–25 μm ($4,000\text{--}400 \text{ cm}^{-1}$). This is sometimes called the mid-IR region. The light source is a heated ceramic (usually a conducting ceramic or a wire heater coated with ceramic) that emits a range of frequencies.

- Spectroscopy: the art of using a spectroscope
- Spectrometry: the act of using a spectroscope

An important variant is the FTIR spectrometer. The main advantages of FTIR are that it is much quicker because it measures all the frequencies simultaneously, and it is more sensitive than dispersive IR spectrometers.

TABLE 10.5 Electromagnetic Spectroscopy

Energy							
E [eV] ($\times 96,485$ from J/mol)	10^{-7}	10^{-5}	10^{-2}	10^{-1}	10^1	10^{-3}	$>10^3$

FIGURE 10.17. Arrangement of mirrors and ray paths in Fourier transform infrared (FTIR) microscopy.

Cryo-cooled HgCdTe detectors are used for weak signals or high resolution.

The key component of an FTIR is the interferometer, which can be understood by considering the Michelson interferometer shown in Figure 10.17. A parallel beam

directed from the source is split at B_s so 50% of the light is transmitted and reflected back by mirror M_F , and the rest is reflected at B_s and then again at M_M . The beams recombine at B_s . The recombined beam shows constructive or destructive interference depending on the difference in the path lengths B_s to M_F and B_s to M_M . As M_M is moved smoothly toward or away from B_s the detector sees a signal altering in intensity. If the recombined beam from B_s is passed through a sample before reaching the detector, sample absorptions show up as gaps in the frequency distribution. The complex intensity distribution received by the detector is Fourier transformed by a computer to produce an absorption spectrum.

Infrared spectra are output in the form of plots of intensity (percent transmittance, %T, or absorbance (A) versus either energy (in joules), frequency (in hertz), wavelength (in micrometers), or wavenumber (per centimeter)). The use of wavenumber is preferred, but some of the standard reference sources of IR spectra use wavelength. FTIR can be used to determine the oxygen content in silicon. The Si–O stretching band occurs at $1,105\text{ cm}^{-1}$, and from the peak intensity the oxygen concentration can be determined using ASTM standard F 121. The FTIR absorption spectra in Figure 10.18 are from $\text{Li}_{0.1}\text{Mn}_2\text{O}_4$ after heating for 8 h at 250°C and 18 h at 300°C . These FTIR readily distinguishes them from the binary oxide MnO_2 .

In Raman spectroscopy, the light is nearly monochromatic and is usually in the visible range. The light source is a laser (e.g., a 50 mW 785 nm diode laser). Raman spectroscopy has become a routine tool for exploring the structure and chemical properties of materials. It can provide more information than IR spectroscopy. There are three types of signal in a typical Raman experiment, as illustrated in Figure 10.19.

FIGURE 10.18. FTIR absorption spectra from $\text{Li}_x\text{Mn}_2\text{O}_4$ insertion electrodes after different heat treatments.

FIGURE 10.20. Example of Raman spectra from a TiO_2 film heated to different temperatures. *R* rutile, *A* anatase.

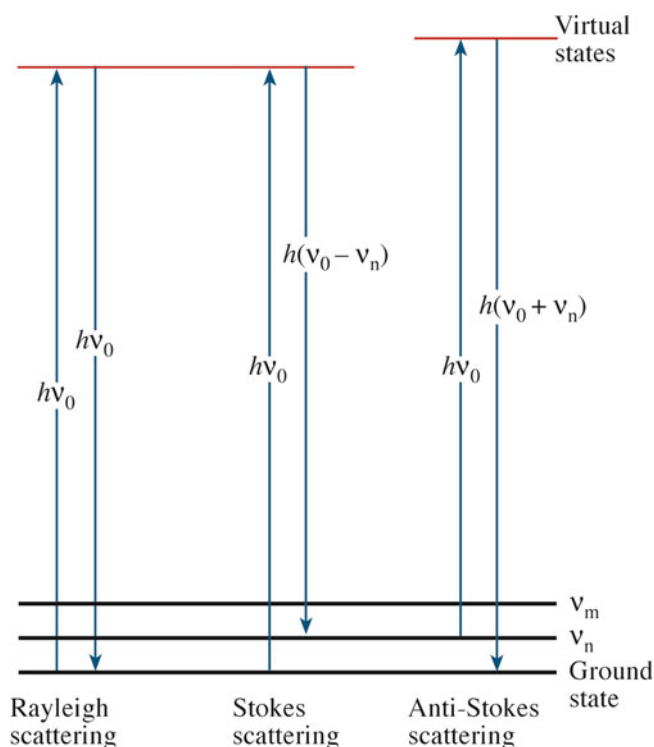

FIGURE 10.19. Transitions occurring in Raman spectroscopy.

The scattering process can be anti-Stokes, Rayleigh, or Stokes. We are then interested in measuring the intensity and the Raman shift.

In *Rayleigh scattering*, a molecule is excited by the incident photon to a virtual energy level. This energy level is caused by distortion of the electron distribution of a covalent bond. The molecule returns to the vibrational ground state by emitting the same energy, E_0 ($E_0 = h\nu_0$). Rayleigh scattering is an elastic process.

Vibrational excitations can be created that cause a decrease in the frequency (i.e., in energy) of the scattered light; or they can be annihilated, which causes an increase. The decrease in frequency is called *Stokes scattering*, whereas the increase is *anti-Stokes scattering*. Stokes scattering is the normal Raman effect, and Raman spectroscopy generally uses Stokes radiation.

Figure 10.20 shows a typical Raman spectrum. It is a plot of scattered light intensity as a function of frequency shift (Raman shift, per centimeter) in which the shift is calculated relative to the laser line frequency that is assigned as zero. The material is TiO_2 films prepared by the sol-gel technique that have been annealed at temperatures between 400°C and 800°C . The features in the spectra only correspond to anatase until the film reaches 800°C . At this temperature, a mixed anatase-rutile phase is seen; the pure rutile phase is obtained only at 900°C .

There are increasing applications for Raman spectroscopy. One application is its use in the identification of different pigments in the characterization of historical artifacts. Table 10.6 lists blue pigments used on or before about 1850 that have been identified by Raman spectroscopy.

Variations in Raman spectroscopy include the following:

Laser Raman Microprobe: Allows information to be collected from small samples via the use of a VLM, which allows the region to be selected from which the Raman spectrum is obtained.

Surface-Enhanced Raman Scattering (SERS): For examining surfaces, oxidation, catalysis, and thin films.

Residual Stress Measurement: Scattering depends on local stress, which can be probed in regions as small as $0.7\ \mu\text{m}$ in diameter by Raman spectroscopy.

TABLE 10.6 Blue Pigments Identified by Raman Spectroscopy

Name	Composition	Band wavenumbers, cm^{-1} and relative intensities	Excitation λ and power	Notes and date
Azurite	Basic copper(II) carbonate $2\text{CuCO}_3 \cdot \text{Cu}(\text{OH})_2$	145w; 180w; 250 m; 284w; 335w; 403vs; 545w; 746w(sh); 767 m; 839 m; 940w; 1,098 m; 1,432 m; 1,459w; 1,580 m; 1623vw	514.5 nm 2 mW	Mineral
Cerulean blue	Cobalt(II) stannate $\text{CoO} \cdot n\text{SnO}_2$	495 m(sh); 532 s; 674vs	514.5 nm 4 mW	1,821
Cobalt blue	Cobalt(II)-doped alumina glass, $\text{CoO} \cdot \text{Al}_2\text{O}_3$	203vs; 512vs	514.5 nm 4 mW	1,775
Egyptian blue	Calcium copper(II) silicate, $\text{CaCuSi}_4\text{O}_{10}$	114 m; 137 m; 200w; 230w; 358 m; 377 m; 430vs; 475 m(sh); 571w; 597vw; 762w; 789w; 992w; 1,012w; 1,040w; 1,086 s	514.5 nm 4 mW	3,000 BC. Also known as cuprorivaite
Lazurite	S3- & S2- in a sodium aluminosilicate matrix $\text{Na}_8[\text{Al}_6\text{Si}_6\text{O}_{24}]\text{Sn}$	258w; 548vs; 822w; 1,096 m	514.5 nm 4 mW	Mineral (<i>Lapis lazuli</i>). Synthetic c.1828 = ultramarine
Posnjakite	Basic copper(II) sulfate $\text{CuSO}_4 \cdot 3\text{Cu}(\text{OH})_2 \cdot \text{H}_2\text{O}$	135vw; 208vw; 278vw; 327vw; 467w; 612w; 983vs; 1092vw; 1139vw	632.8 nm 3 mW	Mineral
Prussian Blue	Iron(III) hexa-cyanoferrate (II) $\text{Fe}_4[\text{Fe}(\text{CN})_6]_3 \cdot 14\text{-}16\text{H}_2\text{O}$	282vw; 538vw; 2,102 m; 2154vs	514.5 nm 2 mW	1,704. Earliest synthetic modern
Smalt	Cobalt(II) silicate $\text{CoO} \cdot n\text{SiO}_2$	462vs; 917 m	514.5 nm 2 mW	~1,500

10.10 NMR SPECTROSCOPY AND SPECTROMETRY

Just as each electron has a spin of $\pm\frac{1}{2}$, each neutron and proton in the nucleus also has a spin, I , of $\frac{1}{2}$. These spins combine, so that each atom has a total nuclear spin of 0, $\frac{1}{2}$, or 1, and an angular momentum P_I , given by

$$P_I = (h/2\pi)\sqrt{I(I+1)} \quad (10.1)$$

The principle of nuclear magnetic resonance (NMR) is that the probing beam is tuned until it couples with the natural angular momentum of the nucleus, which then resonates and emits energy that is measured. The specific quantities depend on the atom that is resonating. The precise value of the energy involved changes slightly if the electron distribution around the resonating nucleus changes, as is the case when the atom is bonded to other atoms; we use NMR to examine this chemical shift. NMR thus probes the bonding of individual atoms. Clearly, for the technique to be applicable the nucleus must have a nonzero total nuclear spin. Fortunately, there are many isotopes, such as ^{29}Si , ^{27}Al , ^{11}B , which are important for ceramics that are suitable. Notice that we have to use ^{29}Si ($I = \frac{1}{2}$) not the more abundant ^{28}Si .

When a nucleus that has a nonzero P_I is subjected to a magnetic field of strength H , the energy levels are split into $2I + 1$ different values. The energy separation of the different levels is

$$\Delta E = \gamma H h / 2\pi \quad (10.2)$$

where γ is called the gyromagnetic ratio of the nucleus. If we then subject this nucleus to electromagnetic radiation and adjust the frequency, ν , to be ν_0 so that it has the same energy ΔE (now $h\nu_0$), the quanta of radiation can be absorbed as transitions between the different nuclear spin energy levels occur. We then detect the NMR absorption in the spectrum as a single peak corresponding to ν_0 , which is broadened because the atoms interact differently depending on their neighbors.

There are two particularly important interactions to consider.

- The dipole interaction is the interaction between adjacent nuclei and the one you are probing (such as an interaction between magnetic dipoles)
- The electrons surrounding the nucleus also move because of the applied magnetic field; this is the chemical shift—electrons determine chemistry

The technique can be carried out using either a continuous wave (CW) or a pulsed spectrometer. Radiofrequency (RF) energy is used to excite the nuclear magnetization. The measurement is the response of the spin system to this excitation. In CW the nuclear magnetization is irradiated at a constant level; the frequency of the irradiation or the magnetic field is then swept across the resonance.

The NMR systems are available in most research universities with a basic system costing from \$200,000 up to more than \$1,000,000, depending mostly on the desired field strength (1–14 T).

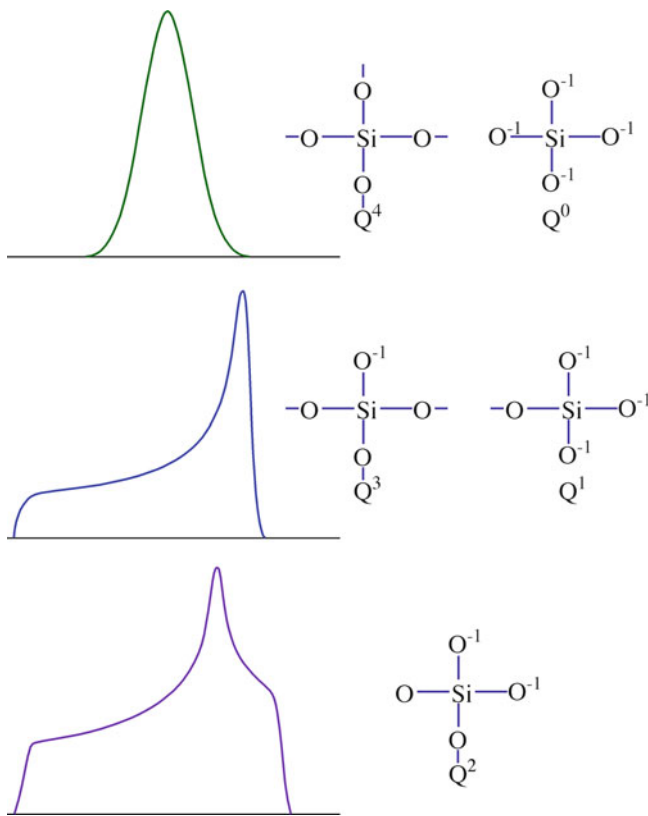

FIGURE 10.21. Nuclear magnetic resonance (NMR) signals from Si.

The following examples are selected to illustrate why NMR is so valuable for the ceramist. The x -axis is in units of parts per million (ppm), which is the chemical shift as a fraction of the applied field or frequency. In Figure 10.21, three NMR powder patterns are shown for silicon in three different chemical environments but where the Si is tetrahedrally coordinated in each case. The differences between the spectra are due to the number of nonbridging oxygen ions that are attached to the Si nucleus being probed: a chemical-shift effect. The value of NMR for studies of silicate glass is obvious.

Figure 10.22 shows a series of NMR spectra from Si–Al glasses. The field used was 11.7 T. The NMR spectra show that not only is the Al present in fourfold, fivefold, and sixfold coordination but there is also undissolved Al_2O_3 present in the glass (denoted “Cor” in the spectra). The chemical shift has been determined using a standard of octahedral ^{27}Al in AlCl_3 solution.

10.11 MÖSSBAUER SPECTROSCOPY AND SPECTROMETRY

Mössbauer spectroscopy is specialized but can be invaluable when it is available. The technique relies on the recoil-free emission and resonant absorption of γ rays by nuclei that are bound in the solid state. (If it’s not in a solid, the

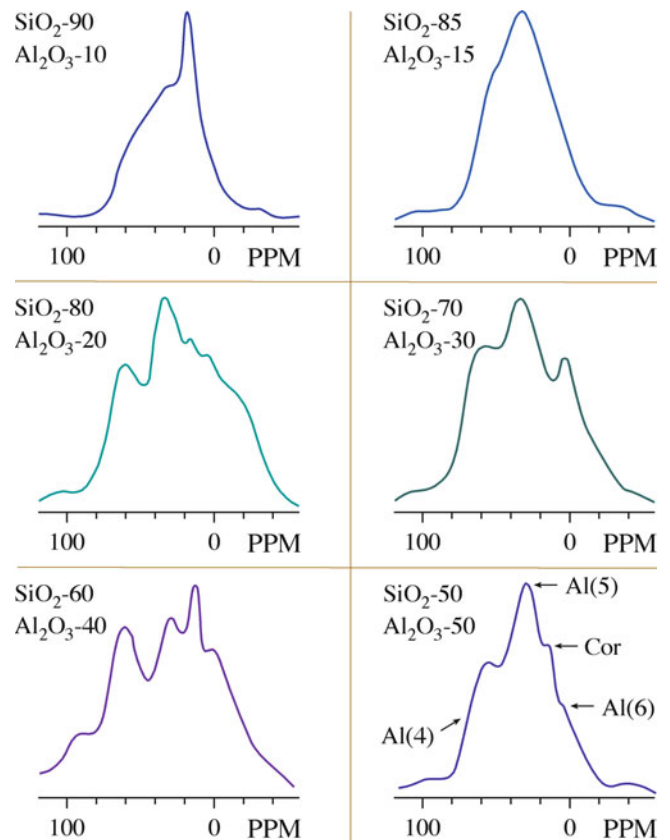

FIGURE 10.22. NMR signals from an Al-Si glass.

free nucleus recoils and you don’t detect a resonance.) To see this resonance, we have to match the energy of the γ -ray emitter to the energy of the absorber (the sample), which means that there are only a small number of elements that can be studied. Two that can be studied are tin and iron. The technique gives information on the bonding and coordination and on the valence (oxidation) state. Because the technique relies on Z , it works for particular isotopes, such as ^{57}Fe for iron with ^{57}Co as the radioactive source of γ rays. (Natural Fe contains ~ 2.19 wt.% ^{57}Fe .)

Figure 10.23 shows a schematic of a Mössbauer spectrometer. The radioactive ^{57}Co source is embedded in a nonmagnetic matrix, which is chosen so as not to affect the sample or to absorb the γ rays too strongly. The system can be calibrated using Fe metal; the six peaks seen in Figure 10.24 correspond to the six transitions expected for ^{57}Fe . The ^{57}Co source has an emission peak at 14.4 keV; the source is moved through a range of velocities using a velocity transducer.

Mössbauer spectra from a series of glasses containing Fe in different oxidation states are shown in Figure 10.25. The differences in the curves are clear; but the analysis needed to determine the percent of Fe in the 2+ state requires extensive calibration of the system. (Notice that peak locations are shown in units of velocity.) The value of the technique is its sensitivity to determining both the oxidation state and the coordination of the Fe ion. Nuclei

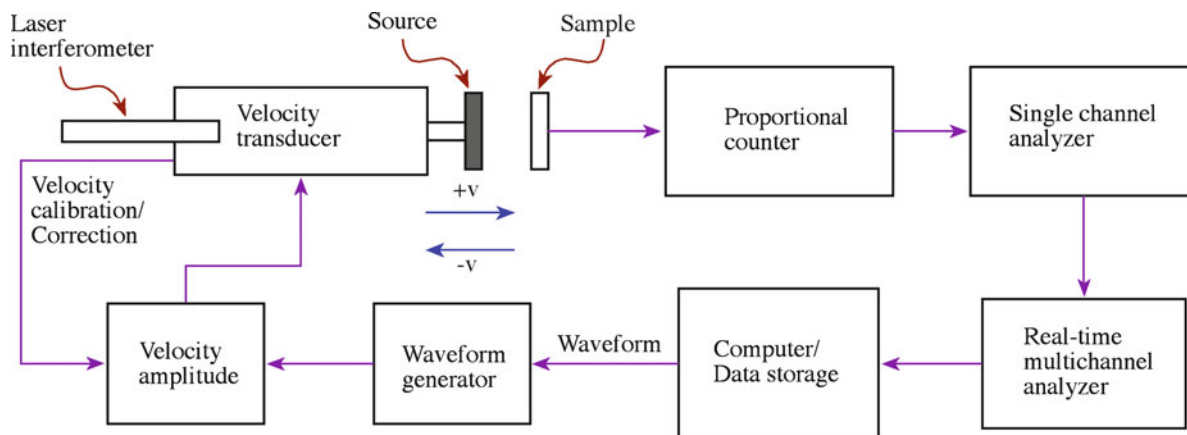

FIGURE 10.23. Setup for Mössbauer spectroscopy.

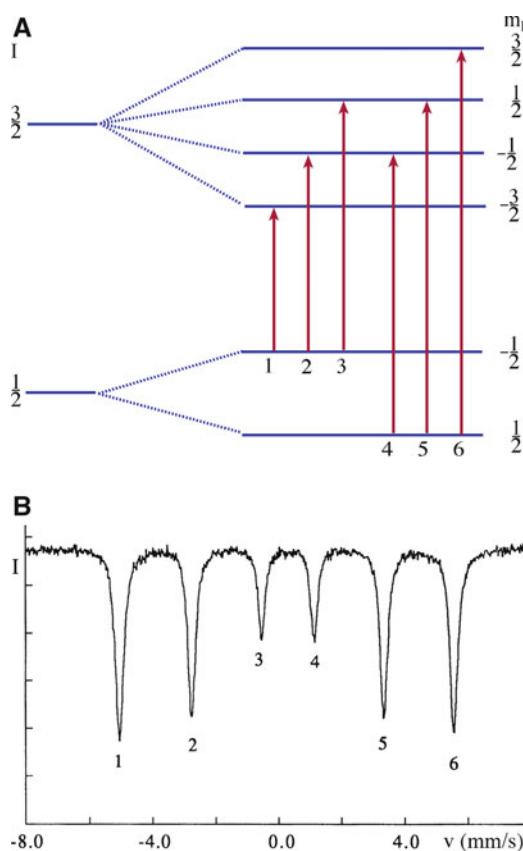

FIGURE 10.24. Transitions in Fe and the resulting Mössbauer spectrum.

in chemical surroundings different from the source do not absorb at the same frequency; this is known as the chemical (or isomer) shift and is the key feature of Mössbauer spectroscopy.

Other isotopes that have been studied are ^{119}Sn (source: metastable ^{119}Sn), ^{121}Sb (source: metastable ^{121}Sb), and ^{151}Eu (source: ^{151}Sm). Table 10.7 lists chemical shifts for tin. It is then quite straightforward to determine the valence state of an unknown tin compound from its Mössbauer spectrum. This type of analysis has been used in studying

FIGURE 10.25. Mössbauer spectra from glasses containing different concentrations of Fe^{2+} .

TABLE 10.7 Chemical Shift of Some ^{119}Sn Compounds

Valence state	Electron configuration	Chemical shift (mm s^{-1})
Sn^{4+}	$5s^05p^0$	0
Sn (4-covalent)	$5(sp^3)$	2.1
Sn^{2+}	$5s^25p^0$	3.7

tin glazes and tin-containing ceramic pigments. It requires quite small amounts of material, typically 50 mg of powder. Bulk materials can also be examined.

10.12 DIFFRACTION IN THE EM

The techniques are:

- Selected area diffraction (SAD) in the TEM
- Convergent beam electron diffraction (CBED) in the TEM
- Electron backscattered diffraction (EBSD) in the SEM

FIGURE 10.26. TEM diffraction patterns obtained using selected-area diffraction (SAD) and convergent-beam electron diffraction (CBED)

Selected-area diffraction involves selecting an area on the sample (actually an image of the area) with an aperture and then looking at the diffracting pattern from that area. The diameter of the area can be as small as 100 nm with a modern machine. In CBED, the diffracting area is selected by focusing the electron beam onto a small area of the sample. The diameter of the area can actually be smaller than the unit cell. Figure 10.26 compares SAD and CBED patterns. From the positions of the spots (in SAD) and the discs (in CBED), we can obtain information about the structure and orientation of our sample. CBED patterns often contain additional, fine structure, which allows determination of symmetry, such as the point group. The value of CBED lies in its ability to provide information on lattice parameters, sample thickness, and local crystallography on a scale of 10 nm or better. We can use the technique to characterize polarity change across antiphase boundaries (APBs) in GaN and AlN, to determine the site occupancy in nickel-titanate spinel and to determine the thickness of a specimen. The latter parameter is used in analyzing the height of steps on surfaces and in quantifying X-ray energy dispersive spectroscopy (XEDS) data.

Diffraction in the SEM can take several forms, but EBSD is now becoming a routine addition to the SEM. The beam penetrates the sample and is backscattered; we can use these electrons to form a BSE image, or we can record the actual diffraction pattern. A schematic of the system is shown in Figure 10.27 together with an example of an EBSD pattern.

FIGURE 10.27. Formation of an electron-beam backscattering diffraction (EBSD) pattern.

determine what atoms they interacted with and where those atoms were located in the sample relative to the surface. RBS uses ions (typically 2 MeV helium ions, $^4\text{He}^+$) as the scattered particle. We can picture the interaction mechanism as being a collision resembling that between two billiard balls: the incoming ion transfers energy (and momentum) to the ion in the sample, it is detected as it recoils, and its energy is determined (Figure 10.28). The data are provided in the form of a plot of backscattering yield versus energy, and a typical spectrum is shown in Figure 10.29. Computer analysis of the spectrum gives us the types of atoms in a sample, their concentration, and their depth. The depth resolution is about 20 nm. RBS has been widely used in studies of ceramic thin films deposited onto ceramic substrates such as BaTiO_3 on MgO.

RBS has poor sensitivity to light elements such as oxygen and nitrogen, which are both important in many ceramics. However, an enhanced oxygen signal can be obtained at an incident energy of 3.045 MeV. RBS is also used to determine

10.13 ION SCATTERING (RBS)

Rutherford backscattering spectrometry again uses ions (a high-energy He beam) to produce the signal but is more akin to electron energy loss spectroscopy (EELS). We analyze the energy of the backscattered ions and thus

10.14 X-RAY DIFFRACTION AND DATABASES

X-ray diffraction is used in several forms depending on the equipment, the sample, and what you want to know. The great advantage of the technique is that a vacuum is not required and that the X-rays can travel through a container before and after interacting with the specimen. For example, the specimen can be heated inside a quartz tube to 1,600°C and examined at temperature. Using a synchrotron, the beam size—and hence the spatial resolution—can be reduced to ~1 μm. A monochromatic beam can be produced such that changes in energy due to absorption can be accurately measured. Table 10.8 lists types of analysis that can be undertaken using X-rays and the specific technique.

One of the most useful sources of information for crystal structure data is the Powder Diffraction File (PDF). The PDF is a collection of single-phase X-ray powder diffraction patterns in the form of tables of interplanar spacings (*d*) and corresponding relative peak intensities. There are more than 80,000 patterns in the PDF. In the early days the patterns were printed as 3 × 5 in. index cards; and even though everything is now on computer, the files are still referred to as “cards.”

Powder XRD this is one of the most widely used techniques to characterize ceramics. The material is in the form of a powder so that the grains will be present in all possible orientations so that all *d* spacings, or θ values, will appear in one pattern. The classical powder pattern was recorded on photographic film. Now the data is

TABLE 10.8 X-ray Diffraction Analysis

Type of analysis	Method	Sample
Crystal geometry	Moving crystal-spot pattern	Single crystal
	Computer positioned diffractometer	Single crystal
	Solution of <i>d</i> -spacing equations	Powder
Arrangement of atoms	Analysis of diffracted intensities	Single crystal
	Refinement of whole pattern	Powder
Symmetry	Moving crystal-spot pattern	Single crystal
	Stationary crystal-spot pattern	Single crystal
Identification of compound	Identification of cell parameters	Single crystal
	Matching of <i>d</i> - <i>l</i> set	Powder
Crystal orientation	Single-crystal back reflection	Large single crystal
	Texture analysis	Powder compact
Size of crystal	Line broadening	Powder
Magnitude of strain	Line shifts	Powder compact
Amount of phase	Quantitative analysis	Powder
Change of state	Special atmosphere chambers	Single crystal or powder
	Direct imaging	Single crystal
Crystal perfection	Line shape analysis	Powder

FIGURE 10.29. RBS data sets obtained using a 2.8-MeV beam of He²⁺ ions with the samples tilted 45°. Each sample has been annealed at 700°C for 2 h followed by 1,020°C for 5 h. The Ni peak shows that the extent of the reaction varies with the surface orientation.

the composition of bulk ceramics and impurity profiles in semiconductors (e.g., As distribution in Si).

RBS DETECTION LIMITS

- 10¹²–10¹⁶ atoms/cm²
- 1–10 at.% for low-*Z* elements
- 0–100 ppm for high-*Z* elements

When the ion beam interacts with the sample, it produces particle-induced X-ray emission (PIXE), which is directly analogous to the production of X-rays in the SEM. PIXE has some special advantages over EDS in the SEM in that the background emission is lower, the depth penetration is large, and the sensitivity is high.

FIGURE 10.30. X-ray diffraction XRD patterns from a mixture of Ca oxide and alumina recorded while heating the sample at different temperatures.

in the form of a plot (known as a diffractogram) of counts or intensity versus scattering angle (2θ) as shown in Figure 10.30. A computer that contains the entire PDF is usually used for peak identification. In many examples you will see in the literature phase identification is the extent to which powder XRD is used. This ability alone makes it a powerful and indispensable tool for the ceramist. In a multiphase material the relative amounts of each phase can be determined from the peak areas.

Powder XRD can be used for estimating the sizes of particles. The Scherrer formula says that

$$\Delta\theta \cdot \Delta x = 2\pi \quad (10.3)$$

where $\Delta\theta$ is the peak width (scattering angle half-width), and Δx is the average particle diameter. The resolution of the diffractometer corresponds to an integral width of 0.32 nm. Notice that the anatase peaks are delta functions at $\Delta\theta = 17.5$ and $\Delta\theta = 33.0$. After correcting for the instrument resolution, the integral widths of the peak are $\Delta\theta = 1.57$ n/m and 1.29 n/m.

Figure 10.31 shows the main components of an X-ray diffractometer. The important features are:

- X-ray source. Often Cu $K\alpha$ $\lambda = 0.154184$ nm because of its high intensity.
- Sample. Usually a powder but can be pressed or sintered. Only a few milligrams are needed.
- Detector. Two main types: proportional detectors use photoelectrons generated in Xe; semiconductor detectors use electron-hole pairs created in p-i-n junctions formed in silicon.

In the $\theta/2\theta$ X-ray diffractometer, the sample and detector rotate relative to the X-ray source; when one moves through θ , the other moves through 2θ . Alternatively, the

FIGURE 10.31. XRD apparatus shows the location of the source, sample, and detector (Siemens D5005).

PDF CARD NUMBERS

21–1272 Anatase
29–1360 Brookite

sample can be held fixed and the detector and source rotated in opposite directions. The conventional XRD geometry is often referred to as the Bragg-Brentano geometry. Several different geometries and modifications are used for studying ceramics.

Thin-film diffractometer. A glancing angle geometry is used with the sample surface at an angle of $5\text{--}10^\circ$ to the X-ray beam. The basic idea is that the penetration depth of the X-rays is reduced so they are analyzing the surface. Longer wavelength X-rays can be used, which also reduces penetration (switch to a Cr $K\alpha$ source $\lambda = 0.229100$ nm). Polycrystalline thin films down to a few tens of nanometers thick can be examined.

Microdiffractometer. Collimators as small as $10\ \mu\text{m}$ are used to produce a small X-ray spot size. The geometry of the detection system is also different from a conventional diffractometer in that it uses an annular detector that allows sampling of the entire cone of diffracted radiation.

Hot-stage XRD. The sample is placed inside a quartz furnace tube that can be heated to temperatures up to $1,600^\circ\text{C}$, often in a range of different atmospheres. The main uses are for studying phase changes and structural transformations as a function of temperature.

Pole figure. Uses a Eulerian goniometer cradle attached to the diffractometer for determination of preferred crystal orientations.

Single-crystal XRD. A single crystal diffractometer allows the orientation of the crystal to be controlled in such a way that every set of planes can be moved into a diffraction condition. The X-rays are usually detected by scintillation. The technique is not as routine as powder XRD, and determination of a crystal structure can take many days or even turn into a thesis.

Laue technique. The diffracted beams produce a pattern consisting of an array of spots. It is used to orient single crystals (with an accuracy of $0.3\text{--}1.0^\circ$) prior to cutting and polishing.

10.15 NEUTRON SCATTERING

The initial obvious statement is that, overall, neutrons interact with matter even less strongly than do X-rays. Table 10.9 summarizes the differences between the two probes. For both neutrons and X-rays, it is not as easy to direct the beam as it is with electrons or ions. In both cases, the experimental method involves measuring the intensity of the scattered beam as a function of scattering angle.

The obvious question is: Why use them when other particles do interact strongly? Neutrons offer distinct advantages over X-rays and other probes. They have a magnetic moment, so they can detect magnetic ordering.

TABLE 10.9 Properties of X-rays and Neutrons

Property	X-ray	Neutron
Wavelength	0.05–0.25 nm	0.01–2.0 nm
Energy	12.4 keV	80 MeV
Velocity	3×10^8 m/s	4×10^3 m/s
Production	X-ray tube Synchrotron	Nuclear reactor Electron linear accelerator pulsed source Proton spallation pulsed source
Detection	Photographic film Proportional counter Scintillation counter	$^{10}\text{BF}_3$ or ^3He proportional counter ^6Li scintillation counter

Because they don't interact strongly, they can be used for obtaining bulk information. A major application is residual stress measurement in materials as a function of depth.

Neutrons have been used to study glasses and show a first sharp diffraction peak at low angles. This implies that there is some ordering in the glass. Intentional patterns of voids in glasses give rise to such peaks. Table 10.10 gives a comparison of the parameters for XRD and neutron diffraction.

Neutrons are produced in several ways, but each requires a reactor. Thus neutron diffraction facilities are generally national facilities. There are seven centers for neutron scattering in the United States and about 30 worldwide. A schematic of a neutron diffractometer is shown in Figure 10.32.

TABLE 10.10 Scattering of X-rays and Neutrons

Dependence	X-ray	Neutron
Nonmagnetic atom	Electrons scatter	Nucleus scatters
θ dependence	Depends on θ through $f(\theta)$	Depends on isotropic scattering length \bar{b}
Variation with Z	$F(0) = Z$	\bar{b} varies with Z
Phase change on scattering	π	Not always π
Isotope dependence	None	\bar{b} depends on isotope
Anomalous dispersion	Near an absorption edge	Near an absorption resonance
Magnetic atom	Nothing extra	Additional scattering (depends on θ)
Absorption coefficient	Absorption large	Absorption usually small

FIGURE 10.32. Schematic of a neutron scattering workstation. The width of the view is 10 s of meters.

10.16 MASS SPECTROMETRY

Mass spectrometry is used to provide qualitative and quantitative chemical analysis. For ceramics we are mainly interested in analyzing solids so a method for ionizing the material is necessary. In spark source mass spectrometry (SSMS) we use a high-voltage spark in a vacuum. The positive ions that are produced are analyzed by the spectrometer based on their mass. For insulating ceramics, the material must be mixed with a conducting powder such as graphite or silver. There are other methods to ionize the sample.

1. Laser ionization MS. Uses a Nd:YAG laser and is ideal for insulators, but it is more qualitative than quantitative because of the absence of standards.
2. Glow discharge ion source. Uses a gas discharge between two electrodes, so the sample must be conductive and formed in the cathode.
3. In secondary ion mass spectroscopy (SIMS) an incident ion beam with energy in the range 4–15 keV, is used to create secondary ions from the sample. SIMS provides high-resolution depth profiles with a detection limit down to 1 ppb.

Scanning ion mass spectroscopy (SIMS) is like SEM but uses ions (usually Ga^+) instead of electrons. Because the ions have more energy, they eject near-surface atoms out of the sample; these atoms are collected and the chemistry of the near-surface area thus determined. By scanning the ion beam we can generate a chemical image of the surface, and by repeating this process (each time ejecting the surface atoms) we can generate a 3D profile of the sample.

10.17 SPECTROMETRY IN THE EM

The chemistry of interfaces can be probed using both XEDS and parallel recording of electron energy-loss spectra (PEELS).

In the earliest studies of solid-state reactions between ceramic oxides, the width of the reaction product produced by bulk diffusion couples was determined by VLM. Using an SEM with a field-emission gun, much more precise EDS profile analysis can be performed and provide chemical analysis at a spatial resolution of ~ 2 nm. Figure 10.33 shows a typical XEDS spectrum: a plot of counts versus X-ray energy. The X-rays are produced as a result of electron transitions within the atoms in the sample. The transitions, and hence the peaks, are characteristic of specific atoms. A doped silicon crystal is used to detect the X-rays, where they cause the formation of electron-hole pairs. New methods for detecting the X-rays are being developed that use the change in temperature caused by the X-ray; they are known as colorimeters.

The electron microprobe or wavelength dispersive spectrometer (WDS) can provide accurate chemical analysis or chemical profile across the interface. The wavelength of the X-rays emitted when the electron beam interacts with the sample is measured. WDS is more accurate than XEDS but is a serial acquisition, so it is slower. Table 10.11 compares WDS and XEDS.

Electron energy-loss spectroscopy counts the number of electrons that have lost particular quantities of energy when the incident electron beam passes through the TEM specimen. The energy loss can occur by interactions with different components of the structure (phonons and plasmons) or by the beam exciting core electrons to a different energy state. The EELS spectrum thus contains

FIGURE 10.33. Example of an XEDS from a sample containing CeO_2 and YSZ in the range up to 20 keV.

TABLE 10.11 Comparison of WDS and XEDS

Factor	WDS	XEDS	Reason for difference
Time for complete spectrum (min.)	25–100	0.5–5.0	(1) Collection efficiency (2) XEDS measures whole spectrum simultaneously
Count rate on one peak (cps/nA)	1,000	10,000	Collection efficiency
Peak/background ratio	1,000	50	XEDS collects spurious X-rays and has high inherent noise
Maximum count rate (cps)	100,000	30,000	XEDS counts all channels simultaneously, and saturates
Resolution, 0.1–10.0 keV (eV)	5–10	150–200	Currently possible
		80–100	Theoretical limit. WDS inferior to XEDS above 25 keV (suitable crystals not available)
Detector limits (weight ppm)	50–1,000	2,000–5,000	WDS used at higher beam current, fewer overlapping peaks XEDS better if current restricted (e.g., to avoid beam damage)
Accuracy of analysis (%)	± 1–2	± 6	Experimentally determined
Light element analysis (min. atomic number)	4	4	Both have ability for light element detection providing windowless or polymer window used
Rough surface work	Bad	Good	XEDS insensitive to source position

FIGURE 10.34. Example of EELS from two commercial ceria powders.

information on the bonding and chemistry of the specimen. As the beam in the TEM can now be as narrow as 0.1 nm, EELS can give highly localized information and is particularly important in ceramics where low-Z elements tend to be particularly important. Figure 10.34 shows part of an EELS spectrum from two commercial ceria abrasives.

The fine structure of the EELS can be compared to the fine structure in X-ray scattering. EELS can be used in purpose-built chambers or, more recently, in the TEM. In the TEM you have the great advantage of knowing where you're getting the spectrum from—it's site-specific. The difficulty with TEM, as usual, is that there are usually two surfaces to consider [you can try reflection (R) EELS—see reflection electron microscopy (REM)]. This technique will be used more in the future with the wider availability of TEM guns with smaller spread in energy. A major application for EELS, which we have only recently begun to use, is direct measurement of bonding.

10.18 ELECTRON SPECTROSCOPY

In the group of techniques known as photoelectron spectroscopy (PES), electrons are emitted from their filled electronic states in the solid by the absorption of single photons. Traditionally, the energy of the photons corresponds to the UV or X-ray wavelengths, and the techniques are known as UPS or XPS. XPS used to be called electron spectroscopy for chemical analysis, or ESCA, and is still the most-used surface-sensitive technique. The difficulty for ceramics is the usual one: as we remove electrons from the sample, the sample becomes charged and attracts the same electrons, which can distort the results. In principle, you could use a flood gun to resupply the electrons, but the challenge is getting the balance right. The techniques do explore the surface region, not just the surface, so the surface effect must be separated from the larger bulk effect. Variations of the

technique include angle-resolved photoemission spectroscopy (ARPES). These techniques are mainly used for quantitative chemical analysis of surfaces by detecting electrons emitted from the surface. They can be differentiated by how the electrons are produced. In Auger electron spectroscopy (AES), the incident species are electrons. In X-ray photoelectron spectroscopy (XPS) and UV photoelectron spectroscopy (UPS), the incident species are photons. In XPS, we illuminate the sample with X-rays and measure the energy of electrons that are then emitted. If the electrons come from regions close to the surface, we can obtain data on the chemistry and bonding close to the surface. The X-rays can be generated in a synchrotron that has both high spatial resolution and high intensity.

Auger electrons are created when an incident electron beam ionizes an atom by removing an inner-shell electron. An electron from a higher energy level fills the hole, and the resulting kinetic energy is transferred to a loosely bound electron, which is detected. These Auger electrons have relatively low kinetic energy and, consequently, a short mean free path. They come from the top 0.5–3 nm of the surface. Their energy is characteristic of the atomic energy levels of the atom from which they came. Therefore, they are sensitive surface probes of chemical composition. Auger electron spectroscopy has been used extensively to study oxide surfaces. The problem is that the surface must be very clean and examined in ultra-high vacuum.

Figure 10.35 shows examples of carbon KVV Auger electron spectra generated from the surface of two carbides, diamond, and graphite. The spectra are in the form of derivative electron yield versus electron energy and show the chemical shift effect and how this could be used for “fingerprinting” an unknown sample. AES is the spectroscopist’s variation of low-energy electron diffraction (LEED) spectroscopy. Its main use is to provide information on the chemistry, rather than bonding, and more specifically to tell if the sample is clean enough for LEED. The beam can be scanned across the sample to produce an image—hence scanning Auger microscopy.

In XPS, electrons with binding energy (E_b) are ejected from core levels by an incident X-ray photon with energy E_0 . The ejected photoelectron has energy ($E_0 - E_b$). Output electron energies are typically >10 eV. XPS, like AES, has excellent depth resolution and is sensitive to the near surface region of a material. The spectrum has the form of intensity versus binding energy.

By sputtering the surface between acquisition of either an AES or XPS spectrum, it is possible to obtain depth profiles. Sputtering must be conducted in the same system as the spectrometer to avoid contamination of the surface. UPS uses UV light to produce electrons. Using these lower photon energies (typically ~ 21 eV), only the valence levels

FIGURE 10.35. Derivative C KVV Auger electron spectra from two carbides, graphite, and diamond.

AUGER NOTATION

KVV refers to the series of electron transitions responsible for the Auger electron. V refers to electrons coming from the valence band of a solid.

are accessible. A major application of UPS is determining the band structure of solid surfaces.

10.19 NEUTRON ACTIVATION ANALYSIS

The basis of neutron activation analysis (NAA) is that if a material containing certain rare earth elements is exposed to a beam of neutrons it can become highly radioactive. If the induced radioactivity is then measured, it is possible to identify the elements that are present in the samples and quantify the amount present. The neutron interacts with the target nucleus and forms an excited nucleus; that is, the neutron loses energy. The excited nucleus then quickly relaxes back to a more stable state by emitting a characteristic γ -ray (this is an n, γ nuclear reaction). The new nucleus may be radioactive, in which case it then begins to decay by emitting additional characteristic γ -rays, but the rate of emission is slower due to the longer half-life of the decaying nucleus. Figure 10.36 gives a schema of the NAA process.

The quick emission of the γ -ray gives the technique PGNAA (prompt γ -ray NAA) and the slower emission gives the more usual technique DGNAA (delayed GNAA—but often just called NAA). Of the three principal types of neutron sources (reactors, accelerators, radioisotope neutron

emitters), nuclear reactors generating neutrons by U fission give particularly high fluxes of neutrons. Thermal neutrons have energies <0.5 eV. If the neutrons are in thermal equilibrium with the moderator of the reactor, they have a mean energy of 25 meV, which means they have a velocity of 2.2 km/s. A 1-MW reactor has a peak flux of thermal neutrons of $\sim 10^{13}$ cm $^{-2}$ /s. Table 10.12 shows how sensitive NAA is for detecting elements in a sample.

An example of an analysis: crush a sample to a fine powder; put 150 mg in a plastic vial and 200 mg in a high-purity quartz capsule. Reference samples of known composition are also prepared. The plastic vial is exposed to 5s of irradiation with a flux of 8×10^{13} neutrons cm $^{-2}$.s $^{-1}$. The γ -rays are then counted for 720 s, which gives a γ -spectrum (PGNAA) for short-lived elements: Al, Ba, Ca, Dy, K, Mn, Na, Ti, V. The samples in quartz are irradiated for 24 h with a flux of 5×10^{13} neutrons cm $^{-2}$.s $^{-1}$. After leaving the sample for 7 days, the γ -rays are counted for 2,000 s. This middle count gives medium half-life elements: As, La, Lu, Ne, Sm, U, Y. After a further 4 weeks, the final count (9,000s) gives a measure of the long half-life elements: Ce, Co, Cr, Cs, Eu, Fe, Hf, Ni, Rb, Ru, Sb, Sc, Sr, Ta, Tb, Th, Zn, Zr. The results are then compared to those from the known material. The accuracy can be better than parts per billion.

Applications have included identifying the origin of archeological ceramics: obsidian can be fingerprinted, the trade patterns of the Olmec civilization can be followed by identifying where the clay originated that they used in their pots, and the source of contamination in semiconductors can be traced at the 1 ppb level.

FIGURE 10.36. Neutron activation analysis (NAA) process.

TABLE 10.12 Sensitivity for Detecting Elements by NAA

Sensitivity (ng)	Elements
0.1	Dy, Eu
0.1–1.0	In, Lu, Mn
1–10	Au, Ho, Ir, Re, Sm, W
10–100	Ag, Ar, As, Br, Cl, Co, Cs, Cu, Er, Ga, Hf, I, La, Sb, Sc, Se, Ta, Tb, Th, Tm, U, V, Yb
100–1,000	Al, Ba, Cd, Ce, Cr, Hg, Kr, Gd, Ge, Mo, Na, Nd, Ni, Os, Pd, Rb, Rh, Ru, Sr, Te, Zn, Zr
1,000–10,000	Bi, Ca, K, Mg, P, Pt, Si, Sn, Ti, Tl, Xe, Y
10,000–100,000	F, Fe, Nb, Ne
1,000,000	Pb, S

10.20 THERMAL ANALYSIS

The term “thermal analysis” actually covers many different techniques that measure a change in a material as a function of temperature. Thermal analysis is particularly useful to characterize decomposition and crystallization during ceramic powder processing. It is then possible to determine optimum calcination temperatures. A list of the main thermal analysis techniques is given in Table 10.13. The two most common are:

- Thermogravimetric analysis (TGA)—measures weight loss during heating
- Differential thermal analysis (DTA)—measures relative changes in the sample’s temperature during heating

These analyses—DTA and TGA—can be performed separately or simultaneously. Figure 10.37 shows examples of DTA and TGA analysis on an initially amorphous CA $_2$

TABLE 10.13 Common Thermoanalytical Techniques

Method	Common abbreviation	Property measured
Thermogravimetry	TG (TGA)	Mass
Differential thermal analysis	DTA	ΔT between sample and reference
Differential scanning calorimetry	DSC	Heat absorbed or evolved by sample
Evolved gas analysis	EGA	Nature and amount of evolved gas species
Thermodilatometry	TD	Dimension
Thermomechanical analysis	TMA	Deformation/nonoscillatory load
Dynamic thermomechanometry	DMA	Deformation/oscillatory load
Thermomagnetometry	TM	Relative magnetic susceptibility

FIGURE 10.37. Differential thermal analysis (DTA) and thermogravimetric analysis (TGA) measurements show the reaction as CA $_2$ crystallizes.

powder as it crystallizes. The TGA plot shows that as temperature is increased the sample loses weight, and by about 600°C the weight loss is complete. The DTA plot shows that the CA₂ crystallization is exothermic.

Thermal analysis techniques are widely used to study ceramic processing. In addition to determining decomposition and crystallization process, it is possible to monitor the burnout of organic binders that are commonly added to

powders prior to shaping and shrinkage during drying. One of the earliest uses for DTA was in studying clay minerals. In montmorillonite, the position of certain cations can have an influence on dehydration behavior. Analysis of DTA curves from samples of montmorillonite containing Li, Na, or K show that the presence of Li stabilizes the water of hydration, and higher temperatures are required for dehydration.

CHAPTER SUMMARY

There are many different techniques for studying ceramics. The choice of which one to use depends on the type of information that we want to obtain and how valuable our material is. TEM is destructive, but so are many other methods if we have to produce a fine powder. Although some of the techniques we described, such as VLM and SEM, are universal, there are many techniques that are available in only a few sites. Those requiring nuclear reactors of very high flux photon beams are usually found at National User Facilities.

A full understanding of a material or a process may require using several complementary techniques. For example, electron diffraction in the TEM combined with FTIR and Raman spectroscopy can unequivocally determine what polymorph of SiO₂ is present in a sample. AES can tell us the composition of the surface of a sample, AFM can give us the surface morphology, and RHEED can give us the surface crystallography.

The technological importance of nanomaterials means that we need high-resolution techniques. It is the need to understand the structure of nanomaterials and processes that occur on the atomic and molecular level that leads to the development of new instrumentation for characterizing materials.

PEOPLE AND HISTORY

Binnig, Gerd (1947–) and *Heinrich Rohrer* (1933–) of the IBM Research Laboratory in Switzerland won the Nobel Prize in Physics in 1986 for their invention of scanning tunneling microscopy (STM).

Mössbauer, Rudolf (1929–) received the Nobel Prize in Physics in 1961 for discovery of the effect.

Raman, Sir Chandrasekhara Venkata (1888–1970), the Indian scientist, discovered the phenomenon in 1928 while studying CCl₄; he was awarded the Nobel Prize in Physics in 1930.

Ruska, Ernst August Friederich was born in Heidelberg in 1906. He did his PhD with Max Knoll (who died in 1969) in Berlin, which led to the first electron microscope in 1931. He died in 1988 having shared the Nobel Prize in 1986, 55 years after the invention!

Rutherford, Ernest (1871–1937), demonstrated ion scattering, which demonstrated the utility of ions for chemical analysis. He won the 1908 Nobel Prize in Chemistry.

Stokes, George Gabriel (1819–1903) was Professor of Mathematics in Cambridge when Rayleigh was an undergraduate.

Strutt, John William (Lord Rayleigh); don't confuse the spelling with Raleigh (Sir Walter) (1842–1919). He won the Nobel Prize in Physics in 1904 for discovering Ar; succeeded James Clark Maxwell as the Cavendish Professor in Cambridge.

Synge, Edward Hutchinson (1890–1957), from Dublin, Ireland, proposed NSOM (Philos. Mag. papers 1928–1932) 50 years before it was discovered. (John Lighton Synge, a mathematician and theoretical physicist, was his younger brother).

EXERCISES

- 10.1 Construct a chart summarizing the principal scattering techniques used to characterize the structure, chemistry, and bonding in ceramics, emphasizing which of the three features is most directly addressed by each technique.
- 10.2 In Figure 10.1 the grains boundaries are described as low-angle grain boundaries. Could this information be obtained directly from VLM? If not, what other methods might have been used to make this determination?

- 10.3 In Figure 10.6, why does the image have a 3D appearance?
- 10.4 In Figure 10.7, the image distinguishes the regions with different chemistry directly and with high spatial resolution. Explain the physical process underlying this observation.
- 10.5 During the processing of ceramics containing crystalline quartz, a phase transformation occurs on cooling/heating between the α form and the β form. The phase transformation produces an appreciable change in volume that can lead to cracking. How would you determine from a fragment of a ceramic plate whether you had the α or β phase present in the sample?
- 10.6 How would you determine whether water vapor has chemisorbed onto the surface of particles of silica gel?
- 10.7 If we are examining steps of atomic dimensions in Figure 10.14, redraw the schematic to scale and explain the factors that determine vertical and lateral resolution in AFM.
- 10.8 Compare the value of NMR and Mössbauer analysis for ceramic materials.
- 10.9 Referring to Figure 10.33, explain why we see multiple peaks for Y and Zn occur at different energies, and why we see Cu.
- 10.10 Examine the DTA/TGA plots in Figure 10.37. What can you say about the curves as the temperature is increased from 25°C to 1,200°C?
- 10.11 Summarize the pros and cons for imaging dislocations in sapphire using X-rays and electrons. (Make at least five points for and against each being quantitative, when possible).
- 10.12 What is the best resolution possible today using SEM? Why do we sometimes use lower voltages even if it means lower resolution?
- 10.13 Why or when does SEM give a greater depth of field than VLM?
- 10.14 Which imaging mode (using BSEs or SEs) would you use to image: (1) steps on sapphire, (2) Pt particles on ceria, (3) the structure of a glass/crystal mixture, and (4) the texture of polycrystalline zirconia?
- 10.15 If the different gray levels in Figure 10.10A correspond to different thicknesses, what can you deduce about the geometry of this sample?
- 10.16 Show how the contrast in Figure 10.11 matches the structure of the crystal; label two independent directions and two edge-on planes.
- 10.17 Do the spacings of the fringes in Figure 10.12 match those expected for these materials?
- 10.18 The caption in Figure 10.16 says the steps are 0.4 nm high. Explain and justify this statement and assess its accuracy.
- 10.19 Mössbauer spectroscopy of rare earth elements such as Nd, Eu, and Dy attracts considerable attention from physicists. Should ceramists be equally interested in these elements and why is Mössbauer spectroscopy a good technique to study them? Briefly explain your answer.
- 10.20 NMR is a favorite technique of chemists but not as popular with ceramists. Discuss the veracity of this state. Should it and will it change?

Part IV

Defects

Point Defects, Charge, and Diffusion

CHAPTER PREVIEW

Point defects are particularly important in ceramics because of the role they can play in determining the properties of a material. The entire semiconductor industry is possible because of minute concentrations of point defects that are added to Si: the dopants determine if the Si is n-type, p-type or semi-insulating; they determine the electrical properties. Solid-oxide fuel cells work because of the large concentrations of oxygen vacancies present: the vacancies provide fast ion conduction pathways. Cubic zirconia (CZ) is cubic because of the presence of point defects that stabilize the cubic structure.

We address three principal questions in this chapter and leave the properties associated with point defects to later chapters, where we discuss conduction, light, and color, for example.

- What point defects are possible?
- How many point defects are present?
- How easily can they move?

To know what defects are possible in a crystal, we need to know its structure. Point defects also exist in glass, but there is the extra problem of how to define what is being “defective.” (What is the perfect structure of the glass?) To estimate the concentration of point defects, we should know (1) what types of defect are present; (2) how they form; which, in turn, determines (3) how many of each kind there are. Answering the third question tells us many of the properties of the materials containing these defects. In some cases we want them to move quickly, in other cases we actually would rather they were immobile. To really understand this subject thoroughly, you need good knowledge of thermodynamics and kinetics. These topics are so large that there are many texts devoted entirely to them.

11.1 ARE DEFECTS IN CERAMICS DIFFERENT?

Until now we have only considered the ideal structures of crystals, where each atom or ion is on a regular site in the crystal. Real crystals contain a variety of imperfections or defects. In crystalline ceramics and glasses, the structure and chemistry of the material is determined by the kinetics of defect movement. For example, the kinetics of the glass-to-crystal transformation are slow if the temperature is low (typically $<1,000^{\circ}\text{C}$) because the transformation occurs by atoms moving—in ceramics, this usually occurs by point defects moving. If point defects move too slowly, the structure with the lowest energy (the equilibrium structure) may never

actually be achieved. How fast they move is determined by their structure.

The really special feature of ceramics is that they can contain charged defects; metals cannot. There are some definite differences when we compare defects in ceramics to similar ones in face-centered cubic (fcc) metal crystals such as Cu.

- The concentration of impurities in ceramics is usually much greater than that of intrinsic defects.
- Dislocations are usually much less important for deformation mechanisms than they are in metals.
- Surfaces and interfaces are even more important for ceramics.
- Pores and voids are often very much more important for ceramics.

THE OTHER DEFECT CHAPTERS

Dislocations—Chapter 12

Surfaces—Chapter 13

Grain boundaries—Chapter 14

Phase boundaries, particles, & voids—Chapter 15

The importance of pores and voids is a good illustration of how time changes our view of materials. In the past, processing ceramics often meant trying to remove pores and voids during sintering because they weakened the final material. Although they still generally do so, we are now also very interested in highly porous ceramics because such materials can have a very large surface area, which may be critical in their application as catalysts, catalyst supports, or filters.

In this chapter, we concentrate on point defects; but remember that they do relate to all other defects in ceramics, and their importance is that they determine many important properties.

11.2 TYPES OF POINT DEFECTS

Defects are often classified in terms of dimensionality. This is known as the defect hierarchy. The classifications are given in Table 11.1. Despite this table, remember that all of these defects are three-dimensional. We first summarize the different types of point defect that can occur in crystalline materials. To give an idea of the importance of point defects, we consider some specific examples.

Vacancies: If an atom is not present on the site that it should occupy in a perfect crystal, then a vacancy is located at that site. A *Schottky defect* is a set of vacancies created by removing one atom for each atom in the chemical formula. Thus, in a stoichiometric crystal such as MgO, we get a pair of vacancies, one on the Mg sublattice and one on the O sublattice, as shown in Figure 11.1. In spinel, a Schottky defect consists of seven vacancies.

Interstitials: If an atom is present on any site that would be unoccupied in a perfect crystal, then that atom is an interstitial. A *Frenkel defect* is a vacancy + interstitial pair formed by removing an atom from its site in the crystal structure and putting it into an interstice, as illustrated in Figure 11.2. Frenkel defects formed in iodine-containing AgBr are essential to the photographic process.

Misplaced atoms: If an atom is present on a crystal site that should be occupied by a different atom, that atom is a misplaced atom and may be called an antisite defect. Antisite defects usually form in covalent ceramics such as AlN and SiC but can also occur in complex oxides that have several different types of cation (e.g., spinels, garnets). (We don't expect to see cations on anion sites and vice versa.)

FIGURE 11.1. Schottky defect drawn in two dimensions.

FIGURE 11.2. Frenkel defect drawn in two dimensions.

Associated centers: When two point defects interact so they can be considered a single defect, they are called an associated center or, if more atoms are involved, a defect cluster or a defect complex. Exposing a material to ionizing radiation such as X-rays and γ -rays can create large numbers of defect clusters.

Solute (substitutional) atoms: In Cu alloys, we can add up to 30 at.% Zn before the structure is changed. All the Zn atoms sit on Cu sites, so they substitute for the Cu; and the crystal is said to be a solid solution of Zn in Cu. The effect

TABLE 11.1 Defect Hierarchy

Dimension	Name	Example
Zero	Point defect	Vacancy
One	Line defect	Dislocation
Two	Planar defect	Grain boundary
Three	Volume defect	Pore

is to add electrons to the d band of the alloy, and it is this change in the electronic structure that determines the solubility limit. We can similarly substitute Ge in Si, but the solubility is limited due to the difference in atomic size. In GaAs, we can replace the Ga atom by Al on the group III sublattice, giving a complete solid solution, $\text{Ga}_x\text{As}_{1-x}\text{As}$, with x running from 0 to 1. GaAs and AlAs have the same structure and similar lattice parameters. We can replace As by P on the group V sublattice to give another continuous solid solution. This type of substitution occurs in both covalent and ionic ceramics and also in metals.

Electronic defects: Electrons and holes can both exist in ceramics. They may be associated with particular ions, in which case they are simply *charged point defects*. This leads to the topic of color centers, which color alkali halide crystals, amethyst, and diamond, among others.

NOTATION SUMMARY FOR S_p^c

S: Species
P: Position in the crystal
c: Charge relative to the perfect crystal
Charge notation:
 Negative: dash, ' $'$
 Positive: point, \cdot
 Neutral: x

We use the Kröger-Vink notation to identify these different point defects, which is summarized in Table 11.2. This notation is completely general in that it can apply to any crystalline compound or even to pure crystals. In this notation, structural elements are denoted as S_p^c .

We make use of the Kröger-Vink notation in many sections in this chapter. We can write simple equations to describe the formation of point defects or their interactions. For example, if we remove a molecule, NaCl, from a crystal of rock salt, we form a vacancy on both anion and cation sublattices. Thus, we have to have a method for distinguishing these defects. The Kröger-Vink notation for the reaction we have just described is:

We need such a notation because of one of the most special features about ceramics—the charge. Other notations are sometimes used, but the Kröger-Vink is the most widely accepted. (You may see variations in this notation, so be careful when translating from one text to another.) The topic of point defects shouldn't be completely new to you. Some of the fields where you may have met point defects before are listed in Table 11.3.

TABLE 11.2 Kröger-Vink Notation for the Binary MX

Defect	Notation	Comments
Vacancy	V_x	V is also the chemical symbol for the element vanadium. If there is a possibility for confusion, such as expressing a vacancy on a vanadium site, then use "Va" for the vacancy
Interstitial	M_i and X_i	No "site"
Antisite atom	M_x and X_M	Usually in covalent solids
Associated defect	(M_iX_M)	Larger associations called "clusters"
Solute	S_x	Impurity substitution
Electron and hole	e' and h	
Schottky	(V_MV_X)	Special associated defects
Frenkel	(V_MM_i)	

11.3 WHAT IS SPECIAL FOR CERAMICS?

Point defects are special in ceramics when they involve either charge (ionic materials) or dangling bonds (covalent materials).

- Vacancies, interstitials, and substitutional defects can all be charged. The special point defect in ceramics is the charged vacancy. Frenkel and Schottky defects are overall neutral.

TABLE 11.3 Examples of Commonly Encountered Point Defects in Materials

Type of point defect	Application	Comments
Solute atoms	Doping silicon for ICs	Concentration of dopant atoms very small, ~0.0001%, can cause 100 times increase in conductivity
Solute atoms	Solid solution strengthening of metals	A 50Cu–50Ni alloy has twice the tensile strength of pure copper
Interstitial	Carburizing of iron and steel	Surface hardening by heating metal in a hydrocarbon gas
Vacancies	Kirkendall effect	Failure mechanism in Au–Al bonds (e.g., Au wire bonds on Al metallizations in ICs)
Vacancies and interstitials	Cold working of metals	At $T < 0.4 T_m$ solid-state diffusion is slow

- Association of defects is particularly important for ceramics because Coulombic interactions are both strong and long range.
- Electronic structure is increasingly important. In the past, the electronic structure was important only because the materials have a large band gap. Ionic materials are insulators. This is no longer the case—many old “insulators” (e.g., SiC) are now also wide-band-gap semiconductors!
- Nonstoichiometry is important because the concentration of point defects can be very large. In ionic materials, point defects are usually charged, and they are often numerous.

Some special rules for ceramics:

- The number of sites is constant. This is the same as in metals, but we often have very different sites available in ceramics.
- The total charge is still zero.
- Intrinsic defect concentrations are often very much lower than impurity concentrations.

11.4 WHAT TYPES OF DEFECT FORM?

Crystals with open lattice structures tend to favor Frenkel defects. These crystals have structures with low coordination numbers and large interstitial sites; for example, the würtzite structure has a coordination number (CN) of four. If there is a large difference in size between the cations and anions, Frenkel defects are usually formed by displacing the smaller ion. In Al_2O_3 , for example, the cation is smaller, and we would expect to form cation Frenkel defects. However, anion Frenkel defects form in UO_2 , CeO_2 , and ThO_2 , all of which have large cations. In contrast, we would expect to find Schottky defects in crystals with high CNs such as MgO .

Vacancies may be present on different sites for the same type of ion. For example, NiFe_2O_4 is an inverse spinel ($\text{Fe}(\text{NiFe})\text{O}_4$); Fe^{3+} ions sit in both tetrahedral and octahedral sites. Thus, we can have Fe^{3+} vacancies on the tetrahedral or octahedral sites, but these two types of vacancy are not the same. You can imagine how complex the situation becomes for more complex crystals. We usually ignore such complications because they are too difficult to handle, but be aware that we are making this simplification.

11.5 EQUILIBRIUM DEFECT CONCENTRATIONS

We need to know how many point defects are present in thermal equilibrium. One of the simplest point defects that we can imagine to occur in a crystal is a vacancy. In a

binary compound (e.g., MgO), where only vacancies exist, we must have an equal number of each type of vacancy to maintain the stoichiometric formula.

At a given temperature there is an equilibrium concentration of point defects in a crystal. The implication of this statement is that a crystal containing point defects must have a lower free energy, G , than a corresponding crystal without any defects. From Chapter 3 we know that the change in free energy accompanying a process, such as the creation of vacancies, is given by

$$\Delta G = \Delta E - T\Delta S \quad (11.1)$$

We can use ΔH or ΔE in equation 11.1. ΔH would refer specifically to the enthalpy to form a point defect. ΔE is the change in the internal energy on forming the defect. The internal energy of the disordered crystal is the energy of the perfect crystal plus nE .

E is strongly affected by the nearest neighbors and the interatomic bonding. It costs energy to produce point defects; we have to break bonds. The internal energy increases when the number of point defects increases. At the same time, the entropy (randomness of the structure) increases, and the product $T\Delta S$ also increases. The change in entropy is complex and consists of terms due to the vibration of the atoms around the defects and the arrangement of defects in the crystal. This configurational entropy relies on statistics (how many) and mechanics (how it is moving); the subject is statistical mechanics. So even though it requires energy to create vacancies, overall G may decrease because of the entropy contribution. The challenge is that to know ΔG we have to know S , the entropy.

Figure 11.3 is a plot of $n\Delta E$, ΔS , and ΔG . From this plot you can see that introducing vacancies lowers the free energy of the crystal until an equilibrium concentration is reached; adding too many vacancies increases G again. At higher temperatures, the equilibrium number of vacancies increases. The implications are important. In pure crystals, we expect to find point defects at all temperatures above 0 K.

FIGURE 11.3. How the free energy decreases to a minimum as the number of vacancies increases.

Point defects are always present in bulk ceramics.

Because these defects are in thermodynamic equilibrium, annealing or other thermal treatments cannot remove them.

Usually the concentration of point defects is controlled by impurities.

Dopant-induced defects are also in thermodynamic equilibrium, so the overall equilibrium is controlled by the dopants.

Schottky defects do not change the composition of the material. The concentration of Schottky defects in a crystal is deduced using standard statistical mechanics, which appears in most thermodynamics

textbooks (because it is such a clear application of basic thermodynamics). For most ceramics, we just need the result from the calculation. Notice that charge is not mentioned at all, and the derivation assumes a pure, simple binary compound, such as MgO or NiAl.

ΔE_s is the energy to form a Schottky defect; and k , the Boltzmann constant, is in $J^\circ C$. If ΔE_s is given in J/mol , then the number of Schottky defects in a unit volume is the same with R replacing k .

We review how n_s is derived for a stoichiometric crystal AB. The derivation shows the importance of disorder. In this discussion, we've separated the equations from the text and mainly comment on the logic of the derivation.

If n_s is the number of Schottky defects per cm^3 in the crystal at T K, then we have n_s vacant cation sites and n_s vacant anion sites. In addition, in a crystal of this type there are N possible cation sites and N possible anion sites per cm^3 . We can determine the entropy change, ΔS , in a system of occupied and unoccupied sites using the Boltzmann equation

SCHOTTKY DEFECTS THE CALCULATION

First define the number of Schottky defects

$$n_s \approx N \exp(-\Delta E_s/2kT) \quad (\text{Box 11.1})$$

The units of ΔE_s are thus $J/defect$. Then determine entropy using Probability Theory.

$$S = k \ln W \quad (\text{Box 11.2})$$

$$W = N! / [(N - n)! n!] \quad (\text{Box 11.3})$$

$$W_A = N! / [(N - n_s)! n_s!] \quad (\text{Box 11.4})$$

$$W_B = N! / [(N - n_s)! n_s!] \quad (\text{Box 11.5})$$

$$W_A = W_B \quad (\text{Box 11.6})$$

$$W_T = W_A W_B \quad (\text{Box 11.7})$$

$$\Delta S = k \ln W_T = k \ln \{N! / [(N - n_s)! n_s!] \}^2 \quad (\text{Box 11.8})$$

$$\Delta S = 2k \ln \{N! / [(N - n_s)! n_s!] \} \quad (\text{Box 11.9})$$

Next use math

$$\ln N! \approx N \ln N - N \quad (\text{Box 11.10})$$

$$\Delta S = 2k \{N \ln N - (N - n_s) \ln(N - n_s) - n_s \ln n_s\} \quad (\text{Box 11.11})$$

Finally do the substitutions

$$\Delta G = n_s \Delta E_s - 2kT \{N \ln N - (N - n_s) \ln(N - n_s) - n_s \ln n_s\} \quad (\text{Box 11.12})$$

$$(\partial \Delta G / \partial n_s)_{T,P} = 0 \quad (\text{Box 11.13})$$

$$\Delta E_s = 2kT \ln[(N - n_s)/n_s] \quad (\text{Box 11.14})$$

$$n_s = (N - n_s) \exp(-\Delta E_s/2kT) \quad (\text{Box 11.15})$$

$$n_s \approx N \exp(-\Delta E_s/2kT) \quad (\text{Box 11.16})$$

(equation Box 11.2). (Note that we are neglecting thermal entropy effects.) W is the number of ways of distributing n defects over N sites at random.

The number of ways we can distribute the n_s cation vacancies over the available sites in the crystal is given in equation Box 11.4, and we can write a similar expression for the anion vacancies, as shown in equation Box 11.5.

Because AB is a stoichiometric compound, we can write equation Box 11.6. The total number of ways, W_T , of distributing these defects is given by the product of W_A and W_B , so we have equation Box 11.7. Therefore, the change in entropy caused by introducing Schottky defects is given by equation Box 11.8, which we can rewrite as equation Box 11.9.

Now we use a standard trick for large N : Stirling's approximation (equation Box 11.10) eliminates the factorials, which leaves us with an expression for the entropy change associated with the formation of Schottky defects (equation Box 11.11).

Substituting equation Box 11.11 into equation 11.1 gives the overall change in Gibbs free energy for forming n_s pairs (equation Box 11.12). At equilibrium, the free energy change is a minimum with

respect to the number of defects and is given by equation Box 11.13. We can thus differentiate equation Box 11.12 and set the result equal to zero. Thus, after a little rearrangement, we arrive at Box equation Box 11.14. In terms of the number of defects we write equation Box 11.15. The final step is another approximation: N is usually very much greater than n_s , so we arrive at equation Box 11.16 (i.e., equation Box 11.1).

We give some experimental values for the enthalpy of formation of Schottky defects in Table 11.4.

We can use these numbers to calculate equilibrium defect concentrations as we have for NaCl in Table 11.5. The population of point defects is very low, but it is clear from equation 11.2 that vacancies are stable in the crystal at any temperature above absolute zero. Because energies for point defect formation in stoichiometric oxides such as MgO and CaO are so high, the concentration of intrinsic defects is going to be very much less than impurity concentrations (usually ~100 ppm or greater). Even close to the melting temperature we find that only one or two sites in one billion are vacant due to intrinsic effects.

To give you an idea of what these numbers mean, calculate the equilibrium number of vacancies that would be in a single crystal of MgO the size of the Earth ($r_{\text{Earth}} \sim 6,400$ km) at room temperature; it's still a pretty small number.

Intrinsic vacancies are much more numerous in metals. For example, in a 1 cm^3 crystal of aluminum at room temperature, there are about nine billion vacancies. In a crystal of silicon in equilibrium at room temperature, there are only about 1×10^{-18} intrinsic vacancies per cm^3 . This is considerably less than typical concentrations of extrinsic point defects (dopants) in silicon—about 0.0001%—another fortunate fact.

Vacancies are important for dislocation motion at high temperatures: the dislocations then move by climb—they absorb vacancies, which are more numerous at higher

temperatures. (The vacancies also move more easily at elevated temperatures).

Frenkel defects, like Schottky defects, also involve vacancies in the crystal structure. In this case, though, the vacancies exist on only one sublattice, and the atom that should occupy the vacant positions is placed in an interstitial site in the crystal. The interstitial is a very special defect: it can exist on one or more nonequivalent sites, which are not lattice sites. Thus, the Frenkel defect is not unique either.

The calculation of the number of Frenkel defects (n_f) in a crystal proceeds along lines that are similar to those for Schottky defects, where we consider the number of ways of distributing N vacancies over N^* available interstitial positions.

The values for ΔE_f are usually quoted in J/mol, and we therefore use the following equation.

$$n_f \approx (N N^*)^{1/2} \exp(-\Delta E_f / 2 RT) \quad (11.2)$$

Experimental values of the energy of formation of Frenkel defects in some oxide compounds are given in Table 11.6.

The actual type of defect found in the crystal depend on the energy of formation. There may be either more Frenkel defects or more Schottky defects, depending on which has the smaller energy of formation. As we have already mentioned, Frenkel defects are more likely to be important in crystals with open structures that can accommodate the interstitials without much lattice distortion.

Frenkel defects are the key to the photographic process. Photographic film contains crystals (called grains) of AgBr or I-doped AgBr. These are dispersed in gelatin, often along with various other chemicals known as sensitizers, on a thin plastic film (it used to be on glass). AgBr has the rock salt structure; but rather than containing mainly Schottky defects (as we find in NaCl), it contains mostly cation Frenkel defects.

During irradiation with light, electrons are excited from the valence band to the conduction band. The band-gap energy is 2.7 eV, which corresponds to a wavelength of 460 nm (blue light). An electron neutralizes one of the silver interstitial ions. To produce what is known as a *latent image*, it is necessary for silver atoms to form

TABLE 11.4 Formation Enthalpy of Schottky Defects in Some Compounds of Formula MX

Compound	ΔE_s (10^{-19} J)	ΔE_s (eV)

clusters of at least four atoms on the surface of the grains. The silver interstitials are mobile and can diffuse to the surface. The exact mechanism for cluster formation is not well understood, but this set of equations shows a possible sequence of reactions. The clusters act as catalysts that lead to the reduction of the AgBr grains in the presence of a suitable developer.

SILVER POINT DEFECTS

11.6 WRITING EQUATIONS FOR POINT DEFECTS

There are many instances where we have to consider reactions that cannot be expressed within the normal chemical nomenclature. For example, if a dopant is incorporated into a crystal, it can have profound effects on the physical and chemical properties of the substance because of the defects that are necessarily introduced. However, defects do not occur in the balance of reactants expressed in the traditional equations, and so these important effects are lost to the chemical accounting system that the equations represent. Using the Kröger-Vink notation, we can build up a *defect chemistry* provided the normal rules for balancing chemical equations are preserved. When writing equations for point defect reactions, we must obey the following rules.

- Maintain the ratio of the number of sites; for example, in M_aX_b the ratio a/b is constant.
- V_M and M_x require sites; M_i does not require a new site.
- Maintain electrical neutrality overall.
- Surface sites are treated as if they are bulk sites (but could be treated separately).

11.6.1 Example: Point defects in the model oxide M_2O_3

We illustrate how to formulate the Schottky and cation Frenkel defect reactions using the Kröger-Vink notation for the model oxide M_2O_3 . For the Schottky defect reaction:

We imagine that the molecule of M_2O_3 condenses at the surface of the material or at another interface. When writing equation 11.3, we maintain the ratio of M-to-O sites and balance the charge.

For the cation Frenkel defect reaction:

The vacancy on an interstitial site is simply saying that there is no interstitial initially. Notice that equation 11.4 can be written for a single cation. We don't need to consider the number of sites, etc. The anion Frenkel defect reaction would be similar but is unlikely to occur in a material such as Al_2O_3 .

11.7 SOLID SOLUTIONS

We consider solid solutions here because we can think of them as being formed by distributing a large number of point defects in a host crystal. As always, we must balance charge and be sure that the size of the "impurity" (guest) ion is appropriate to fit into the available site. If the impurity ions are incorporated in regular crystal sites, the resulting phase is a substitutional solid solution. In an interstitial solid solution, the impurity atoms occupy interstices in the crystal structure. The rules for substitutional solid solutions (the Hume-Rothery rules) can be summarized as follows. Note that the last two requirements are really very closely tied to the first two.

Rule	Example	Comments
Size factor (the "<15% rule")	CdS-CdSe $r_S = 0.106 \text{ nm}$ $r_{Se} = 0.116 \text{ nm}$	If the size difference is outside this range, then substitution is limited or may not occur
Valence factor	Ni^{2+} in MgO	This is not the same in metals, where we do not have to consider charge
Chemical affinity	Al^{3+} in MgO MgAl ₂ O ₄	The possibility of a new phase can limit solid solubility
Structure type	MgO and NiO (same) SiO ₂ and TiO ₂ (similar)	The more similar the structures, the greater is the solubility

We can summarize the comparison to metals

- In metals, we have the same rule for the formation of alloys regarding size; the new factor in ceramics is the charge.
- In elemental semiconductors, the rules are approximately the same; these are ceramics with a large covalent component to the bonding. The valence difference is important in forming *p*-type and *n*-type semiconductors.

- We see later that the silica-based glasses are somewhere between elemental semiconductors and ionic materials but introduce other challenges.

11.7.1 Solid-Solution Example 1: FeO_{1-x}

We saw in our discussion of phase diagrams that FeO never exists. Consider wüstite with composition Fe_{0.95}O. To compensate the charge of V_{Fe}^{''} (i.e., for electrical neutrality), we need to replace 3Fe²⁺ ions by 2Fe³⁺ ions. This is the important point: the Fe ions change their valence from 2 to 3. This point defect reaction happens automatically. You can imagine it occurring by dissolving Fe₂O₃(s) in FeO(s).

To exhibit nonstoichiometry, the cation must be able to exist in two different valence states (so this is not the same as the nonequimolarity that we saw for spinel). The ions Fe, Co, and to a lesser extent Ni can do this; Mg cannot. An alternative way of writing this point defect reaction is to bring oxygen from the gas state into FeO.

What we are doing is oxidizing an oxide. Oxides in which the cation can change its valence state, in general, show a variation of composition with oxygen partial pressure. This dependence can even cause a change in the dimensions of the crystal lattice, as shown in Table 11.7.

11.7.2 Solid-Solution Example 2: Co_{1-x}O

The nonstoichiometry of CoO is similar to that of wüstite but not as pronounced.

We can write this in an alternate form.

TABLE 11.7 Composition and Structure of Wüstite

Composition	Atom % Fe	Edge of Unit Cell (nm)	Density (g/cm ³)
Fe _{0.91} O	47.68	0.4290	5.613
Fe _{0.92} O	47.85	0.4293	5.624
Fe _{0.93} O	48.23	0.4301	5.658
Fe _{0.945} O	48.65	0.4310	5.728

We can apply equilibrium thermodynamics to equation 11.8 and write the equilibrium constant, K, for the reaction

$$K = \frac{[\text{O}_{\text{O}}][\text{V}_{\text{Co}}''][\text{h}^{\bullet}]^2}{(p\text{O}_2)^{1/2}} \quad (11.9)$$

The concentration of anions on anion sites, [O_O], is essentially unity. For each vacancy on the Co sublattice, there are two electron holes; that is, the concentration of vacancies on cation sites is twice the concentration of holes.

$$2[\text{V}_{\text{Co}}''] = [\text{h}^{\bullet}] \quad (11.10)$$

$$K = \frac{[\text{V}_{\text{Co}}'']4[\text{V}_{\text{Co}}'']^2}{(p\text{O}_2)^{1/2}} \quad (11.11)$$

Thus, there is a direct relationship between the oxygen partial pressure, pO₂, and the extent of the nonstoichiometry.

$$(p\text{O}_2)^{1/6} \propto [\text{V}_{\text{Co}}''] \quad (11.12)$$

We can confirm this relationship by measuring the concentration of cation vacancies as a function of pO₂. Brouwer diagrams (also known as Kröger-Vink diagrams) are used to represent defect concentrations as a function of pO₂. The complete diagram for an oxide of the type MO is shown in Figure 11.4. There are three distinct ranges (I–III) that correspond to different values of the oxygen partial pressure.

It is important to keep in mind that these Brouwer diagrams, although useful, can provide only an indication of what might happen; the equilibrium constants needed for accurate calculations are not widely available. Similar diagrams can be drawn for nonoxide systems.

11.7.3 Solid-Solution Example 3: Zn_{1+x}O

The point defect chemistry of ZnO is different partly because there are two charge states of Zn: 2+ (as in ZnO) and 1+. When we heat ZnO in Zn vapor, we form a Zn-rich oxide, Zn_{1+x}O. Experimentally, it is found that the excess Zn sits on interstitial sites (as you would expect from the crystal structure). We can write the basic defect equation for the singly charged interstitial as:

We then write the equilibrium constant for the reaction in the usual way.

$$K = \frac{[\text{Zn}_{\text{i}}^{\bullet}][\text{e}']}{(p_{\text{Zn}})} \quad (11.14)$$

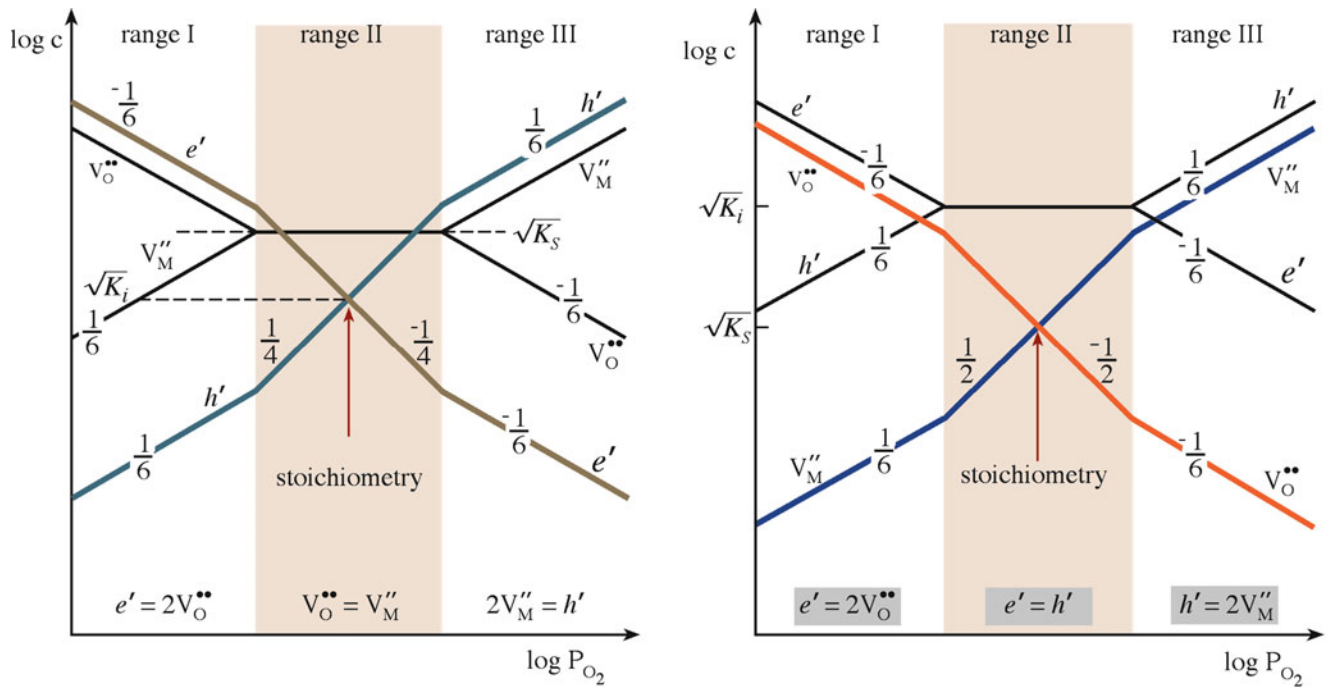

FIGURE 11.4. Examples of Brouwer diagrams in an oxide MO.

From the reaction equation we know that there is one electron for every Zn interstitial.

$$[\text{Zn}_i^\bullet] = [e'] \quad (11.15)$$

$$(p_{\text{Zn}})^{1/2} \propto [\text{Zn}_i^\bullet] \quad (11.16)$$

The excess zinc could be incorporated as a divalent interstitial, which means that there is a second reaction possibility.

$$(p_{\text{Zn}})^{1/3} \propto [\text{Zn}_i^{\bullet\bullet}] \quad (11.18)$$

Experimentally, we can measure the electrical conductivity as a function of the partial pressure of Zn, plot the results, and then look at the exponent. We find that $(p_{\text{Zn}})^{1/2} \propto [\text{Zn}_i^\bullet]$, which tells us that the Zn interstitial has a charge of +1. When you heat ZnO to high temperatures and control the oxygen partial pressure, the composition of the oxide changes. The equilibrium condition depends on p_{Zn} or p_{O_2} .

ZnO is a particularly important ceramic semiconductor: its conductivity decreases with increasing p_{O_2} . A major application for ZnO that makes use of its electrical properties is the varistor (*variable resistor*).

11.7.4 Solid-Solution Example 4: ZrO₂ Doped with CaO

Doping ZrO₂ with Ca is a special example of a ZrO₂ solid solution. We can incorporate ~15% CaO in the structure to

form Ca-stabilized cubic zirconia (CSZ). (CZ is the general abbreviation for cubic zirconia.) The special feature here is that the cubic (fluorite structure) phase is not stable at room temperature unless the ZrO₂ is heavily doped. However, we write the point defect equations as if it were always stable. The Ca²⁺ cation substitutes for the Zr⁴⁺ cation, as shown in Figure 11.5. Because the charges are different, we must compensate with other point defects.

FIGURE 11.5. Accommodation of Ca²⁺ in ZrO₂. Note: this is just half of the unit cell.

The cubic structure can also be stabilized using MgO (with essentially the same equation) or with Y_2O_3 (to form YSZ) when the equation is a little different. Later we see other rare earths partly substituting for Y to give CZ a wide range of colors. The large number of oxygen vacancies makes CZ a material of choice for solid-oxide fuel cells. The material is an electrical insulator but an ionic conductor: oxygen moves quite rapidly through CZ.

POINT DEFECTS AND VARIATION IN pO_2
 Range I – Low pO_2

- The number of O vacancies increases
- The oxide is reduced
- $n = 2V_O^{\bullet\bullet}$

Range II – Intermediate pO_2

- Schottky defects dominate

Range III – High pO_2

- Increase in cation vacancies
- The oxide is oxidized

11.8 ASSOCIATION OF POINT DEFECTS

An association of point defects often occurs when the defect concentrations reach more than about 1 mol%. Then the defects are very close together, and defect interactions may result in lowering the overall energy for defect formation and in defect clustering. Clustering is especially important in nonstoichiometric oxides such as $Fe_{1-x}O$ and UO_{2+x} .

This idea is special for ceramics because the effect is greatly enhanced owing to the point defects being charged. In particular, because vacancies behave as if they are charged point defects, cation and anion vacancies can be strongly attracted to one another to form a defect complex denoted in the following equation by the parentheses.

We can write a law of mass action equation relating the fractional molar concentration of the vacancy pairs. At equilibrium

$$\frac{[(V'_{Na}, V^{\bullet}_{Cl})]}{[V'_{Na}][V^{\bullet}_{Cl}]} = K \quad (11.21)$$

FIGURE 11.6. Plots of the vacancy concentrations varying with T^{-1} : (a) MgO; (b) NaCl.

We can then relate the equilibrium concentration of the vacancy pair to their free energy of formation, ΔG_{vp} , using

$$\Delta G = -RT \ln K \quad (11.22)$$

Hence,

$$\frac{[(V'_{Na}, V^{\bullet}_{Cl})]}{[V'_{Na}][V^{\bullet}_{Cl}]} = Z \exp\left(\frac{-\Delta G_{vp}}{kT}\right) \quad (11.23)$$

In equation 11.23, Z is the number of distinct orientations of the defect complex, which account for the configurational entropy. For example, if the vacancies sit on adjacent sites in NaCl, Z would be 12. Figure 11.6 shows calculated concentrations of Schottky defects and vacancy pairs in NaCl and MgO.

11.8.1 Association of Point Defects Due to Doping

Dissolving $CaCl_2$ in NaCl increases the number of vacancies on the Na sublattice.

If the Ca^{2+} cations form a defect complex with such a vacancy (not now on adjacent sites), we can express this combination as

11.8.2 A Second Example of Doping

Consider what happens when we dissolve a small amount of Al_2O_3 in MgO .

The Al^{3+} sits on Mg sites requiring that vacancies be created on the Mg sublattice. Notice that the reaction can lead to precipitation of spinel, but then we are creating a new structure and, thus, new sites.

This equation emphasizes that four sites are required on each sublattice. We can write the law of mass action equation for the precipitation reaction

$$[\text{Mg}_{\text{Mg}}] [\text{Al}_{\text{Mg}}^{\bullet}]^2 \propto \exp\left(+\frac{\Delta H_{\text{ppt}}}{kT}\right) \quad (11.28)$$

ΔH_{ppt} is the enthalpy of formation

$$[\text{Al}_{\text{Mg}}^{\bullet}] = 2[\text{V}_{\text{Mg}}''] \quad (11.29)$$

$$[\text{V}_{\text{Mg}}''] \propto \left(\frac{1}{4}\right)^{\frac{1}{3}} \exp\left(+\frac{\Delta H_{\text{ppt}}}{3kT}\right) \quad (11.30)$$

In summary, we ask again what is special for ceramics. Why don't we do this for metals? The special feature is the formation of defect associates as a result of the strong attraction between oppositely charged point defects. Of course, defect associates and precipitates are related, and both are clearly volume defects.

11.9 COLOR CENTERS

The term color center is now applied to any defect, including an impurity, that produces color in an insulator. The original observation was made in Germany using X-rays to color alkali halides by producing F-centers ("F" is for *Farben*: German for color). The color is the complement of that which is absorbed by the color center. Colors are produced in most of the alkali halides following irradiation with ionizing radiation and are characteristic of the crystal, not the radiation

COLOR OF F-CENTERS

The crystal and color
 NaCl—orange-brown/blue

 KBr—blue green/orange

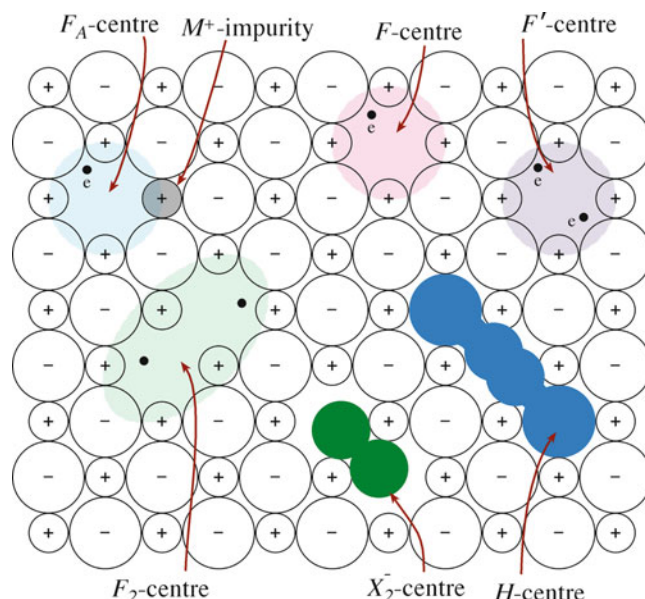

FIGURE 11.7. Color centers in alkali halides.

source used. These F-centers are due to an electron or hole trapped at an anion vacancy site. Other types of color center can give other colors.

Several different types of color center have been identified, and some of the common ones are illustrated in Figure 11.7 for the alkali halides. The V center comprises cation vacancies with trapped holes. Color centers can also form in oxides such as MgO . When a single electron is trapped at an anion vacancy in MgO , the defect is positively charged and referred to as the F^+ -center. An F-center in MgO is a vacancy with two electrons.

Smoky quartz and amethyst are two natural examples of color centers. In smoky quartz, a small amount of Al impurity atoms can substitute for Si. Because of the different valence of the two cations, electron neutrality is maintained by hydrogen ions. Ionizing radiation releases an electron from the $[\text{AlO}_4]^{5-}$ group, which is then trapped by the hydrogen ion:

The color center is the $[\text{AlO}_4]^{4-}$ group, which is electron-deficient, and we can think of it as having a trapped hole. In amethyst, the color center is $[\text{FeO}_4]^{4-}$, which is due to Fe^{3+} impurities substituting for Si.

We discuss more examples of how impurities give rise to color in Chapter 32, but it is interesting to note that NaCl crystals, doped to modify the color and increase the density of point defects, can be used for the NaCl color-center laser.

11.10 CREATION OF POINT DEFECTS IN CERAMICS

There are several ways that we can create point defects in ceramics. We have seen already that point defects can be produced in nonstoichiometric oxides (e.g., ZnO) by heating in either high or low pO_2 . In Nd-doped yttrium aluminum garnet (YAG)—the most widely used solid-state laser crystal—the Nd is incorporated into the YAG structure (it substitutes for Y^{3+} in small amounts) when Nd_2O_3 is added to the YAG melt. A single crystal, which contains the Nd ions in solid solution, is pulled from the melt using the Czochralski method (see Chapter 28).

If a crystal is annealed at a sufficiently high temperature and for long enough, the equilibrium concentration of vacancies increases. Abrupt quenching of the material can “freeze in” unusually high concentrations of point defects.

Vacancies, usually Schottky defects or Frenkel pairs, can be produced as a result of ion bombardment in a process known as ion implantation. For example, many defects are formed in single-crystal MgO when it is bombarded with high-energy Xe^+ ions. Figure 11.8 is a transmission electron microscopy (TEM) image of MgO following implantation with $10^{14} Xe^+/cm^2$ ions at 200 keV in a particle accelerator. The dark regions are typical of

FIGURE 11.8. TEM image of defect clusters formed by ion implantation into MgO.

IONIZING RADIATION CAUSING POINT DEFECTS

Ultra-violet light	$E \sim 10 \text{ eV}$
X-rays	$E = 10\text{--}100 \text{ keV}$
γ -rays	$E = 1.25 \text{ MeV}$
High- E electrons	$E = 100 \text{ keV--}0 \text{ MeV}$
High- E protons	$E = 2\text{--}20 \text{ MeV}$
Fast neutrons	$E > 0.2 \text{ keV}$

numerous point defect clusters. A large amount of work on ion implantation was performed to simulate what happens to materials inside a nuclear reactor when they are bombarded with fast neutrons (energies $>0.1 \text{ MeV}$). The topic is again important as ceramics are used to contain radioactive waste and we start to plan for fusion (rather than fission) reactors. Ion implantation is also the technique that is used to introduce dopant atoms to defined depths during the formation of semiconductor

devices and to harden the surface of metals and ceramics.

Any form of ionizing radiation can be used to produce point defects in materials. The term ionizing radiation is used to describe radiation sources that generate electron or holes when interacting with matter.

11.11 EXPERIMENTAL STUDIES OF POINT DEFECTS

It is very difficult to see individual point defects in a material. It is not that they are too small (TEM has the resolution) but they have to be surrounded by atoms, so we tend to see the surrounding atoms instead! Because point defects (especially substitutional atoms) are so important in determining the electrical properties of semiconductors, a great deal of work has been done to understand these defects. Figure 11.9 is a high-resolution scanning TEM (STEM) image showing columns of silicon atoms in a sample of Sb-doped Si. The brightest columns each contain one Sb atom.

In Table 11.7 we showed how the lattice parameter of iron oxide changes as a function of oxygen to iron ratio. The lattice parameter can be determined to high precision using X-ray diffraction and the precise lattice-parameter method. It can then be correlated with the oxygen/iron ratio, determined by chemical analysis.

We can also correlate point defect concentrations with a property measurement such as electrical conductivity, σ , or density, ρ . The density shows whether the dopant enters interstitially or is a replacement for the host ion.

- An interstitial atom increases density.
- If a substitutional atom replaces a heavier atom, the density may be reduced.

FIGURE 11.9. Atoms of Sb in Si. The Z-contrast image does not show where the atom sits in the column.

FIGURE 11.10. Possible mechanisms occurring during diffusion. (a) Exchange, (b) ring, (c) knock-on, (d) interstitial, (e) vacancy.

11.12 DIFFUSION

Diffusion occurs by atomic defects moving through the crystal; it is not a continuum process. We thus analyze diffusion as a statistical process. This is the kinetics part of the story. Diffusion of point defects is key to understanding their properties. There are four basic mechanisms that can, in principle, occur. They are illustrated in Figure 11.10.

- Direct exchange (difficult and not energetically probable)
- Ring mechanism (cooperative motion: possible but not demonstrated)
- Vacancy mechanism (most common, dominant in metals)
- Movement of interstitials (occurs when you can put interstitials in). Example: Zn in ZnO

Diffusion is a thermally activated process, so we plot the free energy versus distance. The region of high energy in this plot corresponds to an “activated complex.” It occurs because there is an activation energy barrier to

THE DRIVING FORCE

If there is no bias (gradient in the chemical potential), then there is no driving force.

NOTATION FOR DIFFUSION ACTIVATION

AB^*	The activated complex
K^*	K for the activated complex
ν	The Debye atomic jump frequency, 10^{13} Hz
χ	The potential gradient per atom
N	Avogadro's number

diffusion. We can use the reaction rate theory to understand diffusion behavior. First, we consider two features of the process.

- Each step in a difficult process is relatively simple. If it appears more difficult, we break it into smaller steps.
- The reaction path of each step, such as individual atom jump, involves an activated complex, which gives an energy maximum.

For the chemical reaction (the route of transition of the activated complex, AB^* , into the product):

The concentrations are related by the equilibrium constant K^* .

$$\frac{[AB^*]}{[A][B]} = K^* \text{ and } \Delta G^* = -RT \ln K^* \quad (11.33)$$

The reaction rate, k is $\nu[AB^*]$, which can be written as $\nu K^*[A][B]$. Thus, the reaction rate for unit concentration is

just vK^* . If there is no net flow to the right or left because each time a point defect jumps to the right one also jumps to the left, we need to add a driving force (i.e., a potential gradient) to produce a flux. Now the flux of atoms is the rate in the forward direction minus the rate in backward direction. ΔG forward is $\Delta G^* - \frac{1}{2}\chi\lambda$ for unit concentration forward. The analysis makes two assumptions:

1. The activity coefficient is unity.
2. D does not vary with the composition.

The diffusion coefficient does have a strong dependence on temperature.

$$D = D_0 \exp\left(\frac{-Q}{RT}\right) \quad (11.34)$$

The diffusion equations are summarized by Fick's laws. One assumption that is explicit in the derivation of these equations is that there is a well-defined value of D . We see later that because of the high concentrations of defects in ceramic materials, there are many important situations where this assumption is not valid (i.e., D often does depend on the composition).

FICK'S LAWS

Fick's First Law $J = -D \left(\frac{\partial c}{\partial x} \right)$

Fick's Second Law $\frac{\partial c}{\partial t} = D \frac{\partial^2 c}{\partial x^2}$

11.13 DIFFUSION IN IMPURE, OR DOPED, CERAMICS

Now you can compare diffusion in stoichiometric oxides with diffusion in nonstoichiometric oxides. The first question concerns the diffusing species when two species are present. For many ceramics, ΔE_s is large. For MgO , Al_2O_3 , and B_2O_3 , ΔH_s is ~ 600 kJ/mole (~ 6 eV/formula unit). Thus, the intrinsic concentration of vacancies, $[V]$, is $\sim 10^{-4}$ at $2,000^\circ C$. As we lower the temperature, T , the equilibrium concentration of vacancies, $[V]$, decreases too.

Figure 11.11 shows a plot of intrinsic and extrinsic diffusion coefficients. The first part of this plot is almost never observed: most ceramics are never this pure (the exceptions are the semiconductors, Si and Ge, and a few others). This means that an impurity concentration of between 1 part in 10^5 (10 ppm) and 1 part in 10^6 (1 ppm) is sufficient to dominate the vacancy concentration. There is always an attraction between oppositely charged point defects so that they associate with one another, which in turn affects their effective concentrations. (Consider how

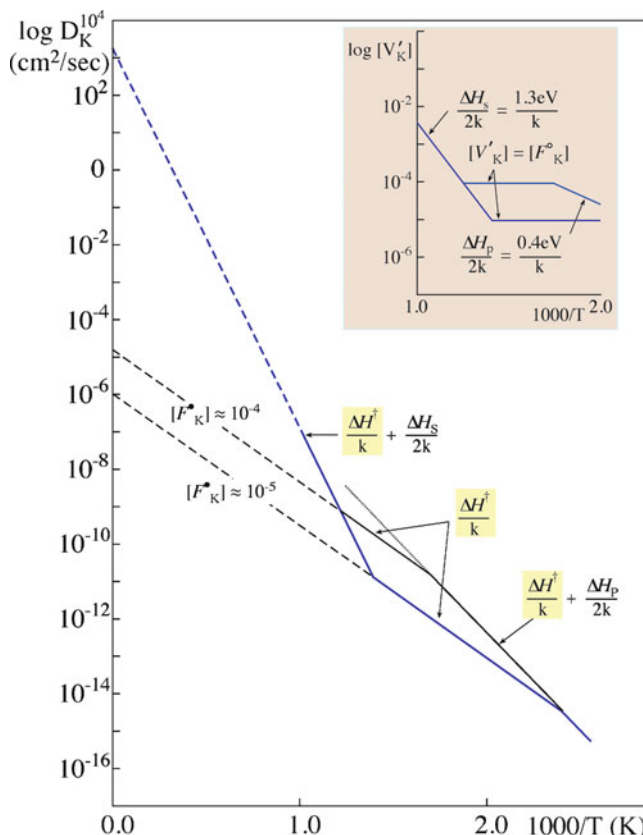

FIGURE 11.11. Diffusion coefficients in the intrinsic and extrinsic ranges. KCl with 10^{-4} and 10^{-5} atomic fraction divalent cation impurities.

far apart point defects can be if the concentration is one in 10^6 : ~ 20 nm, maximum)

We now consider examples that illustrate special features of diffusion in ceramics.

$CaCl_2$ in KCl shows the effect of changing the charge on the cation.

ZrO_2 doped with CaO is special because the structure of CSZ requires the Ca to be present; and CZ is a fast conductor of oxygen.

$Zn_{1+x}O$ is special because interstitials dominate and can have different charges.

FeO_{1-x} and CoO_{1-x} are special, as neither oxide is ever stoichiometric because the cation is always present in two charge states.

CuO_{1-x} is special because it's oxygen deficient but behaves differently to $Zn_{1+x}O$; it shows the importance of crystal structure.

In each case, we clearly have to understand the defects before we can understand their behavior.

11.13.1 Diffusion Example 1: $CaCl_2$ in KCl

When we dope KCl with $CaCl_2$ diffusion of K^+ cations occur by an interchange between K^+ cations and cation

vacancies. The concentration of cation vacancies is given by:

$$[V'_K] = \exp\left(\frac{\Delta G_S}{2kT}\right) \quad (11.35)$$

ΔG_S is the Schottky formation energy. The diffusion coefficient can then be written as:

$$D_K^\bullet = [V'_K] \gamma \lambda^2 \nu \exp\left(-\frac{\Delta G}{kT}\right) \quad (11.36)$$

Here, γ is an orientation factor. The Gibbs free energy can then be rewritten as usual.

$$\Delta G = \Delta H - T\Delta S$$

Thus, the diffusion coefficient is

$$D_K^\bullet = \gamma \lambda^2 \nu \exp\left(\frac{(\Delta S_S/2) + \Delta S^*}{k}\right) \exp\left(\frac{(-\Delta H_S/2) - \Delta H^*}{kT}\right) \quad (11.37)$$

In this equation, $-\Delta H^*$ is the enthalpy of motion of an atom, and ΔH_S is the enthalpy of formation of a Schottky defect. The constants are all well known, with λ being ~ 0.2 nm, γ is ~ 0.1 , and the Debye frequency, ν , is 10^{13} s^{-1} . $\Delta S_S/2 k$ and $\Delta S^*/2 k$ are small positive numbers. Hence, we can estimate that:

$$\gamma \lambda^2 \nu \exp\left(\frac{\Delta S_S/2 + \Delta S^*}{k}\right) \cong 10^2 \text{ or } 10^3 \quad (11.38)$$

Why is diffusion controlled by a small amount of impurity in KCl? We can write an equation describing what happens when we dissolve CaCl_2 in KCl.

Once CaCl_2 is dissolved and you change T , nothing much changes because you have fixed the concentration of vacancies.

$$[V'_K] = [\text{Ca}_K^\bullet] = \text{fixed} \quad (11.40)$$

At high T we have a high intrinsic vacancy concentration; at low T we have a low intrinsic vacancy concentration. At low T the diffusion coefficient is controlled by the starred (dopant) quantities.

$$D_K^\bullet = \gamma \lambda^2 \nu [\text{Ca}_K^\bullet] \exp\left(\frac{\Delta S^*}{k}\right) \exp\left(\frac{-\Delta H^*}{kT}\right) \quad (11.41)$$

The slope is determined only by $\Delta H/kT$. If we increase $[\text{Ca}]$ to 10^{-4} , the curve moves up.

In general, even at high T , $[V'_K]$ due to thermal equilibrium is less than $[\text{Ca}_K^\bullet]$ due to $[\text{Ca}_K^\bullet]$. This is the case for most ceramics.

- Intrinsic diffusion is controlled by defects that are present at thermal equilibrium.
- Extrinsic diffusion is controlled by dopants (impurities) that are present.

The intrinsic part is not usually observed because an impurity concentration of between 1 in 10^5 and 1 in 10^6 is sufficient to control the vacancy concentration. There is another complication we should consider: as we saw in Section 11.8, there is attraction between $[\text{Ca}_K^\bullet]$ and $[V_K]$ that results in defect complexes. The concentration of these complexes depends on the strength of this attraction; formation of these complexes probably reduces the mobility of the point defects and thus decreases diffusion rates.

11.13.2 Diffusion Example 2: ZrO_2 Doped with CaO

We noted above that if ZrO_2 is doped with 15 at.% CaO we can stabilize the cubic phase. The resulting material can be described as $\text{Zr}_{0.85}\text{Ca}_{0.15}\text{O}_{1.85}$. Experimentally, we find that D_O decreases as the concentration of oxygen vacancies increases. Hence, we know that oxygen diffuses by a vacancy mechanism.

In UO_2 , which has the same fluorite structure, oxygen diffuses by an interstitial mechanism. (Look back to our discussion of the structure of fluorite to see why this might be so.) D_O increases as the concentration of oxygen vacancies increases. With such an interstitial mechanism, the interstitial moves onto a regular site and *bumps* the ion occupying that site onto an interstitial site. If you study diffusion using tracer atoms, the tracer atom has now temporarily stopped moving but the interstitial ion may repeat the process and move on through the crystal. The process is thus rather complicated. A typical activation energy for this process might be ~ 120 kJ/mole.

Notice that the crystals in these two examples both have the fluorite structure, but the diffusion mechanism that operates is very different because the point defects involved are different. Experimental data for diffusion in several oxides is plotted in Figure 11.12.

11.13.3 Diffusion Example 3: Zn_{1+x}O

In our discussion of point defects in nonstoichiometric ZnO, we noted that excess zinc is present as interstitials. The oxide is thus metal-rich.

Figure 11.13 shows a plot for D_{Zn} : the steeper the slope, the larger the activation energy. Varying the partial pressure of Zn, p_{Zn} , has a large effect on D_{Zn} in ZnO

FIGURE 11.12. Arrhenius plots for different oxides: diffusion coefficients varying with T^{-1} .

FIGURE 11.13. Plot for D_{Zn} as it varies with T^{-1} .

because, as we saw above, p_{Zn} is proportional to the interstitial concentration. Thus, as p_{Zn} increases, the density of interstitials increases and the diffusion of Zn through the structure increases. This result again emphasizes the difference between a metal and its oxide: In metallic Zn, we don't care about the partial pressure of the Zn; the Zn atoms diffuse by a vacancy mechanism, but the concentration of vacancies does not depend on p_{Zn} .

FIGURE 11.14. Diffusion coefficients varying with p_{O_2} .

11.13.4 Diffusion Example 4: FeO_{1-x} and CoO_{1-x}

As we noted above, the group of binary oxides—FeO, NiO, CoO, MnO (all have rock salt structure)—are metal-deficient. The most important of these is $Fe_{1-x}O$. FeO does not exist (i.e., it is not stable) and can contain as many as 15 at. % vacancies due to the equilibrium concentration of Fe^{3+} cations. We saw earlier that this equilibrium occurs by the cation changing its valence: Fe^{2+} changes to Fe^{3+} . We can write an equation for dissolving excess oxygen in $Fe_{1-x}O$. We can generalize the equation we wrote for FeO and CoO as

where M is the metal, and M_M^\bullet represents an Fe^{3+} cation sitting on an Fe^{2+} site. The rest of the analysis follows from our discussion of CoO. The important point is that diffusion depends on p_{O_2} as illustrated for several oxides in Figure 11.14. There is an energy associated with the reaction and an energy associated with the motion of defects, but point defects are always present in FeO.

Good experimental observations are available for CoO. We can show that the diffusion coefficient for Co can be expressed as

$$D_{Co} = \gamma v \lambda^2 \left(\frac{1}{4}\right)^{1/3} p_{O_2}^{1/6} \exp\left(\frac{\Delta S_0}{3k}\right) \exp\left(\frac{\Delta S^*}{k}\right) \exp\left(-\frac{\Delta H_0^*}{3kT} - \frac{\Delta H^*}{kT}\right) \quad (11.43)$$

Experimentally, we find that D_{Co} is proportional to $p_{O_2}^{1/n}$ with the value of n depending on T .

- $n = 3.1$ at $1,000^\circ\text{C}$
- $n = 3.3$ at $1,200^\circ\text{C}$
- $n = 3.6$ at $1,350^\circ\text{C}$

We expected D_{Co} to be proportional to $p\text{O}_2^{\frac{1}{6}}$. This means that as we increase $p\text{O}_2$ the value of D_{Co} increases faster with vacancy concentration than we had predicted. The reason is that the defects are charged and there is an association of defects (see the discussion of KCl above). We must consider two possibilities. A single cation vacancy might form a complex with one hole or with two holes. In the first case we write

$$\frac{1}{2}\text{O}_2^* = [\text{h}^\bullet] + [(\text{V}''_{\text{Co}}\text{h}^\bullet)] + \text{O}_0 \quad (11.44)$$

$$\frac{[\text{h}^\bullet][(\text{V}''_{\text{Co}}\text{h}^\bullet)]}{p\text{O}_2^{1/2}} = K_1 \quad (11.45)$$

$$[\text{h}^\bullet] = [(\text{V}''_{\text{Co}}\text{h}^\bullet)] \quad (11.46)$$

So that $[(\text{V}''_{\text{Co}}\text{h}^\bullet)]$ is proportional to $p\text{O}_2^{\frac{1}{4}}$, and n is 4. If two holes are involved in the complex, then

$$[(\text{h}^\bullet\text{V}''_{\text{Co}}\text{h}^\bullet)] \propto p\text{O}_2^{1/2} \quad (11.47)$$

Now, $D_{\text{Co}} \propto p\text{O}_2^{\frac{1}{2}}$, and n is 2. Experimentally, we find n is ~ 3 , so we can conclude that the vacancy must be associated with between one and two electron holes. It is not obvious that we actually make another assumption in this treatment. We perform a diffusion experiment, measure D_{Co} , and then assume that a vacancy in a complex moves at the same velocity as free vacancy. Thus, we should say that if the association of a vacancy and holes does not affect the movement of vacancies, then each vacancy must have between one and two electron holes associated with it.

Finally, we comment on the mobility (B_{V}) of the vacancy; B_{V} is proportional to Γ_{V} , the jump frequency. Similarly, for holes, B_{h} is proportional to Γ_{h} . In CoO all the electrical current is carried by the electron holes (i.e., it is a p -type semiconductor) so that the mobility of holes is much greater than the mobility of the vacancies. In CoO we can say that:

$$B_{\text{h}} \gg B_{\text{V}}$$

$$\Gamma_{\text{h}} \gg \Gamma_{\text{V}}$$

Therefore, when a vacancy jumps, holes follow. Thus a hole–vacancy pair moves at a rate determined by the jump frequency of the vacancy, the slower moving defect.

11.13.5 Diffusion Example 5: CuO_{1-x}

CuO is an example of a group of oxygen-deficient oxides, MO_{1-x} , where the nonstoichiometry is accommodated by

oxygen vacancies. We write the equilibrium equation in the usual way.

We can determine the equilibrium constant and relate this to the Gibbs free energy ΔG .

$$[\text{V}_0^{\bullet\bullet}] \cong \left(\frac{1}{4}\right)^{1/3} (p\text{O}_2)^{-1/6} \exp\left(-\frac{\Delta G_0}{3kT}\right) \quad (11.49)$$

$$D_{\text{O}} = \gamma\lambda^2 v [\text{V}_0^{\bullet\bullet}] \exp\left(-\frac{\Delta G^*}{kT}\right) \quad (11.50)$$

$$D_{\text{O}} = \gamma\lambda^2 v \left(\frac{1}{4}\right)^{1/3} (p\text{O}_2)^{-1/6} \exp\left(-\frac{\Delta G_0}{3kT}\right) \exp\left(-\frac{\Delta G^*}{kT}\right) \quad (11.51)$$

If you increase the $p\text{O}_2$, then the diffusion coefficient decreases. This is found for a very wide temperature range and implies that diffusion is a complex process. It is interesting to compare this case to that of ZnO. Both cations exist in the $2+$ or $1+$ charge state, but the crystal structures and point defect chemistry are very different.

11.14 MOVEMENT OF DEFECTS

We often think that only cations move in ionic materials because so much work has been carried out on oxides or halides where the anion is much larger than the cation (e.g., MgO, Al_2O_3 , NaCl). Ceramics that are being used for electronic applications often contain heavier (hence larger) cations, so the assumption is not necessarily valid. In solid-oxide fuel cells, it's the oxygen ion that diffuses.

Most perfect ceramic crystals have more unoccupied volume than there is in metals, so they tend to be less dense. There is thus more open volume for point defects to move through.

Covalent bonds are directional in character and must be “broken” as defects move. We see later that dislocations in Si do not move easily at room temperature, so the material does not easily deform plastically and is brittle at this temperature. This simple fact has many consequences for the electronics industry. Where would silicon technology be if dislocations moved readily under an applied stress? The same consideration applies to point defects, except that interstitials in Si do not need to break bonds!

The charge can affect the concentration of point defects. FeO contains at least 5% vacancies on the cation sublattice so the formula should be written as $\text{Fe}_{1-\delta}\text{O}$ —or, better, $\text{Fe(II)}_{1-2\delta}\text{Fe(III)}_{\delta}\text{O}$. The superconductor YBCO must be off-stoichiometric to optimize its superconducting properties ($\text{YBa}_2\text{Cu}_3\text{O}_{7-\delta}$ or $\text{YBa}_2\text{Cu}_3\text{O}_{6+x}$).

FIGURE 11.15. A probable diffusion mechanism in NaCl.

The movement of grain boundaries is very important in ceramics because of the method of processing and their high-temperature applications. However, the properties of grain boundaries are very different from the bulk material, and they may contain a second phase. Grain boundaries in ceramics are not as dense as in metals because the bonding is different (remember the open space in Si and Al_2O_3); therefore, diffusion of point defects along and across these interfaces is much faster than in the bulk. There may also be an excess charge of one sign at the grain boundary plane, which must be compensated in the bulk (the space-charge region) and, again, affects the diffusion of charged point defects.

CORROSION

Diffusion of oxygen in oxidation scales occurs along grain boundaries. Corrosion of metals is controlled by formation and diffusion of point defects in the ceramic. Corrosion of polycrystalline ceramics also occurs fastest along grain boundaries.

11.15 DIFFUSION AND IONIC CONDUCTIVITY

Some ceramics are important because they are ionic conductors. The band-gap energy, E_g , of these materials is large (typically >5 eV) and the only mechanism for conduction of charge is by the movement of ions. In some cases, the rate of movement of the ions is very rapid and large conductivities are possible. In this section, we mention one application of ionic conductivity; we consider more examples and details in Chapter 30. The ionic conductivity, σ , is

$$\sigma = \sum_i q_i N \mu_i \quad (11.52)$$

where q_i is the effective ionic charge, μ_i is the mobility, and N is the number of mobile defects.

Mobile defects contributing to ionic conductivity include Schottky defects. Figure 11.15 shows the example of Na^+ motion in NaCl. Two different routes are shown for how the Na^+ ion might reach the vacant site. The direct route, although shorter, is unlikely because the two Cl^- ions are very

close together (“touching”), creating a large energy barrier for the migrating Na^+ ion to overcome. Route 2 is more likely. The Na^+ ion first passes through the face of the octahedron, then into the vacant tetrahedral site between the octahedra,

and then through the face of the opposite octahedron and into the vacant site. We can’t prove that this is what happens, but we expect the ion to follow the lowest-energy pathway, which appears to be route 2.

If ionic conductivity and diffusion occur by the same mechanism, then μ and σ are related to D by the Nernst-Einstein equations.

$$\mu = \left(\frac{q}{kT}\right)D \quad \sigma = \left(\frac{Nq^2}{kT}\right)D \quad (11.53)$$

In using equation 11.53, we have to be careful about the following points.

- Some defects may contribute to D but not to σ (e.g., paired cation and anion vacancies in the alkali halides).
- Diffusion may occur along grain boundaries and dislocations. (These are more rapid paths than bulk diffusion).
- Electronic contributions to σ are low. (This is the case in wide-band-gap materials at low T).

For a simple vacancy transport mechanism both σT and D would obey Arrhenius relationships.

$$\sigma T = A \exp(-Q/kT) \quad (11.54)$$

$$D = D_0 \exp(-Q/kT) \quad (11.55)$$

where A and D_0 are temperature independent constants, and Q is the activation energy.

Figure 11.16 shows the variation in σT with T for a relatively pure sample of NaCl. As you can see, the relationship is

FIGURE 11.16. Ionic conductivity of NaCl varying with T^{-1} .

FIGURE 11.17. Schematic of a ZrO_2 -based oxygen sensor and an actual sensor unit.

complicated. The activation energy Q consists of two components: one due to the creation of the defect and one due to its motion. They may have different temperature behaviors. For NaCl at temperatures $>550^\circ\text{C}$, there is good correlation between D and σ . Below 550°C the trend is similar; that is, there is the same change in slope, but the D values are greater than σ values because of the presence of impurities. We can summarize some important characteristics of the plot.

- Stage I'—anion disorder
- Stage I—intrinsic conductivity; cation migration dominates

- Knee region—where the slope changes: separates the intrinsic dominated region from the impurity region
- Stage II—extrinsic conductivity dominated by cation vacancies
- Stage III—vacancy-impurity association

An application that makes use of ionic conductivity is the ZrO_2 oxygen sensor illustrated in Figure 11.17. These sensors are used, for example, to measure the pO_2 in automobile exhaust gases or the gases present in the carburizing process used to harden steel components. Polycrystalline CZ (stabilized with either Ca^{2+} or Y^{3+} substituting for Zr^{4+}) is the electrolyte. At the operating temperature of the sensor ($\sim 900^\circ\text{C}$), CZ is a good oxygen ion conductor. The substitution for Zr^{4+} results in the formation of oxygen vacancies, and these lead to high ion mobilities on the oxygen sublattice. Solid-oxide fuel cells use the same electrolyte or another with the same structure and work on a similar principle.

11.16 COMPUTING

Computer modeling is becoming a more widespread method of studying point defects because computers are now capable of addressing large numbers of atoms. In ceramics, although the structural aspects of point defects may be short range, interactions tend to be long range because of Coulombic forces. Atomistic simulation calculations usually require several steps, and the actual energy may depend on how the structure is able to relax around the defect.

- Choice of a modeling approach
- Choice of an interatomic potential describing the atoms or ions
- A starting model for the point defect or defect cluster

This modeling approach is discussed in more detail later. The size of the modeled crystal must be considered and its other physical properties modeled. Modeling the potential is already much more difficult when the material is a compound rather than an elemental solid, and now we add charge. The choice of the starting model is important because calculations may suggest structures that are metastable but are not the lowest-energy configuration. Table 11.8 compares calculated values and experimental values of defect formation energies where the agreement is good.

TABLE 11.8 Comparison of Calculated and Observed Defect Formation Energies in Ionic Crystals

Compound	Defect	Calculated energy (eV)	Experimental energy (eV)
NaCl	Schottky pair	2.32	2.30
CaF ₂	Frenkel pair	2.75	2.7
MgO	Schottky pair	7.5	5.7
ZnO	Cation Frenkel pair	2.51	—
AgCl	Cation Frenkel pair	1.4	1.45

CHAPTER SUMMARY

This chapter is one of the most basic in ceramics and, for the student, the easiest to learn. You need to know the different types of point defects and their names, the thermodynamic principles leading to the calculation of point defect concentrations, and how point defects make diffusion possible. The next level of complexity concerns how point defects interact with one another. Much of this we touch on in the examples of real materials, where we bring in the fact that the point defects are often (usually) charged. The importance of the topic is that point defects not only *affect* the properties of materials but in many cases *determine* and *control* the properties that interest us. An interesting question is how this discussion changes for nano-ceramics. Are point defects important in nanoceramics? The initial answer is that the surface (a two-dimensional defect) dominates everything when the particle is small, but one point defect in a nanoparticle can be a very high concentration!

PEOPLE AND HISTORY

Frenkel, Jacob Il'ich was born in Rostov-on-Don, Russia and died in Leningrad (1894–1852). He worked on dislocations, twinning, and much more.

Schottky, Walter was born in Zürich, Switzerland and died in Pretzfeld, Germany (1886–1976). He worked under Max Planck in Berlin. Discovered both the electron hole and the Schottky defect.

Kröger, Ferdinand Anne. Lead author on the paper that gave the Kröger-Vink notation. Retired as Professor at University of Southern California in ~1990.

Fick, Adolf Eugen (1829–1901) is best known to us for his laws, which he first applied in 1855. He was also a physiologist and developed a technique for measuring cardiac output but also was one of the first to experiment with contact lenses in 1887.

Wedgwood, Thomas (son of the famous potter) and *Sir Humphrey Davy*, in 1802, reported in a communication to the Royal Institution in London a photographic process using AgCl to record an image.

Boltzmann, Ludwig (1844–1906) lived in Vienna and eventually committed suicide supposedly because his theory was ridiculed by some colleagues. He died before his theories were experimentally proven correct.

EXERCISES

- 11.1 What, if any, is the difference between a Schottky defect in Mg and a Schottky defect in MgO?
- 11.2 Would you expect Frenkel defects to be more likely in Al or Al₂O₃? What factors do we need to consider for answering this question?
- 11.3 How might you expect Si to diffuse in an alumina furnace tube at high temperatures? Would the mechanism be different if the alumina were in the form of a single crystal?
- 11.4 We form a Schottky defect in KCl. What is the difference in energy of the system if the two vacancies are 5.5*a* apart or 3.5*a* apart (*a* being the lattice parameter)? Why do we choose 3.5 rather than 3.0, etc.? Discuss.
- 11.5 We dissolve (add) 100 ppm of Al₂O₃ to a cube of MgO (1 mm on each side). How many vacancies are formed, and how much bigger is the cube?
- 11.6 Construct a table of the different types of point defects in Fe₂O₃. Compare this table with the table you produce for Fe₃O₄.
- 11.7 Write down a point defect reaction for ZnO in which you produce twice as many singly charged defects as doubly charged ones.
- 11.8 Write a balanced defect reaction equation using the Kröger-Vink notation for substitution of Ca²⁺ in CaF₂ by Y³⁺.
- 11.9 During the movement of the Na⁺ ion in Figure 11.15, how does the CN of the Na⁺ ion change as it moves through route 2.
- 11.10 Express, using the Kröger-Vink notation, the formation of Frenkel defects in AgBr and explain why you think they are more numerous than Schottky defects. How might you increase the concentration of Schottky defects in AgBr?
- 11.11 If Table 11.1 is really wrong, what dimension should we use for point defects instead of zero?
- 11.12 How would Figure 11.2 be different if we could draw it in three dimensions?

- 11.13 Without looking at Table 11.2, write down the Kröger-Wink notation for (1) a vacancy, (2) an interstitial, (3) an antisite atom, (4) an associated defect, (5) a solute atom, (6) a Schottky defect in MgO, and (7) a Frenkel defect in NaCl. Why do we specify MgO and NaCl in parts (6) and (7)?
- 11.14 Without looking at the box, prove that $n_s \approx N \exp(-E_s/2kT)$. Then substitute reasonable values into this equation to estimate the density of such defects in NaCl and in MgO.
- 11.15 Look at Table 11.5. Compare (1) MgO, CaO, SrO, and BaO. Can you make sense of these values? Repeat this discussion for (2) LiI, KI, and CsI.
- 11.16 Look at the values for UO_2 , ZrO_2 , and CaF_2 in Table 11.6. What are the Frenkel defects? Discuss why these values differ in this way.
- 11.17 Use our notation to write down the Schottky defect reaction for Fe_2O_3 and the Frenkel reaction for Sc_2O_3 .
- 11.18 We can explain the defects in FeO by imagining that we dissolve Fe_2O_3 in the FeO matrix. Write down an equation to show this and explain the assumptions you are using.
- 11.19 ZnO tends to be oxygen-rich. Write down equations to show how the electrical conductivity depends on the oxygen partial pressure.
- 11.20 F centers are often discussed using the Bohr model. Discuss this idea and give a quantitative explanation for why the F center in NaCl might make NaCl appear blue.

Are Dislocations Unimportant?

CHAPTER PREVIEW

We begin our discussion with a reminder of the basic properties of single dislocations and conclude by considering combinations of dislocations, which leads nicely into the next three chapters, which consider different types of interfaces.

Most students understand dislocations best by thinking about diagrams and high-resolution transmission electron microscopy (TEM) images. Dislocations are line defects; but like all crystal defects, they are actually volume defects. Therefore, we should think of them as tubes, or pipes, whose properties change across the tube radius and that generally do not have cylindrical symmetry.

We are not trying to cover everything about dislocations here but, rather, review the basic understanding of dislocations and then introduce the complexities of ceramics. Remember the important experimental observation that led to the “invention” of dislocations: the stress required to deform a metal single crystal is at least 10^3 times smaller than the theoretical value.

Two vectors define the fundamental properties of any dislocation.

- Line direction
- Burgers vector

The glide plane of the dislocation is the plane that contains both vectors. To summarize:

Geometry	Burgers vector and line direction define the glide plane
Displacement	When a dislocation is present, atoms are displaced from their positions in the perfect crystal; the material is strained so there must be a stress
Movement	Dislocations move and interact (they even intersect)
Reacting	We generate dislocations; they multiply and combine (by intersecting)

Why consider dislocations in ceramics? Conventional wisdom says that dislocations are not nearly as important in the mechanical deformation of ceramics as they are for metals. The reason for saying this is that dislocations in ceramics do not move as easily as those in metals, and they are usually not as numerous. So we should be asking why is the last sentence true. Dislocations in ceramics are extremely important because of what they don't do: they don't glide easily. Si devices would not work for long, and ceramics, in general, would not be brittle, if dislocations could glide easily. Understanding dislocations also helps us understand other, more complex defects: how they interact with point defects and how they can cause planar defects. Dislocations become very important when we use thin crystalline ceramic films, particularly when grown on crystalline substrates.

What is special about dislocations in ceramics?

- Complex and large unit cells are the norm rather than the exception.
- Charge—If you insert an extra half plane to make an edge dislocation, you must consider the charge.
- Directional bonds—If you break a bond, does it reform?

For the student, dislocations are a great test of whether you understand the structure of a crystal. They give a fine *probe* of what is happening in the material. Be aware, though, that much of our understanding of dislocations comes from metallurgy, particularly from studies on Cu alloys. We often compare our dislocations to these because those in metals are quite well

understood, but ceramics introduce new complications. The detailed understanding of dislocations and planar defects in ceramics is not as advanced as that of point defects.

12.1 A QUICK REVIEW OF DISLOCATIONS

Line defects in a crystalline material are known as dislocations (unless they're disclinations, which we ignore because they're much more difficult and not nearly as important in ceramics). In contrast to point defects, dislocations never exist in thermodynamic equilibrium because they have formation energies of ~ 1 eV (or more) per atom along the line and there is no significant balancing entropy contribution as there is for point defects. They are almost always present in crystals because of how the crystal grew or because it was deformed. Dislocations thus usually form due to nonequilibrium conditions, such as thermal and mechanical processing, or for thin films and single crystals, during growth. There are two special types of dislocation.

- Edge dislocations
- Screw dislocations

All other dislocations are referred to as "mixed."

12.1.1 Defining the Burgers Vector and the Glide Plane

The Burgers vector is defined by constructing a closed circuit around the dislocation line. We first draw a circuit around the dislocation in a clockwise (right-handed screw) direction from the start (S) to the finish (F), as shown in Figure 12.1A. We then transfer this circuit to a perfect crystal, as shown in Figure 12.1B. If there is a dislocation, this second loop does not close on itself. We then define the vector FS, which is required to close the loop in the perfect crystal, as the Burgers vector. This method of defining the Burgers vector, \mathbf{b} , is known as the FS/RH perfect-crystal convention. (The vector is named after J.M. Burgers, so there is no apostrophe). The Burgers vector is then defined with respect to the perfect crystal; you wouldn't want to define it in the imperfect crystal!

It is important that you are consistent when using this convention. Some other texts, and even some of the classic papers, use a convention that produces the opposite sign for the Burgers vector. For example, they might use an anti-clockwise circuit, set $\mathbf{b} = \mathbf{SF}$, or draw the circuit in the perfect crystal first. You must use a convention consistently.

- *Edge dislocation*: an extra half-plane of atoms is inserted above the glide plane, as illustrated in Figure 12.1A. The Burgers vector is perpendicular to the dislocation line, \mathbf{u} . The Burgers vector is opposite if the extra half plane is below the glide plane.

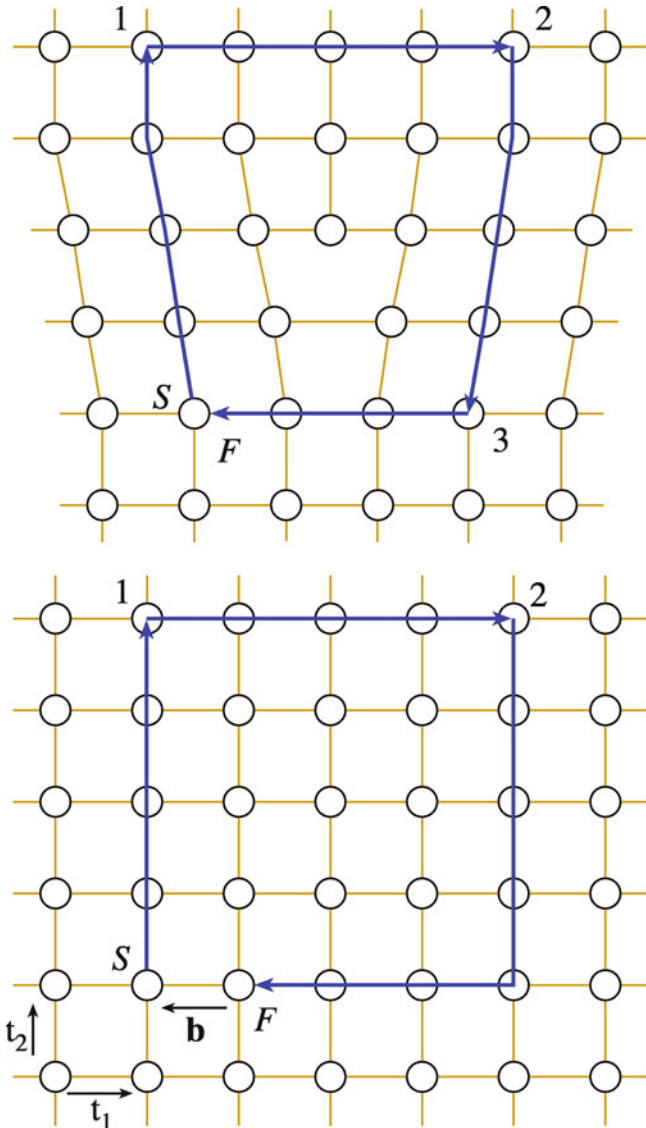

FIGURE 12.1. Burgers circuit in the imperfect and perfect lattices for an edge dislocation in a simple-cubic crystal.

FIGURE 12.2. Screw dislocation.

- *Screw dislocation*: successive atomic planes are connected to form the surface of a helix (or screw) around the dislocation line, as shown in Figure 12.2, where the dislocation is perpendicular to the planes: like the core of a spiral parking ramp. The Burgers vector is parallel to the dislocation line and can point up or down for a left- or right-handed screw.
- *Glide plane*: the plane containing both the dislocation line and the Burgers vector.

The glide plane is not usually an actual plane of atoms but is a plane between two planes of atoms. (Where actually is the dislocation line?) Dislocations are often more complicated than suggested by the two simple examples above, but they can always be resolved into a combination of edge and screw components.

Dislocation lines can end at the surface of a crystal and at grain boundaries but never inside a crystal lattice. Thus, dislocations must either form closed loops or branch into other dislocations. When three or more dislocations meet at a point, or node, it is a necessary condition the Burgers vector is conserved. Consider the dislocation \mathbf{b}_1 in Figure 12.3, which branches into two dislocations, with Burgers vectors \mathbf{b}_2 and \mathbf{b}_3 . A Burgers circuit has been drawn around each dislocation according to the line sense, \mathbf{u} , indicated; and it follows from the diagram that \mathbf{b} is conserved.

$$\mathbf{b}_1 = \mathbf{b}_2 + \mathbf{b}_3 \quad (12.1)$$

The large circuit of the right-hand side of the diagram encloses two dislocations; but because it passes through the same good material as the \mathbf{b}_1 circuit on the left-hand side, the Burgers vector must be the same (i.e., \mathbf{b}_1). It is more usual to define the Burgers circuits by making a clockwise

FIGURE 12.3. Diagram used for proving Frank's rule for conservation of \mathbf{b} .

circuit around each dislocation line looking outward from the nodal point. This reverses the line sense (and hence the Burgers vector of dislocation 1 becomes $-\mathbf{b}_1$) on the left-hand side; then equation 12.1 becomes:

$$\sum \mathbf{b}_i = -\mathbf{b}_1 + \mathbf{b}_2 + \mathbf{b}_3 = 0 \quad (12.2)$$

12.1.2 Elasticity

We usually assume that elasticity (how stress is related to strain) is linear. The assumption is that strains are small so that stresses are linearly related to strains (Hooke's Law). We then think of the crystal as a continuum (a structureless "sponge") with two independent elastic constants (e.g., μ , the shear modulus, and ν , Poisson's ratio). At the core of

the dislocation, the strains are too large for this assumption to be valid so we exclude this region from our calculation and replace it by a "fudge factor" involving r_0 , the core radius (not ideal because it assumes nothing varies across the core and we don't know what r_0 is). One

consequence of linear elasticity is that when Burgers vectors are separated into screw and edge components the stresses due to these separate components can be treated individually and then added to give the total stress.

We don't usually think of ceramics as being elastic; but don't confuse local stresses with macroscopic behavior. Macroscopically, the ceramic may be brittle; but if the atoms move slightly off their perfect-crystal sites because of an applied force, that's an elastic deformation. We can also have anisotropic elasticity (which becomes important for noncubic ceramics) and nonlinear elasticity but usually approximate to the simple case.

R FOR A SCREW DISLOCATION

The displacement of any point on this surface from its "perfect-crystal position" is given by

$$\mathbf{R} = \frac{\mathbf{b}\phi}{2\pi}$$

(ϕ is a fraction of 2π) The strain in the complete unwrapped surface is then

$$\gamma = \frac{b}{2\pi r}$$

The shear stress due to the screw dislocation is then

$$\tau = \mu\gamma$$

12.1.3 Displacement Fields

We usually derive the displacement field of a screw dislocation because it is much easier than that of the edge dislocation.

The screw dislocation is formed from a cylinder of crystal by making a cut along the cylinder and displacing one side relative to the other by a vector \mathbf{b} , where \mathbf{b} is the same value everywhere on the cut and is parallel to the axis of the cylinder; we have to cut out a cylinder at the core first to make this process physically possible. We take the screw dislocation in Figure 12.4 and “unwrap” the surface at a distance r away from the dislocation core; remember that \mathbf{b} is parallel to the dislocation line so it doesn’t matter where we start the unwrapping process. We then calculate the strain, γ , in the unwrapped surface and calculate the shear stress due to the screw dislocation. As you move away from the center of cylinder, the strain decreases as r^{-1} ; and as we noted earlier, when r becomes very small ($\sim r_0$) the assumptions of elasticity break down so this relationship does not hold in the core region.

Remember μ depends on the interatomic bonding; \mathbf{b} depends on the crystal lattice.

FIGURE 12.4. Deducing strain by “unwrapping” a screw dislocation.

For the edge dislocation, we just quote the result for the stress field (equations Box 12.1–12.4). This stress field exerts a force on any other neighboring dislocation. The force is given by:

$$F = \sigma b \quad (12.3)$$

If we were being rigorous we would express the force as $\mathbf{b}\sigma$ because \mathbf{b} is a vector and σ is a tensor.

$$F = (\mathbf{b}\cdot\sigma) \times u \quad (12.4)$$

- The term $\mathbf{b}\cdot\sigma$ represents a force per unit length, F , which acts in a direction that is normal to \mathbf{b} .

An important result of applying equation 12.4 is that the force acting on dislocation 1 due to the stress field of dislocation 2 depends on $\mathbf{b}_1\cdot\mathbf{b}_2$: if $\mathbf{b}_1\cdot\mathbf{b}_2$ is positive, then the dislocations repel one another; if negative then the interaction is attractive (but be careful about the line direction).

STRESSES FOR AN EDGE DISLOCATION

The stresses are referred to xyz coordinates for a dislocation parallel to z . This dislocation does not have cylindrical symmetry.

$$\sigma_{11} = -\frac{\mu b}{2\pi(1-\nu)} \frac{x_2(3x_1^2 + x_2^2)}{(x_1^2 + x_2^2)^2} \quad \text{Box 12.1}$$

$$\sigma_{22} = \frac{\mu b}{2\pi(1-\nu)} \frac{x_2(x_1^2 - x_2^2)}{(x_1^2 + x_2^2)^2} \quad \text{Box 12.2}$$

$$\sigma_{33} = \nu(\sigma_{11} + \sigma_{22}) \quad \text{Box 12.3}$$

$$\sigma_{12} = \frac{\mu b}{2\pi(1-\nu)} \frac{x_1(x_1^2 - x_2^2)}{(x_1^2 + x_2^2)^2} \quad \text{Box 12.4}$$

THE STRAIN ENERGY

For a screw dislocation

$$dE = \frac{1}{2} \mu \left(\frac{b}{2\pi r} \right)^2 l 2\pi r dr$$

$$dE = \frac{\mu b^2}{4\pi} l \frac{dr}{r}$$

$$\text{Screw } E = \int_{r_0}^R dE = \frac{\mu b^2}{4\pi} l \ln \frac{R}{r_0}$$

For an edge dislocation this equation becomes

$$\text{Edge } E = \int_{r_0}^R dE = \frac{\mu b^2}{4\pi(1-\nu)} l \ln \frac{R}{r_0}$$

12.1.4 Dislocation Strain Energy

As a dislocation creates a strain field, which in turn creates a stress field, each dislocation has an associated strain energy. This strain energy is termed the self-energy of the dislocation. We can then determine the strain energy per unit volume by integrating over the volume affected by the strain field (i.e., by determining the area under the triangle in a stress versus strain plot shown in Figure 12.5).

FIGURE 12.5. Elastic energy of a screw dislocation from a plot of stress versus strain.

For the screw dislocation, $l2\pi r dr$ is an element of volume at radius r around a length, l , of the dislocation.

FREE ENERGY OF A DISLOCATION

In Chapter 11 we showed how ΔG could be determined for the formation of point defects in a crystal using

$$\Delta G = \Delta E - T\Delta S$$

ΔS was obtained using statistical mechanics methods. What are the contributions to the entropy of a dislocation? There are three.

- Positional entropy—similar to the configurational entropy we described for point defects
- Entropy due to vibration of the dislocation line about its equilibrium position
- Changes in the vibrational entropy of the surrounding lattice because of the large strains near the dislocation core

The total entropy contribution is only ~ 0.5 eV/atom. Less than E , but not negligible.

At the center of a dislocation the crystal is highly strained, with atoms displaced from their normal sites, and we can't use linear elasticity. Therefore, we again exclude this region from the calculation by making the inner limit r_0 . There must be a contribution to the self-energy of the dislocation from this core, but we need atomistic modeling to estimate the value; it is usually assumed to be about 10% of the total strain energy of the dislocation. As before, we just quote the result for the edge dislocation. The only difference compared to the screw dislocation is the $1-\nu$ factor. We can express the energy of a mixed dislocation as:

$$E = \frac{\mu b^2}{4\pi} \left(\frac{\sin^2\theta}{1-\nu} + \cos^2\theta \right) \ln \frac{R}{r_0} \quad (12.5)$$

The important result is that the strain energy of a dislocation is proportional to the square of the Burgers vector \mathbf{b} and the shear modulus of the material.

$$E = \alpha \mu b^2 \quad (12.6)$$

We normally just take the constant α to be between 0.5 and 1.0. This result provides a criterion for what dislocations can be formed in a given crystal. Those with the smallest allowed Burgers vector have the lowest strain energy and consequently are the most likely to form. (This is very important for a ceramic with a large unit cell—e.g., YAG).

The crystal determines the actual value of \mathbf{b} . If \mathbf{b} is a perfect lattice vector, then the structure of the crystal is not changed by the passage of a dislocation. If \mathbf{b} is not a lattice vector, then a planar defect (a stacking fault) is present on one side of the dislocation and a second so-called partial (or imperfect) dislocation is required to remove the stacking fault.

The important point is that the elastic energy depends on three factors.

- An elastic constant, μ , because the energy of the dislocation depends on the stress and strain it causes in the lattice, and ν if there is an edge component
- The radii, R and r (and r_0), because the total energy of the dislocation depends on the volume of crystal it effects
- The Burgers vector, \mathbf{b} , because this determines the magnitude of the strain

We assume linear isotropic elasticity throughout this discussion.

12.1.5 Compact Core Versus Spread Core

If a dislocation dissociates into partial dislocations, the self-energy is reduced provided the angle between the Burgers vectors is acute (they are parallel, not antiparallel). As a simple demonstration, consider the possibility that 10 partial dislocations, each with Burgers vector $\mathbf{b}/10$, are formed. The strain energy is reduced by a factor of 10! Once formed, these dislocations repel one another because they have parallel Burgers vectors. However, as the Burgers vectors of these partial dislocations are not lattice vectors, a planar defect is created between each pair of partial dislocations. If the energy required to form these planar defects is greater than the reduction in the strain energy, then the dissociation does not occur. The best-known example of dislocation dissociation is found in face-centered cubic (fcc) metals. The dissociation produces two so-called Shockley partial dislocations, which do not have parallel Burgers vectors.

DISSOCIATION

$$b \rightarrow b_1 + b_2 + b_3 + \dots + b_{10}$$

$$b^2 \rightarrow b_1^2 + b_2^2 + b_3^2 + \dots + b_{10}^2$$

For dissociation into two Shockley partial dislocations

$$\mathbf{b} = \frac{a}{2}[110] \rightarrow \frac{a}{6}[121] + \frac{a}{6}[21\bar{1}] = \mathbf{b}_{P_1} + \mathbf{b}_{P_2}$$

In an fcc crystal, the special feature of this dislocation dissociation is that the planar defect formed between the two partial dislocations can be regarded as a mistake in the stacking of the *close-packed* layers, as shown in Figure 12.6. The term stacking fault is then applied to all such planar defects, and the energy per unit area is the stacking-fault energy (SFE, or γ —but don't confuse this γ with strain). Of course, for the general concept, the planes do not need to be close-packed planes; you can stack any planes incorrectly!

When calculating the SFE, we don't equate it to the energy required to create the fault; instead, we consider the force balance. The two partial dislocations try to repel each other ($\mathbf{b}_{P_1}, \mathbf{b}_{P_2} > 0$), but they cannot separate too much because of the SF. Although we have deduced this dissociation for fcc metals using an energy argument, it is also important for the *behavior* of the dislocations. In fcc metals, these partial dislocations allow the atoms to move over "valleys" instead of over "hills" as the dislocation glides, and they restrict glide to the plane of the stacking fault. In Cu and Si, dislocations are widely ($\Delta \sim 4$ nm) dissociated, but the same dislocation in Al has a rather narrow core.

If the dislocation changes its line direction for a short segment, this segment is called a kink if it lies in the glide plane or a jog if it causes the dislocation to step out of its glide plane.

In general, a dislocation itself contains many such defects along its length.

12.2 SUMMARY OF DISLOCATION PROPERTIES

We have not reviewed all the properties of dislocations but have concentrated on those you should know when considering dislocations in ceramics.

- Dislocations cannot end inside the crystal lattice.
- We almost always assume that strains are so small that linear elasticity is a good approximation; so Hooke's Law holds.
- The displacement field for any dislocation falls off, as r^{-1} , as we move away from the dislocation.
- The strain energy (or self-energy) of a dislocation actually depends on the character of the dislocation, but setting $E = \alpha Gb^2$ is a good estimate, where α is ~ 0.5 .
- Parallel dislocations repel one another if the angle between their Burgers vector is $< 90^\circ$. (Be careful with \mathbf{u} .)
- A dislocation can always lower its strain energy by spreading its core or dissociating. Whether this lowers the total energy depends on the energy required to form the distorted region between the "partial dislocations." If dissociation occurs (forming identifiable partial dislocations), then this region is called a stacking fault.
- Dislocations glide by the movement of kinks and climb by the movement of jogs. Because climb requires changing the number of point defects (reacting or absorbing them), we call it nonconservative motion.

12.3 OBSERVATION OF DISLOCATIONS

We can divide the techniques used to "see" dislocations into two categories.

FIGURE 12.6. Intrinsic stacking fault in a face-centered cubic (fcc) crystal.

1. Direct
2. Indirect

Direct techniques allow us to see the arrangement of atoms around the dislocation. The most useful direct technique is high-resolution transmission electron microscopy (HRTEM). The resolution of commercial instruments allows direct observation of columns of atoms, and edge dislocations can be identified as terminating planes of atoms, as shown in Figure 12.7. These images look very much like the schematics we draw to illustrate edge dislocations, and the Burgers vectors can be determined directly from the image using the Burgers circuit construction (unless there is a screw component present).

Indirect techniques rely on the fact that dislocations create a strain field and are regions of high energy. The most widely used of the indirect methods is again TEM. We show you several examples of TEM images of dislocations in ceramics in later parts of this chapter. Figure 12.8 shows how planes near a dislocation may be

FIGURE 12.7. High-resolution transmission electron microscopy (HRTEM) image of the core of a dislocation in Al_2O_3 .

FIGURE 12.8. Diffraction contrast from dislocations in Al_2O_3 .

be bent into an orientation where they are strongly diffracting even when the rest of the crystal is not. The intensity of the direct beam is reduced (and that of the diffracted beam increased), and the dislocation appears as a dark line in the bright-field image. Images of dislocations are often quite difficult to interpret, and the position of the dislocation in the TEM image generally does not correspond exactly to its actual position in the crystal. However, this approach is extremely useful for answering many of the questions that arise about the nature of dislocations in a material.

- Is the dislocation interacting with other dislocations or with other lattice defects?
- Is the dislocation jogged, kinked, or straight?
- What is the density of dislocations in the sample?
- Has the dislocation adopted some special configuration, such as a helix?

By tilting our specimen in the TEM to a condition where the dislocations are invisible (or at least appear faint in the image), if we know the diffracting conditions (specifically the diffraction vector \mathbf{g}), then we can obtain \mathbf{b} using the invisibility criterion (generally needing three independent \mathbf{g} vectors).

$$\mathbf{g} \cdot \mathbf{b} = 0 \quad (12.7)$$

Another indirect (but lower resolution) approach is the etch-pit method. In this technique the surface of the sample is polished and immersed in a suitable chemical etchant. The rate of removal of material around the dislocation (where the crystal is strained) is usually more rapid than in the surrounding crystal, and pits are formed where the dislocation line intersects the surface. The clearest demonstration that etch pits are associated with dislocations is shown for Si in Figure 12.9A, where the dislocations can be seen in cross section due to absorption of infrared illumination by the Cu decorating the dislocation; today, this task might be more easily accomplished using a focused ion-beam instrument (FIB). Figure 12.9B shows a plan-view image of etch pits in a single crystal of Nd-doped YAG. The etch pits were revealed by immersing the polished crystal in concentrated phosphoric acid at 250°C for 8 min.

The etch pit method is usually best when dislocation densities are low ($<10^4 \text{ mm}^{-2}$). If the dislocation densities are too high, the etch pits overlap each other; and it is very difficult to resolve their shape and count densities.

12.4 DISLOCATIONS IN CERAMICS

In discussing dislocations in ceramic materials, the principle is always the same. We deduce the possible Burgers vectors first and then the glide planes. We begin by asking if there is anything special about dislocations in ceramics;

FIGURE 12.9. Etch pits at a dislocation emerging at a surface in Si. (A) Cross-sectional view in Si. (B) Plan view in YAG.

we can preempt the answer by saying: yes, as usual, the bonding and charge can add their own effects. The second best-known special feature of dislocations in ceramics is actually that the unit cell of such materials is usually larger than that for the simple metals, so we see similarities to other materials such as the intermetallics, which also have large unit cells.

The structure of the dislocation core in ceramics depends on three factors.

1. Charge of the ions
2. Size of ions
3. Presence of directional bonds

Perhaps the more important question is: why learn about dislocations in ceramics when ceramics don't deform plastically as easily as metals? This question then leads us to ask why is this statement true? Is it always true? Can we change anything? Modern materials often involve interfaces. Interfaces are directly related to dislocations.

The growth of thin films often involves dislocations. Dislocations also play an important role in radiation damage of ceramics. Thus, there are many reasons for understanding dislocations in ceramics.

12.5 STRUCTURE OF THE CORE

Not much is really known about the core of dislocations in ceramics. For the examples we show, you should remember that we have usually chosen one Burgers vector (usually the most important one), one line direction, and thus one glide plane. Furthermore, we usually draw the edge dislocation because it's easiest to draw, not because it is the most important. In this section, we assume that the dislocation core is compact. The examples are chosen to illustrate particular features.

- NaCl: it is relatively simple and illustrates the effect of charge.
- Si: it illustrates the effect of directional (covalent) bonding.
- Al₂O₃ and olivine: they are noncubic materials.

NaCl structure. Although NaCl and MgO structures are both based on the cubic-F Bravais lattice, like Cu, there is no evidence for any dislocation dissociation. There are detailed atomistic calculations that confirm that the compact core is preferred. A diagram of such a dislocation viewed along the [001] direction is shown in Figure 12.10. All the ions seen here lie in the same (001) plane. If we remove this plane of atoms, the structure looks the same but all the ions are reversed in sign. Thus, charge is balanced so long as there are no jogs or kinks on the dislocation.

The glide plane for dislocations in NaCl and MgO is {110} rather than the {111} you might expect for an fcc. You may read that the glide plane is {110} because this plane is electrically neutral and motion on this plane avoids charged layers gliding over one another. However, ErAs, an exotic semi-metal (no ionic charge), with the NaCl structure, has the same glide system. PbS, a semiconductor with this structure, shows glide occurring on {001} planes and in TiC dislocations glide on {111} planes. The real reason for the {110} glide plane is still being studied. The suspicion is that the core actually does spread on different planes, but that still does not tell us why the spreading depends on the material.

Silicon. The simplest covalently bonded ceramics are Si and Ge. The covalent bond formed by two atoms sharing electrons is a localized and directional bond. Cubic ZnS has the same structure, but the Si-Si basis is replaced by Zn-S, but the bond still has a large covalent component. This feature is important in determining the characteristics of dislocations in covalent materials. Dislocations in these materials tend to be immobile at low temperatures. Extensive slip occurs only at elevated temperatures.

FIGURE 12.10. Core of a dislocation in NaCl.

Of the many covalent crystals, the diamond-cubic and *c*-ZnS structures are among the simplest and most widely studied. Because the crystal lattice is fcc, perfect dislocations have the fcc Burgers vector $\frac{1}{2} \langle 110 \rangle$ (b^2 always wins). Like dislocations in fcc metals, dislocations in Si, Ge, and *c*-ZnS glide on $\{111\}$ planes. Figure 12.11A shows a $(\bar{1}\bar{1}0)$ projection of *c*-ZnS; you can recognize the $\{111\}$ planes (also shown by the projected tetrahedron). We make a dislocation by cutting out half a plane, such as that shown by the box labeled 1564. Then we merge the atom at P and Q; because these are on different levels (one is a large circle, the other small), the dislocation has a component of \mathbf{b} into the page: it's a 60° perfect dislocation. However, we could have removed the slice of material 1234 and joined atoms R and S to make exactly the same \mathbf{b} . Therefore, there are two possible $\{111\}$ slip planes, type I and type II, and two possible dislocation cores. [These slip planes are usually called the glide (I) and shuffle (II) planes, which can be confusing because the dislocation can glide on both!] The 60° dislocation is shown with its extra plane ending at a type II plane. Imagine removing material 1234: there is then one unpaired bond per atom along the dislocation core, as shown in Figure 12.11B. This defect is called a *dangling bond*. This type of dislocation does exist, as illustrated in Figure 12.11C. Here, the dislocation alternates between the compact core and a dissociated structure. The explanation for this change is that the dislocation steps from a type I plane to a type II plane: it dissociates on one but not on the other because the SFE is different on the two planes. The step from the shuffle

plane to the glide plane is a special jog. The dangling bonds can then reconstruct; now the bonds are distorted but not dangling! However, this dislocation can't move at all without re-breaking the reconstructed bonds so the dislocation is *sessile*.

If we left the half plane 1234 where it is but removed the other half, we would create a dislocation with the opposite \mathbf{b} , but instead of the last atom being R(S) it would be T(U): Zn instead of S! The core of the dislocation is fundamentally different: it is still a shuffle dislocation. These two dislocations are fundamentally different because the zinc blende structure does not have a center of symmetry. Similar considerations hold for such materials as AlN and GaN, which also lack a center of symmetry but have the wurtzite structure crystal structure. The stacking fault in the diamond-cubic structure is described as AbBbCcBbCcAaBb: the pair of planes Aa behaves just as if it were one fcc plane in this case. Two possible SFs are shown in Figure 12.11D.

The thoroughly studied metals are either cubic or have the closely related hexagonal close-packed (hcp) structure. Many ceramic materials are neither cubic nor hcp. Olivine and sapphire both have oxygen sublattices, which can be thought of as distorted hcp but the distribution of cations makes them very different.

Olivine. In the olivine group of minerals (important orthorhombic silicates), the energies of the $[100]$, $[010]$, and $[001]$ dislocations are all different. In fact, the energy of the $[010]$ dislocation is much greater because it has a much larger Burgers vector.

FIGURE 12.11. Models for forming dislocations and stacking faults in sphalerite. (A) Two cuts in which to make an edge dislocation. (B) Dislocation made by removing 1234. (C) Dislocation in Si alternating between a compact core and a dissociated structure. (D, E) Intrinsic and extrinsic SFs in Si.

For forsterite (Mg_2SiO_4): $a = 0.475 \text{ nm}$, $b = 1.020 \text{ nm}$, $c = 0.598 \text{ nm}$

For fayalite (Fe_2SiO_4): $a = 0.482 \text{ nm}$, $b = 1.048 \text{ nm}$, $c = 0.609 \text{ nm}$

For monticellite (CaMgSiO_4): $a = 0.4815 \text{ nm}$, $b = 1.108 \text{ nm}$, $c = 0.637 \text{ nm}$

The added complication is that olivine is not an isotropic material, so using μ and ν (which automatically implies elastic isotropy) would be a simplification.

Sapphire. Al_2O_3 is also very anisotropic, although we can use pseudo-isotropic values of μ and ν when dislocations are confined to lie on the basal plane. The most common perfect dislocations do have the shortest Burgers vector $\frac{1}{3}\langle 110 \rangle$, as seen in Figure 12.12, but other perfect dislocations have been reported including $[0001]$. Even when they have the

shortest \mathbf{b} , they may glide (if they do at all) on other planes, such as $\{100\}$. Examples of dislocations in Al_2O_3 are shown in Figure 12.13.

12.6 DETAILED GEOMETRY

As we saw in Section 12.1, dislocations would always like to dissociate because it reduces the strain energy. Whether a particular dislocation dissociates thus depends on the magnitude of the energy associated with the stacking fault. If the dislocation core spreads on the glide plane, it is glide dissociation; otherwise, it is at least partly climb dissociation.

The glide dissociation seen in fcc metals does occur in ceramics. It is seen in III–V compounds, MoS_2 , graphite,

FIGURE 12.12. Schematic shows \mathbf{b} of perfect dislocations in Al_2O_3 .

FIGURE 12.13. Images of dislocations in Al_2O_3 from two directions.

and talc. (The last two are shown in Figure 12.14; more on this below.) In ceramics, because \mathbf{b} is generally large, the energy ($\propto b^2$) can be very large. Crystals with the garnet structure are body-centered cubic (bcc), and the lattice parameter is ~ 1 nm. We can expect core spreading to occur, but there are very few observations available. Climb dissociation need not require adding or removing point defects to the dislocation as a whole because we can move point defects from one partial dislocation to the other, as illustrated for spinel in Figure 12.15 (more on this below). The result of this transfer is that one dislocation undergoes positive climb and the other undergoes negative climb.

12.6.1 Details on Glide Dissociation

Glide dissociation occurs when one of the partial dislocations moves on its glide plane. The classic example

is Si, which, as we saw in Figure 12.11, can dissociate on a $\{111\}$, just like the fcc metals. Compounds such as ZnS, SiC, and GaAs, which have the zinc blende or sphalerite structure, behave in the same way. The illustration in Figure 12.14A–C is instructive. This 60° dislocation in graphite lies on the (0001) plane, and we are looking onto this plane. The partial dislocation on the left is pure edge, whereas that on the right is 30° . Notice that there are no broken bonds within the layers in this structure. The only broken bonds occur between the layers, and these are the very weak van der Waals bonds. For the same reason, the SFE is very small, so such partial dislocations may be widely separated as shown; graphite is sometimes seen to stack in the ABCABC sequence instead of ABAB. The SFE is small in talc and MoS_2 for similar reasons. Talc gives us an interesting example, where more than one type of partial dislocation is formed, as we can see in Figure 12.14D, E.

12.6.2 Details on Climb Dissociation

Climb dissociation occurs when the stacking fault does not lie parallel to the glide plane of the partial dislocations. The phenomenon has not been seen in pure fcc metals, but it can occur in intermetallics. It is found in both covalent and ionic ceramics. We can make two comments here.

- Climb dissociation is always possible, but it may be more common in ceramics.
- Climb dissociation does not necessarily refer to how the configuration was achieved.

Climb dissociation may be more important in a ceramic than in an fcc metal because in fcc metals the glide plane is also the plane with by far the lowest SFE. A point to remember is that the word “dissociation” refers to the final configuration; it does not tell you that the perfect dislocation ever had a compact (undissociated) core.

Example. A complex oxide: spinel. The smallest Burgers vector for a perfect dislocation in spinel is $\frac{1}{2}\langle 110 \rangle$ which is ~ 0.7 nm long. Such a dislocation can dissociate according to the reaction:

$$\frac{1}{2}[110] \rightarrow \frac{1}{4}[110] + \frac{1}{4}[110] \quad (12.8)$$

This reaction reduces the total self-energy by 50%. Because $\frac{1}{4}[110]$ is a perfect lattice vector of the oxygen sublattice, this dissociation creates a stacking fault that exists only in the cation sublattice, so it has a low SFE. We know that in spinel stacking faults can form on $\{001\}$, $\{110\}$, and $\{111\}$ planes. In the example shown in Figure 12.15, the dislocation is dissociated on a $\{110\}$ plane. The “stacking” situation is actually quite complex because we are stacking different layers; and even when the layers are the same, they may be rotated 90° , which is

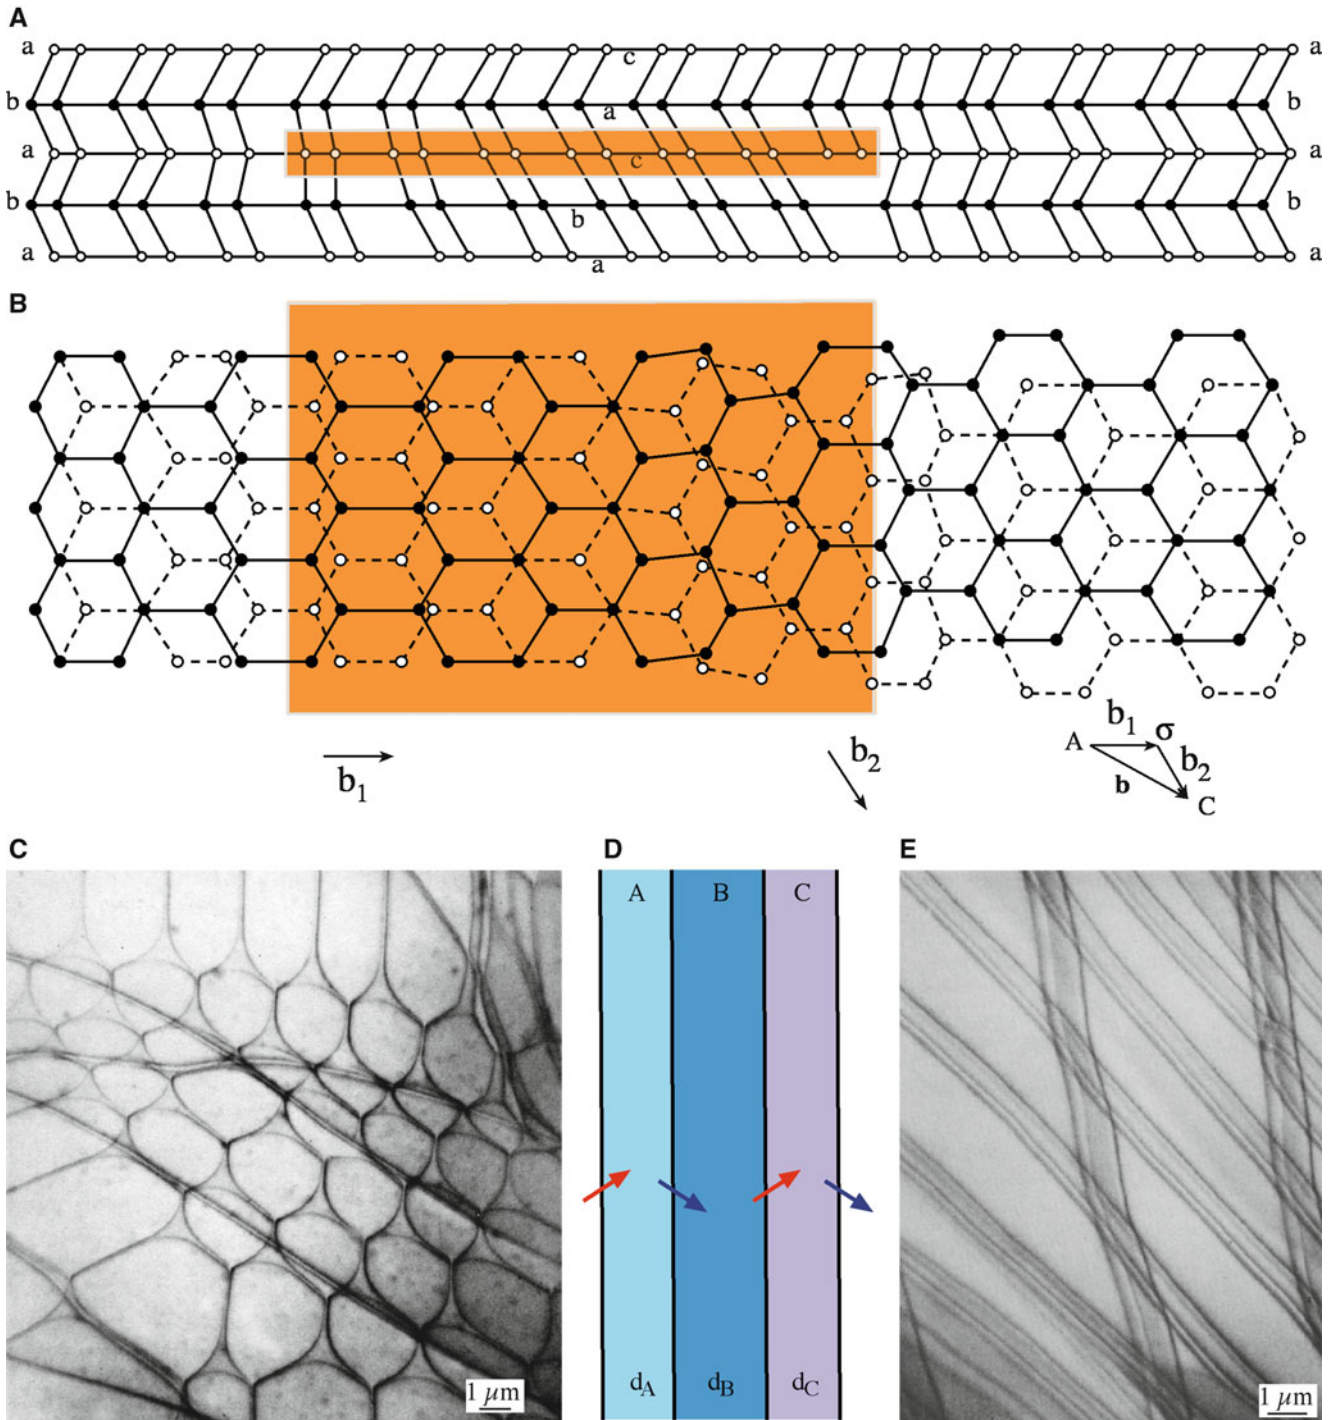

FIGURE 12.14. Dislocations in ceramics with low SFE. (A–C) Dissociation in graphite. (D, E) Dissociation in talc.

important if the layer (as is the case here) does not have fourfold symmetry.

12.7 DEFECTS ON DISLOCATIONS

Even less is known experimentally about defects on dislocations for ceramic materials than for metals. However, the theory has been developed quite extensively and

shows that this is one area where ceramics are fundamentally very different from metals.

Consider a cube of NaCl cut so that every corner is occupied by a Na^+ ion (Figure 12.16A). The overall extra charge of the cube is $+e$. Therefore, each corner has an effective charge of $+e/8$. We can extend this argument to show that there can be a charge at a jog. Consider a jog on a perfect edge dislocation in NaCl, as shown in Figure 12.16B, C. Assume that there is a charge $+q$ on the jog. Now we can

FIGURE 12.15. Climb dissociation of a dislocation in spinel. (A) Schematic. (B) HRTEM image.

FIGURE 12.16. Local charge on defects in rocksalt. (A) A corner is always charged. (B, C) Possibilities for jog on an edge dislocation.

add a negative ion to the jog to produce the same configuration but with the charge on the terminating ion reversed. The charge is now $-q$. Thus, we can identify q .

$$+q + (-e) = -q \quad (12.9)$$

The charge associated with the original jog was $q = +e/2$. Notice that you could not add a charge $+e$ because the jog is already positively charged. If a jogged dislocation in NaCl glides, it can transfer a charge (carry a current). The transfer of current by deformation of NaCl has been measured

experimentally. You can convince yourself of some properties of dislocations in NaCl.

- Straight dislocations are not charged.
- Dislocation kinks may be neutral or charged.
- The point where an edge dislocation meets a surface carries a charge equal to $\pm e/4$.

Figure 12.17 shows two examples of a kink on a screw dislocation. In one case, the kink is charged, whereas in the other it is neutral.

FIGURE 12.17. Kinks on a screw dislocation showing they may or may not be charged.

12.8 DISLOCATIONS AND DIFFUSION

Because point defects exert a strain on the surrounding lattice, they interact with dislocations. It is simplest to consider Figure 12.2A. Large impurity atoms or interstitials preferentially move toward the dilated part of the core at the edge dislocation, whereas smaller impurity atoms or vacancies move to the compressive side of the core. Screw dislocations show no size preference as the strain field is produced by pure shear. However, point defects also produce a local change in the elastic constants (because they change the local bonding), and this does cause an interaction with screw dislocations. We might say that some point defects are “hard” and others are “soft.”

The dislocation core is always a more open region of the crystal. The number of bonds are lower, or there are preexisting broken bonds. Thus, vacancies, interstitials, and other point defects can move more easily in the dislocation core. This leads to the concept of dislocation pipe diffusion.

Taking the NaCl structure again, if we condense a cation vacancy V'_{Na} on a screw dislocation, we can form a pair of kinks and a pair of jogs. Notice that all of these

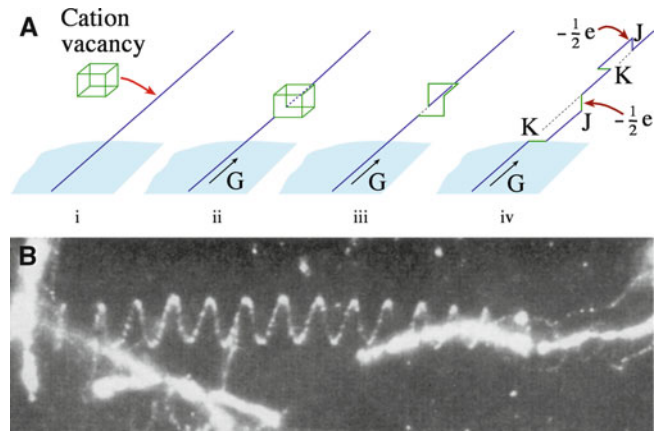

FIGURE 12.18. Forming a pair of kinks and a pair of jogs and how this leads to helical dislocations in MgO.

“steps” can glide along the screw dislocation. These steps can then move apart, as shown in Figure 12.18A. On this screw dislocation, the jogs and kinks each carry a charge of $-e/4$ (giving a total charge of $-e$), so this separation is encouraged by the repulsion of like charges. This process is the nucleation of the transformation of a screw dislocation into a dislocation helix; examples of such helices are shown in Figure 12.18B. Such a dislocation is difficult to move. (What is the glide plane?)

Dislocation pipe diffusion may be quite important in ceramics because there are generally many more point defects present than are found in metals. Although we have very little information on this phenomenon, loop shrinking has been studied in Al_2O_3 . Rows of dislocations loops formed by the breakup of a long loop (dipole) are shown in Figure 12.19.

Movement of neutral atoms can also be enhanced along dislocation cores. For example, if there is a gradient in the oxygen potential, oxygen might move much more rapidly along the dislocation core than through the lattice. Such a process would not require charge balance because the diffusing species is neutral. The point defect is simply using the enhanced distortion at the dislocation core to move more easily: bonds are already broken, so they are easier to distort a little more, if necessary.

12.9 MOVEMENT OF DISLOCATIONS

A dislocation can move in its glide plane or on another plane. In the first case, the motion is glide; in the second, climb must be involved. We nucleate kinks and jogs in pairs, except at a surface where we can create them one by one. Pairs of kinks and jogs are shown in Figure 12.20. The dislocations move as the kinks or jogs move apart. The dislocation is usually drawn as a straight line because dislocations in fcc metals should lie along close-packed directions (the Peierls valleys). The kinks step the dislocation line from one valley to the next.

FIGURE 12.19. Dislocation loops in sapphire.

FIGURE 12.20. (A) Pair of kinks. (B) Pair of jogs.

Glide of an edge dislocation occurs when a half-plane of atoms is moved over the atoms below the glide plane. The movement occurs by the nucleation and movement of kinks. Remember that the reason that dislocations are so important in plasticity is because it is easier to move one block of material over another (shear the crystal) one half-plane of atoms at a time. Similarly, it is easier to move a dislocation by moving a kink along it one atom at a time. In fcc metals, the Peierls valleys are not deep so the energy required to form a kink is small and dislocations bend (create kinks) quite easily.

Climb is nonconservative motion because vacancies and/or interstitials must be absorbed or emitted (their

number is not conserved). When a jog moves, it can either glide or climb. The special point to remember is that the glide plane of a jog is not the same as the glide plane of the dislocation on which it sits. If we force a dislocation jog to move on a plane that is not its glide plane, it must adsorb or emit point defects but it can glide. Because it is charged, it carries a current when it glides.

We know that as a general rule, it is more difficult to move dislocations in ceramics than in most metals. In fact, at low temperatures it is often easier to fracture the sample than it is to propagate dislocations. The questions we must then ask are:

- Why do dislocations not move more readily?
- When they move, what is the chosen glide plane?
- Why do they move more readily as T increases?

We know that dislocations in Ge move on $\{111\}$ planes, but they can also move on $\{001\}$ and $\{011\}$ planes. Is the choice of glide plane due to the Peierls barrier, or is it determined by the need to break bonds?

12.10 MULTIPLICATION OF DISLOCATIONS

The concentration of dislocations is conventionally defined as the number of dislocation lines that intersect a unit area. Carefully prepared crystals may contain 10^2 dislocation lines per square centimeter (cm^{-2}), and some bulk crystals and crystal whiskers have been prepared

free, or nearly free, of all dislocations. After plastic deformation, the concentration of dislocations increases tremendously, being as high as 10^{10} to 10^{11} dislocations per square centimeter for some heavily deformed metals. (We shouldn't use cm^{-2} units, so beware.)

Dislocation multiplication occurs when the dislocations are made to move during deformation. One possible multiplication mechanism is the Frank-Read source. Suppose that a dislocation is pinned at two points that are a distance ℓ apart, as shown in Figure 12.21A. Under the action of an applied stress, the dislocation bows out. The radius of curvature R is related to the applied shear stress, τ_0 .

$$\tau_0 = \frac{\mu b}{R} \quad (12.10)$$

Increasing the stress further causes the bowing to increase (i.e., R decreases). A minimum value of R is reached that is equal to $\ell/2$ (a segment of a circle in the isotropic case). As the stress is inversely proportional to R , this minimum R configuration must correspond to the

FIGURE 12.21. Schematic and infrared (IR) image of a Frank-Read dislocation source in Si.

maximum stress. Consequently, once the dislocation has passed the critical configuration, the half-loop continues to expand until the two segments X and Y meet and annihilate each other, forming a complete loop and reforming the pinned dislocation. The complete loop continues to expand and moves away from the source. The pinned dislocation then repeats the process. Figure 12.21B is an experimental observation of such a source in Si; Figure 12.9A showed a related situation in Si, where half loops had been punched into the sample.

Notice that as a screw dislocation bows, it adds small increments of edge character. The converse is true for bowing edge dislocations. The ease with which either type of dislocation moves depends on the relative energies of the screw and edge components. As you can see from the equations for these energies, the screw dislocation always has the lower energy in an isotropic material, so bowing a screw dislocation is harder than bowing an edge dislocation. Dash illustrated the Frank-Read source in Si. Low-temperature deformation of Si causes straight dislocations because they lie along the Peierls valley. Another glide source that has been observed is the single-ended dislocation source. You can visualize this “mill” by removing half the Frank-Read source, as shown in Figure 12.22. In crystal growth, dislocations are often generated at the neck of the growing crystal; this is the highly stressed region, and dislocations glide more easily at the high temperatures used for growth. Thus, the dislocation source is close to the surface.

The Nabarro-Herring source is very similar to the Frank-Read source, but the dislocations move by climb instead of glide.

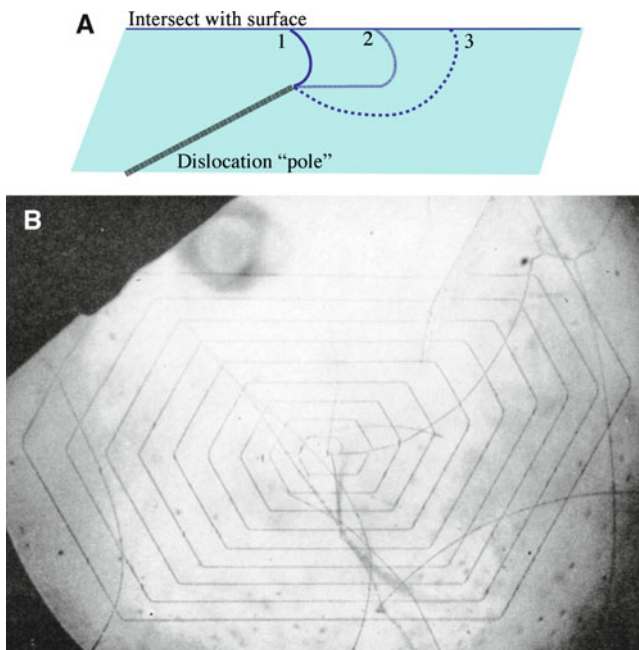

FIGURE 12.22. Schematic and IR image of a single-ended Frank-Read source in Si.

12.11 DISLOCATION INTERACTIONS

Interactions and motion. When dislocations moving on inclined glide planes intersect one another, they form nodes and locks. After the intersection is complete, they have created jogs or kinks in the other dislocation. The intersection process can, instead, result in the two dislocations knitting together to form part of a dislocation tangle; the product dislocation may have a glide plane that is not a favored glide plane for that structure. The Lomer-Cottrell dislocation in fcc metals is an example of such a less mobile dislocation. It is referred to as a lock or barrier because it stops the interacting dislocations from moving and impedes the movement of other gliding dislocations.

Dipoles. Dipoles are commonly seen in MgO and Al₂O₃. They may form by dislocations trapping one another, or they may be pulled out by a moving dislocation that is pinned somewhere along its length. If the temperature is high enough, they anneal out as they form. We can learn a little about local diffusion by carefully annealing samples containing dipoles (Figure 12.19). Consider how a dipole is annihilated and how this process is different in metals. To annihilate a dipole in MgO, we must add or remove ions on both sublattices. In metal alloys, these different atoms can sit on the other lattice, giving an antisite defect. This exchange is unlikely in ceramics because of the charge. It can, however, occur in compound semiconductors, which we sometimes think of as ordered covalently bonded alloys.

Nodes. Dislocation nodes occur when any three dislocations meet, when one dislocation divides into two, or when two dislocations join to form one. Nodes are quite common. The example in Figure 12.23 shows a node in AlN; and Figure 12.14 shows nodes in graphite. Observations of such defects can give a measure of the stacking-fault energy so we can, in principle, learn

something about bonding in such materials. The catch is that the stacking-fault (SF) energy may be significantly lowered by segregation of impurities because the structure of the material is different at the SF. More interesting in ceramics are nodes where climb-dissociated dislocations meet. Consider the node in spinel shown in Figure 12.23B: this is a special defect because it is also the junction of three noncoplanar SFs.

Walls and networks. We discuss walls and networks in more detail when we talk about interfaces. We can arrange an array of dislocations to form a wall or grain boundary. Arrays of dislocations are essentially two-dimensional defects; that is, the dislocations knit together to form a network. The dislocation array in Figure 12.14 is actually a network.

12.12 AT THE SURFACE

Dislocations cannot end inside the crystal, but they can end at a surface, as we saw in Figure 12.9, where they were revealed by chemical etching. They can also be revealed by thermal etching, which is particularly important because it can give insight into how the reverse process—i.e., crystal growth—occurs. Figure 12.24 shows a dislocation emerging at the surface of a TiN crystal. Notice two points: (1) if this interpretation is correct, then if you bonded an atomically flat surface to the surface imaged here you would form a single-ended Frank-Read source; (2) we can't be sure about the Burgers vector because such atomic force microscopy images don't tell us about the component of **b** parallel to the surface. Note that dislocations producing spirals such as shown here are not necessarily screw in character even though you often see them referred to as such (even in some of the classic papers). All that is needed is that a component of the dislocation's Burgers vector is inclined to the surface you are examining; you have to know where the dislocation line is relative to its Burgers vector to be able to say that it has screw character; it could be a pure edge dislocation!

12.13 INDENTATION, SCRATCHING, AND CRACKS

Crack tips are line defects but may resemble disclinations more than dislocations if the sides of the crack are inclined to one another rather than parallel. The differences are significant: deformation at the crack tip may be very large, leading to the generation of dislocations in the plastically deformed region even in brittle ceramics. If this plastic deformation is large, it actually blunts the crack tip and toughens the ceramic.

FIGURE 12.26. Dislocations produced by scratching Al_2O_3 .

12.14 DISLOCATIONS WITH DIFFERENT CORES

Frank predicted the existence of coreless dislocations long before they were unambiguously observed. The idea is that the surface energy associated with a hollow tube may be less than the strain energy associated with a large Burgers vector. Of course, you have to form this large- \mathbf{b} dislocation first. Observations of coreless dislocations have been reported in SiC and GaN; an example is shown in Figure 12.27; in each case, the dislocation is a growth defect, not a deformation defect. Coreless dislocations can, in principle, also occur in materials that are not ceramics; but observations of dislocations in metals tend to concentrate on deformation where such cores are unlikely to occur.

Dislocations can also act as sites for local amorphization of a ceramic because the bonds are already distorted at the core. This is a case of a phase transformation being initiated at a dislocation. An example of this occurring in quartz during electron irradiation is shown in Figure 12.28. The dislocation appears to become much broader, but it actually becomes a tube of amorphous material (not unrelated to the coreless dislocation). It would be very difficult for such a dislocation to move as the core would need to recrystallize.

Dislocations also form when we indent ceramics and are particularly important for nano-indentation studies (Figure 12.25). The reason cracking during indentation is different is that the sample is much more constrained. Cracks also form under the indenter tip itself and may dominate as the process continues; but to see the crack you usually remove the load, which allows it to heal. We can actually use indentation techniques to study the nucleation of dislocations. Again, in the nano-regime we have the additional advantage that computer modeling can be used for samples of similar dimensions. Scratching is essentially a moving indentation test but is not as well controlled; in ceramics, it's the basis of the Mohs test. As shown in Figure 12.26, dislocations are emitted from the region under the indenter and, for low-temperature tests, tend to move out on glide planes (because there are no mobile point defects). This deformation thus provides a method for studying the movement of dislocations in ceramics at room temperature.

FIGURE 12.28. TEM shows amorphization of a dislocation core in quartz.

CHAPTER SUMMARY

Dislocations are often most important in ceramic materials for what they don't do: they don't usually move very easily unless the temperature is very high. Dislocations can be used as local probes as when we look at loop annealing to learn about pipe diffusion versus bulk diffusion. It is important that we understand dislocations if we want to understand structured interfaces, whether grain boundaries or phase boundaries, because these often consist of arrays of dislocations (or even dislocated arrays of dislocations). When materials are used for electronic applications, dislocations become quite common because these materials are often produced by

CHAPTER SUMMARY (continued)

epilayer growth. The discovery of the light-emitting properties of GaN suddenly made all the work on dislocations and interfaces in AlN relevant again.

The most important points to remember is that there are two key parameters: the Burgers vector and the line direction. After this, you need the crystal elasticity parameters and the lattice parameters. The rest follows, with the only complications being charge and directional bonding.

PEOPLE AND HISTORY

Burgers, Johannes (Jan) Martinus (1895–1981). The brother of crystallographer W.G. Burgers, he introduced the Burgers vector in 1939. His work was mainly on fluid dynamics.

Frank, Sir Charles (1911–1998) was born in Durban, South Africa (knighted in 1977). He obtained his degrees from the University of Oxford. During WWII he worked for the Chemical Warfare Establishment at Porton Down and then for the scientific intelligence group at the Air Ministry. He moved to Physics at the University of Bristol in 1946; he retired from Bristol in 1976 but remained active and shared a partitioned office with CBC in 1985/1986. In addition to dislocations, his interests included crystal growth, liquid crystals, nuclear physics, and even polymers.

Hooke, Robert (b. 1635 Isle of Wight; d.1703 London). Proposed the elasticity theory. He also coined the term *cell* in his book *Micrographia* (1665) and much more. He feuded with Newton.

Peierls, Sir Rudolf Ernst (1907–1995). Helped a colleague (Orowan) solve some “simple” math. The result is the Peierls valley and the Peierls-Nabarro force. Peierls was also part of the British contingent of the Manhattan Project.

Volterra, Vito (1860–1940). was born in Ancona, Papal States (now Italy). His began working in mathematics at age 11. Doctor of Physics in 1882, then Professor of Mechanics, then Chair of Mathematical all in Pisa. During WWI Volterra was in the Air Force and returned to Rome after the war. He denounced fascism and left Italy to live mainly in Paris. Some say his most famous work was on integral equations.

EXERCISES

- 12.1 What is the shortest perfect-dislocation Burgers vectors in the following materials: (1) CsCl, (2) NiO, (3) fluorite, (4) BaTiO₃, (5) CZ, (6) YAG, (7) -cristobalite, (8) GaAs.
- 12.2 What are the two shortest (crystallographically different) perfect-dislocation Burgers vectors in the following materials: (1) alumina, (2) graphite, (3) MoS₂.
- 12.3 What are the three shortest (crystallographically different) perfect-dislocation Burgers vectors in the following materials: (1) olivine, (3) wurzite, (3) YBCO.
- 12.4 Draw an end-on diagram for a perfect edge dislocation in PbS having a (001) glide plane. Label b and show its direction with an arrow.
- 12.5 Draw an end-on diagram for a perfect edge dislocation in NaCl having a (110) glide plane. Label b and show its direction with an arrow.
- 12.6 Consider a climb-dissociated 1/2 [110] edge dislocation in spinel. Draw a model for the atomistic structure.
- 12.7 How can 1 cm² of MgO have a dislocation density of 10⁶ yet only contain one dislocation?
- 12.8 If 1 cm² of NiO contains one screw dislocation that is 2 cm long, how many distinct planes does the crystal contain?
- 12.9 A jogged edge dislocation in LiF lies parallel to the (110) surface, which is perpendicular to its Burgers vector. The dislocation contains a series of unit jogs, each with the same sign, spaced every 50 nm along its length. A stress is applied that makes the dislocation glide from the center side of a 1-mm cube until it exits the crystal. Assuming that the dislocation initially always lies parallel to the initial surface, estimate the current that flows across the sample.
- 12.10 Examine Figure 12.21. Estimate the stress required to make this mill operate. Explain all the assumptions and deductions you make—there will be many.
- 12.11 Use Figure 12.4 to explain why the strain around a screw dislocation increases with r and why the energy associated with a single screw dislocation in an infinite crystal is infinite.

- 12.12 The box entitled “Dissociation” might suggest that all dislocations would dissociate. Explain why this is always true but usually not true!
- 12.13 Consider Figure 12.7 and the structure of sapphire and thus deduce the Burgers vectors of the two dislocations shown.
- 12.14 Consider Figure 12.9A. Why is this (probably) the only image showing the relation between etch pits and dislocations. Suggest how it could be repeated for Al_2O_3 .
- 12.15 Use Figure 12.10 to explain why a jog on this dislocation is charged and what that charge is.
- 12.16 The cuts in Figure 12.11A make edge dislocations, but they could make 60° dislocations. What is the difference, and why are there four different 60° dislocations in zinc blende?
- 12.17 Figure 12.14 shows dislocations in graphite. How are these diagrams consistent with the fact that graphite has a very strong covalent bond? How is this question related to graphene? How does this observation prove that 3R graphite is not too different in energy from 2H graphite?
- 12.18 Explain the orientation of the crystal in Figure 12.15. Label two independent directions in the figure and identify the glide plane of each dislocation.
- 12.19 The rows of dislocation loops in Figure 12.19 form from dislocation dipoles. Show why this transformation must involve climb. Discuss why the small loops are closer together than the larger loops.
- 12.20 Discuss what type of dislocation could cause the spiral in Figure 12.24. What is its Burgers vector? Why can't you say it is a screw dislocation?

Surfaces, Nanoparticles, and Foams

CHAPTER PREVIEW

This chapter is the first of a three-part series on interfaces. We are dividing the discussion only to make it manageable. An interface is a planar region separating two domains or materials. Hence, we have the definition of a surface as the region that separates a solid or liquid from gas or vacuum. The reason for using the word “region” is to make it clear from the beginning that the surface has a thickness; it is not the mathematical definition. Powder processing is the traditional route for forming ceramics; in powders the ratio of surface area to volume is large. With nanoparticle powders, the ratio can be huge.

We first discuss two important questions concerning surfaces.

- What do we mean by the word surface?
- Why are surfaces so important for ceramics?

We then consider, from several viewpoints, the two most important properties of surfaces.

- The energy associated with a curved surface is greater than that for a flat surface.
- We add material to the bulk solid by attaching it to the surface.

As always, we keep in mind the question: what is special about ceramics?

13.1 BACKGROUND TO SURFACES

A surface is just the interface between a solid (or liquid) and a gas or vacuum. In general, the surface of a material, or any interface between materials, is a region of excess energy relative to the bulk or matrix. To maintain the lowest total energy for the system, the configuration of the surface adapts itself to minimize this excess energy. Impurities or dopants that lower the surface energy tend to concentrate in the surface. Similarly, such *defects* move to the interface if by segregating there they lower the overall energy of the system even if it raises the interfacial energy. The surface tends to orient parallel to certain crystallographic planes that have a lower energy.

The surface energy can be intentionally lowered using a wetting agent or a (liquid or solid) surfactant. For example, the interfacial energy of liquid Ni in contact with Al_2O_3 can be changed by the presence of Ti at the surface. The Ti is strongly attracted to the oxide interface because of its high chemical reactivity with oxygen. This type of interaction is so common that a major problem in studying ceramic surfaces is to know if the surface is clean. During all ceramic processing we can assume that the surface is not perfectly clean.

Throughout our discussion of ceramic surfaces, we are concerned with four interrelated concepts: energy, formation, movement, charge. As usual, only the final one, charge, is particular to ceramics.

- The *energy* of an surface depends on many factors, including the material and structure (crystalline or not) and, if crystalline, the crystallography and plane. We discuss how to measure this parameter.
- *Formation* occurs only if it is energetically favorable. We need to discuss the relevance of Wulff plots to understand surfaces.
- *Movement* can occur if it does not increase the total energy or if it minimizes this increase.
- *Charge* distribution, and thus the bonding, is different at a surface. Charge must influence the value of the surface energy, but it is almost an unknown factor.

Many features of surfaces, and interfaces in general, are similar in all materials.

- A pressure difference is always present across a curved surface (thermodynamics).

- The structure of surfaces can relax from the bulk-terminated configuration (physics).
- Surfaces can be wetted with a thin layer of impurity or a second phase (energetics).
- The ionicity or covalency and crystallography can affect surfaces (chemistry).

Surfaces and their interaction with impurities and particles are being extensively modeled using the computer. Some researchers might say that computer modeling may be the only method for studying clean surfaces.

13.2 CERAMIC SURFACES

The surface is particularly important for ceramics because we are often using powders at some stage of processing: the surface area-to-volume ratio is larger for powders than for bulk materials. Many uses of ceramics rely on their inertness or reactivity, but nanoparticles of “inert” ceramics can be very reactive, partly because of this enhanced ratio. Failure of a ceramic usually occurs first at the surface. Catalysis is enabled at the surface. Sintering, perhaps the most important processing route for ceramic materials, is the process of joining two surfaces together. Remember during this discussion that in the thermodynamic analysis of surfaces, surface energy and surface tension are properties of the continuum. Surface tension is usually assumed to be synonymous with surface energy, but this is not necessarily so. We must consider how we relate these continuum parameters to the atomic structure.

- Surface steps: when we need to consider the atomistics. Special surface sites influence the energy of surfaces.
- Composition: is the surface clean? If it is clean, does it have the bulk-terminated structure, or has it relaxed?

What is special about surfaces of ceramics? We have to think about surface structure, otherwise we won’t appreciate what is special.

- The charge and covalent bonds: charge cannot necessarily be redistributed.
- Surface energy tends to be much more dependent on the plane in ceramics.
- These two points are probably not independent.

Because the properties of interfaces vary so much, the morphology of interfaces in real ceramics may be

unusual. Therefore, to answer what is special, we need to summarize the features that are common to all materials first. Then we can ask: what is different in comparison to metals? Ionic materials and covalent materials (e.g., Si, Ge, GaAs) both have local charge variations. The directional bonding of the covalent materials means that they can have “unsatisfied” bonds; they are known as dangling bonds. (We have encountered them before when discussing point defects).

13.3 SURFACE ENERGY

Surface energy is clearly a very important quantity. It is almost never well known if it is *known* at all. There are two important questions that we need to answer about surface energy.

- How do we define the energy of a surface?
- What factors determine the surface energy?

Definition. The easiest way to define surface energy is to start with a liquid (it could, for example, be a molten ceramic) and imagine that it is suspended in a wire frame. One bar of the frame is movable and allows us to increase the surface area by an amount dA . The force that we have to apply must be sufficient to overcome the opposing surface tension, γ . The work done, dw , in increasing the surface area is

$$dw = -\gamma dA \quad (13.1)$$

The term “tension” is a little confusing when we consider solids because it implies that there is an associated stress. With our example of a liquid in a metal frame, we are actually stretching the surface, and the atoms in the liquid are moving from the bulk to the surface to increase the surface area. We could not imagine doing

the same thing with a solid except maybe close to the melting temperature. In solids, we regard γ as the energy required to form the surface. It is important to note that the surface energy is not usually equal to the surface stress—the work required to deform the surface—

though we often assume it is. For a liquid they are equal.

From the combined statement of the first and second laws of thermodynamics, we can write that the change in internal energy, dE , is:

$$dE = TdS - PdV + \gamma dA + \sum \mu_i dn_i \quad (13.2)$$

SURFACES OF MINERALS

Interactions of minerals with the environment are important in decreasing contamination and waste management. This is sometimes referred to as the field of environmental mineralogy. Topics include microbial interactions with minerals, anthropogenic influences, contaminated land and waste management.

TABLE 13.1 Surface Energies of Various Materials in Vacuum or Inert Atmospheres

Material		Temperature (°C)	Energy (mJ/m ²)
Water	Liquid	26	72
Cu	Liquid	1,120	1,270
Ag	Liquid	1,000	920
Alumina	Liquid	2,080	700
Cu	Solid	1,080	1,430
Ag	Solid	750	1,140
Alumina	Solid	1,850	905
(100) NaCl	Solid	25	300
MgO	Solid	25	1,000

We can then define the surface energy as:

$$\gamma = \left(\frac{\partial E}{\partial A} \right)_{S,V,n_i} \quad (13.3)$$

A similar expression involving the Gibbs free energy can be written:

$$dG = -SdT + VdP + \gamma dA + \sum \mu_i dn_i \quad (13.4a)$$

The surface energy is written as:

$$\gamma = \left(\frac{\partial G}{\partial A} \right)_{P,T,n_i} \quad (13.4b)$$

Some examples of surface energies are given in Table 13.1. The range of values is quite large. Even if we compare only the values for solids, you can see that, for NaCl, $\gamma = 300 \text{ mJ/m}^2$; it is three times greater for MgO (think about the charge). As a general rule, the surface energy decreases as the temperature increases (Eötvös rule). The surface energy of a liquid is lower than that of the corresponding solid. For example, we can compare values for Al₂O₃:

- Al₂O₃ (solid) $\gamma = 905 \text{ mJ/m}^2$
- Al₂O₃ (liquid) $\gamma = 700 \text{ mJ/m}^2$

In general, you should be very wary when given precise values for surface energies.

13.3.1 Approximation of Surface Energies

The surface energy of a solid depends on the crystal structure and orientation and can be estimated by a simple

calculation. First, we assume that the binding energy of an atom is the result of bonds to its nearest neighbors. The energy, ϵ , of one bond is then

$$\epsilon = \frac{\Delta H_s}{0.5ZN_A} \quad (13.5)$$

ΔH_s is the molar enthalpy of sublimation (the energy to break all the bonds), Z is the coordination number, and N_A is the Avogadro number.

The work, w , required to form a surface—for example, if we cleave a crystal—is going to depend on the number of bonds, x , per atom that we break (so x depends on the cleavage plane).

$$w = \frac{x}{2} \epsilon = \frac{x\Delta H_s}{ZN_A} \quad (13.6)$$

The surface energy, γ , is then

$$\gamma = \frac{x\Delta H_s}{ZN_A} \left(\frac{N}{A} \right) \quad (13.7)$$

The term (N/A) is the number of atoms per unit surface area. You can see from Table 13.1 that this approach gives only a very approximate (but not unreasonable) result, although it looks very precise. The reason is that second-nearest neighbors are not considered in the calculation (these are of course extremely important in ionic crystals), and it is also assumed that the strengths of the remaining surface bonds are the same as the bulk values. The calculation also does not consider charge—an important consideration for ionic ceramics! Estimated values for metals compare much more closely to the experimental values. (The calculation for Cu, for example, is given by Ragone 1995). What calculations using equation

13.7 do show us is that γ varies with crystal structure and surface orientation. The practical application of these differences is evident when we try to etch materials using acids. Different planes etch at different rates.

The chemical etch rates for Ge on the (100), (110), and (111) planes are 1.00, 0.89, and 0.62, respectively.

The implication is that the (100) plane of Ge has a higher energy than either (110) or (111) planes. The importance is that often when we try to etch a semiconductor we want to produce a smooth surface rather than a faceted one—unless we want to make V-MOS devices.

CALCULATING A SURFACE ENERGY

We can estimate the value of γ for the (100) face of NaCl. Take $x = 1$.

$\Delta H_s = 235,000 \text{ J/mol}$ (value for NaCl from Kubaschewski and Alcock 1979).

For NaCl, $Z = 6$.

$$N_A = 6.022 \times 10^{23} \text{ mol}^{-1}$$

$$(N/A) = 1.26 \times 10^{19} \text{ m}^{-2}$$

$$(a_{\text{NaCl}} = 0.5640 \text{ nm})$$

Giving $\gamma = 0.82 \text{ J/m}^2$

13.3.2 Effect of Structure and Orientation

The surface energy, γ , depends on the structure, which depends on the orientation. We have developed two approaches for considering this orientation dependence: the Wulff plot and the inverse Wulff plot.

- The *Wulff plot* draws a graph of γ versus θ . This construction was developed to allow the equilibrium shape of crystals to be determined when the surface energy depends on crystallography.
- The *inverse Wulff plot* shows $1/\gamma$ as a function of θ .

The Wulff plot is the conventional plot for surfaces. An example of such a plot is shown in Figure 13.1. The most important point is that you have cusps in γ versus θ . In ceramics, this certainly occurs; if the energy were isotropic, the Wulff plot would be a circle. What is not certain is how many cusps you have. Note that such γ versus θ plots do not take into account the orientation of the surface plane; that is, having fixed σ , you must still fix \mathbf{n} , the surface normal.

Experimentally, we can determine the equilibrium shapes of crystals by annealing small single-crystal particles at high temperature in an inert atmosphere or by annealing small voids (inverse particles) in a crystal. Figure 13.2 shows an example of a bulk UO_2 sample that has been heat-treated so that the pores achieved a near-equilibrium. The length of the facets in the small void can be used to determine the relative energies of the (100) and (110) planes.

FIGURE 13.2. Faceting of small voids in UO_2 .

13.4 SURFACE STRUCTURE

We illustrate some special surfaces using a series of figures. In continuum models of surfaces, the surface is a smooth curve; at the atomic level, it is always faceted. A terminology for the different surfaces is summarized in Figure 13.3. The surface can form large flat facets (F) that are really facets on two planes separated by a ridge (S) and surfaces that are not atomically smooth at all (K). Beware of the bias that carries over from metals, such as the picture that crystals are built by stacking cubes or that all ions are hard spheres. Ions can relax into the surface (relative to their bulk positions), and this relaxation depends on the crystallography of the surface. The relaxations are also different at steps on the surface.

FIGURE 13.1. Wulff plot looking along the $[1\bar{1}0]$ direction for a face-centered cubic (fcc) crystal.

FIGURE 13.3. Terminology for facets, steps, and kinks on surfaces.

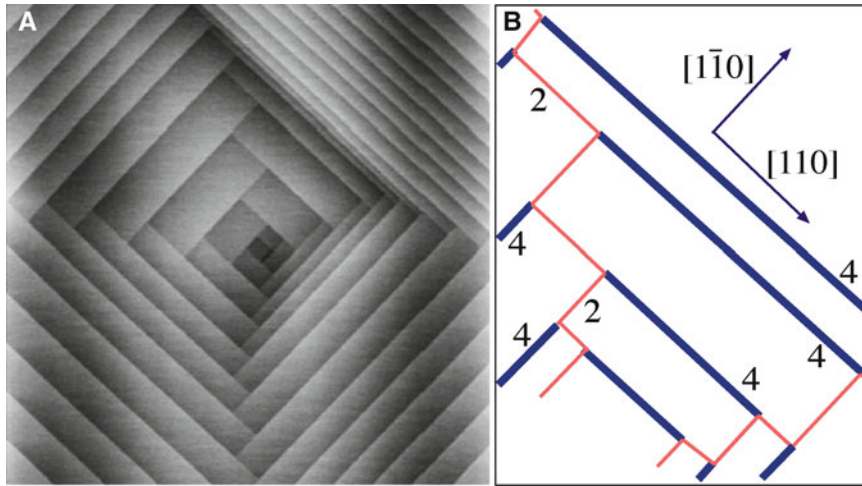

FIGURE 13.4. Faceted shallow thermal etch pit on the (001) surface of spinel. Numbers 2 and 4 refer to the height of the steps (0.2 and 0.4 nm, respectively).

Flat surfaces. The surface of a spinel crystal with an emerging dislocation is shown in Figure 13.4. The reason for choosing this figure is that it shows a ceramic surface that is atomically flat parallel to the step in this figure, for a distance over 10 μm . Step heights can be multiples of a unit value. When the unit cell is large, the definition of an atomically flat surface is less clear. For example, the surface of a zeolite is important in processing, but the surface and near-surface pores are connected: the surface area is much greater than the geometric area of the surface. (Remember the idea of the Mobius strip!)

Rumpled surfaces. The term *rumpled* refers to the local undulations on the surface. The rumpled surface is *crystallographically* flat, but local displacement of the ions means that it is not *geometrically* flat. The difference between relaxation and rumpling is that relaxation refers to the average change in the spacing of the plane nearest to the surface and the second plane when compared to the bulk value. Rumpling, on the other hand, refers to the displacement of the cation layer relative to the anion layer in a direction normal to the surface.

If an initially flat surface is not in its lowest-energy configuration, it *facets* when heated to a high enough temperature. You can envision how this process can occur by considering Figure 13.5. The surface is initially flat; if no extra material is added, a trench must form if a ridge forms. Facet growth thus involves surface diffusion normal to the *geometric* surface.

We might say that the surfaces of *nanoparticles* are their most important feature because they determine all of their properties. As is clear from Figure 13.6, the facet junctions on nanoparticles are also much more prominent.

The *chemistry* of surfaces can be very different from the bulk material. Clearly, the bonding is different on the surface. On oxides, in particular, OH groups may be present even if you think the environment is dry. Detecting hydrogen in or on a material is tricky. Such hydrated surfaces behave differently, and the surface energy can differ from that of the dry surface.

A VERY IMPORTANT BUT SIMPLE CALCULATION

The pressure in the void must do work to change the surface area. The equilibrium condition is then given by the energy balance.

$$\Delta P dv + \gamma dA = 0$$

For simplicity, assume that the void is a sphere (in using one value for γ , we've already assumed that the energy is isotropic). We know dv and dA in terms of r .

$$dv = 4\pi r^2 dr$$

$$dA = 8\pi r dr$$

Combining these three equations gives

$$\Delta P = \gamma \frac{8\pi r}{4\pi r^2} \left(\frac{dr}{dr} \right) = \gamma \frac{2}{r} = \frac{2\gamma}{r}$$

A surface will have two principal curvatures, r_1 and r_2 (which can either be positive or negative); we write

$$\Delta P = \gamma \left(\frac{1}{r_1} + \frac{1}{r_2} \right)$$

One special feature of ceramic surfaces is the result of covalent and ionic bonding. Ceramics have charges and charge dipoles. These charges are often uncompensated at the surface, at least on the short range, as illustrated in Figure 13.7.

13.5 CURVED SURFACES AND PRESSURE

The idea for curved surfaces and pressure is the same as we discussed for the bowed dislocation but we've added a dimension. If we reduce the area of the surface, we lower

FIGURE 13.5. Initiation of faceting on the m-plane of sapphire.

FIGURE 13.6. Fraction of atoms sitting at the surface of a nanoparticle. (A) There are 10 atoms, all on the surface. (B) There are 92 atoms, with 74 on surfaces (80%). (C) There are 792 atoms, with 394 on the surface (50%). (D) High-resolution transmission electron microscopy (HRTEM) image of a faceted nanoparticle of CdSe.

the energy. Hence, if a surface is curved, we can imagine that there is a force that wants to reduce the area of the surface: the force acts on an area of the surface; and the force divided by area is the pressure. Picture how you can take a small ring, fill

it with a soap film and blow a bubble. The pressure is provided by the air: if you stop blowing, the surface becomes flat again. The analogy is quite close except that the surface energy of the soap film is isotropic (and there are actually two surfaces).

FIGURE 13.7. Relating dangling bonds to the 7×7 reconstruction of the {111} Si surface.

TABLE 13.2 Pressure Due to Surface Curvature for Silica Glass (1,700°C; $\gamma = 300 \text{ mJ/m}^2$)

Sphere diameter (μm)	ΔP MPa	$\frac{P}{P_0}$
0.1	12	1.02
1.0	1.20	1.002
10.0	0.12	1.0002

There is also a torque term in the surface tension, just as there is for curved dislocations, but this term is usually ignored. To make this force more physical to us, we regard this surface energy as a surface tension. The pressure difference across a curved interface is real and occurs in all materials. In small gas-filled voids created by implanting Xe into MgO (or Si or Al), the Xe is crystalline if the void is small enough because the internal pressure is so high. The Xe can interact with other defects just like any small crystal inside a crystalline matrix, unless the defect is a crack! A simple example is calculated in Table 13.2.

The concept of pressure due to surface curvature is very important in ceramics because we often encounter very curved surfaces (e.g., at small grains, voids, or particles, which are present because we start processing with powders). Thus, we can have a large pressure difference that provides a large driving force. If r is ∞ , then r^{-1} and ΔP are zero. The result is that we can think of the pressure above a curved surface as being different from that above a flat surface.

13.6 CAPILLARITY

We discuss wetting shortly, but you are already familiar with the capillarity effect from the traditional mercury-based or spirit-based thermometer. From Figure 13.8 we can obtain the following expression:

FIGURE 13.8. Geometry used to calculate the capillarity equation.

$$\Delta P = \frac{2\gamma}{r} = \gamma \frac{2 \cos \theta}{r} = \rho gh \quad (13.8)$$

$$\gamma = \frac{r \rho gh}{2 \cos \theta} \quad (13.9)$$

The equation $\Delta P = 2\gamma/r$ is very important because it says if $r \neq \infty$, then $\Delta P \neq 0$. The vapor pressure above a curved surface is not the same as above a flat surface due to ΔP .

$$V \Delta P = RT \ln \frac{P}{P_0} = V \gamma \left(\frac{1}{r_1} + \frac{1}{r_2} \right) \quad (13.10)$$

where V is the molar volume, P is the vapor pressure, P_0 is the vapor pressure over a flat surface, and R is the gas constant.

$$\ln \frac{P}{P_0} = \frac{V \gamma}{RT} \left(\frac{1}{r_1} + \frac{1}{r_2} \right) = \frac{M \gamma}{\rho RT} \left(\frac{1}{r_1} + \frac{1}{r_2} \right) \quad (13.11)$$

where M is the molecular weight, and ρ is the density. When $r_1 = r_2$, equation 13.11 becomes:

$$\ln \frac{P}{P_0} = \frac{V \gamma}{RT} \frac{2}{r} \quad (13.12)$$

From equation 13.12 we can see that:

- The vapor pressure of a spherical particle is a function of its radius.
- The vapor pressure at the surface of a particle is higher if r is small.

We can also show that:

- Small particles or small voids have large surface energies.
- At high temperatures, small particles tend to dissolve as the large particles grow (Ostwald ripening).
- Small particles have lower melting temperatures than large particles.

FIGURE 13.9. Capillarity effect in a silica nano-thermometer. The bar in (A) is 100 nm.

The thermometer shown in Figure 13.9 was made by filling a silica nanotube with In instead of Hg.

13.7 WETTING AND DEWETTING

The concepts of wetting and capillarity were first explained in ~1800; again, history is important in understanding the terminology. If you place drops of water on a really clean glass slide, it remains as a drop on the surface even though it develops a glass/liquid interface. If you add soap to the water, it spreads over the surface; the liquid wets the glass, and the interfacial (contact) area increases. The soap is a surfactant and lowers the energy of the glass–liquid interface. We see later that we can use surfactants to treat ceramics and liquids other than water. An example of this being used commercially for glass surfaces is the development of new auto-windshield coatings.

As usual, ceramics tend to be more complicated: at the higher temperatures encountered when processing ceramics, vaporization can also occur. At these higher temperatures the solid might not be inert, so it may react with the liquid—this is known as reactive wetting. When we talk about wetting or dewetting, it is not necessary that one of the materials is liquid (both, or neither, could be), but we do need mobility (surface diffusion) for the wetting/dewetting layer to be able to move across the surface.

The relationship between surface and interfacial energies determines, to a large extent, the

FIGURE 13.10. Drops on a solid surface, showing wetting, nonwetting, and a real equilibrium (inset).

wetting behavior of a liquid on a solid surface. Later we see that it also determines the phase morphology of mixtures of two or more phases. There are several interfacial tensions, γ , to contend with (they are identified by the subscripts f, s, and v, representing film, substrate, and vapor, respectively).

If we consider the stable configuration of a liquid placed on a solid surface, the equilibrium shape conforms to the minimum total interfacial energy for all the phase boundaries present. If the solid–liquid interfacial energy (γ_{sl}) is high, the liquid tends to form a ball, having the minimum interfacial area, as shown in Figure 13.10 (Hg on a glass slide does this). If the liquid–vapor interfacial energy (γ_{sv}) is very small, the spreading of the liquid depends entirely on the interfacial energy (γ_{sf}), not the converse.

Young’s equation relates the angle between the solid surface and the tangent to the liquid surface at the contact point. (It’s a force balance in the horizontal direction because we assume the surface is not free to move in the vertical direction). This contact angle, θ , may vary between 0° and 180° . This angle specifies the conditions for minimum energy according to the relation:

$$\gamma_{ls} \cos \theta = \gamma_{sv} - \gamma_{sl} \quad (13.13)$$

Therefore, the contact angle θ depends only on the surface properties of the involved materials. The importance of this equation is that it gives a method for comparing interfacial energies. Thomas Young first derived equation 13.13 in 1805 (Young 1805), but often it is also referred to as the Young-Dupré equation (Dupré 1869). Contact angles can be measured experimentally by the sessile drop technique. For studying the wetting of glass on a ceramic or metal surface, a small particle of the glass would be placed on the solid surface inside a tube furnace, one end of which is clear, allowing observation of the droplet (using a telemicroscope) and the contact angle as a function of temperature. Experimentally, it can be difficult to obtain reproducible values for θ . One of the problems is that of macroscopic surface roughness, which can be expressed as:

$$\cos \phi = r \cos \theta \quad (13.14)$$

CONVENTION

The contact angle, θ , is measured “through” the liquid.

LOTUS LEAF

Water “rolls off” the leaf because the surface is rough.

where r is the roughness, ϕ is the observed contact angle, and θ is the true contact angle. The other problem is that of hysteresis: the measured angle θ depends on whether the liquid is advancing or receding.

Table 13.3 shows measured contact angles for several metals and for a basic slag (think of the slag as liquid silicate glass) on MgO single-crystal surfaces (MgO is used as a furnace lining). As noted earlier, the surface energy of solids is dependent on the crystallographic orientation, which is demonstrated by the variation in wetting angle with crystallographic planes for MgO.

Layers of glass can be deposited on polycrystalline substrates and heat-treated. The resulting faceting of the surface can be monitored while varying the annealing temperature, quench rate, etc. The glass/ Al_2O_3 interfacial energy is not isotropic. An important feature of this demonstration is that the glass does affect the faceting behavior of the surface. This wetting of single surfaces by a glass is more complex than the wetting of most solids by a liquid because the glass can be very reactive at the high temperatures where the wetting actually takes place. For example, at $1,600^\circ\text{C}$ a silicate glass can dissolve alumina. The situation is shown experimentally in Figure 13.11 for the (0001) and $\{10\bar{1}0\}$ surfaces: the glass/ Al_2O_3 surface energy is different for different surfaces. How the glass actually dewets the surface depends on the crystal orientation of that surface.

Wetting/dewetting is also a concern for nonoxides (especially when you want to join them to other materials),

and for metal/ceramic interfaces such as the metal/Si, metal/ SiO_2 and metal/ Si_3N_4 interfaces in the electronics industry and systems such as $\text{Al}/\text{Al}_2\text{O}_3$, which is important in protecting metals against corrosion.

13.8 FOAMS

Foams have been known forever and studied for over a century. They are hot topics in coffee shops and cosmology but are not so well known in ceramics. When they are discussed in ceramics, they are not necessarily recognized as such, as is the case with pumice (more in Chapter 21). These cellular ceramics are also referred to as microporous or macroporous ceramics depending on the size of the cells. The common feature of these materials is that they consist of thin membranes of ceramic that enclose pores of various sizes. Thus, they have a large surface and are lightweight, but they still retain many of the properties of the ceramic. They are rigid, can be used to relatively high temperatures, and can be quite inert to chemical reactions.

Many cellular ceramics, such as the foam shown in Figure 13.12, are made using natural materials such as

TABLE 13.3 Measured Contact Angles of Liquids on Single-Crystal MgO

Liquid	Test temp. ($^\circ\text{C}$)	(100)	(110)	(111)
Cu	1,300	106	159	149
Ag	1,300	136	141	147
Co	1,600	114	153	144
Fe	1,600	59	110	90
Basic slag ^a	1,400	9	17	32

^aComposition: 40% SiO_2 , 20% Al_2O_3 , 40% CaO

FIGURE 13.11. Experimental observations of glass droplets on the surface of Al_2O_3 : (A) c-plane. (B) m-plane.

FIGURE 13.12. Surface of foam.

wood (itself a cellular material) as a template. They are biomimetic ceramics—they mimic biological materials (more in Chapter 35.) Rattan cylinders have been infiltrated with Si liquid and zeolites to make a mixed microporous/macroporous ceramic. The rattan stems were first pyrolyzed and then infiltrated with liquid Si to give the Si/SiC matrix. Finally, the internal surfaces were functionalized with a zeolite. The resulting material was tested as a catalyst for *n*-hexane cracking.

The honeycomb of the catalytic converter gives the large surface area to support the catalyst particles and ensures that the gases pass close to these particles. When used as filters, the pore (channel) diameter is engineered to suit the purpose. The synthetic bone needs the pores to encourage the intergrowth of regrowing natural bone; but if the pores are too large, then the ceramic is weakened. One technique used to provide the porous structure and the strength is to use tape casting (more in Chapter 29) to provide layers of material of different pore size, thus producing a graded porous structure.

We see these foam geometries again when we discuss glass films in grain boundaries.

13.9 EPITAXY AND FILM GROWTH

We have two immediate questions.

- What is epitaxy?
- Why discuss it here?

The reason for discussing epitaxy here is that it essentially involves depositing one material onto the surface of another. If the thin layer coating the substrate is stable, then it is wetting the substrate. If the thin layer is aligned crystallographically with respect to the substrate, we say the film is epitactic. In this case, it is likely to wet the substrate—the interfacial energy is relatively low. Most thin films are not epitactic.

Two ancient Greek words $\varepsilon\pi\iota$ (epi—placed or resting upon) and $\tau\alpha\chi\iota\sigma$ (taxis—arrangement) give the root of the modern word *epitaxy*, which describes an important phenomenon exhibited by thin films. Epitaxy refers to the formation of an oriented (single crystal) film on top of a crystalline substrate. Most people say epitaxial, which is grammatically incorrect but now in dictionaries. Epitaxial or epitactic would be the correct adjectives.

We discuss details (matching, chemistry, bonding, lattice matching, misfit dislocations) of such interfaces in Chapter 15 and what it means for them to be incommensurate. We also discuss there the different techniques for analyzing them. For now, we want to consider how the atomistic topography of the substrate surface influences the behavior of the film. Hence, we are concerned with surface steps and how they influence grapho-epitaxy (an alignment of the film

induced by surface topography). To complicate matters further, in ceramics the film and the substrate may be amorphous, polycrystalline, or monocrystalline.

13.10 FILM GROWTH IN 2D: NUCLEATION

During film growth, atoms or molecules in the vapor phase arrive at the substrate, creating aggregates that either grow in size or disintegrate into smaller entities through dissociation processes.

Nucleate the new phase on the substrate: when an atom from the vapor strikes a solid surface, the collision decreases the energy of the atom so that it becomes partially bound to the crystal surface. Thus, any further motion of the atom is restricted to the surface of the substrate. Isolated nuclei are then formed from groups of such atoms coming together by chance through their thermal motion, as shown in Figure 13.13. Of the groups shown in Figure 13.13, a mobile “new” atom is most easily built into the crystal structure at a ledge corner as this atom interacts strongly with three neighboring atoms, and the local surface energy of the surface due to unsaturated surface bonds does not increase. Other convenient positions are sites such as Y, shown in Figure 13.13. In this way, a continuous supply of atoms leads to completion of the entire crystal plane.

Stabilize the nucleus: continuation of the growth process relies on the formation of a new stable nucleus, shown schematically as a thin cylinder. This new nucleus involves an increase in free energy due to the atoms at the edge and a decrease of free energy as the atoms are incorporated in the interior. Thus, the stability of the nucleus depends on the ratio of volume energy to surface energy. Also, there is a critical radius of the nucleus, r_c , such that if $r > r_c$ the nucleus is stable and can grow.

Grow the nuclei: if the lateral growth mechanism is relatively rapid, the rate of formation of the new nuclei on the completed planes is the decisive factor in controlling the overall growth rate.

The free energy change accompanying the formation of an aggregate of mean dimension r is given by

$$\Delta G = a_3 r^3 \Delta G_v + a_1 r^2 \gamma_{vf} + a_2 r^2 \gamma_{fs} - a_2 r^2 \gamma_{sv} \quad (13.15)$$

FIGURE 13.13. Surface attachment sites and the nucleation of thin films in 2D.

In Chapter 15 we consider homogeneous nucleation of a solid in a liquid. Here (using a simple qualitative model) we consider the heterogeneous nucleation of a solid film on a planar substrate.

13.11 FILM GROWTH IN 2D: MECHANISMS

The many observations of film formation have pointed to three basic growth modes that can be distinguished on the basis of equation 13.13 and are illustrated in Figure 13.14. Each mode is named after two scientists who did not necessarily work together.

- Island growth (*Volmer-Weber*). This occurs when the smallest stable clusters nucleate on the substrate surface and then grow in three dimensions to form islands. This happens when atoms or molecules in the deposit are more strongly bound to each other than to the substrate.
- Layer-by-layer growth (*Frank-van der Merwe*). Here the extension of the smallest stable nucleus occurs overwhelmingly in two dimensions, resulting in the formation of planar sheets. In this growth mode, the atoms are more strongly bound to the substrate than to each other. The first complete monolayer is then covered with a somewhat less tightly bound second layer. Provided the decrease in bonding energy is continuous toward the bulk crystal value, the layer growth mode is sustained.
- Layer-plus-island (*Stranski-Krastanow*). This growth mechanism is an intermediate combination of these two modes. In this case, after forming one or more monolayers, subsequent layer growth becomes unfavorable, and islands form. The transition from two- to three-dimensional growth is not completely understood, but any factor that disturbs the monotonic decrease in the binding energy characteristic of layer growth may be the cause.

FIGURE 13.14. Three modes of thin-film growth.

rates, even at low values of supersaturation. This has been associated with growth taking place at steps provided by dislocations intersecting the interface. Such dislocations can provide a self-perpetuating source of steps as molecules are added to the crystal. The emergence point of the dislocation acquires a higher curvature until a steady state is reached in which the form of the spiral remains constant and the whole spiral rotates uniformly around the dislocation. This process was illustrated in Figure 12.25.

ENERGY OF SITES IN FIGURE 13.13

Site	Energy Gain
A	$E_1 + 4E_2$
B	$2E_1 + 6E_2$
C	$3E_1 + 6E_2$

CONTACT ANGLE AND THE MODELS

Island growth: $\theta > 0$

$$\gamma_{sv} < \gamma_{fs} + \gamma_{vf}$$

Layer-by-layer growth: $\theta = 0$. The deposit “wets” the substrate.

$$\gamma_{sv} = \gamma_{fs} + \gamma_{vf}$$

Layer-plus-island growth:

$$\gamma_{sv} > \gamma_{fs} + \gamma_{vf}$$

Growth ledges: experimentally, we know that the growth of crystals from the vapor phase often occurs at measurable

Experiment: start with well defined facets, so you have regions of planar surfaces. Then consider two cases.

Large entropy charge: produces smooth surfaces, faceted interfaces. Examples are growth of silicates from the melt and growth from vapor or dilute solutions.

Small entropy charge: isotropic with many growth sites. An example is the growth of a metal from the melt.

We can consider sites on the growing phase and, in a simple model (shown in Figure 13.13) of counting the nearest neighbors, assign a binding energy to each of these sites. Let E_1 be the energy of attachment at the first nearest neighbor and E_2 for the second-nearest neighbor. Then we can draw up a table for each site. You can

then determine the growth rate per unit area of interface (U), taking ν to be the usual frequency factor and a_0 the distance that the interface moves when an atom is added.

13.12 CHARACTERIZING SURFACES

The techniques for characterizing surfaces are applications or extensions of those discussed in Chapter 10. They basically fall into two groups—direct and indirect (D and I) techniques—and are summarized for surfaces in Table 13.4. Here we emphasize the application of techniques that are particularly important for ceramic surfaces. Each approach provides different information, and none answers all the questions we have. A major difficulty in studying ceramic surfaces is that many do not conduct electricity well. Thus, techniques using electron beams can have limited application. To study surfaces by transmission (TEM) or scanning (SEM) electron microscopy, we may need to coat the sample with C or even Pt to prevent charge building up on the surface and thus deflecting the electron beam. In doing so, we hope we haven't changed the surface, but of course we have.

Rather than just describe each technique, we go through a set of examples to show just what is possible with the different techniques. In each e-beam technique, coating may be necessary. The rule is: try it first, then gradually increase the thickness of the coating. In SEM, for example, lowering the kilovoltage may allow you to avoid coating altogether. Sometimes, single-crystal sapphire can be studied with TEM without coating. This possibility may depend on how clean your microscope is. You can also flash the sample with an electron beam to induce conduction for the short time that you make the observation/measurement.

Scanned probe microscopy is the method of choice for studying surfaces because it gives a direct picture of the surface and can give superb resolution, and can even give spectroscopic information. It is also much quicker, easier and cheaper than TEM.

Figure 13.15. Not only the well known semiconducting ceramics (e.g., Si, Ge, GaAs) but also the less well known but adequately conducting oxides Fe_2O_3 and NiO have been successfully imaged by scanning tunneling microscopy (STM). The main advantage of STM is that it gives better resolution normal to the plane than any other technique. Thus, we can examine the out-of-plane relaxations and rumpling that are so important in determining surface energies.

Figure 13.16. When the ceramic is not conducting, we can use atomic force microscopy (AFM) to examine the surface. The vertical resolution is not quite as good as STM, but the main loss is in the lateral resolution. This is because the geometry of the probe tip influences the image as shown in Figure 13.17. There are variations of AFM, as summarized in Section 10.6, which can give

FIGURE 13.15. STM of a surface of Fe_2O_3 . 1–5 indicate different rows of atoms.

TABLE 13.4 Surface Characterization Techniques

Technique	Example	Special info.	Limitations
AFM	D	Al_2O_3	How smooth?
SEM	D	Fracture	Self-selective

information on the magnetic fields or even the mechanical properties.

In near-field scanning optical microscopy (NSOM), we use photons to image the sample. The lateral resolution is determined by the diameter of the probe rather than by the wavelength of the light. The drawback is that the technique is rather tricky, and light may penetrate under the ceramic surface.

Diffraction techniques are the classic approach and were widely used by surface scientists before the advent of scanned probes.

Figure 13.18. Low-energy electron diffraction (LEED), as its name implies, produces data in the form of a diffraction pattern, which must then be interpreted. Because the energy of the electrons is low, the beam probes only the region closest to the surface. This is the strength of the technique, but it also means that the surface must be absolutely clean. Thus, LEED experiments are carried out in ultra-high vacuum (UHV) chambers under conditions that you never encounter in ceramics processing.

Figure 13.19. Reflection high-energy electron diffraction (RHEED) is the high-energy version of LEED. Because the electron energy is higher, the beam now probes deeper into the sample, but this is partly compensated by the beam being incident on the surface

at a glancing angle. RHEED is particularly valuable during thin-film growth when the fact that it requires only a reasonably good vacuum may not be a disadvantage.

The TEM is used to study surfaces in many ways. Here we emphasize just three imaging techniques, but note that combining diffraction with imaging at near-atomic resolution in the TEM is its unique capability. We should dispel one bias immediately: TEMs can be UHV instruments. Usually, they are not operated as such because they are required to be multiuser facilities, which is usually incompatible with UHV. Therefore, even though you may see surface steps, the TEM sample usually has a layer (intentional or otherwise) of amorphous material on both surfaces. Another myth: TEM samples are so thin they do not represent the bulk. If you need a thick sample, you use a high-voltage machine where an Si TEM sample can be $5\ \mu\text{m}$ thick (but you won't see atoms). Another myth: the area viewed in the TEM is tiny. Wrong—if the sample is prepared using a focused ion beam (FIB) instrument, the thin area can be $>25\ \mu\text{m}^2$, have a uniform thickness, and be taken from a precisely located region of a bulk sample.

Figure 13.20. Plan-view (conventional) TEM (CTEM). The electron beam is approximately normal to the plane of the thin TEM spinel and Al_2O_3 samples (although a sample may subsequently be tilted by as much as 70°).

Figure 13.21. Cross-sectional TEM (XTEM). The sample is prepared as a sandwich, and a thin section is cut to be normal to the median plane. This geometry allows us to see how features change as we move from the bulk toward the surface. It is particularly useful in thin-film growth, where we need to see the surface and how the layers developed.

Figure 13.22. Reflection electron microscopy (REM) is an old technique that was revived in the 1980s but is still not widely used. The sample is essentially bulk material with just one surface viewed. The electrons are diffracted off the surface, as in RHEED (the diffraction pattern looks just like any other RHEED pattern), and are then imaged by the TEM in the usual way. The resolution is about $0.7\ \text{nm}$; chemical analysis can be

FIGURE 13.20. Plan-view TEM images of steps on MgAl_2O_4 and Al_2O_3 . The steps occur when the thickness of the TEM sample changes abruptly.

FIGURE 13.21. Cross-sectional HRTEM image of a surface of Fe_2O_3 .

considered as shown by the $\text{Al}_x\text{Ga}_{1-x}\text{As}/\text{GaAs}$ superlattice in this image; square millimeters of surface can be viewed just by scanning the sample. Notice the foreshortening.

FIGURE 13.22. Reflection electron microscopy (REM) image from GaAs substrate with a $\text{Al}_x\text{Ga}_{1-x}\text{As}/\text{GaAs}$ superlattice. The substrate has cleaved perfectly.

Transmission electron microscopy is a superb tool for examining surfaces of ceramics. One problem is that you always probe two surfaces at once (except with REM).

The SEM is used to study surfaces in many ways. As noted above, diffraction is also possible, and, again, SEMs can be UHV instruments. In fact, this is necessarily the case in electronics-industry semiconductor fabrication plants (FABs).

13.13 STEPS

We saw in Chapter 12 that dislocations move by the movement of jogs or kinks that are themselves defects on the dislocation. When we consider the movement of surfaces at the atomic scale, the surfaces (like dislocations) actually move by the translation of defects along them. The principle surface defects are line defects known as steps, or ledges if they are higher than a few lattice planes, and these in turn translate by kinks moving along them.

We usually assume that steps on ceramic surfaces are quite straight, as shown for spinel in Figure 13.16B, but they can appear to be smoothly curved, as seen in images of steps on the $\{001\}$ surface of MgO . The lowest-energy plane for MgO is the $\{100\}$ plane, which is also the cleavage plane. Some observations suggest that the $\{111\}$ also has low energy, but this surface may be stabilized by water. Steps are also usually multiples of unit cells in height, but those shown in Figure 13.16A are pairs of steps on the basal plane of Al_2O_3 that are only 0.2 nm high.

Steps on MgO , wurtzite, and rutile surfaces are shown in Figure 13.23A–C. The steps on MgO show theoretically predicted displacements at the step. [Because there is a periodic set of steps, this surface could be called the (501) surface.] The special feature of the steps on the wurtzite

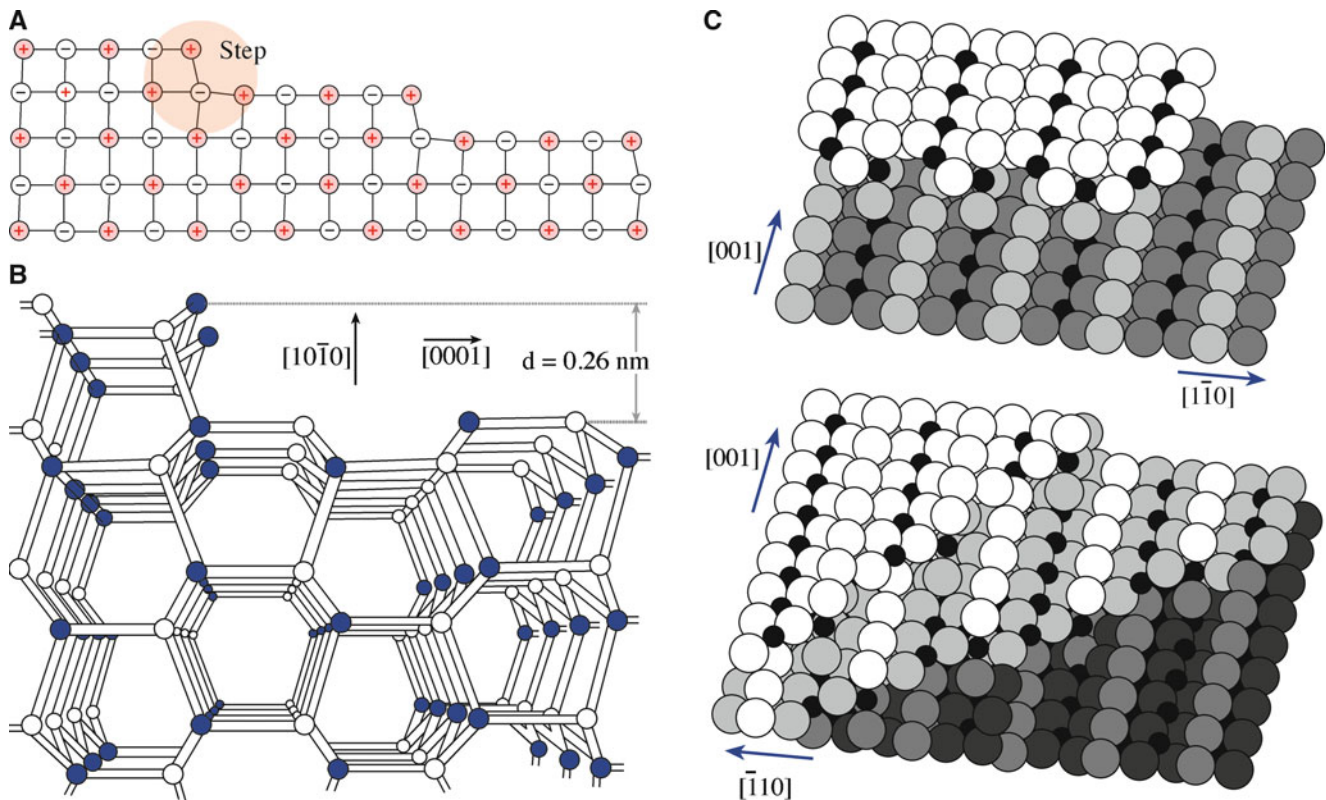

FIGURE 13.23. Representations of surface steps. (A) MgO (100) cross section. (B) Wurtzite. (C) (110) TiO₂.

surface is the presence of dangling bonds, which are localized at the step. The rutile surface shows that even when the surface is modeled using hard spheres the structure of the steps depends on their orientation. [These two vicinal surfaces could be called (223) and (443)].

13.14 IN SITU CONDITION

Many techniques can be adapted to study surfaces in situ at temperature, which is not the case for most other defects because they are not so accessible. The question is: can we learn anything new? The techniques we would most like to use are AFM and STM, neither of which is suitable because the high temperatures quickly change the probe tip. The idea of in situ observation is simply that we do not need to cool the sample to room temperature before examining it, which is a terrific advantage when materials change as we cool them. The problem is that we often cannot control the conditions (e.g., the environment) as well as we would like when making such studies because controlling the environment is often incompatible with the technique we want to use to make the observation/measurement. Electron microscopes operate best in the highest vacuum, and a glass lens placed close to an object at 1,400°C quickly degrades.

Although low-energy electron microscopy (LEEM) currently operates only at ~900°C, it could in principle go higher. LEEM is particularly attractive because it is a

direct imaging technique and gives excellent resolution on the height of the steps. Use of LEEM to study the surface of TiO₂ is illustrated in Figure 13.24. Reflection electron microscopy (REM) should be able to provide similar data. The TEM can provide information on samples at temperatures up to 2,000°C, but the detail tends to become less controllable as the temperature increases. In the image shown in Figure 13.25, a film of NiO has been reduced to Ni metal while heating in the TEM at 1,000°C. New microscope holders and stages are becoming available so we will see much more use of in situ TEM in the future. Most of the work has been carried out using the SEM; environmental SEMs can heat the sample to ~1,500°C, but again the challenge is in controlling the local pO_2 , etc.

13.15 SURFACES AND NANO

Surfaces are generally thought to melt before the bulk. Hence, the melting temperature of small particles is lower than that of the bulk. Such measurements can be made only while the particles are at temperature, so we know this is very difficult experimentally. In comparison, for the computer, it is quite straightforward so long as we can simulate physically meaningful situations. Computer modeling can be used to give clues, as shown in Figure 13.26, which is a case where we are not taking the environment into account. Notice that the surface gradually becomes more rounded starting at the edges.

FIGURE 13.24. Studies of changes occurring at the surface of TiO_2 using low-energy electron microscopy (LEEM). A total of 20 s separates the four images. The different contrast occurs because of the surface reconstruction.

FIGURE 13.25. Changes occurring at a surface studied by in situ TEM. A NiO film had been reduced to Ni, which then dewet the sample and grew on the sapphire substrate.

The shapes shown were calculated using a potential for Au; the graphs are experimental measurements for CdS.

There are examples where the structure of a particular phase appears to be stabilized when in nanoparticle form just as some thin films can have their structure stabilized by being in contact with a substrate. Perhaps the best-known example is that $\gamma\text{-Al}_2\text{O}_3$ appears to be the stable structure at high T when in the form of nanoparticles.

13.16 COMPUTER MODELING

The use of computers to model surfaces and many other aspects of ceramics is a rapidly broadening field where great caution is always needed. Commercial software packages are now available for PCs and supercomputers. The challenge is, now, if a computer analysis is relevant to your research, how can you know if the code was right,

FIGURE 13.26. Nanoparticle melting. (A) Computer modeling for Au. (B) Lattice parameter and melting temperature changes as the size of CdS nanoparticles decreases.

if the program has been applied correctly, if the input data was correctly typed, what potentials were used to describe the ions, etc.? Details such as how the cell was constructed for the calculation are usually given, but it is very easy for these powerful black boxes to produce non-sensical results.

The Madelung problem for surfaces is, in one important way, more complicated than for bulk crystalline materials: a bulk sample must be neutral overall, and the positions of the ions are well defined for each unit cell. At the surface, this is not necessarily the case. MARVIN (the acronym for Minimization And Relaxation of Vacancies and Interstitials for Neutral surfaces program) is one of the best-tested software packages. The essential part of using any software package is that it must be able to reproduce some experimentally determinable facts for the material in

question, which were not used as input to the program! The value of computer modeling is illustrated by a nanoparticle of SrO growing on an MgO substrate in Figure 13.27. Although the two oxides have the same structure, the SrO is slightly misoriented as it grows.

There are three distinctly different ways to terminate a (0001) surface in alumina: a single layer of Al^{3+} ions, a double layer of Al^{3+} ions, or only O^{2-} ions. This basal-plane surface of alumina has a lower energy than the rhombohedral-plane surface because the single outer layer of Al^{3+} ions can relax by moving in toward the bulk. We “know” this from computer modeling. It is very difficult to “observe” the structure experimentally.

Surface Evolver is one of the most fascinating freeware packages available to materials scientists. The program (by Ken Brakker) uses finite-element analysis to

FIGURE 13.27. Computer modeling of oxide clusters on an oxide surface.

compute the morphology of surfaces that are subjected to various forces such as surface tension, interface stress, etc. It runs on most computers, not just the Mac. If you are interested in modeling droplet geometries, for example, this is the program.

Wulffman (NIST) is a software package that allows you to model the Wulff shapes of crystals interactively. You can specify the crystal symmetry. The source for NIST's Wulffman program is available for you to use (www.ctcms.nist.gov/wulffman). There are commercial programs that address the same problem.

13.17 INTRODUCTION TO PROPERTIES

The properties of ceramic surface are so broad and far reaching (as we said in the beginning) that we just give some examples, beginning with the general and becoming more specific, to emphasize this range of topics. The emphasis of this section is to introduce the fundamental ideas so that you can be aware of the possibilities and the pitfalls.

Growth. Thin films are invariably grown on surfaces.

Catalysis. A catalyst is either the surface itself, or it is supported on a surface; usually one or both of these components is a ceramic. Reactions occur at reactive sites, but the principal of catalysis is that the material facilitates, but is not chemically changed by, the process.

Joining. Materials are joined together by contacting two surfaces. In ceramics, the ionic and/or covalent nature

FIGURE 13.28. Self-assembly of Pt nanoparticles due to charging along a surface ridge in Al₂O₃. The particles sit on the ridge, not in the valley!

of the bond tends to make this process more difficult than it is for metals or plastics.

Nanoparticles. The shape of a nanoparticle is determined in part by the surface energies, but the junctions between surfaces—double and triple junctions (i.e., edges and points)—become more important as the size of the particle decreases. We know very little about these surface features.

Voids. We rarely encounter real voids in ceramics except in the computer (they all contain something). They have all the challenges of particles, including the junctions, and can have nano dimensions. Generally, they have not been extensively studied experimentally because they are difficult to see!

Superconductors. The high-T_c superconductors are being used by industry but not to support high-speed trains as some had proposed in the early days. The applications often use thin films for example in superconducting quantum interference devices (SQUIDS) produced by engineering the surfaces to produce particular grain boundaries.

Surface charge. The fact that ceramic surfaces can become charged means that it is possible to align nanoparticles, for example, using this charge. That this can be achieved is illustrated in Figure 13.28 for Pt particles on Al₂O₃.

The concluding message is that we can clearly make enormous use of ceramics without understanding surfaces, but if we do understand them then we can start using ceramics to their full potential.

CHAPTER SUMMARY

The two key properties of any surface are that it has an associated energy and it is directly connected to the two media that it separates (e.g., a gas and a crystal). It is difficult to overemphasize the importance of surfaces, especially in ceramics. We can summarize some of the most important results of this chapter quite briefly.

- The energy of crystal surfaces depends on the orientation of the surface.
- There is always a tendency for a curved surface to lower its energy by becoming flat.
- The surface is critical in the growth of thin films.
- Wetting and dewetting describe the addition to or removal of material from, respectively, a surface. The important consideration is why does one, or the other, occur, and how can we make use of it.
- We can explore the surface structure and chemistry of surfaces at the atomic level because they are so accessible, but the problem is keeping them clean. In ceramic processing, surfaces are rarely clean.

In nanotechnology, surfaces become increasingly more important because a greater fraction of the atoms are at the surfaces. In the smallest nanoparticles, all the atoms may be at the surface of the particle. This property is quite closely related to a completely different group of materials, the foams. One difference between these two situations is the local curvature of the surface.

We will see in the following chapters that the surface is also critical when crystal grains join together (e.g., forming grain boundaries by sintering) or are separated (fracturing ceramics). We also mention the role of surfaces in the polishing process.

PEOPLE AND HISTORY

Binnig, Gerd. Born in Frankfurt, Germany in 1947, he joined the IBM research laboratory in Zürich in 1978. With Rohrer, he developed the scanning tunneling microscope for which they shared the 1986 Nobel Prize in Physics.

Rohrer, Heinrich. Born in St. Gallen, Switzerland in 1933. He did his PhD work at ETH (Swiss Federal Institute of Technology) on superconductivity and spent 2 years in postdoctoral studies at Rutgers University in New Jersey. In 1963 he joined the IBM research laboratory.

Young, Thomas. Born in Milverton, Somerset (UK) in 1773, he was a physicist and physician who made contributions in many areas of science. He introduced the modulus of elasticity (known also as Young's modulus) and the equation used to analyze the wetting of surfaces. His work in optics gave us Young's fringes and Young's slit. He was also an Egyptologist who helped decipher the Rosetta Stone. He died in London in 1829 and is buried in Westminster Abbey, where his epitaph states that he was "a man alike eminent in almost every department of human learning."

EXERCISES

- 13.1 A droplet of liquid silver is placed on an MgO substrate. The MgO(s)–Ag(l) interfacial energy is 850 mJ/m^2 . (a) Calculate the contact angle of the Ag droplet. (b) Does the Ag wet the MgO? (c) If not, how might you lower the contact angle?
- 13.2 Repeat question 13.1 for the $\text{Al}_2\text{O}_3(\text{s})/\text{Ag}(\text{l})$ system. The $\text{Al}_2\text{O}_3(\text{s})\text{--Ag}(\text{l})$ system interfacial energy is $1,770 \text{ mJ/m}^2$.
- 13.3 Determine the number of free bonds/ m^2 on the (100), (110), and (111) planes of germanium. The lattice parameter of Ge is 0.5658 nm.
- 13.4 Using equation 13.7, compare the energy of the (110) and (001) surfaces in MgO.
- 13.5 Can you deduce any properties about the materials from the observations and graph in Figure 13.9?
- 13.6 Figure 13.6B indicates that there are 74 surface atoms. How is a surface atom defined in this context?
- 13.7 Estimate the number of atoms in the particle imaged in Figure 13.6.
- 13.8 Rank the following systems in terms of increasing interface energy: $\text{Al}_2\text{O}_3(\text{s})\text{--silicate glaze}(\text{l})$, $\text{Al}_2\text{O}_3(\text{s})\text{--Pb}(\text{l})$, $\text{SiO}_2(\text{glass})\text{--sodium silicate}(\text{l})$, and $\text{SiO}_2(\text{glass})\text{--Cu}(\text{l})$. Discuss how you arrived at your ranking system, and state any assumptions that you make.

- 13.9 You are attempting to grow a copper thin film on MgO. What characterization technique (or techniques) might you use to determine which of the three growth modes shown in Figure 13.14 occur? What growth mechanism would you think would be most likely?
- 13.10 The most useful way to express surface area is in terms of m^2/g . Using these units, what is the surface area of the Pt catalyst particles in Figure 13.28?
- 13.11 How would you experimentally determine the contact angle?
- 13.12 The contact angle of iron on MgO is lower than that of the other metals given in Table 13.3. Does Fe wet MgO? Briefly explain your answer.
- 13.13 What would be the best technique to image a surface similar to that shown in Figure 13.13?
- 13.14 (a) What is the bulk melting temperature of CdS? (b) How much does the melting temperature of CdS decrease when it is in the form of 2 nm diameter nanoparticles? (c) Are there any uses for CdS nanoparticles?
- 13.15 A scanning electron microscope was used to examine the foam in Figure 13.12. Would a visible light (optical) microscope have produced similar images? Briefly explain your answer.
- 13.16 As the surface steps move in Figure 13.20B, what happens to the small dark particles on the surface?
- 13.17 Are the changes in the DPs in Figure 13.18 consistent with the changes in the accelerating voltage?
- 13.18 What is the ratio of the surface energies for the two liquids shown in Figure 13.10?
- 13.19 Discuss the veracity of the following statement: “MCM-41 is a ceramic foam.”
- 13.20 Challenge: are the graph and images in Figure 13.9B what you would expect for this material. (You will want to research the original work).

Interfaces in Polycrystals

CHAPTER PREVIEW

This chapter is part two of the three-part series on interfaces. Crystalline solids usually consist of a large number of randomly oriented grains separated by grain boundaries (GBs). Each grain is a single crystal and contains many of the defects already described.

A GB is defined as the surface between any two grains that have the same crystal structure and composition.

Many GBs, but not all, can be modeled as arrays of dislocations.

The dislocation model can be misleading. The GBs that may be most important in a ceramic may be the ones that do not appear to contain dislocations. Thus, the warning is: we may sometimes concentrate on a particular type of GB just because we can understand that type of GB. Unless we fully understand GBs in ceramics, we can never have a full understanding of what happens during ceramic processing or why ceramics have certain mechanical properties, conductivity (thermal or electrical), etc. GBs become even more important as fine-grained nanostructured ceramics become more available. We also need to understand the junctions formed when three or four grains join: these are known as triple junctions (TJs) and quadruple junctions (QJs), which we might regard as new line and point defects, respectively. We conclude with a discussion of properties, not because they are unimportant (nor because of the bias of the authors). We want to understand GBs so as to explain some properties and to predict others.

14.1 WHAT ARE GRAIN BOUNDARIES?

Grain boundaries are internal interfaces and behave much like external surfaces; but now we have to be concerned with two crystal orientations, not one. Just as for surfaces, we have a pressure difference associated with the GB curvature and a driving force that tends to lead to an overall increase in grain size whenever possible. Grain morphology and GB topology are two aspects of the same topic. It is instructive to think of the model of soap foams: a soap film is flat when in equilibrium, and it has a finite thickness. Three soap films meet along a line—a triple junction. If you blow on a soap film (apply a pressure) it bows out until the “surface tension” balances the applied pressure.

Whenever we join two grains of the same composition and structure, we form a GB. The grains are related to one another by a rotation axis and meet on a plane, which may be curved. The rotation axis

is fixed only for a given boundary and is not unique even for that boundary; there are different ways to form the same GB. We start by considering two identical grains. Fix one grain and rotate the other about any axis. Cut each crystal parallel to a particular flat plane (to keep it simple) in space and join the grains at this plane. This plane is the GB. Then allow the atoms to relax to a low-energy configuration (which may not be the minimum energy).

The conventional approach is to consider four types of GB based on the symmetry operation used to create them: twist, tilt, mixed, twin.

The first two (and hence the third) designations are really helpful only when the misorientation angle is small (low-angle GBs). This description is based on the location of the rotation axis.

TWIST, TILT, TWIN, LOW, HIGH & ‘GENERAL’

Twist	\mathbf{n} normal to plane
Tilt	\mathbf{n} parallel to plane
Twin boundary	Mirror across GB plane
Low-angle GB	$\theta < 10^\circ$ (Low is small!)
High-angle GB	Structured, $\theta > 10^\circ$
General GB	Not a special GB!

- Tilt boundary: rotation axis (\mathbf{n}) in the boundary plane
- Twist boundary: rotation axis normal to the boundary plane

FIGURE 14.1. Two low- Σ grain boundaries (GBs). (A) $\Sigma = 3$. (B) $\Sigma = 5$.

A symmetric twin boundary can also be described as a twist boundary or a tilt boundary. The difference depends on which aspect of the symmetry we think is most important. Not all twin boundaries are parallel to a mirror plane.

There are two well-known models of GBs that were developed primarily from studies of metals by considering the relative misorientation of the adjoining grains. These are the coincidence-site lattice (CSL) theory and the displacement-shift-complete lattice (DSCl). We first define two special quantities, Σ and Γ . Imagine two infinite arrays of lattice points (one array for each crystal): they both run throughout space and have a common origin. For certain orientations, a fraction of the points in each lattice is common to both lattices.

We call this fraction Σ^{-1} . (Then Σ is always an integer). The lattice made up by these points is called the CSL. The CSL is a lattice of common lattice sites, not common atoms.

If you translate one grain relative to the other, Σ is not changed.

14.1.1 The Idea of Σ

It's easiest to understand these concepts by looking at simple illustrations, as shown in Figure 14.1 for both $\Sigma = 3$ (for Al_2O_3) and $\Sigma = 5$ (for MgO). (Look back to Chapter 6 for the crystal structures.) The $\Sigma = 3$ diagram shows two twin-related unit cells with the lattice sites identified. Overlapping these two cells produces the pattern in the shaded box, and you can see that one in three lattice sites are common to the two grains (the ones at the corners of the box). The CSL for $\Sigma = 5$ (just the lattice sites are shown) is also identified in the shaded box. Note that we must take both ions into account when considering the actual structure (see later). Sometimes it appears that the most valuable feature of the CSL model is that it gives a shorthand notation for talking about GBs. Low-angle

boundaries are all $\Sigma = 1$ GBs. Especially in ceramics, not all twin boundaries have $\Sigma = 3$. [$\Sigma = 3$ occurs in face-centered cubic (fcc) crystals because the stacking of close-packed planes is ABCABC so one in three planes are coincident across the twin boundary.] For a particular GB, if we choose any plane, then a certain fraction of points lie on this plane in both lattices. We call this fraction Γ^{-1} . Again, it is easiest to appreciate the meaning of these definitions by studying the examples in the following sections. Γ is not widely used but might be the most important factor; and it reminds you that the different planes may be very different. Γ can equal 1 for the $\Sigma = 3$ GB but could be 3, 9, or greater.

Throughout our discussion of GBs, you should keep in mind that there are many similarities to surfaces.

- There is a *pressure difference* across a curved GB just as there is across a surface.
- Charge affects the structure and chemistry of GBs.
- The structure of a GB determines its properties and behavior.
- GBs can be wetted and dewetted by GB films just as surfaces are by surface films.

Computer modeling of GBs can give considerable insights, but be careful when using older results in the literature. The complexity of ceramics structures and the Madelung problem cause difficulties, and some older simulations may not be reliable—in part because they used too little material in the calculation because of the capabilities of the computers.

We discuss the properties of GBs later, but you should keep in mind some features as we work through the chapter.

- The density of atoms in GBs is less than in the bulk crystal.
- The chemistry of a GB is not the same as the bulk (because the bonding must be different).
- Properties of GBs must differ from those of the bulk.

All GBs have a thickness (just like the soap films), and the GB is not uniform across that thickness. Therefore, GBs are actually volume defects.

14.2 FOR CERAMICS

Ceramics are usually used in a polycrystalline form. GBs in ionic and covalent materials must be better understood to improve the science of processing of many modern ceramic materials; the properties of polycrystalline ceramics depend directly on the geometry and composition of GBs. The types of GBs commonly found in ceramic materials range from situations where the distance between the grains is $\geq 0.1 \mu\text{m}$ —such grains are separated by a second phase

(glass)—to the basal twin boundary in Al_2O_3 , which is atomically abrupt and potentially very clean.

We need to understand how the presence of glass affects GBs in crystalline materials. This glass can be present on the surface of grains or within GBs as an intergranular film (IGF) in single-phase materials or in materials with an intentionally high (or unavoidable) glass content.

The type of GB present in a sintered (or hot-pressed) compact may be significantly influenced by the surface characteristics of individual particles before and during sintering. Obviously, if there is glass on the particle, there is likely to be glass in the GB. We need to understand the behavior of the surface at high temperatures under conditions appropriate to sintering (see Chapter 24). As GBs can be structured or can contain a thin noncrystalline layer, the chemistry of the region close to the GB is important.

Therefore, we start with asking what is special about GBs in ceramics. This is the question we asked about surfaces and dislocations, and the answer is basically the same.

- Ceramics have localized charge or covalent bonds. Dangling bonds exist at GBs.
- There may be large local changes in density at the interface because the bonding is ionic, covalent, or mixed ionic/covalent. Ceramic GBs have a space charge.
- Because the unit cells of all but the simplest binary compounds are large, it is likely (rather than possibly) that a GB with a fixed misorientation angle and interface plane exists in more than one (meta)stable configuration. There would still be only one minimum energy.
- Energy is dependent on the GB plane, just as it is for surfaces. Accordingly, steps and facets (large steps) on these GBs are also important. They are actually necessary for the GB to move.
- Many ceramics are processed in the presence of a second or third phase far away from conditions of thermodynamic equilibrium, and a remnant of this phase may remain at the GB even if it is not the lowest-energy configuration. Impurities segregate to GBs, as illustrated by the X-ray energy dispersive spectroscopy (XEDS) and EELS plots in Figure 14.2.
- There is the problem of specimen preparation for analysis of interfaces in ceramics. In general, we can't prepare a sample without altering the GB in some way.

The extra difficulty is that we may never see a clean GB; and unlike surfaces, we have no way to clean one: ultra-high vacuum (UHV) doesn't help us once the GB is there. What is different in comparison to metals? Metals try to make the density of atoms uniform due to the nature of the electron gas. GBs in ceramics may be much more open. The density of atoms in the GB can be very different from that in the bulk grains.

Is the CSL theory important for ceramics? The CSL theory is relevant only when the adjoining grains are in

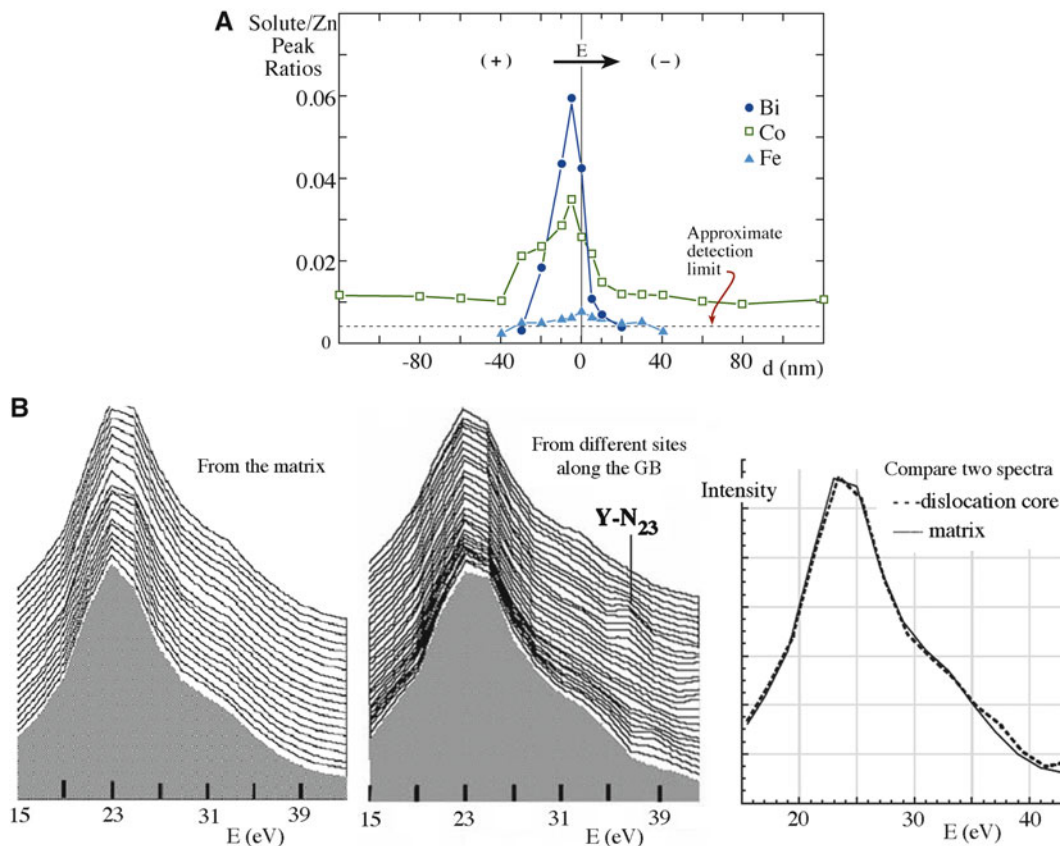

FIGURE 14.2. Solute distribution at GBs. (A) Profiles using X-ray energy dispersive spectroscopy (XEDS). The integrated X-ray solute/Zn peak ratios are plotted against the distance, d , from the GB. (B) Electron energy loss spectroscopy (EELS) spectra used to analyze a GB in sapphire.

direct contact. In ionic materials, we know that surfaces are almost never clean. Adsorption phenomena occur at internal interfaces as they do at surfaces. The driving force for segregation to GBs can be large. In fact, most GBs that have been studied have been “dirty.” Pure polycrystalline ceramic materials do not exist. The layer of glass that may be present at the GB is invariably associated with impurities. Such films are unusual in semiconductors (although they can exist) and would be exceptional in metals.

As with other materials, it is difficult to discuss so-called general GBs rather than special ones. Even special GBs in ceramics are not well understood. Both general and special boundaries are likely to be far less clean than models of such interfaces might lead us to assume. Methods for analyzing interfaces containing IGFs have been compared. It has been concluded that the results can be ambiguous even when a combination of techniques is used. Unambiguous characterization is achieved only when the structure, chemistry, and bonding are assessed simultaneously.

What *facts* are actually known about GBs in ceramics? We can make the following statements.

- *Structured GBs do exist in ceramic materials.* This conclusion applies to both high- and low-angle GBs.

- *GBs in ceramic materials do exist that are not “structured”* but are, instead, wet over their entire area by an amorphous phase (an IGF).
- *The structure of GBs in ceramic materials tends to be relatively more open* (less dense) than is found for interfaces in metals that are otherwise crystallographically similar.
- *The effects of several ions* being present in the unit cell can be recognized. They can produce special interfaces where only one sublattice is affected or can cause a modification of the interface structure itself.
- *A particular interface may not have a unique structure* because of the presence of two ions or because two or more structures are possible that do not have significantly different energies. It is also likely that the presence of impurities at the interface modifies the structure by favoring different polyhedral sites.

14.3 GB ENERGY

The energy of a GB is a very important quantity, but it is even less well known than for surfaces. It is usually determined in relation to surface energies. There are two key questions.

- How do we define the energy of a grain boundary?
- What factor causes a GB to have low interfacial energy?

The GB energy, γ , depends on the misorientation of the two grains and on the orientation of the plane. We can again use the Wulff plot (γ versus θ , where θ now means the misorientation) and the inverse Wulff plot (γ^{-1} versus θ). The challenge of γ versus θ plots is to define the orientation of the GB plane; that is, having fixed θ , you must still fix \mathbf{n} , the GB normal for both grains. Keep in mind that we expect γ to decrease as the temperature increases, as is found for surfaces (Eötvös rule); this dependence on T is important for sintering. One approach to the problem is to plot out the individual Wulff plots for the two separate grains and then to consider what happens when the two grains are joined along a particular plane.

14.3.1 MgO Smoke

One method used to examine the possibility of low-energy GBs is the classic MgO smoke experiment. Mg metal is burned in air, and the resulting MgO smoke particles are caught on a grid. The relative orientations between cube particles can be determined using transmission electron microscopy (TEM). The angles between different $\{001\}$ planes are measured much as Haüy originally did for single crystals; now we do this more accurately using diffraction patterns or high-resolution TEM (HRTEM) images. This experiment is special for ceramics because we are joining nanoparticles at high temperatures although we don't actually know when they joined so we don't know the sintering temperature. Figure 14.3 shows an example of such particles together with the frequency of occurrence, $f(\theta)$, of the misorientation angle. The oxide bicrystal particles form with a strong preference for certain orientations in which the two crystals have a fraction of their lattice sites in common: the coincidence boundaries. This experiment has long been one of the bases for believing that Σ is an important parameter in determining energy of GBs. It doesn't measure γ but does suggest that γ is related to Σ . Unfortunately, results from computer modeling suggest that this is not necessarily the case, but it is such an attractive intuitive concept that it persists.

14.3.2 Energy of Low-Angle GBs

When θ is small, the energy of a low-angle GB is approximated as the total self-energy of the dislocations within a unit area of the boundary. However, as θ increases, the stress fields of the dislocations progressively cancel out, so the energy increases at a decreasing rate and may peak before decreasing to a low value at a special orientation, as shown in Figure 14.4. When the dislocation spacing is small, the dislocation cores overlap, so when θ

FIGURE 14.3. Rotated MgO nanoparticles and their relation to Σ . The frequency of measuring a rotation θ is $f(\theta)$.

exceeds 10° (somewhere in the range of, say, 10 – 16°) it is not possible to identify the individual dislocations.

The Read-Shockley formula for the energy, E , of a low-angle GB considers the stress field and the core energy of the dislocations.

$$E = E_0\theta(A - \ln\theta) \quad (14.1)$$

where E_0 is a constant that is a function of the elastic properties of the material (and hence of the stress field), and A is a constant that depends on core energy (remember our discussion of r_0 , the dislocation core radius).

FIGURE 14.4. Cusp in a plot of GB energy versus the misorientation angle, θ .

We can also define the Gibbs adsorption isotherm for grain boundaries. We extend the analysis from surfaces to the internal interface.

$$\frac{\partial \gamma}{\partial \mu_i} = -\Gamma_i \quad (14.2)$$

where Γ_i is the excess moles of i per unit area of the GB. All the other variables (e.g., P and T) are held constant.

14.4 LOW-ANGLE GBs

Low-angle GBs contain arrays of dislocations. In its simplest form, the structure of the twist boundary consists of two sets of orthogonal screw dislocations, as shown in Figure 14.5A, B; the schematics show the structure before and after relaxation to form the screw dislocations. Figure 14.5C shows how dislocations in a twist boundary might be seen emerging at the surface; you can see that one part of the grain is physically twisted relative to the other because of the screw dislocations. The simplest tilt GBs consist of one set of edge dislocations, as shown in Figure 14.6. Note that the statements both include the word “simplest.” Most tilt boundaries have two different sets of dislocations, and twist boundaries in noncubic materials may be accommodated by only one set of dislocations! Figure 14.6B shows that we must use two sets of edge dislocations if the GB is not symmetric. (We sometimes have to, even if it is symmetric).

Figure 14.7 is a TEM image of a twist boundary in Si; a tilt boundary in NiO is shown in Figure 14.8. The image of this tilt boundary is particularly interesting because it shows that the density is different at the GB.

The spacing of the dislocations, D , is related to the boundary misorientation angle, θ , and the Burgers vector of the dislocations, b .

$$D = \frac{b}{\sin \frac{\theta}{2}} \approx \frac{b}{\theta} \quad (14.3)$$

FIGURE 14.5. Low-angle twist GB. (A) Before and (B) after local atomic relaxations. (C) The twist when the GB emerges at the surface.

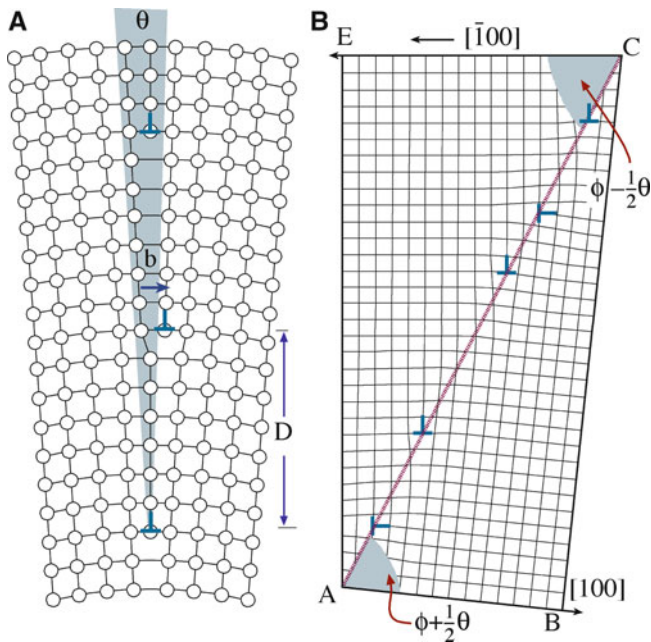

FIGURE 14.6. Low-angle tilt GBs. (A) Symmetric. (B) Asymmetric.

FIGURE 14.7. Two sets of orthogonal screw dislocations in a low-angle (001) twist GB in Si.

The latter relation holds only if θ is very small. In this case, we can reveal the individual dislocations either by decorating them or by etching the surface, as shown in Figure 14.9. Equation 14.3 has been well tested for face-centered cubic (fcc) metals and some simple ceramics.

The structure of dislocations and interfaces in ionic and covalent materials has been the subject of much theoretical and experimental research, motivated in part by the realization that the extensive body of information and concepts that have been accumulated for metallic systems cannot necessarily be directly transferred to these nonmetallic systems.

FIGURE 14.8. Dislocations in a low-angle tilt GB in NiO. The defocus (Δf) images show a change in density at the dislocation cores.

FIGURE 14.9. Seeing low-angle GBs by (A) decoration (silver particles on a GB in KCl) and (B) etch pits (LiF).

The structures of all defects in ceramic materials can be more complex than those of similar defects in the more thoroughly studied pure metals because of the presence of two or more ionic species on two sublattices. The implication of the presence of two types of ions is well known in ceramics as it results in the phenomenon of dissociation by climb of dislocations in the lattice or in the GB. The phenomenon has been recorded for such materials as spinel, Al_2O_3 , and garnet. Actually, this phenomenon can also

FIGURE 14.10. Spinel structure projected along $\langle 1\bar{1}0 \rangle$, summarizing the important crystallographic planes. A and B are parallel but structurally different (111) planes.

occur in more complex metallic, ordered alloys for precisely the same reason. In Al_2O_3 and MgAl_2O_4 , the partial dislocations created by the dissociation process are “perfect” dislocations of the oxygen sublattice; the stacking fault thus formed is therefore only a fault on the cation sublattice.

The effect of the large unit cell is well illustrated by the low-angle 111 twist boundary in MgAl_2O_4 . The (111) interface plane can be chosen as A or B in the schematic of the crystal structure shown in Figure 14.10. In the spinel (111) twist boundary, an $\frac{1}{2}[1\bar{1}0]$ screw dislocation can dissociate on the (111) plane into two parallel $\frac{1}{4}[1\bar{1}0]$ screw partial dislocations (because a is large, and this dissociation produces dislocations that would have been perfect if we considered only the O ions). Because the self-energy of a dislocation is proportional to b^2 , this dissociation halves the total dislocation self-energy. The partial dislocations are separated by a stacking fault (SF) but the energy of this fault depends on whether the glide plane of the plane of the stacking fault is A or B. Thus, there are two different stacking faults on a {111} plane and two different stacking fault energies (SFEs). The consequence of this multiplicity in the value of the SFE is illustrated in Figure 14.11, where the width of the SF takes on two distinct values for both GBs.

MULTIPLICITY

Low-angle and high-angle GBs, twin boundaries that appear to be macroscopically the same can exist with more than one different structures.

Figure 14.12 shows the climb dissociation of edge dislocations in a spinel tilt boundary. (This is just an extension of Figure 12.15.) In Figure 14.13, we can see a so-called extrinsic dislocation (along [100]) interacting

FIGURE 14.11. Low-angle {111} and {001} twist GBs in spinel, showing two structures in each case.

FIGURE 14.12. Low-angle tilt GB in spinel showing an array of climb-dissociated edge dislocations. (A) GB viewed at an angle. (B) Dislocations viewed end-on at higher magnification.

FIGURE 14.13. Extrinsic dislocation interacting with a low-angle {001} twist GB in spinel. Inset: note how all the dislocations are changed by the interaction.

with the screw dislocations that are already present in the interface (to accommodate the twist) in the (001) twist GB.

14.5 HIGH-ANGLE GBs

When θ is $>10^\circ$, the interface is referred to as a high-angle GB. Figures 14.14 and 14.15 show schematics of the $\Sigma = 5$ GB in NiO in the tilt and twist configurations,

FIGURE 14.14. The [001] $\Sigma = 5$ tilt GB in NiO. Only the lower one is actually possible.

FIGURE 14.15. The (001) $\Sigma = 5$ twist GB in NiO showing anions and cations. This structure cannot occur unless some ions are removed.

FIGURE 14.16. High-resolution transmission electron microscopy (HRTEM) images of two high-angle GBs in ZnO. (A) Near-symmetric. (B) Asymmetric.

respectively, and taking into account the presence of two ions. The situation is clearly complex: only the lower structure in Figure 14.14 could exist (the others have similarly charged ions too close together). The same considerations hold for the twist GB shown in Figure 14.15: when two ions of like charge are adjacent, one must be removed. As in the low-angle case, high-angle GBs can exist with more than one structure. Figure 14.16 shows images of two special GBs in ZnO; the difference between a symmetric high-angle GB and the lower-angle asymmetric counterpart is striking; this type of asymmetric faceting often involves low-index planes, as shown here. You can imagine why asymmetric units might be favored after examining Figure 14.17, which shows a schematic of a

GB in Al_2O_3 . Polyhedra that were not present in the perfect crystal in Chapters 6 and 7 can be present at a high-angle GB, and they can accommodate larger impurity ions than can the bulk.

More complex high-angle GBs have been the subject of far fewer studies, in part because of the experimental difficulties in characterizing them. This lack of information is unfortunate as these interfaces are ubiquitous in sintered materials. High-angle GBs formed by hot-pressing together two single crystals of MgO appear to behave as would have been anticipated from studies on the corresponding interfaces in fcc metals and semiconductors. They support the earlier interpretation of experiments on MgO “smoke.” However, such interfaces have been the

subject of extensive computer-modeling studies that often give a contradictory view.

As these observations show, the plane adopted by a high-angle GB is a very important factor. Such GBs in ceramic materials show a particularly strong tendency to facet, so the plane must be important. These facet planes are almost invariably parallel to low-index planes in one or both grains. The basic argument is that low-index planes are the most widely separated planes and thus involve less energy when a “stacking error” is present in the crystal.

A particularly striking illustration that makes us question the importance of Σ as a measure of the energy of a

GB is provided by observations of the $\Sigma = 99$ and $\Sigma = 41$ boundaries in spinel where, by chance, the interface can facet parallel to several pairs of (different) low-index planes in both grains simultaneously. A similar situation exists for phase boundaries. It could be that the faceting onto low-index planes lowers the energy to below that of similar GBs having a lower Σ . There are no atomistic calculations for such GBs.

14.6 TWIN BOUNDARIES

As in metals, twin boundaries are common in many ceramic materials, including MgO, spinel, Al_2O_3 , Fe_2O_3 , the rare earth oxides quartz, and Si, and of course the new high- T_c superconductors. Indeed, it seems certain that such interfaces occur in all crystalline ceramic materials. Some special twin relationships observed in minerals are illustrated in Figure 14.18. The observation of so many twin boundaries is interesting because they are found to facet parallel to low-index planes in at least one grain. We noted that such interfaces can accommodate impurity ions, and this can lead to the phenomenon of chemical twinning, wherein apparently different crystal structures can be related to one another by the periodic repetition of a pair of twin interfaces. This concept can be used to understand the actual mechanism of a phase transformation in a ceramic system.

FIGURE 14.17. GB in Al_2O_3 shows the creation of new polyhedra in the GB. Inset: tilted view of the repeating group of polyhedra.

FIGURE 14.18. Examples of twinned grains found in different minerals. The twin plane is outlined in blue.

14.6.1 Al₂O₃

Several different types of twin boundaries have been seen in Al₂O₃; the basal twin boundary is the $\Sigma = 3$ GB that was discussed in Figure 14.1A. We can form a variety of twin boundaries in Al₂O₃ by mirroring the structure across

FIGURE 14.19. A $(\bar{1}\bar{1}04)$ twin boundary in Al₂O₃. The arrows show the $\langle 0001 \rangle$ directions; the letters show the hexagonal close-packed (hcp) stacking of the anions. The cations are omitted but sit in the octahedral, shown by the shaded rhombi.

low-index planes that are not mirror planes in the perfect crystal; hence, the $(\bar{1}\bar{1}02)$ plane, the $(\bar{1}\bar{1}04)$ plane (illustrated in Figure 14.19), and the $(11\bar{2}3)$ plane all give twin boundaries [as does the (0001) plane, of course]. A rhombohedral twin boundary [the $(10\bar{1}2)$ twin boundary] is shown in Figure 14.20; notice that it is faceted.

THE TWINS

A twin is a grain; a twin boundary is a GB.

14.6.2 Spinel

All interfaces in spinel, even the $\Sigma = 3$, (111) twin boundary, can exist with at least two different structures. In a formal treatment of such interfaces, the different structures considered here can, in principle, be described by choosing different rigid-body translation vectors. However, such translations are not the small relaxations familiar in, for example, the $\{112\}$ lateral twin boundary in Al but are more closely related to stacking faults in fcc metals. The image in Figure 14.21 shows two parallel $\{111\}$ twin boundaries (separated by a microtwin). The translations at the two twin boundaries are different, as you can see in the insets. This translation, which is parallel to the $\{111\}$ plane, is seen because of the location of the cations. As far as the oxygen sublattice is concerned, the twin interface is actually a mirror plane: it's just like the $\{111\}$ twin boundary in fcc Cu.

The lateral $\Sigma = 3$ twin boundary in spinel is also special. The structure of this interface can be entirely described in terms of $\{111\}$ segments (which may have different structures, as noted above) and triangular-prism channels, which lie along $\langle 110 \rangle$ directions and are observed as white spots in high-resolution TEM images. The faceting consists entirely of ordered (aligned) arrays of these prism columns; the interface shown here is actually dislocation-free, although the prisms can be modeled as an

FIGURE 14.20. Rhombohedral twin boundary in Al₂O₃ and its diffraction pattern.

FIGURE 14.21. Two parallel $\{111\} \Sigma = 3$ twin boundaries in spinel having different structures (identified by arrows). Insets: Regions A and B at higher magnification.

FIGURE 14.22. Curved twin boundaries in a thin film of NiO on an Al_2O_3 substrate. (The hexagonal pattern is a moiré interference effect).

array of dislocation dipoles. There was no local strain contrast in the TEM image.

14.6.3 NiO

The images shown in Figure 14.22 are from a thin film of NiO and remind us that GBs that correspond to a special twin orientation are not necessarily flat. In that case, they are probably more similar to other high-angle boundaries. The twin boundaries in the NiO film occur because NiO

FIGURE 14.23. Mimetic twinning in aragonite. This gives rise to trilling twins when the operation is repeated.

can grow on a basal-alumina substrate in two twin-related orientations. We see the twin boundaries because the density is lower at the GB.

14.6.4 Aragonite

An example of how twins can form in a more complex system twins is shown in Figure 14.23 for aragonite. This figure shows the CO_3^{2-} anions as triangles (as we saw in calcite), and the closed circles represent Ca^{2+} ions. (The numbers give the heights of ions in the cells and serve to emphasize the twin symmetry).

14.6.5 Chemical Twins

A special group of closely related oxides is illustrated in Figure 14.24. These oxides consist of blocks of MO_6 octahedra (seen as squares along the cube direction), which can be shifted parallel to certain crystallographic planes (known as shear planes) to produce new structures. The circles are tetrahedral cations. Essentially, the shearing acts to change the chemistry along that plane. *Crystallographic shear planes* are thus like regular stacking faults but the chemistry also changes—they are called *chemical stacking faults*. An example of WO_{3-x} encapsulated in WS_2 is shown in Figure 14.25.

Twin boundaries, like other GBs, can accommodate new ions so that the chemistry changes along the twin plan. A periodic repetition of alternating twin planes, each of which accommodates ordered impurities, can then give rise to a new structure. This process is known as *chemical twinning*. The result for β -alumina is illustrated in

FIGURE 14.24. Shear planes in WO_3 . Dark and light lines are at heights 0 and 0.5.

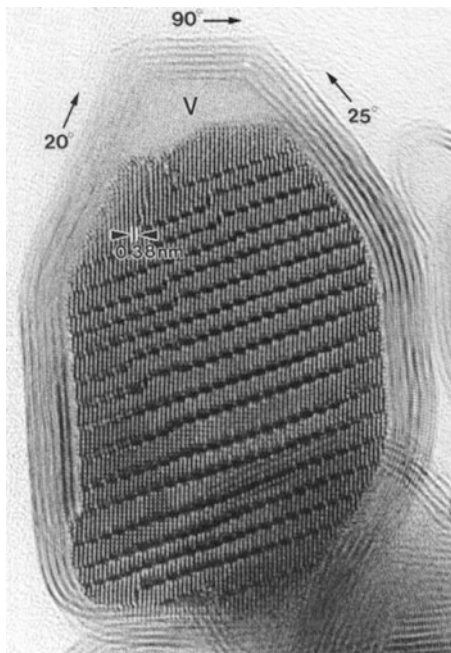

FIGURE 14.25. Defect W oxide encapsulated in a fullerene.

Figure 14.26. Planar defects can readily be incorporated into this structure. This particle of β''' -alumina contains a sheet of spinel; the spinel is like a sheet of a second phase. As we saw in Section 7.12, we can also think of the structure of the β''' - Al_2O_3 as being blocks of spinel that twin on every six $\{111\}$ oxygen planes. The attractive part of this description is that we can then understand the fault in the structure where the twin occurs after only four $\{111\}$ oxygen planes. Remember that the twin planes are not

FIGURE 14.26. Structure of β -alumina as a repetition of chemical twin boundaries. S and F are a block of spinel and a stacking fault, respectively.

actually spinel twin planes because the chemistry is different on the twin plane.

14.7 GENERAL BOUNDARIES

General boundaries may be curved with no specific value of Σ . Can we know if the GB is clean, or what its structure is? We can know if it is not clean and put an upper limit on the impurity content but we still won't know its structure.

The relationship between the physical parameters of any individual interface and the mechanical strength or properties of that interface has not been directly determined for any ceramic material. As with many properties of ceramic materials, measurements on GBs are likely to be controlled by dopants or impurity phases; the latter may be present at the 10% level. Computer modeling is usually carried out for pure materials. Finite element modeling (e.g., used for fracture studies, crack initiation and propagation), generally makes assumptions regarding the elastic parameters that may be very different at an impure interface in comparison to bulk material; the bonding at the interface is different, so the elastic properties must be different too.

14.8 GB FILMS

In Chapter 13, we discussed how a liquid behaves on a solid surface if the solid is not inert. We noted that the situation could change due to evaporation at high temperatures and that the wetting phase need not be a liquid to wet or dewet.

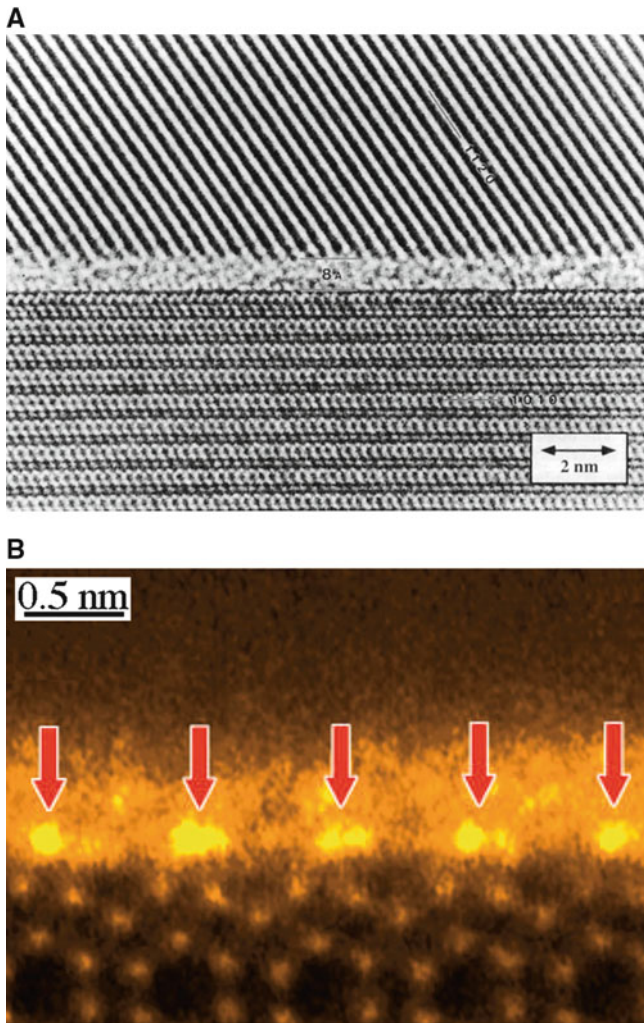

FIGURE 14.27. HRTEM images of intergranular films (IGFs) in Si_3N_4 . (A) Phase contrast image. (B) Z-contrast image showing ordering of rare-earth dopant at the glass/crystal interface.

- GB films are directly analogous to films on surfaces or substrates.
- How thick must a film be before it's a new phase?
- Is a GB containing a film one interface or two?

The simple view of whether a glass film is energetically favorable is that if $2\gamma_{sl} < \gamma_{GB}$ the film is preferred. This statement is too simplistic, in part because GB films are unlikely to be uniform across their thickness. If γ_{sl} is $\sim\gamma_{GB}$, we would expect the GB to be stable; but even in this case the glass must go somewhere.

Any of the four types of GB could contain a GB film. How stable the film would be clearly depends on the energy of the GB with the film versus without it and the availability of a mechanism for removing the film if it would lower the energy.

We know that liquid phases can be very important in polycrystalline ceramic materials. We know that most interfaces in some ceramics (e.g., Si_3N_4) contain a very thin ($\sim 1\text{--}5$ nm) intergranular film (IGF), as illustrated in Figure 14.27A. Thin amorphous layers have been reported to be present in a wide range of ceramic materials (see Table 14.1). It is sometimes incorrectly assumed that all GBs (other than special twin boundaries) in Al_2O_3 contain such a thin amorphous film. In some materials, the same interface may or may not contain an amorphous film, depending on how it was processed.

- Glass is very often present in ceramic materials, whether intentionally included or not. In many oxides, it is present because of impurities in the initial materials used to process the compact. In others, it is intentionally added to lower the processing temperature via the process of liquid-phase sintering.
- The width of glassy GB films can vary from ~ 1 nm to >1 μm .
- The TEM techniques used to identify these films do not always give unambiguous results.
- At high temperatures, the mechanical properties of a ceramic may be drastically lowered if a glass is present. For example, the viscosity of the glass decreases significantly at a relatively low temperature, leading to enhanced creep and related phenomena; remember that the viscosity of soda-lime-silica glass varies from 10^{15} dPa s at 400°C to 10^2 dPa s at $1,300^\circ\text{C}$. At the higher temperature, glass cannot support a shear stress and allows rapid deformation of the material. In other circumstances, the presence of the glass may be beneficial because it may assist in the branching and blunting of cracks by generally weakening grain boundaries.
- It is much easier to process ceramics in the presence of a liquid phase, in part for the same reason—the glass allows deformation at lower temperatures; diffusion is also faster through a glass. The glass thus allows the sample to be shaped and/or densified at lower temperatures.
- The composition of the IGF may vary across its width. In Figure 14.27B, the rare-earth dopant has formed an La-rich monolayer at the glass/crystal interface.

TABLE 14.1 Examples of Intergranular Phases

System	Property affected	Notes
Glass in Si_3N_4	Mechanical	Glass forms from components added as sintering aids and oxide on particle surfaces
Glass films in Al_2O_3	Mechanical	Impurities in the glass can affect its properties
Bismuth oxide in ZnO	Electrical	IGF is key to the operation of varistors
YAG in AlN	Thermal	Y_2O_3 added as sintering aid to allow lower cost production of substrates
Surface contamination	Chemical	Oxidation of SiC can passivate the surface
Clean GB in YBCO	Electrical	GB may not be superconducting; if very thin, they can act as weak links

It is well known that the presence of glass in GBs greatly enhances sintering, in part, because transport of matter along and across the intergranular regions is then even faster than when no glass is present. It is important to realize that the glass does not act simply as a catalyst but also changes the character of the interfacial regions. The glass can dissolve the crystalline grain and reprecipitate it elsewhere. In particular, it tends to encourage faceting of the grains; the scale of this faceting may vary from nanometers to micrometers. After processing, the glass may remain as a thin layer in the interface during preparation of the polycrystalline compact, as was initially demonstrated for Si_3N_4 . The glass may also crystallize to form an intergranular crystalline layer, or it may withdraw from the planar interfaces into three-grain and four-grain junctions (the dewetting process). Even though great care may be taken to ensure that no glass is present during processing, the glass may subsequently enter the interfacial region during processing or service of the component. In either case, the properties of the ceramic may be greatly influenced by the presence of any glass in the grain boundary; a dramatic example is the effect on mechanical properties (e.g., for Si_3N_4 or Al_2O_3), which also aids sintering, although other properties (e.g., the thermal conductivity for AlN) may be just as strongly affected.

Figure 14.28 illustrates another feature associated with glass in crystalline ceramics. The pairs of grains joining at these two boundaries are similarly oriented. Both of the interfaces contain dislocations; that is, they were glass-free after processing. The topology of the two interfaces is, however, clearly different. In Figure 14.28A the interface is wavy, whereas in Figure 14.28B it is flat. The difference can be explained by the processing history; the bicrystal in Figure 14.28B initially contained a layer of glass whereas that

IGFs

A note on very thin films: if a film is ~ 1 nm thick and the system is in equilibrium, then the film may be better described as an adsorbate layer. Experimentally, the challenge is knowing that the system is in equilibrium.

in Figure 14.28A was kept as clean as possible during processing. Hence, the difference in the topography is ascribed to the effect of the glass while it was present in the interface. Clearly this effect can potentially be

very important in understanding such GBs, but it presents a major difficulty as the key component required to explain the structure of the GB had already disappeared before the processed compact could be examined.

Water in silicate GBs can significantly change the mechanical properties of the GB. The GBs really are wet in the everyday sense! The crystal structure of the grains causes ordering in the water and thus changes the viscosity of the water.

The behavior and effects of water in GBs is an important topic in geology. There has been much discussion on the thickness of intergranular glass films. There may be an equilibrium thickness for such films, as has been reported for Si_3N_4 ; but a more common situation is shown in Figure 14.29. This sample was a dense, small-grain, glass-free polycrystal that was intentionally infiltrated with monticellite glass. Here the width of the glass layer clearly varies from boundary to boundary and even along a particular boundary. Nearby boundaries show a layer that is nearly uniformly $2 \mu\text{m}$ wide or that is apparently glass-free at this magnification. This image illustrates an important factor that is often overlooked: most of the glass is contained in triple junctions (TJs) and quadruple junctions (QJs). These junctions serve as “pipes” for transporting the glass. Very little is known of the characteristics of TJs (they are not TEM-friendly) or their role in determining mechanical properties.

Figure 14.30 shows a $\Sigma = 13$ GB in alumina that was processed with an initial layer of anorthite glass that had a uniform thickness of ~ 100 nm. The glass is still present in the interface after processing, but it varies in thickness along its length. Here, the explanation for the thickness

FIGURE 14.28. The same GB in Al_2O_3 processed (A) without glass and (B) with glass.

FIGURE 14.29. Scanning electron microscopy (SEM) image of glass-infiltrated MgO shows glass located at the GB and at triple junctions (TJs), but even in a GB it need not be a uniform layer.

FIGURE 14.30. Intergranular film in Al₂O₃ that was initially uniformly thick but varied in thickness after heat treatment.

variations is clear: the two glass/crystal interfaces facet independently except in the regions (arrowed) where they appear to touch. The controlled preparation of such interfaces is not, in principle, limited to special boundaries because any two such surfaces can be so joined and both the composition and the initial amount of glass can be predetermined and controlled.

Dewetting of GBs has been observed in Si where the glass was the native oxide SiO_x ($x \sim 2$). Figure 14.31 shows TEM images of a $\Sigma = 1$ (low angle) $\langle 110 \rangle$ tilt boundary and a $\Sigma = 5$ (001) twist boundary. In both cases, abrupt changes in contrast can be seen where the glass has dewetted the interface to accumulate in pockets. The pockets actually facet parallel to {001} and {111} planes due to the crystallography of the Si. Thus, even the $\Sigma = 5$ GB can achieve its low-energy structure, including the secondary dislocations, in the presence of a dewetting glass film.

FIGURE 14.31. Dewetting of IGFs in Si GBs. (A) $\Sigma = 1$ {111}. (B) $\Sigma = 5$ {001}.

The possibility of crystallizing intergranular glass layers after processing has been used to modify the mechanical properties of the resulting compact. The yttria-rich glass in polycrystalline Si₃N₄ and monticellite glass in MgO can be crystallized after liquid-phase sintering to change the properties of the polycrystal.

An important remaining question concerns how the presence of the second glass–crystal interface (in a GB) might affect the crystallization process. If topotactic crystallization nucleates at one glass/crystal interface, it is unlikely that the crystallizing glass will form a complex (high-energy) interface when it reaches the adjacent grain. Similarly, if crystallization nucleates at both glass/crystal interfaces, a complex grain boundary, possibly with residual glass, forms when the crystallized glass layers grow together.

14.9 TRIPLE JUNCTIONS AND GB GROOVES

We don't spend much time on TJs because not much is known about them. We can identify three different types of TJ.

FIGURE 14.32. Examples of TJs: (A) Si_3N_4 using TEM. (B) MgO using SEM.

1. One composition: three-grain junctions
2. Two compositions: two phase boundaries plus a GB
3. Three compositions: three phase boundaries

Thus, for example, the groove formed when a GB emerges at a free surface is an example of a two-composition triple junction. Three TJs meet at a QJ. The pockets of second phase at TJs in Figure 14.32 could each be considered as sets of three two-composition TJs. Incidentally, looking at the surface does not give us an unambiguous picture of the dimensions.

A diagram showing how GBs, TJs, and QJs change with changes in wetting behavior is shown in Figure 14.33. Wetting is clearly important when we process ceramics using a liquid phase. For the liquid phase to be effective in densification, we want it to wet the grains: hence $\phi = 0$. However, for optimum properties of the final ceramic, we may not want the grains covered with a second phase. A good example is in AlN ceramics for electronic packaging. The second phase, which almost always has much lower thermal conductivity, should form isolated pockets at the

TJs, leaving a “clean” GB, enabling maximum phonon transport.

A TJ can act like a capillary. The TJ in Figure 14.34 was covered with liquid glass at the processing temperature. When the sample was cooled, the liquid withdrew into the TJ like water escaping a bath (but the physics is different).

14.10 CHARACTERIZING GBs

When studying a GB, we want to know the structure, chemistry, and bonding. How do we characterize a GB? What are the parameters we need? Just to understand the structure, we have to know all the crystallographic parameters, then the chemistry, and then the bonding. No single technique gives us all this information. No ceramic GB has been fully characterized, although we are getting close with a few.

Plane of boundary—Is the GB flat?

Axis of misorientation—The GB is an internal interface, so we need the orientations of both grains.

Atomic structure of boundary—The GB must be flat for HRTEM.

Internal interfaces are fundamentally different from surfaces because of their inaccessibility. The key tool for studying GBs is TEM. This should be obvious from the number of TEM images in this chapter! Although the material must usually be thinned prior to examination by TEM, the area of the GB we do examine is unchanged.

TEM can be used to observe a periodic array of edge dislocations. We use a Burgers circuit to characterize the dislocations.

We can probe a GB by scanning tunneling microscopy (STM) only where the GB intersects the surface. Atomic force microscopy (AFM), on the other hand, is a key tool for characterizing GB grooves.

The specimen-preparation problem for TEM: GBs in ceramics must be considered in terms of both their structure and chemistry (even in so-called pure materials). Because the wetting behavior of a surface may be altered by the doping of the surface layer, it is important to identify and characterize the segregation of impurities and additives to GBs in these materials. The problem here is twofold: the features of the GB (its misorientation and plane) must be identified, and the distribution of “foreign” elements must then be accurately measured. The last part of this process is actually even more difficult than you might expect. The added complexity arises from the methods that are, at present, routinely used to prepare samples of ceramic materials for examination by TEM.

The TEM specimen is usually thinned by ion-milling; crushing fractures the sample along the GBs. This thinning process has been shown to result in cross-contamination of

FIGURE 14.33. Three-dimensional relationships between IGFs, TJs, and QJs as the wetting angle is changed. Lower: a reminder that we usually see sections of these structures.

FIGURE 14.34. Direct evidence for the capillary effect at a TJ. The glass recedes into the TJ on cooling.

the specimen and in the formation of a groove at the interface. The degree of contamination depends on a large number of factors.

The type of oil used in the diffusion pump of the ion-miller. (Old ion-millers may use a silicone-based diffusion pump oil because it is less expensive and more resistant to cracking than are Si-free oils).

The cleanliness of the system used to carbon-coat the thinned TEM specimen is a factor.

The ion-thinning process also preferentially removes the lighter atoms and may deposit what it removes somewhere else on the sample.

FIGURE 14.35. A cautionary tale. The “glass” in the faceted GB is actually material deposited in surface grooves during sample preparation.

Ion thinning can implant Ar into loose, or open, structures (e.g., GBs).

Ion thinning may thus both preferentially thin the GB (forming a groove) and then deposit material in that groove. (Figure 14.35 shows the problem).

It is always best to use bicrystals for model experiments to relate the chemical profile of an interface to its structure because we can then know the initial composition of the GB—but these are not “real” materials.

The principal techniques are:

- Fresnel-fringe technique
- Diffuse-scattering technique
- Direct lattice-fringe imaging where the geometry of the interface is suitable

The diffuse-scattering technique suggests amorphous-film thicknesses, which are 50–100% larger than are found by high-resolution electron microscopy (HREM); that is, at least part of the image obtained from diffusely scattered electrons must be due to factors other than the presence of a thin amorphous film. It is important to use a combination of techniques to characterize, as fully as possible, any given interface. For example, diffuse scattering is very dependent on the specimen preparation techniques. The reasons for using these techniques can be appreciated by noting that the amorphous layer, which may be present at the interface, may be only 1 nm wide. The complexity of image interpretation when examining thin (1 to >5 nm wide) GB films makes computer analysis and simulation necessary. We can use image simulation programs to simulate the formation of Fresnel fringes, taking into account the possibility of GBs grooving at both surfaces.

FIGURE 14.36. Example of GBs in thin films of anorthite on Al_2O_3 . The three grains correspond to three epitaxial orientations, but only one shows the misfit dislocations in this TEM image.

14.11 GBs IN THIN FILMS

Why are we interested in GBs in thin films? Ceramic thin films are becoming increasingly important in the electronics industry for their novel magnetic and electrical properties. Often these films are neither amorphous nor single crystal, so GBs are relevant. There are TJs in the film and at the substrate/film interface (even if the substrate is amorphous). The TJ can form a pit (a three-dimensional groove) at the surface, but it generally doesn't groove at the substrate.

Figure 14.36 is a dark-field TEM image from recrystallized anorthite glass on sapphire. The substrate appears dark, and the anorthite grains have faceted edges. The facets often meet at 60° or 120° angles. The three orientation variants are shown. Two TJs between all three variants can be seen in the image. Variant A contains irregular contrast associated with the interfacial dislocation network; variants B and C show moiré fringes.

14.12 SPACE CHARGE AND CHARGED BOUNDARIES

We introduce this topic now because it shows the fundamental relationship between point defects and interfaces. The concept of a space charge is special for ceramics. Simply put, it is possible for an excess charge of one sign to be present at the interface. This excess charge must be balanced by a space charge farther away from the boundary. There are not many experimental data, but the concept is widely accepted.

Consider NaCl : ions on either sublattice can, in principle, move to a new site on the GB, leaving a vacancy in the lattice.

In general, the energy required to form these point defects at the GB is not the same as it is in the bulk and differs for the two ions. Therefore, we get more of one than the other at the grain boundary. Overall, the crystal is neutral; hence, there must be a space charge in the bulk. Now add CaCl_2 to the NaCl crystal. The impurities (or dopants) give charged point defects.

We are adding the positively charge Ca^{2+} ion and thus increasing the concentration of vacancies on the Na sites. We know that

so adding CaCl_2 to the bulk decreases $[\text{V}_{\text{Cl}}^\bullet]$ in the bulk (because it increases $[\text{V}_{\text{Na}}']$). Because we have increased $[\text{V}_{\text{Na}}']$ in the bulk, $[\text{Na}_{\text{GB}}^\bullet]$ must decrease in the GB, which implies that $[\text{Cl}_{\text{GB}}']$ increases in the GB. Hence, the GB potential is negative. There is a complication: what about $\text{Ca}_{\text{Na}}^\bullet$? What if it all goes to the GB? The radii of the Ca^{2+} and Na^+ ions are about the same (~ 0.1 nm). We don't know the radius of the Ca ion on the Na site. We have also not considered the possibility of forming a defect complex such as $(\text{Ca}_{\text{Na}}^\bullet, \text{V}_{\text{Na}}')$; the binding energy is quite large, ~ 0.4 eV. Therefore, the idea of the GB space charge is important but far from simple, and experimental data are sparse.

14.13 MODELING

The extensive analysis of the structure of GBs in ceramic oxides using computer modeling does not appear yet to explain the experimental observations. One limitation of the modeling approach is that the GB plane is fixed in the calculation. Furthermore, computer modeling of asymmetric interfaces is not routine—constructing the unit cell for asymmetric GBs is difficult. Most of this computer modeling has been directed at understanding the structure of GBs in materials with the rock salt structure. In these materials (primarily NiO and MgO), the oxygen-ion sublattice is in an fcc arrangement, and the cations are located at the octahedral sites. The situation is more complex for most other oxides when different interstices are occupied. As you know, in spinel two-thirds of the cations occupy octahedral interstices, and one-third occupy tetrahedral interstices.

We cannot assume that all the ions have found their “ideal” sites in sintered material (e.g., some Al^{3+} ions in MgAl_2O_4 may be on tetrahedral sites). The structure predicted by computer modeling for the $\{112\}$ lateral twin interface in NiO contains a rigid-body translation. Such a translation is not observed experimentally for the same type of interface in spinel, which has the same

oxygen sublattice. It may be that the reason for this difference is that the translation-free configuration is that which is present on a migrating GB, and it becomes “frozen in” when the sample is cooled. The structure predicted by minimum energy calculations is a stationary structure.

The disagreement between experiment and modeling may be due also to the difficulty in preparing ideal clean interfaces in ceramic materials. For example, the $\Sigma = 5$ GB in NiO can be stabilized by adding Schottky defects to the interface (i.e., by decreasing the density at the GB while keeping it “pure.”) Experimental observations do show that the density at interfaces is generally lower than that of the bulk material.

Most programs use a cell that repeats the structure of the GB, and hence most calculations have been carried out for low- Σ GBs.

14.14 SOME PROPERTIES

Grain boundaries are everywhere in ceramics. The *formation* of GBs is discussed in Chapter 24 because the GB is the initial product of the sintering process. The *movement* of GBs is a necessary process, allowing grain growth to occur, and is also discussed there. GBs influence the behavior of polycrystalline ceramics—both bulk materials and thin films. We discuss their properties extensively in later chapters. Here, we just list a few examples, so you can see their importance.

Example 1: GBs are probably the most important defect in ceramic superconductors. They can dramatically reduce critical currents (J_c). The idea is that the GB acts as if it's a second phase. This sheet is not a superconductor—it may act like a sheet of insulator inside the superconductor. If the GB is very thin, it is possible to use its weak-link nature to fabricate a Josephson junction. Figure 14.37 is a high-resolution TEM image of a near $\Sigma = 29$ GB in an yttrium barium

FIGURE 14.37. HRTEM image of the 45° GB in yttrium barium copper oxide (YBCO) and the diffraction pattern.

FIGURE 14.38. Modeling IGFs in ZnO varistor materials.

copper oxide (YBCO) thin film. The GB is narrow, abrupt, and faceted. We revisit this topic in Chapter 30.

Example 2: GBs in AlN can reduce the thermal conductivity if they are not clean. Because AlN is difficult to sinter to high density without the use of a liquid phase (the bonding is mainly covalent), the GBs often contain a second phase, which always has lower thermal conductivity (see Chapter 34). Yttria may be added to react with oxide in the GBs to form YAG at the triple junctions—a GB-dewetting process.

Example 3: GBs in ZnO are processed intentionally to include a glass film. This film allows the ceramic to be used as a varistor (voltage-dependent resistor), a device that protects circuits from high-voltage spikes (see Chapter 30). Figure 14.38 illustrates an IGF of varying thickness in ZnO and how this films controls the resistance.

Example 4: GBs in Si₃N₄ invariably contain glass films, as shown earlier. At high temperatures, they can lose their mechanical strength when the films soften (see Chapter 18).

Example 5: GBs in magnetic ferrites affect the initial permeability, μ . The permeability of Mn-Zn ferrite increases from about 0.8×10^{-3} up to 3.5×10^{-3} when the grain size is increased from 5 to 15 μm (see

Chapter 33). Although porosity has a role, it has been determined that grain size is more important.

Example 6: GBs affect the scattering of light in transparent materials. Light scattering is greatest when the grain size is close to the wavelength. In addition, IGFs produce a change in refractive index as light passes through a material (see Chapter 32).

In metals, GBs control mechanical properties when the grain size is small, as seen from the Hall–Petch equation.

$$\sigma_y = \sigma_0 + \frac{B}{d^{\frac{1}{2}}} \quad (14.9)$$

The yield strength (σ_y) is expressed in terms of the yield stress, σ_0 (σ_0 is related to the intrinsic stress, σ_i , resisting dislocation motion), and the grain size, d . When this relationship was deduced, it applied to a situation where the grains deformed by plastic deformation and the GBs acted as barriers to dislocation motion. This model is unlikely to be valid in general for ceramics because deformation by dislocation glide is not common. However, the relationship between d and σ_y does hold, as we saw for polycrystalline MgO in Figure 1.2.

CHAPTER SUMMARY

Grain boundaries in ceramic materials are important in almost all applications of these materials because ceramics are usually polycrystalline. GBs have a thickness—we can think of them as thin films even if they are structured. This means that a polycrystalline material is really a composite one. An added difficulty is that essentially every GB “film” is different, but we can think of an *average* GB, which is especially good if there actually is an amorphous film (IGF) at the interface. The most important point to remember is the relationship between GB energy and GB (interface) tension, which includes the idea that there is a pressure difference across a curved GB just as there is across a curved surface. You should be able to define the words twist, tilt, mixed, and twin and understand the concept of Σ (and Γ), how it relates to structure, and why it can be related to GB energy. TJs and the space charge at GBs are very important, but we know little about them. There are two special features for ceramics: the space charge and IGFs. IGFs are special for ceramics because glass is easily formed and maintained, especially when the ceramic contains at least small concentrations of Si.

PEOPLE AND HISTORY

Bollmann, Walter was the pioneer in explaining and popularizing the O-lattice concept. He was an early pioneer of TEM. He died in 2009 at age 88.

Friedel, George was an early contributor to the development of the coincidence-site lattice. Jacques Friedel (Ph.D. from Bristol) is his grandson. The Friedel-Crafts reaction honors George’s father.

Matthews, John. He was best known for his work on misfit, epilayer growth and MgO smoke. His son Dave achieved greater fame.

Mullins, William W. explained and predicted observations on grain boundary grooving. He died in 2002.

EXERCISES

- 14.1 Using the idea of capillarity and relating it to a triple junction, what happens as the temperature increases (so that viscosity decreases)?
- 14.2 Consider a 1-cm cube of a 100% dense ceramic that contains 5% glass that can wet the crystal grains. If the grain size changes from 100 to 10 nm due to heat treatment, how does the distribution of the glass change? Be careful to summarize your assumptions and list as many variables as you can.
- 14.3 Consider two small-angle (2°) tilt grain boundaries in MgO, both having a [001] tilt axis. For one the boundary plane is nearly (100), and for the other it is (110). Discuss the structure of these two grain boundaries.
- 14.4 The structure of the spinel, MgAl_2O_4 , projected onto the (110) plane is shown in Figure 7.1B. Spinel twins on {111} planes. Draw all the different allowed structures for the coherent (IT) plane and discuss which of them is most likely to occur, giving clear reasons. Consider how your analysis might change if the spinel was not equimolar.
- 14.5 If the surface energy for (001) MgO is 1 J/m^2 , what is that in electron volts per oxygen ion on the surface? How does this number compare to the formation energy of the Schottky defect? How would this number be different if the material were NaCl instead of MgO?
- 14.6 Dislocations in a tilt boundary on the (011) plane in silicon lie 200 nm apart. What is the misorientation of the two grains? Would the etch-pit method be a good way to examine this boundary? Explain your answer.
- 14.7 (1) For the TJ shown in Figure 14.34, derive a relationship between GB, SL, and the dihedral angle, θ , which is the angle subtended by the liquid. (2) Assuming that SL is 700 mJ/m^2 , determine GB.
- 14.8 Construct a model for a $\alpha = 7^\circ$ twin boundary in sapphire that is also a tilt boundary with a [0001] rotation axis.
- 14.9 Consider what might happen to the grain boundary charge when MgO is added to Al_2O_3 .
- 14.10 A tilt boundary in olivine lies on the (100) plane with a [001] rotation axis. The dislocations are all the same Burgers vector and are 100 nm apart. What is the rotation angle?
- 14.11 By looking at Figure 14.5B, estimate the maximum twist that could be described by an array of screw dislocations.
- 14.12 By considering Figure 14.6B, show how the dislocation spacing changes when a [001] tilt GB changes from the mean (100) plane to the mean (110) plane.

- 14.13 By referring to the original source of Figure 14.9A, why are we seeing the dislocations? Explain what type of GB we are observing. Justify the assumptions that you make.
- 14.14 Describe the GB plane and the dislocation spacing and character of the GBs in Figure 14.9B. Explain the assumptions that you make.
- 14.15 Propose a model for the dislocation arrangements seen in Figure 14.10.
- 14.16 What are the Burgers vectors of the dislocations shown in Figure 14.12? What are the misorientation angle and the GB plane?
- 14.17 Assuming that the GB in Figure 14.13 is mainly a (100) twist boundary, suggest an explanation for the disruption from a square array of dislocations.
- 14.18 What is the Σ for the GB shown in Figure 14.16? Explain your argument.
- 14.19 Confirm that the GB plane shown in Figure 14.19 is the (1 $\bar{1}$ 04) plane.
- 14.20 If the brighter white dots in Figure 14.26 indicate interfaces, what plane do they lie on in the spinel? Why are they not interfaces in the β -alumina (it's β''').

REFERENCES

GBs have been extensively reviewed in several recent books. These texts cover all crystalline materials but you will still need to go to the original papers to learn more about GBs in ceramics.

Phase Boundaries, Particles, and Pores

CHAPTER PREVIEW

This chapter is both an extension of the chapters on surfaces and grain boundaries (GBs) and essential preparation for those on sintering and phase transformations. The theme of the chapter could be reworded as *interfaces between ceramics and different materials*; the material can be crystalline, amorphous (glassy), liquid, or gaseous (pore). Hence, the topics include three critical areas for ceramics: phase boundaries (PBs), particles, and pores. Examples of PBs include ceramic/metal interfaces, crystal/crystal interfaces, and crystal/glass interfaces. We also include any interfaces that interact with pores, so the topic is a very large and important one. By definition, PBs are the essential feature of composite materials. Solid-state reactions and reactions involving liquids and gases all occur by the movement of these interfaces, but the details of how this motion occurs are often even less well understood than the interfaces themselves.

15.1 THE IMPORTANCE

In ceramic materials, as in other materials systems, interfaces are the most important region of the material because that's where most of the action takes place. PBs are particularly important because they are the interfaces between dissimilar phases.

- Phase transformations take place by the movement of PBs.
- Growing one material on a different material generates a PB (a heterojunction).
- Bonding one material to another generates a PB.
- Most commercial and natural ceramics contain two or more phases and thus many PBs.

15.1.1 Forming PBs: Film Growth

Increasingly, we are growing thin films of ceramic materials on substrates, coating glass, coating metals, etc. A PB separates a ceramic film from the substrate. The behavior and properties of that PB determine the usefulness of the thin film. This is not a new field—the electronics industry has been built on the ability to deposit layers of SiO_2 and Si_3N_4 on Si. The high- T_c superconductors in thin-film form are made this way. GaN is revolutionizing the lighting industry with thin films grown on Al_2O_3 and SiC.

15.1.2 Forming PBs: Processing

We usually process ceramic materials in the solid state (although small amounts of liquid may be present) either to control the grain morphology or because going to the melting temperatures would be too expensive. Particles of different phases join together to form PBs.

15.1.3 Moving PBs

New phases form by a solid-state reaction when ceramic powders are reacted. The new phase grows at the expense of the starting phases: the reaction occurs by PBs moving. We examine these reactions in Chapter 24; here we concentrate on the interfaces themselves.

15.1.4 Properties of PBs

Whether the PBs separate thin films from a substrate or a bulk grain of one composition from one of another composition, the properties of the interface determine the usefulness of the material. There are innumerable examples of why PBs are important to ceramics: seals on Na-vapor lamps are the most likely source of failure; loss of adhesion of thermal barrier coatings (TBCs) leads to failure when the coating separates from the metal; GaAs on Si is not as widely used as was once hoped because the films do not

TABLE 15.1 Examples of PBs in Multiphase Ceramics

PB	Material
Glass/ceramic	Crystallization of a glass to form a glass-ceramic
Fiber composite	Ceramic fiber (e.g., SiC) with metal, ceramic, or polymer matrix
Geomaterial	Granite contains quartz along with other minerals, such as orthoclase and microcline; there are multiple phase boundaries
Cement	A ceramic matrix composite; cement is the matrix, aggregate (sand and small pebbles, or historically pumice) is the reinforcement
Porous ceramic	A very large developing topic (e.g., bioceramics where we want controlled pore size for tissue ingrowth)

align perfectly at the interface and, anyway, they would be unlikely to remain perfect during cooling from the growth temperature.

15.2 DIFFERENT TYPES

Clearly there are many types of PB. We have already considered the solid/vapor, liquid/vapor PB in Chapter 14; we also touched on the solid–liquid PB. Here we discuss the solid/solid PB and use earlier concepts on the solid/gas PB.

We examine two types of particles and the PBs between these and the matrix.

- *Particles* are a distinct second phase. Some could dissolve in the matrix if the temperature were high enough; some may never be able to dissolve until we exceed the melting temperature. They can be equiaxed, platelets or needles. Note that in metals the particles are often precipitates, and the two words are used interchangeably. Particles in ceramic materials are less likely to have formed by precipitation.
- *Pores* are essentially negative particles but with some big differences: (1) there is a gas/solid PB; (2) there are no solid-state reactions at the interface; (3) kinetics of point defect motion are fastest at the surface of the pore (the PB).

The idea of the pore as a particle may seem to be stretching the point at first. We justify including this topic by showing that pores behave like particles and are a major component of many ceramic systems, including composites. Thin interfacial phases can also lie along PBs just as they do along GBs. When the intergranular films at a GB or triple junction becomes thicker than ~10 nm, it is already a second phase, and there are two PBs instead of one GB. We discussed intergranular films (IGFs) in Chapter 14 because the GB is essential to their existence (by definition).

Phase boundaries are everywhere in oxide minerals, so this is an enormously varied topic. We discuss this topic in more detail in Chapter 19.

15.3 COMPARE TO OTHER MATERIALS

How are ceramics different from metals? Metals can be very clean. If particles are wanted, they can often be precipitated by moderate heat treatments. In ceramics, particles are more likely to result from inclusion of insoluble impurities, than from precipitation.

Impurities are common in all ceramics except in pure semiconductors.

Heat treatment may change the oxidation state of the constituent ions.

Alumina with 0.1 mol% impurities would be regarded as being a pure alumina; many commercial aluminas contain less than 98% alumina. In metals, we use precipitates to pin dislocations. In such materials, the aim is to optimize the number and spacing of the particles while controlling the total content. This is not usually done in ceramics—we don't need to pin the dislocations because they're not moving anyway. However, particles in ceramics have become more useful in preventing the movement of cracks—they help toughen the ceramic. We can use ion implantation to harden ceramics (including glass). The process does produce particles but, again, the defects that are impeded are cracks not dislocations. This technique is clearly restricted to the near-surface region.

Historical note. For many years, pores dominated the ceramics literature because of sintering—we wanted to remove them to make dense material. Now we may want to keep them, or we may simply avoid them in the processing route. Intergranular phases are really special for ceramics and can be extremely useful, or disastrous, or both; but they are much more common than in metals. Particles are becoming more than just accidental inclusions present in impure materials as we start to use them in ways that are special for ceramics (e.g., in toughening). The mechanical strength of pores is not great (!), but pores can affect the mechanical properties in different ways. If the pore is small, it actually may be difficult to deform it.

15.4 ENERGY

In the same way that GBs have an associated energy, an interface between two different phases has a PB energy—the energy necessary to form a unit area of new PB. (Two of these PBs were treated in Chapter 13 on surfaces.) This interfacial energy must be less than the sum of the separate surface energies of the two phases, or the two phases do not join.

A low-energy geometry arises by minimizing the surface energy. In general, the interfacial energy between chemically similar phases is low compared with the sum of the surface energies. Thus, liquid metals or oxides on sapphire (or other solid oxides) generally have a small interface energy. The interface energy is also low when there is a strong chemical attraction (i.e., when the two materials are likely to react readily).

Although new approaches have been developed for creating these interfaces, it has always been difficult to control the initial interface. This is an example where the structure is well known, but the energy is usually still a mystery.

15.5 STRUCTURE OF PBs

Phase boundaries can be like GBs where the adjoining two grains may not only be rotated relative to one another but may also (or instead) be structurally and/or chemically different; of course, one or both phases may be a glass, which means the interface is not structured. As with heterojunctions, the word “hetero” is implied when we say “phase boundaries.” Semiconductor heterojunctions are examples of PBs; “heterojunction” usually indicates that we are talking about flat interfaces and thin-film geometry. As is the case with GBs, almost all of the detailed studies have been concerned with “special” PBs. We can summarize this idea and compare some PBs to GBs.

The “ $\Sigma = 1$ ” PB is particularly important because it is often associated with epitaxial growth. NiO grows on MgO with both grains aligned so that corresponding planes and directions in the two crystals are nearly parallel. The difference in lattice parameter (Δa) is accommodated by a square array of misfit dislocations.

When two phases have similar or related structures and are in close alignment, the mismatch due to differences in the lattice parameter may be accommodated by arrays of misfit dislocations. Such dislocations have been extensively studied in semiconductor systems and in some oxide systems. The image of Fe_2O_3 on Al_2O_3 in Figure 15.1 is complex because the $\Sigma = 1$ and the $\Sigma = 3$ interfaces exist side by side (the Fe_2O_3 film contains twin

boundaries). In the $\Sigma = 1$ PB, Δa is accommodated by a hexagonal array of dislocations with Burgers vector $1/3\langle 11\bar{2}0 \rangle$; these are the DSCL vectors for this interface. In the $\Sigma = 3$ PB, the misfit dislocations are $1/3\langle 10\bar{1}0 \rangle$ (so they are closer together and more difficult to image).

The $\Sigma = 3$ PB often occurs in thin-film growth on $\{111\}$ or (0001) substrates: it’s the PB version of the twin boundary.

If the corresponding planes—e.g., in the $(001)_{\text{NiO}}/(001)_{\text{MgO}}$ interface—are rotated about an axis that lies in the plane, then the interfacial dislocations must have a component that is normal to the plane of the interface. Again, this situation has been demonstrated for both semiconductors and oxides. The presence and distribution of these different dislocations have a direct relevance to the movement of any phase boundary and hence to the mechanisms of solid-state reactions because they’re associated with steps in the PB. The latter point is not usually considered when discussing heterojunctions in semiconductor systems because the location of the interface is usually fixed before the growth of the epilayer.

Phase boundaries between ceramic oxides are particularly complex because the structure, the lattice misfit, and the different cations can each be influenced by external conditions, particularly the oxygen activity. The model system $\text{AO}/\text{AB}_2\text{O}_4/\text{B}_2\text{O}_3$ allows all of the above variables to be considered (A: divalent cation; B: trivalent cation). There is an extensive, although by no means complete, database for both the thermodynamic and kinetic aspects of such systems. The growth of spinel into alumina can take place by the movement of interfacial steps rather than dislocations as we see in Chapter 25.

FIGURE 15.1. An Fe_2O_3 film on an Al_2O_3 substrate showing both $\Sigma = 1$ and $\Sigma = 3$ phase boundaries (PBs). The inset shows the hexagonal dislocation network.

FIGURE 15.2. High-resolution transmission electron microscopy (HRTEM) images of two crystallographically different spinel/ Al_2O_3 PBs. White lines show the $\{111\}$ planes in the spinel.

Structurally different variations of the same “chemical” interface can exist, as illustrated in Figure 15.2; new interfaces, such as that in Figure 15.2B, can be thought of as high-angle PBs. This particular PB can also be thought of as a plane-matching boundary, which has been recognized as a special form of GB (see Section 15.14).

At the interface between NiFe_2O_4 and NiO , which is shown in Figure 15.3, the oxygen sublattice is undisturbed by the presence of the interface. The distribution of the cations has changed in a way that is analogous to the stacking fault in spinel in that only the cations are shifted. Because there is actually a lattice-parameter difference, as this particle grows larger dislocations must be nucleated at the interface. The resulting misfit dislocations are illustrated in Figure 15.3B.

Two notes: (1) PBs are more likely to be structured if the particles form by precipitation than if they form by

FIGURE 15.3. Spinel/ NiO PB. (A) HRTEM image of lattice-matched PB. (B) Dislocations present at the interface after relaxation to accommodate lattice misfit. The inset is from the arrowed region.

inclusion during 2-phase sintering. (2) Particles and powders have a common feature—both are contained within another phase.

15.6 PARTICLES

Two particles that are located within the matrix can always lower the total surface energy by coalescing to form a single particle with the same volume but less surface. Questions we ask are: what is the driving force? How long does it take (thermodynamics and kinetics)? What is the influence of crystallinity?

For particles, we need to consider size, shape, and orientation.

The coalescence process is similar to sintering two particles, which we discuss in Chapter 24, and depends on the *size* of the particle. The phenomenon is known as Ostwald ripening—large particles grow, and small particles shrink. The difficulty is that the initial joining of

FIGURE 15.4. Lattice-matched particles of NiO in Ni-Ti spinel. Dark-field TEM image was formed using a spinel reflection (that was not also an NiO reflection).

the particles must involve diffusion through the lattice unless there are defects connecting the particles. Particles of NiO that have grown in Ni titanate spinel are shown in Figure 15.4. The particles have grown following nucleation, but there is a thin layer of spinel separating the particles. This is similar to observations in Ni-based super alloys.

Shape: an example of spinel particles growing in a NiO matrix is given in Figure 15.5. The particles have an interesting shape consisting of six dendrites extending along $\langle 001 \rangle$ directions as they grow. This shape is determined by the soft elastic directions in the matrix and not by the gradients of the diffusing Fe^{3+} , so the shape is determined by the *orientation*. When the same particle is annealed after using all the available Fe^{3+} ions, the shape changes from kinetics-controlled to energy-controlled and becomes the octahedron enclosed by the low-energy $\{111\}$ planes. (More details on internal oxidation and reduction of ceramics are given in Chapter 25).

These processes are similar to those affecting isolated powders. Nanoparticles of inert materials can be extremely reactive because of the driving force for reactions and growth caused by their high surface-to-volume energy ratio.

On low-energy PB: some examples of particles formed by precipitation are summarized in Table 15.2. The particles of $\beta'''\text{-Al}_2\text{O}_3$, which can grow in a relatively pure (99.8%) α -alumina matrix, tend to grow parallel to the basal plane of the $\beta'''\text{-Al}_2\text{O}_3$ no matter what the orientation of the surrounding grain

or grains, as illustrated in Figure 15.6A. Figure 15.6B shows two types of precipitates in a garnet matrix. The large particles of ilmenite are randomly oriented, but the rutile needles are aligned with the matrix. The rutile particles give us the star garnets (e.g., star sapphire but rarer) which we discuss in Chapter 36. The $\beta'''\text{-Al}_2\text{O}_3$ particles have grown as platelets because there is a good lattice match along one plane; the rutile particles are needles because the match is really good only along one direction.

Particles need not be crystalline, as illustrated in Figure 15.7, where a particle of glass has been grown in a thin-film matrix of $\alpha\text{-Al}_2\text{O}_3$. The particle has a shape that is determined by the crystallography of the matrix.

Figure 15.8 shows two examples of precipitate-free zones (PFZs). Figure 15.8A is the classical PFZ at a GB. During cooling from the processing temperature, the Fe^{3+} ions in the doped NiO have segregated to the dislocations in the low-angle GB. Figure 15.8B is a little complex. Here the Fe^{3+} ions have precipitated out onto large NiFe_2O_4 spinel particles that were present at high temperature. As the sample was cooled, the misfit dislocations around these large particles could not move because such movement requires defects on the oxygen sublattice. Hence, the spinel particles grow out between the dislocations—the spinel grows into the NiO.

Finally, you can recognize several triple junctions (TJs) in the images shown in this chapter. For example, the spinel is forming at one TJ in Al_2O_3 in Figure 15.6, and $\beta'''\text{-Al}_2\text{O}_3$ is forming at the other two. Clearly, the new phase is not wetting the Al_2O_3 GB.

15.7 USE OF PARTICLES

What are the properties of particles in ceramics, and can we make use of them? Examples of the uses of ceramic particles in a matrix (rather than as a powder) include the use of glass beads for hardening rubber for tires and adding kaolin to paper to make it smoother and easier to print on. The properties depend not only on the particle but also on the PB that encloses it. Particles are used to seed crystallization and other phase transformations. Hematite particles can be used to seed the growth of $\alpha\text{-Al}_2\text{O}_3$ at temperatures lower than the usual phase transformation so the grain size can be kept small. This is now the basis of the widely used technique of *crystal templating* as illustrated in Figure 15.9. The principle involved is the use of particles for nucleating phase transformations so as to control the grain size during subsequent processing.

In Chapter 26 we use nanoparticles to seed crystallization in glass-ceramics and in other specialty glasses such as Vycor.

PARTICLES IN RELATED FIELDS

You will find many of these processing techniques applied to particles in pharmaceuticals, cosmetics, pigments, paints, etc.

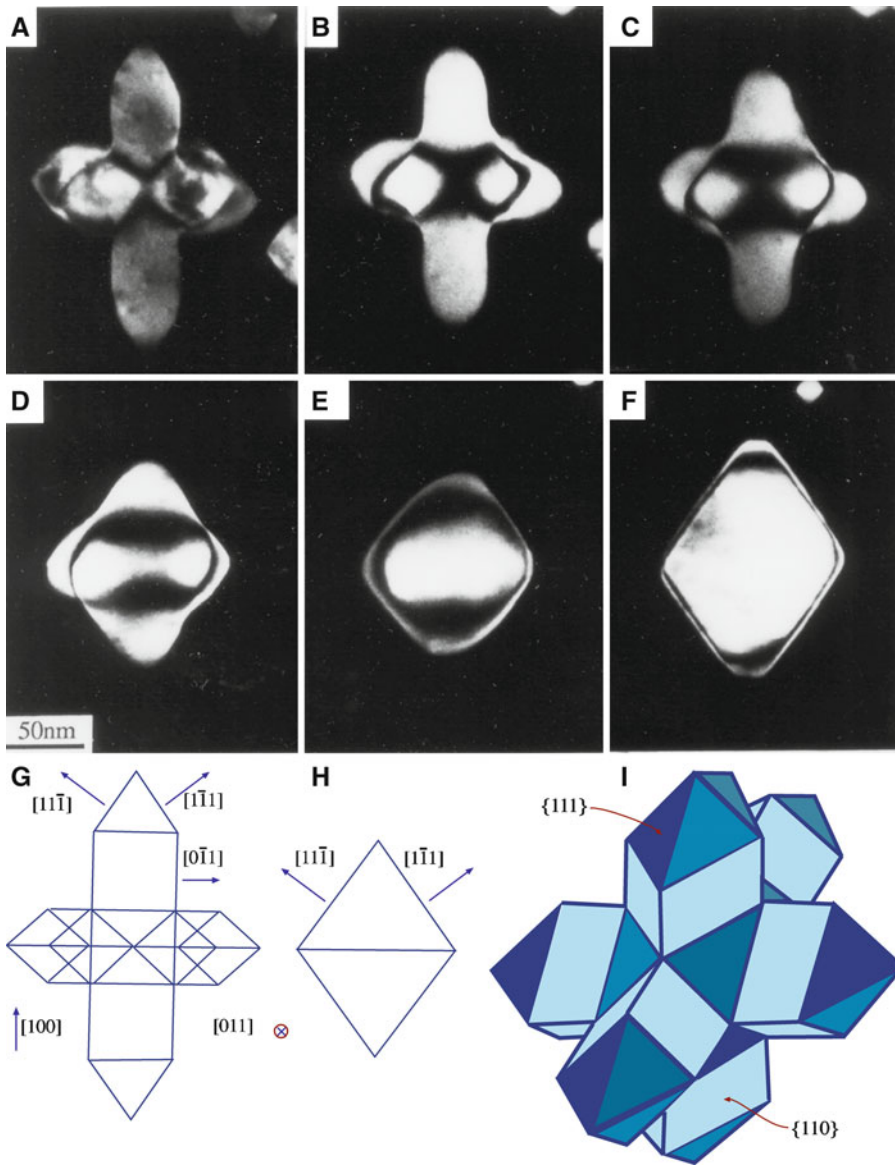

FIGURE 15.5. Spinel particles changing shape in NiO due to heat treatment. (Image formed as for Figure 15.4.) (A) Looking along [011]. Thirty-min heat treatment between images. (B) 800°C. (C) 825°C. (D) 850°C. (E) 875°C. (F) 900°C. The shape change is summarized in the schematics. The three-dimensional figure shows the original shape.

TABLE 15.2 Examples of Particles in Ceramics

Material	Situation
Spinel in NiO	Nucleation and growth
ZrO ₂ in Al ₂ O ₃	Toughening (ZTA)
TiO ₂ in Al ₂ O ₃	Gemstone, star sapphire
Y ₂ O ₃ in AlN	Sink for oxygen, forms garnet (YAG) at the triple junctions
Xe in MgO	Ion implantation; Xe is immiscible with MgO

If a polycrystalline sample of α -Al₂O₃ containing particles of ZrO₂ is heating during consolidation to a temperature where the ZrO₂ is in the tetragonal phase, the matrix can stabilize the high-temperature phase as

the sample is cooled. This is the concept used to toughen α -Al₂O₃, as discussed in Chapter 18.

15.8 NUCLEATION AND GROWTH OF PARTICLES

In metals we often form particles by precipitation from a solid solution as a result of a heat treatment. The particles can adopt different shapes and set up different strain fields in the matrix during cooling. We can follow the same process in ceramics, or we can add particles to the matrix during processing. We actually have an extra variable—we can change the oxygen activity and thus change the oxidation state of an ion. This process is illustrated in Figure 15.5.

FIGURE 15.6. Particle in a matrix. (A) TEM image of a second-phase $\beta\text{-Al}_2\text{O}_3$ growing along a grain boundary (GB) in $\alpha\text{-Al}_2\text{O}_3$. The insets show spinel (S) growing up the GBs. (B) Visible light microscopy (VLM) of rutile needles growing in a garnet grain.

15.8.1 Nucleation

The formation of nuclei requires the formation of an interface between the two phases (e.g., between a liquid and a solid). Thus, the formation of very small particles generally increases the total free energy of the system.

15.8.2 Growth

Once such particles reach a sufficiently large size, the interface energy increase is small compared with the volume energy decrease, so that the total free energy begins to decrease as the particle size increases.

The classic example of precipitate nucleation in metals is the formation of GP zones in Al–Cu alloys. In ceramics, analogous examples include spinel in NiO, rutile in sapphire, and platelets of nitrogen in diamond. When particles are very small, the surface energy dominates. The

NUCLEATION OF A SPHERE

The free energy for a spherical particle depends on the surface area and the volume

$$\Delta G_r = 4\pi r^2 \gamma_{sl} + \frac{4}{3}\pi r^3 \Delta G_v \quad \text{Box 15.1}$$

The two energy terms balance when

$$\frac{\partial(\Delta G_r)}{\partial r} = 0 \quad \text{Box 15.2}$$

The critical particle radius is

$$r^* = -2 \frac{\gamma_{sl}}{\Delta G_v} \quad \text{Box 15.3}$$

The critical value of ΔG^* is then

$$\Delta G^* = \frac{4}{3}\pi r^{*2} \gamma_{sl} = \frac{16}{3}\pi \frac{\gamma_{sl}^3}{\Delta G_v^2} \quad \text{Box 15.4}$$

calculation in equations [Box 15.1–15.4](#) is instructive. Remember that the calculation is for a spherical nucleus, and it ignores kinetics; kinetics are actually important, as we saw in [Figure 15.5](#).

Assuming a spherical nucleus, the total energy required for the formation of a nucleus of radius r is ΔG_r , which is a combination of two terms. The first term relates to the energy required to create the solid/liquid interface; γ_{sl} is the solid/liquid interfacial energy. This term dominates for small particles. The second term relates to the energy liberation associated with the volume change; ΔG_v is the free-energy change per unit volume for the new phase. The second term dominates when the particle size increases, so that once the particles reach some critical size further growth leads to an increasingly lower free energy and hence a more stable system.

We can deduce the size of the particle that has the maximum free energy and that, on further growth, leads to a continuous decrease in free energy by differentiating ΔG_r in [equation Box 15.2](#). The critical value of r is given by [equation Box 15.3](#) and implies that there is a critical value of ΔG^* . When the particles have $r < r^*$, we call them clusters or embryos; nuclei are the stable particles with $r > r^*$.

15.8.3 Heterogeneous Nucleation

If particles nucleate at GBs or at surfaces, they generally require less energy because an interface is already present. This is illustrated in [Figures 15.6A](#) and [15.10](#). The plate of spinel growing along the NiO GB has a topotactic alignment with one grain but not with the other because it is a high-angle GB. The presence of such particles in grain boundaries can change the properties of the material.

FIGURE 15.7. Glass “particles” in a thin film of α - Al_2O_3 , before and after additional heat treatment.

For example, because β''' - Al_2O_3 is a fast ion conductor, such particles in polycrystalline Al_2O_3 provide short-circuit paths for rapid diffusion of Na, which can accelerate the degradation of Na-vapor lighting products.

15.9 PORES

Pores are very important in ceramics, in part because powder processing automatically creates them. The properties of pores are related to the surfaces that define them; but particularly because the surfaces are usually curved, they are not well understood. In ceramics, pores are everywhere and always contain some gas, although for simplicity we often think of them as surfaces enclosing a vacuum. Pores are not as important in metals because they tend to collapse to form dislocation loops unless they contain a gas that cannot dissolve in the metal.

Pores or voids? We generally use the term *pore* because the term *void* suggests that the pore is empty. Most pores in ceramics are created during processing, and most processing does not occur in a vacuum. Hence, in ceramics most pores contain at least some amount of gas.

These volume defects can have very important effects on the properties of crystalline solids and clearly relate closely to Chapter 13. Examples of these defects follow.

- Pores in the matrix: isolated pores and surfaces
- Pores at grain boundaries and other grain junctions

We often start with very porous material so the “concentration of pores” may be large. We extend this

discussion in Chapter 24 (sintering). We may want a porous material (e.g., MCM-41). Pores interact with grain boundaries, phase boundaries, etc.

Does the pore have an equilibrium shape? The shape of the pores is determined by the surface energies. Faceted pores are shown in Figure 15.11. A technique has been developed to study systematically the annealing of pores and the effect of dopants on this process. Channels or pores can be created in a $\Sigma = 1$ or high-angle GB by joining together two flat plates after patterning the surface of one grain using lithography, as illustrated in Figure 15.12. Such pores are formed when two nearly flat plates are joined but are not controlled. The technique has been extensively used to study pore annealing and the effect of dopants on this process in Al_2O_3 but could easily be extended to other materials including glass. (See also the discussion of Figure 14.33).

Pores can coalesce just as particles can. (Think of them as inverse particles.) The driving force is the same: reduction of the total energy by reducing the area of the interface. The difference is that, to shrink, the pore must first nucleate a vacancy. This vacancy must diffuse away through the lattice, along a dislocation or along an interface.

What is the effect of gas in pores? You can’t remove the gas easily once the pore has separated from an interface because you then have to move a neutral atom through the lattice. Pores can move through the matrix as we discuss in Section 24.15, but this process is likely to be slow and involves surface diffusion from one side of the pore to the other; as for a bubble rising in a liquid, we need a driving force.

FIGURE 15.8. Precipitate-free zones in Fe-doped NiO. (A) At a low-angle GB (with precipitation along the GB). (B) At particles of spinel after oxygen diffusion has ceased.

FIGURE 15.9. Templating grain growth. The seed is the elongated grain in the center.

FIGURE 15.10. Growth of a particle along a GB. The particle is topotactically aligned with one NiO grain (along a PB at grain 2) but not the other (grain 1). D: dislocation at the coherent interface.

FIGURE 15.11. Faceted pore in UO₂.

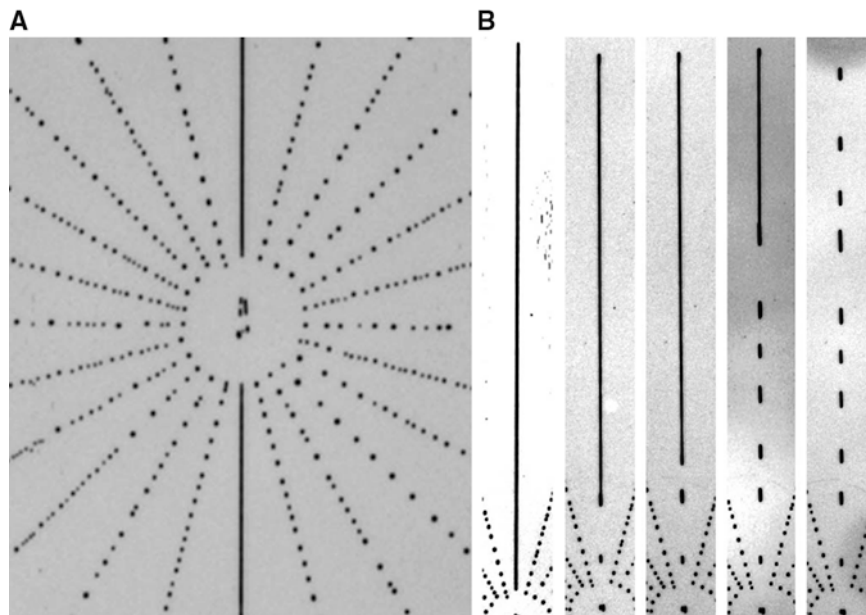

FIGURE 15.12. Method for systematically studying voids. (A) Grooves lying along different crystallographic directions break up to form pores at different rates. (B) Breakup of one channel pore can be followed over time.

Pores are also the principle defect in cement and concrete (see Section 2.7), which makes controlling porosity one of the main tasks of the cement industry. Here, one way of minimizing porosity is to minimize the amount of water used in the cement. With suitable use of plasticizers and so-called microsilica, we can achieve compressive strengths of $>100 \text{ N/mm}^2$ and tensile strengths of $\sim 15 \text{ N/mm}^2$. The plasticizers used for this are water soluble and mainly improve the packing density, thus decreasing pore content. Incidentally, cement can also be reinforced with up to 5% glass fiber, and concrete may be reinforced with polypropylene fiber and of course steel “fibers.”

15.10 MEASURING POROSITY

We are interested in three quantities: (1) the size of the pores; (2) the distribution of the porosity; (3) the total amount of porosity in the sample. Usually the actual shape of the pores is less important, although you can imagine situations where the shape would be a critical factor. We can see pores using transmission electron microscopy (TEM), scanning electron microscopy (SEM), and atomic force microscopy (AFM). If they are large enough, we can also see them with visible light microscopy (VLM). None of these observations give a statistical measurement of the amount of porosity.

PORE PARAMETERS

Some closely related topics: pore size, particle size, total surface area, active surface area, total material density.

The total amount of porosity can be estimated quite accurately if you know the phases present in the sample. You estimate the theoretical density, deduce the actual density, and thus estimate the porosity. The other two quantities are much more difficult to determine. We can infiltrate a liquid and apply mercury-intrusion porosimetry. The principle is that the capillary pressure depends on the radius of the pore. If we vary the pressure on the Hg, it fills pores down to a different size. If we then increase the pressure, more pores are filled. The drawback to this approach is that we measure only the pores that are connected to the exterior. Commercially available equipment for measuring porosimetry is illustrated in Figure 15.13.

A related technique uses nuclear magnetic resonance (NMR) to measure the time taken by a liquid to fill the pores. It measures the relaxation times of the liquid filling the pores and relates this relaxation time to the thickness of the liquid—and hence determines a surface-to-volume ratio for the pores. It is also possible to gain some information on the porosity using electron paramagnetic resonance, but neither electron paramagnetic resonance (EPR) nor NMR is widely used for this purpose.

There are many other uses of porosity measurements; the oil exploration industry is a major example. There is clearly a strong link to powders: in some applications, surface area may be more important than pore/particle size, but the two are not independent.

FIGURE 15.13. Commercial porosimeter.

15.11 POROUS CERAMICS

We discussed the structure of *zeolites* in Chapter 7. The special feature of the crystal structure is the large void that is surrounded by a silicate cage but linked to other voids. A related void is that found in C_{60} and the other buckyballs. This type of void is not what we mean by the term pore as these voids are an essential component of those crystalline structures. They may become filled with gas or liquid, but this is more closely analogous to an impurity occupying an interstice in other crystal structures as He can (e.g., in the fluorite-structured UO_2).

The new *mesoporous materials* have extremely high surface-to-volume ratios. An example of these materials is MCM41, which was invented by DuPont. A simple structure that can be manufactured in the laboratory is illustrated in Figure 15.14. The structure initially contained a periodic array of polymer spheres. When close-packed, these spheres leave 26% of the volume empty. We can infiltrate a liquid into these pores, burn out the spheres, and convert the liquid to a polycrystalline ceramic. Another synthesized porous ceramic is the cordierite honeycomb structure used to support the Pt catalyst in automobile catalytic converters. In this case, the

FIGURE 15.14. Ordered mesoporous material.

FIGURE 15.15. Sintered alumina foam made using a soap-nut slurry with 40 vol. % ceramic.

cylindrical pores are introduced mechanically in the extrusion process.

Pumice is a natural porous ceramic. It's produced by volcanic eruptions, with the gas being trapped inside the solid as it rapidly cools. The matrix is mainly glass but can contain small crystals. Synthetic ceramic foam is illustrated in Figure 15.15. Uses for ceramic foam are summarized in Table 15.3. One of the best-known applications for a porous ceramic is the space shuttle tile. An SEM image of such a tile is shown in Figure 15.16. Notice that in this case the ceramic consists mainly of fiber (pressed not woven), so the principle is the same as for ceramic (glass) fiber for house insulation.

The structures shown in Figure 15.17 illustrate the result of computer modeling of foams. A thin membrane connects the structural ribs, as in a soap bubble in a

TABLE 15.3 Uses for Ceramic Foam

wire frame. Because this film is amorphous, its surface energy is uniform and the film is flat. The structure, of course, looks very similar to the glass films between grain boundaries, at triple junctions, and at fourfold junctions (discussed in Chapter 14), but all the “grain boundaries” are now flat (because the *grains* are pores).

15.12 GLASS/CRYSTAL PHASE BOUNDARIES

Crystals have been grown in glass matrices for hundreds of years. The luster glaze used on some medieval pottery owes its sparkle to nanoparticles of copper in the glass. Household window glass eventually forms crystals of devitrite, an orthorhombic crystal with a formula like $\text{Na}_2\text{Ca}_3\text{Si}_5\text{O}_{16}$; these crystals usually form at the surface first. Crystalline glazes, which can make a pot look spectacular, actually rely on spherulites consisting of many willemite (Zn_2SiO_4) crystals, with each acicular crystal growing in the [001] direction, to achieve the effect. (More on this topic in Section 21.11).

When two crystalline oxides are joined together to form a GB or PB, they are often thought of as being ionic materials even though the bonding may have a relatively large covalent component. Glass is usually viewed in the opposite way. Clearly, we should take the nature of the bonding and the possibility of an interface space charge

FIGURE 15.16. Porous material used to make insulating tiles for the space shuttle.

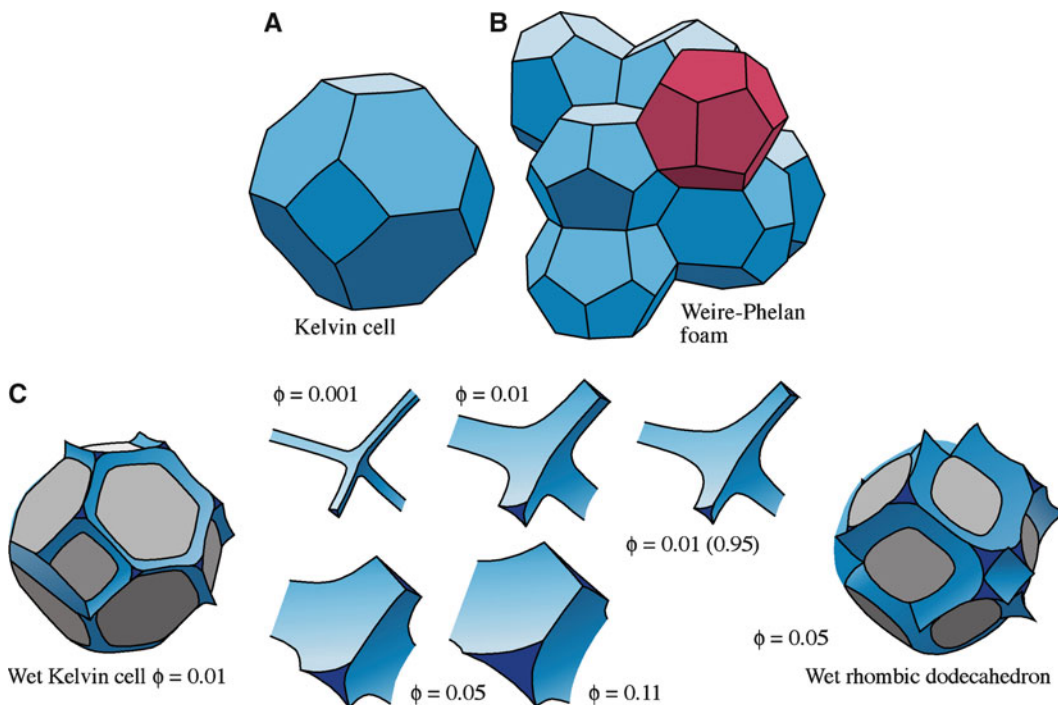

FIGURE 15.17. Intergranular films without grains. (A, B) Models of the Kelvin cell and a Weaire-Phelan foam used to describe soap bubbles. (C) How they relate to the structures of triple and quadruple junctions.

into account when we examine the glass/crystal interface. This point is particularly relevant to the understanding of glass-ceramic materials.

15.13 EUTECTICS

Is there anything special about ceramic eutectics? Not really (although they are very interesting), but it is sometimes a bit of a surprise that they can be formed just as they can in metal systems. Eutectic structures are well known in metals but have not been exploited in ceramics. One reason for this is that eutectics are associated with solidification of a liquid phase, and we don't usually process ceramics using a liquid phase; this also means that the processing temperatures are generally higher. In the examples listed in Table 15.4, one column gives the morphology of the respective phases. The minority phase can be sheets, rods, or particles; which of these actually occurs is determined in part by the energy of the PBs and the way in which the sample is cooled from the eutectic temperature. Directional solidification is generally required to optimize rods and platelets.

In the CoO/ZrO₂ eutectic solid, the two ceramics are both cubic but with very different structures. They grow in

the cube-on-cube orientation, which means that all directions and planes in one material are parallel to the same directions and planes in the other material. As a possible application of such a material, oxygen diffuses rapidly in ZrO₂. It can then react with the CoO to produce a layer of Co₃O₄ at the interface between the two materials to produce the structure illustrated in Figure 15.18. Notice how uniform this spinel layer is: the growth is controlled by the reaction, not diffusion of O through the ZrO₂.

15.14 METAL/CERAMIC PBs

Metal/ceramic PBs are not only the most important feature in ceramic-reinforced metal-matrix composites, they also occur when metals are oxidized, when oxides are reduced to the metal, or when a metal film is grown on a ceramic substrate (or vice versa). In Figure 15.19 particles of W have grown on a single-crystal thin film of SiC. The alignment and lattice mismatch of the two phases can be appreciated from the moiré fringes in the image.

High-resolution TEM (HRTEM) has now shown more details on such interfaces. The position of the misfit dislocation actually depends on the elasticity parameters of the two materials. The diagram in Figure 15.20 illustrates the

TABLE 15.4 Observed Microstructures in Some Ceramic Eutectic Systems

System	T_{eut} (°C)	Growth rate (cm/h)	Comments
PbO-Pb ₂ Fe ₂ O ₄ (12.8 wt% Fe ₂ O ₃)	730	0.5–2	Broken lamellar, two-phase matrix

dislocation stand-off, which is seen at the Nb/Al₂O₃ interface. The dislocations preferentially sit in the metal so as to lower the energy of the dislocation (remember, E depends on the elastic constants, not just **b**) while still accommodating the misfit between the materials.

15.15 FORMING PBs BY JOINING

We form PBs whenever we join dissimilar materials. Table 15.5 summarizes some applications of the joining processes and the type of PB that's formed. Note that when bonding two materials together, we don't always want to produce strong bonds; some applications prefer that the bond be weak (e.g., in fiber composites). The formation of the bond has some requirements.

FIGURE 15.20. Stand-off dislocations accommodating lattice misfit between Nb and Al₂O₃.

TABLE 15.5 PBs in Applications

<i>Bond</i>	<i>Material</i>
Brazing	Joins a ceramic to a metal
Metal-matrix composites	Makes a two-phase material
Electronic interconnects	Bonding metal to a semiconductor
Oxidation of metal	Forms oxide from metal
Catalysis	Supports catalyst particles

- Intimate contact between the two materials—this is the obvious requirement for a strong bond.
- Formation of a chemical bond—covalent bonding would be strong, van der Waals bonding would be weak.
- For a lasting bond, there must be a way to accommodate interfacial stresses.

BRAZING AlN

Using an active metal such as Zr, we can get an idea about the possible reactions by using the Ellingham free-energy diagrams. Figure 15.21 is a plot of free energy of formation of selected nitrides as a function of temperature. The lines represent the reaction

Thus, when AlN is in combination with Zr at high temperatures the reaction

is favored. At 1,123 K the free energy for this reaction is -83.3 kJ/mol

FIGURE 15.21. Ellingham Diagram. The lower line is used when brazing Zr. Red and blue dashes are the melting (M) and boiling (B) points.

The interfacial stresses may arise due to thermal expansion mismatch generated during cooling, after fabrication, or because of temperature changes in operational conditions.

Brazing is joining a metal to a ceramic. The technique is well illustrated by considering metallization processes for AlN. There are several possible routes for forming the interfaces.

- Apply the metal in a liquid form
- Deposit either material from the vapor phase
- Use a solid-state reaction involving oxidation or reduction

Liquid metals have much higher surface energies than most ceramic oxides, and the PB energy is also high. The result is that liquid metals do not readily wet a ceramic and spread unless special precautions are taken. Two approaches have been used for the development of metal brazes for oxides. In one method, active metals such as Ti or Zr are added to the metal. The additives effectively reduce the interfacial energy because they have a strong chemical attraction to the oxide and hence enhance wetting

behavior. The active metal is essentially acting as a surfactant! A braze must react with both the metal and ceramic components that you are joining and reach chemical equilibrium at the interfaces. Metal systems are generally compatible, resulting in wetting; the braze can then bond (by solution or diffusion) to the metal component.

Braze alloys for Al₂O₃-based ceramics might be Ag-Cu, Au-Ni, or Ag-Cu-Zn; but these alloys generally do not wet ceramics. The oxidation potentials of Cu and Ag are less than that of Al, so they do not react with the ceramic. If a small percentage of an active metal (e.g., Ti) is added, then the high oxidation potential of the Ti causes it to undergo a redox reaction with the ceramic (Al₂O₃). The result is the spreading of the braze because an oxide that is compatible with both phases forms at the interface; that is, a chemical bond forms at the interface. Similar approaches have been used to braze nonoxide ceramics. Zr may be a suitable candidate for an active metal for brazing of AlN ceramics.

In making *electronic interconnects*, it is often necessary to metallize the surface of Al₂O₃ (in ceramic packaging for integrated circuit applications). We describe how

metallization is accomplished using thick film processing in Chapter 27. The development of an interlocking glass/ceramic and glass/metal structure is required for good adhesion because it provides mechanical interlocking in addition to chemical bonding between phases. To achieve the required microstructure at the conductor/substrate interface, it is necessary for the glass to have the appropriate surface tension and viscosity during the firing process and for it to wet the substrate.

In thin film metallization by evaporation or

sputtering of thin metal films onto a ceramic surface (see Chapter 28), it has been demonstrated that a sequence of layers of different metals is required for optimum film properties. The first layer is usually a refractory metal, such as Ti, Cr, or NiCr; this layer provides adhesion to the ceramic. These elements are reactive and bond through redox reactions with the substrate. The second layer acts as a diffusion barrier. The barrier material is usually a noble metal, preferably Pt or Pd. The top layer is the metal of choice for the particular application, such as Au for wire-bonding applications or Ni or Ag-Pd for solderability.

METALLIZING ALUMINA

A commercial process for metallizing debase alumina uses Mo or W; the alumina grains in the debase alumina are held together by a glassy phase binder. The Mo is applied to the surface as a powder, often mixed with manganese oxide, and fired in a reducing atmosphere with a controlled dew point so that the Mn is present as MnO and Mo as the metal. The MnO reacts with both the alumina grains and the liquid glassy phase. The glassy phase from the Al₂O₃ migrates into the metal powder under the influence of capillary forces and bonds the metal particles to each other and to the Al₂O₃ surface, producing a wettable surface layer. In the case of pure Al₂O₃ and oxides without binder phases, it is necessary to add glasses to the metallizing mixtures. The Mo coating is generally electroplated with Ni to provide a clean and continuous surface as well as one on which an applied braze would easily spread. A similar process is applied for W metallization

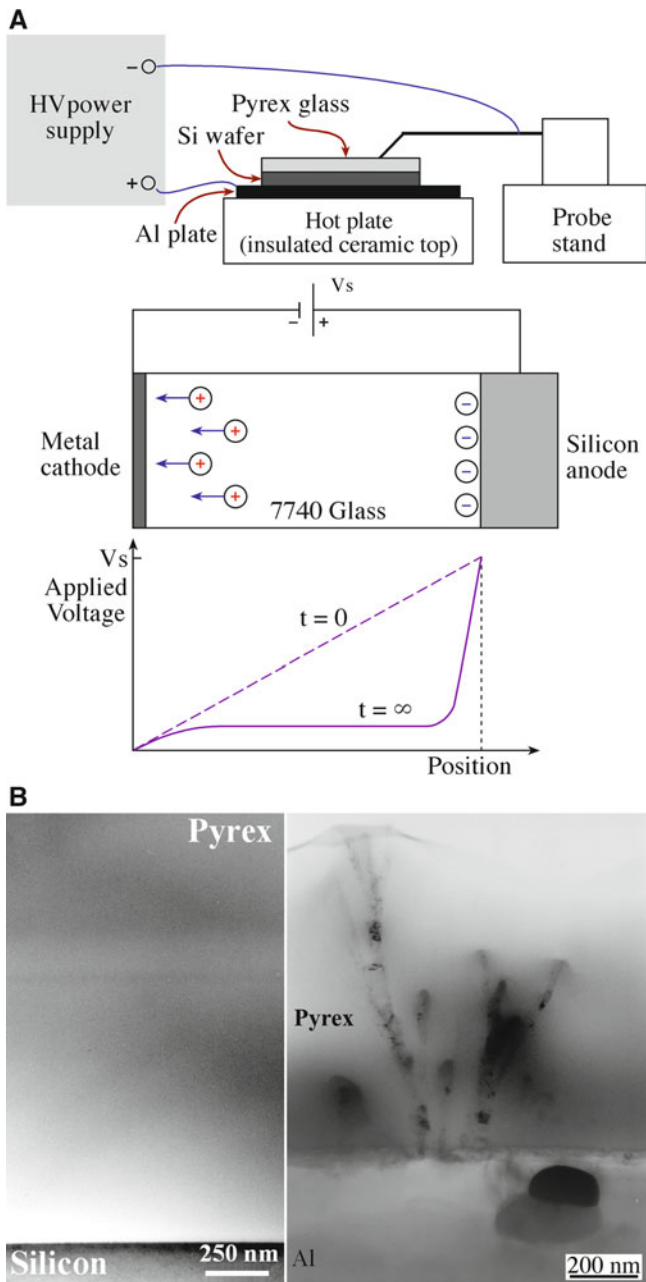

FIGURE 15.22. Setup for the anodic bonding of glass to Si and an example of a glass/Si/glass sandwich produced using this process.

FIGURE 15.23. Au catalyst particles on a ceramic nanowire.

A schematic for the process of *anodic bonding* is shown in Figure 15.22. The concept is that two materials are joined together by heating them while applying voltage across the assembly (hence, it is also known as field-assisted bonding). The temperature is typically between 300°C and 450°C, and the applied voltage is ~80 V. Glass can be bonded to glass or to Si with this process. In principle, the limiting factor is being able to polish the abutting surfaces to a roughness of <100 nm. Glass works particularly well because the cations are quite mobile.

Some final examples of PBs:

In *catalysis*, it is usually not possible to examine the interface between the support and the catalyst particle. An example of catalyst particles on a silica nanowire is shown in Figure 15.23.

We discuss *composite materials* in more detail later, but we note that the filler material (fiber or particle) and the matrix can be glass, crystalline ceramic, or other (see Chapter 20).

CHAPTER SUMMARY

There are several key ideas in this chapter. PBs are present wherever we have a second phase, particle, or precipitate in a matrix; we treat pores as a special particle. (The surface is actually a special PB.) PBs are like GBs and are everywhere in ceramics; we could develop a notation similar to the Σ for GBs but rarely use it. When a phase transformation occurs, the mechanism is the movement of a PB. Particles can be different in structure and/or composition in a ceramic matrix; precipitates are particles that have developed by a specific process. Pores are present in most ceramics and play important roles in determining properties. We have developed special methods for characterizing porosity and ceramics where the pores are actually the major phase—porous ceramics. We just touched on some special PBs, namely glass/crystal interfaces and metal/ceramic interfaces. We will see much more of the former in later chapters.

PEOPLE AND HISTORY

This topic has a relatively short history from the point of view addressed here. Some is given in Chapter 25.

Ellingham, Harold Johann Thomas (1897–1975) studied at Imperial College when it was called the Royal College of Science. His diagrams were particularly important for the steel industry.

EXERCISES

- 15.1 Given the information in the text, determine the orientation of the samples.
- 15.2 What is the crystallographic relationship between the two grains shown in Figure 15.2A? How does it differ from that of the interface shown in Figure 15.2B?
- 15.3 Using reasonable values of the solid/liquid interface energies and ΔG_v , estimate r^* for spinel in MgO versus Cu in Si.
- 15.4 Do you expect the conduction of Na^+ ions in an ionic conductor to depend on crystallography? If so, why? What are the implications?
- 15.5 How would you propose characterizing nanoparticles in the glaze on a priceless pot? Breaking the pot, even a little bit, is not allowed.
- 15.6 In Section 15.14 we noted that dislocations can be present at metal/ceramic interfaces. When is this most likely? When is it least likely? How do the interfacial energies and strengths differ?
- 15.7 What is the relationship between the methods used to form the images in Figures 15.4 and 15.8? Explain why this technique works.
- 15.8 Assuming that the interfaces labeled in Figure 15.7 are all viewed edge on, what is the viewing direction (the direction defined with respect to the sapphire crystal)?
- 15.9 Suggest reasons for the shape of the particle shown in Figure 15.5. How does this explanation compare with that for the shape of the particle in Figure 15.11?
- 15.10 List the possible applications for zeolites and mesoporous ceramics.
- 15.11 By exploring the literature, give four examples of phase boundaries in minerals such as orthoclase and microcline. (Give the references for your sources).
- 15.12 Consider Figure 15.1. What is the Burgers vector of the widely spaced (whiter) dislocations? What is their spacing? How does it compare to what you expected?
- 15.13 Explain the crystallographic relationships for the two-phase boundaries shown in Figure 15.2
- 15.14 Explain the crystallographic relationships for the phase boundary shown in Figure 15.3 and determine the main boundary plane.
- 15.15 Explain the crystallographic orientation of the particle in Figure 15.5 by looking at the initial and final shapes of the particle.
- 15.16 By examining Figure 15.8A, estimate the doping level of Fe in the NiO. You must explain all your assumptions.
- 15.17 Why is the critical particle size given by the equation Box 15.3
- 15.18 How can you tell that the lower interface in Figure 15.10 is coherent and the other is not? Why do we see fringes at the coherent interface?
- 15.19 Go into the literature and then discuss why the pores in Figure 16.12 break up and as they do here. (Reference where you find your clues).
- 15.20 What is the fundamental difference between the Kelvin model and the Weaire-Phelan model?

Part V

Mechanical Strength and Weakness

Mechanical Testing

CHAPTER PREVIEW

The concepts of stress and strain and the elastic moduli should already be familiar. Where ceramics differ from most metals and polymers is that at room temperature most of them are brittle. Flaws play a major, often dominating, role in the mechanical behavior of ceramics. As a result, obtaining properties such as elastic moduli is often more difficult than it would be for metals: preparing the sample can lead to the introduction of flaws. Stress–strain curves for ceramics are usually obtained using a bending test rather than a tensile test. We need only to make our ceramic into a rectangular block. The brittle behavior of ceramics gives them low fracture toughness, a property that can most conveniently be obtained from indentation testing. A key point in this chapter is that when we use ceramics in load-bearing applications we need to understand the importance of flaws and how to incorporate that into our design approach.

16.1 PHILOSOPHY

The classical view of ceramic materials is:

- (a) They're brittle.
- (b) Dislocations are not important because they don't move.
- (c) They are polycrystalline and fracture along grain boundaries.

Once again the classical view of ceramics and many of our preconceived ideas of how they behave are not always correct.

- We can bend a sheet of silicon into a tube.
- We can bend an alumina fiber into a circle.
- Dislocations move ahead of crack tips, are present at heterojunctions, and can be produced in large numbers during single crystal growth.
- Single crystal ceramics also fracture. (Figure 16.1 shows an Nd-doped YAG single crystal boule that fractured during growth).

Therefore, the modern view of ceramics is very different because:

- (a) We may be using the ceramic as a thin film where stresses may be very high.
- (b) Deformation at high temperatures may be important.
- (c) In some special “new” ceramics, displacive transformations become important.

It is important to keep these ideas in mind when you read older texts. We are not going to provide a treatise on mechanical properties of ceramics. There are many existing books that do, and some of them are listed at the end of the chapter. What we do is look at what is special for ceramics.

The general need is to understand the response of a material to an applied stress. The stress may be applied externally or be induced by altering other parameters such as temperature (which can cause a phase transformation). The fundamental idea is the link to bonding. In Chapter 4, we described how the Young's modulus is related directly to the bond–energy curve. In Chapter 12, we described the nature of dislocations in ceramics.

The following three chapters have three special themes.

- Mechanical testing—how to do it plus the fundamentals of elastic constants, etc.
- Plastic deformation and how it is accommodated.
- Fracture and how to control it.

The starting point for most discussions of mechanical properties of materials begins with a stress–strain (σ – ϵ) curve for a material in tension. Figure 16.2 shows σ – ϵ curves for three different materials at room temperature.

Material I: has high Young's modulus, high failure stress, low ductility, low toughness, and fractures without significant plastic deformation. *This behavior is characteristic of many ceramics.*

Material II: has moderate strength, moderate ductility, deforms plastically prior to failure, and is the toughest

FIGURE 16.1. Cracking in an Nd-doped YAG boule.

FIGURE 16.2. Idealized stress–strain curves for different materials classes.

of the three. *This behavior is characteristic of many metals.*

Material III: has low Young’s modulus, is very ductile, has low ultimate tensile strength, and limited toughness. *This behavior is characteristic of many elastomers.*

The strength of ceramics is affected by many factors, and this complexity is illustrated in Figure 16.3. The composition and microstructure are particularly significant, and mechanical properties depend strongly on these characteristics. Figure 16.4 shows two specific examples that illustrate the role of microstructure on the strength

FIGURE 16.3. Factors affecting the mechanical properties of ceramics.

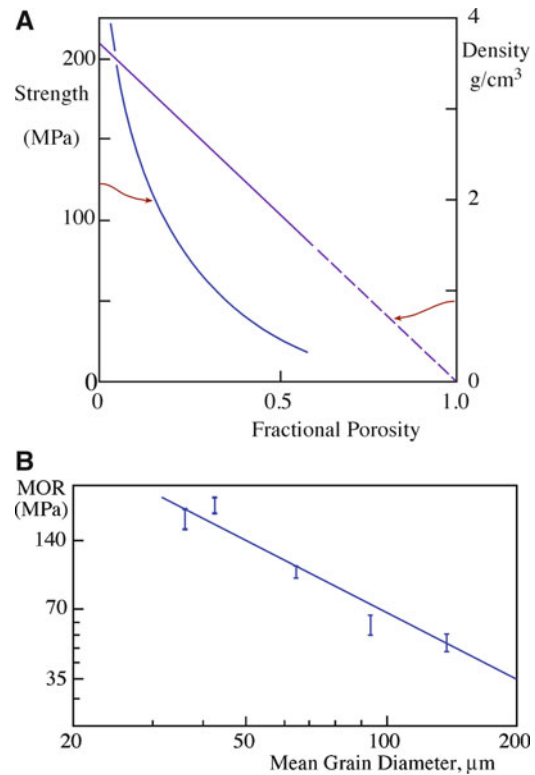

FIGURE 16.4. (A) Effect of porosity on the strength of polycrystalline Al_2O_3 . (B) Effect of grain size on the strength of BeO.

of ceramics. In Figure 16.4A, the strength of a porous polycrystalline alumina is shown to decrease much more rapidly than its density. The reason is that pores act to concentrate stress, which is not uniform throughout the ceramic. The strength of nonporous ceramics decreases with increasing grain size, as illustrated for the case of BeO in Figure 16.4B. Again, the observed behavior is due to flaws in the material that act as stress concentrators. In large grains, there can be larger flaws. The effect of

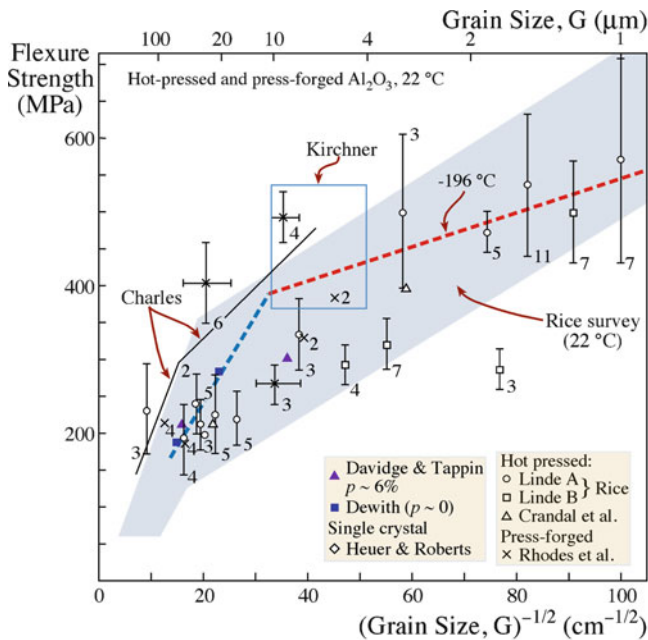

FIGURE 16.5. Compilation of strength data as a function of grain size for polycrystalline Al_2O_3 .

grain size is often more complicated than that shown in Figure 16.4B when we consider ceramics where the grain size is just a few microns. Figure 16.5 is a compilation of flexural strength results for polycrystalline alumina at room temperature as a function of grain size. Despite the considerable scatter in the data, there are clearly two distinct regions. In both cases, strength is proportional to the reciprocal square root of the grain size ($d^{-1/2}$) with different constants of proportionality. The reason for this behavior is that in addition to the preexisting flaws causing brittle fracture there is a competing fracture mechanism that links dislocations and crack nucleation to subsequent failure.

It is therefore essential that when the mechanical properties of a ceramic material are listed that some details of the microstructure are also provided. As you can see from Figure 16.3, the measured value of a mechanical property may be affected by the test method. This is particularly true in the case of hardness.

High-performance structural ceramics combine the traditional advantages of ceramics (chemical inertness, high-temperature capabilities, hardness) with the ability to carry a significant tensile stress. The majority of the high-performance ceramics are based on silicon nitride, silicon carbide, zirconia, or alumina. Structural ceramics come in many forms: monoliths, composites, coatings, fibers, whiskers.

16.2 TYPES OF TESTING

Ideally, before we use a ceramic in a load-bearing application we would like to have the following information about it.

- Young's modulus
- Average strength and Weibull modulus
- Toughness
- Crack propagation rate
- Cyclic fatigue resistance
- Creep curves
- Stress rupture data

We would also like to know these parameters as a function of temperature, in particular over the temperature range at which our ceramic component is going to be used. Many different types of test are used to obtain the mechanical properties of ceramics. There are big differences between how metals are tested compared to ceramics.

- It is often difficult to do tension tests on ceramics because of the possibility of introducing flaws.
- Ceramics are stronger in compression than they are in tension because of how cracks propagate.
- For ceramics, we need to be concerned with statistics because we don't know where the largest flaws are.

Because some mechanical properties depend on how the material was tested, it is important and necessary to establish specified test methods. Standard test methods have been adopted for ceramics. In the United States, ASTM International (originally the American Society for Testing and Materials, or ASTM) is the primary organization developing standards for materials testing. ASTM Committee C-28 on Advanced Ceramics has completed several standards. Those related to mechanical properties and testing are listed in Table 16.1. Specialized subcommittees work on specific areas within the field of advanced ceramics. Committee C28.01 is involved with standards related to mechanical properties and performance of monolithic ceramics. Committee C28.02 deals with reliability issues. The National Institute of Standards and Technology (NIST) has established several free databases that list mechanical properties of ceramics.

16.3 ELASTIC CONSTANTS AND OTHER "CONSTANTS"

In this section we define some of the parameters that describe the mechanical behavior of materials. Some of these parameters are constants, such as Young's modulus \mathcal{E} . Some, such as hardness, are not. Hardness depends on how the material was tested.

Table 16.2 lists four elastic constants for different ceramics. These are the four that you will find crop up most commonly.

1. \mathcal{E} (or Y , but be careful because Y is also used in our expression for stress intensity factor)—Young's modulus (also referred to as the elastic modulus) is a

^aStandards for both three-point and four-point bending, -XX: year of current version of standard, e.g., -10 is 2010

material constant defined by equation 16.1 for a linear elastic material under uniaxial tensile or compressive stress.

$$\sigma = E\varepsilon \tag{16.1}$$

It is therefore the slope of a σ - ε curve where only elastic deformation occurs.

- ν —Poisson's ratio is the negative ratio of the transverse strain (ε_T) to longitudinal strain (ε_L).

$$\nu = -\varepsilon_T/\varepsilon_L \tag{16.2}$$

For many ceramics and glasses it is in the range 0.18–0.30.

- μ —Shear modulus is the ratio of shear stress to shear strain.

$$\mu = \tau/\gamma \tag{16.3}$$

- B —Bulk modulus is the ratio of stress to strain for hydrostatic compression.

$$B = -P(\Delta V/V) \tag{16.4}$$

Although these constants are related directly to bonding forces between atoms, in real ceramics they are affected by microstructure (e.g., porosity and the presence of second phases). Because strain is dimensionless, elastic moduli have the same dimensions as those of stress: force per unit area (N/m^2) or, in the SI classification, Pa.

Some texts use a pair of related elastic constants λ and μ . These are known as the Lamé constants. We already defined μ , so it is only λ that is new. The expressions that relate elastic moduli are given in Table 16.3.

K_I —Stress intensity factor is a combination of flaw size, c , and applied stress, σ .

$$K_I = \sigma Y \sqrt{c} \tag{16.5}$$

Y in equation 16.5 is a dimensionless parameter that depends on the crack and loading geometries. For a simple interior crack of length $2c$ and tensile loading, $Y = \sqrt{\pi}$ (this is the original geometry considered by Griffith); for a surface crack under similar loading, $Y = \sqrt{(\pi/2)}$. The units of K_I are $\text{MPa}\cdot\text{m}^{1/2}$.

The subscript refers to the type of loading geometry. There are three fundamental deformation modes that can be important for crack propagation. These modes are illustrated in Figure 16.6.

- Mode 1 opening. The most important for crack propagation in brittle solids. Can be achieved by an applied uniaxial tension
- Mode 2 sliding
- Mode 3 tearing

K_{Ic} —Critical stress intensity factor or fracture toughness. Fracture of a material in tension occurs when $K_I \geq K_{Ic}$.

H —Hardness. There are different types of hardness. Why? Because the value of a material's hardness depends on how it is tested. The hardness of a material is its resistance to the formation of a permanent surface impression by an indenter. You also see it defined as resistance of a material to deformation, scratching, and erosion. Hence, the geometry of the indenter tip and the crystal orientation (and therefore the microstructure) affect the hardness. In ceramics, there tends to be wide variations in hardness because it involves plastic deformation and cracking. Table 16.4 lists hardness values on the Mohs' hardness scale, a scratch test that can be used to compare hardness of

FIGURE 16.6. The three deformation modes for fracture: (A) Mode I opening. (B) Mode II sliding (in-plane shearing). (C) Mode III tearing (anti-plane shearing).

TABLE 16.4 Mohs' Hardness

13		Silicon carbide	2,480
14		Boron carbide	2,750
15		Diamond	7,000

different minerals. For example, quartz has a Mohs' hardness of 7, which made flint (a cryptocrystalline quartz) particularly useful in prehistoric times for shaping bone (mineral component is apatite: hardness of 5) and shell (mineral component is calcite: hardness of 3). Mohs' was not the first scratch hardness technique. As long ago as 1690, Christian Huygens, the famous astronomer, had noticed anisotropy in scratch hardness.

Brittleness—Although not widely used, the brittleness index (BI) has been used to quantify the brittleness of a ceramic, where $BI = H/K_{Ic}$.

16.4 EFFECT OF MICROSTRUCTURE ON ELASTIC MODULI

In Chapter 4, we showed that Young's modulus is a property that is directly related to the bonding forces between atoms. We also showed that it varies as a function of temperature. In real ceramics, we have to consider the fact that we often have more than one phase present. The overall modulus is then going to be a combination of the properties of each of the phases and lie somewhere between the high- and low-modulus components.

Two analytical expressions represent the upper and lower bounds for Young's modulus.

16.4.1 Voigt Model

Assumption: strain in each constituent is the same. Represents upper bound of Young's modulus.

$$\mathcal{E} = V_2\mathcal{E}_2 + (1 - V_2)\mathcal{E}_1 \quad (16.6)$$

FIGURE 16.7. Comparison of predicted values of Young's modulus for an Al_2O_3 -tetragonally stabilized ZrO_2 composite with experimental data.

16.4.2 Reuss Model

Assumption: Stress in each phase is the same. Represents lower bound of Young's modulus.

$$\frac{1}{\mathcal{E}} = \frac{V_2}{\mathcal{E}_2} + \frac{(1 - V_2)}{\mathcal{E}_1} \quad (16.7)$$

Hashin and Shtrikman (HS) developed a narrower, more useful, set of bounds using basic elasticity energy theorems. The HS bounds have been shown to be best for the bulk modulus and are given by:

$$\frac{B - B_1}{B_2 - B_1} = V_2 \left[\frac{V_1(B_2 - B_1)}{B_1 + H} \right]^{-1} \quad (16.8)$$

where $H = 4 \mu_2/3$ or $H = 4 \mu_1/3$. Young's moduli can be obtained from B if ν is known and reasonable fits with experimental data can be obtained, as shown in Figure 16.7 for alumina-tetragonally stabilized zirconia (Al_2O_3 - ZrO_2) composites.

If the second phase is porosity, as is often the case in polycrystalline ceramics, then intuitively we realize that there is a decrease in the elastic modulus. A pore has zero stiffness. Several relationships have been developed to account for the change in Young's modulus with porosity, P . They are shown in Table 16.5, where the "constants" a and b are often empirically determined; E_0 is the Young's modulus of the dense material.

16.5 TEST TEMPERATURE

Mechanical properties often show strong variations with temperature. We already considered in Chapter 4 how temperature affects Young's modulus. For some mechanical properties, the change with temperature may be more abrupt than the gradual decrease in \mathcal{E} with increasing temperature. The ductile-to-brittle transition, which occurs

TABLE 16.5 Relations Between Porosity, P , and Young's Modulus, E

$E = E_0(1 - aP)$	Linear decrease in Young's modulus with porosity when P is small $a \sim 4$
$E = E_0(1 - aP + bP^2)$	For a low concentration of spherical pores ($a \sim 1.9$, $b \sim 0.9$)
$E = E_0(1 - aP)^b$	For solid foams with very high porosity $P > 0.7$ ($a = 1$, $b = 2$)
$E = E_0 \left[\frac{(1 - P)^2}{1 + (a - 1)P} \right]$	a is a shape factor with values depending on porosity: $a = 2.5$ for interconnected porosity ($1/a = 0.4$) $a = 3.3 - 1.4$ for porosity that resembles ribbons ($1/a = 0.3 - 0.7$) $a = 0.6 - 1.0$ for isolated pores ($1/a = 0.6 - 1.0$) ($1/a$ is known as the Nielson shape factor)
$E = E_0 \exp(-aP)$	Empirical for oxides with porosity in the range 0–40% ($a \sim 4$)

FIGURE 16.8. Effect of temperature on fracture stress for a ceramic. The key temperatures are T_{AB} and T_{BC} .

with decreasing temperature, is an important topic in metals. The significance of this phenomenon really came to light during World War II, when there were reports of serious fractures in some of the Liberty ships (mass-produced vessels of predominantly welded construction). One of the most striking instances of this type of fracture was the T2 tanker S.S. Schenectady built in Portland, Oregon, which suddenly broke into two sections at 10.30 p.m. on January 16, 1943. The reason was that the steel alloy used to construct the hull had undergone a ductile-to-brittle transition at a temperature of 4°C . This event gave particular impetus to the study of fracture in brittle materials.

Do ceramics experience a ductile-to-brittle (or the converse) transition, and is it important? Ceramics can exhibit both types of behavior over different temperature ranges. Figure 16.8 illustrates the temperature dependence of strength for ceramics.

- **Region A:** fracture is brittle, and the fracture strain $\sim 10^{-3}$. There is no significant plastic deformation prior to failure, and the strength varies little with temperature.

FIGURE 16.9. Stress–strain curve for Si_3N_4 at $1,400^\circ\text{C}$ for various amounts of silica. The machine compliance is the inherent displacement within the instrument.

- **Region B:** fracture is again brittle, but slight plastic deformation occurs prior to failure. The failure strain is usually in the region of 10^{-3} – 10^{-2} , and strength falls with increasing temperature.
- **Region C:** appreciable plastic flow occurs, with strains of the order of 10^{-1} prior to failure. This behavior is rarely observed in ceramics, even in ductile polycrystalline ceramics.

The critical temperatures, T_{AB} and T_{BC} , vary greatly for different ceramics. For polycrystalline MgO the brittle-to-ductile transition occurs at $\sim 1,700^\circ\text{C}$ ($0.6 T_m$). There is no plastic deformation in $\beta\text{-SiC}$ below $2,000^\circ\text{C}$. Talc, MoS_2 , and graphite all deform at room temperature. MoS_2 and graphite are widely used as solid lubricants.

The transition can be important in structural ceramics (particularly nonoxides such as silicon nitride) when they are used in high-temperature applications. Densification in these ceramics is often achieved using a second phase that forms a glass at grain boundaries and triple points. At temperatures near the glass-softening temperature, very extensive plastic flow occurs. Figure 16.9 shows σ – ϵ curves for silicon nitride at $1,400^\circ\text{C}$ containing different amounts of silica. For silica contents > 20 wt%, macroscopic plastic deformation occurs. At high silica contents, it is believed that the glassy phase is no longer constrained at the triple points.

16.6 TEST ENVIRONMENT

In some cases, the environment that the ceramic is exposed to is a very important consideration. For example, you often see that mechanical tests on bioceramics are performed either in vivo or in vitro. Tests performed in the body are referred to as in vivo. Tests performed outside

the body, often under conditions that seek to replicate or approximate the physiological environment, are referred to as in vitro. ISO Standard 6474 for alumina bioceramics specifies a bend strength >450 MPa after testing in Ringer's solution. Ringer's solution is a model liquid that resembles human body fluid.

RINGER'S SOLUTION (PARTS BY VOLUME)	
NaCl solution 0.9%	94
KCl solution 1.15%	4
CaCl ₂ solution 1.22%	3
KH ₂ PO ₄ solution 2.11%	1
MgSO ₄ solution 3.82%	1
NaHCO ₃ solution 1.3%	14
NaHPO ₄ solution 1 M	13

Young's modulus is the same because the curves have the same slope.

One ceramic that is widely tested in compression is concrete. Concrete is a ceramic-matrix composite consisting of a mixture of stone and sand (called the aggregate)

in a cement matrix. The aggregate provides the strength and the cement the workability. When concrete is used in construction it must always be loaded in compression. As shown in Figure 16.10, cracks behave

16.7 TESTING IN COMPRESSION AND TENSION

The tensile test is the most used procedure to determine the tensile strength of a metal. However, it is not used as widely for ceramics because of their inherent brittleness. It is difficult to make the typical "dog bone"-shaped samples, where the cross-sectional area is reduced in the gauge length. We could do this with a ceramic, but the machining needed to give this shape is likely to introduce surface flaws. In many tensile test instruments, the sample under test is connected by means of a screw thread. This is often tricky to machine with a ceramic, and it may also break in the grips. Finally, because ceramics fail after only about 0.1% strain, the specimens under test must be perfectly aligned; otherwise we introduce bending stresses, which complicate things.

In some practical situations, we require ceramics to support a tensile load. Consider the growth of silicon single crystals by the Czochralski process, which involves pulling the crystal from the melt. The crystal is supported entirely by a narrow region called the neck, about 3 mm in diameter. It is possible to support a total crystal weight of about 200 kg. This requirement determines the maximum overall volume of a silicon boule. The diameter is controlled by our ability to produce dislocation-free crystals, as we describe in Chapter 29. Steel reinforced concrete and safety glass are two examples of where a ceramic is prestressed in compression to increase its ability to support a tensile load.

RULE OF THUMB

Compressive fracture strength is 10–15 times greater than tensile fracture strength.

Stress-strain curves for metals look very similar and provide similar results whether the testing is carried out in tension or compression. Ceramics are generally stronger in compression and can tolerate high compressive loads. Some examples are given in Table 16.6. However, reliable compressive strength data are limited for ceramics. Note that the

TABLE 16.6 Ratio of Compressive Strength σ_{cc} to Bending Strength, σ_c		
Ceramic	Grain size (μm)	σ_{cc}/σ_c
TiB ₂	20–50	4–6
ZrB ₂	20–50	4–6
B ₄ C	1	7
WC	1–6	4–6
Al ₂ O ₃	1–100	4–30
MgAl ₂ O ₄	1	7
ThO ₂	4–60	13–17
UO ₂	20–50	5–18

FIGURE 16.10. Unstable and stable crack propagation for a brittle material in tension (T) and compression (C), respectively. Stable crack propagation leads to crushing.

differently in compression than they do in tension. In compression, cracks twist out of their original orientation and propagate stably along the compression axis. The result is that the sample crushes rather than fractures. Fracture is not caused by rapid unstable crack propagation as it is in tension.

In tension, we are concerned with the largest crack, the “critical flaw,” particularly if it is on the surface. In compression, we are concerned with the average flaw size, c_{av} . We can estimate the compressive stress to failure by substituting c_{av} into equation 16.5 and using a multiplier between 10 and 15. Teeth are ceramic composites: they survive for years even when many cracks are present.

16.8 THREE-POINT AND FOUR-POINT BENDING

To avoid the high expense and difficulties of performing tensile tests on ceramics, tensile strength is often determined by the bend test. There are two geometries, which are illustrated in Figure 16.11. The main advantage of the

MODULUS OF RUPTURE EQUATIONS

3-Point Bend: $\sigma_r = \frac{3PL}{2BW^2}$
 4-Point Bend: $\sigma_r = \frac{3PD}{BW^2}$

FIGURE 16.11. Geometries for three- and four-point bending.

bend test, other than its lower cost, is that we use simple sample geometries. The specimens have either a rectangular or cylindrical geometry. The four-point bend test is preferred because an extended region with constant bending moment exists between the inner rollers.

The maximum tensile stress in the surface of the beam when it breaks is called the modulus of rupture (MOR), σ_r . For an elastic beam, it is related to the maximum moment in the beam, M .

$$\sigma_r = \frac{6M_r}{BW^2} \quad (16.9)$$

where W is the height of the beam, and B is its thickness. For the case of bend-testing a ceramic, this equation is applicable only when the distance between the inner rollers is much greater than the specimen height.

Other terms are also used including flexural strength, fracture strength, and bend strength. The bend test is also

known as a flexure test; and the resistance of a beam to bending is known as its flexural rigidity. The terminology can be a little confusing, but this test is important because it is widely used and probably the most well

studied strength test for ceramics.

Examples of data from such tests are shown in Figure 16.12 for polycrystalline alumina. The main comment that can be made is that there is a wide variation in the values!

FIGURE 16.12. Flexural strength of polycrystalline Al_2O_3 as a function of test temperature.

Grain size differences between the samples clearly comprise one of the factors contributing to this variation.

The main disadvantage of the bend test is that the stress distributions can be complex and nonuniform. The consequence is that under certain conditions, particularly when the largest flaws in the sample are located in the interior of the specimen, the strength of the ceramic can be overestimated.

16.9 K_{Ic} FROM BEND TEST

There are several techniques to determine K_{Ic} for a ceramic. The two main approaches are to use indentation or bending. In the bend test, a notch is introduced (usually using a diamond-tipped copper cutting wheel) into the tensile side of the specimen, as shown in Figure 16.13.

In (a) the notch is flat (single-edged notched beam, SENB), in (b) it is chevron-shaped. The specimen is loaded, usually in a four-point bend, until it fails at F_{Max} , and K_{Ic} is calculated.

SENB AND CN SPECIMENS

Typical dimensions
 $B = 3$ mm, $W = 4$ mm,
 $S_2 = 20$ mm, $S_1 = 40$ mm
 Crack depth $c/W \sim 0.5$
 Total specimen length 50 mm

FIGURE 16.13. Geometries for single-edged notched beam (SENB) and chevron notched (CN) specimens used to determine K_{Ic} .

For the SENB:

$$K_{Ic} = \frac{3\sqrt{c}(S_1 - S_2)\xi F_{Max}}{2BW^2} \quad (16.10)$$

where c is the length of the initial crack that we introduced, and ξ is a calibration factor. The advantage of the SENB test is that it is quite simple but tends to overestimate K_{Ic} because the crack is often not atomically sharp. For ceramics with very fine grain sizes, it is necessary that the notch is very narrow.

For the chevron notched (CN) specimen

$$K_{Ic} = \frac{(S_1 - S_2)\xi^* F_{Max}}{BW^{\frac{3}{2}}} \quad (16.11)$$

where ξ^* is a compliance function. Sometimes you see equation 16.11 written in such a way that all the geometrical terms are grouped together as a single geometric function Y^* . Then we have:

$$K_{Ic} = \frac{F_{Max}}{B\sqrt{W}} Y^* \quad (16.12)$$

The value of Y^* is then necessary for different specimen geometries and different notch geometries. Two approaches can be used to obtain Y^* .

The advantage of the CN geometry is that we don't need to worry about introducing a sharp precrack. Our original notch is made by two saw cuts to produce a triangular shaped cross section. A crack is easily initiated at the tip of the chevron, but the increasing cross section of the crack front causes crack growth to be stable prior to failure. Further crack extension requires an increase in the applied load, and it is possible to create an atomically sharp crack before the specimen fails. Also, you can see from equation 16.11 that we don't need to know the actual crack length. In fact, we don't need to know any of the materials' properties.

CAUTION

Fracture toughness values for different ceramics may depend on technique used to measure them.

16.10 INDENTATION

Measuring the hardness of a ceramic is important, and it is usually done using an indentation test. The basic idea is that a permanent surface impression is formed in the material by an indenter. We then measure the actual or projected area of the impression. The hardness is then determined by dividing the applied force, F , by this area. The processes that happen under the indenter tip can be

FIGURE 16.14. Indentation stress versus indentation strain.

FIGURE 16.15. Plasticity under the indenter (shaded area) causes the deviation from Hertzian behavior.

quite complex. We often see a deviation from what is called “Hertzian” behavior, where the indentation stress is proportional to the indentation strain (Figure 16.14). The deviation is due to plasticity beneath the indenter, as illustrated in Figure 16.15. We discuss this more in Chapter 17. Cracking can also occur on indenting and can be used as a means of determining fracture toughness.

There are many different hardness tests, and each gives a different number. The common hardness tests are listed in Table 16.7, and the geometries of the impression are shown in Figure 16.16. It is possible to convert between different hardness scales, but the conversion depends on both the material and its microstructure. The most reliable data are for steels because most of the work has been done on these alloys. Detailed conversion tables for metals and

FIGURE 16.16. Evolution of common hardness tests and the corresponding indenter shapes.

alloys are available in ASTM Standard E 140, “Standard Hardness Conversion Tables for Metals.” There are different regimes of hardness based on the load used, as shown in Table 16.8. These divisions are somewhat arbitrary but commonly accepted.

16.11 FRACTURE TOUGHNESS FROM INDENTATION

We can obtain the fracture toughness from indentation tests. The basic idea is illustrated in Figure 16.17. We get an indent and radial cracks. The hardness is then

$$H = P/\alpha a^2 \quad (16.13)$$

TABLE 16.8 Hardness Regimes

Regime	Applied load (N)	Comments
Microhardness	0.0098–1.96	Hardness value decreases as load increases. Possibility for very large variation in values depending on technique used and microstructure. Surface effects may dominate
Low load hardness	1.96–98.1	
Standard hardness	>98.1	Hardness independent of applied load and microstructure

TABLE 16.7 Details of Common Hardness Tests

Test	Indenter	Description	Equation	Notes
Brinell	Hardened steel ball	Brinell hardness number BHN is applied force divided by surface area of indentation	$BHN = F/\pi Dt$	Spherical indenters not used for ceramics
		Meyer hardness number MHN uses projected area	$MHN = 4 F/\pi d^2$	
Vickers	Square pyramid	Vickers hardness number (VHN) using contact area	$VHN = 1.854 F/a^2$	The ceramics community uses mainly the number calculated using the projected area. Need to be careful when comparing data from different sources
		VHN using projected area	$VHN = 2.000 F/a^2$	
Knoop	Elongated pyramid	Knoop hardness number KHN	$KHN = 14.2 FL^2$	
Rockwell	Various indenter types/loads	Dimensionless number and various hardness scales		Widely used for metals, not often for ceramics except cemented carbides

FIGURE 16.17. Cracks at an indent allow determination of K_{Ic} .

where α is a numerical factor that depends on the shape of the indenter. For a Vickers indenter, $\alpha = 2$. P is the load in newtons.

The critical stress intensity factor is obtained by assuming that the applied stress intensity caused by the load is equal to the critical stress intensity for crack propagation:

$$K_{Ic} = \frac{\zeta(\mathcal{E}/H)^{\frac{1}{2}}P}{c^{\frac{3}{2}}} \quad (16.14)$$

where ζ is a dimensionless constant, which for ceramics has an average value of 0.016 ± 0.004 . The use of indentation techniques for determining K_{Ic} has been the subject of many studies since being introduced by Lawn and Wilshaw (1975). The most commonly used variant, termed the indirect method, uses indentation followed by determination of the strength after indentation using bend testing. The main concern is to ensure that the crack does not grow between indentation and bend testing. To minimize effects of reactive species, such as water, a drop of oil may be placed on the indent. Tests seem to give reproducible values for K_{Ic} .

16.12 NANOINDENTATION

The nanoindentation technique was developed in the 1980s because of the need to determine the mechanical properties of thin films and surfaces that had been modified (e.g., by ion implantation). To avoid the influence of the substrate, it is necessary that the penetration depth of the indenter is $>10\%$ of the film thickness. Consequently, penetration depths are on the order of nanometers rather than millimeters, which is common for conventional indentation tests.

Nanoindentation is also used to test small volumes of material. The low loads used mean that the extent of cracking is much smaller than with conventional indentation methods.

The two parameters that are often of most interest in nanoindentation testing are:

- Elastic modulus
- Hardness

Load (P) versus depth of penetration (h) curves, also called compliance curves, are the output from a nanoindentation test. The curves are obtained as load is applied to the indenter tip up to some maximum value and then back to zero. Figure 16.18 shows a general compliance curve for a material that undergoes both elastic and plastic deformation. When the load applied to the indenter is released, the material attempts to return to its original shape. The slope of the elastic unloading region (dP/dh) can be used to determine the modulus and hardness. There are several different equations depending on the tip geometry. If the material is plastically deformed, it cannot return to its original shape and there is a residual impression, h_r , as seen in Figure 16.18. The magnitude of h_r is greater for a metal such as steel than for a ceramic such as sapphire.

Nanoindentation is a powerful technique because the shape of the load–displacement curve can be used to

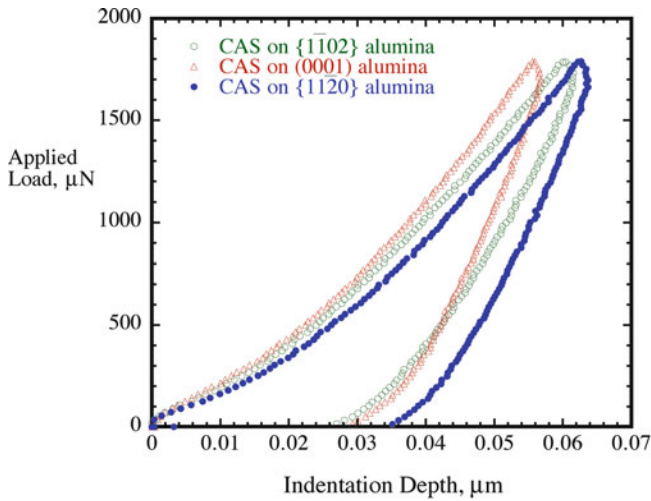

FIGURE 16.18. Load–displacement data on the 1.8 mN indentations of CAS films on three different alumina substrates.

identify effects such as phase transformations, cracking, and film delamination during indentation. It is also important when studying the mechanical properties of nanomaterials, such as carbon nanotubes. There is reference now to a picoindenter, which is a combination of a nanoindenter and an atomic force microscope.

16.13 ULTRASONIC TESTING

The basic principle of ultrasonic testing is that the velocity of an ultrasonic wave through a material is related to its density and elastic properties. This is one example of a dynamic method for determining elastic constants, such as Young’s modulus and shear modulus. Dynamic methods are more accurate than static methods, with uncertainties of <0.5% ($\pm 10\%$ would be more typical for static methods).

To determine the shear modulus and Poisson’s ratio, we need the velocity of the longitudinal and transverse waves, v_L and v_t . The equations are:

$$\mu = \rho v_t^2 \quad (16.15)$$

$$v = \frac{1 - 2(v_t/v_L)^2}{2[1 - (v_t/v_L)^2]} \quad (16.16)$$

$$\mathcal{E} = 2\mu(1 + \nu) \quad (16.17)$$

Conversely, if we know the elastic moduli, we can determine the magnitude of the sound velocities. For ceramics with high moduli and low density, the sound

velocities are much higher than for many metals. The propagation of sound waves through ceramics is particularly important during earthquakes. The Earth’s crust is composed primarily of silica and aluminosilicates. Using equations 16.15 and 16.16, we can show that for SiO_2 (the primary constituent of rocks such as granite) the longitudinal waves are the first shocks to arrive after an earthquake, followed by the transverse waves: $v_L = 6.04 \text{ km/s}$ and $v_t = 4.1 \text{ km/s}$ for quartz. The surface waves are the last to arrive, having a velocity $< 4 \text{ km/s}$, but they often have the most devastating effect.

Ultrasonic testing is widely used in the concrete industry for determining the presence, or absence, of voids, cracks, and other imperfections and for measuring deterioration that might have occurred due to age or through fire or frost damage.

16.14 DESIGN AND STATISTICS

When we measure the strength of a series of equivalent ceramic specimens, we typically find considerable scatter in the results. The reason is due to the size distribution of flaws that are responsible for failure. This behavior is very different from that of metals. Consequently, we have to adopt different design approaches when we use ceramics.

When we design components using metals, we determine the maximum stress present in the component and then select a metal that has a larger strength. A reasonable safety margin is often included. This approach is referred to as deterministic design. It does not work with ceramics because of the large scatter. Rather, we have to use a probabilistic approach where we represent this scatter in a quantitative way so

that these materials can be used safely. The most popular method is to use Weibull statistics, which are based on the weakest link approach. The analogy is to consider a chain the strength of which is determined by the weakest link.

The Weibull distribution function is shown in Figure 16.19 and gives the probability of survival (P_S) or, alternatively, the probability of failure (P_F), of a stressed volume V .

$$P_S = 1 - P_F = \exp \left[- \int_V \left(\frac{\sigma - \sigma_{\min}}{\sigma_0} \right)^m dV \right] \quad (16.18)$$

The Weibull distribution function contains three parameters:

$m =$ Weibull modulus tells us how rapidly the strength falls as we approach σ_0

FIGURE 16.19. Weibull distribution function.

σ_0 = characteristic strength for which the survival probability is 0.37 ($1/e$)

σ_{\min} = stress level below which the probability of failure is zero.

Because there is always a possibility, albeit slight, of our component having a very large flaw, we usually set $\sigma_{\min} = 0$. This leads to the two-parameter form that is used for ceramics.

$$P_S = \exp \left[- \int_V \left(\frac{\sigma}{\sigma_0} \right)^m dV \right] \quad (16.19)$$

If the full volume is under uniform uniaxial tension, then we can write equation 16.19 as:

$$P_S = \exp \left[- \left(\frac{\sigma}{\sigma_0} \right)^m \right] \quad (16.20)$$

For other geometries, we need to include the loading factor, L_F . This takes into account the stress distribution. For uniaxial tension $L_F = 1$; for other loading geometries see Table 16.9. The product ($L_F V$) is often termed the effective volume, V_{eff} , as it indicates how “effectively” the body is being stressed.

Taking the natural logarithm of both sides of equation 16.20 we get:

$$\ln \left(\frac{1}{P_S} \right) = \left(\frac{\sigma}{\sigma_0} \right)^m$$

If we take natural logarithms, again we get

$$\ln \left[\ln \left(\frac{1}{P_S} \right) \right] = m \ln \left(\frac{\sigma}{\sigma_0} \right) = m \ln \sigma - m \ln \sigma_0$$

Now, if we plot $-\ln \ln (1/P_S)$ versus $\ln \sigma$, we get a straight line of slope $-m$, as shown in Figure 16.20. The higher the Weibull modulus, the lower is the

TABLE 16.9 Examples of Loading Factors

Geometry	Loading factor, L_F
Uniaxial tension	1
Pure bending	$1/[2(m+1)]$
3-Point bending	$1/[2(m+1)^2]$
4-Point bending	$(mL_i + L_o)/[2L_o(m+1)^2]$

L_i inner span, L_o outer span

FIGURE 16.20. Weibull plot showing probability of failure as a function of fracture stress.

FIGURE 16.21. Effect of m on survival probability. When m changes, P_s changes.

variability of strength. Values for ceramics are often in the range of 5–20 (compared, for example, to steels, which have values of about 100). Figure 16.21 shows how the Weibull modulus affects the survival probability.

The Weibull modulus, which is the parameter in which we are often most interested, is obtained experimentally by testing a batch of samples. We need a large number of specimens to get an accurate value of m . Usually a minimum of 30 samples is required, and this typically gives m within 20%. Up to 100 samples is not uncommon, and it gives m with >90% confidence.

Sequence of steps to determine m from a set, N , of measured strengths:

1. Rank the specimens in order of increasing strength.
2. Determine P_S . For the j th specimen this is often given as the approximation $P_S(j) = 1 - j/(N + 1)$. A more accurate expression that may be used instead is $P_S = 1 - [(j - 0.3)/(N + 0.4)]$.
3. Plot $-\ln \ln(1/P_S)$ versus $\ln \sigma$ the slope. This can be determined by a least-squares fit and gives m .

In ceramics, there is a volume dependence of the strength. You can illustrate this quite easily using a stick of chalk. As the chalk gets smaller, it gets stronger. The reason is again due to flaws. There is an increased probability of finding a larger flaw in a larger body, as illustrated in Figure 16.22. This effect can be expressed mathematically as

$$P_S = \exp \left[- \left(\frac{V}{V_0} \right) \left(\frac{\sigma}{\sigma_0} \right)^m \right]$$

where $V = nV_0$. An example of the size effect is shown in Figure 16.23 for Si_3N_4 springs. The springs have different diameters of the wire and of the coil, and different numbers of coils were measured.

Complications arise if we have different flaw populations; for example, we may have pores and inclusions introduced during

STRENGTH & VOLUME
The strength of metal samples does not depend on volume.

FIGURE 16.22. The largest flaw is the weakest link and the source of failure. Smaller samples have smaller flaws.

FIGURE 16.23. Fracture stress as a function of volume for Si_3N_4 springs.

sintering and surface flaws introduced during grinding. The different flaws may lead to different Weibull distributions and different Weibull moduli. Figure 16.24A illustrates superposition of two flaw types and Figure 16.24B for a sample containing surface and volume flaws. Then, we have new equations:

For two different surface flaw types:

$$P_S = \exp \left[- \left(\frac{\sigma_c}{\sigma_1} \right)^{m_1} - \left(\frac{\sigma_c}{\sigma_2} \right)^{m_2} \right]$$

For flaw type 1, we have σ_1 and m_1 ; for flaw type 2 we have σ_2 and m_2 .

For two different types of volume flaws:

$$P_S = \exp \left[- \frac{V_{\text{eff}1}}{V_0} \left(\frac{\sigma_c}{\sigma_{v1}} \right)^{m_1} - \frac{V_{\text{eff}2}}{V_0} \left(\frac{\sigma_c}{\sigma_{v2}} \right)^{m_2} \right]$$

As you now realize, it is impossible to design a ceramic where the probability of failure is zero. Table 16.10 gives some examples of what might be considered acceptable probabilities of failure.

Proof testing can be used to truncate the extreme tail of the Weibull distribution. Components are tested up to a certain proof-test stress, σ_{PT} (Figure 16.25) for a short period of time. The weakest ones obviously fail and can be weeded out. We then have increased confidence in the remaining components. We often have to proof test to stresses close to the design stress. For a ceramic with $m = 10$, reducing the risk of rupture from 0.10 to 0.05 requires that the component be proof tested to 93% of the design stress. To reduce the probability of failure by an order of magnitude, down to 0.02, the part must be proof tested to 99% of the design stress (Figure 16.26). We have

FIGURE 16.24. (A) Different flaws lead to different values of m . (B) Weibull plot for a sample having both surface and volume flaws.

TABLE 16.10 Suggested Failure Probabilities

P_F	Possible consequences of failure	Example
0.3	Slight inconvenience	Sticks of chalk
10^{-2}	Inconvenience and small expense	Ceramic cutting tool
10^{-6}	Injury	Window on a vacuum system
10^{-8}	Loss of life and significant expense	Ceramic protective tile on space shuttle

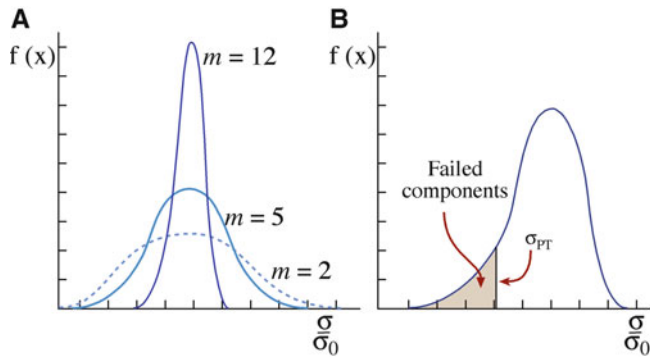

FIGURE 16.25. (A) Probability distributions for different values of m . (B) Proof testing up to σ_{PT} removes the weakest components from the distribution.

a good level of confidence in the remaining components withstanding any stress $< \sigma_{PT}$.

CARES (Ceramics Analysis and Reliability Evaluation of Structures) is a public-domain program from the National Aeronautics and Space Administration (NASA) that incorporates Weibull statistics. The program was

FIGURE 16.26. Plot showing the risk of rupture after proof testing to the ratio of proof test stress to design stress.

formally known by the less friendly acronym SCARE (Structural Ceramics Analysis and Reliability Evaluation).

NASA CARES program is available at: <http://www.grc.nasa.gov/WWW/LPB/cares/life/refs.html/>.

Considerations and assumptions with the use of Weibull statistics:

- We need to ensure that the conditions under which we are testing match those in service. For example, flaws in a component may appear during service as a result of oxidation or corrosion that might not be present in the test sample.
- There is a complex distribution of flaws.
- More than one type of flaw may be present.

16.15 SPT DIAGRAMS

Stress–probability–time diagrams incorporate the time dependence of strength into failure statistics and give life-time predictions. An illustration of the use of SPT diagrams is in bioceramics.

An important requirement for any implant material is how long it will last. Because of the nature of failure of ceramic components, it is not possible to provide a specific and definite lifetime for each individual implant. Rather, we have to express failure in terms of probabilities. Figure 16.27 is an applied stress versus probability of time to failure (SPT) diagram for medical grade alumina. It shows that for a 30-year survival period, with failure of no more than 1 in 100 components, the maximum tensile stress that can be applied is limited to <200 MPa. If stresses of 250 MPa are applied to the ceramic component, within 3 years 4% of the implants are likely to fail and by 30 years 7% will probably fail. Use of SPT diagrams such as these, together with finite element analysis of local stress distributions, make it possible to design ceramic components that have very low probabilities of failure during the lifetime of the patient. Numerous clinical studies have been performed on patients receiving a total hip prosthesis. One of the main problems that have been

FIGURE 16.27. Stress–probability–time (SPT) diagram for medical-grade Al_2O_3 . Survival probability decreases with increasing stress and longer times.

TABLE 16.11 Average Annual Wear Rates of Articulating Surfaces in Total Hip Prosthesis

Materials	Wear Rate ($\mu\text{m}/\text{year}$)
Co-Cr-Mo Alloy/UHMWPE	200
Alumina/UHMWPE	20–130
Alumina/alumina	2

encountered is that of wear between the head (ball) and the socket. Although there is considerable variation in the data, it is generally found that the wear rate for systems with metal balls is much higher than that with alumina balls. Also, alumina balls in alumina sockets produce the least wear of any combination of materials, as indicated in Table 16.11.

CHAPTER SUMMARY

Flaws dominate the mechanical properties of ceramics. They determine how we test them and how we design components from them. Flaws are also the reason why ceramics are stronger in compression than tension. In this chapter, we described the methods used to measure mechanical properties of ceramics. The important ones are bend testing, compression testing, and indentation. To determine the mechanical properties of small volumes we use nanoindentation. This technique is especially important for thin films, surfaces, and nanomaterials. An understanding of statistics is particularly important when using ceramics in load-bearing applications. The Weibull approach is the one most widely used for ceramics.

PEOPLE AND HISTORY

Mohs, Fredrich (1773–1839). A German mineralogist, his original paper on the scratch test and the eponymous hardness scale was published in *Grundriss der Mineralogie* in 1822.

Poisson, Siméon Denis (1781–1840). A French mathematician, he was more suited to mathematics than medicine because of his clumsiness. This was not an impediment for a mathematician! In 1837, he published a

paper on probability, which described the Poisson distribution. During his career, Poisson published more than 300 mathematical works and was reported to have said “Life is good for only two things, discovering mathematics and teaching mathematics.”

Ringer, Sidney (1835–1910). A British physician and physiologist, his original salt solution was developed in 1882 and used to prolong the survival time of tissue taken from a frog’s heart. The solution used to test biomaterials differs in composition from that developed for amphibians.

Young, Thomas (1773–1829). An English physician physicist, he could read fluently by age two and presented his first paper to the Royal Society at the young age of 20. By 1801, he was a professor at the Royal Institution in London. He was probably best known for his classic double-slit experiment, which demonstrated the wave nature of light.

Weibull, E.H. Waloddi (1887–1979). He was a Swedish engineer. The original paper describing his statistical analysis was published in 1939, “A Statistical Theory of the Strength of Materials” (*Ingenjörsvetenskaps-akademiens Handlingar* 151, 1–45). Weibull was a frequent visitor to Wright Patterson Air Force Base in Ohio and lectured at the Air Force Institute of Technology. In 1972, he was awarded the American Society of Mechanical Engineers gold medal for his achievements. King Carl XVI Gustav of Sweden presented Weibull the Great Gold medal from the Royal Swedish Academy of Engineering Sciences in 1978.

EXERCISES

- 16.1 In Figure 16.7, the experimental data for the unstabilized samples deviate from the predicted values for Young’s modulus. (1) What do we mean by “unstabilized”? (2) How can you account for the difference in the predicted values and experimental values?
- 16.2 Is Young’s modulus affected more by the presence of an intergranular glass phase or an equal amount of porosity? Justify your answer with a suitable calculation.
- 16.3 Ten rectangular test specimens of MgO were tested in three-point bending. The bars were 1 cm thick and 0.5 cm high and were tested over a 5-cm span. The failure loads for each are given in ascending order: 140, 151, 154, 155, 158, 165, 167, 170, 173, and 180 kg. Calculate the modulus of rupture (MOR) for each sample and the average MOR for this group of samples.
- 16.4 A commercially available polycrystalline alumina is tested using three different methods: three-point bend, four-point bend, uniaxial tension. The resulting MOR values are 550, 410, and 175 MPa, respectively. What conclusions can you make about the material from these data?
- 16.5 The soda-lime silicate glass sample shown in Figure 16.17 was indented with a load of 20 N. Estimate the (1) hardness and (2) fracture toughness. (3) How else might you obtain the fracture toughness?
- 16.6 For the data shown in Figure 16.20, determine the Weibull modulus.
- 16.7 The following data were obtained in a series of tensile strength tests on polycrystalline silicon carbide specimens (in MPa): 334, 289, 232, 294, 252, 337, 256, 339, 308, 365, 311, 341, 286, 314, 274, 285, 382, 379, 282, 324, 316. (1) Determine the Weibull modulus for these samples. (2) Would you expect the value of m for a set of steel specimens to be higher or lower than the value you calculated in part (1). Assuming that these SiC specimens were made by hot pressing, would you expect m for a series of SiC made by sintering to be higher or lower?
- 16.8 Calculate using the Voight and Reuss models the bounds for Young’s modulus of MgO–Al₂O₃ composites as a function of volume fraction.
- 16.9 Explain briefly why there is a size dependence for the strength of ceramics but not for metals.
- 16.10 Sketch stress–strain plots for polycrystalline MgO at (1) 25°C, (2) 1,000°C, (3) 1,700°C, and (4) 2,800°C.
- 16.11 Explain why the mode I load type is most important for ceramics.
- 16.12 We haven’t listed any values for K_{1c} . Discuss and research some values using the library or other resources and compare them to metals and a polymer such as polymethylmethacrylate (PMMA). (Acknowledge your resources).
- 16.13 If the fracture toughness of steel is 50,000 psi $\sqrt{\text{in}}$, how does this compare to that of glass and concrete? (We are deliberately using antique units: convert them). How much can the value for glass vary?
- 16.14 Consider three otherwise dense, small-grain ceramic cubes with the same overall density but with equally spaced spherical pores of diameters 10 nm, 100 nm, and 1 μm , respectively. How will this porosity affect the elastic moduli?
- 16.15 Mohs hardness is widely used in one field and indentation in another. Discuss the advantages of the former.
- 16.16 Figure 16.16 stops in the early 1980s. Use library resources to discuss this observation. Discuss the indenter shape that would be suitable for a fiber.

- 16.17 Figure 16.18 shows three curves. Calculate the different properties of the three orientations.
- 16.18 Explain why the Voigt and Reuss assumptions lead to equations 16.6 and 16.7, respectively.
- 16.19 Challenge: relate Figures 16.20 to 16.21.
- 16.20 Challenge: we refer to the $d^{-1/2}$ dependence in Figure 16.5. How can this be true for both distributions, and what does it tell us?

Plasticity

CHAPTER PREVIEW

In this chapter, we are concerned with the deformation of ceramics leading to a permanent shape change. This is known as plastic deformation and is both nonrecoverable and irreversible. There are several mechanisms that are responsible for plastic deformation in crystalline materials: dislocation motion, vacancy motion, twinning, phase transformation. In metals at room temperature, dislocation motion is the most important of these mechanisms. In Chapter 12, we noted that dislocations don't move easily in ceramics, and that this is the reason for their inherent brittleness. Nevertheless, dislocation motion is observed in ceramics under specific loading conditions. In general, plastic deformation of ceramics requires high temperatures, and this is important because:

- We often process ceramics at high temperature.
- Many potential applications for ceramics, such as in fuel cells and engines, require them to be stable at high temperature.

We know that glass flows and that we can produce complex shape changes in glass. There are no dislocations in glass, so how does plastic deformation occur? The other question is: does the plastic deformation of glass always require a high temperature?

Selecting ceramics for use at high temperatures or under applied load requires consideration of their long-term stability. Time-dependent deformation is known as creep, and creep resistance is a critical design parameter. Even if creep doesn't lead to failure, a change in shape or size may render a component useless. The mechanism responsible for creep depends on temperature, stress, and the microstructure of the ceramic.

17.1 PLASTIC DEFORMATION

The onset and extent of plastic deformation is often measured when the $\sigma - \epsilon$ behavior of a material is being determined. We showed some general $\sigma - \epsilon$ curves in Chapter 16. In Figure 17.1, $\sigma - \epsilon$ curves obtained for crystals of KBr and MgO tested in bending are shown. From these curves we can identify several parameters that may already be familiar to you from discussion of the mechanical properties of metals.

Proportional limit P : corresponds to departure from linearity and is defined as the onset of plastic deformation. If the transition from elastic to plastic deformation is gradual, it may be difficult to determine precisely where P is, and sometimes it is better avoided.

Yield strength, σ_y : the stress determined by drawing a line parallel to the linear part of the $\sigma - \epsilon$ curve at some specified strain offset. We usually use a strain of 0.002. To compare the values of σ_y in Figure 17.1, you may

recall that for metals we see a wide range of values (e.g., for a low-strength aluminum alloy, $\sigma_y = 35$ MPa; for a high-strength steel, $\sigma_y > 1,400$ MPa). We usually say yield strength rather than yield stress. Strength is a material property; stress is a measure of the applied load.

Fracture strength, σ_F : the stress at fracture. Because ceramics are often tested in bending, we don't see any reduction in cross-sectional area during the test as we often do in a tensile test with a metal. As a result, we would not expect to see a maximum in the $\sigma - \epsilon$ curve corresponding to the tensile strength or ultimate tensile strength.

Figure 17.2 shows a $\sigma - \epsilon$ curve for LiF that illustrates an abrupt elastic-plastic transition. Plastic deformation begins at the upper yield point, and there is a decrease in stress. At the lower yield point, deformation continues at a lower stress level. This type of behavior is similar to that of some low-carbon steels and also aluminum oxide and magnesium oxide at high temperatures.

17.2 DISLOCATION GLIDE

Dislocation glide (or slip) is a primary mechanism for plastic deformation in crystals. Slip takes place discontinuously in bands, as illustrated in Figure 17.3. Although we often think of dislocations in ceramics as immobile, they can glide, as shown in Figure 17.4A. In this case, a crystal of LiF has been plastically bent, and the dislocations are revealed by etching. Figure 17.4B is a dark-field transmission electron microscopy (TEM) image that shows a glide band in spinel. The dislocations are visible in the dark-field image as the bright lines against a dark background.

Both the direction of slip and usually the slip plane have a definite crystallographic orientation; together they are known as the slip system. Slip systems for several ceramics are given in Table 17.1. Primary slip systems are those for which slip is easiest; it is more difficult on secondary slip systems and is usually activated at higher temperature. What determines the slip system for ceramics?

The slip direction is usually that having the smallest spacing between atoms or ions of the same type (highest linear density). In metals, the slip plane is often the closest packed plane (highest planar density). In ceramics, we

consider planar density, but there is often the additional consideration of electrostatic interaction between ions. We can illustrate these considerations by

looking at the familiar rock salt structure (structure of NaCl and MgO). This is an interesting example to start with because the first studies of crystal plasticity, which were conducted by Reusch in 1867, were conducted using sodium chloride. He concluded that the slip system for NaCl is $\{110\}\langle 1\bar{1}0\rangle$.

FIGURE 17.1. Stress–strain curves for KBr and MgO crystals tested in bending.

SLIP SYSTEM

A plane and a direction and is represented as $\{hkl\}\langle uvw\rangle$.

FIGURE 17.2. Stress–strain curve for a LiF single crystal.

FIGURE 17.3. Slip bands. (A) Macroscopic appearance. (B) Atomic movements.

FIGURE 17.4. (A) Glide bands in LiF revealed by etching. (B) “Glide” bands in spinel: (top) 200°C; (bottom) 950°C.

The choice of slip plane has often been explained by considering the position of ions during slip. Figure 17.5 compares the ion positions during slip on {100} and {110}. The key difference is that slip on {100} would increase the distance between opposite ions, whereas during slip on {110} oppositely charged ions are brought closer together. The overall effect is that slip on {110} would lead to a decrease in electrostatic interaction energy. Clearly, this is not the complete story, as we mentioned in Section 12.5. Not all crystals with the rock salt structure share the same

slip system as shown in Table 17.2. The primary glide plane depends on the atoms present. For PbS and PbTe, the primary glide plane is {100}, not {110}. The explanation proposed back in 1930 by Buerger is based on the polarizability or “deformability” of the ions. As the sum of the polarizability of both ions increases, there is increasing ease of slip on {100} and increasing plasticity.

17.3 SLIP IN ALUMINA

The slip system for α -alumina (corundum) is given in Table 17.1. The primary slip plane is the basal plane, (0001); the slip direction is $\langle 11\bar{2}0 \rangle$. The arrangement of atoms on the slip plane is shown in Figure 12.13A. For the oxygen ions, the close-packed direction is actually $\langle 1100 \rangle$; this is not the slip direction because we need to consider what happens to the aluminum ions, which occupy only two thirds of the octahedral interstices. Slip along $\langle 11\bar{2}0 \rangle$ preserves the stacking sequence of the aluminum ions. Temperatures around 1,300°C are needed before significant plastic deformation is observed in single-crystal alumina. At even higher temperatures, other slip systems become activated, as summarized in Table 17.3.

Because of the large Burgers vector involved, the combined motion of partial dislocations may lead to slip. You can remember the background to this argument from Chapter 12. Graphite is another hexagonal ceramic where slip has been found to occur by the motion of partial dislocations.

17.4 PLASTIC DEFORMATION IN SINGLE CRYSTALS

There are many mechanisms that can lead to plastic deformation in single crystals, but the most important is slip. The two things that we need to consider are the inherent resistance to the movement of dislocations provided by the periodicity of the lattice and the orientation of the crystal with respect to the applied stress.

Lattice Resistance: the stress, τ_f , needed to move a dislocation along the slip plane is known as the Peirels-Nabarro (or frictional stress) and is given by c :

$$\tau_f = \mu \exp\left(-\frac{2\pi w}{b}\right) \quad (17.1)$$

The stress is clearly a function of the crystal structure and bonding, it depends on b and w . You may recall from Chapter 12 that dislocation widths in covalent solids are quite narrow ($w \sim b$) compared with those in face-centered cubic (fcc) metals ($w \sim 10b$).

- For metals $\tau_f \sim 10 \text{ MPa} \sim 10^{-4} \mu$, these stresses are fairly small, and dislocations can move freely. The yield stress is determined primarily by interactions

TABLE 17.1 Slip Systems for Several Ceramics

Material	Crystal structure	Slip systems		Activation temperature (°C)	
		Primary	Secondary	Primary	Secondary
Al ₂ O ₃	Hexagonal	{0001}<1120>	Several	1,200	
BeO	Hexagonal	{0001}<1120>	Several	1,000	
MgO	Cubic (NaCl)	{110}<110>	{001}<110>	0	1,700
MgO·Al ₂ O ₃	Cubic (spinel)	{111}<110>	{110}<110>	1,650	
β-SiC	Cubic (ZnS)	{111}<110>		>2,000	
β-Si ₃ N ₄	Hexagonal	{1010}<0001>		>1,800	
TiC, (ZrC, HfC, etc.)	Cubic (NaCl)	{111}<110>	{110}<110>	900	
UO ₂ , (ThO ₂)	Cubic (CaF ₂)	{001}<110>	{110}<110>	700	1,200
ZrB ₂ , (TiB ₂)	Hexagonal	{0001}<1120>		2,100	
C (diamond)	Cubic	{111}<110>			
C (graphite)	Hexagonal	{0001}<1120>			
β-SiO ₂	Hexagonal	{0001}<1120>			
CaF ₂ , (BaF ₂ , etc.)	Cubic	{001}<110>			
CsBr	Cubic (CsCl)	{110}<001>			
TiO ₂	Tetragonal	{110}<110>	{110}<001>		
WC	Hexagonal	{1010}<0001>	{1010}<1120>		

FIGURE 17.5. Comparison of slip in the rock salt structure on {100} and {110} planes.

between dislocations and other defects, such as impurities.

- For simple ionic ceramics (e.g., NaCl and CaF₂) $\tau_f \sim 10\text{--}100 \text{ MPa} \sim 10^{-4} \mu \text{ to } 10^{-3} \mu$.

- For complex ionic ceramics (e.g., Al₂O₃) and covalent ceramics (e.g., SiC), $\tau_f \sim 1,000 \text{ MPa} \sim 10^{-2} \mu$. Dislocations have low mobility, and lattice resistance is the main obstacle.

Orientation: plastic deformation depends not only on how easy it is for the dislocations to glide on their slip plane but also the orientation of the slip plane and the slip direction with the applied stress. If we consider a single crystal subject to uniaxial tension, as illustrated in Figure 17.6, the shear stress acting on the slip plane in the slip direction is:

$$\tau_r = \sigma \cos\phi \cos\psi \quad (17.2)$$

where τ_r is the resolved shear stress.

For some structures it is possible to orient the crystal so that τ_r on all operative slip systems is zero. If this is the case, dislocation motion does not occur, and the crystal does not plastically deform at stresses below the theoretical lattice strength. For example, in MgO τ_r is zero when σ is applied along $\langle 111 \rangle$. Under these loading conditions at elevated temperatures ($>300^\circ\text{C}$), slip may occur on the secondary slip system: $\{001\}\langle 110 \rangle$.

The critical resolved shear stress, τ_{crss} , is the minimum shear stress required to initiate slip for a particular slip system defined when $\sigma = \sigma_y$.

$$\tau_{\text{crss}} = \sigma_y (\cos\phi \cos\psi) \quad (17.3)$$

Figure 17.7A shows the stress–strain behavior for a single crystal that is favorably oriented for plastic flow.

TABLE 17.2 Comparison of Primary Glide Planes in Crystals Having the Rock Salt Structure

Crystal	Primary glide plane	Polarizability (10^{-30} m^{-3})			Lattice constant (nm)
		Anion	Cation	Total	
LiF	{110}	0.03	1.0	1.03	0.401
MgO	{110}	0.09	3.1	3.19	0.420
NaCl	{110}	0.18	3.7	3.88	0.563
PbS	{100}	3.1	10.2	13.3	0.597
PbTe	{100}	3.1	14.0	17.1	0.634

TABLE 17.3 Slip Systems in α -Alumina (Corundum)

System name	Slip system	Remarks
Basal	(0001) $1/3\langle 2\bar{1}\bar{1}0 \rangle$	Dominant system under shear superimposed on 1 atm of pressure
Prismatic	$\{1\bar{2}10\}\langle 10\bar{1}0 \rangle$ $\{1\bar{2}10\}\langle 10\bar{1}1 \rangle$	Occurs above 1,600°C under shear superimposed on 1 atm of pressure
Pyramidal	$\{1\bar{1}02\}\langle 01\bar{1}1 \rangle$ $\{10\bar{1}1\}\langle 01\bar{1}1 \rangle$	Occurs above 1,600°C under shear superimposed on 1 atm of pressure

FIGURE 17.6. Geometry used to determine the critical resolved shear stress.

This type of behavior is seen in MgO and other ceramics with the rock salt structure. There are three distinct stages.

- Stage I: easy glide of dislocations with the possibility of large strains (~20%)
- Stage II: interaction of dislocations on intersecting slip planes, resulting in work hardening
- Stage III: cross-slip

FIGURE 17.7. (A) Stress–strain curve for a crystal suitably oriented for plastic flow. (B) Temperature dependence of the normalized critical resolved shear stress for two strain rates, where $\dot{\gamma}_1 > \dot{\gamma}_2$.

The value of τ_{crss} depends on test conditions, such as temperature and strain rate, as shown in Figure 17.7B. We can again identify three distinct behaviors.

- Region I: τ_{crss} decreases with increasing temperature and decreasing strain rate. Thermal fluctuations enhance dislocation motion.
- Region II: τ_{crss} is independent of temperature and strain rate. There is interaction between dislocations and between dislocations and other defects.
- Region III: τ_{crss} again decreases with increasing temperature and decreasing strain rate. At high temperatures diffusion processes can become important.

17.5 PLASTIC DEFORMATION IN POLYCRYSTALS

Plastic deformation is more difficult in polycrystals than in single crystals because now we have to consider what happens at the grain boundaries. Grain boundaries act as barriers to dislocation motion; and if adjacent grains are not favorably oriented for slip to continue, dislocations pile up at the boundary.

A polycrystal needs five independent slip systems before it can undergo an arbitrary strain. This requirement is known as the von Mises criterion. A slip system is independent if the same strain cannot be produced from a combination of slip on other systems. From Table 17.4 you can see why MgO might be ductile when stressed as a single crystal, whereas in polycrystalline form it is brittle except at high temperature where secondary slip systems operate. For polycrystalline MgO, the brittle-to-ductile transition occurs at $\sim 1,700^\circ\text{C}$, as shown in Figure 17.8. Some cubic materials (e.g., TiC, MgAl_2O_4) do have enough independent slip systems; but the Peierls-Nabarro stress is high, making dislocations immobile except at high temperature.

The Hall–Petch relation (equation 14.9) tells us the effect of grain size, d , on the stress required to make the dislocation move in a polycrystalline sample. The origin of the relation is that the stress to operate a Frank-Read source increases as the size of the source decreases. If the grain size decreases, then the maximum size of the Frank-Read source also decreases. The result is the famous $d^{1/2}$ relationship.

Hence, the grain size of a polycrystalline ceramic is important in determining the yield strength and the fracture strength of ceramics. Figure 17.9 illustrates the background to equation 14.9. Slip starts in the most favorably oriented grains. If the material is to plastically

FIGURE 17.8. Stress–strain curves for polycrystalline MgO as a function of temperature.

FIGURE 17.9. Slip propagation from grain A to grain B.

TABLE 17.4 Independent Slip Systems for Some Ceramics

Lattice type	Crystal	Slip system	No. of independent systems
Rock salt	MgO, NaCl, LiF, NaF	$\{110\}\langle 1\bar{1}0\rangle$	2
Rock salt	MgO, NaCl, LiF, NaF	$\{110\}\langle 1\bar{1}0\rangle$ $\{001\}\langle 1\bar{1}0\rangle$ $\{111\}\langle 1\bar{1}0\rangle$	5 at high temperature

deform, then slip must propagate from one grain to the next. Stress concentrations are built up at the grain boundary at P, and they are greater when the length of the slip band, or the grain size, is large. For deformation to continue, the stress must be sufficient to start dislocation motion in an adjacent grain; and this is easier for large-grain samples. The increase in strength of polycrystalline KCl as the grain size decreases (an illustration of the Hall–Petch phenomenon) is shown in Figure 17.10.

In some cases, the Hall–Petch equation appears to hold when the grain size is on the order of several nanometers. In these cases, deformation cannot be due to dislocation glide, and perhaps equation 14.9 is best thought of as a scaling law. Figure 17.11 shows a Hall–Petch plot for TiO_2 over a wide range of grain sizes. At the very smallest grain sizes studied, the behavior is inverse or negative Hall–Petch. The reasons for this transition are not well understood, and the transition does not appear to occur for all nanomaterials.

17.6 DISLOCATION VELOCITY AND PINNING

Figure 17.12 shows the stress dependence of dislocation velocity for CaF_2 . At low stresses, the relationship has the form:

$$v = \left(\frac{\tau}{\tau_0} \right)^p \quad (17.4)$$

FIGURE 17.11. Compressive yield stress as a function of grain size for nanocrystalline TiO_2 at three levels of porosity.

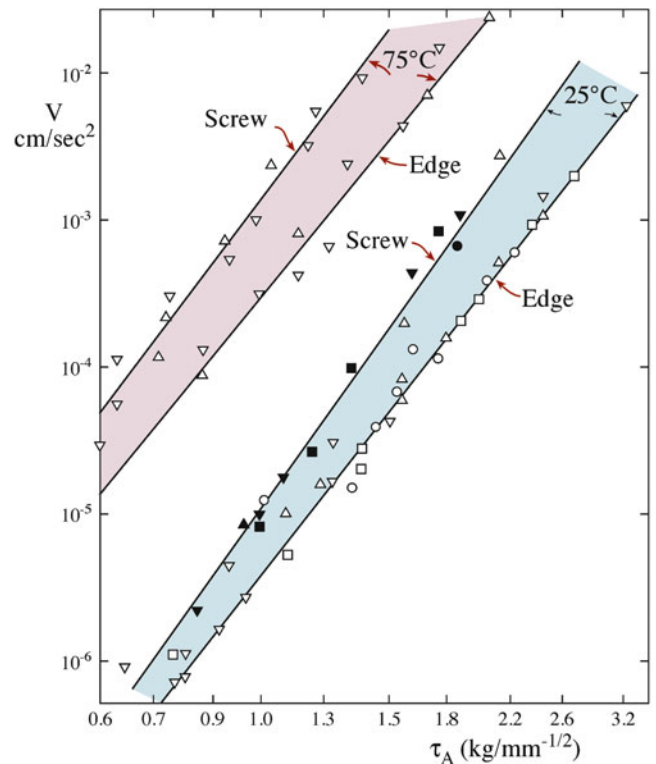

FIGURE 17.12. Stress dependence of dislocation velocity.

Both τ_0 and p are material constants: τ_0 is the shear stress for unit dislocation velocity, and p is the velocity stress exponent that describes the stress dependence of the dislocation velocity. Values are given for some materials in Table 17.5. At very high stresses, equation 17.4 does not hold as the maximum dislocation velocity in a crystal

TABLE 17.5 Values of the Constants in Equation 17.4 for Some Materials^a

Material	τ_o (MPa)	ρ
Zn	0.03	1
Cu	0.03	1
Mo	64.8	7
Nb	48.3	16
Fe + 3%Si	193.1	30
NaCl	1.45	8
LiF	11.7	25
Ge (440°C)	965 GPa	1

^aAt room temperature, except for Ge

equals the velocity of sound. Determination of dislocation velocity has been done using the etch-pit technique, as illustrated in Figure 17.13 for LiF.

Dislocations in ceramics can be pinned by solute atoms just as they can in metals, as shown in Figure 17.14. The dislocations are impeded because of their interaction with the stress field around the impurity. This effect has long been used to strengthen metals.

17.7 CREEP

Creep is time-dependent permanent deformation that is often due to diffusion processes rather than dislocation motion. Engineers need to consider creep in cases where ceramic components are used in load-bearing applications at high temperature. It is necessary to specify a particular

FIGURE 17.14. Solute hardening in MgO.

FIGURE 17.15. Creep curve illustrating three distinct regimes.

maximum strain that is acceptable during the anticipated lifetime of the component.

In general, creep behavior of ceramics is similar to that of metals. However, in ceramics it usually occurs at higher temperatures, typically $>0.5T_m$. In comparison, creep is a consideration in aluminum alloys at 100°C and in polymers at room temperature. Creep is particularly important in ice, which creeps extensively at low temperatures. The creep of ice is responsible for the movement of glaciers and the spreading of the Antarctic ice cap.

Figure 17.15 shows a general creep curve. There are three regimes.

- Transient or primary creep: following spontaneous elastic strain, the creep rate (also referred to as creep strain rate) decreases with time from an initially high value. This stage of creep is often represented by an equation of the form:

$$\epsilon = \beta T^m \quad (17.5)$$

where β is a constant, and M varies from 0.03 to 1.0 depending on the material, stress, and temperature. In some ceramics (e.g., SiC fibers) this may be the only stage shown.

- Steady-state or secondary creep: strain increases linearly with time, the creep rate is constant, and deformation may continue for a long time. This is the most important regime. The equation for secondary creep is:

$$\epsilon = Kt \quad (17.6)$$

where K is a constant that depends on stress and temperature. The mechanisms for this stage are discussed in the next sections.

- Tertiary creep: a rapid increase in creep rate just before failure. This stage is often missing for ceramics.

The creep behavior of a ceramic is determined by measuring the strain rate as a function of load. In the simplest approach, a load is attached to the sample, which is heated; the deformation is then measured as a function of time. Because of the problems we mentioned earlier of performing tensile tests on ceramics, the load is usually applied by bending. The disadvantage of bending tests is the inhomogeneous stress state, which changes during creep deformation. The creep behavior of ceramics is different if the load is applied in tension or compression; and compressive creep tests may, although rarely, be performed.

STRAIN & CREEP

Elastic strain: $\epsilon_0 = \sigma/\mathcal{E}$

Creep rate: $\dot{\epsilon}_c = \frac{d\epsilon_c}{dt}$

ϵ_c is the creep strain

There are three mechanisms for creep, and we describe each of them in the following sections.

17.8 DISLOCATION CREEP

Dislocation creep occurs by dislocation motion (i.e., glide and climb). For the climb-controlled process, the creep rate can be expressed as:

$$\dot{\epsilon} = \frac{\alpha D_L \mu b}{kT} \left(\frac{\sigma}{\mu} \right)^n \quad (17.7)$$

which we can simplify by taking all of the “constants” into a temperature-dependant constant Γ .

$$\dot{\epsilon} = \Gamma \sigma^n \quad (17.8)$$

This is a simple power law equation; and when $n > 1$, we refer to it as power law creep. For climb, n is in the range of 4–5; for a glide-controlled process, $n = 3$.

17.9 DIFFUSION-CONTROLLED CREEP

Diffusion-controlled creep is due to atomic diffusion. There is no dislocation motion. Considering the single crystal shown in Figure 17.16, Nabarro (1948) showed that vacancies would move from the faces under tension to those under compression. There is a counterflow of atoms, and we get a permanent shape change as a result.

TERMS IN CREEP EQUATIONS

α	A constant
D_L	Lattice diffusivity
k	Boltzmann's constant
b	Burgers vector
T	Absolute temperature
σ	Applied stress
μ	Shear modulus
m	Grain size exponent
n	Stress exponent
Ω	Atomic volume
d	Grain size
D_{gb}	Grain boundary diffusivity
δ	Grain boundary width
A	Dimensionless constant
D	Diffusion coefficient

For Nabarro-Herring creep, the creep rate is given by:

$$\dot{\epsilon} = \frac{\alpha D_L \sigma \Omega}{d^2 kT} \quad (17.9)$$

In this case, the constant, α , depends on the extent of grain-boundary sliding, as determined by Herring (1950).

FIGURE 17.16. Nabarro-Herring creep.

For simple tension test measurements under steady-state conditions, $\alpha = 13.3$.

We assume that:

- The main source and sink for vacancies are grain boundaries.
- We have equilibrium.
- There is no cavitation.

The important points about Nabarro-Herring creep are:

- Temperature has to be high enough to allow significant vacancy diffusion.
- Diffusion is considered to occur through the bulk of the material.
- Because of the d^{-2} dependence, the creep rate increases with decreasing grain size (shorter diffusion distance).
- The creep rate is proportional to the applied stress (at least for lower stresses).
- There is linear dependence between the strain rate and stress.

At lower temperatures and for fine-grained ceramics, grain boundary diffusion may be the dominant path. In these situations, the process is termed Coble creep (Coble 1963); and the creep rate is:

$$\dot{\epsilon} = \frac{150\Omega\delta D_{gb}\sigma}{\pi d^3 kT} \quad (17.10)$$

The important points to note from equation 17.10 are:

- Creep rate varies as d^{-3} —hence it is important for very fine-grained ceramics.
- $D_{gb} > D_L$, so Coble creep is favored at lower temperatures.

Nabarro-Herring and Coble creep can take place in parallel, so that the creep rates involve both components and both diffusion coefficients. In ceramics, we also have the situation where both anions and cations are diffusing, adding further complications to the creep rate equations. If there is a large difference in the diffusion rates, then the creep rate is controlled by the slower diffusing species along the faster diffusing path.

17.10 GRAIN-BOUNDARY SLIDING

In some ceramics, an intergranular film (IGF) forms during fabrication, often due to the addition of a sintering aid. If this phase softens at high temperature, then we get creep by grain boundary sliding. The glass viscosity, η , which is a function of temperature, controls the creep rate. As the temperature increases, the viscosity decreases, which is usually represented by an empirical relation known as the

Vogel-Fulcher-Tammann (VFT) equation or sometimes simply the Fulcher equation.

$$\ln \eta = A + \frac{B}{T - T_0} \quad (17.11)$$

A , B , and T_0 are constants for a particular glass. The VFT equation works very well except at temperatures close to the glass transition temperature, T_g .

There are several mechanisms that can result in a permanent change in shape. In one mechanism, the glass is squeezed out of the boundaries during compression flowing to those under tension. Proof of this mechanism comes from high-resolution TEM, which can be used to measure directly the thickness, w , of the IGF. In these cases:

$$\dot{\epsilon} = \frac{\alpha w^3 \sigma}{\eta_0 d^3} \quad (17.12)$$

Another proposed mechanism is that of dissolution and precipitation, which is illustrated in Figure 17.17. Here, grains dissolve in the liquid at points of high stress, and this solute then diffuses through the liquid and precipitates at regions of low stress. In this case the creep rate is:

$$\dot{\epsilon} = \frac{\alpha w \sigma \Omega^{\frac{2}{3}}}{\eta_0 d^3} \quad (17.13)$$

FIGURE 17.17. Dissolution-precipitation mechanism that could be operative in ceramics containing a glassy phase at the grain boundary.

This latter mechanism is similar to what happens during liquid-phase sintering (see Chapter 24). The requirements are that:

- The solid must have a certain amount of solubility in the liquid.
- The liquid must wet the solid.

The composition of the IGF is important in determining overall creep behavior. For example, using Y_2O_3 as a sintering aid for silicon nitride ceramics has been found to be superior to using MgO. Other important aspects of the microstructure are the grain size and the volume fraction of liquid present.

17.11 TERTIARY CREEP AND CAVITATION

Tertiary creep represents the final stage of creep deformation and involves an acceleration of the creep rate followed by failure of the component. This stage does not occur in all ceramics; and as we noted already, certain ceramics exhibit only primary creep. Tertiary creep involves the formation of cavities that lead to crack formation, often along grain boundaries. The cracks can propagate rapidly particularly under tensile loading.

Although the nucleation of cavities does not seem to be well understood at present, it is clear that cavitation depends on the microstructure. Porosity and second-phase particles, which are sources of stress concentration (see Chapter 18), can act as nucleation sites for cavitation and subsequent crack growth. Remember that pores can be found in most ceramics; even “pore-free” materials such as hot-pressed alumina may contain small pores. Cavitation occurs also in ceramics with IGFs. Nucleation of the cavities usually occurs at regions where the IGF is not homogeneous (e.g., nonwetted regions, gas bubbles, impurity particles).

Figure 17.18 shows cavity size distribution data for two polycrystalline aluminas. One is Lucalox (there is no glassy phase), and the other is 99% pure alumina with a glassy phase. The data were obtained using small-angle neutron scattering. For Lucalox, the number of pores increase with increasing creep strain, but their size does not increase—nucleation is the dominant process. For the alumina with a glassy phase, both the number and size of the pores increase with creep strain—we are getting both nucleation and growth.

17.12 CREEP DEFORMATION MAPS

From the previous sections you can see that there are a large number of creep mechanisms. They can be expressed by one general equation.

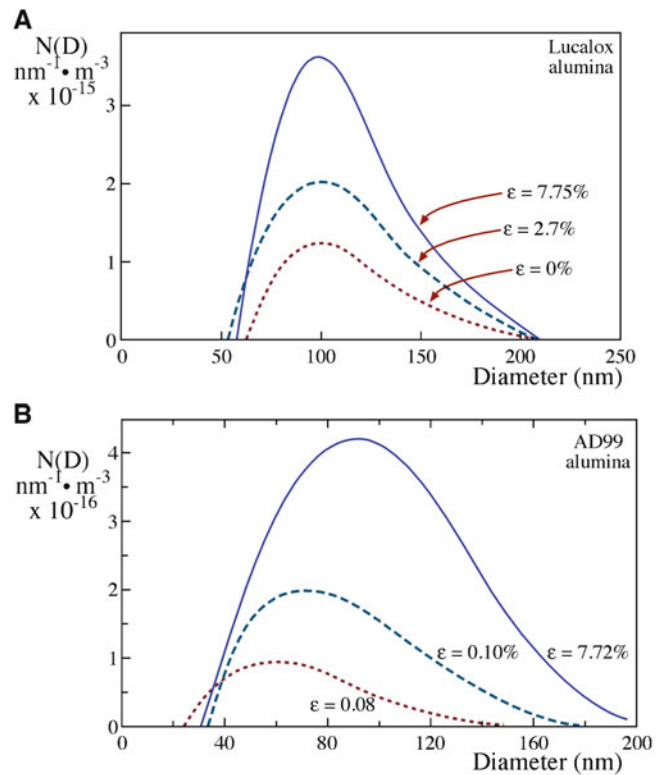

FIGURE 17.18. (A) Cavity-size distribution as a function of creep strain in alumina without a glassy phase (Lucalox). (B) Cavity-size distribution as a function of creep strain in alumina with a glassy phase (AD99).

TABLE 17.6 Creep Equation Exponents and Diffusion Paths for Various Creep Mechanisms

Creep mechanism	m	n	Diffusion path
<i>Dislocation creep mechanism</i>			
Dislocation glide climb, climb controlled	0	4–5	Lattice
Dislocation glide climb, glide controlled	0	3	Lattice
Dissolution of dislocation loops	0	4	Lattice
Dislocation climb without glide	0	3	Lattice
Dislocation climb by pipe diffusion	0	5	Dislocation core
<i>Diffusional creep mechanisms</i>			
Vacancy flow through grains	2	1	Lattice
Vacancy flow along grain boundaries	3	1	Grain boundary
Interface reaction control	1	2	Lattice/grain boundary
<i>Grain boundary sliding mechanisms</i>			
Sliding with liquid	3	1	Liquid
Sliding without liquid (diffusion control)	2–3	1	Lattice/grain boundary

$$\dot{\epsilon} = \frac{AD\mu b}{kT} \left(\frac{b}{d}\right)^m \left(\frac{\sigma}{\mu}\right)^n \quad (17.14)$$

The various creep mechanisms give rise to different values of the exponents, m and n , as shown in Table 17.6.

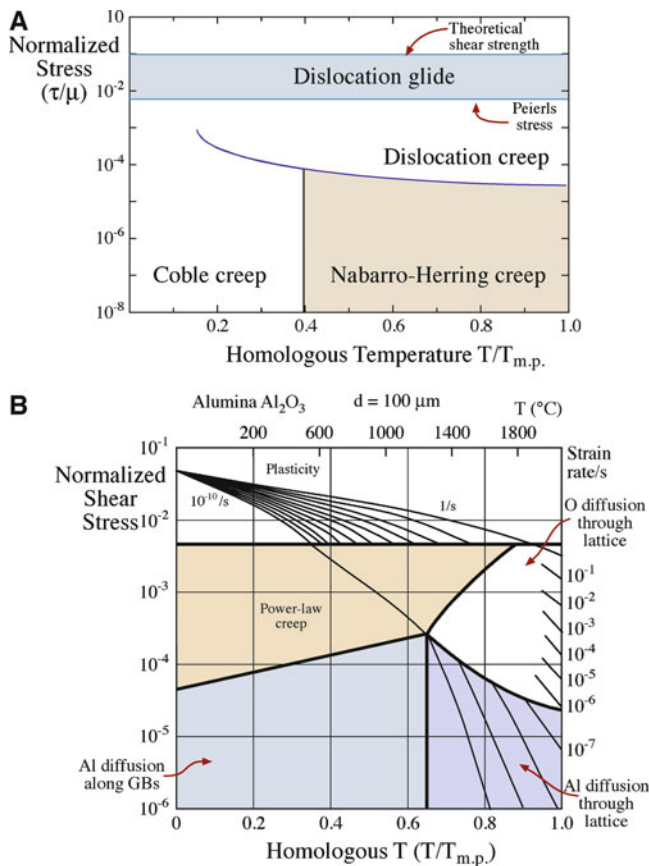

FIGURE 17.19. (A) Creep deformation map for a polycrystalline ceramic. (B) Creep deformation map for Al_2O_3 .

For a given ceramic, a specific creep mechanism may dominate at certain temperatures and stresses. This can be represented on a creep deformation map, as illustrated in Figure 17.19A for the general case and in Figure 17.19B for the specific case of Al_2O_3 . As you can imagine, these maps are based on a large amount of experimental data.

17.13 VISCOUS FLOW

Viscous flow is an important mechanism for permanent deformation in glasses. It allows us to form complex shapes, as shown in Figure 17.20. Viscous flow is also a mechanism by which ceramics containing IGFs undergo creep. Thus, it is a characteristic that is both beneficial and deleterious—but unavoidable at high temperature.

Under most conditions, oxide glasses behave as Newtonian fluids (i.e., the strain rate, $d\gamma/dt$, is a linear

FIGURE 17.20. Detail from a glass sculpture by Dale Chihuly.

function of applied shear stress, τ). An important consequence of this behavior is that when we draw glasses, such as during the formation of optical fibers, the cross section reduces at a constant rate. In other words, we don't get necking of narrow sections of the fiber. At high stress levels, non-Newtonian behavior, which is common in polymers, may be observed in oxide glasses.

Models of viscous flow

Absolute-rate theory: viscous flow is a thermally activated process involving a high-energy activated state. Viscosity follows an Arrhenius expression with activation energy for viscous flow, E_v . The preexponential term has a weaker dependence on temperature than the exponential term. This theory is applicable only over a narrow range of temperatures.

Free-volume theory: molecular motion involves the availability of vacancies. The vacancy volume is the free volume, V_F , of the liquid—approximately the difference in the volume of the liquid, V_L , and crystalline, V_C , forms. V_F is a function of temperature. D is a constant close to unity. The Williams-Landel-Ferry (WLF) equation uses a similar approach, where f_g is the fraction of the free volume at T_g , about 0.025, and β_L and β_C are the volumetric thermal expansion coefficients of the liquid and solid, respectively.

Excess-entropy theory: there is a decrease in the configurational entropy, S_c , of a liquid when it is cooled down—fewer molecular arrangements are possible.

This makes deformation more difficult. E_s is proportional to the potential energy barrier for molecular rearrangement.

VISCOUS FLOW

Newton's Law

$$\tau = \eta d\gamma/dt$$

EQUATIONS FOR VISCOUS FLOW

Arrhenius:

$$\eta = \eta_0 \exp\left(\frac{E_v}{RT}\right)$$

Turnbull and Cohen:

$$\eta = \eta_0 \exp\left(\frac{DV_c}{V_F}\right)$$

Williams-Landel-Ferry (WLF):

$$\eta = \eta_0 \exp\left(\frac{D}{f_g + (\beta_L - \beta_C)(T - T_g)}\right)$$

Adams-Gibbs:

$$\eta = \eta_0 \exp\left(\frac{E_s}{TS_c}\right)$$

Vogel-Fulcher-Tammann (VFT):

$$\eta = \eta_0 \exp\left(\frac{C}{T - T_0}\right)$$

The Vogel-Fulcher-Tammann (VFT) equation is an empirical expression relating η to T and can be interpreted in terms of the different models. The VFT expression is accurate over a wide range of temperatures and is widely used in many practical applications.

The viscosity of a specific glass depends on temperature, as shown in Figure 17.21. Glass blowing is often performed at viscosities of ~ 10 MPa·s. This is at the top end of the working range, which extends from 1 kPa·s

FIGURE 17.21. Temperature dependence of viscosity for a soda-lime-silica glass.

FIGURE 17.22. Microblown silica shape formed on oxidized SiC.

to 10 MPa·s. Figure 17.22 shows a microblown feature formed in a silica scale on oxidized SiC at $1,800^\circ\text{C}$, which for pure silica corresponds to the softening point. If the viscosity was at the fining temperature (~ 5 Pa·s), the gas would have been able to escape easily. If the viscosity were too high, the glass would not have been able to deform in this way.

There is also time dependence to the viscosity, particularly near T_g and above. At these temperatures, structural relaxation occurs.

17.14 SUPERPLASTICITY

Superplasticity is the ability of a material to sustain very large strains. From our discussions so far on the mechanical properties of ceramics, you may think it unlikely that any ceramic would exhibit superplasticity. Superplasticity, though has been observed in, for example, tetragonal ZrO_2 stabilized with Y_2O_3 . Elongations of 800% were observed for ceramics stabilized with 3 mol% Y_2O_3 and 1,038% for tetragonal zirconia stabilized with 2.5 mol% Y_2O_3 containing 5 wt% SiO_2 . The general requirements are that the grains should be:

- Small (typically $< 1 \mu\text{m}$)
- Equiaxed

The mechanism for superplasticity in ceramics must clearly be different from that in metal alloys because there

is no appreciable change in grain shape. Several models have been proposed. The one illustrated in Figure 17.23 involves grain switching and accounts for the constancy of grain shape during deformation, but it cannot account for the increase in surface area resulting from plastic deformation. Other models involve grain boundary sliding but, again, don't appear to fully account for the process.

Although superplasticity is a useful forming process for metals, it tends not to work for ceramics because of the problem of cavitation and the requirement of high temperatures.

FIGURE 17.23. Model shows how grain switching can produce a shape change.

CHAPTER SUMMARY

Although we often think of the mechanical properties of ceramics entirely in terms of their brittleness, in this chapter we showed that plastic deformation is also important. The main difference between plasticity in ceramics and in metals is that for ceramics the primary mechanism of plastic deformation may not be the motion of dislocations. If dislocations are involved, then we are invariably at high temperatures. Plastic deformation is a key engineering design consideration in the use of ceramics in structural applications. Consequently, understanding creep behavior is essential, which means we have to understand point defects (see Chapter 11) and in many cases the role of IGFs (see Chapter 15). As an illustration of why we devoted an entire chapter to this topic, remember the example from the final section: elongations in excess of 1,000% have been observed in some ceramics. This is clearly not the conventional wisdom when it comes to ceramics and probably something that you would not have expected prior to reading this chapter. Unfortunately, we have not been able to come up with a clear explanation for this property.

PEOPLE AND HISTORY

Herring, W. Conyers (1914–2009) was Emeritus Professor of Applied Physics at Stanford University. He was elected to the National Academy of Sciences in 1968. In 1988, he could be seen in the café at Xerox PARC.

Nabarro, Frank Reginald Nunes (1916–2006). Born in London in 1916, he studied at Oxford and Bristol University. In 1953 he became head of the Physics Department at the University of the Witwatersrand in South Africa. He is remembered by name in Nabarro-Herring creep and the Peierls-Nabarro force.

von Mises, Richard (1883–1953). He was born in Lemberg, Austria-Hungary, which is now Lviv, Ukraine. A mathematician and engineer, he worked in a number of areas including statistics, probability theory, and mechanics. He died in Boston.

EXERCISES

- 17.1 An MgO single crystal is loaded in uniaxial compression, with the [001] direction parallel to the compression axis. Assuming that dislocation motion occurs on the primary slip system when the applied stress is 30 MPa, what is the inherent lattice resistance to dislocation motion?
- 17.2 The lattice parameter of MgO is $a = 0.4211$ nm. Calculate the distance between Mg^{2+} and O^{2-} ions prior to slip (Figure 17.5A, C) and at the midpoint position (Figure 17.5B, D) during slip on {100} and {110} planes
- 17.3 Figure 17.14 shows the hardening effect of NiO additions to MgO. Based on what you know about these two ceramics, would you expect the NiO/MgO system to show a complete range of solid solubility? You must justify how you arrived at your answer.
- 17.4 Figure 17.22 shows a microblown silica shape formed on SiC. What gas do you think would be formed at the SiO_2/SiC interface and lead to the shape shown? Would the gas be different at different temperatures?
- 17.5 For each of the ceramics listed in Table 17.1, would a tensile stress applied parallel to the c axis give a nonzero resolved shear stress?
- 17.6 The following dislocation reaction has been proposed for dislocation motion in graphite: $a/3 [2\bar{1}\bar{1}0] = a/3 [1\bar{1}00] + a/3 [10\bar{1}0]$ Is the reaction favorable as written? Justify your answer and state any assumptions that you make.

- 17.7 The addition of impurity atoms can pin dislocations in single crystals. The addition of small amounts (0.002%) of NdF_3 to CaF_2 can be very effective at increasing the yield stress because of the formation of point defect complexes. Using the Kröger–Vink notation, show that adding NdF_3 to CaF_2 can result in the formation of a defect complex.
- 17.8 Creep is a concern for structural ceramics at high temperatures. Discuss possible creep mechanisms for SiC and Si_3N_4 .
- 17.9 A major multinational company hires you as a consultant because of your knowledge of ceramics. You are asked to recommend a ceramic that has the maximum possible creep resistance at an operating temperature of $1,200^\circ\text{C}$. What material would you select and why? Also consider how you would process it.
- 17.10 Using the data in Figure 17.21, determine the activation energy for viscous flow in the soda-lime-silica glass. Based on your knowledge of glass structures, would you expect the activation energy to be higher or lower for a pure silica glass? Briefly justify your answer.
- 17.11 Which is softer— MgO or KCl ? What are the main deciding factors?
- 17.12 What can you learn from Figure 17.2?
- 17.13 Is Figure 17.3 consistent with Figure 17.4A?
- 17.14 Several secondary slip systems are missing from Table 17.1. Why are they missing, and what might they be?
- 17.15 Consider Table 17.2: what are the slip systems, and which obvious one is missing?
- 17.16 Derive equation 17.2.
- 17.17 Explain in words how MgO is deforming in each situation shown in Figure 17.8.
- 17.18 Explain the number of independent slip systems in Table 17.4.
- 17.19 When a dislocation moves from grain A to grain B in Figure 17.9, what happens to the grain boundary?
- 17.20 Are the two diagrams in Figure 17.13 consistent? Explain your reasoning.

Fracturing: Brittleness

CHAPTER PREVIEW

The previous two chapters on mechanical properties described how we test ceramics, their elastic response, and how under certain conditions they can permanently deform. In this chapter we describe why and how ceramics break. The main topics are

- Fracture
- Toughening
- Fatigue

Some of these topics may already be familiar from classes on metals. The exception is probably toughening. Ceramics are not tough. Toughening requires making the material absorb energy during fracture by mechanisms such as local phase transformations, plastic deformation near the crack tip, or crack bridging behind the crack tip. Fracture requires cracks. Fatigue is where crack growth occurs as a result of cyclic loading—even at small loads.

We begin this chapter by showing some of the key equations. The most important work is that of A.A. Griffith, the “father of fracture mechanics.” Griffith showed the importance of flaws, which act as stress concentrators. Because it is almost impossible to make ceramics without flaws, they often are the dominant cause of failure. Hence, there is a link between this chapter and Chapter 16.

18.1 IMPORTANCE OF BRITTLINESS

Most ceramics at room temperature are brittle. That is, they fracture with very little plastic deformation. Many archeologists believe that our very existence depended on the brittleness of ceramics, particularly flint. The fracture of flint, like cubic zirconia, diamond, and glass, is termed conchoidal—producing shell-like fracture surfaces. These surfaces are very sharp and were utilized in early stone tools to cut and shape wood and to butcher animals required for food. The hides were used for clothing and were attached to wooden frames to make shelters. Stone tools were necessary for cutting vegetation and cultivating plants, allowing a change from a food-gathering economy to one of food production, which happened around the eighth millennium BCE in southwestern Asia. This revolutionary change from hunting to farming laid the foundation of civilization.

Bulletproof glass, which is a laminate of glass and polycarbonate, is a dramatic illustration of the utilization of brittle fracture. The glass absorbs the energy of the projectile either in elastic changes or ultimately in the creation of new surfaces when it fractures. The polymer provides an additional mechanism for absorption of energy before the

projectile exits the final layer. Table 18.1 gives the kinetic energy of several different types of handgun bullets.

The brittle behavior of ceramics is critical to the successful operation of ceramic armor. In addition to brittleness, the basic requirements are that it is:

- Hard
- Lightweight

The first ceramic used in this application was alumina backed with a laminate of fiberglass and polyester resin called “Doron.” Boron carbide (B_4C) ceramic armor was developed during the Vietnam War and used in the mid-1960s for both helicopter and infantry armor. It provides the same protection as alumina but with a 20% savings in weight. A quarter inch (0.64-cm) plate of B_4C can stop a 30 caliber armor-piercing projectile (one containing a tungsten carbide core). Boron carbide was being used during the conflict in Iraq. Small arms protective inserts are made of boron carbide. They stop up to a 7.62 mm round with a muzzle velocity of ~850 m/s.

Brittle fracture is used for shaping and machining ceramics after they have been fired. We can modify ceramics to make them machinable. This is called controlled

TABLE 18.1 Kinetic Energy of Handgun Projectiles

Handgun size	Missile size (g)	Missile velocity (m/s)	Energy (J)
0.38	10	243	295
0.22	2.6	305	133
0.45	15	259	503
0.357	10	381	725
9 mm	8	332	440

fracture and is the approach we adopt with machinable glass-ceramics such as Macor (see Chapter 26). Of course, many ceramics already are machinable and can be shaped into intricate and beautiful forms, as illustrated in the carved marble sculpture shown in Figure 18.1.

In many of the applications where we use or would like to use ceramics nowadays, their brittleness can be a serious limitation. Think about:

- Space shuttle tiles are made of silica glass. We need to be concerned about the impact of space debris.
- Radomes are made of fused silica and silicon nitride. They have to be transparent to infrared and radio waves and resist the impact of atmospheric particles.
- Ceramic bearings are used in low-load applications (watch bearings of ruby or sapphire “jewels”); but for high-load and high-speed use, metals are often preferred because ceramics have low fracture toughness.

It is important to remember that metals and polymers can also fracture in a brittle manner, but brittle fracture often occurs only at temperatures below room temperature.

FIGURE 18.1. Marble sculpture in a fountain outside the Pantheon in Rome.

18.2 THEORETICAL STRENGTH: OROWAN EQUATION

We consider brittle fracture at the atomic level where we are separating two planes of atoms, as shown in Figure 18.2A. In many crystalline materials, fracture occurs along crystallographic planes that are relatively densely packed. These planes are known as cleavage planes. In MgO, {100} is the cleavage plane. [It is interesting that {111} is the growth plane for MgO and that fluorite is exactly the opposite!] In glasses and in some crystals (diamond and cubic zirconia, for example), fracture is noncrystallographic.

Figure 18.2B shows a plot of stress versus distance. Note that we are using X for distance (rather than r , as we did in Chapter 3) because we are now thinking about planes of atoms rather than individual atoms. The curve

FIGURE 18.2. (A) Model of a crack tip. The interplanar spacing is a_0 . (B) Stress versus distance plot.

is the same; it is only the notation that changes. If a stress is applied that exceeds the theoretical strength, σ_{th} , the ceramic fractures. This is the strength of the ceramic if there is no plastic deformation and there are no defects. It is “theoretical” because we can rarely, if ever, achieve it. We would like to be able to obtain an expression for σ_{th} , and there are several different approaches we can use. The one we have selected is simple, works well, and gives values similar to those obtained by more complex methods.

The part of the σ - X curve near the equilibrium interplanar spacing, a_0 , can be approximated as being sinusoidal, and we can write:

$$\sigma = \sigma_{th} \sin(2\pi x/\lambda) \quad (18.1)$$

where x is the displacement of the planes beyond their equilibrium value, and λ is the wavelength of the sine wave.

Two new surfaces are created during fracture—the fracture surfaces. They have a total energy 2γ , which must be equal to the work required to separate the two planes of atoms (i.e., it is the area under the curve or the integral of equation 18.1 between 0 and $\lambda/2$):

$$2\gamma = \int_0^{\lambda/2} \sigma_{th} \sin(2\pi x/\lambda) dx = \lambda \sigma_{th} / \pi \quad (18.2)$$

Rearranging equation 18.2 gives:

$$\sigma_{th} = 2\pi\gamma/\lambda \quad (18.3)$$

For low stresses, the material is elastic, Hooke’s law is obeyed, and we can write the Young’s modulus as:

$$E = \sigma a_0/x \quad (18.4)$$

and

$$d\sigma/dx = E/a_0 \quad (18.5)$$

For small displacements, we can make the approximation $\sin x \sim x$, and from equation 18.1 we can write:

$$d\sigma/dx = 2\pi\sigma_{th}/\lambda \quad (18.6)$$

Combining equations 18.5 and 18.6 gives:

$$2\pi\sigma_{th}/\lambda = E/a_0 \quad (18.7)$$

By substitution of equation 18.3, we get the Orowan equation:

$$\sigma_{th} = (E\gamma/a_0)^{1/2} \quad (18.8)$$

Theoretical strength thus depends on:

- Surface energy
- Young’s modulus
- Lattice spacing

Putting in reasonable values for γ (see Chapter 13) and a_0 , we find that $\sigma_{th} \approx E/5$ to $E/10$. This is a useful relationship to remember. Values of σ_{th} for some materials calculated using the Orowan equation are given in Table 18.2. These values are possible only in very special forms, such as silica fibers with pristine surfaces. Whiskers and fibers of sapphire and silicon carbide have been made with measured strengths of about $\sigma_{th}/2$ (Table 18.3).

For most polycrystalline ceramics, measured strengths are in the range of $E/100$ to $E/1000$ or even less. The question is: why is there such a large discrepancy between theoretical and measured strengths? The reason is the presence of preexisting cracks on the surface or inside the ceramic and the sharp corners that may be introduced during processing. The presence of cracks does not mean that samples fracture spontaneously: our teeth are full of cracks.

18.3 EFFECT OF FLAWS: GRIFFITH EQUATION

To explain the discrepancy between theoretical strength predicted by equation 18.8 and experimental data, Griffith (1920) suggested that preexisting flaws in the materials act to concentrate stress. Figure 18.3 shows data obtained by

TABLE 18.2 Values of Theoretical Strength

Material	Direction	E (GPa)	γ (J/m ²)	σ_{th} (GPa)
α -Fe	<111>	132	2	30
Si	<111>	188	1.2	32
NaCl	<100>	44	0.25	6.3
MgO	<100>	245	1.2	37
Al ₂ O ₃	<0001>	460	1	46

TABLE 18.3 Comparison of Theoretical Strength and Actual Strength

Material	E (GPa)	Estimated theoretical strength (GPa)	Measured strength of fibers (GPa)	Measured strength of polycrystalline specimen (GPa)
Al ₂ O ₃	380	38	16	0.4
SiC	440	44	21	0.7

FIGURE 18.3. Tensile strength of glass fiber as a function of fiber diameter.

Griffith for the tensile strength of glass fibers as a function of their diameter. As the fibers get smaller, the probability of having a crack decreases and the size of the largest crack also decreases. Consequently, they get stronger. This is the basis of the “weak link” approach adopted in Weibull statistics that we described in Chapter 16. Hence, there is a direct relationship between flaws and the probability of failure.

Griffith’s approach is an energy balance: a crack propagates when the additional energy created by the formation of the fracture surfaces, E_s , is offset by a decrease in the stored elastic energy, E_e , in the stretched bonds (this is the area under the stress–strain curve). The Griffith energy balance condition can be expressed as

$$\frac{dE_e}{dc} = \frac{dE_s}{dc} \quad (18.9)$$

Note that we are using E for energy to avoid any confusion with Young’s modulus (\mathcal{E}). The elastic energy term is:

$$E_e = \pi\sigma^2 c^2 / \mathcal{E} \quad (18.10)$$

The surface energy term is

$$E_s = 4c\gamma \quad (18.11)$$

Because E_s scales linearly with c and E_e scales quadratically with c , there is a maximum in the total energy E_{tot} of the system, which corresponds to the critical crack size, c_{crit} . This balance can be represented graphically, as shown in Figure 18.4.

- A crack smaller than c_{crit} is stable; the surface energy dominates.

SCRIBING

A simple illustration of the effect of surface flaws is the ease with which a sheet of glass can be ‘cut’ after light scribing using a diamond tip.

FIGURE 18.4. Plots of energy versus crack length. U_{tot} is the sum of U_s and U_e . The right plot corresponds to a greater applied stress (on this scale, the stress is greater by $\sqrt{2}$, and c_{crit} is correspondingly reduced by a factor of 2).

FIGURE 18.5. “Griffith” crack of length $2c$.

- A crack larger than c_{crit} is unstable; the released strain energy dominates.

For an atomically sharp crack of length $2c$, as illustrated in Figure 18.5, the energy balance approach shows that:

$$\sigma_f = (2\mathcal{E}\gamma/\pi c)^{1/2} \quad (18.12)$$

Equation 18.12 is often called the Griffith equation and shows that fracture stress depends on:

- Young’s modulus (a property of the material)
- Surface energy (a property of the material)
- Crack length

Griffith confirmed this equation using experimental data on glass, as shown in Figure 18.6. Although the energy balance approach works well, kinetic effects may also be present during

fracture, as demonstrated for the fracture of mica flake.

FIGURE 18.6. Verification of equation 18.12. Tensile strength of glass as a function of crack length.

18.4 CRACK TIP: INGLIS EQUATION

In our discussions of fracture, so far we have assumed that the crack looks much like that shown in Figure 18.2a. The crack separates planes of atoms, is atomically sharp, and the only deformation is elastic and ahead of the crack tip. This is the situation encountered in many ceramics at room temperature.

For the geometry in Figure 18.5, the maximum tensile stress at the crack tip is:

$$\sigma_m = 2\sigma(c/\rho)^{1/2} \quad (18.13)$$

where ρ is the crack tip radius. The ratio σ_m/σ is called the stress concentration factor. As an illustration of how big the stress concentration factor can be, we consider an example of a ceramic with a flaw size c of 50 μm . The stress concentration at the crack tip is about 1,200.

For fracture to occur in an ideal brittle material, the maximum stress must reach the theoretical strength of the material to provide a mechanism for fracture (i.e., $\sigma_m = \sigma_{th}$). If we set the applied stress (σ) equal to the fracture stress (σ_f), we obtain:

$$\sigma_f = \left(\frac{E\gamma}{4c} \frac{\rho}{a_0} \right)^{1/2} \quad (18.14)$$

From equation 18.14, you can see why sharp cracks are so deleterious to the strength of ceramics. For metals, there is often a plastic zone ahead of the crack tip that is due to dislocation motion. This leads to blunting of the crack tip and a corresponding decrease in stress concentration.

A crack in a brittle material passes between adjacent planes of atoms, and a reasonable estimate for the tip radius is half the atomic spacing. Therefore, we can simplify equation 18.14:

$$\sigma_f = (E\gamma/8c)^{1/2} \quad (18.15)$$

The fracture process, although not far from ideal in ceramics, can be quite complex. Real cracks differ from those assumed in the model in that there is often no distinct crack edge. There are attractive interactions between atoms on opposite sides of the crack when the spacing is quite small.

18.5 STRESS INTENSITY FACTOR

We introduced the stress intensity factors in Chapter 16. These are a combination of c and σ for different loading geometries with respect to crack position.

The most important geometry for ceramics is mode I, the opening mode. The mode I stress intensity factor is

$$K_I = \sigma Y \sqrt{c} \quad (18.16)$$

where Y is a dimensionless term that depends on crack configuration and loading geometry. For a simple interior crack of length $2c$ and tensile loading, $Y = \sqrt{\pi}$ (this is the original geometry considered by Griffith); for a surface crack under similar loading, $Y = \sqrt{(\pi/2)}$.

The critical stress intensity factor for mode I loading, K_{Ic} , at which the crack propagates and leads to fracture is known as the fracture toughness (sometimes denoted as T). Table 18.4 lists some values for ceramics. You can see that the values are generally low, and a significant amount of research has been undertaken over the last four decades to increase K_{Ic} . We look at some of the approaches that have been used a little later in this chapter.

If the material is not perfectly brittle (i.e., there are energy-dissipating mechanisms in addition to the creation of new surfaces), then we introduce a term G_c , which is an energy (its units are J/m^2) representing crack extension by all the available processes. You may find G_c referred to as total work of fracture, crack extension force, and the strain energy release rate.

For plane stress (the sample is a thin plate):

$$K_{Ic} = \sqrt{(EG_c)} \quad (18.17)$$

AI ALLOYS
Fracture toughness $\sim 40 \text{ MPa/m}^2$

TABLE 18.4 Fracture Toughness for Several Ceramics

Ceramic	K_{Ic} (MPa/m ²)
Al ₂ O ₃	2.0–6.0
Al ₂ O ₃ (single crystal, 10–12)	2.2
Al ₂ O ₃ (single crystal, 0001)	>6.0
MgO	2.5
MgAl ₂ O ₄	1.9–2.4
Mullite (fully dense)	2.0–4.0
ThO ₂	1.6
Y ₂ O ₃	1.5
ZrO ₂ (cubic)	3.0–3.6
ZrO ₂ (partially stabilized)	3.0–15.0
SiC (hot pressed)	3.0–6.0
SiC (single crystal)	3.7
Si ₃ N ₄ (hot pressed)	3.0–10.0
TiC	3.0–5.0
WC	6.0–20.0
CaF ₂	0.80
KCl (single crystal)	~0.35
MgF ₂	1.00
SrF ₂	1.00
Aluminosilicate glass (Corning 1720)	0.96
Borosilicate glass (Corning 7740)	0.75
LAS (glass-ceramic)	2.00
Silica (fused)	0.80
Silica (96%)	0.70
Soda-lime silica glass	0.82

For plane strain (the sample is a thick block):

$$K_{Ic} = \sqrt{\frac{EG}{(1 - \nu^2)}} \quad (18.18)$$

When fracture occurs we can write:

$$G_c = dE_s/dc = R \quad (18.19)$$

Where R is the crack resistance of the material and is called the crack resistance “force.” The material fractures when $G_c = R$; that is, the crack extension force is equal to the crack resistance force. If the fracture is entirely brittle, the energy is required only to create new surfaces; then $R = 2\gamma$. (Note: the surface energy term used here differs from that in equation 18.11 by a factor of two because G_c is associated with a single crack tip.)

Table 18.5 compares some measured values of G_c to some theoretical values based on surface energies. You can see that for MgO the two values are in good agreement. This is not the case for the metal alloys.

18.6 R CURVES

The crack resistance R is related to fracture toughness as we just described. It was assumed that R and T are independent of crack length, but this is not necessarily so. The R curve, which is a plot of fracture toughness versus crack length, relates the crack resistance to crack length, as shown in

TABLE 18.5 Theoretical and Measured Values of G_c for Some Materials

Material	Theoretical $G_c = 2\gamma$ (N/m)	Measured G_c (N/m)
Glass	3.5	14
Plexiglass	11.4	480
MgO	14.9	17.5
High-strength steel	22.8	53,000
High-strength aluminum	7.0	17,000
High-strength titanium	10.5	105,000

FIGURE 18.7. A material showing R curve behavior (*bold curve*) exhibits a region with stable crack growth and flaw-tolerant behavior. The lighter curves, σ_1 and σ_2 , represent typical Griffith behavior.

Figure 18.7. The fracture toughness increases as the crack grows. We can explain the shape of these curves by considering what happens in the wake of the crack. If there is a mechanism that bridges the crack, then the energy required for crack propagation increases. There are several mechanisms that can be envisaged, for example, a phase transformation associated with crack propagation or ligaments that bridge the crack after the crack tip has passed. Both mechanisms are described when we discuss how we actually try to toughen ceramics.

Eventually, a plateau is reached beyond which fracture toughness does not increase. This is the steady-state condition. The implications for ceramics that show R curve behavior are:

- Strength degradation less dependent on flaw size (illustrated in Figure 18.8).
- Increased reliability. There is a region where the strength is insensitive to crack size.
- Decreased fatigue resistance.
- Better thermal shock resistance.

FIGURE 18.8. Effect of R curve behavior on strength. There is a region where the strength is insensitive to flaw size.

18.7 FATIGUE AND STRESS CORROSION CRACKING

The cracks that we have been describing so far lead to rapid fracture. We call them “critical cracks.” Ceramics may contain many other cracks, called “subcritical cracks,” that can lead to time-dependent fracture. Static fatigue, also known as stress rupture, is where subcritical cracks grow under an applied load. Failure occurs gradually and is often unexpected; it may occur after a component has been in service for many years.

CORROSION & FAILURE

The corrosion rate of silica glass in water is 10^{-17} m/s.
The rate of stress corrosion cracking (SCC) is 10^{-3} m/s.

The slow growth of cracks is often the result of a combination of stress and corrosion. This is the field of stress corrosion cracking (SCC), which is important in metals such as gold jewelry alloys and many ceramics. Figure 18.9 shows experimentally measured crack velocities in soda-lime glass tested in nitrogen of varying relative humidity. We can identify three distinct regions.

Region I: crack growth is sensitive to K_I and follows a relationship of the form:

$$v = A^* \exp \alpha K_I \quad (18.20)$$

where A^* and α are fitting parameters. From an engineering point of view this is the most important region.

Region II: crack growth independent of K_I

Region III: very rapid crack growth leading to fracture

For many materials there exists a threshold value of K_I , below which the crack does not grow. This value is not seen in Figure 18.9 because of the experimental difficulties of measuring very small values of crack velocity.

FIGURE 18.9. Crack velocity in soda-lime glass as a function of K_I , the stress intensity factor. The percentages indicate the relative humidity, and the Roman numerals indicate the three regions of crack propagation.

Figure 18.10 illustrates the process that is happening at the crack tip. The corresponding reaction, which involves breaking of Si-O bonds, is:

Other small polar molecules, such as methanol (CH_3OH) and ammonia (NH_3), can promote SCC in glass. The main requirement is that they are small enough to fit into the crack (<0.3 nm).

Ceramics can also fail by cyclic fatigue. The mechanisms are complicated and not well understood. Fatigue failure in metals is pervasive and due to dislocation motion.

Because fatigue is due to propagation of cracks, it is related to K . During a fatigue cycle, K varies, so what we are actually interested in is ΔK , the difference between K at maximum load (K_{\max}) and K at minimum load (K_{\min}).

$$\Delta K = K_{\max} - K_{\min} \quad (18.21)$$

Figure 18.11A shows a log-log plot of the crack growth rate (dc/dN), where N (the number of cycles—hence the odd units) is plotted against ΔK . We can identify three distinct regions.

FIGURE 18.10. Environmental effects at the crack tip. A water molecule diffuses to the crack tip, chemisorbs, and rotates such that the lone pairs on the oxygen are aligned with the unoccupied electron orbitals of the Si atom.

Region I: the lower limit to the curve ΔK_T is the threshold stress intensity factor range for crack growth. In this range, crack growth with cyclic loading is negligible, if indeed it occurs at all.

Region II: the plot is linear, and the crack growth rate can be described by the following equation (sometimes called the Paris-Erdogan equation)

$$dc/dN = B(\Delta K)^q \quad (18.22)$$

where B and q are materials constants that are determined empirically.

Region III: at high ΔK values, crack growth is very rapid; and fracture would be characteristic of normal static failure.

Figure 18.11B shows examples of cyclic fatigue plots for several ceramics. The curves are linear and very steep, implying a high value of q in equation 18.22 and that fracture is rapid. The fatigue fracture we see in metals is rare in ceramics.

18.8 FAILURE AND FRACTOGRAPHY

Here we discuss the appearance of different surfaces formed when a ceramic fractures. This is the topic of fractography and is always a postmortem analysis. Fractography is used not only to determine the failure mechanism but also the origin of fracture. Examples of where fractography is used include:

- Dentistry (e.g., examination of teeth to improve survivability)
- Liability cases (e.g., hip implants to determine who's to blame)
- Disasters (e.g., space shuttle tiles to make sure problem doesn't recur)

Figure 18.12 illustrates two different crack paths through a material. In Figure 18.12A, the crack passes between grains, and fracture is termed intergranular. Intergranular fracture is most likely when the grain boundaries are weak. A striking example of intergranular fracture is shown in Figure 18.13A. The ceramic is AlN that was prepared by sintering, with Y_2O_3 added as a sintering aid. The individual grains, which are faceted, can be clearly seen in the scanning electron microscopy (SEM) image.

In transgranular (or cleavage) fracture, the crack passes through the grains, as illustrated in Figure 18.12B. The fracture surface may be smooth or show steps, which form as the crack front moves from one plane to another. Figure 18.13B shows transgranular fracture in polycrystalline SiC. In conchoidal fracture, there are no distinct cleavage planes. As we mentioned earlier, conchoidal fracture occurs in flint, cubic zirconia, diamond, and glass.

When fracture surfaces are examined, in addition to determining the failure mechanism we also are often interested in the origin of fracture, which might help identify the cause. By reassembling the pieces and looking for where cracks come together, as illustrated in Figure 18.14, it is possible to determine crack initiation sites. They may be associated with flaws (e.g., pores or inclusions) introduced during processing.

The extent of crack branching provides information about the amount of energy associated with crack propagation. There is more branching if the applied stresses are large or if there are large residual stresses that are released as the crack advances. The latter principle is utilized in tempered glass. Extensive crack branching occurs, causing the glass to eventually break into many small pieces.

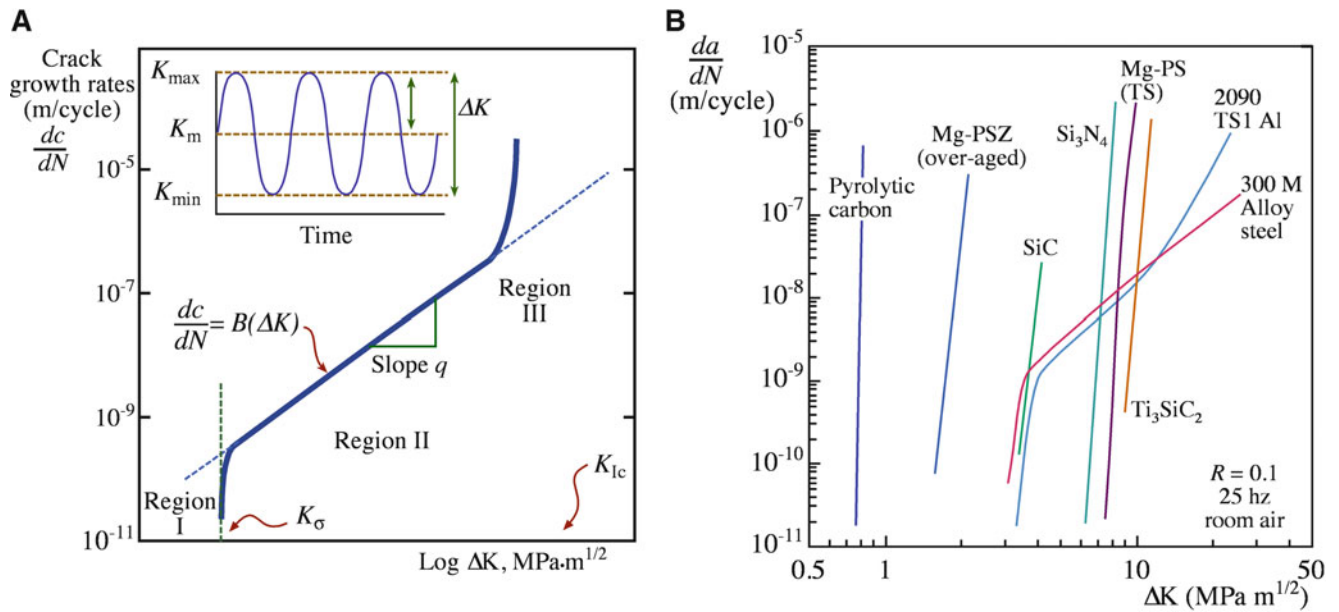

FIGURE 18.11. (A) Log-log plot of crack growth rate dc/dN versus K (defined in the inset). (B) Cyclic-fatigue crack growth rates for several ceramics and metal alloys as a function of applied stress intensity range, ΔK .

FIGURE 18.12. (A) Intergranular cracking. (B) Transgranular cracking.

In glasses it is often quite easy to determine the origin of fracture, as shown in Figure 18.15. We can identify three distinct regions on the fracture surface.

Mirror—The region around the crack origin. The crack travels in a single plane, accelerating as it goes. The fracture surface is smooth and highly reflective. It can

FIGURE 18.13. (A) Fracture surface of polycrystalline AlN. (B) Fracture surface of polycrystalline SiC.

FIGURE 18.14. Determination of crack origin and failure mechanism by postmortem examination of glass fragments.

be seen in polycrystalline ceramics, but reflectivity is lower.

Mist—The crack deviates because it reaches a critical velocity, intersects an inclusion, or there is a change in the internal stresses in the glass. The fracture surface is rougher and less reflective. This region is often difficult to see in polycrystalline ceramics.

Hackle—Crack branches form larger ridges and further increase the roughness of the fracture surface. By tracing the hackle lines backward, we can usually determine the origin of fracture.

Hackle is also referred to as river patterns because of the similar appearance to a river branching into tributaries. Figure 18.16 illustrates river patterns on the fracture surface of an Nd-doped YAG single crystal that fractured during growth. The irregular-shaped voids seen in the image are where failure originated.

18.9 TOUGHENING AND CERAMIC MATRIX COMPOSITES

Ceramics usually have low fracture toughness. For many engineering applications, we must increase the toughness. The desire to toughen ceramics is not new. Toughening of brick using straw was known in 9,000 BCE. The basic idea is how to stop crack movement, thereby increasing the amount of energy required for crack propagation.

TOUGHENING
We want to increase G_c to toughen the ceramic.

The toughening mechanisms for ceramics are summarized in Table 18.6. A stress–strain curve for a toughened ceramic is shown in Figure 18.17. In this particular case, reinforcing the ceramic matrix—a lithium aluminosilicate (LAS) glass ceramic—with fibers (SiC) produced the desired toughening. The resulting fracture surface is shown in Figure 18.18. Toughening is achieved by bridging of the crack surfaces behind the crack tip by a strong reinforcing phase. The stress intensity at the crack tip is reduced, and this slows crack propagation. The fibers absorb energy as the crack front advances. An additional energy-absorbing process that often accompanies crack bridging is fiber pullout away from the crack plane, as illustrated in Figure 18.19.

The factors that contribute to the fracture toughness of a composite are:

- Volume fraction of reinforcement. Figure 18.20 shows how fracture toughness increases for SiC whisker-reinforced ceramics as a function of increasing whisker content.
- Young’s modulus of matrix and reinforcement. If a matrix is reinforced with high-modulus, high-strength fibers, then more of the stress can be carried by the fibers.
- Strength of the matrix/reinforcement interface. In fiber-reinforced composites, a strong interface can lead to transfer of the stress from matrix to the fibers; a weak interface can lead to debonding and crack deflection.

For the specific case where toughening is due to elastic deformation of a partially debonded reinforcement with no interfacial friction, K_{Ic} has been determined to be:

$$K_{Ic} = \sqrt{\{E_c G_m + \sigma_f^2 [(r V_f E_c \gamma_f) / (12 E_f \gamma_i)]\}} \quad (18.23)$$

The subscripts c, m, and f refer to the composite, matrix, and reinforcement, respectively. Increases in fracture toughness are predicted by:

- Increasing V_f
- Increasing E_c/E_f
- Increasing γ_f/γ_i

The last item in the list implies that toughness is enhanced when the interface between the fiber and matrix is weak. The crack then passes around the fiber, as shown in Figure 18.21.

An important toughening mechanism involves a phase transformation in zirconia (ZrO_2). The best-known example is zirconia-toughened alumina (ZTA), which contains 10–20 vol% of fine ZrO_2 particles. At elevated

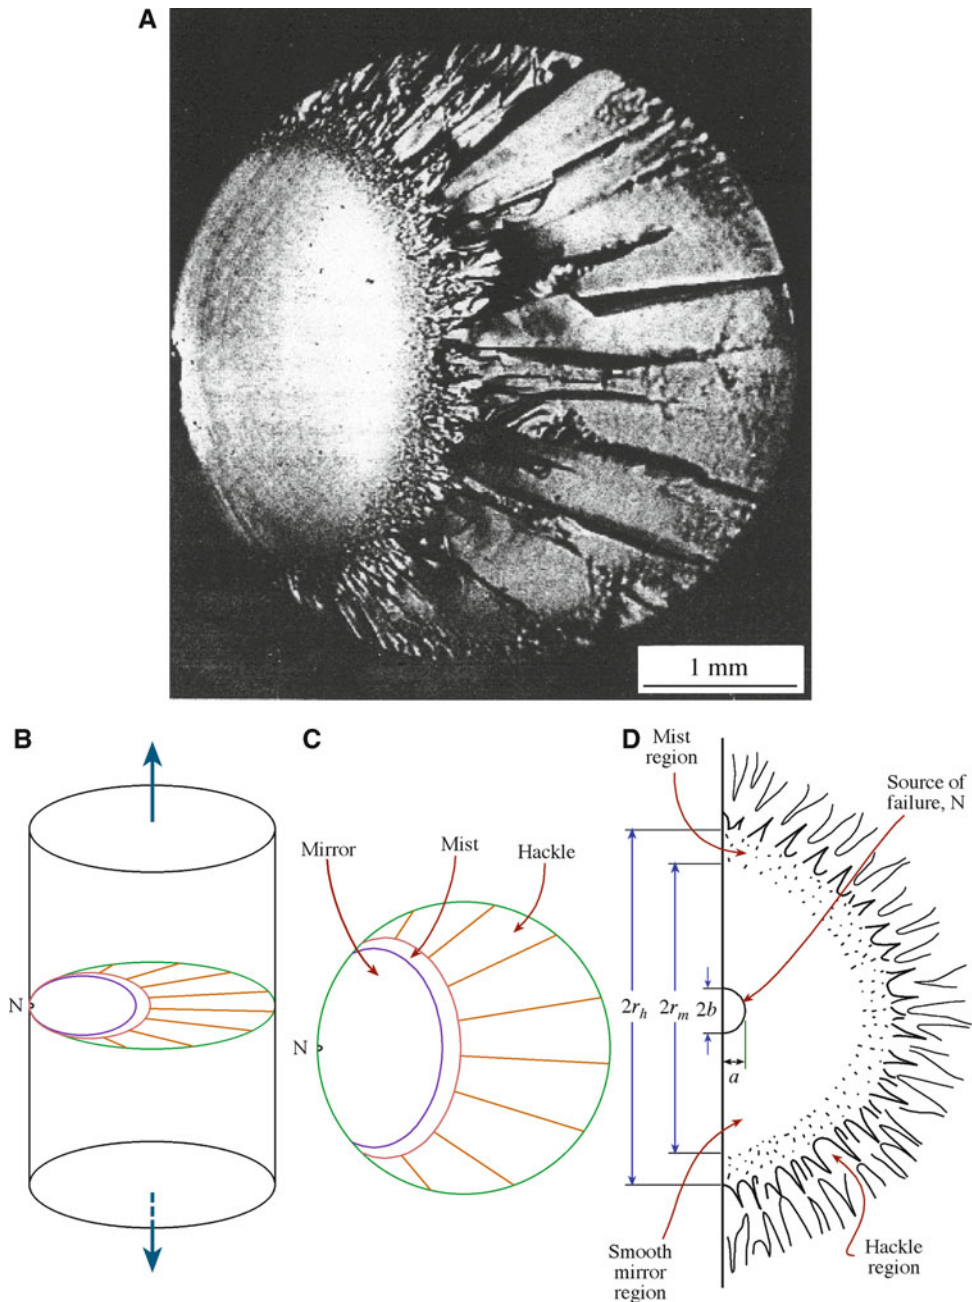

FIGURE 18.15. Fracture surface of a glass rod and corresponding schematics illustrating the distinct regions of the surface.

temperatures the equilibrium structure of ZrO_2 is tetragonal (t), and at low temperatures it is monoclinic (m). On cooling ZTA from the high temperatures required for fabrication, $t \rightarrow m$ transformation may occur in the zirconia particles. This transformation is accompanied by an increase in volume of about 3%.

The transformation is athermal; that is, it is not time-dependent and proceeds very rapidly. If the transformation takes place in the ZrO_2 particles during fabrication of ZTA ceramics, then the 3% volume change produces stresses in the alumina matrix around the transformed particle, leading to microcracking. These microcracks increase the toughness of the ceramic because of their ability to deflect

and bifurcate a propagating crack. Control of the extent of the microcracking determines the increase in toughness. The optimum conditions are when the particles are large enough to transform but only small enough to cause limited microcrack development. If microcracking becomes extensive, the cracks can interact, resulting in a decrease in strength. Zirconia particle size is controlled by:

- Milling prior to sintering
- Aging after sintering

If a stabilizing oxide (e.g., 3 mol% Y_2O_3) is added to the zirconia, then it is possible to suppress the $t \rightarrow m$

FIGURE 18.16. Scanning electron microscopy (SEM) of the fracture surface of Nd-doped YAG. River marks are indicated by arrows.

FIGURE 18.18. SEM image shows fiber pullout on the fracture surface of AlPO_4 -coated alumina/mullite fiber/ Al_2O_3 CMC, hot pressed at $1,250^\circ\text{C}$ for 1 h.

TABLE 18.6 Classification of Toughening Mechanisms in Ceramics

General mechanism	Detailed mechanisms
Crack deflection	Tilt and twist out of crack plane around grains and second-phase additions
Crack bowing	Bowing in crack plane between second-phase crack-pinning points
Crack branching	Crack may subdivide into two or more roughly parallel cracks
Crack tip shielding by process zone activity	Microcracking Transformation toughening Ductile yielding in process zone
Crack tip shielding by crack bridging	Second-phase brittle fibers with partial debonding Frictional and ligamentary grain bridges Second-phase ductile ligament bridging

FIGURE 18.19. Crack bridging mechanism with debonding and fiber pullout.

transformation on cooling from the fabrication temperature. The ZrO_2 particles can be retained in the metastable tetragonal form at room temperature. Whether the transformation takes place or not depends on the amount of stabilizing oxide and the particle size. The presence of the alumina matrix makes it difficult for the volume expansion associated with the transformation to be accommodated. The constraint is such that small particles are less likely to transform than large particles. With a suitable combination of the amount of stabilizing oxide and particle size, it is possible to obtain a dispersion of metastable tetragonal particles.

FIGURE 18.17. Stress–strain curve for a tough fiber-reinforced ceramic matrix composite.

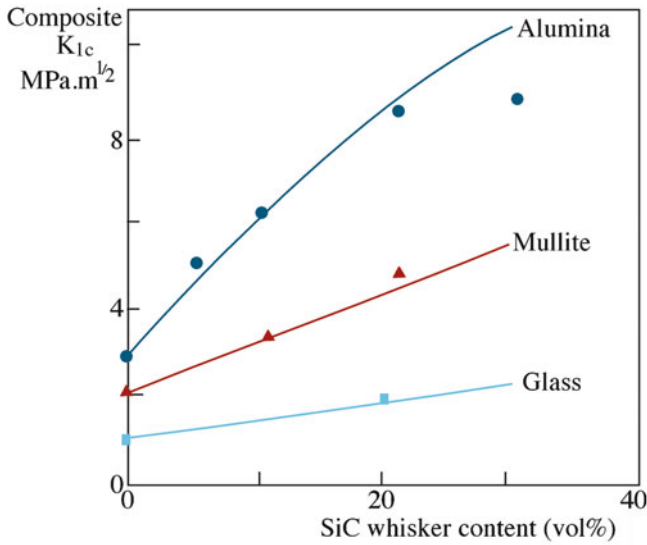

FIGURE 18.20. Effect of SiC whisker content on toughness enhancement in different matrices.

FIGURE 18.21. SEM shows crack propagation around a saphikon (Al_2O_3) fiber in a calcium aluminosilicate (CAS) glass-ceramic.

Under the influence of the stress field at a crack tip, these particles transform athermally to the monoclinic state. This leads to transformation toughening. The toughening increment ΔK_T that can be achieved by this mechanism is:

$$\Delta K_T = AV_{\text{ZrO}_2} \varepsilon_T \mathcal{E}_m w^{1/2} \quad (18.24)$$

where A is a constant with a value close to unity, V_{zirc} is the volume fraction of the metastable particles, ε_T is the volume strain accompanying the transformation, \mathcal{E}_m is Young's modulus of the matrix (often alumina), and w is the width of the process zone around a crack containing transformed particles (shown in Figure 18.22).

It is important to note that, in contrast to ZTA toughened by microcracking, transformation toughening can lead to an improvement in both toughness and strength and consequently is the preferred toughening mechanism.

The effectiveness of the different toughening mechanisms for structural ceramics appears to decrease in the following order.

- Continuous fiber reinforcement (most effective)
- Metal dispersed particles
- Transformation toughening
- Whiskers/platelet/particle reinforcement
- Microcracking (least effective)

Some examples and associated toughness values are given in Table 18.7. It is worth remembering that although the values are higher—in some cases by an order of magnitude—than for single-phase polycrystalline ceramics they are still much lower than most engineering metal alloys.

18.10 MACHINABLE GLASS-CERAMICS

Machinable glass-ceramics (MGCs) rely on controlled fracture. In Macor[®], a commercial MGC made by Corning, the crystalline phase is fluorophlogopite mica.

FIGURE 18.22. Transformation toughening in a ceramic matrix containing ZrO_2 particles.

TABLE 18.7 Effects of Different Toughening Mechanisms

Mechanism	Highest value achieved (MPa/m ²)	Exemplary systems
Continuous fiber reinforced	>30	SiC-SiC; Glass-SiC

FIGURE 18.23. Fracture surface of Macor[®].

The mica forms as randomly oriented grains in a borosilicate glass matrix. During machining, cracks propagate along the glass/mica interface (intergranular), and material is removed. Figure 18.23 shows the fracture surface of Macor[®] where the mica crystals, which look like packs of cards, can be clearly seen. MGCs can be machined using either high-speed steel or tungsten carbide cutting tools. They can be used at high temperatures (up to 1,000°C); and because of their high chemical resistance, they are used for precision valves and nozzles in the chemical industry. Table 18.8 lists the composition of Macor[®] and some of its properties.

18.11 WEAR

Wear resistance is the ability of a material to resist mechanical (or chemical–mechanical) abrasion. There are two main mechanisms that lead to removal of material from the surface of a ceramic.

TABLE 18.8 Composition (wt%) and Properties of Macor[®], a machinable glass-ceramic

SiO ₂	Al ₂ O ₃	B ₂ O ₃	K ₂ O	MgO	F
46	16	7	10	17	4
Property

- Grain pullout—In polycrystalline ceramics with weak grain boundaries
- Cracking—Fracture due to abrasion, gouging, or erosion

Wear resistance is usually closely associated with hardness and corrosion resistance. For example, Table 18.9 shows how erosion resistance correlates directly with hardness. Erosion usually specifies wear of a material by an abrasive in a fluid, the type of situation encountered when ceramics are polished.

Although ceramics are generally characterized as being wear-resistant, their commercial use as wear parts is less than 10% of the overall market.

Alumina is the most commonly used wear-resistant ceramic. One of the early applications was in seal faces for rotary water pumps for automobiles. Alumina is particularly suitable because it is resistant to engine cooling fluids. Another application for alumina, which we mentioned in Chapter 16, is in total hip prostheses. In terms of wear rates at the contact surfaces between the ball and socket, alumina is far superior to the alternative metal and polymer systems.

Alumina and toughened zirconia ceramics are used in the wire drawing industry as capstans, pullets, and guides. Improved product quality, longer component service life, and lower manufacturing costs have been attributed to the use of ceramics. For example, ceramic capstans last up to 10 times longer than carbide-coated capstans.

As with other mechanical properties, there are standard tests to measure wear resistance. The main method is described in ASTM G99, which uses a pin-on-disk apparatus. This test is used to measure sliding wear of ceramics and ceramic coatings.

18.12 GRINDING AND POLISHING

Grinding and polishing both use controlled fracture. Abrasives are the basis of an important ceramic industry. For example, the abrasive used in Emory paper is SiC; sandpaper uses SiO₂. The historically important abrasive was jeweler's rouge (hematite). Now, ceria (CeO₂) is often preferred for glass and ceramics, and colloidal silica (e.g., Syton™) is used for Si. Abrasive particles are almost always ceramics (usually oxides, carbides, or diamond). The polishing action actually involves an interaction between two surfaces, with the second surface being that of the abrasive particle. Figure 18.24 illustrates mechanical polishing using abrasive grains held in a soft pad. Table 18.10 lists some of the common abrasives used for polishing ceramics together with their hardness.

The abrasive is often applied as slurry onto a soft pad. A series of polishing steps are used, with abrasives of decreasing particle size (eventually down to as small as

Abrasive	Mohs hardness	Knoop hardness
Zirconia	8	1,160
Garnet	8	1,360
Calcined alumina	9	2,100
Silicon carbide	9–10	2,480
Boron carbide	9–10	2,750
Cubic boron nitride	10	4,500
Diamond	10	7,000

4 nm). The final step produces a smooth specular surface, which is good enough for film deposition.

Chemical/mechanical polishing (CMP) may also be used. In this case, an abrasive is used together with a chemical (usually either an acid or a caustic solution) that produces an etching action. CMP is actually very complex and still not fully understood. Final CMP may involve an abrasive that is softer than the materials being polished.

An example of a modern commercial polishing cloth is shown in Figure 18.25. The pyramids are particles of ceria bound in a polymer on a flexible cloth. This type of fixed abrasive has the advantage over a slurry in that the abrasive is well controlled and can be easily changed/renewed and that there is always a clear channel for the electrolyte to reach the polishing site.

FIGURE 18.24. Polishing process using abrasive grains held in a soft pad. This method is the one most often used in university metallography laboratories.

FIGURE 18.25. SEM of ceria particles in a modern polishing cloth.

CHAPTER SUMMARY

Although we often think of the brittleness of ceramics as a distinct disadvantage, the very existence of our civilization depended on this property. We make use of brittleness in many applications, such as in sculptures and for polishing; but for reliable structural uses, we often need better fracture toughness. One way to achieve this is to form a composite by adding some fibers to a ceramic matrix. The fibers provide additional mechanisms for energy absorption during fracture. The key work in understanding brittle fracture goes back to that of Griffith.

(continued)

CHAPTER SUMMARY (*continued*)

He showed that flaws act as stress concentrators, which lead to measured strengths—significantly, those predicted by theory. The work of Griffith is the link to the Weibull statistics we described in Chapter 16. By examining fracture surfaces, a process called “fractography,” we can often determine how and why a brittle material failed. This information can be useful in guiding processing methods to avoid stress concentrators, such as porosity and inclusions.

PEOPLE AND HISTORY

Griffith, Alan Arnold (1893–1963), known as “the father of fracture mechanics” and “bubble Griffith”—the first for his classic work in fracture mechanics and the role of flaws, the second for his work on soap films. He was a British aeronautical engineer who worked at Rolls-Royce from 1939 to 1960 designing turbojet engines.

Inglis, Sir Charles Edward (1875–1952) was professor of engineering at Cambridge University. He was best known for his work on stress in metal plates when cracks are present.

Orowan, Egon (1901–1989) was born in Budapest, Hungary and died in Cambridge, Massachusetts. In addition to his work on fracture, he showed the importance of the dislocation in plastic deformation. He joined MIT as a professor in 1950.

EXERCISES

- 18.1 Carbon nanotubes have been proposed as a material for the next generation of ceramic armor. (1) What are the properties of carbon nanotubes that make them of interest for this application? (2) Are there practical limitations that currently prevent their widespread use?
- 18.2 Calculate the theoretical strength of MgO. Are there any conditions under which this value would be attainable?
- 18.3 A sharp notch 0.1 mm long is introduced into the surface of a fused silica plate. The plate is then loaded to 100 MPa in tension normal to the notch. (a) Does the plate fracture? (b) If not, what is the applied stress that would lead to fracture? (c) If the plate was made of a lithium-aluminum-silicate (LAS) glass-ceramic, what applied stress would lead to fracture?
- 18.4 A soda-lime silica plate failed at 100 MPa. (1) Estimate the flaw size and state any assumptions you make. (2) If the plate were made of fused silica and contained the same flaw size, what is the maximum applied stress it could withstand without breaking? Assume the glass has $\mathcal{E} = 70$ GPa.
- 18.5 A manufacturer of silicon nitride jet engine parts found that a recent batch of samples became damaged during processing and had surface flaws about 50 m deep. The normal average flaw size in these parts is about 10 m. (1) Estimate the tensile strength of these samples. (2) Estimate the compressive strength of these samples.

Ceramic	Maximum flaw size (μm)	Average flaw size (μm)
Si_3N_4	20	15
SiC	30	18
MgO	10	7
Al_2O_3	5	3

- 18.6 You have been hired as a consultant and asked to choose the best ceramic for a load-bearing application. A vendor has offered you the following options. Which one would you take and why? Are there any other factors that you need to consider before you make your final recommendation?
- 18.7 In Table 18.6, we list different toughening mechanisms for ceramic–matrix composites (CMCs). Illustrate each mechanism using a sketch and, where appropriate, indicate the differences between using particles, platelets, and fibers as the reinforcement.
- 18.8 Explain how the addition of zirconia particles can lead to toughening of a ceramic. Suggest other additions that might produce similar toughening effects.
- 18.9 Draw sketches similar to Figure 18.10 to indicate how (1) ammonia and (2) methanol might lead to stress corrosion cracking in glass.

- 18.10 Figure 18.13A shows the fracture surface of polycrystalline AlN. Can you see any evidence of transgranular failure?
- 18.11 Explain why we can write equation 18.1.
- 18.12 Using the values in Table 18.2, discuss the theoretical strength of MgO and NaCl. Do these values seem sensible, and why are they so different?
- 18.13 Explain how Figure 18.3 is related to Weibull statistics.
- 18.14 In deriving equation 18.12, we say it assumes an atomically sharp crack. How does this assumption affect the formula, and is it reasonable for an MgO?
- 18.15 Why does Figure 18.6 verify equation 18.12? What information can you deduce from such a graph?
- 18.16 Using Table 18.4, discuss and compare K_{Ic} for (1) both forms of zirconia; (2) MgO and KCl; (3) CaF₂ and ThO₂; (4) LAS and silica glass.
- 18.17 Why are equations 18.17 and 18.18 different? How does this affect our use of ceramics?
- 18.18 Explain to a metallurgist what Figure 18.9 is showing.
- 18.19 Explain how Figures 18.10 and 18.22 are related.
- 18.20 What value of toughness do we need for ceramic armor?

Part VI

Processing

Raw Materials

CHAPTER PREVIEW

In this chapter, we look at several important raw materials used in the ceramics industry. Obtaining the necessary raw materials is the first step in the fabrication of ceramic components. This topic used to be addressed by many departments of mining and mineral engineering. It is no less important today, but few such departments still exist. There are two basic sources for these raw materials.

- Naturally occurring minerals
- Synthetic minerals

For naturally occurring minerals, we describe, in general terms, their origin, in what locations they are found, and their relative abundance. Naturally occurring minerals require extraction, which is often a regional industry located close to abundant quantities of the natural deposit. Most minerals need to go through some form of physical or chemical processing before use. The collective term for these processes is *beneficiation*. When you understand how oxides are manufactured, it is clear why they are often impure and why Si, Na, Ca, and the major impurities.

Materials that don't occur in nature or are rare must be synthesized (so calling them minerals is a misnomer), and we describe the processes used for their synthesis. Carbides, nitrides, and borides are becoming more common but are generally expensive and require special processing environments. For many nonoxides, the main impurities are often components of the starting material that have not reacted (e.g., Al in AlN or Si in Si₃N₄).

There are many other raw materials that play important roles in specific ceramics; but rather than provide a comprehensive discussion about every raw material, we focus on representative examples of naturally occurring minerals and synthetic ones. There are two ways of looking at this topic: the mineral we start from and the material we want to form. Here, we mix the two approaches.

19.1 GEOLOGY, MINERALS, AND ORES

Figure 19.1 shows a cross section of the Earth. The Earth has a mean radius of about 6,370 km and consists of three distinct concentric layers. The outermost layer is known as the crust and is relatively thin. The continental crust ranges in thickness from about 20 to 60 km, averaging approximately 30 km. It is the minerals that occur here that are important to us as raw materials for ceramics.

The continental crust is composed chiefly of the silicates of Mg, Fe, Al, Ca, and the alkali metals plus Al and free SiO₂. Table 19.1 lists the abundance of the major elements in the continental crust, from which you can see that O, Si, and

Al together account for almost 90 wt% of the elements in the crust.

Beneath the Earth's crust is the mantle. This thick layer is thought to be composed of Mg silicates and Fe silicates, free Fe, and minor Fe sulfides. Minerals in the mantle (and the core) are presently inaccessible to humans; for this reason we won't discuss them further. However, geologists can identify rocks that have moved from the mantle to the crust by natural processes.

An ore is defined as a mineral from which a constituent can be profitably mined or extracted. As examples, hematite (Fe₂O₃) is the major ore of Fe and ilmenite (FeTiO₃) is the major ore of Ti but is also an Fe-containing

MINES

The deepest mine is ~5 km deep.

FIGURE 19.1. Cross section of the Earth.

TABLE 19.1 Abundances of the Major Elements in the Continental Crust

Element	wt%	at%	vol% of ion
Oxygen	47.2	61.7	93.8
Silicon	28.2	21.0	0.9
Aluminum	8.2	6.4	0.5
Total iron	5.1	1.9	0.4
Calcium	3.7	1.9	1.0
Sodium	2.9	2.6	1.3
Potassium	2.6	1.4	1.8
Magnesium	2.1	1.8	0.3
Hydrogen	Trace	1.3	0.0

mineral. Pyrophanite ($MnTiO_3$) is neither a Ti nor Mn ore; it is actually a rare mineral.

19.2 MINERAL FORMATION

Minerals are the constituents of rocks, which make up the entire inorganic, solid portion of the earth. Rocks are usually not composed of a single mineral but, rather, an aggregate of two or more minerals. Broadly speaking, geologists divide rocks into three types: igneous, metamorphic, and sedimentary.

Igneous rocks form when magma cools and solidifies. Magma is a complex molten material that originates deep within the earth. The word igneous comes from the Latin word *ignis*, which means “fire”; igneous rocks then are “formed from fire.” Magma is rich in the elements Si, O, Al, Na, K, Ca, Fe, and Mg. Table 19.2

TABLE 19.2 Major Oxides in Igneous Rocks and Their Ranges of Composition

Constituent (oxide)	Concentration (wt%)
SiO_2	30–78
Al_2O_3	3–34
Fe_2O_3	0–5
FeO	0–15
MgO	0–40
CaO	0–20
Na_2O	0–10
K_2O	0–15

shows the composition ranges for the major elements (expressed as oxides) in igneous rocks. These are the elements that when combined with SiO_2 form the silicate minerals. A limited number of silicate minerals account for over 90% of all igneous rocks.

All silicate minerals contain tetrahedral silicate (SiO_4) groups. Classification of the silicate minerals is based upon the way in which these groups combine, as we described in Chapter 7.

The specific mineral crystallizing from magma depends both on the composition and temperature of the magma. The order of crystallization of the main silicate minerals is given by Bowen’s Reaction Series, which is shown in Figure 19.2. Olivine and Ca feldspar form at high temperatures and may separate early from the melt. Other minerals solidify as the temperature falls. The last minerals to crystallize are K feldspar, muscovite mica, and quartz, the major constituents of granite. Finally, water in the magma carries metals and S in solution through cracks in the surrounding rock and deposits them as sulfides in veins.

Metamorphic rocks have undergone structural and/or chemical transitions (metamorphism or metamorphosis) from their original form as a result of high temperatures and pressures deep beneath the earth’s surface. These transitions occur in the solid state without melting and result in the formation of new minerals, such as kyanite, staurolite, sillimanite, andalusite, and some garnets. Other minerals, such as some of the igneous minerals, may be present in metamorphic rocks but are not necessarily the result of metamorphism.

The word “metamorphic” has a Greek origin coming from *meta*, meaning “change,” and *morpe*, meaning “shape.”

Sedimentary rocks are formed when small particles or precipitated crystals become cemented together. Sedimentary rocks are classified as either clastic or chemical.

IGNEOUS ROCK

Granite: magma cooled near earth’s surface
 Rhyolite: fine grain granite
 Obsidian, pumice and scoria: volcanic origin
 Basalt: very small grains usually rapidly cooled lava
 Gabbro: like basalt but larger grains
 Mafic: dark igneous (e.g., basalt)
 Intermediate: e.g., diorite. Mg- and Fe-rich
 Felsic: light igneous (e.g., granite). Quartz-rich

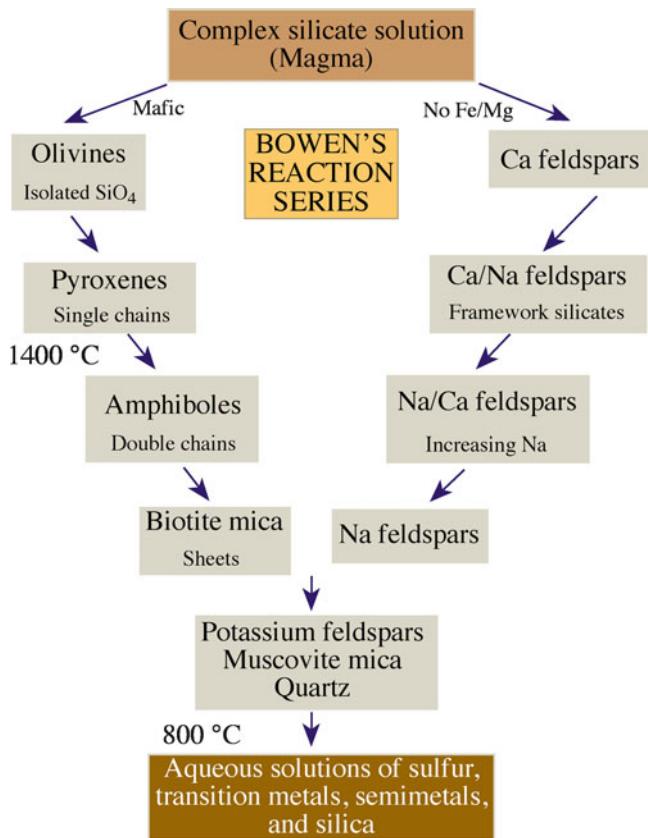

FIGURE 19.2. Bowen's reaction series.

Clastic sedimentary rocks form when rock particles produced by mechanical and chemical weathering are transported by water, ice, and wind to new locations where they become cemented together.

Chemical sedimentary rocks form when highly soluble ions, such as, Na^+ , K^+ , Ca^{2+} , Mg^{2+} , Cl^- , F^- , $(\text{SO}_4)^{2-}$, $(\text{CO}_3)^{2-}$, $(\text{PO}_4)^{3-}$, from existing rocks are dissolved in water and subsequently precipitate, forming layers in oceans and lakes, where they become cemented together. The composition of sedimentary rocks depends on:

- Composition of original source rocks
- Chemical and mechanical resistance of each mineral component
- Distance traveled

Resistant minerals such as quartz are common constituents of sedimentary rocks, and some more rare minerals (e.g., garnet, rutile, zircon) have similar properties. Feldspar is less resistant but is so common that it is a major constituent of many sedimentary rocks. Precipitated minerals include the carbonates (e.g., calcite, dolomite), the sulfates (e.g., gypsum, anhydrite), chlorides, and chalcedonic silica (e.g., chert, flint).

The three rock types are compared in the summary below. Figure 19.3 shows what is called the rock cycle.

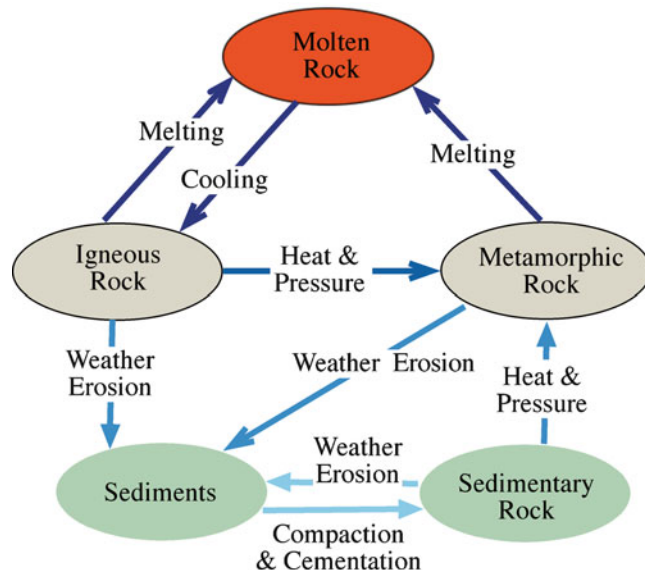

FIGURE 19.3. Simplified diagram of the rock cycle.

Igneous	Rocks formed by cooling and solidification of magma
Metamorphic	Rocks that have undergone structural and/or chemical transitions
Sedimentary	Rocks formed when smaller particles become cemented

19.3 BENEFICIATION

Beneficiation is the process that most minerals need to go through before they can be used in producing ceramics. Physical beneficiation includes crushing and grinding of coarse rocks. The particle size of the raw material may affect subsequent steps in the production process. An example that we use is producing alumina from bauxite, a process that involves a chemical reaction.

Chemical beneficiation includes processes of separating the desired mineral from unwanted waste products—for example, by dissolution in a suitable solvent followed by filtration. The Bayer process for producing alumina is also a good example of chemical beneficiation. Bauxite contains many impurities.

The purity of the raw materials is reflected in the composition of the final product. For many ceramics, careful control over purity is required. For these applications, the raw materials are synthesized. Furthermore, several important ceramics do not occur naturally in mineral form and must be fabricated chemically. Synthesis of ceramic powders can have advantages not only in purity but also in allowing the generation of fine particle sized powders having a well-defined morphology. We show in Chapter 24 the importance of particle size on the densification of a ceramic component by sintering.

19.4 WEIGHTS AND MEASURES

The SI unit of mass is the kilogram (kg). The kilogram is interesting for a couple of reasons. It is the only basic SI unit defined with a prefix (kilo) already in place, and it is the only one defined by reference to a physical object—a mass of platinum-iridium held at Sevres in France. To express the large quantities of material that we encounter in the extraction and processing of ores, it is usual to use the metric ton (sometimes written tonne: symbol t).

$$1 \text{ t} = 1 \text{ Mg} = 10^3 \text{ kg}$$

Possible confusion exists because of special British and U.S. units that are still in use in these countries.

$$1 \text{ t} = 0.984 \text{ UK(long)ton}$$

$$1 \text{ t} = 1.103 \text{ US(short)ton}$$

The situation is even more complicated in Britain, where the short ton is often used in mining metal-containing ores, but the long ton is used in coal mining. We use the metric ton (written simply as ton) unless specifically stated otherwise. You can see that for “ballpark” estimates of mass it really doesn’t make much difference. When we discuss single crystals in Chapter 29, we introduce units of mass that are used to describe very small quantities of a material.

Finding out the quantities of all commercial minerals produced is straightforward. The United States Geological Survey maintains updated information on their website in the Mineral Commodity Summaries and the Minerals Yearbook. These sources provided most of the numbers given in this chapter. Obviously, like all commodities, the production of minerals may vary from year to year based on many different factors, such as supply, demand, and reserves. The exercises at the end of this chapter help you think about some of those factors for specific minerals.

19.5 SILICA

Silica (SiO_2) is an important raw material for ceramics. The major use (accounting for about 38% of U.S. production) is in glass manufacture. For example, incandescent lamp bulbs are made of a soda-lime silicate glass containing about 70 wt% SiO_2 . The SiO_2 content of high-quality optical glasses can be as high as 99.8 wt%.

A major source of silica is sand. Industrial sand and silica sand are two terms used by the ceramics industry for sands that have a high percentage of SiO_2 . In some of the high quality silica sand sources mentioned below the SiO_2 content is $>99.5\%$.

Sand is defined by the American Society for Testing and Materials (ASTM) as granular rock particles that pass through a No. 4 mesh (4.75-mm aperture) U.S. standard sieve, are retained on a No. 200 mesh (75- μm aperture) sieve, and result from the natural disintegration or comminution of rock. Sands are also produced by physical beneficiation of rocks by crushing. These sands have various chemical compositions, determined by the type of rock being mined.

The United States is the largest producer of industrial sand in the world. The states of West Virginia, California, Illinois, Pennsylvania, Ohio, and New Jersey supply more than about 80% of all the high quality silica sand used domestically. In Illinois and Missouri, practically all the glass-grade silica is derived from the St. Peter sandstone formation. Other quality deposits are the Oriskany sandstone deposits in West Virginia and Pennsylvania. Deposits are usually found in dune forms or in deposits lying 20–30 m under layers of silts, clays, and shales.

The mining of industrial silica is, in general, a regional market. Unless the material possesses unique characteristics, such as a certain grain size or shape, the geographic market of a plant rarely extends beyond 200 miles. This is because of the high transportation cost relative to materials price and the extensive location of mines.

In recent years, environmental regulations have been placed on the mining of silica sand due to health risks associated with this product.

Quartz, the principal silica mineral, is a constituent of igneous rocks such as granite. It is also found in most metamorphic rocks, comprising a major portion of the sandstones. It is also found in the pure form in veins running through other rocks. Optical quality quartz crystals are quite rare, but there are economically viable methods to produce quartz crystals as we see in Section 29.11.

SILICA PRODUCTION

Annual production of silica in the U.S. is approximately 30 Mt valued at around \$700 million.

19.6 SILICATES

We discussed the silicates in Chapter 7. Here we discuss the use of these materials to form commercial ceramics.

Feldspar	70% used for glass
Kaolin	Used in fine china, paper, and rubber
Mica	$>200,000$ t of low-quality mica used each year
Mullite	600,000 t are used each year for refractory furnace blocks

19.6.1 Feldspar

Feldspars constitute an abundant mineral group and make up an estimated 60% of the earth’s crust, as shown

TABLE 19.3 Abundance of Minerals in the Earth's Crust

<i>Mineral Groups</i>	<i>vol%</i>
Feldspars	58
Pyroxenes, amphiboles	13
Quartz	11
Micas, chlorites, clay minerals	10
Carbonates, oxides, sulfides, halides	3
Olivines	3
Epidotes, aluminosilicates, garnets, zeolites	2

in Table 19.3. They are present in many sedimentary deposits and are found in almost all igneous and metamorphic rocks.

The glass industry uses most of the feldspar produced. Feldspar is a source of Al_2O_3 , which improves the mechanical properties of glass, such as its scratch resistance and its ability to withstand thermal shock. It is also used in whiteware bodies as a flux, which produces a glassy phase during firing, increasing the strength and translucency of the body.

The Republic of Korea is the largest producer of feldspar in the world. Annual feldspar production in the United States is about 800,000 t, with a value of about \$45 million. The largest producing states are North Carolina, Connecticut, and California. The typical procedure for processing feldspar deposits is:

- Drilling and blasting at the quarry
- Transporting to a mill for crushing and grinding (physical beneficiation)
- Froth flotation, separating the minerals according to their relative wettability in aqueous solution (chemical beneficiation)
- Drying
- Grinding to a No. 20 mesh (841 μm aperture size) for glassmaking; <No. 200 mesh (aperture size 74 μm) for most other ceramic applications

In the froth flotation process, air is bubbled through a water suspension containing the crushed minerals to form a foam or froth. The wetted particles (those that are hydrophilic) remain in the water suspension, whereas hydrophobic particles collect at the air bubble/water interface and can be removed from the liquid. Various agents, such as amino acids (having a high molecular weight), can be used to enhance the relative wettability of the solids in a mixture; these agents are adsorbed selectively on the surface of certain species in the mixture. The process is carried out in stages.

1. Remove mica
2. Remove iron-bearing minerals, especially garnet
3. Separate feldspar from a residue consisting mainly of quartz

19.6.2 Clays and Kaolin

Clay is the primary ingredient in traditional ceramics and is a general name given to the layer silicates with a grain size $<2 \mu m$. Any of the layer silicates could qualify as a clay mineral. There are six types of commercial clays, and they are listed in Table 19.4. They are distinguished by various characteristics, including their composition, plasticity, color, and firing characteristics.

Mechanical and chemical weathering of feldspars in igneous and metamorphic rocks forms kaolin, a key ingredient in China clay. It may be disintegrated in situ or transported by water or wind and redeposited elsewhere. Primary kaolin deposits are located at the site of the original rock. They typically contain large amounts of quartz and mica, which also are formed during weathering. Large, primary kaolin deposits are found in southwest England, Ukraine, and China.

Secondary kaolins were washed from the original weathering site, naturally beneficiated, and redeposited in large areas of pure kaolin. The major commercial deposits of secondary kaolin in the United States were formed

TABLE 19.4 Commercial Clays, Their Main Uses, and Annual U.S. Production

<i>Type</i>	<i>Main uses</i>	<i>Annual U.S. production (Mt)</i>	<i>Comments</i>
Ball clay	Floor and wall tiles Sanitaryware	1.3	Also called "plastic clay" because it improves workability
Bentonite	Foundry sand bond Absorbents	4.4	U.S. imports bentonite from Canada
Common clay	Bricks Cement	26	Also called "brick clay" Red color comes from iron
Fire clay	Refractories	0.3	Fire clay refractories contain 25–45% alumina
Fuller's earth	Absorbents	3.2	Textile workers (or "fullers") cleaned raw wool by kneading it in a mixture of water and fine earth, which adsorbed oil, dirt, and other contaminants
Kaolin	Paper	7.2	Kaolinite is a hydrous aluminum silicate; kaolin is a white firing clay, primarily composed of kaolinite

50 million years ago and occur as a continuous belt stretching along the ancient coastline from Alabama north-east to North Carolina.

19.6.3 Mica

The mica group consists of 37 minerals, known as phyllosilicates, which have a layered or platy texture. The Greek word *phylon* means leaf. Some of the mica minerals are listed in Table 19.5 together with the location of their principal sources. The micas are classified as either true or brittle.

True micas contain univalent cations (e.g., Na⁺ or K⁺) between each set of layers and show perfect basal cleavage, allowing the crystals to be split into thin sheets. The cleavage flakes are flexible and elastic.

In brittle micas, the interlayer cations are divalent (e.g., Ca²⁺). The bond is stronger; and although the layered structure still imparts basal cleavage, they are more brittle. Brittle micas are uncommon minerals and not of any real interest.

Muscovite is the principal mica used because of its abundance and superior electrical properties. Phlogopite is stable at higher temperatures and is used in applications where a combination of high heat stability and electrical properties are required. Both are used in sheet and ground forms.

Micas occur in igneous, sedimentary, and metamorphic rocks in a great many contrasting geologic environments. The reason for this range of occurrence is their wide thermal stabilities. Figure 19.4 shows a pressure–temperature diagram for muscovite mica. At very high temperatures (>600°C) it becomes unstable, breaking down in the presence of quartz to give potassium feldspar and sillimanite.

Muscovite occurs in low-grade metamorphic rocks, where it forms from pyrophyllite (Al₄[Si₈O₂₀](OH)₄) and illite (K_{1-1.5}Al₄[Si_{7-6.5}Al_{1-1.5}O₂₀](OH)₄). It also occurs as

a primary crystallizing mineral in igneous rocks (e.g., granites, pegmatites) and is a common constituent of sedimentary rocks, especially the arenites. Muscovite mica is locally common in many parts of the United States.

The largest producer of mica is Russia, which produces about one-third of the world's annual supply of 300,000 t. The United States produces about 75,000 t of scrap and flake mica each year. Although historically the United States was a producer of sheet mica, domestic reserves have declined to zero, and commercial production is all scrap and flake.

The principal use for ground mica is as a filler and extender in gypsum wallboard joint compound where it produces a smooth consistency, improves workability, and prevents cracking. It is also found in paints, molded

MICA

The commercially important mica minerals are muscovite and phlogopite.

FIGURE 19.4. Pressure–temperature phase relations for the bulk composition K₂O·3Al₂O₃·6SiO₂–2H₂O.

TABLE 19.5 Principal Sources and Occurrence of Mica Minerals

Mineral	Chemical formula	M, H, O	Type	Source
Muscovite	KAl ₂ (Si ₃ Al)O ₁₀ (OH) ₂	M	True	USA, India, Brazil, Russia
Phlogopite	KMg ₃ (AlSi ₃ O ₁₀)(OH,F) ₂	M,H	True	Madagascar, Canada, Mexico, Sri Lanka
Paragonite	NaAl ₂ (Si ₃ Al)O ₁₀ (OH) ₂	M	True	USA, Switzerland, Italy
Biotite	K(Mg,Fe) ₃ (Al,Fe)Si ₃ O ₁₀ (OH,F) ₂	M,H	True	USA, Canada, Ireland, Scotland

rubber products including tires, and toothpaste. Mica flakes are being used as a replacement for asbestos in brake linings and clutch facings.

India is the largest producer of muscovite sheet mica. Madagascar is the principal supplier of phlogopite sheet mica. The prices for sheet mica range from less than \$1 per kilogram for low-quality material to more than \$2,000 per kilogram for the highest-quality mica. High-quality muscovite mica is used as a dielectric in capacitors.

19.6.4 Mullite

Mullite ($3\text{Al}_2\text{O}_3 \cdot 2\text{SiO}_2$) does not exist in nature in large quantities and must be produced synthetically. Mullite has many properties that make it suitable for high-temperature applications. It has a very small coefficient of thermal expansion (giving it good thermal shock resistance) and is creep resistant at high temperature. Most importantly, it does not react readily with molten glass or with molten metal slags and is stable in the corrosive furnace atmosphere. Hence, it is used as a furnace lining and in other refractory applications in the iron and steel-making and glass industries.

There are two commercial approaches to producing mullite.

- Sintering
- Fusing

Sintered mullite may be obtained from a mixture of kyanite (Al_2OSiO_4) (a naturally occurring mineral found in metamorphic rocks), bauxite, and kaolin. This mixture (in the correct ratio) is sintered at temperatures up to about $1,600^\circ\text{C}$. The sintered quality contains 85–90% mullite, with the balance being mainly glass and cristobalite (a crystalline polymorph of SiO_2). South Africa is the major producer of kyanite, at about 165,000 t per year. The United States has the largest resources of kyanite, which are located mainly in the Appalachian Mountains region and in Idaho. Andalusite and sillimanite are other aluminosilicate minerals, similar to kyanite, which can be used as a raw material for mullite.

By fusing the appropriate amounts of alumina and kaolin together in an electric-arc furnace at about $1,750^\circ\text{C}$, a higher-purity mullite can be made. The fused product contains >95% mullite, the rest being a mixture of alumina and glass.

19.7 OXIDES

The raw materials used for oxide ceramics are almost entirely produced by chemical processes to achieve a high chemical purity and to obtain the most suitable powders for component fabrication. The important oxides are summarized in Table 19.6 and are discussed individually.

TABLE 19.6 Oxide Raw Materials

Alumina	Refractories, abrasives, substrates
Ceria	Catalysts, fuel cells, chemical/mechanical polishing
Ferrites	Magnets
Magnesia	Refractories
Rutile and anatase	Paints
Zincite	Rubber, adhesives, varistors
Zirconia	Additives, furnace components

19.7.1 Alumina

Aluminum oxide (Al_2O_3 , alumina, corundum) is the most widely used inorganic chemical for ceramics and is produced from the mineral bauxite using the Bayer process. Bauxite is a mixture of hydrated aluminum oxide with iron oxide (Fe_2O_3), silica (SiO_2), and titania (TiO_2) impurities. It results from the decay and weathering of aluminous rocks, often igneous, under tropical conditions. Like kaolin, bauxite occurs as both primary and secondary deposits.

The Bayer process produces a nominal 99.5% Al_2O_3 product. The alumina can be prepared in a range of grades to suit specific applications. The grades differ by the size and shape of the crystals and the impurity content. The dominant impurity, accounting for up to 0.5%, is Na_2O . The crystal size can be adjusted to measure between 0.1 and 25 μm . Figure 19.5 shows a refinery that produces alumina from bauxite using the Bayer process.

The steps in the Bayer process are as follows.

Physical beneficiation: the bauxite from the mine is first ground, fairly coarsely, to a particle size of <1 mm. Grinding increases the total surface area of the particles, leading to a reduction in the processing time for the chemical reaction in the following step.

Digestion: the coarsely ground bauxite is treated with sodium hydroxide (NaOH) solution at $150\text{--}160^\circ\text{C}$ and 0.5 MPa total pressure. Most of the hydrated alumina goes into solution as sodium aluminate:

Filtration: the solid impurities—mainly SiO_2 , TiO_2 , and Fe_2O_3 —remain undissolved and are separated by filtration.

Precipitation: after cooling, the filtered sodium aluminate solution is seeded with very fine gibbsite—a naturally occurring hydrated alumina, $\alpha\text{-Al}(\text{OH})_3$ —and at the lower temperature the aluminum hydroxide reforms as the stable phase. Reducing the pH by bubbling CO_2 through the solution encourages precipitation.

Washing: the precipitate is filtered and washed to reduce the sodium content

Calcination: the powder is calcined at temperatures in the range $1,100\text{--}1,200^\circ\text{C}$ to convert the hydroxide to the oxide:

FIGURE 19.5. Alcoa refinery in Wagerup (Western Australia) that supplies 15% of the world's alumina.

At this stage, the alumina is in the form of agglomerates of small grains about 5–10 μm in diameter.

Milling: the powder is then milled to give the desired particle size and particle size distribution.

The alumina produced in this way contains $\geq 99.5\%$ Al_2O_3 , and as mentioned earlier the major impurity is Na_2O . The powder may also contain small amounts of SiO_2 , on the order of 0.001%. This level of purity is sufficient for many applications. Careful control of the precipitation conditions, thorough washing of the precipitate, and control of the calcination/milling conditions can give aluminas of up to 99.99% purity. The cost of normal calcined alumina is about $\$0.60 \text{ kg}^{-1}$ and can go up to over $\$2.00 \text{ kg}^{-1}$ for higher purity calcined aluminas. The price for metallurgical-grade (suitable for conversion into Al) alumina is around $\$150 \text{ t}^{-1}$.

Table 19.7 gives typical compositions of the main forms of calcined aluminas. The presence of Na_2O can be unacceptable. For example, the Na^+ ion is mobile in an electric field and causes degradation of electrical insulation. Also, during high-temperature processing, a sodium β -alumina ($\text{Na}_2\text{O} \cdot 11\text{Al}_2\text{O}_3$) phase can form that leads to a

TABLE 19.7 Composition of Calcined Aluminas

	Normal Na_2O	Low Na_2O	Reactive
Al_2O_3	98.9–99.7	99.5–99.8	>99.5
SiO_2	0.02–0.05	0.07–0.12	0.04–0.08

Na_2O	0.3–0.6	<0.13	0.08

Results are in wt%

reduction in density, strength, thermal shock resistance, and corrosion resistance of the final product. Table 19.8 shows the Na_2O content required for various applications of calcined alumina prepared by the Bayer process.

Australia is the world's largest producer of bauxite, producing almost 60 Mt per year. The major regional producer of bauxite in the United States is Arkansas, with smaller deposits in Georgia, Alabama, and Mississippi. Domestic mines supply less than 1% of the U.S. bauxite requirement, and hence the United States is a major importer of bauxite, importing >10 Mt per year.

Of all the bauxite mined, about 95% is converted to alumina. World production of alumina is about 50 Mt

TABLE 19.8 Soda Contents Required of Calcined Aluminas in Commercial Applications

Application	Median crystal size (μm)	Na_2O content range (%)
Electronic ceramics	<0.5 to 5.0	<0.02 to 0.1
Sodium vapor lamps	<0.5	<0.02 to 0.1
Structural ceramics	<0.5 to 5.0	0.02 to >0.4
Fused abrasives	<0.5 to 1.0	0.2 to >0.4
Ceramic fibers	<0.5 to 1.0	0.2 to >0.4
High-tech. refractories	0.5–3.0	<0.1 to 0.25
Spark plugs	2.5 to >5.0	0.02–0.2

per year. The vast majority (about 90%) of the alumina is used for the production of aluminum; most of the rest goes into nonmetal uses such as specialty aluminas. It is this latter quantity that is of interest to us in ceramics. The primary suppliers of specialty aluminas in the United States are Alcoa, Alcan, AluChem, LaRoche, and Reynolds.

High-purity aluminas can also be prepared directly from aluminum metal, for which there are several routes, as shown in Figure 19.6.

19.7.2 Magnesia

Magnesium oxide (MgO , magnesia) occurs naturally as the mineral periclase, a metamorphic mineral formed by the breakdown of dolomite, $\text{CaMg}(\text{CO}_3)_2$, and other magnesium minerals. Occurrences of periclase are rare and of no commercial importance. The principal commercial sources of MgO are magnesite (MgCO_3) and magnesium hydroxide ($\text{Mg}(\text{OH})_2$).

Major deposits of magnesite occur in many countries, including China, Turkey, and Russia. The magnesite contains varying amounts of impurities including silica, iron, aluminum, manganese, and calcium, usually present in the form of various minerals (e.g., quartz, talc, mica, magnetite). After mining, the ores must be beneficiated. The methods for beneficiation vary but include crushing, screening, washing, magnetic separation, and froth floatation.

After the impurities have been separated, the magnesium carbonate is calcined. Calcining at temperatures of 800–900°C produces a very reactive fine-grained MgO called caustic magnesia. Sintered, or dead burned, magnesia is obtained by calcining the magnesium carbonate at

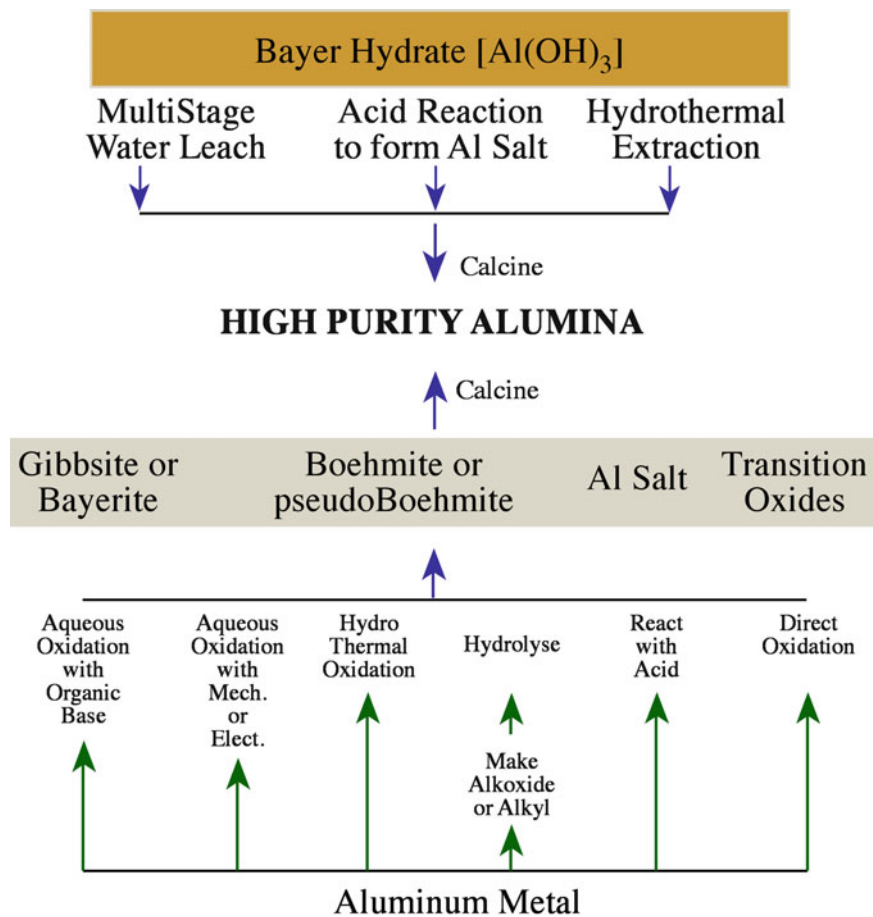

FIGURE 19.6. High-purity alumina production routes.

temperatures $>1,700^{\circ}\text{C}$. During this process, the reactive crystals grow and lose their activated state.

Magnesia can be produced from seawater and magnesium-rich brines. About 60% of the U.S. production of magnesium compounds is from these sources. Seawater contains about $1.28\text{ g Mg}^{2+}/\text{kg}$. The most important process for the production of MgO from seawater is precipitation of magnesium hydroxide ($\text{Mg}(\text{OH})_2$) from solutions of magnesium salts by a strong base.

The $\text{Mg}(\text{OH})_2$ precipitate is washed, filtered, and calcined to produce MgO .

Another means of obtaining magnesia is from brines. This process is based on the decomposition of MgCl_2 at $600\text{--}800^{\circ}\text{C}$.

World magnesia production capacity is about 10 Mt/year: ~ 9.0 Mt from natural magnesite and ~ 1.5 Mt from seawater and brines. Prices for magnesia are range from $\$150\text{ t}^{-1}$ to more than $\$1,200\text{ t}^{-1}$ depending on purity.

The major application for magnesia is as a refractory lining in furnaces. In lesser quantities, it is made into a well-known milky solution and ingested. It is also used to manufacture other ceramics, such as chrome-free spinels. Nonchrome spinel is not available in nature on an industrial scale. At Asahi Glass, spinel is produced by electrofusing magnesia with alumina.

19.7.3 Zirconia

Zirconium dioxide (ZrO_2 , zirconia) is principally derived from zircon, ZrSiO_4 , which occurs in igneous rocks, such as granites and pegmatites. Decomposed pegmatites have been worked for zircon in Madagascar and Brazil. Zircon is also a constituent of some metamorphic rocks as well as occurring as secondary deposits in beach sands in Australia, Brazil, India, and Florida. In these secondary deposits, which have been worked commercially, the zircon occurs together with other minerals such as ilmenite, rutile, and monazite.

There are a number of commercial approaches to producing pure zirconia from zircon. Zircon dissociates above $1,750^{\circ}\text{C}$ into ZrO_2 and SiO_2 . Injection of zircon sand into a plasma (at temperatures $>6,000^{\circ}\text{C}$) results in dissociation and melting. The zirconia solidifies first, in the form of dendrites, and the silica solidifies as a glassy coating on the zirconia. The silica may be removed by leaching in boiling sodium hydroxide solution. The residue is washed and the zirconia removed by centrifuging.

The main production method for zirconium oxide is electric arc melting of zircon at $2,100\text{--}2,300^{\circ}\text{C}$. Dissociation still occurs at these lower temperatures, but solid

zirconia is produced along with liquid silica. The purity of the ZrO_2 produced is about 99%.

Another, although commercially less significant, source of zirconia is baddeleyite (impure monoclinic ZrO_2). Baddeleyite is found in small deposits and usually contains contaminants such as silica, iron oxide, and titania. Baddeleyite deposits are mined commercially in Brazil and South Africa.

Zirconium ores all contain varying amounts of hafnium, typically 1.5–3.0 wt% of the Zr content. As a result of the chemical similarity of Hf to Zr, separation techniques are expensive. Unless specifically required, separation is not performed and technical-grade zirconia is sold containing up to 3 wt% Hf.

19.7.4 Zincite

Zinc oxide (ZnO) occurs naturally as the mineral zincite. Chemically pure ZnO is white. Zincite is red because it contains up to 10% Mn; traces of FeO are usually also present. Naturally occurring sources of zincite are not commercially important. There are two production methods for forming zinc oxide.

- Oxidation of vaporized zinc metal in air
- Reduction of sphalerite (ZnS) with carbon and CO

Sphalerite is a naturally occurring mineral and the most important ore of zinc. Large deposits are found in limestone of the Mississippi Valley, around Joplin (Missouri), and Galena (Illinois). Significant deposits are also found in France, Mexico, Spain, Sweden, and the United Kingdom.

The largest consumers of ZnO are the rubber and adhesives industries. Zinc oxide is also found in some latex paints, tiles, glazes, and porcelain enamels; and it is the most widely used material in the manufacture of varistors.

19.7.5 Rutile and Anatase

Rutile (TiO_2 , titania) occurs as a constituent of igneous rocks such as granites and is in metamorphic derivatives such as gneiss. It is found also as fine needles in slates, biotite mica, quartz, and feldspar. Economically, the most important deposits are segregations in igneous rocks, as found in Virginia, Canada, and Norway. Rutile also is an important constituent of beach sands resulting from denudation of rutile-bearing rocks, as in Australia, Florida, and India.

Titania is also produced by reacting ilmenite FeTiO_3 with sulfuric acid at $150\text{--}180^{\circ}\text{C}$ to form titanyl sulfate, TiOSO_4

Titanyl sulfate is soluble in water and can be separated from undissolved impurities and the precipitated iron sulfate by filtration. Hydrolyzing at 90°C causes the hydroxide $\text{TiO}(\text{OH})_2$ to precipitate.

The titanyl hydroxide is calcined at about 1,000°C to produce titania TiO_2 .

19.8 NONOXIDES

Most of the important nonoxide ceramics do not occur naturally and therefore must be synthesized. The synthesis route is usually one of the following,

- Combine the metal directly with the nonmetal at high temperatures
- Reduce the oxide with carbon at high temperature (carbothermal reduction) and subsequently react it with the nonmetal

In this section, we look at several important nonoxide ceramics. To show the variety of nonoxide ceramics, we have taken examples of carbides, nitrides, and borides. There are, of course, many other nonoxide ceramics that are of interest.

SiC	Abrasives, harsh-environment electronic packing
TiC	Bearings, cutting tools
AlN	Electronic packaging, crucibles
Si_3N_4	Future gas-turbine and diesel engine components
ZrB_2	Crucibles and thermowell tubes (steel)
WC	Abrasives, cutting tools
C	Graphite: solid lubricant; diamond: abrasive

19.8.1 Silicon Carbide

Silicon carbide (SiC) is the most widely used nonoxide ceramic. Its major application is in abrasives because of its hardness (surpassed only by diamond, cubic boron nitride, and boron carbide). Silicon carbide does not occur in nature and therefore must be synthesized. It occurs in two crystalline forms: the cubic β phase, which is formed in the range 1,400–1,800°C, and the hexagonal α phase, formed at >2,000°C.

Silicon carbide is synthesized commercially by the Acheson process, which involves mixing high-quality silica sand (99.5% SiO_2) with coke (carbon) in a large, elongated mound, or furnace, and placing carbon electrodes in opposite ends. Each mound consists of about 3,000 t of material. An electric current is passed between the electrodes resistively heating the coke in the mound to about 2,200°C. The total electrical energy consumed during a standard furnace run is about two

FIGURE 19.7. SiC produced by the Acheson process.

million kWh (about 7 TJ). The average power input during the furnace run is 9,000–10,000 kW.

At the high temperatures, the coke reacts with the SiO_2 to produce SiC plus CO.

Heating is continued (2–20 days depending on the size of the transformer and the furnace) until the reaction is completed on the inside of the mound. After cooling, the mound is broken up and sorted. The core contains high-purity green hexagonal SiC crystals suitable for electronic applications. The purity of the SiC can be determined based on the color of the crystals.

- Light green 99.8% pure
- Dark green 99% pure
- Black 98.5%

Around the core is a zone of lower purity ($\geq 97.5\%$), which is suitable for abrasives. The outer layer consists of a mixture of SiC, unreacted SiO_2 , and C that is reused in the next batch. Figure 19.7 shows examples of SiC crystals produced by the Acheson process.

The world's largest producer of SiC is China, which produces about 450,000 t per year. The largest U.S.-based manufacturer for SiC is Exolon-ESK in Hennepin (Illinois), which produces about 40,000 t of SiC annually. Figure 19.8 shows several of the furnaces at the Hennepin plant in various stages of production. The cost for SiC powders produced by the Acheson process is in the range \$10–40 kg^{-1} .

19.8.2 Titanium Carbide

Titanium carbide (TiC) is another nonoxide ceramic that is not available in nature. It is prepared either by the carbothermal reduction of TiO_2 or by direct reaction

FIGURE 19.8. Exolon-ESK plant in Hennepin (Illinois). This plant is one of the newest SiC facilities in the world, producing 45,000 t of both high-quality metallurgical and crystalline SiC annually. It is North America's only manufacturer of SiC. The plant features 16 furnaces operating off of four transformers.

between the elements titanium and carbon. As in many of these reactions, high temperatures are required. The carburization temperature is 2,100–2,300°C.

19.8.3 Aluminum Nitride

There are several large-scale methods for producing AlN, two of which are currently used in industry. One method is direct nitridation of aluminum.

Aluminum powders are converted directly to the nitride at temperatures above the melting point of the metal. Careful process control is necessary to avoid coalescence of the metal prior to nitridation.

Reducing alumina using nitrogen or ammonia in the presence of carbon is another method to produce AlN.

The mixture of alumina and carbon are reacted with a nitrogen-containing atmosphere above 1,400°C. Fine powders and extremely good control of mixing are required to result in complete conversion to AlN.

In both processes the major impurities are O (~1.0 wt%) and C (<0.07 wt%). Other impurities are silicon, iron, and calcium, which typically occur at levels of <50 ppm each.

The main vendors for AlN powders are Advanced Refractory Technologies (United States), H.C. Starck and Elf Atochem (Europe), and Toyo Aluminum and Tokuyama Soda (Japan). The world market for AlN powder is about 200 t/year. Prices range from \$20 kg⁻¹ to \$180 kg⁻¹ depending on supplier, powder characteristics, and quantity.

Many of the applications of AlN require it to be consolidated in the form of substrates or crucibles. It is an electrical insulator and has high thermal conductivity (better than Fe), which makes it attractive for use in electronic packaging. Aluminum nitride crucibles are used for containing metal melts and molten salts.

19.8.4 Silicon Nitride

Silicon nitride (Si₃N₄) is another synthetic mineral. It occurs in two crystalline forms. The lower-temperature α form is usually preferred as a raw material because the transformation to the β form during sintering favors the development of an elongated crystal structure. Several routes are available for the synthesis of Si₃N₄ powder, similar to those used to form AlN.

- Nitridation of Si powder
- Carbothermal reduction of silica in N₂
- Vapor phase reaction of SiCl₄ or silane (SiH₄) with ammonia

Most commercially available powder is made by reacting silicon powder with nitrogen at temperatures of 1,250–1,400°C, according to the reaction.

The powder generally consists of a 90:10 mixture of α - Si_3N_4 and β - Si_3N_4 polymorphs. Seeds of Si_3N_4 powder are often mixed with the silicon to hasten the reaction, and they also help prevent formation of the undesired β phase. Nitrided powder contains impurities such as Fe, Ca, and Al—originally present in the Si or picked up during subsequent milling. Higher-purity Si_3N_4 powder can be made by carbothermal reduction in the range 1,200–1,550°C

Although this process leads to powders with residual carbon and oxygen, it produces high surface area powder with a high α content. Si_3N_4 seeds may again be used to speed up the reaction.

High-purity powders are also made via vapor phase reactions such as:

Powder from these reactions is amorphous, but the product on heating to 1,400°C is mostly α - Si_3N_4 .

Worldwide production of Si_3N_4 is about 500 t per year; Japan is the primary market. The cost for this powder is between \$30 kg^{-1} and \$150 kg^{-1} , depending on the particle size and the quantity ordered.

Silicon nitride exhibits high strength at elevated temperatures and excellent thermal shock, creep, and oxidation resistance in hostile environments, which makes it ideal for gas turbine and diesel engine applications. The SiAlONs are variations on this theme. For example, SiAlON is being combined with boron nitride (BN) to produce a composite material that is reported to have incomparable thermal shock resistance.

19.8.5 Zirconium Diboride

ZrB_2 is useful as a crucible material for metal melts because of its excellent corrosion resistance. It is also used in Hall-Heroult cells (for Al production) as a cathode and in steel refining, where it is used as thermowell tubes.

Several different processes can be used to produce ZrB_2 that are similar to those used to form carbides and nitrides. Commercially, either direct reaction between zirconium and boron

or carbothermal reduction of zirconia

are used. All these reactions must be carried out at high temperature in an inert atmosphere or in a vacuum. The typical price of ZrB_2 powder is \$60–\$100 kg^{-1} .

19.8.6 Tungsten Carbide

Tungsten carbide is a wear-resistant material used in the metalworking, mining, and construction industries for machine parts and dies that are subject to severe service conditions. It is produced by carburization of tungsten powder. The United States uses about 5,500 t of tungsten carbide each year.

19.8.7 Carbon

Graphite is one of three crystalline forms of carbon, the others being diamond and fullerenes. Graphite is unlike most of the nonoxide ceramics in that it occurs naturally in metamorphic rocks such as marble.

The graphite used in industry comes from both natural sources (where it is mined in open pits) and underground operations. It is also synthesized. The largest producers of natural graphite are China and India; and total world production is around 1 Mt per year. Although graphite is not currently mined in the United States, the country does produce about 300,000 t of synthetic graphite annually with a value of almost \$1 billion.

There are several methods used to produce synthetic graphite. Many of them involve heating nongraphitic carbons $>2,500^\circ\text{C}$. For example, a high-purity form is produced by heating a calcined mix of petroleum coke and coal tar pitch to $3,000^\circ\text{C}$. The high temperature allows the carbon atoms to order into the graphite structure. Synthetic graphite can also be obtained by chemical vapor deposition from hydrocarbons at lower temperatures ($\sim 1,800^\circ\text{C}$)

Most of the synthetic graphite produced in the United States ($>60\%$) is used in the massive electrodes in carbon-arc furnaces to melt steel and in much smaller battery electrodes. Other major applications include lubricants and in steelmaking as carbon raisers. Synthetic graphite is used in replacement heart valves, an application we describe in Chapter 35.

The largest uses for natural graphite are in refractories (45%) and brake linings (20%). Natural graphite costs around \$500 t^{-1} , whereas synthetic graphite costs $>\$2,000 \text{ t}^{-1}$.

The quantity of industrial diamonds produced in the United States is much smaller than the amount of synthetic

graphite. About 300 million carats, or 60 t, are produced each year, with major applications in stone cutting and highway/building repair.

The fullerenes were discovered in 1985 and the related carbon nanotubes in 1991. Both are now available in commercial quantities, but at present they are very expensive and the applications are limited to specialty products such as Nanodesu bowling balls, which use fullerenes as an

additive in a polymer coating. Graphene, single layer planar sheets of graphite, is an emerging material that may soon begin to have commercial impact. In 2010 over 400 United States patents were issued on graphene. Potential applications include super-strong composites and transparent conductive coatings. Some experts forecast the market for graphene to really take off in 2015. We shall have to wait and see.

CHAPTER SUMMARY

This chapter described the processes used to obtain the raw materials necessary to make ceramics. The significant points to remember from this chapter as you continue your study of ceramics are:

- Where and how we get the raw materials determine impurity concentrations in the final powder (e.g., Na is the major impurity in Bayer alumina).
- The abundance of a mineral may affect the cost of the final ceramic component. For example, SiO₂ comes from sand; and it is abundant and inexpensive. Glass bottles are cheap; the cost of a Si wafer is not related to the cost of sand.
- If the raw materials are not oxides, then they have almost certainly been synthesized. For example, we use 0.5 Mt of SiC (mostly for abrasives), which must be synthesized. The cost of the powder depends on how pure it is.
- Gemstones are found during mining but are not abundant. For example, about 200 mg of diamonds come from 1 t of ore, and the market price of diamonds can justify this dilution.

PEOPLE AND HISTORY

Acheson, Edward Goodrich (1856–1931) was an American chemist who worked with Thomas Edison before establishing his own laboratory. He developed a process for producing silicon carbide while trying to make synthetic diamonds. In 1891, he founded the Carborundum Co. to produce SiC for abrasives and was granted a patent in 1893 for SiC. In 1926, the U.S. Patent Office named his patent for SiC as one of the 22 most responsible for the industrial age.

Bayer, Karl Joseph (1847–1904) was the Austrian chemist (born in Bielitz) who described the Bayer process in 1888.

Dana, James Dwight (1813–1895) was educated at Yale University and made contributions to the fields of geology, mineralogy, and zoology. He developed classification systems that are still in use in these fields today.

Moisson, Ferdinand Frédéric-Henri (1852–1907) is known in the field of ceramics for his unsuccessful attempts at diamond synthesis (he actually produced SiC). Moisson was awarded the 1906 Nobel Prize in Chemistry for isolating fluorine on June 26, 1886. It was in Moisson's laboratory at the University of Paris in France that tungsten carbide was first made.

Bauxite is named after the small French town of Les Baux de Provence, which is near Arles.

Graphite. The word is derived from the Greek word *graphein*, to write. Graphite is used as the “lead” in pencils, among many other applications.

Kaolin refers to an area of Jiangxi province, which is why it's also called China clay.

Mullite is named after the Isla of Mull off the west coast of Scotland where the rare mineral is found.

Muscovite mica was first used in 1850 by James Dwight Dana and is derived from the term “Muscovy glass,” which it was previously known by because of its widespread use as a glass substitute in the old Russian state of Muscovy.

Phlogopite mica. The name comes from the Greek word *phlogopos*, meaning fiery, in reference to the reddish color seen on some specimens of this mica.

EXERCISES

- 19.1 How many pounds of mullite are there in 1 t of the material? How many kilograms?
- 19.2 What are the major impurities you would expect to find in high-quality deposits of silica sand? Why do you think rock quartz is not used widely as a source of silica?
- 19.3 In the brief description of Edward Acheson we noted that the U.S. Patent Office named silicon carbide as one of the 22 patents most responsible for the industrial age. Why do you think it was such an important material?

- 19.4 What factors do you think contribute most to feldspar sales in the United States?
- 19.5 Why are magnesia sales related to steel production?
- 19.6 What is the difference between zircon and zirconia? Which of these, in single crystal form, is the diamond simulant?
- 19.7 A commercial supplier of ceramic powders sells 1 g of HfO₂ (purity 99%) for about \$2 but charges only 15 cents for the same amount of ZrO₂ (purity 99%). Both powders come from the ore zircon. Explain the differences in the price.
- 19.8 Quartz, basalt, and obsidian are all formed when magma cools (they are all igneous). Relate the microstructure of each of these materials to the expected relative rate of cooling of the magma. (We described obsidian in Chapter 2; you may need to look in a geology book for the microstructure of basalt.)
- 19.9 Synthetic graphite is used primarily for electrodes and as a carbon raiser in steel production, whereas the major applications of natural graphite are refractories and brake linings. Why does the source of graphite matter, and what are some of the considerations end users might make in deciding where to buy their graphite?
- 19.10 We covered mica and graphite quite extensively; they have some similar properties. Using the library and other sources, compare the international commercial value of each today.
- 19.11 Alumina and zirconia are processed and used internationally. Using the United States Geological Survey (USGS) and other sources, compare their economic impact on the world economy.
- 19.12 Mullite has often been neglected in ceramics courses. Discuss the reasons and validity of this neglect.
- 19.13 We all know what sand is. Show that most people don't and discuss the commercial uses of the different sands.
- 19.14 Describe the chemistry of the six clays listed in Table 19.4.
- 19.15 Our section on clays and kaolin is very brief in view of the importance of these materials (Table 19.4). Summarize the different types of clay that are extracted worldwide.
- 19.16 There is a growing interest in "geopolymers." Explain what they are, why this question is in this chapter, and why there is so much interest.
- 19.17 TiO₂ is one of the hottest materials even if it is not used in large quantities. Using USGS and international sources, describe how it is extracted, in what quantities, and what is the value of the TiO₂.
- 19.18 We haven't mentioned fluorides and sulfides, yet they do occur as minerals. Do we use the mineral sources? If so, in what quantities? Where? Why? (Use USGS and international resources to answer this question.)
- 19.19 We have said that Ge, GaAs, and InP are all good ceramics. What raw materials are used in their manufacture, in what quantities, and where are these sources?
- 19.20 Today's batteries depend on Li. What raw materials are used in its manufacture, where are they located, and what are the economics of producing ceramics based on Li?

Powders, Fibers, Platelets, and Composites

CHAPTER PREVIEW

The topic of this chapter is how to produce particles of a particular shape, chemistry, and size and then how to characterize them. We describe the methods used to produce ceramic powders, from the traditional ball-milling technique to more recent vapor-phase approaches that can produce nanometer-sized particles. It's worth remembering that powder processing is used to produce some special metals (e.g., tungsten filaments for incandescent lamps), in the pharmaceutical industry, for making catalysts, and for preparing many food ingredients.

Producing powders of a consistent quality and composition is an important industry. In the United States, the total market for powders of advanced ceramics (e.g., electronic and structural ceramics) alone is around \$1 billion per year.

To specify powders for particular applications and products, we need to be able to determine their physical and chemical characteristics, often with a high degree of accuracy and with statistical significance. In this chapter we describe the different analytical techniques used for particle characterization and indicate which technique works best. In addition to powders, there are other important dimensionally constrained forms of ceramics. Whiskers and fibers are long in one dimension but restricted in the other two. Ceramics in these forms are important reinforcement phases in composites such as:

- C fibers in polymer–matrix composites (PMCs)
- Al₂O₃ fibers in metal–matrix composites (MMCs)
- SiC whiskers in ceramic–matrix composites (CMCs)

If the particles are constrained in only one dimension, we have platelets. The amount of space we devote to platelets does not correlate with their commercial importance: remember that clay particles are platelets. The excuse is that most platelet particles are produced in nature, and we are concentrating on particles we “design.”

If we limit the size in two or three dimensions to <100 nm, we have nanomaterials.

20.1 MAKING POWDERS

There are many methods that are available for the preparation of ceramic powders. They can be divided into just three basic types.

- Mechanical
- Chemical
- Vapor phase

Mechanical methods use coarse-grained materials that have generally been derived from naturally occurring minerals. They are subjected to a series of processes, collectively referred to as comminution, in which the particle size is gradually reduced. The final step is known as milling, which produces particles of the desired size. Mechanical methods of powder

production are used widely in the production of traditional ceramic products where high purity powders are not required and cost is one of the most important requirements.

Chemical methods, such as sol–gel processing, offer several advantages over mechanical methods because they allow exceptional control over particle morphology and purity. Chemical processes are used widely in the production of advanced ceramic materials.

Vapor-phase processes can be used to produce ceramic powders. They tend to be expensive but offer many advantages, such as the ability to produce particles of nonoxides. Vapor phase techniques are also used to produce nanoparticles (particles with diameters of a few to tens of nanometers).

Table 20.1 lists the desirable powder characteristics for advanced ceramics. For most processing methods, we want

TABLE 20.1 Desirable Powder Characteristics for Advanced Ceramics

Powder characteristic	Desired property
Particle size	Fine ($<1 \mu\text{m}$)
Particle size distribution	Narrow
Particle shape	Spherical or equiaxed
State of agglomeration	No agglomeration or soft agglomerates
Chemical composition	High purity
Phase composition	Single phase

a small particle size. The small size helps with shaping the product and during densification (sintering) at high temperature, allowing higher density bodies at lower firing temperatures.

20.2 TYPES OF POWDERS

Powders can have a complex structure, and to describe this structure it is necessary to follow a consistent terminology. The terminology we use here follows that used in the ceramic processing industry.

- **Primary particles**—The smallest clearly identifiable unit in the powder. Primary particles may be crystalline or amorphous and cannot easily be broken down into smaller units.
- **Agglomerates**—Clusters of bonded primary particles. Soft agglomerates are easily broken up; hard agglomerates, because of the stronger interparticle bonds, are more difficult. Hard agglomerates should be avoided in ceramic powder processing as much as possible.
- **Particles**—General term applied to both primary particles and agglomerates. Some of the techniques that we refer to in the next section often measure particle size, with no distinction between agglomerates and primary particles.
- **Granules**—Large agglomerates, usually 0.1–1.0 mm in diameter, that are formed by the addition of a granulating agent (e.g., a polymer binder). The mixture is tumbled, producing large, nearly spherical granules that flow freely and can be used for filling complex molds and in automated processes.
- **Flocs**—Clusters of particles in a liquid suspension held together electrostatically.
- **Colloids**—Very fine particles (can be as small as 1 nm in diameter); held in fluid suspension by Brownian motion. Consequently, colloidal particles settle very slowly.
- **Aggregates**—Coarse constituents, $>1 \text{ mm}$, in a mixture. The important example is the addition of gravel to cement to make concrete. In early concrete structures, such as the Pantheon in Rome, pumice was used as aggregate.

20.3 MECHANICAL MILLING

For traditional raw materials such as clay and the oxides produced from ores, it is often necessary to eliminate aggregates and reduce the particle size. Compound formation during firing and densification during sintering require diffusion between neighboring particles. Diffusional processes are proportional to the square of the particle size.

The most common method for reducing particle size is ball milling. A ball mill is a barrel (usually made of a ceramic, although for small-scale milling in the laboratory a small plastic bottle works well) that rotates on its axis and is partially filled with a grinding medium (called media) in the form of spheres, cylinders, or rods.

Figure 20.1 shows a cross section of a ball mill. The media is in such quantity that the rotation of the mill causes it to cascade, creating both shear and crushing actions on the powder.

The media should have a high density (ρ) as this provides for the most effective collisions. The choice of media is also based on the cost, wear resistance, and the possibility of introducing contamination into the powder.

Depending on the amount of powder to be milled, the size of the mill, and the final particle size required, the media could range from $>8 \text{ cm}$ in diameter to 0.6 cm , which is used for fine grinding. The powder is often milled in a liquid with a surface-active agent added. Ball milling eliminates aggregates and can typically reduce the particle size down to 1–10 μm .

POPULAR MILLING MEDIA
Porcelain ($\rho = 2.3 \text{ Mg/m}^3$)
Alumina ($\rho = 3.6 \text{ Mg/m}^3$)
Zirconia ($\rho = 5.5 \text{ Mg/m}^3$)
Steel ($\rho = 7.8 \text{ Mg/m}^3$)
Tungsten carbide ($\rho = 15.6 \text{ Mg/m}^3$)

FIGURE 20.1. Cross section of a ball mill showing the movement of the media as the mill rotates about its axis.

The advantages of ball milling are that the equipment is:

- Simple (although experimentally straightforward, there are many theoretical aspects that are quite complex)
- Inexpensive (at least for small batch sizes).

The disadvantages of ball milling are that it:

- Can't produce ultrafine particles
- Can add impurities to the powder from the media and the inside of the mill
- Is inefficient—less than 2% of the energy input goes into creating new surfaces

You've seen polished stones of hematite, quartz, etc. These are obtained by tumbling in the same type of mill; the "particle" size is just bigger. The biggest "ball" mill is the seashore where pebbles are eventually changed into sand.

There are many other mechanical methods that can be used to achieve comminution. The possible particle size range for each is compared in Table 20.2. We describe three of the methods in more detail below.

Fluid-energy milling, also called *jet milling*, achieves particle size reduction by particle–particle impact in a high-velocity fluid, usually either compressed air or superheated steam. The powder is added to the fluid and injected into the grinding chamber at sonic or near-sonic velocity. The design of the chamber maximizes particle–particle impact while minimizing particle–wall impact. Coating

MILLING

The minimum particle size possible by ball milling is ~0.1 μm.
Vibratory milling is 10× faster than ball milling.

of the walls of the chamber (e.g., with a polymer) can further reduce contamination. Fluid-energy milling can achieve controlled particle size (down to about 1 μm) with a narrow size distribution. Table 20.3 shows examples of ceramic powders formed by fluid-energy milling. The main drawback with this method is collecting the fine powder that is mixed into the gas stream.

In *vibratory milling*, the drum containing the media and powder is vigorously shaken. The collisions between the media are much more violent than they are in ball milling, and this can shorten milling times and also produce nanopowders. Polymer balls can be used as media, which means that any contamination can be burned off during subsequent firing.

Attrition milling, or *agitated ball milling*, differs from conventional ball milling in that the milling chamber does not rotate. Instead, a slurry containing the

TABLE 20.2 Possible Particles Sizes for Different Milling Techniques

Jaw crushers	To 5 mm
Cone crushers	To 5 mm
Crushing rolls	To ~1 mm
Hammer mill	To ~0.1 mm
Jet mill	1 to ~50 μm
Vibratory mill	1 to ~50 μm
Ball mill	0.5–10.0 μm
Attrition mill	0.1–5.0 μm
Roller mill	0.1–5.0 μm

Nanopowders down to 20 nm have been produced by high energy vibratory "shaker" ball milling.

FIGURE 20.2. Attrition mill.

TABLE 20.3 Examples of Ceramic Powders Produced by Fluid Energy Milling

Material	Mill diameter		Grinding medium	Material feed rate		Average particle size obtained	
	cm	in.		kg/h	lb/h	μm	in.
Al ₂ O ₃	20.3	8	Air	6.8	15	3	0.00012
TiO ₂	76.2	30	Steam	1,020	2,250	<1	<0.00004
TiO ₂	106.7	42	Steam	1,820	4,000	<1	<0.00004
MgO	20.3	8	Air	6.8	15	5	0.0002
Dolomite	91.4	36	Steam	1,090	2,400	<44	<0.0018
Fe ₂ O ₃	76.2	30	Steam	450	1,000	2–3	~0.0001

particles and media is stirred continuously at frequencies of 1–10 Hz. The grinding chamber is aligned either vertically, as shown in Figure 20.2, or horizontally, with the stirrer located in the center of the chamber. The media consists of small spheres (0.2–5.0 mm) that make up 60–90% of the available mill volume. Most attrition mills work on a continuous basis, with the powder to be milled fed in at one end, and the milled product collected at the other. Attrition mills are more energy-efficient than the other methods we have described and can also handle higher solid contents in the slurry. The rapid milling time, because of the use of small media, helps reduce contamination. Lining the chamber with a polymer or a ceramic and using ceramic stirrers and media can further reduce contamination.

20.4 SPRAY DRYING

Spray drying is an example of powder production from solution. It is used widely for preparing ferrites, titanates, and other electrical ceramics. Fine droplets produced by an atomizer are sprayed into a drying chamber, and the powder is collected (Figure 20.3). There are different types of atomizer. One uses ultrasonic atomization, where the solution is passed over a rapidly vibrating piezoelectric membrane. Droplet sizes in the range 10 to >100 μm can be produced.

FIGURE 20.3. Spray dryers. (A) Centrifugal atomizer with co-current air flow. (B) Nozzle atomizer using mixed-flow conditions.

In the drying chamber, the flow pattern of the hot air determines the completeness of moisture removal and the maximum temperature that the particles experience. Finally, the particles are carried out of the chamber in the air stream and captured in a bag or another form of collector. The particles produced by spray drying are often agglomerated with a primary particle size <0.1 μm .

The variables in spray drying are:

- Droplet size
- Solution concentration and composition
- Temperature and flow pattern of the air in the drying chamber
- Chamber design

For small-scale laboratory experiments, nitrates and acetates are often used because of their relatively low decomposition temperature. Chlorides and oxychlorides are frequently used in industrial spray drying operations due to their high solubility in aqueous solutions. The capacities of industrial spray dryers are up to several hundred kilograms per hour. The spray drying process is not limited to aqueous solutions; for example, alcohol solutions of alkoxides can be used.

Table 20.4 lists examples of salt precursors and their decomposition temperatures. The decomposition of salts to oxides is an example of a solid-state reaction. These reactions are often referred to as calcination and are frequently governed by kinetics rather than thermodynamics. As a consequence, they may be carried out at temperatures much greater than those necessary based on thermodynamic calculations. A feature of the decomposition reactions is that they often result in the production of extremely fine particles.

A variation of the spray drying process, known as spray pyrolysis, uses a higher temperature and a reactive (often an oxidizing) environment in the chamber. This allows the salts to be dried and decomposed directly. Figure 20.4

TABLE 20.4 Salt Precursors and Their Decomposition Temperatures in Air

Precursor	T ($^{\circ}\text{C}$)
$\text{Zn}(\text{NO}_3)_2 \cdot 6\text{H}_2\text{O}$	360
$\text{Ni}(\text{NO}_3)_2 \cdot 6\text{H}_2\text{O}$	400
$\text{Ni}(\text{CH}_3\text{COO})_2 \cdot 4\text{H}_2\text{O}$	350
$\text{Fe}(\text{NO}_3)_3 \cdot 9\text{H}_2\text{O}$	200
MgSO_4	1,000

FIGURE 20.4. Stages in the spray pyrolysis process.

shows the stages in the spray pyrolysis process. In addition to producing powders, this technique has been used to produce thin films and fibers.

20.5 POWDERS BY SOL–GEL PROCESSING

Sol–gel processing is one of the topics we describe in Chapter 22. It is best applied to the formation of films and fibers. We discuss the technique here because, although expensive, it can produce powders with a high surface area, which allows sintering to nearly full density at much lower temperatures than are normally required when the particles have been made by other techniques.

In nearly all sol–gel processes, the reactants are solutions of metal alkoxy compounds. Alkoxides result from the reaction of metals (Me) with alcohols. The general reaction is given as:

where R is an organic group. For ethanol, R is the ethoxy group C_2H_5 . Catalysts are often necessary to increase reaction rates. For example, aluminum reacts with isopropanol at 80°C in the presence of a small amount of HgCl_2 . In this case, the catalyst breaks down the protective oxide layer that forms on the aluminum.

A number of metal alkoxides are commercially available in high purity. To make metal oxide powders from these organometallic precursors, we start with a solution (a “sol”) of the metal alkoxide in alcohol. (The alcohol is usually the same one that was used for alkoxide formation.) Water is added to the alcohol solution. Two reactions then occur, which using aluminum isopropoxide as an example, may be written as:

Reaction 1: hydrolysis

Reaction 2: condensation

The remaining alkoxy groups ($-\text{OR}$) of the condensation product can be hydrolyzed further to form a cross-linked, three-dimensional network of metal–oxygen bonds. The actual reactions that occur appear to be significantly more complex than those represented by equations 20.2 and 20.3.

There are several variables in the sol–gel process.

- Rates of hydrolysis and condensation (relative differences in the rates can be used to modify the microstructure of the powder)
- Type of alkoxide (mixing of the alkoxides in the solution is achieved at a molecular level giving the powders have a high degree of chemical homogeneity)
- Reaction temperature (affects the degree of polymerization of the gel)
- Amount of water added (affects the degree of polymerization of the gel)
- Solution pH (rates of hydrolysis and condensation can be increased by the addition of acids or bases, respectively)

Gelation times vary from seconds to several days. When the gel forms, it may contain only about 5 vol% of the oxide. The dried gel is calcined to completely convert it to oxide. Powders produced by the sol–gel method are amorphous. A crystallization step is required for the production of crystalline bodies, and this is often performed after sintering.

20.6 POWDERS BY PRECIPITATION

To cause precipitation, it is necessary to produce a supersaturated solution. This can be achieved, for example, by changing the pH or the temperature. A higher quantity of a soluble component (e.g., a metal salt) can be dissolved in a solution at high temperature than at a lower temperature. You know that not only does sugar dissolve more quickly in hot tea than in iced tea but more sugar dissolves. The relation between solubility and temperature for several ionic compounds is shown in Figure 20.5. There are

FIGURE 20.5. Solubility (grams of solute in 100 g H_2O) versus temperature for several ionic compounds.

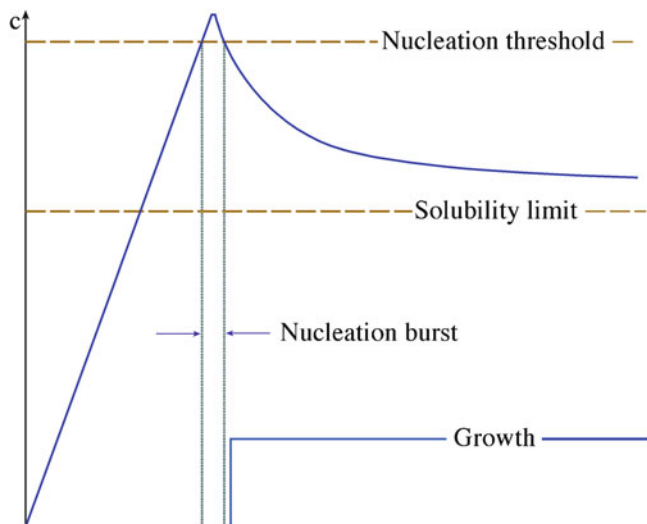

FIGURE 20.6. Concentration versus time for a solution where the concentration is first increased to the point of nucleation (e.g., by evaporation) and then declines as a precipitate grows.

some exceptions to prove the rule: cerium sulfate is less soluble at higher temperatures because its heat of solution is negative ($\Delta H_{\text{sol}} < 0$).

At a supersaturation that exceeds the concentration threshold for homogeneous nucleation, a large number of nuclei form suddenly. Their formation lowers the solution concentration below that at which nucleation occurs, but enough excess solute remains for the existing nuclei to grow. If the solution is kept uniform, growth of all the particles proceeds at the same rate, giving powders with extremely uniform size distribution. The variation of solute concentration with time during the nucleation and growth of particles from solution is shown in Figure 20.6. This diagram is often referred to as a LaMer diagram after the work of LaMer and Dinegar.

Precipitation of mixed oxides is possible. For example, in the fabrication of nickel ferrite (a magnetic ceramic used for memories), a mixed aqueous solution of iron and nickel sulfates is used. The solution is kept at about 80°C, and precipitation occurs when the pH is increased to around 11 with ammonium hydroxide. A mixed hydroxide precipitates, which is washed to remove the residual sulfate and then dried to a powder with a particle size between 50 nm and 1 μm.

The Pechini method is a commercial process for the preparation of titanates and niobates for the capacitor industry. With slight modifications, it is also referred to as the “citrate gel” process or the “amorphous citrate” process. Figure 20.7 shows a flow chart for the preparation of strontium titanate powder. Metal ions from such starting materials as carbonates, nitrates, and alkoxides are complexed in aqueous solution with α-carboxylic acids

PRECIPITATION

It is important to make sure that nucleation occurs homogeneously. Good housekeeping is essential as specks of dirt can act as nucleation sites causing heterogeneous nucleation.

FIGURE 20.7. Flow chart for preparing SrTiO₃ powders by the Pechini method.

(e.g., citric acid). When heated with a polyhydroxyl alcohol (e.g., ethylene glycol), polyesterification occurs. On removal of the excess liquid, a transparent resin is formed. The resin is heated to decompose the

organic constituents, ground to break up large agglomerates, and finally calcined. The powders produced are not as uniform as those from the sol-gel process: they often contain hard agglomerates.

20.7 CHEMICAL ROUTES TO NONOXIDE POWDERS

Many important engineering ceramics are nonoxides (e.g., Si₃N₄, SiC). These often don’t exist in nature or are rare and so must be produced synthetically. In Chapter 19, we described how nonoxide powders are obtained by solid-state reactions, such as between SiO₂ and C to produce SiC. We have also described direct nitridation processes, such as the reaction between Al and N₂ to produce AlN. Now we’re concerned with liquid-phase reactions that lead to the formation of nonoxides.

It is possible to produce submicron particles of α-Si₃N₄ by reacting silicon tetrachloride, a liquid at room temperature, and ammonia. The reaction involves the

formation of silicon diimide, $\text{Si}(\text{NH})_2$, as an intermediate phase.

This process is used commercially by Ube Industries in Japan to produce Si_3N_4 . The particle morphology is controlled by the calcination time and temperature.

- Fine-grained equiaxed powders form at low temperatures.
- Needle-like and coarse-grained hexagonal particles form at temperatures $>1,500^\circ\text{C}$.

Another example of a liquid-phase reaction used to produce precursors for nonoxide powders involves reductive dechlorination of halide solutions. An example is the reaction between silicon tetrachloride, carbon tetrachloride, and sodium in heptane at $\sim 300^\circ\text{C}$:

The amorphous precursor can be crystallized by heating at $1,400\text{--}1,800^\circ\text{C}$ in 5% H_2/Ar . This process has also been used to produce powders of TiB_2 and B_4C .

20.8 PLATELETS

Platelets are particles that are constrained in one dimension. They are commercially important because this is the shape of clay particles and mica. Another example of platelets we have encountered already is SiC , which forms as flat hexagonal crystals by the Acheson process. An in situ process has been developed to produce platelet-reinforced intermetallic composites. The reaction is:

The SiC is in the form of platelets in a MoSi_2 matrix.

20.9 NANOPOWDERS BY VAPOR-PHASE REACTIONS

Vapor phase processes are relatively expensive, but there are several good reasons for using them for preparing powders, especially when we want:

- High purity
- Discrete and nonaggregated particles
- Nanoparticles with narrow size distributions
- Versatility in producing powders of oxides and nonoxides

FIGURE 20.8. Gas-condensation chamber for nanoparticle synthesis.

Figure 20.8 illustrates a gas-condensation chamber developed specifically for this purpose. Material is evaporated from the two sources and condenses in the gas phase. The condensate is transported by convection to the liquid nitrogen cold finger. The clusters are scraped from the cold finger and collected via a funnel. It is possible to have the particles transferred directly into a cold press, where they can be compacted. With this technique, ceramic powders with very small particle size have been produced (e.g., TiO_2 powders with an average particle size of 10–15 nm).

Figure 20.9 shows a typical plasma reactor that can also be used to produce ceramic nanoparticles. The gaseous reactants are introduced into an argon plasma, where they are decomposed into free atoms, ions, and electrons. Quenching of these highly excited species results in the formation of ultrafine powders with sizes typically <20 nm.

20.10 CHARACTERIZING POWDERS

There are several techniques that can be used to obtain particle size and particle size distribution, and they are compared in Table 20.5. The choice of technique depends on several factors, such as applicable particle size range, sample size required, and the analysis time. In addition, we often have to consider instrument cost, availability, ease of operation, and maintenance.

FIGURE 20.9. Plasma reactor.

TABLE 20.5 Summary of Particle Size Analysis Techniques

Method	Medium	Size (μm)	wt (g)	<i>t</i>
Light microscopy	Liquid/gas	400–0.2	<1	S-L
Electron microscopy	Vacuum	20–0.002	<1	S-L
Sieving	Air	8,000–37	50	M
	Air	5,000–37	5–20	M
	Liquid	5,000–5	5	L
	Inert gas	5,000–20	5	M
Gravity sedimentation	Liquid	100–0.2	<5	M-L
Centrifuge sedimentation	Liquid	100–0.02	<1	M
Electrical sensing zone (coulter counter)	Liquid	400–0.3	<1	S-M
Fraunhofer scattering	Liquid/gas	1,800–1	<5	S
Mie scattering	Liquid	1–0.1	<5	S
Intensity fluctuation	Liquid	5–0.005	<1	S
X-ray line broadening	Air	< 0.1	<1	S-M

S = Short, M = Medium, L = Long

Obtaining accurate and representative measurements of particle size is not trivial. Beyond selecting the right experimental method to use, you may have to perform a statistical analysis of the data to obtain meaningful results.

20.11 CHARACTERIZING POWDERS BY MICROSCOPY

The most straightforward method to determine the size of particle is to look at it. We described the various microscopy techniques in some detail in Chapter 10. If the size of

the particle is $>1 \mu\text{m}$, then visible light microscopy (VLM) is fine. Particle size measurements are made either directly at the microscope or from micrographs (photographs taken using the microscope). The main challenge is in determining the size of three-dimensional grains on the basis of planar images. Several procedures have been employed for making these measurements. The Heyn intercept method is one of the most useful approaches and is ideally suited for nonequiaxed grains. The number of grain or grain boundary intersections of a straight or curved line is measured, and from this information the grain size determined. It is possible to make these measurements by hand using a ruler, but to get a statistically relevant sample it would take a long time. A large number of particles can be measured quickly using image-analysis methods on a computer. The data are often then plotted as a histogram of frequency of occurrence versus particle size.

For submicron particles, it is necessary to use an electron microscope. For scanning electron microscopy (SEM), and in particular transmission electron microscopy (TEM), the total amount of material that can be examined is quite small. Hence, it is essential to make sure that the sample examined is representative of the entire powder batch.

The digital readout on TEM is not better than $\pm 10\%$ accurate. If more accurate measurements are required, you must first calibrate the magnification of the instrument.

20.12 SIEVING

Sieving is the oldest method for determining particle size distribution. Actually, sieving is used for sorting particles according to size, rather than measuring their size. Typically, sieves with decreasing mesh size are stacked with the largest mesh at the top. The term “mesh size” denotes the number of openings per linear inch in the sieve screen. The National Bureau of Standards (now the National Institute of Standards and Technology, or NIST) developed the sieve numbering system based on the “fourth root of two” ratio; this series is known as the American Society for Testing and Materials (ASTM) E-11 standard. This ratio ($=1.189$) means that the sieve openings are an exact geometric series.

Table 20.6 lists the aperture (hole) size of standard sieves; this size corresponds closely to the International Organization for Standardization (ISO) standard. As you can see, sieving is not applicable to the smallest particle sizes ($<5 \mu\text{m}$), which are often used in the fabrication of components from advanced ceramics. Sieving is used in the traditional ceramics industry for size determination of raw materials. It is particularly suited for powders with particle size $>56 \mu\text{m}$. The particle size distribution obtained by sieving is normally only approximate because it is often too time-consuming to sieve for long enough periods to achieve the final distribution of particles in the various sieves.

TABLE 20.6 Aperture Size of U.S. Standard Sieves

Sieve no.	Aperture (μm)	Sieve no.	Aperture (μm)
3.5	5,660	60	250
4	4,760	70	210
5	4,000	80	177
6	3,360	100	149
7	2,830	120	125
8	2,380	140	105
10	2,000	170	88
12	1,680	200	74
14	1,410	230	63
16	1,190	270	53
18	1,000	325	44
20	841	400	37
25	707	600	30
30	595	1,200	15
35	500	1,800	9
40	420	3,000	6

50	297	14,000	1

20.13 SEDIMENTATION

A spherical particle of diameter, d , falling through a viscous liquid soon reaches a constant velocity, v , where its weight is balanced by a frictional force, F , exerted by the liquid, as shown in Figure 20.10. Stokes' law gives the important relationship between F and v :

$$F = 3\pi\eta dv \quad (20.7)$$

FIGURE 20.10. Force balance during settling of a particle in a Newtonian fluid with laminar flow.

where η is the viscosity of the liquid. Equating F to the effective weight of the particle (i.e., the downward force) gives:

$$v = d(\rho_s - \rho_l)g/18\eta \quad (20.8)$$

where g is the gravitational constant, and ρ_s and ρ_l are the densities of the particle and the liquid, respectively. Equation 20.8 is Stokes' equation, from which we can determine d by measuring the sedimentation rate.

The sedimentation technique is reliable for particle size determination when d is in the size range 2–50 μm . The falling rate of smaller particles is affected by Brownian motion resulting from collisions with the molecules of the liquid and other interactions between particles. Stokes' law is valid only for laminar or streamline flow (i.e., when there is no turbulence). The Reynolds number (Re) is a measure of when the process transitions from turbulent to laminar flow.

$$Re = v\rho_l d/\eta \quad (20.9)$$

Laminar flow is restricted to Reynolds numbers of <0.2 .

If there is a narrow distribution of particle sizes, then sedimentation is experimentally very simple. A dilute suspension of the particles is shaken in a tall graduated cylinder. After a few seconds, the suspension becomes stagnant, and the particles start to settle at a constant (terminal) velocity. A clear layer of liquid forms at the top of the cylinder and grows as the particles continue to settle. The velocity of the downward movement of the interface between the clear liquid and suspension is v , which can readily be obtained using a stopwatch and the cylinder graduations.

The technique becomes more complicated if there is a distribution of particle sizes. In these cases, it is more usual to measure the particle concentration at some point in the fluid. One way of doing this is by determining the turbidity of the fluid (i.e., its clarity). We use either light or X-rays and measure the intensity of the transmitted beam as the powder settles. The ratio of the intensity of the transmitted beam, I , to that of the incident beam, I_0 , is given by the Beer-Lambert law.

$$I/I_0 = \exp(-KAcx) \quad (20.10)$$

where K is the extinction coefficient, A is the projected area per unit mass of particles, c is the concentration by mass of the particles, and x is the path length of the light through the suspension.

For a dilute suspension containing roughly equal amounts of two particle sizes, Figure 20.11 shows the way turbidity changes with time at a distance, L , below the top of the liquid. Turbidity is usually expressed in terms of nephelometric turbidity units (NTu). This is in reference to a specific type of measurement technique.

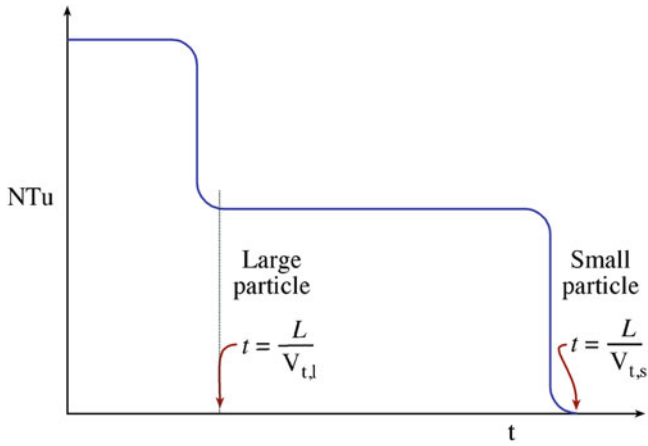

FIGURE 20.11. Result of sedimentation measurements using turbidity for two particle sizes in a solution; V_t : terminal velocity.

A nephelometer specifically measures the light reflected into the detector by the particles.

The particle size can be determined from Stokes' equation. Clearly, if the particle size distribution is broad, the interpretation of turbidity measurements is not simple! Turbidity measurements are widely used to assess water quality. In the United States, the allowable turbidity in drinking water is 1 NTu. Many drinking water utilities try to achieve levels as low as 0.1 NTu.

20.14 COULTER COUNTER

The Coulter counter, shown in Figure 20.12A, measures the number and size of particles suspended in an electrolyte by causing them to flow through a narrow orifice, on either side of which an electrode is immersed. As a particle passes through the orifice, it displaces an equivalent volume of electrolyte and causes a change in resistance, R . The magnitude of this change is proportional to the particle size.

The changes in R are converted to voltage pulses that are amplified, sized, and counted to produce data for the size distribution of the suspended particles. The peak height depends on the particle size, as illustrated in Figure 20.12B. Peak A corresponds to a larger particle passing through the orifice than peak B. The peak width is a measure of how long it takes the particle to move through the orifice. The Coulter counter can measure particles in the size range 0.5–100 μm .

20.15 CHARACTERIZING POWDERS BY LIGHT SCATTERING

When a beam of light strikes a particle, some of it is transmitted, some is absorbed, and some is scattered. When the particles are larger than the wavelength of the

FIGURE 20.12. Results of Coulter counter measurements for two particle sizes, A and B. R : resistance between the electrodes (shown as shaded squares).

incident light, they cause Fraunhofer diffraction. The intensity of the forward-scattered light (i.e., light travelling in roughly the same direction as the incident light) is proportional to d^2 . Figure 20.13 shows examples of the light scattered from two particles of different sizes.

- Smaller particles scatter a small amount of light through a large angle
- Large particles scatter a greater amount of light but through a smaller angle

The relationship between scattering angle (θ) and d is:

$$\sin\theta = 1.22\lambda/d \quad (20.11)$$

The light source is usually a He-Ne laser with $\lambda = 0.63 \mu\text{m}$. For this wavelength, the reliable particle size range is 2–100 μm . Light-scattering methods have the following advantages.

- Accuracy
- Speed
- Small sample size
- Can be automated

FIGURE 20.13. Scattering of light by large and small particles.

20.16 CHARACTERIZING POWDERS BY X-RAY DIFFRACTION

In Chapter 10 we discussed X-ray diffraction (XRD) and how it can be used to obtain crystallite size. Because of the widespread use of this technique and its applicability to very small particles, we reiterate some of the key points as they apply to characterizing powders. The width of the diffraction peaks, β , is related to d by the Scherrer equation.

$$d = 0.9\lambda / (\beta \cos \theta) \quad (20.12)$$

where λ is the X-ray wavelength, and θ is the Bragg angle. From equation 20.12, you can see that as d increases β decreases. When d is greater than about 0.1 μm , the peaks are so narrow that their width cannot be distinguished from instrumental broadening. Consequently, XRD is most applicable to fairly small particle sizes. Figure 20.14 shows a series of XRD profiles for the 111 peak (arising from diffraction of the X-rays by the {111} planes) of a ZrO_2 powder doped with 3 mol% Y_2O_3 . Higher calcination temperatures lead to particle coarsening and a corresponding decrease in β .

It is important to remember that when determining particle size in a powder by measuring the width of X-ray peaks it is actually the size of the individual crystals that are being measured. As a consequence, if the particles are agglomerated, XRD gives the size of the primary particles and *not* the agglomerate size.

Similarly, the reflections (spots) in an electron diffraction pattern are broadened if the sample is composed of small

FIGURE 20.14. X-ray line broadening for a $\text{ZrO}_2/3 \text{ mol\% } \text{Y}_2\text{O}_3$ powder prepared by hydrothermal synthesis.

crystals. TEM is not normally used in this way for particle size determination because the number of particles that can be examined is fairly small and because it is better to just look at the image and make the measurements directly.

20.17 MEASURING SURFACE AREA (BET METHOD)

Surface-area methods rely on the adsorption of gases onto a particle surface at low temperature. The mass of gas adsorbed is measured as a function of gas pressure at a fixed temperature (typically liquid nitrogen).

The method developed by Brunauer, Emmett, and Teller (BET) for estimating the particle size relies on determining the surface area of the powder, which is calculated from the N_2 -isotherm observed at the boiling point of N_2 .

The BET equation is:

$$P/[V_a(P_o - P)] = (V_m C)^{-1} + (C - 1)P/[P_o V_m C] \quad (20.13)$$

P = gas pressure

P_o = saturation vapor pressure for adsorbate at the adsorption temperature

V_a = adsorbate volume at relative pressure P/P_o

PEAK WIDTH

Depends on where it is measured relative to its maximum height
 Full width at half maximum
 Full width at tenth maximum

V_m = adsorbate volume per unit mass of solid for mono-layer coverage

C = BET constant

V_m is determined in the relative pressure ranges $P/P_0 \sim 0.05$ and $P/P_0 \sim 0.2$; according to BET theory this is the amount of nitrogen necessary to form a mono-molecular layer on the particle. Because one nitrogen molecule requires a surface area of 0.162 nm^2 , the surface area of the particle can be easily estimated in square meters per gram.

A plot of $P/V_a (P_0 - P) / P/P_0$ gives a straight line from versus which V_m and C can be determined. The specific surface area, S , of the powder can then be calculated using

$$S = N_A \sigma V_m / V' \quad (20.14)$$

where N_A is Avogadro's number, V' is the molar volume = $22,410 \text{ cm}^3/\text{mole}$, and σ is the cross-sectional area of the adsorbate molecule (0.162 nm^2 for N_2).

For spherical particles, the particle radius, a , can be obtained from

$$a = 3/\rho S \quad (20.15)$$

where ρ is the density.

20.18 DETERMINING PARTICLE COMPOSITION AND PURITY

In addition to knowing particle size and particle size distribution of our powder we often need to know its composition and purity. Table 20.7 lists the composition of a typical high-purity alumina powder. Industrial ceramic powders can contain over 30 detectable elements, but in most cases less than 10 are present at levels $>0.01\text{--}0.05\%$. Many industries use wet chemical techniques, such as precipitation and titration, for such analysis. These techniques are used because they are often simple to perform and give a quick result. For example, in the industrial

TABLE 20.7 Composition of a High-Purity Alumina Powder (wt%)

Oxide	%
Al_2O_3	99.8
Na_2O	0.06
MgO	0.05
SiO_2	0.03
Fe_2O_3	0.03
U oxide	≤ 0.0005

production of red lead (Pb_3O_4) it is necessary to determine the amount of free Pb and litharge (PbO). This analysis is typically done hourly, and the results are used to modify the furnace temperature or throughput.

In addition to using wet chemistry, there are a host of analytical methods that can give us chemical composition and impurity levels, and they are summarized in Table 20.8.

The choice of technique depends on several factors.

- Type of material (Is it readily soluble in common solvents? Is the powder agglomerated?)
- Amount of material (Do we have milligrams or kilograms?)
- Possible impurities (alkali metals, H, rare earths)
- Amount of impurities (parts per million or percent)
- Availability and cost of instrument (Do we need to use a national facility?)

Of these factors, cost is often the most important.

Examples of choices:

- X-ray fluorescence (XRF) would not be a good choice to determine the amount of low Z elements present
- Flame-emission spectroscopy (FES) is a good choice if we have very small amounts of the alkali metals
- Nuclear magnetic resonance (NMR) can be used to determine H concentrations but is often expensive to use and not as widespread as atomic absorption spectroscopy (AAS)

TABLE 20.8 Chemical Analysis of Powders

Bulk Techniques	Comments
Emission spectroscopy (ES)	Elemental analysis to the ppm level; frequently used for qualitative survey analyses; 5 mg powder sample
Flame emission spectroscopy (FES)	Quantitative analysis of alkali and Ba to the ppm level; ppb detectability for some elements; solution sample
Atomic absorption spectroscopy (AES)	Industry standard for quantitative elemental impurity analyses; detectability to ppm level, solution sample
X-ray fluorescence (XRF)	Elemental analyses; detectability to 10 ppm; $Z > 11$; solid/liquid samples
Gas chromatography/mass spectrometry (GC/MS)	Identification of compounds and analysis of vapors and gases
Infrared (IR) spectroscopy	Identification and structure of organic and inorganic compounds; mg dispersed powder in transparent liquid or solid or thin-film sample
X-ray diffraction (XRD)	Identification and structure of crystalline phases; quantitative analysis to 1%; mg powder sample
Nuclear magnetic resonance (NMR)	Identification and structure of organic and inorganic compounds; sample to 5 mg for H and 50 mg for C

- For phase determination and phase proportions in a powder mixture, XRD is useful, allowing quantitative phase analysis down to ~1% in a powder sample
- With a field-emission source in TEM, chemical analysis with atomic resolution is possible; X-ray interaction volume can be as small as $\sim 10^{-8} \text{ mm}^3$

20.19 MAKING FIBERS AND WHISKERS

Ceramic fibers and whiskers are used in the fabrication of composites, where they are dispersed within a matrix, which may be a ceramic, a polymer, or a metal. The choice of matrix depends on the proposed applications for the composite. A primary consideration is the desired operating temperature. Polymers are stable up to a maximum temperature of about 300°C and metals up to about 900°C, whereas ceramics are usable at temperatures $>1,800^\circ\text{C}$. Ceramics can be used as the reinforcement phase in all types of matrix. The major requirements are that they are strong and stiff.

Whiskers are small single crystals a few tens of microns in length with a diameter typically $<1 \mu\text{m}$. Whiskers have extremely high strengths, approaching the theoretical strength, because of the absence of crystalline imperfections such as dislocations.

20.20 OXIDE AND CARBIDE FIBERS

Oxide fibers have been commercially available since the 1970s. Control of the microstructure through careful processing is essential to obtain the desired properties, which for ceramic fibers for structural applications are:

- Low porosity
- Small grain size (for low-temperature applications)
- Large grain size (for high-temperature applications, where creep is a concern)
- High purity

Ceramic fibers cannot usually be produced by the techniques used to produce glass fibers because of the very high melting temperatures (often $>2,000^\circ\text{C}$) and the low viscosities when molten. There are four general methods to produce ceramic fibers.

- From slurry
- By sol-gel processing
- By chemical vapor deposition
- From polymer precursors

As you can see, chemistry plays an important role; and consequently there is overlap with Chapter 22. In this section, we give one typical example of each of the

methods, but bear in mind that it is possible to produce fibers of many other ceramics by similar routes.

20.20.1 Alumina Fibers from Slurry

Fiber FP was developed in 1974 by DuPont and was the first commercially produced alumina fiber. It has now been discontinued, but the process is a good illustration of the use of a slurry.

Step 1. Slurry formation. The slurry is an aqueous solution containing aluminum oxychloride, $\text{Al}_2(\text{OH})_5\text{Cl}$, together with additions to stabilize the suspension (deflocculents) and polymers to modify the viscosity. The viscosity must be adjusted such that the slurry is spinnable.

Step 2. Spinning. The slurry is extruded through a spinnerette into “green” fibers and dried. A similar process produces polymer fibers, such as nylon.

Step 3. Firing. The “green” fibers are fired initially at low temperatures to drive off the organic additives and convert the aluminum oxychloride to the oxide. It is during this stage that shrinkage of the fiber is controlled. Firing at higher temperature causes sintering, which results in solid fibers with a controlled amount of porosity and grain size. The resulting fiber is 99% $\alpha\text{-Al}_2\text{O}_3$, 98% theoretical density, with a diameter of 10–20 μm and a grain size of

$\sim 0.5 \mu\text{m}$. The mechanical properties of these fibers at room temperature are good, but the fibers are susceptible to grain growth at temperatures $>1,000^\circ\text{C}$, which leads to a considerable fall in strength.

ALKYL CHAINS

Straight chains are always designated as normal, and the word is usually abbreviated to *n*-. So in *n*-butoxide the alkyl chain is $[\text{CH}_3\text{CH}_2\text{CH}_2\text{CH}_2-]$.

20.20.2 Zirconia Fibers by Sol-Gel Processing

Step 1. Sol formation. Zirconium *n*-butoxide, $\text{Zr}(n\text{-OBU})_4$, is mixed with hydrogen peroxide (H_2O_2), nitric acid (HNO_3), and a solution of yttrium nitrate, $\text{Y}(\text{NO}_3)_3 \cdot n\text{H}_2\text{O}$. The zirconium *n*-butoxide undergoes hydrolysis, producing zirconium hydroxide and a molecule of alcohol.

Step 2. Gelation. After mixing, the solution is heated to 60°C, where the alcohol evaporates. The viscous solution is passed through a spinnerette to produce gel fibers.

Step 3. Firing. The gel fibers are fired to produce a ceramic. The zirconia is stabilized in the cubic fluorite structure by the presence of yttrium in the structure. The polycrystalline fibers are typically 5–10 μm in diameter. The grain size depends on the sintering temperature. At temperatures $\leq 1,000^\circ\text{C}$ the grain size is $<0.1 \mu\text{m}$. If the sintering temperature is 1,500°C, the grains are $\sim 1 \mu\text{m}$ in diameter.

20.20.3 Silicon Carbide Fibers by Chemical Vapor Deposition

Chemical vapor deposition (CVD) often involves decomposition of a volatile gas to produce a nonvolatile solid. The reaction usually proceeds at high temperature, and the solid is deposited onto some form of substrate. In the case of fiber formation, the substrate is a wire. SiC can be formed by decomposing methyltrichlorosilane, CH_3SiCl_3 .

The substrate or core in this case is a 10 μm diameter tungsten wire. The deposit consists of fine crystals of β -SiC oriented preferentially with the {111} planes parallel to the fiber axis. These fibers, which are sometimes called monofilaments, have diameters in the range of 100–150 μm . It takes about 20 s in the reactor to obtain a monofilament of 100 μm . Because of their large diameter and high Young's modulus, monofilaments are not flexible and, as a consequence, cannot be easily woven. The properties of the fiber are degraded above about 1,000°C because of the formation of W_2C and W_5Si_3 .

POLYCRYSTALLINE Si

Used by industry to manufacture Si boules and solar cells. Prepared by decomposing silanes onto high purity Si cores or in fluidized bed reactors (FBRs).

20.20.4 Silicon Carbide Fibers from Organic Precursors

The processes described here allow the production of thinner fibers (10–20 μm in diameter) than those produced by CVD.

Step 1. Precursor synthesis. For SiC fibers, the precursor is polycarbosilane, a high-molecular-weight polymer containing both Si and C. Polycarbosilane is synthesized by dechlorination of dimethylchlorosilane (a commercially available organic compound) by reacting it with sodium to produce polydimethylsilane. Thermal decomposition and polymerization of polydimethylsilane leads to polycarbosilane. The average molecular weight of the resulting polymer is about 1,500.

Step 2. Melt spinning. The polymer is melt-spun from a 500 hole nozzle at about 350°C under N_2 to obtain the so-called preceramic continuous precursor fiber.

Step 3. Firing. The precursor fiber is quite weak and must be converted to a strong SiC fiber by firing. The heat treatment involves several stages. Initially, the precursor fiber is oxidized in air at 200°C to induce cross linking of the polymer chains. Heating is continued slowly in N_2 . Above 200°C, the side chains containing hydrogen, and methyl groups decompose. The conversion to SiC is complete above about 850°C.

The SiC is in the form of small (~2 nm) crystals of β -SiC. The fiber is not pure SiC as some oxygen remains from the low temperature heat treatment; also excess silicon and carbon are present. A typical composition is 59% Si, 31% C, 10% O.

20.21 WHISKERS

The SiC whiskers are the strongest materials known that are produced in commercial volumes. There are two methods that are used.

- Vapor–liquid–solid (VLS) process (described in Chapter 29)
- From rice hulls (described below)

In the mid-1970s, a process for obtaining SiC whiskers by pyrolyzing rice hulls was developed. Rice hulls are a waste by-product of rice milling. For each 100 kg of rice milled, about 20 kg of rice hull is produced. The rice hulls contain silica, which comes from the soil and is closely mixed into the cellulose structure of the rice hull in fortuitously near-ideal amounts for producing SiC. The rice hulls are heated (called “coking”) in an oxygen-free atmosphere at 700°C, and the volatile constituents are driven off. The cooked rice hulls, containing about equal amounts of SiO_2 and free carbon, are further heated in an inert or reducing atmosphere (flowing N_2 or NH_3 gas) at 1,500–1,600°C

for about 1 h to form SiC.

About 10% of the product is in the form of whiskers and the remaining as particles, generally platelets. The whiskers may be separated out to give a 90–95% “pure” product.

The SiC whiskers are used commercially in a number of different applications. Alumina reinforced with 25–30 wt% SiC whiskers is the material of choice for inserts used in high-speed cutting of nickel-based superalloys (for aerospace applications). However, whiskers do have a number of disadvantages over particles. It is difficult to produce homogeneous dispersions as the whiskers tend to form entwined agglomerates; and, even if well dispersed, some orientation of the whiskers occurs leading to anisotropic properties.

20.22 GLASS FIBERS

“Glass fiber” is a generic term, like “carbon fiber” or “steel.” There are many types of glasses, but from the point of view of composite technology only silica glasses are currently important. However, even within this group of glasses, the composition, and hence properties, vary considerably. The compositions of three glasses commonly used in fibers are given in Table 20.9.

TABLE 20.9 Approximate Chemical Compositions of Some Glasses Used in Fibers (wt%)

	<i>E glass</i>	<i>C glass</i>	<i>S glass</i>
SiO ₂	55.2	65.0	65.0
Al ₂ O ₃	8.0	4.0	25.0
CaO	18.7	14.0	—
MgO	4.6	3.0	10.0
Na ₂ O	0.3	8.5	0.3
K ₂ O	0.2	—	—
B ₂ O ₃	7.3	5.0	—

The “E” in E-glass is an abbreviation for electrical. E glass is a good electrical insulator as well as having good strength and a reasonably high Young’s modulus. This glass is based on the eutectic in the ternary CaO–Al₂O₃–SiO₂ with some substitution of B₂O₃ for SiO₂ and MgO for CaO. The B₂O₃ lowers substantially the liquidus temperature, giving a longer working range and consequently making fiber drawing easier. More than 90% of all continuous glass fiber produced is of the E glass type and is used mainly as a reinforcement in PMCs.

S-glass is based on the SiO₂–Al₂O₃–MgO system. This fiber has higher stiffness and strength (hence the designation “S”) than E glass. It also retains its mechanical properties to higher temperatures. However, S glass is more difficult to draw into fibers due to its limited working range and is therefore expensive.

C glass has a high SiO₂ content, and this results in a glass having high corrosion resistance in acid and alkaline environments.

Producing glass fibers is a well-established technology. Figure 20.15 shows a conventional procedure for forming glass fibers. The raw materials are melted in a hopper, and the molten glass is fed into electrically heated platinum-rhodium bushings; each bushing contains 200 holes at its base. The bushing diameter is 1–2 mm. A constant head of molten glass is maintained in the tank. The glass flows by gravity through the holes, forming fine, continuous filaments that are gathered together and passed around a fast-rotating collet, followed by drawing rapidly at a speed of 1–2 km/min. The diameter of the glass fibers depends on the diameter of the bushing orifice, the viscosity of the melt (which is a function of temperature and composition), and the head of glass in the hopper. Typically, fibers produced in this way have a diameter on the order of 10 μm. A “size” consisting of an aqueous polymer emulsion is applied before the fibers are wound onto a drum. Sizing protects the surface of the fibers from damage and also helps in handling of the fibers by binding them into a strand.

Optical fibers require much more precise control over composition and impurities than glass fibers for composites; hence, they are prepared by very different means. We describe the methods for preparing optical fibers in Chapter 32.

E GLASS: E IS FOR ELECTRICAL
Most applications of E glass do not utilize its electrical properties.

FIGURE 20.15. Fiber forming process using either a glass melt or marble feed.

20.23 COATING FIBERS

The interface between fiber (or whisker) and matrix is key to the overall mechanical properties of a composite. A weak interface allows a propagating crack to be deflected, which increases the toughness of the composite. A strong interface allows transfer of the load from the matrix to the fiber and produces an increase in modulus and stiffness of the composite. In CMCs we are usually more interested in producing a weak interface so that debonding occurs, which often leads to fiber pull-out by frictional sliding and substantial absorption of energy.

Figure 20.16 shows the effect of carbon coatings of increasing thickness (D_c) deposited on Nicalon™ (a commercial SiC fiber produced from polymer precursors) fibers prior to composite formation. The interfacial shear

FIGURE 20.16. Effect of carbon coating thickness (D_c) on the mechanical properties of Nicalon™ fibers in a SiC matrix. Interfacial shear strength was measured by push-down testing and toughness from the area under the stress–strain curve during loading along the fiber axis.

strength decreases with increasing coating thickness, but the macroscopic toughness increases.

When ceramic fibers are in contact with metals at elevated temperatures (e.g., during fabrication of MMCs) extensive reaction can occur that leads to interfacial cracking and degradation in the properties of the composite. These reactions are particularly severe for titanium matrices, which are of interest for high-temperature applications. Applying a protective coating (called a diffusion barrier) can reduce the extent of the reaction. These coatings must be:

- Thermodynamically stable
- Nonpermeable to migrating reactants
- Robust

Although it is difficult to meet all these requirements, particularly the first one, coatings that provide protection to ceramic fibers in titanium MMCs have been developed. Examples are carbon and duplex C/TiB₂.

Glass fibers, widely used as reinforcements in PMCs, are often coated to improve their durability in aqueous environments. Reaction with water can result in the formation of a weak, porous surface on the fiber and weak bonding between fiber and matrix. Coating a glass fiber with a coupling agent can lead to strong interfacial bonding. There are many types of coupling agent, and the principles of how they work can be illustrated with silane coupling agents. These agents have the general formula R-Si-X₃, where X represents hydrolyzable groups such as ethoxy (-OC₂H₅). The R group is chosen based on the type of polymer used for the matrix. The processes leading to bond formation between a glass fiber and a polymer matrix via the use of a silane coupling agent is illustrated in Figure 20.17.

20.24 MAKING CMCs

Monolithic ceramics generally have reasonably high strength and stiffness but are brittle with low toughness. One of the main reasons for forming CMCs is to increase

FIGURE 20.17. Processes involved in joining a polymer and glass using silane coupling agents. (A) Hydrolysis of the silane to the corresponding silanol. (B) Hydrogen bonding between hydroxyls on the silanol and those attached to the glass. (C) Polysiloxane bonded to the glass following condensation during drying. (D) Bonding between the functional group R and the polymer.

toughness. Naturally, it is also hoped, and often found, that there is a concomitant improvement in strength and stiffness.

The development of CMCs has lagged behind MMCs and PMCs for two main reasons.

- Most of the processing routes for CMCs involve high temperatures and can be employed only with high-temperature reinforcements. It was not until fibers and whiskers of ceramics such as silicon carbide were readily available that there was there much interest in CMCs
- Differences in coefficients of thermal expansion, α , between the matrix and the reinforcement lead to thermal stresses on cooling from the processing temperature. These stresses can lead to cracking of the matrix

The number of feasible methods for producing CMCs is limited, and very few of them are commercially viable at the present time.

20.25 CMCs FROM POWDERS AND SLURRIES

Making CMCs from powders and slurries is simply an extension of the powder route for producing monolithic ceramics. A powder of the matrix constituent is mixed with the toughening constituent, which is in particulate or whisker form, together with a binder. The mixture is then pressed and fired or hot-pressed.

Difficulty can be experienced in obtaining a homogeneous mixture of the two constituents, and high proportions of the toughening phase cannot be easily achieved. Additional problems may arise with whiskers. Whiskers tend to aggregate, causing a significant reduction in packing efficiency. Also, damage to the whiskers can occur during the mixing and pressing, particularly when cold pressing.

Because of the difficulties encountered in obtaining homogeneous mixtures by conventional powder processing, wet processing is sometimes favored. It is essential that the constituents remain deflocculated (i.e., well dispersed) in the slurry. Deflocculation is achieved by controlling the pH of aqueous solutions and by ultrasonic agitation of the slurry.

The slurry process can also be used to produce composites by tape casting. An example is the fabrication of laminated SiC whisker reinforced mullite composites. The steps are:

1. Mullite is mixed with an organic binder in a ball mill for 24 h. SiC whiskers, at 10–50 vol%, are added and mixed for a further 24 h.
2. The mix is tape cast to produce sheets having a thickness of 50–200 μm . The whiskers are all oriented with their long axes parallel and aligned to the edges of the tape.
3. Several sheets (40–80) are laminated together at 80°C and 35 MPa for 10 min.
4. The binder is burned out by heating the laminate to 600°C at a rate of 2°C/min. The hold time at this temperature is 2 h.
5. The laminate is hot-pressed at 1,550–1,850°C for 30–70 min at a pressure of 35 MPa. An oriented SiC whisker composite is produced.

Another slurry-based process to form CMCs involves passing the fibers (e.g., SiC) through a slurry of glass powder, water, and a binder. The bundles of fibers (called tows) impregnated with the slurry are wound onto a mandrel to form a monolayer tape. The tape is cut into plies that are stacked into the required stacking sequence (e.g., unidirectional, cross-ply) prior to burnout of the binder. Hot pressing is used to consolidate the matrix. In glass-ceramic composite production, some crystallization occurs during hot pressing, but an additional heat treatment may be required to complete devitrification.

20.26 CMCs BY INFILTRATION

Melt infiltration techniques, although well established for MMCs, have met with only limited success for CMCs. The main problems are:

- Reactions with the reinforcement due to the high melting temperatures of refractory ceramics and the reactivity of molten glasses
- Low rates of infiltration resulting from the high viscosities

The most successful of the melt techniques is matrix transfer molding, which was originally developed for glass matrix composites but can also be used for glass-ceramic matrix composites. The advantage of matrix transfer molding is that it permits fabrication of components such as tubes, which are difficult to produce by other methods. In tube production, a preform and a glass slug are inserted into a cylindrical mold. Application of heat and pressure forces the fluid glass into the pores in the preform, and after cooling the composite tube is ejected from the mold.

If a sol is poured over a preform, it infiltrates because of its fluidity. The sol is then dried by a subsequent heat treatment. The processing temperature is normally low, thus reducing the risk of damage to the preform, and complex shapes can be produced. However, there are disadvantages of high shrinkage and low yield; consequently, repeated infiltrations are necessary to increase the density of the matrix. Furthermore, for some materials higher temperatures than those needed just for drying are required to produce the desired ceramic; for example, $\text{Zr}(\text{OH})_4$ needs to be calcined at about 550°C to give ZrO_2 .

Infiltration can be done in the vapor phase using a CVD process. In composite technology, CVD is used, as we have already seen, to produce fibers. It is also used to coat fibers and to infiltrate porous preforms to form the matrix. In the latter case, the process is called chemical vapor infiltration (CVI).

This CVI is very similar to the CVD processes we have already described. The gaseous reactants infiltrate the heated substrate positioned in the reactor. A chemical reaction occurs in the gaseous state, and deposition of the matrix takes place. The maximum deposition rate is about 2,500 $\mu\text{m}/\text{h}$.

The best-established CVI process is for the production of carbon-carbon composites. It has also been employed for the production of a wide range of ceramic matrices, including carbides (e.g., B_4C , SiC, TaC, TiC), nitrides (e.g., BN, Si_3N_4), TiB_2 , and Al_2O_3 .

The advantages of CVI are:

- Complex shaped preforms can be coated
- Relatively low temperatures (800–1,000°C) can be used

- In situ fiber surface treatments can be made prior to densification

The main disadvantages are that the process is time-consuming and expensive.

20.27 IN SITU PROCESSES

The Lanxide process, developed and patented by the Lanxide Corporation, involves the formation of a ceramic matrix by the reaction between a molten metal and a gas (e.g., molten aluminum reacting with oxygen to form alumina). Growth of the ceramic occurs outward from the original metal surface and through a preform, as illustrated in Figure 20.18. A preform is not a prerequisite. By simply placing powder particles above a liquid, metal particulate-reinforced composites may be produced. In both cases, the only requirements are that the fibers/particles do not react with the gas and are wetted by the ceramic. One of the big advantages of this type of process is that near-net-shape forming is possible.

A number of novel techniques are being studied whereby the composite is formed in situ via a chemical reaction. One possible reaction is:

Such reactions have the potential to give good homogeneous distributions of the toughening phase, and the raw

FIGURE 20.18. Lanxide process for making a shaped ceramic matrix composite.

materials may be less costly than the products (e.g., BN is expensive).

CHAPTER SUMMARY

In this chapter, we described ceramic particles and their use in making composite materials. We paid particular attention to how ceramic powders are produced. The important characteristics of ceramics powders are their size and size distribution, shape, and chemical composition

As is often the case, this is a big subject. For many traditional ceramic products, cost is one of the overriding concerns; and the most inexpensive method of producing powders is often selected. For advanced ceramics products, such as those used in the electronics industry, obtaining fine-grained uniform particles of high purity is often the dominant issue. For these applications, chemical routes such as sol-gel are used for powder production. For nonoxide ceramics (e.g., Si_3N_4), vapor phase routes are used to produce powders. A major advantage of vapor phase routes is that we can produce nanoparticles with narrow size distributions.

We also described the different analytical techniques used for characterizing powders in terms of both their size and composition. For determining particle size, it is necessary to choose a method that has sufficient sensitivity. Sieving is a low-cost method and reliable when the particle size is greater than about 60 μm . However, if the particles are smaller than this, as is often the case, then the use of light scattering or X-ray diffraction should be considered. In determining both particle size and chemical composition, it is essential that the specimen we choose for analysis is representative of the entire powder sample.

Ceramics in the form of fibers and whiskers are often used as reinforcing phases in composites. We described the different methods used to produce whiskers and fibers and how they are incorporated into PMCs, MMCs, and, particularly for our interest, CMCs. One of the current directions in the production of CMCs is to produce the matrix and fiber in situ.

PEOPLE AND HISTORY

Brunauer Stephen (1903–1986) (of the BET method) was born in Budapest. *Paul Emmett* (1900–1985) was born in Portland, Oregon and was in the same Ph.D. class as Linus Pauling. *Edward Teller* was also born in Hungary (1908–2003) and is also known for his work in physics.

Coulter, Wallace H. (1913–1998) was born in Little Rock, Arkansas. He patented the Coulter Principle in 1953 and began production of the Coulter Counter with his brother Joseph. The instrument was originally used for counting blood cells. He established the Coulter Corporation in Miami, Florida in 1961.

Reynolds, Osborne (1842–1912) published his famous paper that described the Reynolds Number in 1883. “An experimental investigation of the circumstances which determine whether motion of water shall be direct or sinuous and of the law of resistance in parallel channels” was “presented by Mr. Reynolds” and published in *Philos. Trans R Soc.*

Stokes, Sir George Gabriel (1819–1903) was Master of Pembroke College, Cambridge, Lucasian Professor of Mathematics (a position once held by Sir Isaac Newton and now held by Stephen Hawking), and a former President of the Royal Society. Stokes was one of the foremost mathematicians of his time and established the field of hydrodynamics.

EXERCISES

- 20.1 (a) Explain briefly the differences between jet milling, vibratory milling, and agitated ball milling. (b) Which technique would you use if you wanted to obtain a particle size of $<1 \mu\text{m}$? (c) Which technique would you use if maintaining the purity of your powder was your primary concern?
- 20.2 Why does the sol–gel process allow outstanding control of purity and chemical homogeneity of ceramic powders?
- 20.3 In Section 20.6, we described the Pechini method for producing SrTiO_3 powders. Other multicomponent oxide powders, such as $\text{YBa}_2\text{Cu}_3\text{O}_7$ (YBCO), have been made by a similar process. Identify suitable reactants to make YBCO powders by the Pechini method.
- 20.4 You have been employed as a consultant by a company making ceramic powders. Your first assignment is to recommend a technique for measuring particle sizes. An external analysis company has found that the powders typically have a size in the range of 5–30 μm . The powders are also sensitive to moisture. What technique(s) would you recommend and why?
- 20.5 You are given a sample of a whisker-reinforced CMC. How would you go about determining the relative amount of whiskers in the composite and also the composition of the whiskers and matrix phases?
- 20.6 Compare the material costs involved in making a BN-reinforced Al_2O_3 CMC composite by (1) combining the individual constituents, and (2) using an in situ reaction involving AlN and B_2O_3 . Would you expect the two composites to have similar microstructures?
- 20.7 What are the different forms of commercially available fiber that contain mainly alumina and silica?
- 20.8 Assuming that Figure 20.14 was recorded using $\text{Cu-K}\alpha$ radiation, plot the change in particle size as a function of annealing temperature.
- 20.9 Are there any commercially available ceramic nanopowders? If so, what compositions are available, and how much do they cost compared to a “conventional” powder of the same material?
- 20.10 Compare the use of scattering of visible light and that of X-rays to determine particle size distributions.
- 20.11 Mechanical milling is known by various names and is also used for producing fine metal powders. Use the literature to expand on Table 20.2 by giving examples of materials milled, when these techniques can be applied to metals, and what complications may be encountered.
- 20.12 Figure 20.6 shows a LaMer diagram. Consult the literature and discuss how this technique can be used to produce sub-100 nm silica particles. List some applications for this technology.
- 20.13 The Coulter counter is available commercially. How big is such a commercial instrument, and how many samples can it process per 8-h shift?
- 20.14 When you characterize powders by light scattering, what wavelength light would you ideally use? What are the limitations of this measurement technique?
- 20.15 You decide to buy a BET surface-area and pore-size analyzer. What is the cost, what were the specifications that you listed, and why did you not just build a system?
- 20.16 Several techniques for analyzing powders are listed in Table 20.8. Which of these use commercially available equipment? You have three powders (1–50 μm size) to analyze by these techniques: Al_2O_3 , CaO , and Fe_3O_4 . Which techniques can give the best results for each powder?

- 20.17 We mention “Fiber FP” in the text but say it has been discontinued. What ceramic fibers are manufactured today? What was the application for “Fiber FP”?
- 20.18 We say that SiC whiskers are the strongest materials produced in commercial volumes. Criticize this statement in detail.
- 20.19 You have been offered venture capital (VC) funding to produce a new ceramic fiber. What fiber are you planning to produce? What are its applications? How much will it cost? (Be sure to give the units for the last part.)
- 20.20 Discuss the motivation for linking these four materials—powders, fibers, platelets, and composites—in one chapter.

Glass and Glass-Ceramics

CHAPTER PREVIEW

The structure of glass, particularly silica glass, was introduced at the end of Chapter 7. In this chapter, we discuss the different types of glass and some of their various applications. Then, in Chapter 26, we concentrate on processing glass and the wide variations in compositions. We have only two chapters devoted to glass due to space limitations; don't take this as a reflection on its importance. Glass is arguably our most important material. It is used for windows, containers, lenses, optical fibers, insulators, glazing and enameling, surgical knives, spectacular art, and road signs! Glass is usually recyclable and environmentally friendly. The Egyptians were great glassworkers, but they were not the first. Glass was actually used much earlier; and obsidian, a natural black volcanic glass, was important during Paleolithic times. We can say that glass has played a major role in shaping our civilization.

However, there is some difficulty in defining a glass. We discuss why the words glassy, vitreous, and amorphous are all used to describe glass and try to answer the question: what is glass? Two thoughts to keep in mind while studying this chapter:

- The assertion by Sturkey: “glass at high temperatures is a chemical solution.”
- If glass is a supercooled liquid, it's not a solid so it's not a ceramic (but it is).

The mechanical, optical, and electrical properties of glasses are discussed in detail, along with other ceramics, in these topical chapters.

21.1 DEFINITIONS

The classic definition of glass is based on the historical method of formation: this is a very unusual way of defining any material. The result is that glass is now defined in several different ways.

The classic definition: *glass is a super-cooled liquid.*

The problem with this definition is that, in some cases, a particular glass can be prepared such that it never has been in the liquid state.

The American Society for Testing and Materials (ASTM) definition: *an inorganic product of fusion that has cooled to a rigid condition without crystallizing.*

This essentially says the same thing as the classic definition but excludes polymer glass. It is clearly not ideal to rely on the method of production to define a class of materials. We wouldn't consider doing this for crystalline materials.

Alternative definition 1: *glass is a solid material that does not show long-range order.*

“No long-range order” means not longer than, say, one, two, or three times the basic building block of the

glass. This definition is consistent with experimental observations—e.g., using X-ray diffraction (XRD), transmission electron microscopy (TEM)—but is clearly a little arbitrary because it depends on the size of the building block.

Alternative definition 2: *glass is a liquid that has lost its ability to flow.*

This definition is consistent, but broader, than the one given by ASTM and uses a mechanical property to describe glass. It is actually close to the more modern physicist's view of glass.

The main glasses we discuss are the network oxide glasses, specifically the silicates. Then, our definition of such a glass is:

Alternative definition 3: *a solid assembly of vertex-sharing tetrahedra lacking long-range order.*

We are concerned only with ceramic glass, but you should know that there are metallic glasses and polymer glasses. How metallic glasses are formed gives a clue as to why they exist: they have complicated compositions to “frustrate” crystallization when they are quenched quickly from the melt (a process known as splat quenching). For the same

reason, glycerin can be a glass below -90°C . With this *understanding* in mind, we can discuss the basic features of glasses.

21.1.1 Structure

Glasses are essentially noncrystalline (or amorphous) solids often obtained by freezing supercooled liquids. Long-range order (LRO) in the atomic arrangement does not exist over distances greater than, say, 1 nm. The regular arrangement resulting from the distribution over long distances of a repeating atomic arrangement (unit cell), which is characteristic of a crystal, is missing. There is often evidence of a short-range order (SRO) in glasses, which corresponds to the atomic arrangement in the immediate vicinity of any selected atom. Numerous attempts have been made to explain the formation or the nonformation of glasses. We have two basic approaches.

- Consider the structure
- Consider the kinetics of crystallization

In the first case, we examine the geometry of the constituent entities that make up the glass, the nature of the interatomic bonds, or the strength of the bonds. In the second, we consider how the liquid transitions to a solid as the temperature drops below the melting point.

21.1.2 Glass Transition Temperature

We consider a plot of specific volume as a function of temperature, as shown in Figure 21.1. This is a form of time–temperature–transformation (TTT) diagram for a glass. On cooling the liquid from a high temperature, two phenomena may occur at the point of solidification, T_m .

- If the liquid crystallizes, there is a discontinuous change in V and a discontinuity in the rate of cooling (associated with the heat of crystallization).
- If no crystallization occurs, the liquid passes into a supercooled state and V decreases at about the same rate as above T_m .

At the glass transition temperature, T_g , the slope of the curve decreases to become close to that of the crystalline solid. This break in the cooling curve marks the passage from a supercooled liquid to a glass. Below T_g , the glass structure does not relax very fast because it is now a solid. In the region of T_g , the viscosity is about 10^{13} dPa·s. The expansion coefficient for the glassy state is usually about the same as that for the crystalline solid. If slower

FIGURE 21.1. Plot of volume versus temperature for a liquid that forms a glass on cooling and one that forms a crystalline solid. The glass transition temperature, T_g , depends on the cooling rate and is not fixed like T_M .

cooling rates are used so that the time for the structure to relax is increased, the supercooled liquid persists to a lower temperature, and the resulting glass may have a higher density, as shown in Figure 21.1.

The physics of glass examines the concept of fragility; this is actually a property of glass-forming liquids above T_g and is a measure of the strength of the interatomic bonding. We talk about water dissolving glass or glass containers for

water; what is less well known is that you can freeze water into the glassy state by quenching it in liquid ethane. It is a fragile glass, but it is thought that most of the water in the universe exists in this state!

21.2 HISTORY

In Chapter 2, we gave a brief history of glass. We expand on that discussion here. Glass, like flint, is intimately connected with human history because of the use of obsidian, which is a natural glass. Nobody knows for sure when the first glass objects were made. The oldest finds date back to $\sim 7,000$ BCE or possibly even earlier. Methods of

FIGURE 21.2. Glass head of a pharaoh (believed to be Amenophis II) as a Sphinx (1,400–1,390 BCE). It was made by lost-wax casting and is ~3.2 cm high.

FIGURE 21.3. Core-formed bottle shaped like a multi-fish (1,390–1,336 BCE). This example is unusual because it is in polychrome glass. The length is ~14.5 cm.

manufacturing glass for its own sake, not just as a glaze for pots, had already been discovered in Mesopotamia by approximately 4,500 BCE. The use of glass as the glaze in pottery dates back even earlier.

Around 3,000 BCE, Egyptian glassmakers systematically began making pieces of jewelry and small vessels from glass. Glass had both a functional and a decorative role. Pieces of glass jewelry have been found on excavated Egyptian mummies; an example is the turquoise blue glass figure shown in Figure 21.2. By about 1,500 BCE, Egyptian glassmakers during the reign of Tuthmosis III had developed a

technique to make usable hollowware. A most striking example is the core-formed bottle in the shape of a *bulti*-fish, shown in Figure 21.3. This vessel was made between 1,352 and 1,336 BCE and was believed to be used for holding scented oil (based on the narrowness of the neck). The wave pattern is very typical of core-formed objects and was made by drawing a sharp object along the softened glass.

The Roman author Pliny the Elder (23–79 CE) explained the invention of glass in his encyclopedia *Naturalis Historia*

There is a story that once a ship belonging to some traders in nitrum put in here [the coast of modern Lebanon] and that they scattered along the shore to prepare a meal. Since, however, no stones for supporting their cauldrons were forthcoming, they rested them on lumps of nitrum from their cargo. When these became heated and were completely mingled with the sand on the beach a strange liquid flowed in streams; and this, it is said, was the origin of glass.

Nitrum is a naturally occurring soda, an important ingredient in both ancient and modern glasses. The ashes of plants also provided the glassmaker with a rich source of sodium. The plants saltwort and glasswort (known as halophytes) were both used to supply sodium.

Aside: Gerard’s Herbal (1633) says that “saltwort was called Kali by the Arabians”: hence the word *alkali* and the ashes are called *soda*.

One of the most common methods used to form glass is glassblowing. Although this technique was developed over 2,000 years ago, the glassblowing pipe has not changed much over that time. The main development that has been made in glassblowing is the automated blowing processes that are used to produce glass containers and light bulbs and the technique of blowing the glass inside a mold. Most of the important milestones in the history of glass, particularly in the twentieth century, are associated with developments in manufacturing technology. These developments have led to the low-cost production of commercial glasses (e.g., window glass) and the use of glass in new applications, such as optical fibers.

Many of the topics summarized here have been rediscovered many times. Now we have the tools, but we can see that nature often preempted humans.

21.2.1 Ancient History

- 50,000–1,000 BCE—Glass used in potter’s colored glazes.
- 7,000–1,500 BCE—Ancient glass artifacts (possibly as early as 10,000 BCE).
- 2,600 BCE—Earliest actual dated glass.
- 1,500 BCE—Egyptians manufacturing glass articles.
- 1,200 BCE—Earliest glass molding.
- 100 BCE—Blown glass invented with the glassblowing pipe (Romans in Syria).
- c100 BCE—In Alexandria, the introduction of manganese oxide into the glass composition together with improvements in the glass-melting furnaces enabled the first successful production of colorless glass.
- 450 CE—Stained glass used.

21.2.2 Beginning to Engineer Glass

- 1200s—In Germany, a new process was developed to make mirrors. The back of a piece of flat glass was coated with a lead-antimony layer to produce a quality (“silvered”) mirrors. The mirror format remains essentially unchanged today.
- 1268—Eyeglasses described by Bacon. They had convex lenses for the correction of near sightedness.
- 1291—Murano, a small island near Venice, became a glass center. Glass workers on Murano were generally not allowed to leave the island.
- c1590—The first telescope lenses were made in Italy and later, in 1604, in The Netherlands.
- 1609—Glass was made in Jamestown (Virginia, USA).
- 1612—Publication of the textbook *L'Arte Vetraria* by Antonio Neri in Pisa. The first systematic account of the preparation of the raw materials for glassmaking.
- 1676—George Ravenscroft, an English glassmaker, developed lead-crystal glass (also known as flint glass). The addition of lead oxide to the glass formula yielded a glass of high brilliance and a pure ring. It's not crystal, but it does contain a lot of lead and it's heavy.
- 1688—Bernard Perrot, a glassmaker in France under Louis XIV, invented the plate-pouring process. This process allowed mirrors with a large surface area to be produced. Examples are the magnificent wall of mirrors in the Galerie des Glaces at Versailles.
- Late 1700s—Joseph von Fraunhofer (1787–1826), a German mirror maker and student of glassmaking technology, produced optical quality glasses for telescopes and microscopes. (Fraunhofer diffraction and the Fraunhofer Institutes are named in his honor).

21.2.3 Modern “Times”

- 1857—William Clark of Pittsburgh patented a sheet-drawing process: a plate glass.
- 1861—A British patent was granted to C.W. and F. Siemens. Their patent included a discussion of the application of the principle of regeneration to glass melting. Regenerative heating is still used in glass-melting furnaces today.
- 1865—A U.S. patent was issued for a press-and-blow process.
- 1875—Corning Glass Works was incorporated. The company was founded by Amory Houghton Sr. (1812–1882) and was named after the town in upstate New York where it is still located. Houghton already owned the Brooklyn Flint Glass Works but moved to Corning because real estate was cheaper.
- 1881—Thomas Edison brought out his first incandescent electric lamps using glass bulbs made by the Corning Glass Works.
- 1884—Otto Schott (1851–1935), Ernst Abbe (1840–1905), Carl Zeiss, and Roderick Zeiss establish the Glastechnisches Laboratorium Schott und Genossen, which later became the Jenaer Glaswerk Schott und

Gen and in 1952 the Schott Glaswerke. In 2006, this company was the leading European glass company.

- 1893—The Enterprise Glass Company in the United States develops a press-and-blow mold that led to the wide-spread production of wide-mouth containers.
- 1903—The automatic bottle-blowing machine invented by the American Michael Owens (1859–1923) began production. A machine for drawing large cylinders of glass that were then flattened into window glass was developed by another American, John Lubbers.
- 1913—Emile Fourcault, a Belgian, developed a flat-glass machine for commercial operation.
- 1917—Edward Danner at the Libbey Glass Company introduced an automatic method for tube making. The company remains in operation today and is the largest manufacturer of glass dinnerware in the United States.
- 1926—The Corning ribbon machine for high-speed automatic production of glass light bulbs was developed.

21.2.4 Present Technology

- 1957—Corning introduced the Pyroceram® brand of glass-ceramics.
- 1959—Sir Alastair Pilkington's float process for producing flat glass worked.
- 1960—Glass-ceramics was patented by S. Donald Stookey of Corning Glass Works.
- 1966—Optical fibers were developed.
- 1975—Glass recycling became accepted/required.
- 1980—Acid-leaching process was introduced for producing 99.6–99.9% silica fibers that resist devitrification up to 1,370°C. These fibers were used as insulation for the space shuttle.
- 1991—Schott produced an 8.2-m diameter telescope blank from their glass ceramic ZERODUR®, which had been introduced in 1968.
- 1997—Corning produces glass for the Subaru Telescope mirror. Weighing 27 t and measuring more than 26 ft across, it is one of the largest pieces of glass ever made.
- 2001—Pilkington introduces the first “self-cleaning” window glass—Activ™. It has a photocatalytic TiO₂ coating applied.
- 2009—Corning produces Gorilla® glass that is used in most smartphones. The glass has a high compressive strength.

New and improved methods for processing glass are being developed. One of the main thrust areas for these activities is our concern for the environment. Reducing energy costs and reducing polluting emissions are important in the modern glass industry.

21.3 VISCOSITY, η

Viscosity is a key property of glass. We need to know its viscosity at different temperatures so it can be formed, shaped, and annealed. The concept of viscous flow was

TABLE 21.1 Viscosity Values for Glass Processing

Viscosity (dPa·s)	Example
$10^{1.5}-10^{-2.5}$	ASTM melting
$10^{3.7}-10^{3.8}$	Casting plate glass
$10^{3.8}$	Seal glass to metal
$10^{5.3}$	Begin updrawing or downdrawing
10^6	Sinter glass powder to produce a porous body
10^8	Sinter glass powder to produce a solid body
$10^{11.3}-10^{11.7}$	Glass deforms under gravity
$10^{12.7}-10^{12.8}$	Practical annealing range (stress relief in seconds)

described (and illustrated) in Chapter 17 because this is the process by which permanent deformation occurs in glasses. Viscosity is a mechanical property. Consider the tangential force, F , required to slide two parallel plates a distance d apart past one another when they are separated by a layer of viscosity, η .

$$\eta = (Fd)/(Av) \tag{21.1}$$

where A is the common area, and v is the velocity of the planes relative to one another. Essentially, then, viscosity is a measure of the liquid’s response to shearing. Liquids have viscosities measured in centipoises (cP), and gases have viscosities measured in micropoises (μ P). In the SI system, we would say that liquids have viscosities in millipascal-seconds (mPa·s), and gas viscosities are tenths of micropascal-seconds (μ Pa·s) (so we stick with the poise).

Table 21.1 lists some of the viscosity values that are important for glass processing. The values given in Table 21.2 are used to define certain characteristics of a glass (again with an emphasis on processing). Many of the values listed in this table of viscosities are “standards.” For example, ASTM C338-93(2003) is the “Standard Test Method” for determining the softening point of glass.

Determine the softening point of a glass by determining the temperature at which a round fiber of the glass, nominally 0.65 mm in diameter and 235 mm long with specified tolerances, elongates under its own weight at a rate of 1 mm/min when the upper 100 mm of its length is heated in a specified furnace at the rate of 5°C/min.

The viscosities of some common liquids are given in Table 21.2 for comparison. Notice that at the working point the glass has a viscosity similar to that of honey at room temperature. For a typical soda-lime-silicate flat-glass composition, this viscosity is achieved in the temperature range 1,015–1,045°C. The other key reference value to remember is that a solid has a viscosity of $>10^{15}$ dPa·s.

TABLE 21.2 Viscosity “Milestones”

Viscosity (dPa·s)	Example
10^{-2}	Water at 20°C
10^0	Light machine oil
10^1	Heavy machine oil
10^2	Olive oil at 20°C
10^4	Runny honey at 20°C. Some measure it to be 10^2 dPa·s
10^4	Glass at its <i>working point</i> . Begin working at 10^3
$10^{7.6}$	<i>Shortening point</i> (deforms under its own weight; softening at $10^{7.7}$)
10^8	Upper limit for low viscosity
10^{13}	<i>Annealing point</i> (ASTM)
$10^{13.4}$	Glass at T_g
$10^{14.6}$	The <i>strain point</i> of glass (ASTM)
$>10^{15}$	Solid
10^{16}	Upper limit for measuring viscosity

The shortening point is also called the softening point.

The viscosity of glass varies dramatically with temperature, as shown in Figure 21.4A for various silicates. The fictive temperature, T_f , is the temperature at which the liquid structure is frozen into the glassy state and is defined by the crossing of the extrapolated curves from high and low temperatures on the η against T plot.

The fictive temperature such as T_g is related to structural transformations in glass; T_g is slightly lower.

Figure 21.4B shows the temperature dependence of viscosity for the main glass-forming oxides as a function of temperature. You can notice that from the slope of these lines we can obtain the activation energy for viscous flow, E_v (see Section 17.13). Table 21.3 some gives some values for η and some measured crystallization velocities, v . The latter term refers to the rate of movement of the solid/liquid interface. The very low v for SiO₂ is indicative of its excellent glass-forming ability: it is very difficult to crystallize a solidifying melt of SiO₂.

There are several methods for measuring viscosity—which one is used depends on the expected value of the viscosity.

Mergules viscometer	$\leq 10^7$ dPa·s
Fiber elongation	$\leq 10^7-10^9$ dPa·s
Beam bending	$\leq 10^9-10^{14}$ dPa·s

Figure 21.5 illustrates the first two approaches to measuring η . The viscometer is used for low viscosities, and the method is similar to the concentric cylinder viscometer used to determine the sol-gel transition that we describe in Chapter 22. The spindle is rotated at an angular velocity, ω , and the resistance to its motion is measured.

VISCOSITY & POISE

If a force of 1 dyn is required to move an area of 1 cm² of liquid or gas relative to a second layer 1 cm away at a speed of 1 cm/s, then the viscosity is one P (poise).

$1\text{P} = 1\text{dPa}\cdot\text{s}$

FIGURE 21.4. (A) Viscosity as a function of temperature (T) for several silicate glasses: units of η are dPa·s. (B) Viscosity as a function of temperature ($1/T$) for the main glass-forming oxides. Notice the effect that a small amount of water has on the viscosity of silica glass.

TABLE 21.3 Crystallization Velocities and Viscosities of Glass-Forming Liquids				
Glass	T_M (°C)	v_{max} (cm/s)	Temp. for v_{max} (°C)	$\text{Log } \eta$ at T_M (dPa·s)
Vitreous SiO_2	1,734	2.2×10^{-7}	1,674	7.36
Vitreous GeO_2	1,116	4.2×10^{-6}	1,020	5.5
P_2O_5	580	1.5×10^{-7}	561	6.7
$\text{Na}_2\text{O} \cdot 2\text{SiO}_2$	878	1.5×10^{-4}	762	3.8
$\text{K}_2\text{O} \cdot 2\text{SiO}_2$	1,040	3.6×10^{-4}	930	
$\text{BaO} \cdot 2\text{B}_2\text{O}_3$	910	4.3×10^{-3}	849	1.7
$\text{PbO} \cdot 2\text{B}_2\text{O}_5$	774	1.9×10^{-4}	705	1.0

FIGURE 21.5. (A) Instruments used to measure viscosity. (A) Viscometer. (B) Fiber elongation method (Source: From Orton website The molten-glass viscometer).

For higher viscosities the fiber elongation method is used. A load is attached to a glass fiber, which can be heated to a range of temperatures. The strain rate of the fiber as it elongates is then measured.

21.4 GLASS: A SUMMARY OF ITS PROPERTIES, OR NOT

We can summarize what we *know* about glass—and probably be wrong.

Glass is inert. This depends on the environment. It's nearly true if the glass is a silicate and essential if it is going to contain radioactive waste; but not all glasses are inert. Bioglass[®] is designed not to be inert.

Glass is homogeneous. This depends on how the glass was formed and its composition. We can process glass to make it inhomogeneous.

Glass can be reshaped. This is generally true and is the reason why glass is so recyclable. Some glasses are designed so that they can be modified by light, by diffusion, by irradiation, etc.

Glass has a small expansion coefficient. This is usually true, but not all glass is Pyrex[™].

Glass is transparent. This is essential for optical fibers, but we can make it translucent or opaque (see Figure 21.2). Most early glasses were not very transparent because they contained impurities and inclusions.

Glass is cheap. This has been true for window glass since the invention of the float-glass process. Thin films may be expensive. Some glass is colored red by doping it with Au. Some vases can cost >\$50,000.

Glass is a bulk material. This is true unless we grow it as a thin film, or it is present as an intergranular film (IGF) or is a pocket in, or on, a crystalline ceramic.

Hence, the lesson is: beware of your preconceived ideas when thinking about glass.

The mechanical, optical, thermal, and electrical properties of glasses are discussed in detail, along with other ceramics, in these topical chapters. Here, we just give you some things to think about in relation to glass.

21.4.1 Some Mechanical Properties of Glass

The theoretical strength of silicate glass is around 10 GPa (using the criterion given in Section 18.2), but this is usually much reduced by the presence of surface flaws (cracks and seeds). Glasses are elastic but break in tension. They can be strengthened by creating a compressive surface layer (by ion exchange or tempering) or by removing the surface flaws (acid-polishing or applying a protective coating). Prince Rupert's drops are an interesting and entertaining illustration of the effect of residual stress on the mechanical properties of glass. Small gobs of molten glass are dropped into cold water to form tadpole-shaped drops. The surface cools much more rapidly than the surface creating internal residual stresses and a very high surface tension. The solidified drops can be hit with a hammer without breaking. But if the tail is broken off the entire drop shatters into powder.

21.4.2 Some Electrical Properties of Glass

Glass usually has a high electrical resistivity because of the large band gap energy (see Chapter 30). In cases where they are conductive, the charge is carried by ions, with alkali ions (e.g., Na^+) being the fastest. Thus, conductivity increases significantly as T is increased; and it is different for silicate glasses, borate glasses, and phosphate glasses because the glass network is different in each. The mixed alkali effect is an interesting phenomenon that occurs in glasses that contain more than one different alkali ion. The resulting conductivity has been found experimentally to be significantly lower than what you would expect from simply adding their individual conductivities. This has application in, for example, high-wattage lamps.

The dielectric constant of glass is quite high but not high enough for some advanced memory applications such as dynamic random access memories (DRAMs) (see Chapter 31). The capacitance is a measure of the amount of charge stored and is related to the thickness of the dielectric. As the layer gets thinner the capacitance increases, but electrical breakdown can occur. SiO_2 glass

has a high dielectric strength, but it's not as high as some polymer dielectrics, (e.g., phenolic resin).

21.4.3 Some Optical Properties of Glass

Transmission in the ultraviolet (UV), visible, and infrared (IR) depends on several factors including Rayleigh scattering, which is determined by impurities. The IR edge and the UV edge are the values where transmission of these frequencies cut off. A UV edge blocker removes the UV, and a UV edge transmitter allows it through.

Refraction depends on the refractive index and on dispersion. Reflection, which occurs at the surface, can be internal. Because the optical properties of glass are so important, a lot of Chapter 32 is devoted to this topic.

21.4.4 Some Thermal Properties of Glass

Expansion coefficients of glass are generally smaller than for metals, but often we want to make the connections to metals. For example:

Glass-to-metal seals: an obvious important technological process.

SiO_2 : metal-insulator junctions for the electronics industry.

Graded seals: for example, a graded seal structure can be constructed by joining a series of glass pieces, each of which has a slightly higher thermal coefficient of expansion (α).

Thermal conductivity is ~1% of that of a metal. The implications and applications of this fact are obvious.

21.5 DEFECTS IN GLASS

The idea is that although glass does not have a crystalline matrix, it can still contain point defects and precipitates, undergo segregation, and contain internal interfaces. Glass can be used to trap radioactive elements as point defects or as a "second phase." The future value of this capability depends in part on how fast components can diffuse through glass. This applies to whether the radioactive material is diffusing out or other components are diffusing in (perhaps to leach out the trapped material).

21.6 HETEROGENEOUS GLASS

Just because glass is a "supercooled" liquid doesn't mean it must be homogeneous. Certain glasses can separate into two phases, which need not be a crystallization process. When these two phases are both glassy, there may be no barrier to the separation (a spinodal decomposition), or as

in the case of liquid/liquid phase separation there may be a nucleation step. In either case, diffusion is important.

The principle of immiscibility in glass is very important to today's technology. For example, immiscibility plays a role in forming glass-ceramics, making Vycor[®] and opal glass, and precipitation in glass. Many of the binary and ternary oxides with silica as a component show miscibility gaps. A miscibility gap is a region in the phase diagram where a liquid separates into two liquids of different composition (see Section 8.11). The following are examples of systems exhibiting this effect.

Figure 21.6 shows the silica-rich side of the phase diagram for several $\text{SiO}_2\text{--R}_2\text{O}$ systems. In the low-T corner of the diagram, one liquid phase separates into two chemically distinct, different liquid phases below the immiscibility dome. For the $\text{SiO}_2\text{--K}_2\text{O}$ system, the dashed line represents the estimated region of immiscibility. The difficulty in making these measurements is that phase separation occurs at lower T, where the kinetics are slower. There is an interesting comparison with crystallization. Phase segregation may be energetically

less favorable than crystallization, but it is easier to accomplish because it requires only the segregation, not the correct rearrangement of the atoms.

As a general rule for silica, immiscibility is increased by the addition of TiO_2 , but decreased by the addition of Al_2O_3 .

The Vycor process described in Chapter 8 uses the principle of phase separation. The resulting glass is 96% SiO_2 and 4% pores, which is used as a filter and a bioceramic where porosity is important. It can be densified (after shaping) to allow processing of a pure SiO_2 shape at a lower T than for pure quartz glass.

21.7 YA GLASS

Yttrium–aluminum (YA) glasses can be formed in the composition range ~59.8–75.6 mol% Al_2O_3 . With 59.8–69.0 mol% Al_2O_3 , a two-phase glass forms with droplets of one phase in the other. The glass can spontaneously crystallize to form YAG or a mixture of Al_2O_3 and YAIO_3 (YAP, where P represents perovskite). These YA glasses show a phenomenon known as polyamorphism, meaning that they exist with different amorphous structures.

21.8 COLORING GLASS

Although many applications for glass require a colorless product, others require colored glass. Windows in a church do not look as impressive when all the glass is colorless. Glass is often colored by adding transition-metal oxides or oxides of the rare-earth elements to the glass batch. Table 21.4 lists the colors produced by some of the common glass colorants. We look at how these additives result in the formation of color in Chapter 32, but at this stage you should already know why glass bottles are often green. Bright yellow, orange, and red colors are produced by the precipitation of colloids of the precious metals. Au produces a ruby red coloration, but it is not cheap. CdS produces a yellow coloration, but when it is used in conjunction with Se it produces an intense ruby red color.

The questions are:

- How does coloring “work”?
- What causes the colors?
- Is it the same as for crystals?

Glass is intentionally colored by adding dopants (we are creating point defects in the glass). The color of the glass depends on the dopant and its state of oxidation. The explanation is the same as for coloring crystals; but because the glass structure does not have LRO, the absorption spectra can be broader.

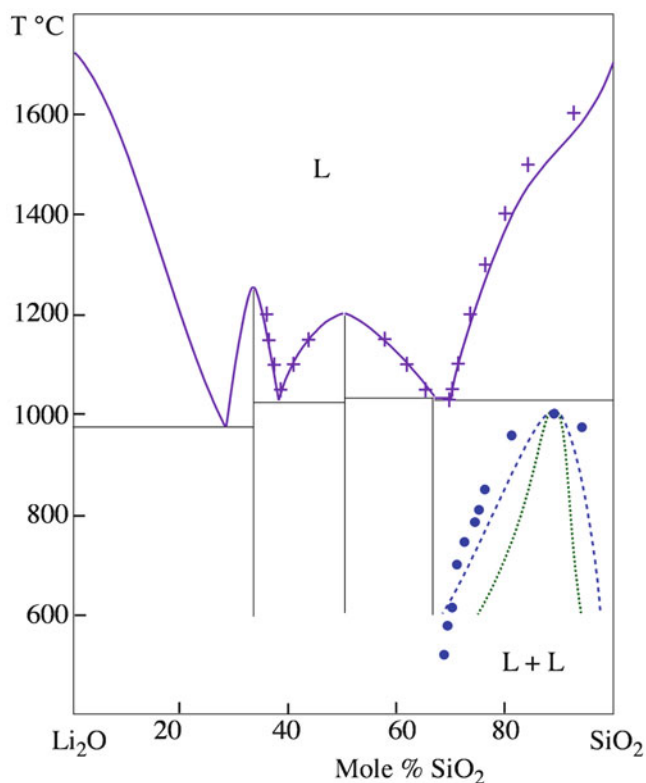

FIGURE 21.6. Regions of liquid–liquid immiscibility for various silicates of the form $\text{SiO}_2\text{--R}_2\text{O}$. Notice that we are only showing the silica-rich end of the phase diagrams.

Combinations of dopants can decolorize, mask, or modify the effect. For example, we can compensate the coloring effect of Fe by adding Co; if too much Cr^{3+} is added, Cr_2O_3 can precipitate out. When the glass is blown, these platelets of Cr_2O_3 can align to give “chromium aventurine.” Cu was used to produce Egyptian blue glass. Co is present in some twelfth century stained glass and, of course, was used in the glazes on Chinese porcelains in the Tang and Ming dynasties. The color it produces is known as cobalt blue.

In a CdS-doped glass, adding more Se can result in “Selenium Ruby.” The details of all these colorings depend on just what glass batch is used and the firing conditions.

Corning makes microbarcodes (i.e., very small barcodes) by doping glass with rare earths (REs); the REs have particularly narrow emission bands. Of 13 RE ions tested, four (Dy, Tm, Ce and Tb) can be excited with UV radiation used in fluorescence microscopy but don’t interfere with other fluorescent labels. These microbarcodes can be used for biological applications since they are not toxic; tags using quantum-dots may be less benign. These bar codes can even label genes. The REs can be used together to give more color combinations.

Some special colored glasses:

Ruby and cranberry glass. Ruby glass is produced by adding Au to a lead glass with Sn present. Cranberry glass is paler (usually a delicate pink) because it contains less gold. It was first reported in 1685. The secret of making red glass was lost for many centuries and rediscovered during the seventeenth century.

Vaseline glass or uranium glass. Uranium produces a deep red when used in high-Pb glass. There are other uranium-containing glasses: the so-called “uranium depression ware” glass (also called Vaseline glass), which has a green color. True “depression ware” is actually greener than Vaseline glass because it contains both iron and uranium oxides. What is special is that the glass actually fluoresces when illuminated with UV radiation (Vaseline ware more strongly because of the higher uranium concentration). Since 1940 or so, only depleted uranium has been used as a dopant, and it is quite plentiful; but for the previous 100 years, natural uranium was used. Figure 21.7 shows an example of Vaseline ware.

FIGURE 21.7. Example of Vaseline ware produced by coloring with uranium.

FIGURE 21.8. Examples of phosphate laser glass. Individual laser rods vary from 0.6 to 1.2 mm in diameter.

with a charge voltage of ~ 4 kV, giving a pulse duration of ~ 0.8 ms. The Nd:glass laser gives efficiencies up to 2%, which is four times that of the ruby laser, and the Nd:glass rod can be made even bigger. The thermal conductivity of the glass is lower, so it requires more time to cool between firings.

21.9 GLASS LASER

Rare-earth elements (e.g., Nd) are used to dope glass to create lasers and other optical devices (Figure 21.8). The Nd-doped glass laser works like the ruby laser but has some differences, which relate to the glass. The laser rod is about $\frac{1}{4}$ – $\frac{1}{2}$ in. diameter and usually pumped by a helical lamp to give a longer discharge length than from a linear lamp. The energy is stored in a capacitor (e.g., 500 mF)

21.10 PRECIPITATES IN GLASS

Precipitation in glass is generally inevitable given time. The question is only how long it requires to occur, especially if nucleation is homogeneous (i.e., no seeds are present). We may introduce seeds to produce particular effects. Nucleation of crystals in glass follows the classic theory. We examine the topic more in Chapter 26 and see there that precipitates can also cause the coloring of glass.

21.11 CRYSTALLIZING GLASS

We address processing these materials in Chapter 26. Here we explain what a glass-ceramic is and relate it to other two-phase ceramics. We can crystallize a droplet of glass, as shown in Figure 21.9, or a complete film, as shown in Figure 21.10. We can also crystallize a bulk object almost completely to produce a glass-ceramic. The basic idea is that there is sometimes a great advantage in processing a ceramic as a glass but producing the finished object as a polycrystalline body.

Opal glass has a milky (opalescent) appearance caused by the formation of small crystallines. Even window glass crystallites; given time it devitrifies to form devitrite.

FIGURE 21.9. Example of crystallization in a glass droplet.

FIGURE 21.10. Spherulitic crystallization of an amorphous SiO_2 film on SiC. Spherulites are cristobalite.

The visible light microscopy (VLM) image shown in Figure 21.11 illustrates the growth of perfectly symmetric individual crystals inside a glass matrix. The crystals and the matrix are all transparent, so the full shape can be appreciated. The scanning electron microscopy (SEM) images in Figures 21.12 and 21.13 show that the glass and crystal appear very different even on a fractured surface. Breaking a sample can quickly reveal a “grain” size down to $\sim 0.1 \mu\text{m}$. To probe the structure on a near-atomic level with high spatial resolution, TEM can be used, as shown in Figure 21.14; but its use has been limited, in part because of the difficulties of preparing the TEM sample: the thickness of the sample tends to be greater than the dimensions of the crystalline phase.

FIGURE 21.11. Visible light microscopy image showing crystallization in a glass.

FIGURE 21.12. Scanning electron microscopy (SEM) of crystallized glass. The glass is a binary Li-Be fluoride opal glass 40 mol% LiF, 60 mol% BeF₂ containing small amounts of Ag and Ce (0.001 and 0.01 mol%, respectively). The glassy droplets (BeF₂-rich) are surrounded by crystallized matrix.

FIGURE 21.14. Transmission electron microscopy shows crystallization on a nanometer scale in a lithium aluminum silicate (LAS) glass-ceramic.

FIGURE 21.13. SEM images of (A) Na-Be and (B) K-Be fluoride glass 15 mol% KF (or NaF), 85 mol% BeF₂. This glass is cloudy; if the droplets were smaller, the glass would be clear. Replacing K by Rb actually reduced the droplet size to 10–20 nm.

21.12 GLASS AS GLAZE AND ENAMEL

Glazes are everywhere, just as glass is. In this section, we summarize the topic of complete books, namely the glazes on pottery and enamels. Glazing uses the viscous properties

of glass to form a (usually) smooth continuous layer on a ceramic substrate (a pot); enameling does the same thing for a metal substrate. One thing that you may notice is that generally when it comes to ceramics potters did it first. The science of ceramics is often still unraveling just what they did. (In materials science, ceramists usually did it first).

FLUX AND MODIFIERS

The flux in a glaze is a modifier in glass. The clear glaze is glass: i.e., silica and alumina with added modifiers. The clear glaze may contain lead but Pb should not be used for modern food containers. Strong colored glazes also often contain heavy metals.

First, we summarize some terms in pottery. (The processing of pottery was summarized in Chapter 2).

Underglaze. When a pot—white bisqueware (also called biscuit) is ideal—is decorated, the first coating is the underglaze. This is essentially a paint layer made by mixing oxide, carbonate, sulfate, etc., an opacifying agent to make it opaque, and a flux to make it adhere better to the pot. The mixture is calcined, ground, and then usually combined with a liquid to allow smooth application. The decorated pot is then typically coated with a clear glaze before it's fired. In the majolica technique, the pot is coated with an opaque white glaze first, then decorated, and fired so that the colors bond to the white coating, forming an in-glaze (rather than under-glaze) decoration.

Glaze crawling. The glaze separates from the underlying pot—it dewets the pot surfaces during firing.

Crackle glazes. If the α of the glaze is greater than that of the underlying ceramic, the glaze may fracture as

it cools; this crackling can easily be achieved using higher concentrations of Na or K in the glaze. In most technological applications, this is not desirable. Some glazes, however, are designed to have a pattern of hair-like cracks for the artistic effect; they are known as crackle glazes. Fast cooling produces a finer pattern of glazes.

Celadon, tenmoku, raku, and copper glazes are particular glazes that you find in the ceramics art world.

Celadon glazes (first produced 3,500 years ago) vary from light blue to yellow-green and can be quite dark. The color is produced by iron (0.5–3.0 wt% Fe_2O_3 added to the glaze). The glazed pot is then fired a second time at about 1,300°C. An example of Korean celadon pottery is the small water container, 23 cm tall, given to former U.S. President Harry Truman in 1946 by the government of Korea. It is now valued at \$3M.

Tenmoku glaze (from the Sung Dynasty) is dark brown or even black; 5–8 wt% Fe_2O_3 is included in the glaze to produce the effect. An interesting variation of the tenmoku glaze is the oil-spot tenmoku, where bubbles begin to form in the glaze as it starts to melt; if the potter catches them just in time, they leave spots all over the surface. If a tenmoku glaze is fired in reducing conditions, the Fe_2O_3 is partially reduced to FeO , which acts as a modifier instead of an intermediate, in glass terms. Hence, this glaze behaves differently under oxidizing and reducing conditions, and the color changes. Copper glazes may use 0.5 wt% CuCO_3 as the Cu source, but it breaks down to give CuO during firing, and this reacts with CO in the furnace to give particles of Cu in the glaze. These particles of Cu give the red color.

Raku glazes often appear metallic as if produced by coating with Ti metal. One modern method of raku glazing involves firing the pots in the usual way and then plunging them into a reducing environment (e.g., sawdust) and then quenching them before they can oxidize. These glazes are often the exception to the rule in that they can change with time. This is simply because they oxidize when treated as other pots. The glaze is thus not as inert as others and is used only for decoration. (However, see the historical note on Chojiro Rakuyaki).

Crystalline glazes. These are decorative glazes but are directly related to the formation of technologically important glass-ceramics. The crystals form by slowly cooling the glaze to allow a few large crystals to grow. The growth is interesting because the glaze is typically only ~0.5 mm thick and the crystals must therefore form as platelets. A seed of TiO_2 is usually used to nucleate the crystal in a low-viscosity glaze, giving what is termed “rutile breakup,” which is actually the formation of PbTiO_3 . The chemistry of the glaze is thus important, with SiO_2

FIGURE 21.15. Spherulitic crystallization in a glass.

SPHERULITES

Dana described spherulites in obsidian in 1863; these are the snowflakes in snowflake obsidian. In 1879 Rutley noted that artificial glass may develop a spherulitic structure.

and Al_2O_3 being low and PbO at 8–10 wt%. The growing crystal tends to incorporate Fe from the glaze but can also preferentially exclude other dopants.

Modern potters tend to use Zn as the modifier and produce willemite

crystals. [Willemite is a somewhat rare zinc mineral (except as kidney stones) but is abundant at Franklin, New Jersey]. The technique is tricky because the addition of large amounts of Zn (a network modifier) to the glaze causes its viscosity to remain low even at low temperatures, so that it tends to run off the pot! The crystals appear to grow out from a seed as in the spherulitic growth seen by VLM in Figure 21.15. Each spherulite is actually a mass of radiating crystals that are similarly aligned with respect to the center of the spherulite.

Opaque glazes. If crystals are added to the molten glaze, it can be made opaque. SnO_2 was long the standard, but zircon is much cheaper. ZnO_2 is used to make zircon glazes white. TiO_2 is less used because larger rutile crystals are a golden color and thus make the glaze yellow. We can also make the glaze opaque by forming crystals (e.g., wollastonite; CaSiO_3) using a suitable thermal treatment, by trapping gas (F_2 or air), or by causing a liquid/liquid phase separation.

Matt glazes are produced by forming very small crystals—e.g., wollastonite for a “lime matt” or willemite (Zn_2SiO_4) for a “zinc matt”—across the surface of the glaze. The wollastonite can be formed by adding calcite (also known as whiting) to an SiO_2 -based glaze. An alternative is to add so much crystalline material to the glaze that it remains unchanged by the firing. A satin or vellum glaze, with smaller crystal sizes, might contain 18% SnO_2 or ZnO and 4% TiO_2 in a high-lead glaze fired at 1,000°C.

FIGURE 21.16. Example of glaze color produced by nanoparticles.

Color in glass and glaze is the subject of much active research, with the realization that some colors are produced by nanoparticles in the glass/glaze as for the luster-glazed plate in Figure 21.16. In general, Ag and Au nanoparticles produce the gold color, and Cu nanoparticles produce the red; in the case of Cu especially, the ions may be reduced to the metal during processing. Explanations for the color of glazes is actually more complicated than for glass because the glaze is supported by a substrate and does not have to be transparent; so it can be a thin film or a multilayer and fired in a reducing or oxidizing environment. This is a very big topic being condensed into a paragraph! Cipriano Piccolpasso described luster preparation in 1557. Who says the use of nanomaterials is new!

Colored glazes must use stable ceramic pigments if the color is to be consistent over repeated batches (e.g., for industrial production of sanitaryware, tiles). You can use cheaper metal oxide colorants when variability is acceptable or desirable, as in the pottery crafts. Of course, many glaze colorants are the same as we use for coloring glass (see Table 21.4). Co_3O_4 is a black powder but <1% gives a glaze a deep blue color, although it is usually added as the carbonate. Because Co^{2+} is present when it dissolves, it changes the viscosity of the glaze. Cr_2O_3 (2–3% can be added but only 1.5% dissolves in the glaze) is intriguing because you expect green but can produce red, yellow, pink, or brown. The red can occur if Pb is present in the original glaze; if Zn is present, the glaze becomes brown unless Pb is also present, when the glaze becomes yellow. MnO_2 (added as the carbonate) gives a brown glaze but can produce red, purple, or even black; the color depends in part on how much Na is

TABLE 21.4 Colors Produced by the Inclusion of Different Ions in a Glass

Copper	Cu^{2+}	Light blue (red ruby glass for Cu nanoparticles)
	Cu^+	Green and blue (includes turquoise blue)
Chromium	Cr^{3+}	Green
	Cr^{6+}	Yellow
	$\text{Cr}^{3+} + \text{Sn}^{4+}$	Emerald green
Manganese	Mn^{3+}	Violet (present in some Egyptian glasses)
	Mn^{2+}	Weak yellow/brown (orange/green fluorescence)
Iron	Fe^{3+}	Yellowish-brown or yellow-green
	Fe^{2+}	Bluish-green
	FeS	Dark amber (add C to reduce it)
Cobalt	Co^{2+}	Intense blue (especially if K^+ is present); in borates and borosilicates, pink
	Co^{3+}	Green
Nickel	Ni^{2+}	Grayish-brown, yellow, green, blue to violet, depending on glass
Vanadium	V^{3+}	Green in silicates; brown in borates
Titanium	Ti^{3+}	Violet (melting under reducing conditions)
Neodymium	Nd^{3+}	Reddish-violet
Praseodymium	Pr^{3+}	Light green
Cerium	Ce^{3+}	Green
	Ce^{4+}	Yellow
Uranium	U	Yellow (known as Vaseline glass)
Gold	Au	Ruby (ruby gold, Au nanoparticles)

present in the initial glaze. CuO is equally interesting: 1–2% added to an Na-rich glaze gives turquoise, whereas an up to 3% addition produces a clear green-blue. If even more CuO is added, the glaze can give a metallic appearance like pewter. If the glaze (0.3–2.0% CuO) is fired in a reducing atmosphere, the classic copper red is formed. This color is caused by the presence of colloidal Cu. If you see the bright yellow glaze, this might be the CdS/CdSe yellow (which also produces orange and red) glaze. If Pb is present, then PbS can form, which makes the glaze black. Zircon is used in industry to help stabilize these Cd-based colors. In fact, $(\text{V,Zr})\text{SiO}_4$ (vanadium zircon blue) and $(\text{Pr,Zr})\text{SiO}_4$ (praseodymium zircon yellow) are most important in the whitewares industry. Uranium is added to glazes but tends to produce a dark brown rather than the pale yellow found in Vaseline glass; it can be yellow or bright red-orange, but this depends on the glaze composition.

Salt glaze. The pot is reacted with salt in the furnace while at temperature. In practice, the potter actually throws salt over the pot when it is in the kiln. The technique was used by early potters in Iran and by the English in the 1700s. You can see many examples in Germany where a blue coloring is often produced using metal oxides. The salt reacts with the clay, forming a glass layer on the surface; essentially, the process is high-temperature soda corrosion of the fired clay.

The term *enamel* usually implies a glaze applied to a metal, but it can be a glaze applied on top of a glaze.

The market is large, varying from toilet fixtures (whitewares) to jewelry. Enamel is the ever-lasting paint with the organic component replaced by glass.

21.13 CORROSION OF GLASS AND GLAZE

We think of glass as being inert. Citric acid and acetic acid (present in lemon and vinegar, respectively) can chelate with metal ions present in a glass and form water-soluble complexes. (A chelate is a complex compound with a central metal atom attached to a large molecule, a ligand, in a ring or cyclic structure like the claw of a crab). The effect can actually be greater than for what we think of as stronger acids (sulfuric, nitric, and hydrochloric acids readily attack metals and skin). The Ca, Mg, and Al ions usually increase the chemical durability of a glass but react with these “food” acids. The tannic acid present in red wine and tea can have a similar effect. Thus, Pb can be released from glass when the glass is in contact with acid (even fruit juice). This means that we shouldn’t use Pb in glazes; however, it has often been done because such glazes can be so brightly colored.

Silicate glass is strongly corroded by hydrogen fluoride (HF). The process of “frosting” glass light bulbs was

carried out for many years by blowing HF vapor into the glass envelope and then evacuating it after a short period.

Glass dissolves in water, particularly at elevated temperature and pressure: we use this fact for growing all the quartz crystals used by industry. Dishwashers make glass dull. Roman glass (Figure 21.17) is iridescent because the glass has reacted with acid in the soil. (The iridescence was not present in Roman times.) The corrosion products form several distinct layers and hence generate the interference known as iridescence. It can easily be duplicated, as shown by Tiffany and others.

Not all glass is attacked equally readily. As we described in Chapter 8, we leach one component of a phase-separated glass during the preparation of Vycor but leave the other intact.

It is possible to minimize these reactions to some extent by adding inhibitors, such as Zr or Be, to the glass. This question of reactivity is closely related to the phenomenon of ion exchange.

H^+ can replace alkali ions when glass is weathered.

K^+ can replace Na^+ and Na^+ can replace Li^+ when we want to strengthen the surface of glass.

Ag^+ and Cu^+ can replace Na^+ to “stain” glass.

A special feature here is that we have point defects (and large defects) in glass just as we do in crystals. Our challenge is to understand what determines the properties (e.g., diffusion) of such defects when we don’t have a reference lattice.

21.14 TYPES OF CERAMIC GLASSES

Not all glass is based on the silica tetrahedron. The structural units are summarized in Table 21.5, and some representative glass compositions given in Table 21.6.

21.14.1 Silicate Glass (Soda-Lime Glass)

Silicate glass is based on SiO_2-Na_2O-CaO (usually containing MgO and Al_2O_3). It is relatively inexpensive and durable and is widely used in the building and packaging industries. It is not negligible, and it’s not a good insulator. The main uses are in sheet glass, bottles, tableware, and in the light industry for envelopes (bulbs). The alkaline aluminosilicate glasses ($SiO_2-Al_2O_3-RO$, where R is the alkali) have low α values, are durable, and are better electrical

FIGURE 21.17. Example of iridescence in Roman glassware.

insulators. They also have a high strain point. Uses include combustion tubing, envelopes for halogen lamps, and substrates in the electronics industry.

21.14.2 Lead Glass

Generally, the composition of lead glass is a lead-alkali silicate glass SiO₂–PbO–R₂O, so the PbO replaces the CaO in soda-lime glass. These glasses have high resistivity, a large α , a low softening temperature, and a long working range. The reason that Pb glass has been used to make so-called lead crystal glass is that it has a high refractive index. Besides being used in art objects, it is used for lamp tubing, TVs (the “bulbs”), and thermometer tubing. In a traditional English lead crystal, the concentration of PbO is at least 30%: a European Union (EU) directive required that glass must contain $\geq 24\%$ to be lead crystal. The EU then had to exempt crystal glass from recycling laws! Lead glass used for radiation shielding may contain as much as 65% PbO. Applications include TV tubes, although Ba glass may be used in the face or panel of the TV. The electrons hitting the TV screen can create X-rays that the glass must then absorb. Lead-borate glasses can be used as glass solder—they contain little SiO₂ or Al₂O₃ and are quite inert.

Flint glass is a high-dispersion, lead-alkali silicate glass and was originally made by melting flint rock, which is a particularly pure form of silica. Note that this rock is now calcined and is still used extensively in the pottery industry.

Crown glass has quite a low dispersion and is based on soda-lime glass. It is still made by initially blowing the glass, flattening it, and transferring it to the pontil (a solid iron rod rather than the blow pipe), where it is spun until it

FIGURE 21.18. Crown glass with bull's-eye.

is in the form of a disc that can be 1.5 m in diameter (Figure 21.18). The disk shows concentric ripples from the spinning and has a bull's-eye at the center of the crown. The disk can be very smooth, having been flame-annealed without mechanical polishing. Historically, windowpanes could be cut around the bull's-eye or could contain it.

21.14.3 Borate Glass (Borosilicate Glass)

The alkali borosilicates, SiO₂–B₂O₃–R₂O (where R is the alkali), are special for their low α . They are durable and have useful electrical properties. The cookware material, Pyrex™ is a borosilicate. Borosilicate glass is widely used

in the chemical processing industry. Some borate glasses melt at very low temperatures ($\sim 500 \pm 50^\circ\text{C}$), so they can be used to join together other glasses. Zinc-borosilicate glass, known as passivation glass, contains no alkalis, so it can be used for Si electronics components.

21.14.4 Fused Silica

Being essentially pure SiO_2 , fused silica is the glass used for high-temperature applications. It has a near-zero α . It is known as ultra-low expansion (ULE) silica and is used for telescope mirrors and substrates. ULE[®] glass containing 7% TiO_2 is being used for photolithography masks—for extreme UV lithography (EUVL)—at a wavelength of 13.4 nm. Another silica glass that can be used for 157-nm lithography was made by removing the water and adding fluorine ions to change the composition of the silica; this process allows transmission of wavelengths down to 157 nm. We've already discussed Vycor, which can be pure (porous) silica after we remove the second phase.

21.14.5 Phosphate Glass

Phosphate glasses are important because they are semiconducting. One application is in the manufacture of electron multipliers (hence amplifiers) using Er-doping (with Er_2O_3). The cations here are usually V and P but Oak Ridge National Laboratory (ORNL) developed a lead indium phosphate glass that has a high index of refraction and a low melting temperature and is transparent over a wide range of wavelengths. As it can also dissolve significant concentrations of rare-earth elements (it was designed to be a container for radioactive waste), it is being explored for new optically active devices (e.g., fiberoptic amplifiers and lasers). Nd-doped (using Nd_2O_3) phosphate glasses are being used in solid-state lasers (1.054 μm wavelength). The typical composition is 60 P_2O_5 –10 Al_2O_3 –30 M_2O (or MO); the Nd concentrations is ~ 0.2 –2.0 mol%. We see more on calcium phosphate glass when we discuss bioceramics in Chapter 35.

21.14.6 Chalcogenide Glass

Based on As, Se, and Te, these glasses are IR transparent. They are nonoxide semiconductors and are used in special electronic devices and lenses. The devices use the abrupt change in electrical conductivity that occurs when a critical voltage is exceeded. The applications have to be special because these glasses are not durable and have low softening temperatures.

21.14.7 Fluoride Glass

In general, halide glasses are based on BeF_2 and ZnCl_2 and are used in optical waveguides (OWGs), where the cost can be justified.

21.15 NATURAL GLASS

It surprises some people that not only does glass occur in nature it is relatively common.

Tektites are formed within the impact craters of meteors. Moldavite is a green glass from Moldavia in the Czech Republic. Libyan desert glass is formed the same way but is yellow.

Fulgarites are fragile tubes of glass that can be formed when lightning strikes a sandy soil.

Obsidian is the glass formed in volcano flows. The usual black color is due to impurities; green and red obsidian also occur. Obsidian was used to make tools during the Paleolithic period. The advantages of using glass for scalpels have only recently been rediscovered: the cut made by a glass knife is particularly even, so it heals fast. It has been proposed that the Aztec Civilization may not have developed metallurgy because it was so adept at using obsidian. There are many sources of obsidian in the volcanic mountain ranges of Peru and Ecuador in particular.

Pumice is another glass formed in volcanic eruptions. It can be very porous if it contains a high concentration of gas. Pumice is thus the porous form of obsidian.

Trinitite is not really a natural glass but one that we might say forms unintentionally. This glass has been found at the Trinity site where the nuclear bomb was exploded in New Mexico.

Diatoms. Why are we including this topic here? Because it is both interesting and surprising. Not all living things on Earth are based on carbon. Diatoms are small aquatic microorganisms, or one-celled plants that live by ingesting silica that is dissolved in water—we usually think of seawater, but it can be a freshwater lake. The diatoms then use the silica to form and grow a pair of shells, illustrated in Figure 21.19. The two shells resemble a pillbox. The shells come in many varieties—there are thousands of species of diatoms. When the microorganisms die, their siliceous skeletons have formed layers up to 3,000 ft thick: they are not rare! The result is that there are regions where deposits of silica have built up to form what is known as diatomite or diatomaceous earth. The comparable process for carbon-based creatures would be the formation of limestone and chalk. Diatoms do contain chlorophyll, so they are plant-colored while alive.

The *Venus flower basket* (genus *Euplectella*) is a sponge that lives in the deepest parts of the oceans in the tropics. It has a skeleton that looks like a mesh of glassy silica fibers (Figure 21.20). Each fiber actually consists of coaxial cylindrical layers with different optical properties. It is reminiscent of the cladding used today on commercial optical fibers, but nature did it eons earlier. The optical properties of the natural fibers are not as good as those of human-made fibers, but they are more resistant to breaking. Note that these layers are deposited at ambient water temperatures!

21.16 PHYSICS OF GLASS

We now discuss glass from the physicist's point of view. We've left this topic until last so as either to confirm your excitement or not completely put you off the subject.

The idea is that glass is a condensed phase—just as liquids and crystals are. The atomic interactions can be described by a potential energy function, ϕ .

If we describe the energy of a glass plotted against the coordinates of the glass, we would find a multidimensional energy hypersurface, which is multiply dented with structured valleys. The glass structure corresponds to one of those valleys, but there may be another valley or a minimum not far away on the surface. Then, we have the concept of polyamorphism where the glass can have several distinct amorphous structures. (The comparison to crystalline materials is instructive!)

The experimental observation is that the viscosity of some glasses decreases suddenly above T_g in a non-Arrhenius way. It's as if the structure of the glass collapsed because it was fragile (the term fragile strictly refers to the liquid, not the glass). Hence, fragility is a property of some glass-forming liquids above T_g , but we talk about fragile and strong glasses. If we plot $\log \eta$ versus T_g/T (the reduced T_g , as shown in Figure 21.21A), the curve would be straight if it was Arrhenius-like behavior. For SiO_2 and other highly polymerized network glasses (strong glass-formers), it is nearly straight. If the bonds are not directional, the plot deviates significantly from Arrhenius behavior; this is a fragile glass-former. Two approaches have been used to explain this behavior.

- Free volume
- Configurational entropy

Each connects η to the macroscopic quantities of either volume or entropy. A newer approach considers factors

FIGURE 21.19. SEM image of diatoms.

FIGURE 21.20. Sea sponge.

FIGURE 21.21. Viscosity versus temperature for strong and fragile liquids.

affecting the kinetics of the transformation. There are fast relaxation processes (known as β processes) and low-frequency processes that contribute to the dynamic structure factor. In the glass's vibrational spectra detected by Raman or neutrons, these features are known as the boson peak. The boson peak is large for strong glass-formers; low-frequency excitations in a glass suggest intermediate-range order: thus, more order indicates a stronger glass.

The molar heat capacity, c_p , is a well-defined quantity. At very low temperatures ($T < 1$ K: a temperature familiar

to physicists but less so to ceramists), glasses show a linear term in c_p due to an anharmonic contribution. At $T \sim 5\text{--}10$ K, an excess vibrational (harmonic) contribution causes a bump in c_p . The excess vibrational contribution to c_p at this bump (i.e., $c_p - c_D$) can be plotted against the fragility of the glass. The resulting correlation suggests that the excess vibration and the fragility have a related origin. Therefore, SiO_2 , a particularly strong glass, has a large c_p/c_D , whereas a fragile glass, such as CKN , $\text{Ca}_{0.4}\text{K}_{0.6}(\text{NO}_3)_{1.4}$, has a small c_p/c_D .

CHAPTER SUMMARY

The location of the chapter is after “powders” but before “processing” because we are still emphasizing the material. Glass is an extremely important material—society might not be civilization without glass, so the history of this topic is particularly rich. Remember that glazes on pots and enamels on metals are essentially two variations on a single theme—protecting other materials by coating them with glass. The variety of glasses is large, and we have only touched on the range here. Remember that, historically, silica-based glass was for a long time synonymous with the word glass. It has dominated our thinking about glass. New glasses are being developed that may contain no Si, and the properties may be very different: there is not just one material called glass any more than there is one material called crystal. Glass crystallizes given time; although glass-ceramics were the new materials of the 1960s, they were already old friends to the potter. The basic science of glass is more difficult than for crystals because we have no “frame of reference.” However, there are point defects in glass (remember the origins of color). Glass has both internal and external interfaces. Glass does have special structural features. Of the many important properties, transparency and viscosity must be the most important; but for many applications, the small, or controllable, expansion coefficient is the key to the value of glass.

As we explained from the beginning, glass appears throughout our discussion of ceramics. The processing of glass is treated in Chapter 26, mechanical properties are in discussed in Chapter 18, and Bioglass is in Chapter 35. The reason we treat glass separately is partly historical and partly because its behavior is often so different from that of crystalline ceramics, which underlines the point we made in Chapters 5–7 that bonding and structure determine the properties and thus the applications.

PEOPLE AND HISTORY

Bacon, Roger a Franciscan Friar who described reading glasses made using two lenses in 1268. Salvino D'Armato of Pisa is sometimes credited with the invention in 1284.

Cassius, Andreas (1685) in the book *De Auro*, described how to produce this ruby red color, which thus became known as “Purple of Cassius.”

La Farge, John created a “Colored-Glass Window” (patent no. 224,831; February 24 1880), which was the original patent on opal glass, followed shortly by Louis Comfort Tiffany's patent (no. 237,417; February 8 1881) with the same title “Colored-Glass Window.”

Lipperhey, Hans was a lens grinder in The Netherlands; applied to patent the telescope in 1608.

Pascal, Blaise (1623–1662) was born in Clermont-Ferrand, France and died in Paris. The SI unit of pressure (stress) is named after him. Argued against Descartes in favor of the existence of vacuum.

Perrot, Bernard (1619–1709) was a well-known early French glassmaker.

Poiseuille, Jean Louis Marie was the French physician (1799–1869) after whom we named the Poise.

Prince Rupert of Bavaria (1619–1682) was grandson of James I of England and nephew of Charles II. He introduced his drops to England in the 1640s, where they became party pieces in the court of Charles II. The famous diarist Samuel Pepys wrote about them in his diary on January 13, 1662.

Rakuyaki, Chojiro, (died 1859) was the first member of the family that began the tradition of raku. Their home is now an exquisite museum illustrating tea bowls made by 15 generations.

van Leeuwenhoek, Anton (1632–1723) was born in Delft, Holland and worked as a cloth merchant. He devised a simple microscope that succeeded so well because he was a skilled lens grinder. The microscope itself was invented in the 1500s and was used by Robert Hooke.

Warren, Bertram Eugene (1902–1991) was at M.I.T. 1930–1976. He is known for his textbook on X-ray diffraction and his studies of the structure of glass and carbon black. His work began small-angle scattering research into nonperiodic and nearly periodic structures.

EXERCISES

- 21.1 What causes refraction in glass?
- 21.2 Why is smoky quartz smoky?
- 21.3 If you increase the wavelength, how does the refractive index change?
- 21.4 What is dispersion, and why does glass cause it?
- 21.5 If Pb were added to a typical lead crystal glass, what weight percent would be added? What atomic percent of Pb would the glass then contain? What is actually added in industrial practice, and will this practice continue in the future?
- 21.6 If you are given crystalline SiO₂, quartz glass, silica gel, and a sample of liquid SiO₂, how would you analyze the bonding of the Si in each case? Would you detect a difference?
- 21.7 How would you expect the properties of GeO₂ glass to differ from those of SiO₂ glass? Be as quantitative as possible.
- 21.8 We can make glass based on B and on P. What are the bonding characteristics of these two glasses? Suggest three modifiers for each glass. Compare the densities you expect for these glasses.
- 21.9 Libyan desert glass was produced naturally. Is pressure or temperature the more important factor? Explain your reasoning as quantitatively as possible.
- 21.10 Na is a network modifier for SiO₂ glass. How would Li and K compare to Na in this role? Similarly, Ca is present in soda-lime glass. If the Ca were replaced by an equal atomic percent of Mg or Ba, how would the properties of the glass change?
- 21.11 We define the glass transition temperature using Figure 21.1. Why does it depend on the cooling rate, and how does this affect the definition?
- 21.12 Which is the better word to describe glass: amorphous or vitreous? Explain.
- 21.13 How was the bulti fish made?
- 21.14 If Amenophis's head was made by the lost-wax technique, is this the oldest use of the technique? What other materials is this used for?
- 21.15 Diatoms have interesting structures and abundant. Are there any applications for diatoms? Describe these applications and remember to cite your sources.
- 21.16 Explain why Mergules viscometer and fiber elongation are both used to measure viscosity but not necessarily on the same glass. Could they be used on the same glass?
- 21.17 Why would you use 10^{3.8} dPa·s to make a glass-to-metal seal but 10⁸ dPa·s to sinter glass?
- 21.18 Discuss the following statement: "glass is simpler than crystals because we don't have to worry about lattices or dislocations."
- 21.19 What is the difference between glass, enamel, and glazes? Discuss carefully!
- 21.20 When you have read the chapter, discuss Sturkey's assertion.

Sols, Gels, and Organic Chemistry

CHAPTER PREVIEW

Extensive research and development in the past decade have resulted in increasing awareness of the importance of chemical synthesis, particularly using organic precursors, in the processing and fabrication of ceramics. The sol–gel process is one method that is used commercially in many applications, such as forming coatings on window glass. It is also used, as we have described already, for forming powders and fibers. The process gives us excellent control of product purity and composition for the simple reason that we start with pure materials. It allows us to deposit films and coatings on a range of different surfaces, enabling a flexibility that is not present in many vapor-phase methods.

We can summarize the key advantages offered by the sol–gel process.

- It uses relatively low temperatures.
- It can create very fine powders.
- It produces compositions not possible by solid-state fusion.

There are some disadvantages of the sol–gel process.

- The cost of the raw materials (the chemicals) may be high. As an example, MgO powder with a purity of 98% is available in small quantities for \$30 kg⁻¹. Magnesium ethoxide, a chemical source for making MgO, costs about \$200 kg⁻¹.
- There is often large volume shrinkage and cracking during drying (we have to remove the “organics”).
- Organic chemistry often uses confusing terminology and is avoided by ceramists whenever possible.

In Chapter 20 we described how sol–gel processing (and other chemical methods) are used to make ceramic powders and fibers. Why do we need another chapter on this topic? There are two main reasons. First, to use sol–gel processing scientifically you must understand the chemistry (the terminology and the reactions). Second, chemical methods for making powders are going to be even more important in the future because they can be used to make nanoparticles and even to coat them.

22.1 SOL–GEL PROCESSING

The sol–gel process consists of two steps. First we form a *sol*. Then we transform it into a *gel*. In ceramic synthesis, two different sol–gel routes have been identified and depend on the gel structure.

- Particulate gel—using a network of colloidal particles
- Polymeric gel—using an array of polymeric chains

The process that occurs depends on the form of the sol (i.e., whether it is a solution or a suspension of fine

particles). A flow diagram indicating each of the processes is shown in Figure 22.1.

In this chapter we’re only concerned with the polymeric gel route because it is the approach that is most useful to ceramists. This method has been successful in preparing a range of advanced ceramics, such as lead zirconate titanate (PZT) and the high- T_c oxide superconductors.

THE TERM SOL–GEL

It is convention to use the term “sol–gel” rather than “sol/gel”, but the latter might be more correct; “sol” and “gel” are two independent concepts.

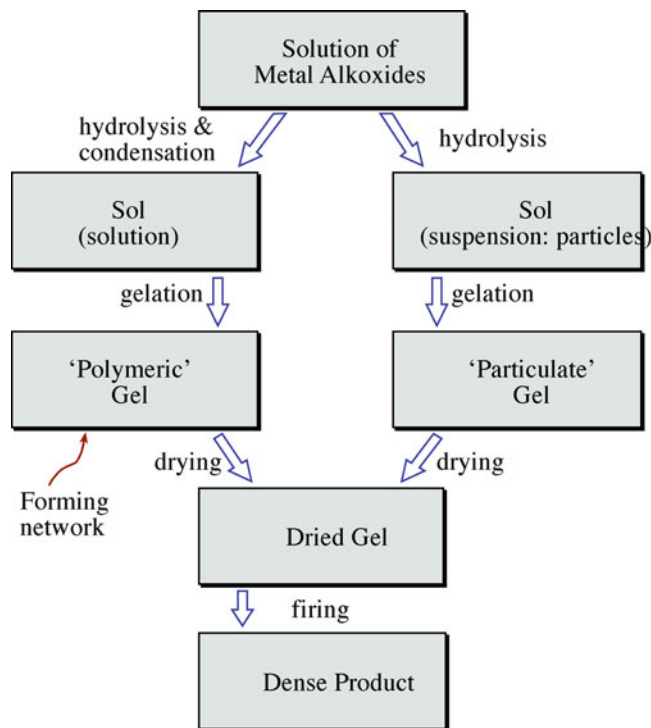

FIGURE 22.1 Flow chart comparing sol-gel processing using a solution and a suspension of fine particles.

The significant advantage of sol-gel processing of ceramic powders is that homogeneous compositions can be prepared at temperatures lower than required for conventional powder processes. Furthermore, the reactants used in sol-gel processing are available in very high purities, which allows the formation of high-purity powders of crystalline ceramics and glasses.

A commonly studied approach for synthesizing oxides has been to hydrolyze the appropriate metal alkoxides. There are several advantages to using metal alkoxides as precursors for ceramic powders. Most of the alkoxides of interest can be easily prepared or are commercially available and can be readily purified prior to use. Interaction of alkoxides with water yields precipitates of hydroxides, hydrates, and oxides. The size of the precipitate particles usually ranges from 0.01 to 1.0 μm , depending on the hydrolysis conditions. Thus, we can easily produce nanoparticles.

DEFINITION OF SOL AND GEL

Colloidal particles or molecules, are suspended in a liquid or solution, a “sol”.

The sol is mixed with another liquid, which causes formation of a continuous 3D network, a “gel”.

METAL ALKOXIDE

$\text{M}(\text{OR})$

For convenience we will say “metal alkoxide” even when referring to alkoxides of non-metals such as silicon and boron.

TABLE 22.1 Examples of Metal Alkoxides

Name	Chemical formula	Physical state
Aluminum <i>s</i> -butoxide	$\text{Al}(\text{O}^\circ\text{C}_4\text{H}_9)_3$	Colorless liq., $T_B \sim 203^\circ\text{C}$
Aluminum ethoxide	$\text{Al}(\text{OC}_2\text{H}_5)_3$	White powder, $T_M 130^\circ\text{C}$
Aluminum isopropoxide	$\text{Al}[\text{O}^\circ\text{C}_3\text{H}_7]_3$	White powder, $T_M 118.5^\circ\text{C}$
Antimony ethoxide	$\text{Sb}(\text{OC}_2\text{H}_5)_3$	Colorless liq., $T_B 95^\circ\text{C}$
Barium isopropoxide	$\text{Ba}(\text{O}^\circ\text{C}_3\text{H}_7)_2$	Off-white powder
Boron ethoxide	$\text{B}(\text{OC}_2\text{H}_5)_3$	Colorless liq., $T_B 117.4^\circ\text{C}$
Calcium methoxide	$\text{Ca}(\text{OCH}_3)_2$	Off-white powder
Iron ethoxide	$\text{Fe}(\text{OC}_2\text{H}_5)_3$	$T_M 120^\circ\text{C}$
Iron isopropoxide	$\text{Fe}(\text{O}^\circ\text{C}_3\text{H}_7)_3$	Brown powder
Silicon tetraethoxide	$\text{Si}(\text{OC}_2\text{H}_5)_4$	Colorless liq., $T_B 165.8^\circ\text{C}$
Silicon tetraheptoxide	$\text{Si}(\text{OC}_7\text{H}_{15})_4$	Yellow liq.
Silicon tetrahexoxide	$\text{Si}(\text{OC}_6\text{H}_{13})_4$	Colorless liq.
Silicon tetramethoxide	$\text{Si}(\text{OCH}_3)_4$	Colorless liq., $T_B 121\text{--}122^\circ\text{C}$
Titanium ethoxide	$\text{Ti}(\text{OC}_2\text{H}_5)_4$	Colorless liq., $T_B 122^\circ\text{C}$
Titanium isopropoxide	$\text{Ti}[\text{O}^\circ\text{C}_3\text{H}_7]_4$	Colorless liq., $T_B 58^\circ\text{C}$
Yttrium isopropoxide	$\text{Y}[\text{O}^\circ\text{C}_3\text{H}_7]_3$	Yellowish-brown liq.

22.2 STRUCTURE AND SYNTHESIS OF ALKOXIDES

Alkoxides have the general formula $\text{M}(\text{OR})_z$ where M is usually a metal but can also be a nonmetal such as Si, and R is an alkyl chain. Table 22.1 lists some common alkoxides used in the preparation of ceramics.

The nomenclature adopted for the simple alkoxides follows the basic rules of organic chemistry.

Methoxide R = CH_3 Example is $\text{B}(\text{OCH}_3)_3$

Ethoxide R = C_2H_5 Example is $\text{Si}(\text{OC}_2\text{H}_5)_4$

Propoxide R = C_3H_7 Example is $\text{Ti}(\text{O}^\circ\text{C}_3\text{H}_7)_4$ (*n*-, *iso*-)

Butoxide R = C_4H_9 Example is $\text{Al}(\text{O}^\circ\text{C}_4\text{H}_9)_3$ (*n*-, *iso*-, *sec*-, *tert*-)

In these molecular formulae, the superscripts *n*, *t*, *s*, and *i* refer to normal, tertiary, and secondary or iso alkyl chains, each of which is illustrated for the butoxide group in Figure 22.2. These are common names and don't follow the

Commission on the Nomenclature of Organic Chemistry of the International Union of Pure and Applied Chemistry (IUPAC). In the case of higher alkoxides (i.e., those with five or more C atoms), the nomenclature is derived strictly from IUPAC conventions. For example, the alkoxide group $(\text{CH}_3)_3\text{CCH}_2\text{CH}_2\text{O}$ - would be referred to as 2,2-dimethylbutoxide. The old name is neohexoxide.

FIGURE 22.2 Nomenclature for metal alkoxides.

FIGURE 22.3 Three-molecule coordination complex of aluminum isopropoxide.

Most metal alkoxides contain lower aliphatic alkyl groups and are coordinated complexes, not single molecules. Figure 22.3 shows an example of a coordination complex of aluminum isopropoxide consisting of three molecules.

TABLE 22.2 Alkoxides of Metals with Different Electronegativities

Alkoxide	Electronegativity of metal	State
Na(OC ₂ H ₅)	0.9	Solid (decomposes above ~530 K)
Ba(O ⁱ C ₃ H ₇) ₂	0.9	Solid (decomposes above ~400 K)
Y(O ⁱ C ₃ H ₇) ₃	1.2	Solid (sublimes at ~475 K)
Zr(O ⁱ C ₃ H ₇) ₄	1.4	Liquid (b.pt. 476 K at 0.65 kPa)
Al(O ⁱ C ₃ H ₇) ₃	1.5	Liquid (b.pt. 408 K at 1.3 kPa)
Ti(O ⁱ C ₃ H ₇) ₄	1.5	Liquid (b.pt. 364.3 K at 0.65 kPa)
Si(OC ₂ H ₅) ₄	1.8	Liquid (b.pt. 442 K at atmospheric pressure)
Fe(OC ₂ H ₅) ₃	1.8	Liquid (b.pt. 428 K at 13 Pa)
Sb(OC ₂ H ₅) ₃	1.9	Liquid (b.pt. 367 K at 1.3 kPa)
B(O ⁱ C ₄ H ₉) ₃	2.0	Liquid (b.pt. 401 K at atmospheric pressure)
Te(OC ₂ H ₅) ₄	2.1	Liquid (b.pt. 363 K at 0.26 kPa)

Even when using the IUPAC convention, there is still the distinct possibility of encountering confusion when reading the literature. For example, you can find silicon tetraethoxide referred to as tetraethylsilicate, tetraethylorthosilicate (TEOS), and tetraethoxysilane!

The first alkoxide to be synthesized was silicon tetraisopentoxide (formerly called silicon tetraisomyloxide), made by a reaction between silicon tetrachloride and isopentanol (formerly isoamyl alcohol)

Many alkoxides are available commercially, particularly those of Si, Al, Ti, B, and Zr. These are not generally expensive materials; for example, TEOS, a colorless liquid, costs about \$40 kg⁻¹. However, nonstandard alkoxides—e.g., Ba(OC₂H₅)₂—are more expensive. Barium isopropoxide is an off-white powder and costs about 250 times as much as TEOS (\$10 g⁻¹). A 10% w/v solution of Ba(OC₂H₅)₂ in ethanol costs about \$2 mL⁻¹.

22.3 PROPERTIES OF ALKOXIDES

The properties of metal alkoxides depend on the electronegativity of the metal. Pauling's electronegativity scale was given in Chapter 3.

Alkoxides of alkali metals (e.g., sodium alkoxides) and alkaline earth metals are ionic solids. Alkoxides of Ge, Al, Si, Ti, and Zr are often covalent liquids. Because most alkoxides are either liquids or volatile solids (examples are given in Table 22.2), they can be purified by distillation to form exceptionally pure oxide sources, as shown in Table 22.3.

TABLE 22.3 Effect of Distillation on the Purity of Silicon Tetraethoxide

Form/Impurity (ppb)	Mn	Cr	Fe	Co	Ni	Cu
As supplied	10	15	86	0.7	<200	<200
Once distilled	0.8	2	31	0.3	11	<20

22.4 SOL-GEL PROCESS USING METAL ALKOXIDES

The three basic steps in the sol-gel process are summarized in Figure 22.4. The conversion of the sol to a gel occurs by hydrolysis and condensation reactions. The gel is converted to the oxide by drying and firing. We now look at each of these steps in a little more detail.

22.4.1 Preparing the Sol

The sol-gel process can be used to make single or multi-component oxides. First, we consider the case of a one-component system—silica. Of the many available silicon alkoxides, TEOS is commonly used. TEOS is insoluble in water, but water is necessary for the hydrolysis reaction; hence, we need to select a solvent for both the alkoxide and water. Ethanol is a suitable solvent, and a typical formulation contains three main components:

FIGURE 22.4 Basic steps in the sol-gel process using metal alkoxides.

For small-scale sol-gel processing in the laboratory, the equipment is relatively simple and inexpensive and consists of a:

- Three-necked flask (contains the mixed solutions)
- Mechanical stirrer (the mixture is stirred constantly)
- Reflux condenser (needed to prevent the solution from evaporating)
- Constant temperature bath (the rate of hydrolysis depends on the temperature)

Multicomponent sols can be prepared by mixing different precursors, which are selected to give eventually an oxide of the desired composition. Table 22.4 gives examples of typical formulations for both single-component and multicomponent alkoxide solutions. There may be problems if the hydrolysis rates of the precursors are different, and this can create inhomogeneities in the subsequent gel. We can allow for this possibility by partially hydrolyzing the less reactive component—e.g., $\text{Si}(\text{OC}_2\text{H}_5)_4$ —before adding the more reactive one—e.g., $\text{Ti}(\text{O}^i\text{C}_3\text{H}_7)_4$.

SAMPLE RECIPE

PZT thin films can be prepared using a solution of zirconium butoxide [$\text{Zr}(\text{O}^n\text{C}_4\text{H}_9)_4$] and titanium propoxide [$\text{Ti}(\text{O}^n\text{C}_3\text{H}_7)_4$] in 2-methoxyethanol ($\text{CH}_3\text{-OCH}_2\text{CH}_2\text{OH}$) mixed with lead acetate trihydrate [$(\text{CH}_3\text{CO}_2)_2\text{Pb}\cdot 3\text{H}_2\text{O}$] that is also dissolved in 2-methoxyethanol.

For some metals, such as the alkali metals and alkaline earth metals, it is not possible or inconvenient to use alkoxides because they are either unavailable or difficult to prepare. You can see from Table 22.2 that alkoxides of these metals are solids with low volatility. In many cases, they also have low solubility. In these situations, alternative reactants must be found. Metal salts such as acetates and citrates, which are soluble in organic solvents, are a

TABLE 22.4 Formulations for Single-Component and Multicomponent Alkoxide Solutions

Precursor	One component: 100 mol% SiO_2				Two components: 94 mol% SiO_2 + 6 mol% TiO_2				Three components: 15 mol% Li_2O + 3 mol% Al_2O_3 + 82 mol% SiO_2

viable alternative. Many of them can be obtained in a high-purity analytical grade. In cases where we use both alkoxides and metal salts, it is usual to first form a solution of all the components that are to be added as alkoxides. Then add the salts as solutions in alcohol or, if this is not possible, in the water that is to be used for the hydrolysis reaction. The final solution is homogenized by stirring.

22.4.2 Hydrolysis and Condensation

Metal alkoxides undergo hydrolysis very easily (meaning they react with water). In many cases, they are so sensitive to moisture that special precautions must be taken in their handling and storage (e. g., the use of a N₂ glove box and dehydrated solvents). The product vendor provides information on the sensitivity of the compound.

During the initial stage of hydrolysis an alcohol molecule, ROH, is expelled.

This is an example of a condensation reaction involving the elimination of an alcohol (e.g., ethanol).

The hydroxy metal alkoxide product can react by a further condensation reaction to form polymerizable species.

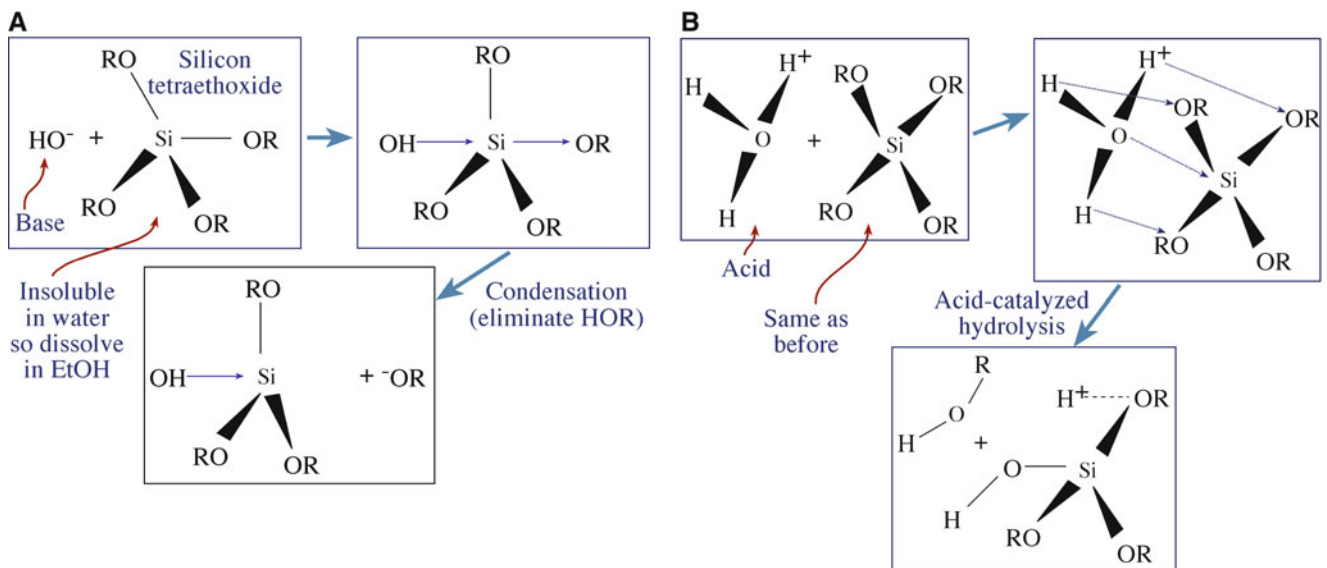

FIGURE 22.5 Reaction mechanisms for base-catalyzed (A) and acid-catalyzed (B) hydrolysis of silicon alkoxides.

Hydrolysis can be carried out under either basic or acidic conditions, as shown in Figure 22.5 for TEOS. In the context of sol-gel processing, acid-catalyzed conditions are defined as pH <2.5; base-catalyzed conditions are when it is pH >2.5. Of course, this is not our usual definition of acid and base, where neutral pH is 7, but corresponds to the point of zero charge (PZC) at which the surface is electrically neutral.

Hydrolysis may go to completion, leading to the formation of the silicic acid monomer; but this generally does not occur except at low pH and high water concentrations. The silicic acid monomer is not stable, and condensation of silanol groups (Si-OH) leads to polymer formation before silanol groups substitute for all the alkoxy groups. This

process is illustrated for the general case in Figure 22.6A. For different metal alkoxides, the situation is shown in Figure 22.6B.

The experimental variables used in the first stage of the sol-gel process determine the kinetics of the hydrolysis of the sol to form a gel and have a major influence on gel structure. The relevant variables are:

- Alkoxide concentration
- Reaction medium
- Concentration of catalyst—The rates of hydrolysis and condensation can be affected by the addition of small amounts of acid (e.g., HCl) or base (e.g., NH₄OH), respectively
- Temperature

22.4.3 Sol–Gel Transition

Viscosity is a key parameter that is used to determine when the sol–gel transition occurs. At the transition, there is an abrupt increase in viscosity. The structural changes that occur during gelation for acid-catalyzed and base-catalyzed reactions are illustrated in Figure 22.7.

FIGURE 22.6 Condensation reactions in (A) single metal alkoxide solutions and (B) mixed metal alkoxide solutions.

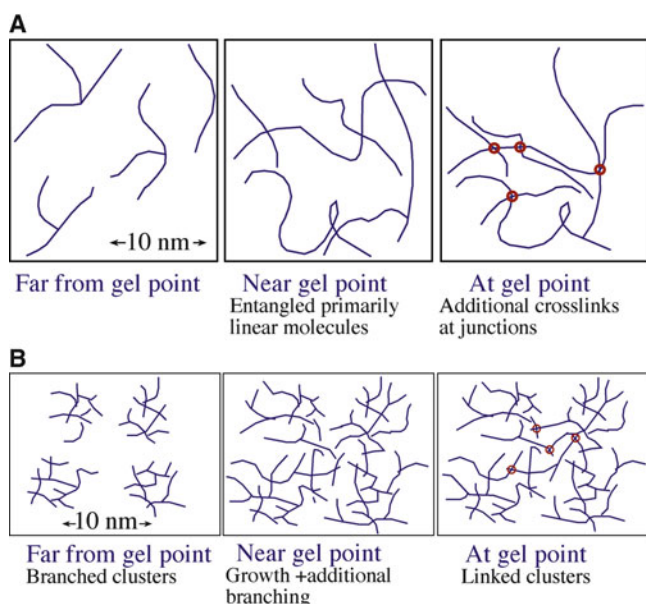

FIGURE 22.7 Acid-catalyzed (A) and base-catalyzed (B) polymerization and gelation.

Viscosity can be measured by two simple methods.

- Capillary flow– most common
- Rotation—using “Couette flow”

The Ostwald viscometer, illustrated in Figure 22.8, is an example of a capillary method used to study the sol–gel transition. The solution is introduced into the viscometer such that it reaches levels B and C. Liquid is then drawn up into the left-hand limb until the liquid levels are above A and at the bottom of the right-hand bulb. When the liquid is released, the time for the left-hand meniscus to pass between the marks A and B is measured. As the pressure driving the liquid through the capillary at any instant is proportional to its density, we write:

$$\eta = k\rho t \quad (22.5)$$

where k is a constant known as the viscometer coefficient, ρ is the density of the liquid, and t is the flow time. The capillary measurement is simple to operate and quite precise (0.01–0.1%).

VISCOMETERS

Used for glass, sol-gels, blood, polymers, etc. The ‘cup and bob’ types define the volume of sample to be sheared in a test cell. The torque needed to achieve a particular rotational speed is measured. The two geometries are known as the ‘Couette’ or ‘Searle’ systems; the difference is whether the cup or bob rotates. The cup can be a cylinder.

FIGURE 22.8 Ostwald viscometer. The liquid is initially at B and C and then drawn up to A.

Rotational methods are particularly suitable for studying the flow of non-Newtonian liquids. An example is the concentric cylinder (or Couette) viscometer. The liquid is sheared between concentric cylinders that are moving relative to one another. The outer cylinder can be rotated (or oscillated) at a constant rate and the shear measured in terms of the deflection of the inner cylinder, which is suspended by a torsion wire. Alternatively, the inner cylinder can be rotated with the outer cylinder stationary, and the resistance offered by the motor is measured. The coefficient of viscosity is given by

$$\eta = K\theta/\omega h \quad (22.6)$$

where K is an instrument constant (usually obtained by calibration with a liquid of known η), ω is the angular velocity of the rotating cylinder, and h is the effective height of liquid in contact with the cylinders. This method is essentially the same as the Mergules viscometer (see Section 21.3) that is used to measure the viscosity of glass melts, but the temperature is very different.

22.4.4 Drying and Firing

After gelation, the gel usually consists of a weak skeleton of amorphous material containing an interconnected network of small liquid-filled pores. The liquid is usually a mixture of alcohol and water, which must be removed. Shrinkage during this step is usually large.

There are several different methods used to dry gels. Each method produces a dried gel with a specific microstructure. In most cases, we obtain either an aerogel or a xerogel, but other microstructures are possible, as shown in Table 22.5.

The drying process is complicated, particularly when we want to form monolithic ceramics. One problem is cracking, which is more likely with high drying rates and thick

SHRINKAGE

During drying: linear shrinkage 50%, volume shrinkage 90%
 During firing: linear shrinkage 20%, volume shrinkage 50%

(>1 cm) gels. A number of procedures have been developed to increase drying rates while avoiding cracking.

- Increase the pore size of the gel.
- Decrease the liquid/vapor interfacial energy (e.g., use a solvent with a low γ_{lv}).
- Strengthen the gel.
- Use supercritical (hypercritical) drying: the liquid is removed above its critical temperature, T_c , and critical pressure, p_c . The values of T_c and p_c for the commonly used sol-gel liquids are: water 647 K and 22 MPa; ethanol 516 K and 6.4 MPa.

During firing, further changes occur as the gel densifies. The driving forces for these changes are:

- The large surface area of the dried gel. A xerogel has a solid/vapor interfacial area of 100–1,000 m²/g. Reduction of the surface area provides a driving force for densification.
- The low cross-linked density of the dried gel. The free energy, ΔG_f (298 K), of the polymerization reaction (equation 22.7) is -14.9 kJ/mol, and it acts as a driving force for increasing the amount of cross linking.

- Structural relaxation of the solid skeletal phase of the gel as the structure approaches that of a supercooled liquid (if the gel forms a glass) or a crystalline solid (if the gel forms a crystalline ceramic).

TABLE 22.5 Various Types of Dried Gels

Type	Drying conditions	Microstructure
Aerogels	In an autoclave, the fluid is removed by hypercritical evacuation	A network consisting of ~95% porosity
Xerogels	Natural evaporation	Dried gel has about 40–60% of the fired density and contains small pores (as small as 2 nm)
Sonogels	Gel exposed to ultrasound in the 20-kHz range prior to autoclave treatment	Assists in the formation of multicomponent gels
Cryogels	Freeze-dried	Finely divided powder, not suitable for producing monolithic ceramics
Vapogels	A fluid stream of SiCl ₄ is injected into acidified water. This allows rapid gel formation. The gel is then dried to a xerogel	Allows incorporation of additives into the gel (e.g., GeO ₂ if the fluid stream also contains GeCl ₄)

22.5 CHARACTERIZATION OF THE SOL–GEL PROCESS

Many techniques, in addition to measuring viscosity changes, have been used to follow the transitions that occur during sol–gel processing. The two parts of the process that we are interested in are the:

1. Transition from sol to gel
2. Transition from gel to oxide

Examples of techniques used to characterize sol–gel processes and the type of information they can provide are listed in Table 22.6. We described most of these techniques in Chapter 10.

22.6 POWDERS, COATINGS, FIBERS, CRYSTALLINE, OR GLASS?

Sol–gel processing is versatile because it can be used to produce ceramics in a number of different forms.

Powders—because we can make very small particles and control the composition.

Example application: bioactive glass powders, with a composition of $\text{SiO}_2\text{–CaO–P}_2\text{O}_5$.

Coatings—because the sol is a viscous liquid and can be applied to a substrate by spinning.

Example application: TiO_2 -based antiglare coatings on glass.

Example application: coat steel with alumina to improve wear resistance.

Fibers—because we can pull a thread out that is liquid and dry it, coat it, etc.

Example application: SiO_2 fibers used for space shuttle tiles.

Crystalline or glass? We have the choice.

Example application: high-purity porous silica glass for filtration.

22.6.1 Powders

Powders can be obtained via a sol–gel process using metal alkoxides or a combination of metal alkoxides and metal salts. Because the mixing of the constituents is achieved at a molecular level, the powders are chemically homogeneous. Powders produced by the sol–gel method are usually amorphous. This characteristic, together with their high surface area, allows them to be sintered to nearly full density at lower temperatures than are normally required when the particles have been made by other techniques. For example, gel-derived mullite powders can be sintered to full density $<1,300^\circ\text{C}$, whereas the sintering temperature is $\sim 1,600^\circ\text{C}$ for crystalline mullite powders. However, the cost of the raw materials limits the use of the sol–gel method for producing many ceramic powders except for those used for specialty applications.

22.6.2 Coatings and Films

Ceramic coatings can be prepared using a sol–gel process involving metal alkoxides. The coatings may be formed by:

- Dipping
- Spinning

TABLE 22.6 Methods Used to Characterize Sol–gel Processes

Technique	What is Measured	How It's Used
Ellipsometry	Thickness, optical constants of films	To measure film thickness changes (e.g., during drying)
Fourier transform infrared spectroscopy	Vibrational frequencies of chemical bonds, qualitative and quantitative identification of functional groups	Chemical changes during gelation, drying, and firing
Raman spectroscopy	Vibrational frequencies of chemical bonds, compound identification, structural order, and phase transitions	Chemical and structural changes during gelation, drying, and firing
Solid-state nuclear magnetic resonance (NMR) spectroscopy	Interaction between nuclear magnetic moments in atoms in the sample with radiofrequency electromagnetic waves, sensitive indicator of structural and chemical bonding properties. Phase identification and characterization of local bonding environment	Polymerization kinetics, time evolution of condensed species Chemical shifts in ^{29}Si NMR are functions of the state of silicon polymerization
Transmission electron microscopy	Crystallinity and phase identification by diffraction; microstructure at high spatial resolution	Transformation from amorphous to crystalline during firing. Experiments can be performed in situ
X-Ray diffraction	Crystallinity and phase identification, averaged microstructural information	Transformation from amorphous to crystalline during firing. Experiments can be performed in situ

TABLE 22.7 Applications of Sol–Gel Films and Coatings

Field	Property	Examples
Electronic	Ferroelectric	BaTiO ₃ , PZT
	Piezoelectric	PZT
	High-T _c superconductor	YBa ₂ Cu ₃ O ₇
	Ferrimagnetic	Doped Fe ₂ O ₃
	Transparent conductors	Indium tin oxide
Optical	Antireflective	TiO ₂ /SiO ₂
	Solar reflecting	TiO ₂ /Pd
	Electro-optic	PLZT
Protective	Corrosion resistant	SiO ₂
	Abrasion resistant	Organic modified silicates
	Barrier films	YSZ
Biomaterials	Bone cell regeneration	Calcium apatites

PLZT lead-lanthanum-zirconate-titanate, PZT lead zirconate titanate, YSZ yttria-stabilized zirconia.

**FIGURE 22.9** Spinnerette used to produce fibers and yarn.

- Spraying
- Lowering (similar to dipping except the substrate remains stationary, and the liquid is lowered)

Spinning is widely used for applying sol–gel coatings. One particular application is to produce thin coatings of PZT for micro-electro-mechanical systems (MEMS). Alkoxide-derived coatings are used for both antireflective layers on glass substrates and solar reflecting coatings on flat glass. Table 22.7 lists a number of applications for sol–gel films and coatings.

The advantages of forming coatings via sol–gel reactions are:

- Large areas
- Uniform composition
- Conformal coating of irregularly shaped substrates (e.g., fibers)
- High purity
- Microstructural control—i.e., pore volume (0–65%), pore size (<0.4 to >5.0 nm), and surface area (<1 to 250 m²/g)
- Less expensive than vapor-phase processes such as chemical vapor deposition and sputtering

22.6.3 Fibers

In Chapter 20, we described various methods of making ceramic fibers, including the sol–gel process. Fibers can be drawn directly from viscous sols, which are usually made by acid-catalyzed hydrolysis using low H₂O:M ratios. At viscosities greater than ~1 Pa·s (glycerine has a viscosity of ~1 Pa·s at room temperature), the sol is sticky; and we can produce fibers by forcing the sol through a spinnerette, illustrated in Figure 22.9. The spinnerette can be rotated to produce a yarn. This process is used commercially to produce polymer fibers.

Applications for sol–gel derived fibers include:

- Reinforcement in composites
- Refractory textiles
- High-temperature superconductors

Examples of fibers produced by sol–gel are:

- SiO₂
- SiO₂–TiO₂ (10–50 mol% TiO₂)
- SiO₂–Al₂O₃ (10–30 mol% Al₂O₃)
- SiO₂–ZrO₂ (10–33 mol% ZrO₂)
- SiO₂–Na₂O–ZrO₂ (25 mol% ZrO₂)

The properties of some commercial sol–gel fibers are given in Table 22.8.

22.6.4 Glasses

Glasses can be synthesized using the sol–gel process. This process allows the possibility of forming the disordered glass network, not directly at high temperatures from the melt but at low temperatures by chemical polymerization in a liquid.

The Owens-Illinois Company started an investigation of bulk glass systems formed by the sol–gel process in 1967. The dried gels were melted and fabricated by conventional techniques. The advantages that they found were:

- Lower melting temperatures could be used (the gel is already amorphous).
- It was not necessary to stir the melt (the gel is homogeneous).

Also, it was found that glasses fabricated from gels and those of the same composition made from oxide powders had essentially the same physical properties. The work was

TABLE 22.8 Properties of Commercial Gel-Derived Ceramic Fibers

Producer	Name	Composition	Tensile strength (MPa)	Tensile modulus (GPa)	Density (g/cm ³)
3M	Nextel 312	Al ₂ O ₃ , SiO ₂ , B ₂ O ₃	1,750	154	2.70
3M	Nextel 440	Al ₂ O ₃ , SiO ₂ , B ₂ O ₃	2,100	189	3.05
3M	Nextel 480	Al ₂ O ₃ , SiO ₂ , B ₂ O ₃	2,275	224	3.05
DuPont	PRD-166	Al ₂ O ₃ , ZrO ₂	2,100	385	4.20
DuPont	FP	α-Al ₂ O ₃	1,400	3,853	3.90
Sumitomo		Al ₂ O ₃ , SiO ₂	Ave. 2,200	Ave. 230	3.20

discontinued because of the high cost of the gels compared to the cost of the traditional powders. Also, in terms of processing considerations, the gel must be heated very slowly to the melting temperature to ensure that any residual organics and water are removed; otherwise, a very seedy and foamy melt can be obtained.

Sol-gel processing can really be justified only for glasses of certain compositions, such as those with high melting temperatures and high-viscosity glasses that are difficult to melt conventionally. However, glass coatings made by the sol-gel process are still important commercially.

22.6.5 Monolithic Ceramics

There are basically two routes that can be used to produce monolithic ceramics via a sol-gel process.

- Firing: use xerogels or aerogels
- Compaction and firing: use gel-derived powders

Making monolithic ceramics directly by a sol-gel process is still a challenge. The main issue is how we can dry the gel without introducing cracks in the dried body. The advantages of using a sol-gel route compared to conventional ceramic methods is that we're working in uncontaminated conditions and using lower temperatures.

The compaction-and-firing process is similar to traditional methods for producing ceramics from powders except that the powders are derived from the sol-gel process. The pros and cons are the same as those mentioned when forming powders using this method.

MONOLITHIC CERAMICS

The instruction to build a wall in “monolithic” concrete, indicated that it should be a wall of concrete built in place and then hardened into a solid unbroken mass. Hence a monolithic ceramic is “built” in situ.

22.6.6 Particles in Sol-Gel Films

Because the sol-gel films are essentially amorphous in their as-prepared state, we can heat treat them to grow nanoparticles, which are then embedded inside an amorphous matrix. The amorphous SiO(C) film in Figure 22.10 was produced by pyrolysis of a sol-gel precursor. The co-hydrolysis of triethoxysilane and methyl-diethoxysilane (in a molar ratio of 9:1) used the addition of acidic water (pH 2.25) to produce the xerogel. The xerogel was pyrolyzed at 1,000°C for 1 h to produce a Si-rich glass. The films were heated for another 10 h and then 100 h to produce the images shown here. The dark regions in the images are O-depleted and Si-rich. High-resolution transmission electron microscopy showed that these were crystalline Si nanoparticles (which have potentially interesting luminescent properties). Thus, not only does this type of study produce an interesting material, it also sheds light on Ostwald ripening and devitrification of a glass.

FIGURE 22.10 Use of sol-gel processing to produce Si nanoparticles in a glass matrix. The time indicates the length of the heat treatment.

CHAPTER SUMMARY

You should know that a sol and gels are different concepts and that sol–gel uses both. You can't avoid learning the basic organic chemistry: it is messy and has confusing terminology but is amazingly versatile and can produce nanomaterials routinely. Sol–gel processing is a method that can be used to form ceramic powders, thin films and coatings, fibers, and monolithic ceramics. The advantages of sol–gel processing are that we have excellent control of the composition, purity, and homogeneity of our product; how much control depends on the purity of the chemicals we start with. It also allows us to process materials at lower temperatures than any other method because we have small reactive particles. The disadvantages are that the reactants are often expensive, and there are problems in producing bulk ceramic components because of shrinkage. Sol–gel processes are used commercially to produce fibers, coatings, and coated fibers, particularly of ceramics with a high SiO₂ content (because processing temperatures are much lower). It is also particularly suited to producing thin films of multicomponent oxides such as PZT, which have application in MEMS, and how can you put a more uniform coating on a nanoparticle?

PEOPLE AND HISTORY

Couette, Maurice Frédéric Alfred (1858–1943) was professor of physics at the University of Angers in France. During his lifetime he published only seven papers. The idea for a viscometer based on shearing a liquid between two surfaces came from his Ph.D. thesis.

Ostwald, Wilhelm (1853–1932) won the Nobel Prize in Chemistry in 1909. He held academic positions at several institutions; and from 1887 until his retirement in 1906 was Professor of Physical Chemistry at Leipzig University. His famous students included Arrhenius (Nobel Prize 1903), Van't Hoff (Nobel Prize 1901), and Nernst (Nobel Prize 1920).

EXERCISES

- 22.1 Sol-gel coatings are usually prepared using either dipping or spinning. What are the advantages and disadvantages of the two methods?
- 22.2 Why would spinning, rather than dipping, be used to produce lead zirconate titanate (PZT) films for applications such as micro-electro-mechanical systems?
- 22.3 The ceramic fibers listed in Table 22.8 are made by sol–gel processing. (a) Why do you think this processing method was chosen? (b) What starting chemicals would be suitable for making these fibers? (c) Are there any alternative approaches that could be used to produce these ceramic fibers? If so, what are they, and how do they compare to sol–gel?
- 22.4 Discuss the economic issues involved in using the sol–gel process to form ceramic powders.
- 22.5 Explain why ²⁹Si nuclear magnetic resonance can be used to study the amorphous-to-crystalline transition in a silica gel. [Note: you may find the following references of use: Brown ID, Shannon RD (1973) Empirical bond-strength bond-length curves for oxides. *Acta Crystallogr A* 29:266; Smith KA, Kirkpatrick RJ, Oldfield E, Henderson DM (1983) High-resolution ²⁹Si nuclear magnetic-resonance spectroscopic study of rockforming silicates. *Am Mineral* 68:1206]
- 22.6 What is the difference between a particulate gel and a polymeric gel?
- 22.7 What would be appropriate starting chemicals for producing YBa₂Cu₃O₇ films by sol–gel?
- 22.8 Explain briefly the problems with shrinkage as they apply to sol–gel processing.
- 22.9 Compare the raw materials costs of preparing PZT powders by conventional solid-state reactions and sol–gel processing. What are the pros and cons of each approach?
- 22.10 Nylon is prepared by a condensation reaction. Compare this process to that occurring during sol–gel processing of ceramics using metal alkoxides.
- 22.11 Define what you mean by the terms “sol,” “gel,” and “sol–gel.”
- 22.12 Delve into the literature to estimate what is the most frequently used alkoxide for preparing sol-gels. Be careful and justify your answer.

- 22.13 What is TEOS and when do you use it? Be specific.
- 22.14 You are told: “if you need to produce a pure complex ceramic, use the sol–gel technique rather than mixing powders.” Was this good advice? Discuss and be specific, giving three commercial examples.
- 22.15 What do we mean by the term “gel point”?
- 22.16 We mentioned five types of gels. List them and explain what each is.
- 22.17 We listed four ways to coat a material with a sol–gel. List them and explain what each is and when would you use it by preference.
- 22.18 We listed four applications for sol–gel coatings. List the four and give examples of when you would use each one.
- 22.19 3M makes different types of ceramic fiber under the name Nextel™. In addition to the properties we listed in Table 22.8, what other properties can you find for these fibers? What are the primary applications for each of the fiber types?
- 22.20 The components in Nextel™ fibers are Al₂O₃, SiO₂, and B₂O₃. How are different properties obtained for fibers with these three constituents?

Shaping and Forming

CHAPTER PREVIEW

This is the pottery chapter! Many of the techniques that are now being used to shape high-tech ceramics have been used by potters for millennia but have been refined for today's high-tech applications and for new ceramic materials. We try to relate shaping to the potter's craft throughout the chapter.

We can just process dry powder and sinter it, but it's much more common to add some amount of liquid, just as the potter adds water to clay; we then shape the object and fire it. Shaping transforms an unconsolidated powder mixture into a coherent, consolidated body having a chosen geometry. The selection of a shaping operation for a particular product is dependent on the size and dimensional tolerances of the product, the requisite microstructural characteristics, the levels of reproducibility required, economic considerations, and of course the required shape. We cover shaping of glass in Chapters 21 and 26, so here we consider the similarities in processing glass and crystalline ceramics. Similarly, we discuss thick films in Chapter 27; here we concentrate on three-dimensional objects ranging from fishhooks to turbine blades. However, we do cover slip casting, which we use in only a limited way for thin films.

23.1 THE WORDS

There's a special vocabulary for shaping ceramics because it's an ancient art. Once the constituent powders have been prepared in the desired purity and particle size, the next step in the processing of most ceramic products is fabricating them into useful shapes. Many shaping methods are used for ceramic products, and they can be grouped into three basic categories, which are not necessarily independent.

1. Powder compaction: e.g., dry pressing, hot pressing, cold isostatic pressing
2. Casting: using a mold with the ceramic as, or containing, a liquid or slurry
3. Plastic forming: e.g., extrusion, injection molding—using pressure to shape the green ceramic

Powder compaction is simply the pressing of a free-flowing powder. The powder may be dry pressed (i.e., without the addition of a binder) or pressed with the addition of a small amount of a suitable binder. The pressure is applied either uniaxially or isostatically. The choice of pressing method depends on the shape of the final product. We make simple shapes by applying the pressure uniaxially; more complex shapes require isostatic pressing.

Casting ceramics is carried out at room temperature and generally requires the ceramic powder particles to be

suspended in a liquid to form a slurry; note that this process is quite unlike the casting of metals. The slurry is then poured into a porous mold that removes the liquid (it diffuses out through the mold) and leaves a particulate compact in the mold. This process is known as slip casting. The process has been used to form many traditional ceramic products (e.g., sanitaryware) and more recently in forming advanced ceramic products (e.g., rotor blades for gas turbines). The other main casting process for ceramics is tape casting, which, as you'd guess, is used to make thick films or sheets; it is described in Chapter 27.

Plastic forming is done by mixing the ceramic powder with a large volume fraction of a liquid to produce a mass that is deformable (plastic) under pressure. Such processes were developed and used originally for clay and have since been adapted to polymeric materials. For traditional clay-based ceramics, the liquid is mainly water. For ceramic systems that are not based on clay, an organic liquid may be used in place of, or in addition to, water. The binders are often complex and contain multiple components to achieve the required viscosity and burn-out characteristics.

Table 23.1 lists the major methods that are included in each of the above categories and the types of shape that can be produced. First, some of the words:

Binder: a component that is added to hold the powder together while we shape the body.

Slurry: a suspension of ceramic particles in a liquid.

TABLE 23.1 Various Shaping Methods for Ceramic Components

Shaping method	Type of feed material	Type of shape
Dry pressing	Free-flowing granules	Small and simple
Isostatic pressing	Fragile granules	Larger and more intricate
Extrusion	Plastic mass using a viscous polymer solution	Elongated with constant cross section
Injection molding	Organic liquid binder giving fluidity when hot	Complex
Slip casting	Free-flowing cream	Mainly hollow

Plasticizer: the component of a binder that keeps it soft or pliable. It improves the rheological properties.

Green: a ceramic before it's fired. Brown, white, or gray potter's clays are well-known green ceramics.

Slip: the liquid-like coating used to form the glaze when fired.

Some of the shaping methods we describe in this chapter produce a ceramic compact that is strong enough to be handled and machined; but it is not fully dense, and the bonds between the grains are not strong. This is called the "green" state and represents a transition state between the loose powder and the high-density sintered product. Other shaping methods—those that involve the use of high temperatures and pressures—can directly produce a very dense sintered product. Much of what we talk about here has a parallel in the field of powder metallurgy; the theme is often *processing powders*, which are not necessarily ceramic powders (e.g., they could be pharmaceuticals).

23.2 BINDERS AND PLASTICIZERS

It is often necessary to add a binder to the ceramic powder. The binder has two functions. In some shaping methods, such as extrusion, the binder provides the plasticity necessary for forming. The binder also provides the dry (green) shape with sufficient strength that it can survive the handling process between shaping and sintering. One of the most important requirements for the binder is that we must be able to eliminate it from the compact during the firing process without any disruptive effect: polymers are thus often ideal binders.

In pottery, the binder is often water, which is present in sufficient quantity to make the clay easily shaped

but retains the shape during firing. The idea is that we then add a plasticizer to optimize the rheology of the material. Note that these processes are not exclusive to ceramics but are general to powder processing. The distinction between binder and plasticizer is sometimes not too clear.

Binders can also be used when metal powders are processed (e.g., PMC, or precious-metal clay).

23.3 SLIP AND SLURRY

The word slip appears to come (according to Webster's) from the Old English words meaning cream: "the suspension of curds in the liquid when making cheese." The cheese was actually sieved through a "slippe clothe."

In general, slip consists of fine (<10 μm) ceramic-powder particles that are suspended in a fluid. In the pottery industry, the liquid is usually water. The suspension can have a solid content up to ~60 vol%. Deflocculants are added to the slip to modify the electrical environment of each particle so the particles repel each other.

Deflocculants: as deflocculation is defined as the process by which floccules present in a liquid break up into fine particles producing a dispersion, a deflocculant is an additive that causes this process. In other words, deflocculation is the opposite of coagulation. (A floccule is a small piece of matter, or a floc).

Colloids: defined very generally as any substance that consists of particles substantially larger than ordinary molecules but much too small to be visible without optical magnification (~1 nm to 10 μm). They can be linked or bonded together in various ways. Colloidal systems can take several forms; the one relevant to us is the dispersions of one substance in another. Brownian motion has interested scientists for generations. Slip is a colloid. We can change the properties of the slip by

adding flocculants or deflocculants.

Slurry: clay particles are suspended in a liquid (water in the case of pottery). As the amount of water is decreased, it becomes more solid. Glazes used in pottery have the same base as the clay but with more

water content. Potter's clay is made by first producing a slip from naturally occurring clays. The slip is repeatedly filtered to produce a consistency that is constant over long periods of manufacture. Slabs of clay are then formed from this colloid by allowing most of the water to evaporate. The final product may be shaped by extrusion and packaged to prevent further loss of water.

BINDERS

Poly(vinyl alcohol) (PVA) and poly(ethylene glycol) (PEG) are the two most popular binders for dry-pressing ceramics:

PVA provides high green strength.
PEG provide a high green density.

FIGURE 23.1. Stages in dry pressing.

23.4 DRY PRESSING

Dry pressing is ideally suited to the formation of simple solid shapes and consists of three basic steps: filling the die, compacting the contents, ejecting the pressed solid.

Figure 23.1 shows the double-action dry-pressing process. In a double-action press, both the top and bottom punches are movable. When the bottom punch is in the low position, a cavity is formed in the die; and this cavity is filled with free-flowing powder. In dry pressing, the powder mixture contains 0–5 wt% of a binder (so dry does not imply that there is no binder). Once the cavity has been filled, the powder is struck off level with the top of the die. The top punch descends and compresses the powder either to a predetermined volume or to a set pressure. During pressing, the powder particles must flow between the closing punches so that the space between them is uniformly filled. A particle size distribution of 20–200 μm is often preferred for dry pressing: a high volume fraction of small particles causes problems with particle flow and also results in sticking of the punches. The pressures used in dry pressing may be as high as 300 MPa, depending on the material and press type, to maximize the density of the compact. After pressing, both punches move upward until the bottom punch is level with the top of the die and the top punch is clear of the powder-feeding mechanism. The compact is then ejected, the bottom punch lowered, and the cycle repeated.

Because the dry-pressing process is so simple and involves low-cost capital equipment, it is the most widely used high-volume forming process for ceramics. Production rates depend on the size and shape of the part and on the type of press used. For large components (e.g., refractories) or complex parts (e.g., grinding wheels), the production rates are 1–15 parts per minute. During a tour of the Wedgwood factory, you can see dinner plates being dry-pressed in a continuous process. Simpler or smaller shapes (e.g., seal rings and nozzles) can be produced at rates up to several hundred per minute. Small flat parts (e.g., insulators, chip carriers, cutting tools) can be produced at rates up to several thousand per minute.

23.5 HOT PRESSING

Pressing can also be performed at high temperatures; this process is known as hot pressing. The die assembly used for hot pressing is very similar to that described in

FIGURE 23.2. Essential elements of a hot press.

Section 23.4 for dry pressing. The main difference is that in hot pressing the die assembly is contained within a high-temperature furnace, as shown in Figure 23.2. During hot pressing the ceramic powders may sinter together to form a high-density component.

We can summarize the advantages of this process.

- The powder does not have to be of the highest quality.
- Large pores that are caused by nonuniform mixing are easily removed.
- We can densify at lower temperatures (typically half the melting temperature of the material) than are needed for conventional pressureless sintering.
- Extensive grain growth or secondary recrystallization does not occur when we keep the temperature low during densification.
- We can densify covalently bonded materials such as B_4C , SiC , and Si_3N_4 without additives. The principal disadvantage is also important.
- Dies for use at high temperatures are expensive and generally don't last long.

Most metals are of little use as die materials $>1,000^\circ\text{C}$ because they become ductile, and the die bulges. Special alloys, mostly based on Mo, can be used up to $1,000^\circ\text{C}$ at pressures of about 80 MPa. Ceramics such as Al_2O_3 , SiC , and Si_3N_4 can be used up to about $1,400^\circ\text{C}$ at similar pressures. Graphite is the most widely used die material and can be used at temperatures up to $2,200^\circ\text{C}$ and pressures of 10–30 MPa. The difficulty is that a graphite die tends to produce a very reducing environment. (You can make an Al_2O_3 sample vanish using a graphite die!)

However, graphite does have many properties that make it suitable for a die.

- Easy to machine (but the dust is toxic if inhaled—like coal dust)
- Inexpensive
- Strength increases with increasing temperature
- Good creep resistance
- Excellent thermal conductivity
- Relatively low coefficient of thermal expansion

Hot pressing, like dry pressing, is limited to simple solid shapes, such as flat plates, blocks, and cylinders. More complex or large shapes are difficult and often impossible to produce by hot pressing. Hot pressing is widely used in the research laboratory for processing very dense, high-purity ceramic components. Although it is extensively used in university and government laboratories, the technique is limited as a production tool because of its high cost and low productivity. For any mass-produced ceramic product, there would be considerable commercial pressure for a company to find a less expensive alternative. However, some commercial hot-pressed ceramic products are available. These products are those that require a small grain size, high density (low porosity), or low impurity levels. Examples of such products are given in Table 23.2.

Isostatic pressing involves the application of hydrostatic pressure to a powder in a flexible container. The advantages of applying pressure in all directions are that there is more uniform compaction of the powder and more complex shapes can be produced than with uniaxial pressing. Isostatic pressing can be performed either with or without applied heat.

23.6 COLD ISOSTATIC PRESSING

There are many variations on using the cold isostatic press (CIP); here we just emphasize some basic themes. Figure 23.3 illustrates the so-called wet-bag CIP process. Powder is weighed into a rubber bag, and a metal mandrel is inserted that makes a seal with the mouth of the rubber bag. The sealed bag is placed inside a high-pressure chamber that is filled with a fluid (normally, a soluble oil–water mixture) and hydrostatically pressed. The pressures used can vary from ~20 MPa up to 1 GPa depending on the press and the application. For production units, the pressure is usually ≤ 400 MPa. Once pressing is complete, the pressure is released slowly, the mold is removed from the pressure chamber, and the pressed component is removed from the mold.

The advantages of the wet-bag process are:

- Wide range of shapes and sizes that can be produced
- Uniform density of pressed product
- Low tooling costs

The disadvantages are:

- Poor shape and dimensional control (particularly for complex shapes)
- Products often require green machining (described in Section 23.14) after pressing
- Long cycle times (typically 5–60 min) that give low production rates

A small wet-bag isostatic press, for producing laboratory samples and low-volume production parts, might have an internal diameter of 150 mm and a depth of 460 mm. Large wet-bag presses may have cavity diameters >1.8 m and lengths up to 3.7 m. The wet-bag CIP process can be automated.

TABLE 23.2 Hot Pressed Products

Product	Types of material
Optical windows	IR: MgF_2 , ZnS, ZnSe. Visible: Y_2O_3 , MgAl_2O_4
Ceramic armor	B_4C , TiB_2 , SiC, Al_2O_3
Cutting tools	Al_2O_3 particle-reinforced TiC, Si_3N_4 , Si_3N_4 -AlN- Al_2O_3
Tooling (molds and dies)	Al_2O_3 -SiC _w composites, SiC, Al_2O_3
Sputtering targets	Cr-SiO, TiN, Si_3N_4 , B_4C , Al_2O_3
Heat engine components	Si_3N_4 , SiC
Ceramic bearings	Si_3N_4
Microwave absorbers	MgO-SiC particulate composites, BeO-SiC, Al_2O_3 -SiC
Varistors	ZnO
Electro-optic materials	PLZT
Titanates	BaTiO_3 , CaTiO_3
Microelectronic packages	Co-fired W-metallized AlN
Resistors	Si_3N_4 matrix with particulates of TiB_2 , TiC, TiN, or SiC as the dispersed conducting phase

FIGURE 23.3. Wet-bag isostatic pressing system.

A mold for the dry-bag CIP is shown in Figure 23.4. The main distinction of the dry-bag process is that the rubber mold is now an integral part of the press. The high-pressure fluid is applied through channels in the mold. After pressing, the pressed part is removed without disturbing the mold at all. Hence, the dry-bag press can be readily automated. Fully automated units are widely available and have been operating in the high-volume production of ceramic parts for over two decades. Production rates of up to one part per second are being achieved industrially.

The dry-bag CIP has been used for many years to press spark-plug insulators. The steps in this process are shown in Figure 23.5. Notice the insertion of the inner pin in the mold. The world's largest producers of spark plugs produced by this method are Champion and AC Spark Plug.

FIGURE 23.4. A die for dry-bag isostatic pressing of a spark plug insulator.

FIGURE 23.5. Making spark plugs. Hydrostatic pressure is applied by pumping oil around the rubber container, which is part of the press and thus easily removed.

23.7 HOT ISOSTATIC PRESSING

The hot isostatic press (HIP) uses the simultaneous application of heat and pressure. We refer to this process as HIPing and the product as being HIPed (but you see variations on these abbreviations). A furnace is constructed within a high-pressure vessel, and the objects to be pressed are placed inside. Figure 23.6 shows a typical HIP arrangement. Temperatures can be up to 2,000°C, and pressures are typically in the range 30–100 MPa. A gas is used as the pressure medium—unlike in the CIP where a liquid is often used. Argon is the most common gas used for

FIGURE 23.6. Hot isostatic pressing apparatus.

HIPing, but oxidizing and reactive gases can also be used. Note that the high-pressure vessel is not inside the furnace.

There are two variants of HIPing.

- Encapsulated: using a deformable container
- Not encapsulated: shape and sinter first, then HIPed

In the original HIPing method, the ceramic powder was filled into a deformable metal can and then subjected to heat and pressure. This method was subsequently modified for small particle size powders. The powder compact was preformed to the desired shape by a process such as dry pressing or injection molding. The green compact was then encapsulated in a glass envelope that could be removed from the product after HIPing, as shown in Figure 23.7.

The second variant does not involve encapsulation at all. The ceramic powder is first compacted using another shaping method, such as dry pressing or injection molding, and then sintered at relatively high temperatures in a furnace to close all the surface pores, thereby preventing the entry of the gas during subsequent HIPing. The steps in this process, which is sometimes referred to as sinter-plus-HIP, are shown in Figure 23.8.

Now HIPing is used for a wide variety of ceramic (and metallic) components, such as alumina-based tool bits and the silicon nitride nozzles used in flue-gas desulfurization plants by the utility industry. The advantages of the HIPing process are becoming more important as interest in structural ceramics (e.g., Si_3N_4) grows.

Nonoxide ceramics can be HIPed to full density while keeping the grain size small and not using additives. Very high densities combined with small grain sizes (because of the relatively low temperatures) leads to products with special mechanical properties. HIPing has also been applied to the formation of piezoelectric ceramics—

FIGURE 23.8. Individual steps of milling, cold forming, sintering, and HIPing in the sinter plus HIPing process.

HIP & HIPING

Used initially for fabricating the cladding for nuclear fuel elements and was called “gas-pressure bonding.” We use the acronym HIP to identify the press and HIPing to identify the action. You will also see HIP used to mean HIPing and you will see HIPing spelt HIPping! We then say a sample has been HIPed rather than HIPped. Only nano is HYPed

e.g., BaTiO_3 , SrTiO_3 , lead zirconate titanate (PZT)—for use in acoustic wave filters and oscillators.

Uses: produces dense materials without growing the grains
Disadvantage: cost

23.8 SLIP CASTING

For slip casting, the slip is poured into a mold (usually plaster of Paris: $2\text{CaSO}_4 \cdot \text{H}_2\text{O}$) that has been made by casting around a model of the required shape, which was itself suitably enlarged to allow for shrinkage of the cast ceramic on drying and sintering. The fineness of the powder (in the slip) and the consequent high surface area ensure that electrostatic forces dominate gravity so that settling does not occur. The electrochemistry of the slip is quite complex: Na silicate (or soda ash) is added to the slip to deflocculate the particles. The water passes, via capillary action, into the porous plaster, leaving a layer of the solid on the wall of the mold. (We consider this model in Section 25.7.) Once a sufficient thickness has been cast, the surplus slip is poured out, and the mold and cast are allowed to dry. These steps are shown in Figure 23.9. This variant of slip casting, which is the most widely used, is also called *drain casting*. A very effective technique used by some potters is to produce a multilayer slip, parts of which are removed before firing.

Slip casting is a low-cost way to produce complex shapes. In the traditional pottery industry, it is the accepted method for the production of teapots, jugs, and figurines, although handmade items are likely to be hand-thrown. Large articles, such as wash-hand basins and other whitewares, are also mass-produced by slip casting. (Whitewares are not necessarily white.) One of the telltale signs of a ceramic product made by slip casting is that it is hollow. A variant of the slip casting process is solid casting.

FIGURE 23.7. Individual steps of milling, cold preforming, canning, HIPing, and stripping in the standard HIPing process.

FIGURE 23.9. Drain-casting process. (A) Fill mold with slip. Mold extracts liquid, forming compact along the mold's walls. (B) After excess slip is drained, the dried green ceramic is removed.

In solid casting, slip is continually added until a solid cast is made. These items will not be hollow—relatively, they will be heavier.

Slip casting is also used in the fabrication of some technical and structural ceramics. It is the standard method used to make alumina crucibles and has been successfully used to make complex structural ceramic components such as gas-turbine rotors. The technique of doctor-blading, which we discuss in Chapter 27, is just another method of shaping the slip—ensuring that the slip is spread as a uniform layer.

23.9 EXTRUSION

Extrusion involves forcing a deformable mass through a die orifice (e.g., toothpaste from a tube). The process is widely used to produce ceramic components having a

FIGURE 23.10. Extrusion of (A) a rod and (B) a tube.

uniform cross section and a large length-to-diameter ratio, such as ceramic tubes and rods, as illustrated in Figure 23.10. Clay with a suitable rheology for the extrusion process (essentially a paste) can be made by controlling the amount of water. Clay-free starting materials (e.g., Al_2O_3) are mixed with a viscous liquid such as polyvinyl alcohol or methylcellulose and water to produce a plastically deformable mass. Table 23.3 lists examples of compositions of extrusion bodies. Extrusion of polymers has been used since the 1860s; early on, it was used to process natural rubber. An extrusion press such as that shown in Figure 23.11 is standard equipment in the potter's barn.

Extrusion is also used to produce the alumina shells for sodium vapor lamps and the honeycomb-shaped catalyst supports for automotive emission-control devices (see Chapter 38). The catalyst supports are designed to give a high surface area; they can consist of hundreds of open cells per square centimeter and a wall thicknesses of $<100\ \mu\text{m}$. To produce these shapes, the cordierite ceramic powder is mixed with a hydraulic-setting polyurethane resin.

TABLE 23.3 Examples of Compositions of Extruded Bodies

Refractory alumina		High alumina		Electrical Porcelain	
	vol%		vol%		vol%
Alumina ($<20\ \mu\text{m}$)	50	Alumina ($<20\ \mu\text{m}$)	46	Quartz ($<44\ \mu\text{m}$)	16

FIGURE 23.11. Extruding clay. Manual and electric extruders.

The mix is extruded into a water bath at a rate that matches the rate of cure of the polyurethane (~2 mm/s). It is then fired to produce the final ceramic.

23.10 INJECTION MOLDING

Injection molding is another technique that is widely used in shaping thermoplastic polymers. A thermoplastic polymer is one that softens when heated and hardens when cooled. Such processes are totally reversible and may be repeated. Injection molding can be applied to shaping and forming ceramic components if the ceramic powder is added to a thermoplastic polymer. When forming ceramics by injection molding, the polymer is usually referred to as the binder (but we could instead have called the material a ceramic-loaded polymer). The ceramic powder is added to the binder and usually mixed with several other organic materials to provide a mass that has the desired rheological properties. Table 23.4 shows the additives that have been used to form SiC shapes by injection molding. The organic part of the mix accounts for about 40 vol%.

The plastic mass is first heated, at which point the thermoplastic polymer becomes soft; and then it is forced into a mold cavity, as shown in Figure 23.12. The heated mixture is very fluid and is not self-supporting (this is different from the situation encountered in extrusion). The mixture is allowed to cool in the mold, during which time the thermoplastic polymer hardens. Because of the large volume fraction of organic material used in the mixture, there is a high degree of shrinkage of injection-molded components during sintering. Shrinkage of 15–20% is typical, so precise control of component dimensions is difficult. However, complex shapes are retained with very little distortion during sintering because the densities, though low, are uniform.

Injection molding is used to fabricate ceramic components with complex shapes; and because cycle

TABLE 23.4 Additives for Injection Molding of SiC

Function	Example	Quantity (wt%)	Volatilization temperature (°C)
Thermoplastic resin	Ethyl cellulose	9–17	200–400
	Polyethylene		
	Polyethylene glycol		
Wax or high-temperature volatilizing oil	Paraffin	2.0–3.5	150–190
	Mineral oils		
Low-temperature volatilizing hydrocarbon or oil	Vegetable oils	4.5–8.5	50–150
	Animal oils		
	Vegetable oils		
Lubricant or mold release	Mineral oils	1–3	
	Fatty acids		
	Fatty alcohols

times can be rapid, injection molding can be a high-volume process. The major limitation is that the initial tooling costs of the mold can be quite high. The mold to fabricate an individual turbine blade can be >\$10,000 and a

mold for a turbine rotor >\$100,000, but such molds are reusable because they are never subjected to high temperatures.

23.11 RAPID PROTOTYPING

Rapid prototyping (RP), or solid free-form fabrication (SFF), is a relatively recent approach to forming ceramic components. There are various forms of RP techniques, but they are based on a common principle: a computer directly controls the shaping process by accessing computer-aided design (CAD) files. We can thus use RP to form a three-dimensional component without the use of a die or a mold. RP techniques are used commercially for fabrication of parts from polymers for design verification and form-and-fit applications; these techniques have more recently been applied to forming parts out of ceramics.

In this section we look at just two of the several RP methods.

Stereolithography (SLA)

Fused deposition modeling (FDM)

Both these methods have been successfully used to form ceramic components. The SLA process is illustrated in Figure 23.13. In SLA, the component is formed from an epoxy resin. As the z-stage elevator is lowered, an ultraviolet laser beam whose position is controlled by a computer cures successive layers of the uncured resin. In this way, a three-dimensional component is made, one layer at a time. It can take many hours to build a large complex object, but this is still rapid compared to the time taken to form a component by, for example, injection molding, where fabrication of the tools can take a considerable amount of

FIGURE 23.14. Fused deposition (FD) SFF process.

time. To form ceramic components by SLA, it is necessary that the polymer is loaded with ceramic powders. Si_3N_4 , SiO_2 , and Al_2O_3 powders have all been used for SLA.

In FDM, the source material is a thermoplastic polymer filament that is heated and extruded to form the product, as shown in Figure 23.14. The product is formed in a layer-by-layer manner, similar to building up layers of icing on a cake. The computer controls the x - y position of the filament and the deposition rate. The filament can be loaded with up to 60 vol% ceramic powders; once the part is completed, the binder is removed and the part is sintered. Most of the work in the RP of ceramic parts by FDM has involved Si_3N_4 . The feasibility of making components out of Al_2O_3 , SiO_2 , and PZT has also been demonstrated. The abbreviation FDC (fused deposition of ceramics) is used to identify this special application of FDM.

FIGURE 23.13. Stereolithography (SLA) solid free-form fabrication (SFF) process.

23.12 GREEN MACHINING

To obtain the desired shape of a ceramic product, it is often necessary to machine it. Machining can be performed either before or after the product has been sintered. If the machining is done before sintering, while the component is still in the green state, the process is called green machining. The advantages of green machining compared to machining the sintered product are that there is a considerable reduction ($10\times$) in machining time and a $20\times$ reduction in cost because of less tool wear and the possibility of using cheaper tools. Table 23.5 compares the use of different tool materials in the green machining of a Si compact before nitriding it to form Si_3N_4 .

In the processing of spark plug insulators, the final step prior to firing involves green machining, as shown earlier in Figure 23.5.

TABLE 23.5 Comparison of Cutting Speed Versus Tool Life for Selected Abrasives, Showing Cost-Effectiveness of Green Machining of a Presintered Silicon Compact in the Fabrication of Reaction-Bonded Si₃N₄

Tool material	Cutting speed (m/min)	Workpiece material removed (cm ³)	Relative cost factor
Cubic BN	30	8.2	×
Ti-coated carbide	30	13.1	×
Co-coated WC	30	19.7	×
Diamond	90	8,500	10×

23.13 BINDER BURNOUT

In pottery, the binder burnout is the removal of water from the shaped clay. The rest of the firing process causes structure changes and transformations in the silicate itself. Forming methods for engineering ceramics (e.g., injection molding) produce green bodies that can contain 30–50 vol% of organic binder. We generally want to remove this binder without cracking or distorting the ceramic compact. Binder burnout is one of the most likely stages to form defects in the processing of a ceramic: macroscopic defects, such as cracks and blisters, can be introduced at this stage; and they affect the mechanical strength and other properties. An additional complication is that the binder system used in fabricating many commercial ceramic parts often consists of several components. These components have different boiling points and decomposition temperatures.

The components with low boiling points (e.g., waxes) may be removed by evaporation at fairly low temperatures.

Oxidation or decomposition at higher temperatures removes components with high molecular weight.

For oxide ceramics, the binder can be oxidized to form H₂O, CO, and CO₂ when the green compact is heated in air. Binder burnout in air generally presents no problem. However, there are some situations where binder burnout in air can be a problem. An example is the use of poly(vinyl butyral) with Al₂O₃, where carbon residues can be as high as thousands of parts per million even after burnout in air at 700°C for 24 h. Nonoxide ceramics generally cannot be heated in oxidizing environments, and binder burnout in inert or reducing atmospheres is more difficult. Pyrolysis of many binders in these environments is not well understood, and most binders leave some carbonaceous residue that could be detrimental to the subsequent sintering stage.

The process of binder removal is kept slow to reduce the possibility of macrodefects being produced. Figure 23.15 shows a plot of a binder removal cycle. In this plot, a pressurized gas, called a *sweep gas*, has been passed over the part to help sweep away the vapor. The cycle time depends on the size of the part. Thin

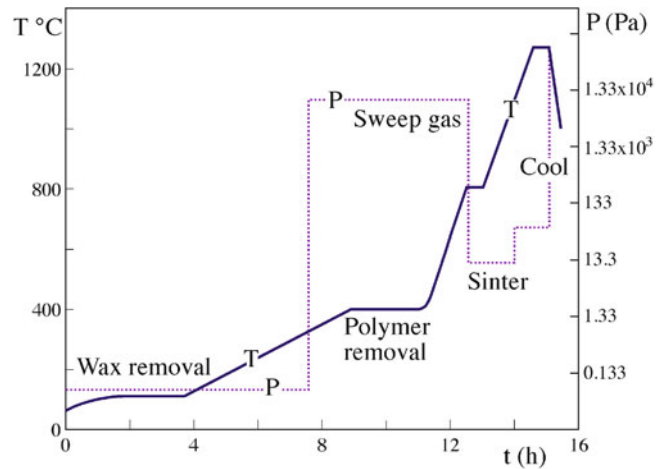

FIGURE 23.15. Pressure-induced binder removal cycle.

sections take much shorter times than thick sections. The *debinding* time is proportional to the square of the section thickness of the compact—the familiar parabolic kinetics seen in our discussion of reactions.

Binder burnout continues to be an active area of ceramics research, with one of the main thrusts being in developing models of binder decomposition and diffusion.

23.14 FINAL MACHINING

Ideally, the shaping and forming processes that are employed would produce the ceramic component in the desired shape with the specified dimensional tolerances and with an acceptable surface finish. However, in many cases, this is not the situation and some final machining (after firing/sintering) of the ceramic is necessary. Generally, final machining is required to:

- Meet dimensional tolerances
- Improve the surface finish
- Remove surface flaws

Machining fired ceramics can be expensive and can represent a significant fraction of the total fabrication costs. Ceramic materials are difficult to machine because they are hard and brittle. The tooling costs are high because diamond tools are likely to be required; or if conventional tools are used, the tool life is very short. Also, the time required to machine ceramics is long because high tensile loads cannot be applied to the ceramic part; otherwise, it may fracture.

Mechanical approaches to machining ceramics include:

- *Grinding* using tools where abrasive particles are embedded in a softer matrix such as glass, rubber, or polymer resin, or even a metal (as for WC in Co).
- *Lapping* using loose abrasive particles placed on a soft cloth.

FIGURE 23.16. Abrasive waterjet cutting process.

- *Sandblasting* using abrasive particles accelerated by compressed air and directed through a nozzle at high velocity.
- *Water-jet machining* using a high-pressure (~400 MPa pumping pressure) water jet to transport the abrasive particles to the ceramic surface.

The water-jet method is gaining popularity as a high-speed method for machining hard ceramics. Figure 23.16 shows the basic components of an abrasive water jet cutter. Cutting rates depend on the material being cut and can vary from 130 mm/min for glass to 5 mm/min for a dense hard ceramic such as TiB₂. In a waterjet, the water is pressurized to ~380 MPa and forced through a sapphire orifice at a velocity of up to ~750 m/s. In the abrasive jet, the speeds may be a little lower, but garnet powder is pulled into the water stream and acts as the abrasive to cut through, for example, 25 mm of Ti or steel. It can also cut through ceramics and glass. Dentists use the same technique when working on our teeth. The Grand Canyon was formed on a larger scale by essentially the same process. Masons use sandblasting to clean the surfaces of old stone buildings.

23.15 MAKING POROUS CERAMICS

In many traditional applications for ceramics, particularly in structural and electrical applications, the sintered ceramic component is required to have minimum porosity. However, in a growing number of applications (e.g., in

ceramic humidity and gas sensors), porosity is not just desirable, it is required. Several different methods can be used to produce porous structures.

- Use large particles with a very small size distribution to avoid dense packing.
- Underfire a green compact to leave a large amount of fine pores.
- Add organic particles (diameter >20 μm) to the powder mixture. When they burn out, they leave behind porosity. We use a controlled version of this technique elsewhere to produce mesoporous photonic materials.
- Use a binder system that contains a foaming agent and produces a large amount of gas bubbles in the mixture.
- Impregnate a foam that has continuous porosity, and then burn it out.
- Use a glass composition that phase-separates and then leaches out (e.g., using an acid) one of the phases to produce a porous glass.

Mesoporous materials, which have quite a uniform distribution and a very high density of pores, were discussed in Chapter 15.

23.16 SHAPING POTTERY

We stated at the beginning that this is the pottery chapter. We now summarize where many of the techniques described above have been used in pottery—in some cases for millennia. Then we can do the same for glass. Classical porcelain can be as thin as a sheet of paper (<0.2 mm). Bone china, so called because even today it is made by adding ~50% bone ash to a conventional hard-porcelain clay mixture, can be so thin that it is translucent. This ingredient is so critical that the United Kingdom imports bone ash from Argentina.

Paper clay is a relative new material for the potter, being a mixture of clay and paper in approximately equal amounts by volume. The paper (cellulose fiber) gives added strength to the green body, so it can even be made into a sheet that can then be cut and shaped before firing. The firing burns out the organics and leaves a ceramic body that is lighter than usual. Figure 23.17 shows a sheet of paper clay being lifted off the plaster “substrate” (see also Section 25.7). As you might guess, there are many variations on this process, which of course is related to the ancient use of straw in making house bricks.

Throwing a pot, as shown in Figure 23.18, is the process of producing hollow clay objects on a revolving pottery wheel. The potter may use her or his hands, as shown here, or other tools—the step to industry is then a small one.

Coiling, *pinching*, and *slabbing* are used to form large pottery objects. Their common feature is that the total

FIGURE 23.17. Removing paper clay from the substrate.

FIGURE 23.18. Throwing a pot.

thickness of the ceramic piece is kept constant so that the drying and firing process is even. *Wedging* is not a shaping process, although the end result is a slab of clay. Rather, the process is used to remove porosity from clay before it is used to make a pot. This is now carried out mechanically in a pug mill. If you pinch the clay or carve it, you can combine different colored clays and then shape and fire them to produce the *neriage* (marbled) style—the potters' version of *millefiori*.

23.17 SHAPING GLASS

Glass can be shaped using many different processes.

Casting or molding: examples are the 20-in. thick Palomar telescope mirror and sub-millimeter thick molded-glass aspheric lenses that are used in everything from laser printers to optical disk storage devices and optical communications systems.

Pressing needs a mold that is gray cast iron (to 1,000°C), stainless steel (can use for borosilicates at 1,185°C and glass ceramics at 1,480°C), or even bronze. Usually, though, the mold is cooled. The process uses a viscosity of ~4 kP and has been applied to objects weighing 5 g to 15 kg. The finished object can be fire-polished. This process, shown in Figure 23.19, is quite similar to the HIPing technique shown in Figure 23.2 and predates it, of course.

Sagging or slumping is a simple method whereby the glass is heated, so that it “slumps” into the mold. The technique can also be used for clay; effectively, it is pressing, with gravity providing half the press.

Glass blowing was clearly in use in the first century BCE. The temperature is critical as it determines the working range. There are other factors as well, such as the air pressure, the role of gravity and the centrifugal force produced by the blower. The craftsman produces free-blown objects or can blow the glass inside a mold. When a ribbon or hub machine is used, the glass is invariably blown into a mold.

Drawing is used for glass tubes and sheets. For tubes, the variations are Danner (e.g., tubes for fluorescent lights), Vello (large-diameter tubes), downdrawn tubes (used for vacuum tubes or uses a vacuum), and updrawn tubes (for glass thermometers). Sheets are drawn in the same way: using a slot orifice, with an overflow pipe, using updraw or floating.

FIGURE 23.19. Automated pressing glass.

Spinning is used for fibers and is very reminiscent of the beginnings of industry (the spinning jenny).

Rolling is an old technique that is still in use. It is similar to slabbing in pottery.

The *lost wax process* of forming glass shapes has been used since the fifth century CE to make glass shapes. Originally, the molten glass was poured into an outer mold made of beeswax, which could easily be removed.

Inlays in glass, such as sandwiched-gold glass—gold leaf is pressed between two layers of glass—was made perhaps as early as ~250 BCE.

Final *machining* is done using Vycor (the “cor” is from Corning), Macor, or similar specially treated glasses. (Vycor contains “built-in” pores; Macor contains small grains of mica).

Core forming was one of the earliest methods used to shape glass (see Figure 21.2) A shape was fashioned in clay, and the glass was then trailed around the core until it completely covered it. It could be heated further so that the coils fused together. When cool, the clay core would be removed, leaving a stand-alone glass vessel.

CHAPTER SUMMARY

In this chapter, we described the methods used to shape and form ceramic components. There are a number of possible choices, and the best one depends on the shape being produced, the cost of the component, and the number of units being made. For predominantly covalently bonded ceramics, it is necessary to use shaping techniques that involve the application of pressure and heat if the objective is to obtain a high-purity material. Because ceramics can't be softened in the same way as polymers and metals, it is often necessary to form a plastic mixture of the ceramic prior to shaping. These methods may leave a large amount of organic residue that must be removed during sintering. Binder removal is tricky because it can lead to the formation of voids and cracks in the ceramic component. Machining of ceramics is often performed when they are in the green state—before sintering. This is because the presintered component is much softer, and tooling costs are significantly reduced. A relatively recent approach to forming ceramic components is rapid prototyping. The advantage of this technique is that three-dimensional parts can be made without using a die or a mold. The technique has been well established for producing parts made of polymeric materials and is now being extensively investigated for forming ceramic components.

PEOPLE AND HISTORY

Brown, Robert was the Scottish botanist (1773–1858) who, among other activities, studied the movement of particles (pollen and inorganic) in water and thus recognized Brownian motion.

Champion, Albert founded two companies: Champion and AC Spark Plug. In the 1990s, between them they produced over one-half of the world's spark plugs. McDougal (1949) gave a review of these two companies.

Hamada, Shoji (1892–1978) was born in Tokyo. His home and pottery are in Mashiko, which is a ceramics town just a short drive north of Tsukuba.

Kawai, Kanjiro (1890–1966) lived in Kyoto in a house that is now another wonderful museum.

Leach, Bernard Howell (1887–1979) is probably the best-known British potter. He was born in Hong Kong and worked in Japan (with Shoji Hamada) and at St. Ives in England.

Spode, Josiah (1733–1797) founded his pottery in 1770 at Stoke. He developed the formula for bone china that is still used.

Tomimoto, Kenkichi (1795–1835) was born and raised in Japan and helped make style part of everyday Japanese pottery.

Wedgwood, Josiah (1730–1792) was born in Burslem, Staffordshire. He joined the firm of Thomas Wheildon at Fenton, who gave him the freedom to experiment. He then founded a factory in Etruria with his business partner Thomas Bentley. Elected a Fellow of the Royal Society for inventing the pyrometer, he used the fact that porcelain shrinks in the furnace to measure the temperature of the furnace. His daughter, Susannah, had a son, Charles Darwin.

Yanagi, Soetsu (1889–1961) created the mingei (folk art) movement in Japan in the 1920s; this movement has influenced much of Japan's stunning pottery.

EXERCISES

- 23.1 Explain briefly why melting and solidification can be used for shaping glasses (as well as many metals and polymers) but, in general, not for forming crystalline ceramics.

- 23.2 Briefly describe the differences between hot pressing and cold pressing.
- 23.3 Explain why hot pressing is often used when ceramics with a small grain size are required. For what applications must grain growth be minimized?
- 23.4 Why are graphite dies widely used for hot pressing? Under what conditions would the use of graphite not be appropriate?
- 23.5 Which method would you choose to form each of the following shapes: (a) a cylinder; (b) a tube; (c) a cube; (d) a teapot; (e) a rotor blade; (f) a spark plug insulator; (g) an insulator for a power cable? Briefly justify your choice.
- 23.6 Why is it necessary to use an organic binder when forming a ceramic component by extrusion? What are the main requirements for the binder?
- 23.7 Why is it difficult to use injection molding for near net shape manufacturing?
- 23.8 Briefly explain why it is better to machine a ceramic component when it is in its green state rather than when it has been fired.
- 23.9 Keramika is a new company that wants to manufacture alumina furnace tubes, and they hire you as a consultant. You are asked to propose a process for the fabrication of such tubes. Give a general description of the process you would propose. Explain the roles of the different steps involved.
- 23.10 Porcelain figurines are manufactured worldwide in large quantities. In most cases, many figures are made with an identical shape. As you know, such figures are often hollow. Explain the process used to form such figures economically.
- 23.11 We say that shaping ceramics is an ancient art. How ancient is it for clay, porcelain, alumina, Si_3N_4 , and mullite? Do we use slips and slurries for any of these materials?
- 23.12 What is PMC?
- 23.13 A pharmaceutical company consults you about improving their manufacture of tablets. What concepts from this chapter would carry over and which would not?
- 23.14 Clays can be extruded. List as many other examples of extrusion as you can and summarize the mechanical properties of each material during extrusion. Can you use extrusion for crystalline ceramics?
- 23.15 Use the Internet or other sources to find the largest and smallest applications of extrusion for ceramics. Explain why this method is chosen for this application.
- 23.16 Critique the methods for making and shaping porous ceramics. What is the most porous natural and synthetic ceramic, and how do these porosities compare quantitatively?
- 23.17 What technical ceramics are made by a technique similar to that shown in Figure 23.17?
- 23.18 Glass blowing has been used for centuries. Estimate the pressure needed to blow a 12-in. spherical vase, explaining all your assumptions.
- 23.19 Drawing has been used for making glass tubes. We list some variations. Give a more complete list and describe the industrial facility needed for the thermometer tubing.
- 23.20 Ceramic capacitors and MCMs (multilayer chip modules) can use the same ceramics processing. List as many different ceramics as you can find that are processed in this way and explain what the processes have in common.

Sintering and Grain Growth

CHAPTER PREVIEW

Sintering is the process of transforming a powder into a solid body using heat. Why a whole chapter on sintering? Partly for historical reasons—it has traditionally been the principal method of processing ceramic bodies. Sintering is still the most important process in making bulk ceramics, but the process is not unique to ceramics. There is a large field known as “powder metallurgy” that considers many of the concepts and problems we address for ceramics. One of the reasons for processing metals by sintering is to control the grain size, which is precisely what we usually need to do in ceramics.

We can discuss the topic at different levels of complexity. The phenomenon is quite straightforward and involves deciding how best to pack particles (that are usually modeled as spheres), understanding the movement of grain boundaries (GBs), and knowing how the packing geometry and GB migration is affected by the need to balance surface tensions (interface energies). The quantitative analysis of the process is much more difficult because it involves transport of several different species with different chemical driving forces. In multiphase systems, quantitative analysis is not yet possible.

The other point to emphasize is that for many years the aim of sintering has been to make dense ceramics. The terms sintering and densification were used almost interchangeably. Today, there are many uses for porous ceramics, and these materials must also be sintered. The aim is then different, and the process must change accordingly. Most of the time we assume that the material we’re sintering is single phase, so we make some assumptions that aren’t necessarily valid for multiphase materials that also need to be sintered.

24.1 SINTERING PROCESS

The idea of sintering is to join particles together without melting them. We may, however, use an additive that does melt. The particles can be crystalline or amorphous: we can sinter glass marbles so long as we don’t melt them; of course, the particles need not be spheres. If we go to too high a temperature, the marbles also deform.

The problems involved in sintering can be appreciated by examining Figure 24.1. We often model sintering by packing together spheres of various sizes. If we use spheres of only one radius, then the maximum initial density would be 74%. You should note that Figure 24.1 is only an idealized two-dimensional picture of the packing of circles! The lower diagram shows you a partly disordered structure of the same size “spheres” so there is even more open space. If we fill this space with smaller spheres, we can achieve a much higher “density,” as you see in the adjacent region. Also keep in mind that the object is to produce a product like that shown in Figure 24.2, which is a sintered SiC radiant-heat U tube. The actual structure

of the sintered body looks something like that shown in Figure 24.3. The SiC particles involved in forming the tube in Figure 24.2 tend to be strongly faceted parallel to the close-packed planes: $\{111\}$ if cubic or (0001) if hexagonal.

Consider the logic of the sintering process.

- When crystalline powder particles join together, the junction is a GB.
- It’s likely that the solid body thus formed is not 100% dense, so it contains pores.
- Pores are a structural component of the solid body (see Chapter 15). Pores often behave like grains of a different material.
- Although sintering explicitly involves solid powder grains, a liquid may form if a component that has a low melting temperature is present. This is then known as liquid-phase sintering (LPS) (see Section 24.7). We must thus consider films, tubes, and droplets (or particles) of noncrystalline material. It may happen that there is no trace of the liquid when the sample is

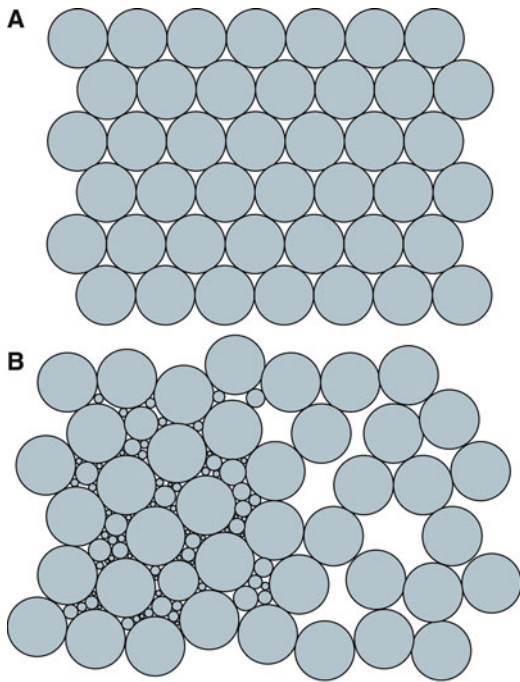

FIGURE 24.1. Model grain/shape distributions in two dimensions. Packing identical spheres can never achieve less than 26% porosity. (A) Ideal planar packing. (B) Less-dense packing of larger spheres, some with inserted smaller spheres giving a higher local density.

FIGURE 24.2. Radiant U tube produced by sintering SiC.

examined at room temperature after sintering; such a liquid is referred to as a transient phase.

- After and during sintering, some grains grow, consuming others. This process is known as grain growth and is essentially an Ostwald ripening process.

FIGURE 24.3. SiC processed with Al_2O_3 addition at $2,050^\circ\text{C}$; etched polished surface.

Note: the topic is often referred to as solid-state sintering. We have to be careful about making assumptions. It is often an implicit assumption in our analysis that all grains have the same composition. This chapter includes a real example of the packing of spheres (i.e., the formation of opal). (We also include the inverse opal).

- How do we maintain a porous structure? (Why do we want some materials to be porous?)
- How do we achieve full density?
- How do we maintain the shape of the green body?
- What changes in the analysis/process if the grains are not all the same composition?

We are often preoccupied with grain boundaries, but triple junctions may be even more important in the sintering process because they may be open pipes for transporting material. Part of the reason for this bias is that triple junctions are very difficult to study and to model (see Section 14.9). The topic of capillary forces was introduced in Section 13.6. This topic is extremely important in sintering when there is a liquid phase present. The overall “plan” of our discussion is shown in Figure 24.4.

24.2 TERMINOLOGY OF SINTERING

Because sintering is an ancient process, it has its own language, much of which preceded the scientific analysis.

Green bodies. All types of unfired ceramic.

Volatiles. During processing we may remove volatile materials; even though we think of sintering as a

FIGURE 24.4. Thinking about sintering—some of the concepts and processes.

solid-state phenomenon, the gas phase is important. The gaseous component may form as water, other solvents that are removed, or organics that undergo burnout.

Hot pressing is the addition of pressure (uniaxial or hydrostatic) while sintering. This is a large topic, so we address it again in a separate section.

Desintering is the reverse of sintering and may be associated with the reverse of densification.

A *monolithic* ceramic is a single-phase ceramic.

The importance of the shape of the particles before and during sintering is an extra complication. Corners and sharp junctions are difficult to treat in any continuum model of sintering.

24.3 CAPILLARY FORCES AND SURFACE FORCES

A curved surface always wants to become flat, as we discussed in Chapter 13. The result is that there is a pressure difference, ΔP , between the inside and the outside of a curved surface.

$$\Delta P = 2\gamma/r \quad (24.1)$$

where γ is the surface free energy, and r is the radius of the sphere. The radius of curvature r is positive or negative depending on whether the center of radius is inside or outside the material, respectively. Consequently, negative pressure is exerted on the concave surface.

We should remember that the principle that leads to equation 24.1 assumes that there is only one value of the surface energy; the surface energy is assumed to be isotropic. When the particle size of the powder is small, the

powder has a large surface area in comparison with a similar volume of bulk solid. We can say that a small particle, which is assumed to be a sphere, has surface properties that are different from those of a bulk solid because it has a large surface-to-volume ratio and because its surface has a small radius of curvature.

In sintering, we see the effect of this curvature first when grains (viewed as spheres) join together. This is the curvature of the initial particle surfaces. Then the GBs move: this is the same effect as for internal surfaces and leads to grain growth during sintering.

24.4 SINTERING SPHERES AND WIRES

Models in Sintering. We first summarize the steps that must occur during sintering and then consider simplified models that allow us to examine aspects of these different processes. The processes we need to examine are:

- How do two grains join together?
- How do we remove pores once they are formed (the essential step in densification)?
- Why do we want to densify the material?
- Why do some grains absorb others, and how does this occur?

After the ceramic has been shaped as a green body, it must be fired (often at very high temperatures) to develop useful properties. The sintering process has several distinct stages.

- We consolidate the product during firing.
- We remove the pores between the starting particles.
- The components shrink.
- Some grains grow while others shrink.

The simplest model is that of two spheres in two dimensions, shown in Figure 24.5. Notice that the two “spheres” can no longer be spherical if we have started to form the neck, as shown in Figure 24.5A. Notice also that in Figure 24.5B the centers of the two spheres must have moved toward one another. We know the starting situation and the end; the question is: what happens in the middle? We can even do the experiment of joining two such spheres, as shown in Figure 24.6 for the macroscopic case and in Figure 24.7 for the nearly nanoscale case. These schematics of the two spheres emphasizes some important points and omits others.

There are two radii to consider (x and ρ).

There is a GB between the two spheres if they are single crystals; if they are glass spheres, then there is no GB; if the spheres are polycrystalline, there are many GBs. There is always a GB groove where the GB meets a free surface.

FIGURE 24.5. Sintering and curvature. Two-sphere model showing the transport paths, the two curvatures (ρ and x), and the process leading to densification.

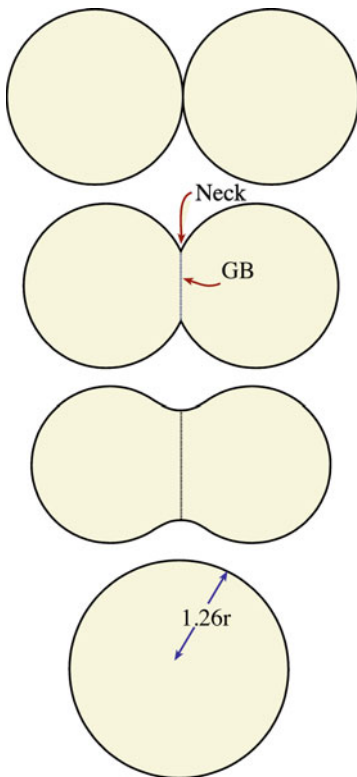

FIGURE 24.6. Coalescence of two spheres.

FIGURE 24.7. Transmission electron microscopy (TEM) image showing two Si spheres partly sintered.

TABLE 24.1 Mechanisms and Transport in Sintering (Diffusion to the Neck)

Mechanism	Transport path	Source
SD	Surface diffusion	Surface
VD	Volume diffusion	Surface
E-C	Evaporation-condensation	Surface
GB	GB diffusion	GB
VD	Volume diffusion	GB
PF	Plastic flow	Dislocations

Changes that occur during the firing process are related to (1) changes in grain size and shape, (2) changes in pore size and shape. Before firing, a powder compact is composed of individual grains and may contain as much as 60 vol% porosity. The amount of porosity depends on the size and size distribution of the powder particles and the shaping method (see Chapter 23). For maximizing properties such as compressive strength, translucency, and thermal conductivity, we want to eliminate as much of this porosity as possible (i.e., we want dense ceramics). This objective can be achieved during firing by the transfer of material from one part of the structure to another. There are several mechanisms for material transfer, and some of the processes are listed in Table 24.1. Note that sink and source refer to matter, not defects. As sintering progresses, the two spheres move together. This movement is the essential step in densification.

We can extend this analysis to three or more spheres, as shown in Figure 24.8, and then to three dimensions. With three spheres, we introduce another degree of freedom: the outer spheres can also move together until they form a pore. A model experiment that avoids this movement uses a wire wound on a reel and sintered; the experiment can, in principle, be adapted for ceramics but maybe using straight fibers.

FIGURE 24.8. Sintering three spheres, showing the diffusion paths from the grain boundary (GB) to the neck surface and the development of a pore [two-dimensional (2D) projection].

24.5 GRAIN GROWTH

For a grain structure to be in metastable equilibrium, the surface tensions must balance at every junction between the GBs. It is theoretically possible to construct a three-dimensional polycrystal in which the boundary tension forces balance at all faces and junctions; but in a real random polycrystalline aggregate, there are always going to be boundaries with a net curvature in one direction and thus curved triple junctions. Consequently, a random grain structure is inherently unstable; and on heating at high temperatures, the unbalanced forces cause the boundaries to migrate toward their center of curvature.

The effect of GB curvatures in *two dimensions* is shown in Figure 24.9. It has been assumed that equilibrium at each two-dimensional GB junction results in angles of 120° . Therefore, if a grain has six boundaries, they can be planar (i.e., flat) and the structure metastable. However, if the total number of boundaries around a grain is less than six, each boundary must concave inward. These grains therefore shrink and eventually disappear during sintering. Large grains, on the other hand, have more than six boundaries and grow. The free-energy change that gives rise to grain growth is the decrease in the surface area between the fine-grained material and the larger-grain-sized product and the corresponding lowering of the GB energy.

The effect of the pressure difference caused by a curved GB is to create a difference in free energy (ΔG) on two

FIGURE 24.9. Angles and grains. In two dimensions, the grains shrink if there are less than six sides and expand if there are more than six sides.

sides of the boundary; this is the driving force that makes the boundary move toward its center of curvature.

$$\Delta G = 2\gamma V/r \quad (24.2)$$

where V is the molar volume. We might expect that the rate at which the boundary moves is proportional to its curvature and to the rate at which the atoms can jump across the boundary.

24.6 SINTERING AND DIFFUSION

There is a most significant difference between the paths for matter transport, shown in Figure 24.8. Transfer of material into the “pore” must occur if the porosity of the compact is to shrink. You can imagine that in three dimensions this requires that matter transfer from the bulk of the grain, from the GB between particles, or from the outer surface by diffusion through the grain or through the GB. (Alternatively, you can think of vacancies moving out from the pores).

For the case of matter transport from the GB to the neck by lattice diffusion, we can derive an equation for the rate of growth of the neck area between particles.

$$x/r = (40\gamma a^3 D^*/kT)^{1/5} r^{-3/5} t^{1/5} \quad (24.3)$$

where a^3 is the volume of the diffusing vacancy, and D^* is the self-diffusion coefficient. In view of the approximations in the model, it's not worth learning this equation, but notice the terms involved.

FIGURE 24.10. Calculated densification curves at the final stage of sintering at 1,727°C for alumina powder compacts for grain sizes of 0.8 and 4.0 μm (B) at 90% density. The curves are calculated using different equations but show the same trends.

With diffusion, in addition to the increase in contact area between particles, particle centers move toward one another. We can derive an equation for the rate of this approach.

$$\begin{aligned} \Delta V/V_0 &= 3\Delta L/L_0 \\ &= 3(20\gamma a^3 D^* / \sqrt{2kT})^{2/5} r^{-6/5} t^{2/5} \end{aligned} \quad (24.4)$$

The decrease in densification rate gives rise to an apparent endpoint density if experiments are carried out for similar time periods, as shown in Figure 24.10. The same comments hold for the details (beware) and the suggested trends (good). It is seen that the sintering rate steadily decreases with time, so that merely sintering for longer periods of time to obtain improved properties is impractical. Once again, control of particle size is very important.

Consider how the curved GB in Figure 24.11 moves; the classical picture for the change in energy as an atom changes its position is shown in Figure 24.12, but the reality is clearly much more complex. This diagram is

FIGURE 24.11. Atomistic model for GB migration.

FIGURE 24.12. Activation barrier model for GB migration.

drawn to show the (100) surface of MgO. If the curved interface is actually normal to the plane of the figure, the GB is pure tilt in character. It is clear from this figure that not all the ions move in the same direction. If you select different ions in Figure 24.11, you can appreciate that some move to the right, and others may move at 90° to this direction. (This should remind you of atom motion during the glide of dislocations). Some ions cannot move until others have moved as a result of Coulomb interactions. The frequency of atomic jumps in the forward direction is given by

$$f_{AB} = v \exp(-\Delta G^*/RT) \quad (24.5)$$

The frequency of reverse jumps is given by:

$$f_{BA} = v \exp((-\Delta G^* + \Delta G)/RT) \quad (24.6)$$

For the net growth process:

$$U = \lambda(f_{BA} - f_{AB}) \quad (24.7)$$

where λ is the distance of each jump, and U is given by:

$$U = v\lambda[\gamma V/RT(1/r_1 + 1/r_2)] \exp \Delta S^*/R \exp(-\Delta H^*/RT) \quad (24.8)$$

The important result is that the rate of growth increases exponentially with temperature.

When considering ceramic sintering processes, you should always remember that the oxidation state of the cations may vary depending on the environment. For example, when CeO_2 is sintered at high temperatures, the Ce^{4+} may be partially reduced to Ce^{3+} , which can cause cracking in the compact. Such cracking, of course, changes the available diffusion paths.

24.7 LIQUID-PHASE SINTERING

Liquid-phase sintering (LPS) is the sintering of a powder in the presence of a liquid; the liquid generally solidifies below the sintering temperature. The details depend on the interfacial energies: is the liquid wetting or not? Either way, liquid may be present in the triple junctions (TJs), quadruple junctions (QJs), and GBs because it simply can't get to the external surface. If it can reach the outer surface, then we have another capillary geometry, as shown in Figure 24.13. As the sample cools after processing,

FIGURE 24.13. Liquid at surfaces.

the still-molten liquid can be drawn back into the grains because of differences in the thermal expansion coefficients. We then see liquid at the GBs in the image. We may also precipitate out crystalline material as the glass cools.

The densification of LPS materials takes place in three stages.

- The solid particles quickly rearrange when the liquid forms.
- Solute reprecipitation takes place if it is thermodynamically possible (if some solid can dissolve in the liquid).
- Microstructural coarsening occurs with slow solid-state sintering of the solid.

In the first stage, capillary forces play a major role as voids are removed from the body.

There are several points we should keep in mind.

- Glass may dissolve the matrix, which may reprecipitate elsewhere on the grains.
- Diffusion through the glass is almost always faster than through a structured GB.
- Crystal/glass interface energies *do* depend on the orientation of the interface.

Some of the difficulties include:

- The composition of the glass may not be uniform.
- When the layer is thin, it may be more appropriate to call it an absorption layer.
- The viscosity of glass changes with temperature.
- The composition of the glass in equilibrium with crystal changes with temperature.
- The viscosity of glass changes with changes in composition.
- The expansion coefficient of glass generally is not the same as for the crystal grains.

Examples of processing using LPS are given in Table 24.2. It's a useful exercise to identify the liquid in each case.

TABLE 24.2 Applications of Liquid-Phase Sintering

Material	Application
BaTiO ₃ /LiF/MgO	Capacitors
BaTiO ₃ /SiO ₂	Capacitors
Co/WC; TiC/Mo/Ni	Cutting tools
Fe/Al ₂ O ₃ /C	Friction materials
Al ₂ O ₃ /glass	Grinding materials

AlN/Y ₂ O ₃	Substrate
ZnO/Bi ₂ O ₃	Varistor

24.8 HOT PRESSING

We noted in Section 24.1 that we are able to sinter glass spheres so long as we don't melt them. This process is a special sintering situation because we don't form GBs. You can imagine that if we heat the spheres to a temperature below T_g , we can decrease the viscosity significantly and then apply a pressure so that the spheres plastically deform (change shape), thereby filling the empty space, especially if we did it in a vacuum. The deformation of the glass spheres occurs by viscous flow. (We see this again when discussing paté de verre in Section 26.14.) Exactly the same process happens if the particles are crystalline except that the deformation of the particles occurs by other mechanisms (movement of crystal-lattice defects); the precise deformation mechanism depends on the temperature of the treatment and the applied pressure. In this case, GBs are formed. Hot pressing allows us to produce material with very little porosity; and because the temperature is not taken too high, grain growth is minimized.

Hot forging is the application of a uniaxial stress while the sample is held at temperature. Discontinuous hot forging has been used to extract the temperature dependence of the so-called constitutive sintering parameters for alumina. This analysis showed for alumina that creep and densification during sintering are kinetic processes that are

both controlled by GB diffusion. Such studies of sintering are aimed at producing a set of constitutive parameters that allow the sintering behavior of materials to be predicted even if the shape of the body is complex or if materials are being co-sintered. These parameters include viscosity, a viscous Poisson's ratio, and the sintering stress. This stress is the driving force for sintering and results from the interfacial energies associated with pores and GBs. In this situation, the concept of viscosity is not taken to imply that the material is liquid but, rather, that the strain rate is linearly related to the strain rate of the free sample and, through a uniaxial viscosity, E_p , to the stresses in the material.

24.9 PINNING GRAIN BOUNDARIES

When grains grow to be so large that they are nearly the same size as the specimen in one or more dimensions, grain growth stops or becomes very slow. Similarly, inclusions increase the energy necessary for the movement of a GB and inhibit grain growth. If we consider a moving GB, the total interface energy is decreased when it reaches an inclusion, as shown in Figure 24.14A–D: the energy decrease is proportional to the cross-sectional area of the inclusion because we remove that much GB. (This assumes

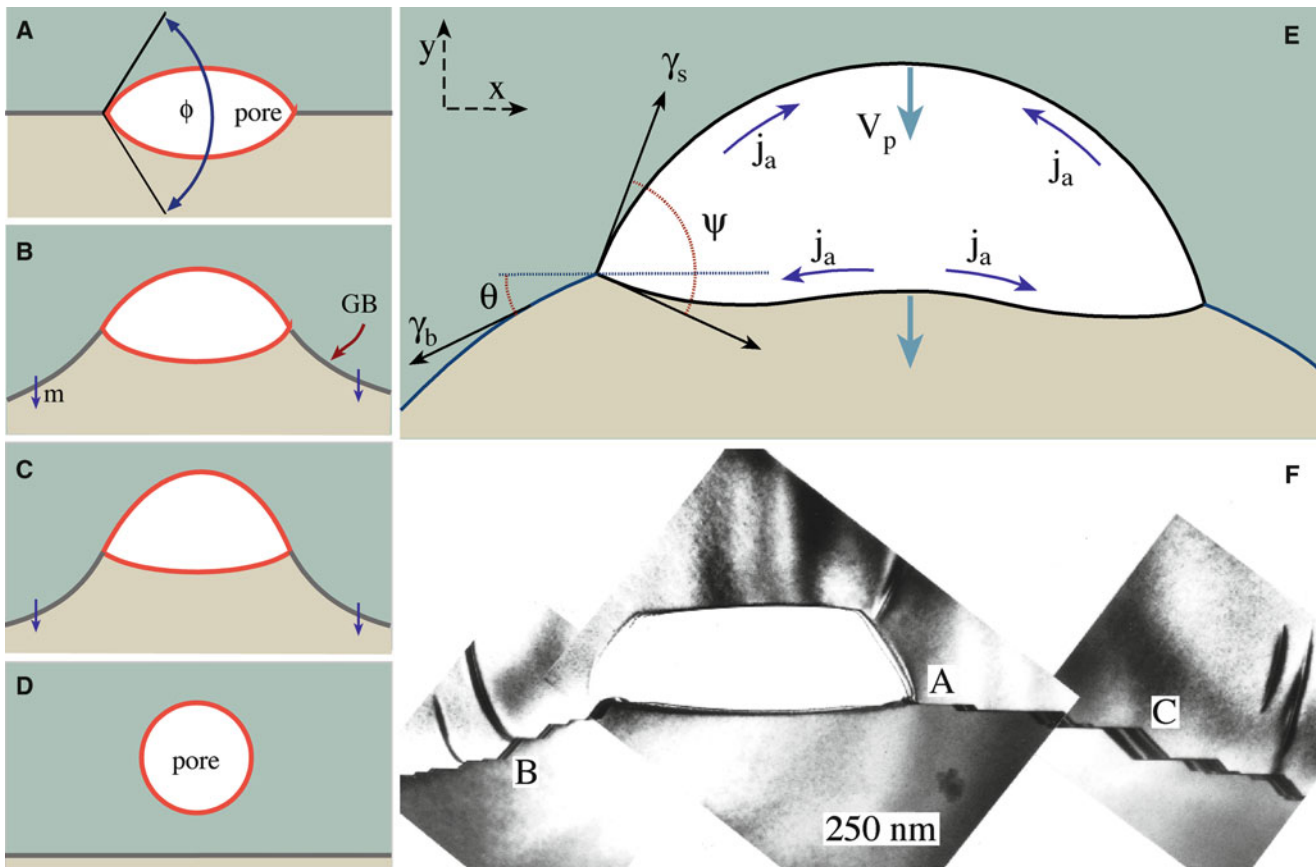

FIGURE 24.14. GB–pore interaction: the break-away process.

that the surface energies are the same, which you know is not necessarily true). The total energy must be increased again to pull the GB away from the inclusion.

Consequently, when a number of inclusions are present on a grain boundary, its normal curvature becomes insufficient for continued growth after some limiting size is reached. We can estimate this limiting grain size using a simple equation.

$$d_l \approx d_i / f_{di} \quad (24.9)$$

where d_i is the particle size of the inclusion, and f_{di} is the volume fraction of inclusions.

For the process shown in Figure 24.14A–D, the boundary approaches, becomes attached to, and subsequently breaks away from a pore; the diagrams have been drawn to encourage you to think about how the shape of the pore changes. Actually, the process is similar whether the obstacle is a pore or a particle; just the details of the interface differ. Figure 24.14E reminds us that the pore is probably faceted in a material such as alumina, although the details of the faceting may vary with temperature. Another possibility is that the grain boundary drags the obstacle, which remains attached to the boundary as it moves. If the obstacle is a particle, the second phase gradually becomes concentrated at boundary intersections and agglomerates into larger particles as grain growth proceeds.

Now, if we take TJs into account, the picture becomes more complicated, as shown in Figure 24.15: the TJ becomes the pinning defect.

In the next section, we consider what is really happening at the atomistic scale (i.e., dissolution and precipitation). Inhibition of grain growth by solid-phase inclusions has been observed for MgO additions to Al_2O_3 and for CaO additions to ThO_2 .

24.10 MORE GRAIN GROWTH

The classic idea is suggested in Figure 24.16: large grains grown, and small grain shrink. The direction of GB movement is always toward the center of curvature (which reduces the area of the interface). The idea behind this

FIGURE 24.15. Coalescence of three triple junctions due to grain shrinkage and the associated increase of material in the pocket.

schematic is to apply the principle of balancing interfacial tensions (illustrated in Figure 24.9) to a polycrystal. The problem is that the diagram is two-dimensional, so it can be misleading. Figure 24.17 makes the problem clear. The same area is shown before and after annealing; the dashed

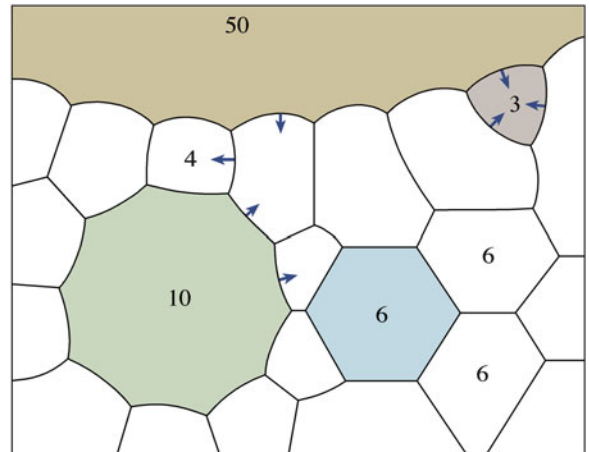

FIGURE 24.16. Growth of the largest grain.

FIGURE 24.17. Atomic force microscopy shows grooves at migrating GBs.

FIGURE 24.18. Side view schematic of “small grain” growing.

FIGURE 24.19. GB movement in a bicrystal, showing large- and small-scale faceting.

lines in Figure 24.17B show the original position of the GBs (from Figure 24.17A). The grain that is smallest in the original atomic force microscopy (AFM) image has grown. (Aside: look back at Figure 14.23 and then look again at the upper part of these two figures). Figure 24.18 gives the explanation for the growth of the smallest grain. This *small* grain is actually a *large* grain, but only part of it is seen at the polished surface. Thus, grains that appear to be large and many-sided can shrink, and others that appear to be small and have less than six sides can grow.

You can appreciate how GBs move from Figure 24.11. Matter is transported across the GB from one grain to the other. The example shown here is a curved $\langle 100 \rangle$ tilt boundary in MgO. On the atomic scale, the motion takes place by ions moving from one facet to the other as would occur for the GB shown in Figure 24.19. We know the direction of migration in this case because it is a bicrystal, and we can see the remnant groove. In Figure 24.11, these facets are only atomic in size but are clearly recognizable.

Some final points: moving MgO GBs have been observed in real time using transmission electron microscopy (TEM) with a heating holder going to $\sim 2,000^\circ\text{C}$. Diffusion-induced GB migration (DIGM) has been reported in ceramics. The difficulty is that all observations are made after cooling the specimen to room temperature. Diffusion along GBs (as opposed to across them) is an important process in sintering.

EBSD

Although we've always known that diffraction occurs in the SEM, EBSD is a relatively new technique, partly because of the experimental challenge of recording electron diffraction patterns that are noisy but image processing solves this problem. The power of the technique is that you can collect XEDS data at the same time so you have an image, the chemistry and the crystallography from the same area.

FIGURE 24.20. Scanning electron microscopy shows two electron-beam backscattering diffraction (EBSD) patterns from a series of engineered GBs in Al_2O_3 . The upper DP is from point X, and the lower DP is from the large grain on the left, showing the basal-twin relationship.

An image and two electron-beam backscattering diffraction (EBSD) patterns from Al_2O_3 are shown in Figure 24.20. One DP is from the large grain on the right, the other is from the point marked X. You can see that the two DPs are related by a mirror running down the middle of the page so that grain X and the large grain are basal-twin related. EBSD is able to determine the orientations of very large numbers of grains and thus to produce an orientation map. The value in grain growth studies is clear from this figure. The basal twin boundary has not moved. Even more importantly, most of the GB above it has not moved, although one facet has started to move, and this eventually moves the whole GB: the mobility of a GB depends on its orientation.

24.11 GRAIN BOUNDARIES, SURFACES, AND SINTERING

Crystallography is important in determining the geometry of surfaces, glass/crystal interfaces, and GBs. For example, at temperatures at least as high as $1,450^\circ\text{C}$, Al_2O_3 shows a strong tendency to facet parallel to the basal plane when heated in air, although the $\{11\bar{2}0\}$ and $\{10\bar{1}2\}$ planes are also favored. The presence of glass enhances this faceting because it increases the kinetics of the process. The crystallography of surfaces during sintering is clearly important in understanding the behavior of pores during this process.

Particles that are initially spherical facet when a powder is heated to the sintering temperature. Thus, again using alumina as the example, particles may join with their basal facets parallel to one another so that either a single crystal or twinned bicrystal may form ($\Sigma = 7, 13, 21,$ and 39 may also be favored). The twin interface is a low-energy grain boundary, and the bicrystal “grain” effectively has twice the volume of the initial particles; if the grains are slightly rotated away from the exact twin misorientation, secondary dislocations form in the resulting interface. Such an unusually large particle may initiate exaggerated grain growth. Twin boundaries are found in many large grains in sintered materials. This process can occur even for a high-angle grain boundary, such as the $\Sigma = 13$ boundary (rotate nearly 30° about the $[0001]$ axis); a high-resolution image of a $\Sigma = 13$ boundary—which was formed subsequently by hot-pressing together two crystals of Al_2O_3 —showed that the interface appears to very abrupt.

Several parameters are involved in determining whether or not special GBs form during sintering.

The kinetics of faceting

The crystallography and size of the surface steps

The crystallography of the facet planes

Because sintering of Al_2O_3 usually takes place at temperatures in excess of $1,600^\circ\text{C}$, such faceting almost certainly occurs both before and during sintering. At higher temperatures, roughening transitions may become important, but we have no observations on this process for ceramics.

24.12 EXAGGERATED GRAIN GROWTH

A primary requirement in many sintering processes is the need to control the grain size. In ceramics, we usually refer to secondary recrystallization as *discontinuous* or *exaggerated* grain growth. The process occurs when some small fraction of the grains grows to a large size, consuming the surrounding smaller grains. Once a grain grows to such a size that it has many more sides than the neighboring grains, the curvature of each side increases, and it grows more rapidly than the smaller grains with fewer sides (Figure 24.21).

Aside: classical *primary crystallization* is the nucleation and growth of new strain-free grains in a matrix of heavily deformed material. The driving force arises from the decrease in strain energy. There is an induction period as the system forms stable nuclei.

Secondary crystallization is particularly likely to occur when continuous grain growth is inhibited by the presence of impurities or pores. Under these conditions, the only boundaries able to move are those with a curvature much larger than average. Secondary recrystallization is common for titanate and ferrite ceramics, in which grain growth is frequently inhibited by minor amounts of second phases or by porosity during the sintering process. The result is that both the sintering of the ceramic and the

FIGURE 24.21. Elongated exaggerated grain in Al_2O_3 .

resultant properties change. Excessive grain growth is frequently detrimental to mechanical properties.

Modeling grain growth experimentally is illustrated in Figure 24.22. Such studies are an extension of the measurement of GB migration.

Ostwald ripening. The driving force is the reduction of total energy. The mechanism may require diffusion of one component through the other, as shown in Figure 24.23, which thus imposes an activation barrier.

An application in which secondary recrystallization has been useful is in the development of textured ceramics, where the preferred orientation is produced by seeding (more later). The magnetically hard ferrite, $\text{BaFe}_{12}\text{O}_{19}$, may be thus produced with large grain sizes. For this ferri-magnet, it is desirable to obtain a high density as well as a high degree of preferred orientation in the sintered product. Particles of the powdered material can be oriented to a

considerable extent by subjecting them to a high magnetic field while forming. On sintering, there was a 57% alignment after heating to $1,250^\circ\text{C}$. On further heating at $1,340^\circ\text{C}$, the preferred orientation increased to 93% alignment, corresponding to the structural change brought about by secondary recrystallization. It seems apparent that the few large grains in the starting material are more uniformly aligned than the fine surrounding material. These grains serve as nuclei for the secondary recrystallization process and give rise to a highly oriented final product.

24.13 FABRICATING COMPLEX SHAPES

We consider shaping in Chapter 23 but mention some features here. The method used depends on the material. Use either brute force or a plasticizer. The classic example is pottery—we mold the clay. Then, we have the alumina thermal conduction module (TCM), cordierite honeycombs, Si_3N_4 fishhooks, and carbide blades for kitchen knives.

The TCM process involves sintering as many as 40 layers of ceramic. Vias are drilled through the layers before firing (much easier and cheaper than after firing) but must still line up after sintering when each layer has shrunk considerably.

Changing the mechanism with liquids. A significant proportion of ceramic products used in low-temperature applications are predominantly crystalline materials containing a minor amount of a glass phase (as noted in Section 24.6); for example, alumina substrates used in the electronic packaging industry usually contain 96% Al_2O_3 and 4% silicate glass. The liquid phase may be a glass added to the crystalline ceramic compact or a mixture of oxides that become liquid at the sintering temperature.

Liquid-phase sintering occurs most readily when the liquid completely wets the surfaces of the solid particles at the sintering temperature. The liquid in the narrow channels results in the development of a substantial capillary pressure, as illustrated in Figure 24.13. For submicron sizes, capillaries with diameters in the range of $0.1\text{--}1.0\ \mu\text{m}$ develop pressures on the order of 7 MPa for silicate liquids.

The capillary pressure developed between the particles results in dissolution of material into the liquid and its subsequent precipitation elsewhere.

The degree of wetting depends on the relationship between the interfacial and grain boundary energies according to the relationship:

$$\cos \phi/2 = (1/2)(\gamma_{ss}/\gamma_{sl}) \quad (24.10)$$

where γ_{ss} is the GB energy, γ_{sl} is the interfacial energy, and ϕ is the dihedral angle, as illustrated earlier.

- When $\phi > 120^\circ$, the second phase forms as isolated pockets at the GBs.

FIGURE 24.22. Using a single-crystal sphere to model exaggerated grain growth in Al_2O_3 doped with 1 wt.% MgO at $1,800^\circ\text{C}$ for 60 min.

FIGURE 24.23. Ostwald ripening.

- When ϕ is 60–120°, the second phase partially penetrates along the GBs.
- When $\phi \text{ or } \sigma < 60^\circ$, the second phase is stable along the entire GB length, forming triangular prisms at the TJs.
- When $\phi = 0$, the grains are completely separated by the second phase.

The resulting microstructure for each of these cases is shown in Figure 14.35. The LPS process is also important in forming dense powder compacts of nonoxide ceramics, such as the nitrides. In these ceramics, where the bonding is predominantly covalent, atomic mobility is limited and sintering to high density is difficult in the absence of a liquid phase or without the application of high pressure.

An example of such a system is AlN, which is important as a substrate material for electronic packaging applications because of its high thermal conductivity. Its ability to remove heat from a mounted device is decreased if oxide is present in the GBs. It is made commercially by sintering AlN powder and Y_2O_3 at temperatures $>1,800^\circ\text{C}$. The Y_2O_3 reacts at high temperature with the oxide coating on the AlN grains to form a liquid phase. On cooling, the liquid phase crystallizes to form Y-Al oxides (particularly YAG). These phases are located mainly at triple points.

24.14 POTTERY

As ceramic studies began with pottery, we should consider how sintering relates to pottery. In pottery, the green body is the clay pot before it is fired; in this state, it can easily be shaped. The binder is generally water. A slurry or slip is prepared by adding just enough water to the clay that the viscosity of the green body is low. Some pots are given a low-temperature (biscuit or bisque) firing to remove the water and binder and to give the pot some mechanical strength so that it can then be glazed and fired to a higher temperature to give the final ceramic body. The processes occurring during the firing a pot are much more complex than sintering alumina, for example, because phase transformations occur simultaneously with the sintering. One important process that occurs is the formation of glass in the silicate body, which allows sufficient mobility for the surface tension to consolidate the article and thus reduce porosity. Shrinkage at this stage can be 40%. The same liquid-forming process occurs externally in the formation of salt glazes as we saw elsewhere; in this case, the NaCl reacts with the silicate to produce a low-viscosity glass—the glaze.

24.15 PORES AND POROUS CERAMICS

The challenge in sintering porous ceramics is the need to avoid densification rather than attain it. Figure 24.24 shows a rather uniform distribution of pores in a sintered

FIGURE 24.24. Pores trapped in grains.

body. Many of these pores have become isolated within the grains, so that further reduction in their size requires lattice diffusion unless another GB migrates and intersects them during further processing.

Pillared interlayered clays (PILCs) are a special group of porous ceramics. We saw in Chapter 7 that clays are layered materials. The idea behind PILCs is to intercalate a large polyoxocation between the silicate sheets, forcing the sheets to separate, and then converting these large particles into large metal-oxide clusters by heating to cause dehydration and dehydroxylation. Although some processes involve heating to only 400°C (not too high), some of the PILCs are stable to $>700^\circ\text{C}$. The metal-oxide clusters are then called pillars and permanently hold the clay layers apart. The interlayer spacing is still small due to the size of the molecules, and the new material has a microporous structure. The intercalation process is also known as a cation exchange reaction, but we don't need to exchange anything; we can intercalate Na between the layers of graphite or MoSi_2 , for example. The most studied process uses montmorillonite, but mica, vermiculite, and other layered materials have also been examined. The polycation $\text{Al}_{13}\text{O}_4(\text{OH})_{24}(\text{H}_2\text{O})_{12}$ (known as Al_{13}) is widely used, and the resulting materials are then referred to as Al-pillared clays. Today, a wide range of cations can be incorporated into the pillars. These PILCs are used as catalyst supports; the active metal is intercalated between the widely spaced sheets, giving an extremely high surface area. By changing the active cation, many different reactions involving organic-compound conversion can be catalyzed. The idea of pillaring has been extended to layered titanates, for example; in principle, any layered material can be used. Although these materials are primarily used in catalysis at present, they are also potential hosts for storing waste materials.

The International Union of Pure and Applied Chemistry (IUPAC) definition of porous describes three ranges of pore size: microporous (<2 nm), mesoporous (2–50 nm), macroporous (>50 nm). In 1992, a new porous material—similar in many ways to the natural zeolites and known as MCM-41—was patented; the name stands for Mobil Composition of Matter No. 41. Actually, this is just one of a family of mesoporous molecular sieves known as M41S. It has a hexagonal array of mesopores, giving channels of 1.5–10.0 nm diameter and a surface area of up to 700 m²/g. The mechanism proposed for their formation is referred to as liquid-crystal templating (LCT), which is similar to one model proposed for the formation of natural zeolites. The idea is that we start with two phases and burn out one, leaving a porous medium. MCM-41 is essentially a honeycomb structure (it has hexagonal symmetry), but it could have been an ordered foam. Honeycombs and foams are two forms of cellular ceramics.

We can also make porous (cellular) ceramics by simply adding air to the green body before firing; this is exactly how nature produces pumice, of course, except the green body is molten glass. By analogy with pumice, a simple route is to add pores to a slurry. This is essentially the route taken to make MCM-41. Such materials may be referred to as reticulated ceramics—the result of a replication process. A completely different approach is to foam a liquid that contains the ceramic precursor (the approach used by nature to form pumice). We can use mechanical agitation, bubbling gas through the liquid, or generating the gas in the liquid. An example of a structure produced by this method is shown in Figure 24.25 (Compare to the pores in Chapter 15).

24.16 SINTERING WITH TWO AND THREE PHASES

What is new? There are two situations: (1) where reactions occur between the components, (2) where no reaction occurs. You can see from Figure 24.26 that this is related

FIGURE 24.25. Porous ceramic.

FIGURE 24.26. Multiphase ceramics. (A) Two phases. (B) Three phases.

FIGURE 24.27. Two-phase ceramics. As sintered (A) and heat-treated (B) at 1,600°C for 30 h. ZTA 30% (zirconia-toughened alumina with 30 vol% YSZ containing 10 mol% yttria).

to the tiling problem. In a two-dimensional cross-sectional view of a two-phase structure, you must see both GBs and phase boundaries (PBs). In Figure 24.26A, we have two phases. If the GBs in phase B move, we can generate a microstructure of isolation grains of phase A inside a single-crystal matrix of phase B. (Phase A could, for example, be porosity). A three-phase system could, in principle, contain only PBs with no GBs (or the GBs could disappear by “local” grain growth inside that particular phase). The grains of the three phases shown here cannot grow unless we have diffusion of material A along the interface between phases B and C, for example. As was the case in Figure 24.16, the situation in three dimensions would be more complex, with more connections and the likelihood of percolation phenomena.

Two images of a two-phase material are shown in Figure 24.27. The material is ZTA30% (zirconia-toughened

alumina with 30 vol% yttria-stabilized zirconia (YSZ), which contains 10 mol% yttria). The smaller grains are in the as-sintered material; the larger grains are after heat-treating at 1,600°C for 30 h. In both cases, the microstructure closely resembles Figure 24.26A, showing that the phases remain dispersed after a long anneal. You can imagine the three-phase situation if we add a nonreaction metal (e.g., Nb) to the two oxide phases. The result would be a cermet (ceramic–metal composite); a type of composite material that is widely used in different compositions. You can see how the materials can quickly become complicated. The only requirement is that the different phases are not reacting. One phase could be a glass (or even a polymer), in which case we needn't worry about GBs in that phase.

24.17 EXAMPLES OF SINTERING IN ACTION

Some of these examples of sintering in action are discussed in detail elsewhere in the text. Here we are concerned with why should we use the sintering process.

Alumina lamp envelopes. Why do we use translucent polycrystalline alumina rather than single-crystal alumina, which is transparent? Why use alumina and not yttria for this application? (The yttria would allow the lamp to operate at higher temperatures, producing a whiter light). The answer in both cases is the cost; both are technologically possible. The alumina envelope is particularly interesting because of the use of MgO to limit grain growth.

Templated growth of materials such as BaTiO₃ presents an attractive route to producing a textured ceramic. Templated grain growth of alumina was discussed above. The principle involved here is the use of a seed to initiate exaggerated grain growth.

Nanomaterials are very reactive, which means that we can usually sinter nanoparticles at temperatures that are much lower than for conventional powders. However, they are also reactive when you don't want them to be. In this case, we can coat the nanoparticles to induce a repulsion or simply to physically prevent them from joining.

Materials are bonded together during packaging in integrated circuit (IC) fabrication using several different technologies, such as *anodic bonding*, *Si-fusion bonding*, *surface-activated bonding*, and *intermediate-thin-film bonding*. In each scheme, heat is applied to sinter two surfaces together. Diffusion bonding of Si wafers may require very little diffusion if the wafers are nearly atomically flat. We can improve the bonding by applying a voltage; this is the anodic bonding process and is used to join Si to SiO₂.

Millefiore paperweights are essentially formed using sintering. The individual canes of glass are bonded together in a glass matrix: the essential point is that the canes do not melt.

24.18 COMPUTER MODELING

Sintering can be modeled in many different ways. One particularly interesting approach is to use Surface Evolver to model how the shape of spheres change when they are placed in contact. In the calculation, which can in principle be extended to many more contacting spheres, the surface is allowed to move with a velocity that depends on the local curvature of the surface. At this time, the model assumes isotropic surface energies, and sintering occurs by an evaporation/condensation mechanism. The approach is illustrated in Figure 24.28A, which shows two spheres that have started to sinter together. The surface of the sphere on the right is represented as a triangular mesh; the triangles are essentially small facets of a particular surface orientation. The total surface area determines the surface energy since it is isotropic. Surface Evolver lets the surface change towards a minimum value under some constrained conditions and a GB, with energy proportional to its area, is included in the calculation. The gradient of the energy is a force that is then converted to give the velocity of the interface.

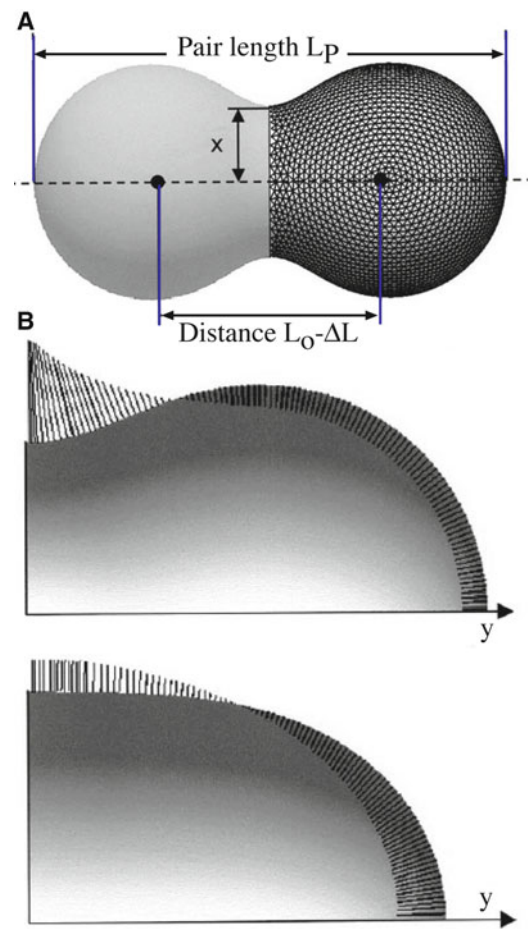

FIGURE 24.28. Modeling sintering using Surface Evolver.

The motion of the surface is some multiple of the velocity; this scale factor can then be regarded as the time step, which is used in determining the dynamics of motion. The GB energy and the surface energy are related in the usual way through Young's equation, so the calculation can be run for different GB-to-surface energy ratios, which influences the development of the neck geometry, as shown in Figure 24.28B.

Many other aspects of sintering are now becoming amenable to computer modeling. New understanding of the relative importance of the different stages of sintering and the different diffusion parameters will become more widely available in the near future. Indeed, most sintering models come from what has been termed the pre-“computer-simulation age.” Already new models are relating these different processes at the different stages.

CHAPTER SUMMARY

The fundamental feature of the sintering process is the joining together of two particles without either of them melting. This process can take place fully in the solid state, or there may be a liquid involved, as in the case of LPS. In fact, liquids in the form of a binder are common in commercial processes. In practice, the process may be even more complex because phase transformations may occur at the same time as sintering, and there may be more than one phase present. A full understanding of sintering makes use of everything we learned about GBs, grain growth, diffusion, and second phases in the form of pores. Computer modeling is beginning to be applied to sintering and should become more commonplace in the future.

PEOPLE AND HISTORY

Coble, Robert (Bob) L. (1928–1992) is best known for showing that small additions of MgO made it possible to form polycrystalline translucent alumina (Lucalox) while at the General Electric Research Laboratory in Schenectady, NY. He joined MIT in 1960. [More in the special alumina issue of *JACerS* 77(2), 1994.] He is also known for Coble creep.

Kingery, W. David (1926–2000). Awarded the Kyoto Prize in 1999, David Kingery put the *science* into *ceramic science* for two generations of ceramicists. His books, including those exploring the link between the (really) old ceramics and the new are always worth studying.

EXERCISES

- 24.1 You have sintered your ceramic at 1,800°C for 12 h and attained 95% theoretical density. You then continue to heat treat it for another 12 h at the same temperature but detect no change in density. Could the grain size of the material have changed?
- 24.2 You have two 1 μm diameter spheres of amorphous Si and two similar spheres of crystalline Si. You bring the two pairs of spheres into contact without any applied pressure and heat for 1 h at 1,000°C. Discuss all the differences you find when comparing the two pairs of dumbbells.
- 24.3 You place two spheres of crystalline MgO in contact without applying pressure. You find that each sphere experiences a stress due to contact with the other. Why is this so?
- 24.4 A sample consists of two slabs of TiO₂ separated by a 100- μm film of silica. The sample is heated to 1,500°C. What do you expect to occur? How would you make use of information on the Hamacker constant when discussing this material?
- 24.5 A translucent alumina is prepared commercially by adding up to 200 ppm of MgO before sintering at 1,800°C. This addition allows the alumina to be sintered to full density. Summarize the possible reasons for this effect and suggest an alternative additive.
- 24.6 What would be the advantages and disadvantages of making Na-vapor lamp envelopes using yttria instead of alumina?
- 24.7 You are given batches of powder of LiF, NaCl, and KCl; each has a grain size (grain diameter) of 100 nm. You cold isostatic press (CIP) each sample to 95% density and then sinter each at 1,100°C. After 5 h you remeasure the percent density. What results do you expect to see?
- 24.8 A glass contains pores that are 1 μm in diameter and are filled with N₂ at 0.8 atm pressure. If the surface tension of the glass is 28 Pa and the relative density is 0.85, what will the pore size be when the gas pressure just balances the pressure due to the surface tension? Repeat this calculation for pores that are 0.1 μm and 10 μm in diameter and discuss the changes.

- 24.9 In a sample of MgO held at 1,500°C, grains of MgO grew from 1 to 10 μm diameter in 1 h. If the grain boundary diffusion energy is 250 kJ/mol, what will the grain size be after 2 and 4 h? If the experiment were repeated at 1,600°C, how would these results change?
- 24.10 Imagine making a close-packed material by filling a container with 20 μm diameter glass spheres. You then heat this “material” for 12×10^3 s at 650°C, and the “material” shrinks by 5 vol%. You take an identical sample and find that the same shrinkage is achieved in 360 s at 700°C. Assuming that the surface energy of the glass is 0.3 J/m², calculate the viscosity of the glass at each temperature and deduce an activation energy.
- 24.11 By delving into the literature, explain the origin of the word “sinter.”
- 24.12 If sintering is a solid-state process, what is liquid-phase sintering?
- 24.13 Discuss this statement: “sintering small marbles is an ideal demonstration of sintering.” Also, compare this process with sintering sapphire spheres.
- 24.14 In the early days of yttrium barium copper oxide (YBCO), the green body was sometimes sintered until it changed from brown to black. Explain what this sentence is saying.
- 24.15 Show that r of the large sphere is 1.26 times larger than the r of the small spheres in Figure 24.6.
- 24.16 How many particles do we need to form a pore? Does the pore grow or shrink if we heat this geometry. Explain your answer.
- 24.17 Which way is the grain boundary moving in Figure 24.11? Do the small arrows agree with this conclusion?
- 24.18 In Figure 24.3, there are more particles than when we started. Is this reasonable? If so, why does it occur?
- 24.19 Redraw Figure 24.15 for the simplest three-dimensional (3D) case. How much does the glass/crystal interface area decrease when the pores coalesce?
- 24.20 Discuss how the grains grow in Figure 24.16 and find an example for each case in the recent literature. Reference your findings. Extend your argument to consider the 3D case.

Solid-State Phase Transformations and Reactions

CHAPTER PREVIEW

A phase transformation occurs when one material changes its composition or structure. The transformation can be caused by a change in temperature so that no other material is involved, or it may involve the reaction with another material, which may or may not be a ceramic and may be in the liquid or gaseous phase. In this chapter, we restrict the discussion to phase transformations where the ceramic is in the solid state. Whenever a phase transformation occurs, a phase boundary must move.

Phase transformations occur at interfaces and require the interface to move. A solid-state phase transformation occurs when the interface between two grains that are chemically or structurally different moves. If the grains are chemically the same but have different structures, the process is referred to as a (structural) phase transformation, and local atomic movements can induce the change; if the grains have a different chemistry, then long-range diffusion must occur and the process is most likely part of a solid-state reaction. Clearly, there are many features in common with grain growth where the grains are chemically and structurally the same. In particular, the ideas of curvature and capillarity carry over. This chapter thus builds on our discussion of all types of interfaces.

25.1 TRANSFORMATIONS AND REACTIONS: THE LINK

In Chapters 14 and 15, we discussed grain boundaries (GBs) and phase boundaries (PBs), respectively. Those two chapters described the interfaces and crystal defects. In Chapter 24, we then examined how the movement of GBs can lead to sintering, grain growth, and densification. In the present chapter, we examine how the movement of PBs leads to transformations and reactions. Some examples of reactions involving the movement of a PB are given in Table 25.1: not all of these are solid-state reactions.

How special is this topic for ceramics? These processes do occur in metal/semiconductor systems. In ceramics, solid-state reactions usually involve the movement of two species because the species are likely to be charged, and we must maintain electrical neutrality. The special feature in ceramics is therefore the movement of charge and the requirement for overall electrical neutrality. We can thus apply a voltage to the system and cause an electric or ionic current to flow. As in other systems, the slower-moving species controls the rate of the reaction.

The reason phase transformations are so important for ceramics is that ceramics are usually processed in the solid state. A major difficulty in studying these processes is that they usually occur at high temperatures.

We consider three types of phase transformation: (1) crystal \rightarrow crystal, (2) glass \rightarrow crystal, and (3) crystal \rightarrow amorphous. Transformations (1) and (2) are closely related to solidification from the melt and dissolution into a liquid. Solidification is a major theme in Chapter 29. The two topics to address are:

Do atoms move further than atomic distances?
Is charge transferred during the process?

We can put these questions another way: is the driving force due to a gradient in the chemical potential or in the electrochemical potential? It is important to remember that phase diagrams describe the equilibrium state. Phase transformations occur because the system is not in its equilibrium state. We can change P , T , or c and then examine how long it takes to reach equilibrium and how we can get there. Our main tool is our understanding of point defect mobility and diffusion. In general, we consider model systems but even then the data available are often not very good.

TABLE 25.1 Reactions by Phase Boundary Movement

System	Examples of special features and challenges
Calcination	Removing CO ₂ and other gases during firing
Dehydration	Removing water before and during firing
Gas/solid reactions	Vapor phase at high temperature: oxidation or corrosion
Hydration reactions	Cement; changes over long time periods
NiO/Al ₂ O ₃	Large structure change at one interface, less at the other
NiO/CoO	Need diffusion data; the Darken equation required
Precipitation	With control: glass-ceramics Lacking control: devitrification of glass
Transport through a fluid	Important for glass crystallization (e.g., after nucleation)
Vitrification	Phase separation in glass Pottery; salt glazes

25.2 TERMINOLOGY

As we described in Chapter 5, the polymorphic form of a material that has the lowest free energy is the most stable. The free energy, G , of each phase is given by the usual relation $G = E - TS$. At absolute zero, the entropy term (TS) is zero, and the phase with the lowest internal energy is most stable. However, at higher temperatures, other polymorphic forms can exist despite their higher internal energy because of the dominance of TS (see Figure 5.10).

- Polymorphic transformation: the chemistry is unchanged.

Polymorphic transformations can be classified in two general types, depending on the kind of changes occurring in the crystal. Displacive transformations, as the name suggests, involve displacements of the atoms only; there is no structural rearrangement. The displacive transformation that has been extensively studied in metals is the martensite transformation. Martensitic transformations are actually quite common in ceramics, but they are generally not as rapid as in metals even though they are transformations.

Reconstructive phase transformations are associated with high activation energies. The structural change involves breaking of bonds. The energy required is at least partly recovered when the new structure is formed. Reconstructive transformations are frequently sluggish, and consequently the high-temperature forms can often be cooled to room temperature without reverting to the thermodynamic stable form.

- Displacive transformations: atoms remain attached to the same neighbors.
- Reconstruction transformations: bonds are broken, and atoms are rearranged.

The driving force for reactions is either a chemical potential or an electrochemical potential. The electrochemical potential takes account of the fact that in ceramics we have charged defects, and these charged defects may move at different rates.

25.3 TECHNOLOGY

From a general technological viewpoint, not only are polycrystalline ceramics almost always very impure by metallurgical standards (3N, i.e., 99.9%, being typical high purity), but it is common practice to add other oxides to enhance densification during processing. If the concentration of the additives exceeds the solubility, a second phase may form. Remembering our discussion in Section 24.1, imagine sintering blue and yellow colored marbles. If the temperature stays low, the marbles remain distinct but deform and rearrange to form a dense material. If the temperature increases, the glasses may mix to give a uniform green glass, which in our analogy is the reacted material. So, whether or not a reaction takes place depends on such factors as the temperature; changes in the morphology of reactants can be affected by other considerations.

25.3.1 New Materials

Solid-state reactions are also used to produce new materials. For example, although equimolar Mg-Al spinel (i.e., MgAl₂O₄ or MgO·Al₂O₃) powder is available commercially, nonequimolar Mg-Al spinel powders may be less easy to obtain. (A similar processing method is used to produce many of the spinel-structured ferrites). These spinel powders may have useful properties because they can be used to produce polycrystalline compacts that deform more readily than the equimolar material. Such materials can be prepared by firing an intimate mixture of the equimolar spinel with high-purity alumina powder. A closely related process (structurally the opposite) occurs when γ -alumina is transformed to α -alumina, as takes place when alumina is prepared from boehmite.

Yttrium barium copper oxide (YBCO), (Sr,Ba)TiO₃, bismuth strontium calcium copper oxide (BSCCO), and lead zirconate titanate (PZT) are all essentially prepared by combining oxides or their precursors.

25.3.2 Multiphase Materials

There is a growing interest in the development of multiphase ceramics. Both the processing and the use of each of the materials described above may involve a solid-state reaction and the movement of a phase boundary. There are, of course, many other situations where solid-state reactions are important. In electronic packaging, chromium is first bonded to alumina; and the copper conduction lines are

FIGURE 25.1. Technical application 1. Monazite on alumina fibers as a barrier layer in a ceramic matrix composite.

FIGURE 25.2. Technical application 2. Yttrium barium copper oxide (YBCO) on yttria-stabilized zirconia (YSZ).

then, in turn, bonded to the chromium. It is likely that thin spinel layers are formed in the process. Ore reduction is another important example, as illustrated by the reduction of hematite to Fe via magnetite and wüstite. A special case is the reaction that can take place when fibers are encapsulated in a matrix to enhance mechanical properties of the matrix, as illustrated in Figure 25.1. If the fiber reacts with the matrix, the two are no longer able to deform independently, and the mechanical properties of the composite is degraded. For this reason, barrier layers may be used to coat the fibers before enclosing them in the matrix.

25.3.3 Growth of Thin Films

The first example of the growth of thin films, shown in Figure 25.2, occurred when YBCO was grown on a substrate of ZrO_2 . The intermediate layer grew by a solid-state reaction during the deposition. This can be a problem because complicated multilayer devices are needed for many new applications. The use of ferroelectric materials

FIGURE 25.3. Technical application 3. Thermal barrier coating on a metal with a reaction layer and a bonding layer.

almost always involves manufacturing multilayers. It is essential that the layers should not react with one another.

25.3.4 Changing Properties

We can add a second phase to modify the mechanical properties of a ceramic. An example that we discussed in Chapter 18 is the toughening of alumina using zirconia. In this application, again, the materials should not react (which is why zirconia is used).

25.3.5 Degrading Thermal Barrier Coatings

A model thermal barrier coating (TBC) is shown in Figure 25.3. The white band separates the Al-rich bond coat from the underlying Ni-rich superalloy. Capping the structure is the columnar yttria-stabilized zirconia (YSZ) TBC. The role of the bond coat, as its name implies, is to ensure that the coating continues to adhere to the metal during oxidation. Between the bond coat and the YSZ is an oxide layer that forms during oxidation (the overlayer or thermally grown oxide, or TGO). Between the bond coat and the superalloy is a thin reaction layer.

25.3.6 Impurity Phases

A well-known example of this process is the addition of MgO to alumina to permit sintering to theoretical density, as required for the production of translucent alumina tubing (see Section 24.17). If, in this example, MgO is added in excess of the solubility limit (~ 210 ppm is used; the actual solubility varies with temperature), spinel is formed, which may in turn react with Na during use to produce a precipitate of β''' -alumina. This reaction can cause the failure of sodium-vapor lamps. Because oxides are frequently processed at high temperatures, it is also likely that the vapor pressure can become appreciable for certain additive oxides.

FIGURE 25.4. Corrosion of YSZ by V_2O_5 vapor.

25.3.7 Corrosion of Oxides

Even sapphire and YSZ can be corroded at relatively low temperatures. Figure 25.4 shows polycrystalline YSZ being corroded by V_2O_5 vapor to form a reaction layer of YVO_4 . This process may actually be important when a burning fuel contains V and the TBC contains YSZ. The Y that is stabilizing the YSZ diffuses out to react with the V_2O_5 and form YVO_4 . The result is that the Y is no longer available to stabilize the ZrO_2 , which therefore undergoes a phase change and can fracture.

25.4 PHASE TRANSFORMATIONS WITHOUT CHANGING CHEMISTRY

Phase transformations are, of course, closely linked to phase diagrams; but remember that if a phase transformation is occurring, the system is not in equilibrium and the equilibrium phase diagram can be used only as a guide. Metastable phases may form during a reaction. The stability of a phase is determined by the relative value of G . Although the chemistry does not change, the redistribution of charge can be very significant, leading, for example, to the piezoelectric effect. Polymorphic transformations do not change the chemistry of the material. Because displacive transformations do not require a change in the first coordination of the atoms, there is no bond breaking, only bond bending. The distorted form is a derivative structure of the starting material, usually losing one or more symmetry elements. Displacive transformations to lower-temperature forms commonly result in twins. As we saw in Chapter 14, a crystal is twinned when one

FIGURE 25.5. Twins in transformed particles. (A) Experimental observation. (B) A possible mechanism.

portion of the lattice is a mirror image of the neighboring portion, the mirror being the twinning plane. This can lead to the formation of twinned “particles,” as shown in Figure 25.5A. You can get an idea of how this might occur by considering Figure 25.5B. The particle effectively contracts along its length by the $(001)_c$ planes, rotating to the $(001)_m$ planes of twin-variant 1 and back to the $(001)_m$ planes of twin-variant 2, so there is no long-range shear. Where $(001)_{m1}$ planes change to $(001)_{m2}$ planes, we form a twin boundary. Depending on the details of the crystallography (which planes match best), the twin boundaries may lie along the short (as here) or long axis.

A displacive transformation is diffusionless and requires only a shear of the parent structure to produce the new phase; consequently, the rate of transformation at any temperature occurs nearly instantly. An important example of the displacive transformation is the change from tetragonal to monoclinic ZrO_2 . In this example, there is a 5 vol% increase during cooling, which can result in internal stresses in the ceramic and lead to weakening or even fracture. However, the controlled transformation of ZrO_2 particles in a ceramic matrix (e.g., Al_2O_3) can be used as a means of strengthening of the matrix. (We discussed fracture of ceramic materials in Chapter 18). The addition of MgO , CaO , or Y_2O_3 to ZrO_2 can stabilize the cubic (fluorite) structure. When ZrO_2 transforms from the cubic to the tetragonal phase or from the tetragonal to the monoclinic phase, the volume changes. This volume change is

the key to using such mechanisms in toughening ceramics because it relaxes local stresses at a crack tip.

Barium titanate is cubic with the perovskite structure. However, at room temperature (actually below the Curie temperature of 120°C), it is tetragonal with a spontaneous electric polarization in the direction of the c-axis (only the higher temperatures form is shown in Figure 7.2). In this ferroelectric condition, a crystal of BaTiO₃ has a domain structure.

The classic example of a reconstructive phase transformation in ceramics is the transformation between the low and high forms of SiO₂: the distorted form of quartz structure is stable at the lower temperature. Twins are, again, often formed during reconstructive phase transformations when they lead to a decrease in symmetry because the change often occurs in symmetry-related ways; the twins are then related by the “lost” symmetry element.

25.5 PHASE TRANSFORMATIONS CHANGING CHEMISTRY

For short-range or long-range chemistry changes, it is necessary for ions to move. Atoms diffuse, and charge is transferred. If charge is moved, then an electric field may develop in the material or we can influence the transformation by applying an electric field. The structure may also change, so the beginning of the process (the nucleation stage) may be controlled by the difficulty in changing the structure. At a later stage, diffusion almost invariably controls such reactions.

The reaction can be considered as involving three steps.

1. Transport to the interface
2. Reaction at the interface
3. Transport away from interface of the product and heat

As usual, the slowest step controls the rate. The rate of such reactions is controlled by gradients in the chemical potential or, if there is a local variation in charge, by the electrochemical potential.

This concept is very important because the chemical potential and the electrical potential can act in opposite directions. There are many model and technological applications of this concept.

Silver sulfides provide a model system for studying this effect, partly because the processes occur at relatively low temperatures.

In oxides such as ZrO₂, flow of oxygen ions can be measured and related to the difference in oxygen partial pressure across the ZrO₂ layer because an electrochemical potential is generated.

In the formation of NiAl₂O₄ by solid-state reaction, we have diffusion of Al³⁺ ions and Ni²⁺ ions. If the Al³⁺

FIGURE 25.6. Movement of interfacial dislocations between hematite and NiFe₂O₄ spinel during oxidation, leading to thickening of the precipitate.

ion moves faster than the Ni²⁺ ion, then we would build up charge, which would create an electric field that in turn would act to reverse the flow of ions, rather than allow a buildup of charge. (More details are in Section 25.9).

25.5.1 Precipitation

Precipitation usually involves a change in local chemistry. Because we are creating a new particle, we form a new PB (see Chapter 15). As the particle grows, this PB moves. The balance between kinetics (of interface motion and diffusion) and energy (of the new bulk and the new PB) may determine the shape of the particle during growth. Three factors in particular must be considered.

1. Number of particles per unit volume
2. Shape of the particles
3. Size of the particles (and hence volume fraction of the precipitate)

As for metals, we can change the temperature or the chemical potential. Particles in ceramics have not been as widely used as in metals because we don't need to pin dislocations. However, particles can still inhibit GB motion, act as sinks for impurities, or modify mechanical properties. The widespread occurrence and usefulness of precipitation in ceramics is becoming more fully recognized. Things happen slowly in ceramics. If there is good alignment between the matrix and the precipitate, the transformation can occur by the movement of dislocations, as in Figure 25.6, which shows a plate of hematite growing in an Ni-Fe spinel matrix. Notice that the interfacial dislocations bow out in the direction of movement and that the plate thickens as they move.

FIGURE 25.7. Growing particle of spinel in a matrix of Fe-doped Al_2O_3 during internal reduction.

25.5.2 Internal Oxidation and Reduction

A thought experiment: imagine a 1-mm cube of Fe-doped Al_2O_3 where all the Fe is in the 3+ state. Now heat the cube in a reducing atmosphere at $\sim 1,500^\circ\text{C}$. The matrix is unchanged (it's Al_2O_3), but the Fe^{3+} is reduced to Fe^{2+} . Initially, this phase change can happen only at the surface, where the oxygen activity has been lowered; but then the “reduction” front moves into the cube like a PB (but there is no change in phase). The Fe^{2+} is no longer soluble in the matrix and precipitates out as FeAl_2O_4 spinel. The result is that we can see where the front has passed through by where the precipitates, such as that in Figure 25.7, have formed. (Notice the curvature of the dislocations, implying their direction of movement). The converse process (i.e., internal oxidation) can be demonstrated using a similar cube of Fe(II)-doped NiO.

25.6 METHODS FOR STUDYING KINETICS

We need to understand what controls the rate of a phase transformation. We can monitor both chemical and structural changes to address the sometimes subtle question: which change (chemistry or structure) occurs first? The answer depends on why the phase change itself occurs. The experimental techniques we use are those given in Chapter 10, so we just give some specific illustrations here. The classical approach used to study the kinetics of solid-state reactions between two ceramic oxides is to react a bulk diffusion couple in much the same way as, for example, when studying the Kirkendall effect in metals.

25.6.1 Using Weight Change

We can weigh the sample and plot the fraction that has reacted as a function of time, as illustrated in Figure 25.8. Today's microbalances allow us to make this technique

FIGURE 25.8. Reaction by weight, where f^2 is the square of the fraction reacted.

FIGURE 25.9. Particle of Ni-Al spinel growing on an Al_2O_3 thin film.

very sensitive. A modern microbalance can weigh samples up to 3.5 g with an accuracy of 0.1 μg . A quartz-crystal microbalance (QCM) can actually measure mass changes in the nanogram range. Therefore, we use a piezoelectric ceramic, a thin plate of quartz, to make the device that then allows us to study reactions in ceramics (and other materials).

25.6.2 Using VLM, the Microprobe, and SEM

The reacted microstructure is often best analyzed using low-voltage scanning electron microscopy (LVSEM) in the backscattered-electron (BSE) imaging mode. The low voltage means that we need only a thin conductive coating (if any) to prevent an insulator from charging. The BSE mode allows the phases present to be readily recognized because the backscatter coefficients are likely to be different for the reactants and the reaction product.

25.6.3 Using TEM

The movement of a particular PB is illustrated in Figure 25.9. A spinel particle has been grown on the edge

FIGURE 25.10. Rutherford backscattering spectrometry (RBS) of a reaction between NiO and Al₂O₃ substrates for different surface orientations.

of a thin film of Al₂O₃ by reacting the film with NiO vapor, looked at by transmission electron microscopy (TEM), replaced in the reaction chamber, and looked at again. You can see that the spinel has grown into Al₂O₃. In this case, the PB moves in the solid state, but the NiO is provided from the vapor phase. The spinel particle changes only when it grows into the sapphire.

25.6.4 Using RBS

Rutherford backscattering spectrometry (RBS) is very direct and measures the thickness of a reaction layer. The lateral resolution is the width of the ion beam (~0.1 μm). An example from a thin layer of NiO reacting with differently oriented surfaces of Al₂O₃ is illustrated in Figure 25.10. The thickness of the spinel is obtained by fitting the data to a simulated profile (using RUMP). It shows in this example that the rate of growth of the spinel layer does indeed depend on the orientation of the surface.

25.7 DIFFUSION THROUGH A LAYER: SLIP CASTING

We consider the kinetics of slip coating or slip casting for two reasons: (1) as a model for the transport of a reactant through a planar boundary layer, and (2) because it is a very important aspect of ceramic processing. The model actually applies to reduction, oxidation, and

HOW THIS PARABOLIC RELATIONSHIP ARISES

- J is proportional to $\frac{dx}{dt}$: J depends on velocity.
- J is also proportional to $\frac{1}{x}$: ΔP is the driving force.

So, $\frac{dx}{dt}$ is proportional to $\frac{1}{x}$: hence it is parabolic

When x is very small, $\frac{dx}{dt}$ is very large.

When x is very large $\frac{dx}{dt}$ is very small.

FIGURE 25.11. Slip drying to form a slip-cast layer.

MgO/Al₂O₃ reactions. In slip casting, a mold is made from gypsum (plaster of Paris: CaSO₄·2H₂O). Gypsum contains fine capillaries that remove water from a slip at a predictable rate. The clay particles in the slip are platelets, as shown in Figure 25.11, so a more compact layer forms as the water is removed. In the compacted cast layer, there are fewer capillaries, so it becomes more difficult to remove more water. Hence, as the thickness increases, the rate of material transported decreases.

We can write an expression for the flow (current) of atoms (the transport equation) as:

$$J = \frac{KdP}{dx} \quad (25.1)$$

where dP/dx is the water pressure gradient, and K is the permeation coefficient, which depends on the particle size, viscosity, and temperature. The pressure at the surface of the slip, P_{slip} , is 1 atm. The pressure at the slip/mold interface (B), P_{mold} , is determined by the surface tension in the capillaries (which are assumed to have a fixed radius r_c).

$$\begin{aligned} \Delta P &= P_s - P_m \\ &= \frac{2\gamma}{r_c} \end{aligned} \quad (25.2)$$

The flux can also be expressed as a volume (proportional to ρ^{-1}) multiplied by the velocity of the slip/layer interface.

$$J = \frac{1}{(\kappa\rho)} \frac{dx}{dt} \quad (25.3)$$

Combining equations 25.1–25.3 gives:

$$J = 1/(\kappa\rho) \frac{dx}{dt} = K \frac{dP}{dx} = -K \frac{\Delta P}{x} = -K \frac{2\gamma}{r_c x} \quad (25.4)$$

Then, by rearranging we get an expression for the interface velocity.

$$\frac{dx}{dt} = -K\kappa\rho \frac{2\gamma}{r_c x} \quad (25.5)$$

If we integrate, we find that x^2 is proportional to t , so the kinetics are parabolic.

A pot can be slip cast to a thickness of several millimeters in a few hours. The potter would then pour off the remaining slip, let the pot dry and shrink, and remove it from the mold, which can then be re-used.

25.8 DIFFUSION THROUGH A LAYER: SOLID-STATE REACTIONS

In solid-state reactions, the reactants are initially in contact and combine chemically to form the reaction product. The kinetics of the initial stage of such a reaction depends on the parameters of the interface (e.g., the crystallography of the contacting surfaces). The fundamental point is that we start with one interface and immediately create two new interfaces. We consider the example of NiO/Al₂O₃. Similar systems include MgO/Al₂O₃ and FeO/Fe₂O₃.

The mechanism for such reactions was proposed by Wagner to be the counter-diffusion of cations. It has been found that this mechanism does occur for purely ionic materials. Counter-diffusion of cations in ionic systems is dictated by charge-balance considerations rather than cation mobilities. Thus, significant deviations from the predicted balance may occur when electronic carriers (i.e., electrons and holes) are present.

The initial position of the interface between the reactant oxides can be labeled by “inert” Pt markers or recognized by the presence of voids. Some early measurements were not in agreement with this model but may have suffered from the fact that inert markers can move even though they remain inert.

25.9 SPINEL-FORMING REACTION

The phase transformation at the Al₂O₃/spinel PB involves both a change in the distribution of cations and a change in the structure of the oxygen sublattice. At the spinel/NiO interface, the oxygen sublattice remains cubic, although misfit dislocations may be introduced. It is not possible to observe directly the movement of particular interfaces using bulk samples. Techniques are used that allow the actual movement of individual interfaces to be studied and the kinetics of the earliest stages of the reactions to be determined.

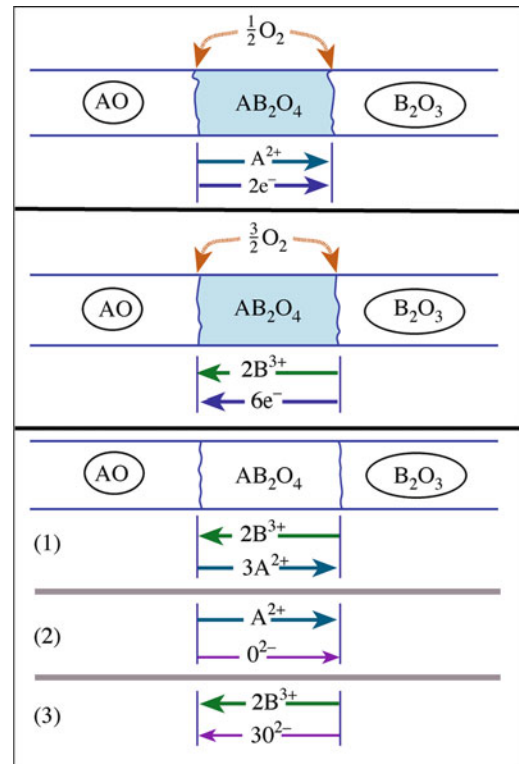

FIGURE 25.12. Mechanisms for the reaction between AO and B₂O₃.

When alumina and NiO react to form a layer, the equation is:

There are many possible reaction paths. The chosen path may depend on whether or not the reaction occurs in air. In all three cases, electrical neutrality is maintained.

The three main possibilities are:

1. 2B³⁺ ions move in one direction; electrons or O²⁻ ions move in the opposite direction.
2. 3A²⁺ ions move in one direction; electrons or O²⁻ ions move in the opposite direction.
3. 2B³⁺ move in one direction, and 3A²⁺ move in the opposite direction.

These processes are summarized in Figure 25.12. Mechanisms 1 and 2 require that O²⁻ diffuse, which may not be likely, or that electrons can move, which may be the case in semiconducting oxides unless it is prevented. The third mechanism is the counter-diffusion of cations, which avoids the buildup of electric charge but does not require O²⁻ ions or electrons to move: it is a purely ionic process. When thickness is plotted against time for the bulk reaction (Figure 25.13), the gradient of the straight line depends on the temperature, and we can directly determine a value for the diffusion coefficients.

We know that if there is a charge buildup we have an electrochemical potential, η_i , rather than the simple chemical potential, μ_i . These two potentials are related by taking account of ϕ , the electrical potential acting on this charge.

$$\eta_i = \mu_i + Z_i F \phi \quad (25.7)$$

where the subscript i refers to the i th species, which has an effective charge of Z_i ; and F is the Faraday constant. The current is the product of charge and velocity.

$$j_i = c_i v_i \quad (25.8)$$

Remember that velocity is mobility times force.

$$v_i = -B_i \cdot \text{Force} = -B_i \frac{1}{N} \frac{d\eta_i}{dx} \quad (25.9)$$

and

$$j_i = -\frac{c_i B_i}{N} \frac{\partial \eta_i}{\partial x} \quad (25.8)$$

We can then define a diffusion coefficient, D_i .

FIGURE 25.13. Kinetics of reaction between bulk NiO and bulk Al_2O_3 to form spinel.

$$D_i = -\frac{RTB_i}{N} \quad (25.10)$$

The parabolic rate law holds when the reaction layer is thick. When trying to be quantitative, there is the obvious question how do you “mark” the location of the original interface. An additional complication arises if AO and AB_2O_4 are both cubic but not lattice-matched; then misfit dislocations must be present at the interface, and they can move only if point defects on the O sublattice move.

25.10 INERT MARKERS AND REACTION BARRIERS

We saw examples of structures where reactions would destroy the device in Section 25.1 – this is where we need barriers. When we study the kinetics of reactions, we want to mark the initial location of the interface(s). This is where we need markers. In both cases, the requirement is that the barrier/marker be inert; that is, it should not participate in any reaction. This topic can be illustrated by two examples.

- Behavior of rows of Pt particles forming a marker layer
- Failure of a coating on a fiber during formation of a fiber-reinforced composite

We consider the example of diffusion couples prepared by depositing an In_2O_3 thin film on a cleaved bulk single-crystal substrate of MgO and identify the location of the initial interface by an array of Pt particles, as illustrated in Figure 25.14. The Pt particles are prepared by first sputter-coating the MgO substrate with a 2 nm thick continuous film of Pt. The Pt film/ MgO substrate couple is then heated to $1,175^\circ\text{C}$ for 5 min. This heat treatment causes the Pt film to dewet the MgO surface and thus form small islands. This array of small Pt particles then serves as the marker layer. After dewetting, thin films of MgIn_2O_4 and In_2O_3 can be deposited onto the decorated substrate using pulsed-laser deposition (PLD). This intermediate MgIn_2O_4 layer acts as the nucleation layer for the reaction product, so that the markers do not affect the initial nucleation of the spinel. (It can also be grown on the MgO before depositing the Pt).

Markers of various compositions and sizes have been used in numerous studies to track the movement of interfaces

FIGURE 25.14. Scanning electron microscopy (SEM) backscattered electron images of an as-deposited In_2O_3 film on MgO with Pt markers.

FIGURE 25.15. D as the composition varies. (A) Using tracer diffusion at two values of T in CoO-NiO mixed oxide. (B) Diffusivities for MgO-NiO mixed oxides.

in a wide variety of material systems. In many of these studies, the markers were intended to serve as a fixed reference point and were typically used to aid in determining which species were diffusing during a reaction process. In most cases when a material is used as a marker, it is assumed to be inert—the marker should neither affect nor be affected by the reaction process. Direct analysis of these thin-film diffusion couples can show directly whether or not the markers are inert and how they behave during such reactions. The markers may affect the reaction process, or the reaction process may cause the markers to move. The interface between the marker and the surrounding matrix plays a critical role in determining the inertness of the marker. This is especially significant when diffusion couples are reacted in an applied electric field.

The idea of a barrier layer is to prevent two materials that would react from coming into contact. Applications include protecting reinforcing fibers and separating layers in multi-layer thin films. Such barrier layers could also be used to exclude water from hydrophobic layers.

25.11 SIMPLIFIED DARKEN EQUATION

The diffusion coefficient actually depends on the composition. Consider NiO/CoO , which is a nearly ideal solid solution. The activity coefficient is ~ 1 .

$$\mu_i = \mu_i^0 + RT \ln c_i \quad (25.11)$$

We can write an “average” diffusion coefficient as:

$$\tilde{D} = D_{\text{Co}}^T x_{\text{Co}} + D_{\text{Ni}}^T (1 - x_{\text{Co}}) \quad (25.12)$$

In this equation, which is known as the Darken equation, x indicates the mole fraction of Co or of Ni. The equation assumes local equilibrium everywhere; and \tilde{D} is a chemical or interdiffusion coefficient in a chemical potential gradient. The matrix is $\text{Co}_x\text{Ni}_{1-x}\text{O}$. D is plotted as a function of concentration for both Ni and Co diffusing in the mixed oxide at 1,300 °C and 1,445 °C in Figure 25.15A. The mean value from equation 25.12 is plotted in Figure 25.15B. It can also be plotted as a function of temperature, as shown for many more oxide systems in Figure 25.16.

This analysis is useful—but be cautious. The oppositely charged point defects Ni^{3+} and V'' form an associated defect, which diffuses at a different rate. You can measure D , but modeling \tilde{D} is difficult. Essentially, predictions are tricky.

25.12 INCUBATION PERIOD

The initial stage of a solid-state reaction was historically referred to as the “incubation period.” Early studies of such reactions in oxides lacked the required spatial resolution, so measurements were not made until the reaction layer was

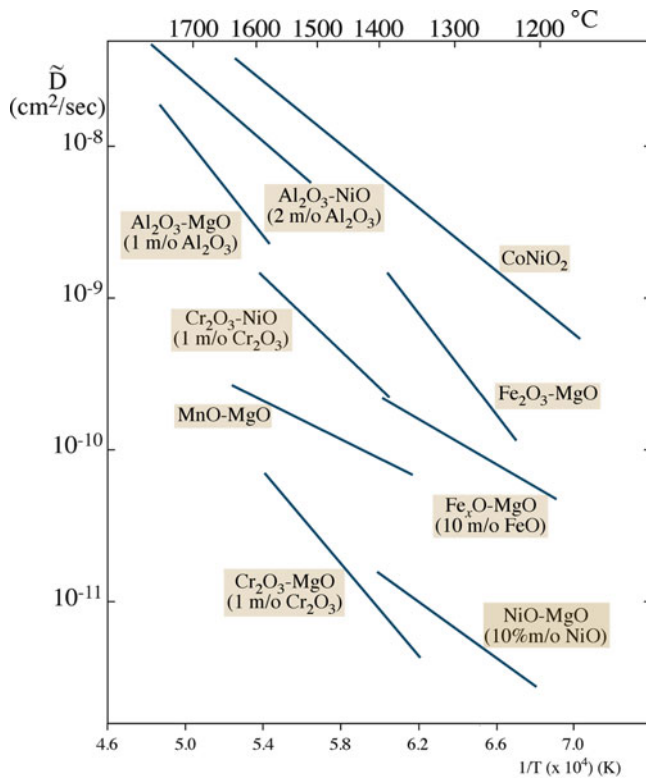

FIGURE 25.16. Dependence of diffusion coefficients on T for different oxides.

$\sim 1 \mu\text{m}$ thick (the resolution limit for chemical analysis in a microprobe operating at $\sim 30 \text{ kV}$). Often, the reactants were not initially in ideal contact. The nucleation of spinel or other reaction products can now be detected at a very early stage using TEM. The kinetics of such early stages of reactions are often controlled by the difficulty of nucleating the reaction product, which may indicate a crystallographic factor. Thus, for example, the basal plane in Al_2O_3 tends to dissolve less readily than, say, a prismatic plane; so reactions at basal planes tend to nucleate more slowly than on prismatic planes (more in Section 25.14).

25.13 PARTICLE GROWTH AND THE EFFECT OF MISFIT

The lattice misfit at moving PBs is accommodated by misfit dislocations, lattice rotations, etc. An important consideration is the role of size in determining these effects—neither misfit dislocations nor lattice rotations may be

MISFIT AND SPINEL FORMATION
 When NiO and Al_2O_3 react, the lattice misfit at the initial NiO/ Al_2O_3 interface (when perfectly aligned) is shared almost equally between the NiO/ NiAl_2O_4 and the NiAl_2O_4 / Al_2O_3 interfaces. However, when NiO and Fe_2O_3 react, the misfit at the NiO/ NiFe_2O_4 interface is close to zero so that nearly all the misfit is accommodated at the NiFe_2O_4 / Fe_2O_3 interface.

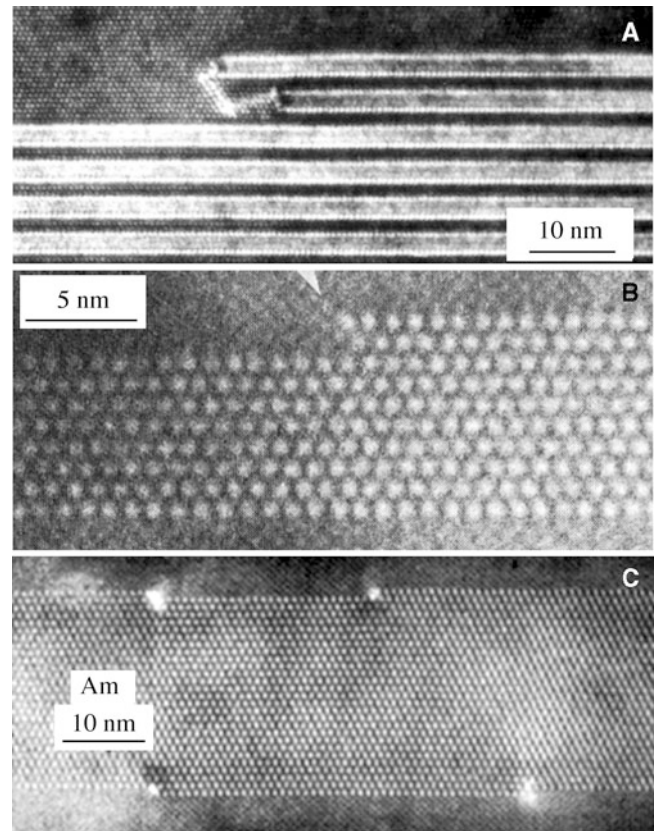

FIGURE 25.17. Chemical reactions by movement of steps on an interface. (A) $\beta\text{-Al}_2\text{O}_3$ growing in spinel. (B, C) Amphibole growing in orthopyroxene.

necessary when the new phase is very small. The chemical abruptness of the interface is particularly interesting when the oxygen sublattice is almost common to the two materials, as we saw in Section 15.6 for the NiO/ NiFe_2O_4 interface. This interface can then move by only the cations moving. However, if misfit dislocations are present, as in Figure 15.8, the anions must also move.

The growth of β -alumina into spinel, shown in Figure 25.17A, is an example of a special situation where the misfit between the precipitates and the matrix is very small along one plane, thus creating a low-energy interface. This situation is not unique, as shown in Figure 25.17B. The result of such a reaction is the formation of particles that

appear to be very large in one direction: the particle may also be large in two directions—hence a platelet. Isolated steps move across the larger surface. Incidentally, always remember that most observations of such phenomena are made at room temperature.

FIGURE 25.18. SEM images of reactions at grain boundaries (GBs) in thin films of NiO deposited on (0001) Al₂O₃.

25.14 THIN-FILM REACTIONS

Understanding how phase boundaries in oxides move is essential for a comprehensive understanding of solid-state reactions between ceramic oxides. The factors that determine the mobility of a PB may involve the usual aspects of structure, bonding, and chemistry. Because thin-film reactions can be carried out at low temperatures, the morphology of the interface can easily be “frozen in.” GBs and other defects can affect the rate of a reaction in several ways. They can act as short-circuit paths to allow more rapid diffusion of reactants or simply act as nucleation sites for the growth of a new structure. Evidence for both of these mechanisms was found in the study of the reduction of Fe-doped Al₂O₃. It has also been shown that GBs are a necessary product of the growth of spinel into alumina.

By combining TEM and field emission gun (FEG)-SEM, we find that the formation of spinel occurs more quickly along GBs in thin-film reaction couples, as illustrated in Figure 25.18. At the earliest stages of these reactions, the kinetics are controlled by the interface mobility, rather than by diffusion through the reactant.

Thin-film reaction couples can be prepared by growing thin films on a specially prepared substrate. PLD works well for the deposition, but molecular beam epitaxy (MBE) and chemical vapor deposition (CVD) could be equally well used. This geometry offers many advantages over bulk samples.

- The reaction temperatures can be much lower than with bulk reaction couples.
- The cooling rate can be very rapid.
- We control the microstructure, crystallography, and morphology of the substrate.
- We can study the same interface before and after the reaction.
- We can thus directly study the role played by steps on the surface of the substrates and GBs in the thin films.
- We can use a combination of materials or a graded reactant.
- We can grow material M₁ on a single crystal of material M₂, or vice versa, and thus predetermine the location of GBs.
- We can control the oxidation state of the reactants.

This approach overcomes the difficulty encountered using classical bulk diffusion: we know that there is intimate contact between the substrate and the thin film. If the materials are not in direct contact, the earliest stages of the reaction likely involve a vapor phase component.

The key feature is always that PBs move during solid-state reactions. Defects and GBs influence both the mechanisms and the rates of solid-state reactions; but with bulk reactants you don’t know what is there to start with. The volume probably changes during the reaction.

When the epilayer contains GBs, the thin-film approach allows us to examine how the nucleation rate depends on the type of GB (e.g., misorientation, GB) intersecting the PB. The growth of the product depends on the nucleation site.

If, as is often drawn schematically, a continuous reaction layer forms, the volume change may be accommodated by an expansion normal to this layer (analogous to the tetragonal distortion in semiconductor multilayers). If the reaction occurs initially along the triple junction where a GB meets the substrate, the constraints are very different. The thin film can become extensively deformed in accommodating this volume change. There is, for example, an ~7% volume expansion when NiO reacts with Al₂O₃ to form the spinel.

Two types of reaction sample are illustrated in Figures 25.18 and 25.19. In the first, the reactant material is grown directly on the substrate so as to examine the *nucleation* of the reaction product and to quantify the role of GBs in the polycrystalline material. We can easily reverse the layer/substrate geometry to examine the role of GBs in the two materials separately.

In the second type of sample, a *buffer layer* of the reaction product or a *reaction-barrier layer* is grown before growing the reactant layer. This geometry allows us to quantify the *kinetics of the reaction* separately from the nucleation. We can then examine the morphological development of the two moving interfaces and the effect of lattice misfit on this morphology. The expansion that occurs when the spinel forms can be readily

accommodated if a buffer layer is present and forming a uniform layer, as you can see in Figure 25.19. In this case, the kinetics can be deduced directly, as shown in Figure 25.20. Notice that T and $\Delta\xi$ are much smaller

FIGURE 25.19. SEM images of the growth of spinel between thin films of NiO and (0001) Al_2O_3 when an initial buffer layer of spinel is present.

than in Figure 25.13 and that the kinetics are linear. At the early stages of the reaction, the rate is determined by the interface.

This reaction geometry can be extended to the situation where there are several reaction products, as illustrated for the $\text{Al}_2\text{O}_3/\text{Y}_2\text{O}_3$ system in Figure 25.21. Finally, we should note that reactions often take place more easily at surfaces because there is no volume constraint.

A special thin-film reaction (though it becomes more general as it proceeds) is the corrosion of a ceramic by a

FIGURE 25.20. Kinetics of reactions between thin films of NiO deposited on (0001) Al_2O_3 when an initial buffer layer of spinel is present.

FIGURE 25.21. Forming yttrium aluminum garnet (YAG) by a thin-film reaction. (A) Intermediate state. (B) Final state for the same film. (C) Equilibrium phase diagram.

FIGURE 25.22. Corrosion of Al_2O_3 by reaction with K_2O vapor showing a transmission electron microscopy image, the DP, and a schematic of the DP.

metal or another ceramic. PBs form during the corrosion process just as they do when a metal oxidizes or when an oxide is reduced; the only special feature is that the action takes place close to the surface so there are fewer constraints. Figure 25.22 illustrates the PB formed when K_2O vapor corrodes (reacts with) alumina. The diffraction pattern (DP) shows that the two phases are topotactically aligned.

25.15 REACTIONS IN AN ELECTRIC FIELD

Diffusion in ionic materials occurs primarily by the movement of charged species. Therefore, the application of an electric field can provide a very powerful driving force for mass transport. There have been numerous studies on the effects that electric fields have on transport phenomena. Several studies have been performed on the evaporation of alkali halides in the presence of an external field. These investigations

showed that the application of an electric field caused enhancement of the evaporation of the crystal species. Similar studies have been performed on oxide ionic conductors, including ZrO_2 and β -aluminas. However, there have only been a few experiments performed on classical insulating oxides such as α - Al_2O_3 and MgO (perhaps because they are insulators).

Polycrystalline diffusion couples can be studied in a similar way. Results show increased transport and consequently an increase in the growth of the reaction product. However, the polycrystalline nature of the compacts makes it difficult to separate the influence of GB diffusion and bulk diffusion.

This thin-film geometry can also help us understand how an electric field affects heterogeneous solid-state reactions and transport phenomena. The spinel-forming reaction between MgO and Fe_2O_3 deposited on thin single-crystal

films of iron oxide on $\{001\}$ MgO using PLD is shown in Figure 25.23A. The diffusion couples are then reacted at elevated temperatures under an applied electric field. The electric field can increase mass transport in the bulk and can change the resulting microstructure and the interface topology, as shown in Figure 25.23B, C. The controlled nature of the experiment and the simple reaction geometry allow the transport phenomena and reactions to be examined

directly. We can study the reaction with NiO , instead of MgO , with the electronic contribution to the process removed by including layers of ZrO_2 next to the Pt electrode.

We can grow thin films of AlN on sapphire by applying an electric field to a sample heated in a nitrogen-rich atmosphere with extremely low oxygen partial pressure. By applying an electric field with an appropriate electrode

material at elevated temperatures across Al_2O_3 , a flux of Al^{3+} cations toward the cathode is induced. The cations arriving at the surface of the Al_2O_3 then react with a nitrogen gas atmosphere to form a thin epitaxial film of AlN on the Al_2O_3 . The hydrogen portion of the mixture serves to help reduce the oxygen activity in the gas atmosphere so that Al_2O_3 does not reform.

DIFFUSION COUPLES

The diffusion couple (approximately 1-mm thick) is placed between two Pt electrodes with the thin film in contact with the cathode and the bulk MgO substrate in contact with the anode as illustrated in Figure 25.23A. The reaction takes place in air with a voltage of ~ 210 V applied across the sample. T depends on the material, $\sim 1,350^\circ\text{C}$ for $\text{In}_2\text{O}_3/\text{MgO}$ but as low as 700°C for $\text{Fe}_2\text{O}_3/\text{MgO}$. A second diffusion couple, without the applied field, is placed with the thin film down on a piece of Pt foil to ensure similar reaction conditions. The two samples are kept close together to ensure they are reacted at the same temperature.

GROWING AlN IN AN ELECTRIC FIELD

Place a single-crystal of α - Al_2O_3 between two Pt electrodes in an N_2 -rich environment. The Pt electrodes act as chemically inert conductors with a high melting temperature. We have to scratch the Pt electrodes with an abrasive to roughen the surface and thus allow the nitrogen to reach the entire surface of the Al_2O_3 . If N_2 transport across the surface is inadequate, the Al^{3+} cations arriving at this surface would either evaporate or form an alloy with the Pt electrodes. After the furnace is evacuated to 10^{-6} Torr and heated to remove excess water, backfill with a 5% H_2 /95% N_2 gas mixture and react.

FIGURE 25.23. Reaction between a thin film of Fe_2O_3 and a layer of MgO in an electric field at $1,150^\circ\text{C}$ for 2 h. (A) The setup. (B) Field with nothing applied. (C) Field with 2 kV/cm applied. The MgO has grown on top of the spinel. The reaction is fastest at GBs in the thin film.

Under the reaction conditions used for the formation of these films, it is estimated that the partial pressure of oxygen in the chamber is between 10^{-21} and 10^{-26} ! For a more accurate determination, we would need to know the amount of water vapor in the chamber. The gas mixture used for this study is critical: for example, using 99.999% N_2 gas results in the formation of only Al_2O_3 (the oxygen activity is too high). The Al_2O_3 is reacted at, for example, $1,250^\circ\text{C}$ for 2 h. The properties of AlN make it an interesting material for applications in the microelectronics industry: it has a large band gap, good thermal conductivity, high-temperature stability, and chemical inertness. Thin AlN films on basal Al_2O_3 substrates are used as buffer layers for the growth of GaN on alumina.

NUCLEATING AGENTS

Different types are used to promote the process of crystallization.

The Pt group and noble metals: concentration $\sim 0.05\%$
 Fluorides (e.g., Na_2AlF_6 or Na_2SiF_6): concentration 2–4%

TiO_2 : concentration 2–21 wt%

FIGURE 25.24. Dissolution of sapphire in a $\text{CaO-Al}_2\text{O}_3\text{-SiO}_2$ silicate melt.

25.16 PHASE TRANSFORMATIONS INVOLVING GLASS

The crystallization of glass is so well established it is responsible for the development of a whole class of materials known as glass-ceramics. There is therefore a large body of literature on this subject. When glass is present in a GB, there is an additional constraint on the crystallization because a second “nucleating” interface is present. For example, it is possible that a glass that crystallizes on a free surface may not do so in a GB due to the competition between the two “seed” grains. There are a growing number of studies of the crystallization of

glass in different systems, but few relationships between the new crystals and the crystalline grains have been reported. Much of the work on this topic has been carried out on commercially available material, where other elements may be present in the glass.

Glass can dissolve crystal.

The kinetics of dissolving crystalline sapphire in a $\text{CaO-Al}_2\text{O}_3\text{-SiO}_2$ melt are shown in Figure 25.24. We see parabolic kinetics—it’s a diffusion-controlled reaction.

Glass can penetrate polycrystalline compacts and dissolve or redistribute the crystalline phase. In the case of polycrystalline MgO , further heat treatment caused the glass to crystallize as monticellite. A particularly interesting observation in this study was that the impurities that were present in the sintered MgO (primarily ZrO_2 : a grain-growth inhibitor) were swept into the residual glass regions

between the crystalline monticellite grains (known as the snow-plowing process).

Glass can crystallize. Glass-ceramic materials are produced by the controlled crystallization of appropriate glasses. The glass-ceramic consists of typically 95–98 vol% of very small crystals, generally $<1 \mu\text{m}$ in size, with the residual glass phase making up the rest of the pore-free material. When these materials are fabricated, the required shape is produced using conventional glass-forming techniques. To obtain small crystals of uniform size in the glassy matrix, a uniform density of nuclei of the order of $10^{12}\text{--}10^{15} \text{ cm}^{-3}$ is required. Selected nucleating agents are added to the batch during the melting operation and while performing a controlled heat treatment.

The role of the different nucleating agents and the mechanism that leads to subsequent volume crystallization is not yet entirely clear. For the metals, the solubility decreases as the temperature in the glass melt decreases and small metallic particles precipitate out. In the case of oxide nucleating agents, the crystallization process appears to take place by an induced phase separation (demixing) followed by crystallization. (We considered phase separation of glasses in Section 21.11). For TiO_2 -nucleated $\text{Li}_2\text{O}\text{--Al}_2\text{O}_3\text{--SiO}_2$ glass-ceramic, the nucleation involves a phase separation on a scale of $\sim 5 \text{ nm}$ followed by the formation of a crystalline TiO_2 -rich nucleating phase.

As a result of carefully controlled thermal treatment, the initial glass is converted to a polycrystalline material in which the final properties depend on the nature of the precipitated phases, the final degree of crystallinity, the size of the crystallites, etc. The material is generally opaque, although translucent and even transparent glass-ceramics have been produced. The small size of the grains and the absence of porosity are characteristics of glass-ceramics, which results in excellent mechanical properties. This is explained in part by the action of the microcrystallites, which limit the propagation of flaws. (See also the discussion in Section 21.11, including the mention of devitrite).

25.17 POTTERY

The phase transformations that take place in pottery and glazes on pottery have not been studied to the same detail as the model $\text{NiO}/\text{Al}_2\text{O}_3$ reaction in part because the processes are complex and perhaps because they are not the basis of high-tech applications. The glazes are usually silica-based with high concentrations of dopants to lower T_g or produce other special properties. The best example of a phase transformation in a glaze is the crystallization

glaze discussed in Section 21.12. So, what happens when we heat clay depends on the clay which depends on where you are since most clay firing is local. The topic is enormous and varied. When we glaze the pot, the formation and behavior of the different glazes depend not only on the composition of the glaze but also on the firing temperature and environment.

25.18 CEMENT

Cement is not only an extremely important ceramic but is also a very complex one. One factor in this complexity results from the importance of hydration reactions. Cements are, by definition, powder ceramics that react with a liquid (usually, though not necessarily water) to undergo a chemical reaction to form a solid structure. A cement paste is the suspension of this powder in a liquid phase. Some cement pastes require the presence of air or CO_2 , to harden, while others can harden under water. Pozzolanic cements are Si- or Al-based powders that can react with water providing $\text{Ca}(\text{OH})_2$ is also present. The situation can be further confused by the presence of non-reactive constituents that are added to change the rheology of the mixture. The rheological properties change as the fresh cement hardens. This setting process is thus quite like the solidification of glass but takes place at ambient temperature and involves a change in structure. (So, it's completely different). The two fundamental (don't say basic, since the basicity of CaO is an important factor here) reactions with CO_2 and H_2O are illustrated by these simple equations.

The water content can vary producing different hydrate phases. If sulfur is present (in gypsum), the reaction becomes more complex and leads to the formation of the mineral ettringite, $\text{Ca}_6\text{Al}_2(\text{SO}_4)_3(\text{OH})_{12} \cdot 26\text{H}_2\text{O}$, during the hydration of Portland cement.

In an alkali silica cement, we see a new setting/hardening reaction, with quartz becoming a factor.

PORTLAND CEMENT

Hydraulic cement produced by pulverizing Portland-cement clinker and usually containing CaSO_4 ($<5\%$). Portland clinker is produced by heating a mixture of CaO , SiO_2 , Al_2O_3 and Fe_2O_3 until partly molten. C_3S is the essential constituent of Portland clinker; C_2S , C_3A and $\text{C}_2(\text{A},\text{F})$ will also be present.

We mentioned cement terminology in Chapter 2: C is CaO , S is SiO_2 , and A is Al_2O_3 . CA is the main constituent in calcium aluminate cement (referred to as CAC). In high-alumina cement (HAC), the Al_2O_3 content ranges from 40%

to 80%; it contains some C_2S but no C_3S . Its value is that it sets much more quickly than Portland cement.

For reasons that are obvious, pores are an important component in concrete and are the main flaw in the material. This is unfortunate in a material primarily needed for its strength.

Not all cement is based on CS_x or CA_x . A group of cements known as glass ionomer cements (GICs) are used as cements in dentistry. The reaction involves an ion-leachable alumina-silicate glass and an aqueous solution of polyalkenoic acid. The resulting cement consists of glass particles in a polysalt matrix. This is a specialty topic but with far-reaching applications.

25.19 REACTIONS INVOLVING A GAS PHASE

The gas phase becomes important when a vapor is intentionally used in a reaction or a vapor is created during a reaction, as is the case of decomposition of a product. The problem is illustrated by the carbonate reaction shown in Figure 25.25. Many ceramics are processed from their salts rather than from the oxides themselves. As the $CaCO_3$ decomposes to form the oxide, emitting CO_2 , heat moves into the core of the particle, and CO_2 moves outward. The result is another reaction layer forming, which slows down further decomposition. Of course, in this case we can expect the CaO to be porous, so that the CO_2 can evolve quite easily.

When SiO_2 dissociates, the situation is not as simple. This reaction is important not just because SiO_2 itself is important but also because SiO_2 is present in glass, furnace bricks, and alumina furnace tubes.

FIGURE 25.25. Processes involved in decomposing a carbonate.

At $1,320^\circ C$, we can write the reaction coefficient in terms of the partial pressures.

$$K_{eq} = \frac{(P_{SiO})^2 p_{O_2}}{(a_{SiO_2})^2} = 10^{-25} \quad (25.17)$$

Assuming the concentration of SiO_2 to be unity (it is the principal component), we can express P_{SiO} in terms of the oxygen partial pressure. [We are using p_{O_2} (as conventional) to represent the partial pressure of O_2 but P_x for the partial pressure of X —to keep the notation clear!]

$$P_{SiO} = \frac{K_{eq}^{1/2}}{p_{O_2}^{1/2}} \quad (25.18)$$

This equation tells us that the oxygen partial pressure controls the vaporization of the silica. For example, if the p_{O_2} is 10^{-18} atm (a reasonable value in a reducing atmosphere of H_2 or CO), then the P_{SiO} is $\sim 3 \times 10^{-4}$, which is quite high so the SiO_2 evaporates. Hence, SiO_2 would not be a good refractory in a dry reducing atmosphere. You can minimize the effect by adding a small amount of H_2O if H_2 is present.

A similar situation arises when reacting an oxide in a chloride gas. This reaction is actually used in growth of thin films by vapor transport.

The reaction of the active gas with the ceramic increases the vapor transport. What we are actually doing is controlling the chemical potential (concentration) of the reaction gases and hence controlling the rate of deposition. We can apply Fick's law.

$$\frac{dn}{dt} = -AD \frac{\partial c}{\partial x} = -AD \frac{\Delta c}{L} = -AD \frac{c_h - c_c}{L} \quad (25.21)$$

With some manipulation, we can express the concentration difference as a pressure difference. We see that the diffusion from hot (h) to cold (c) is driven by the concentration gradient, and the direction of the reaction is just due to the enthalpy of the reaction. At equilibrium, we can write an expression for ΔG .

$$\Delta G_h = -RT \ln \left(\frac{P_{FeCl_2} P_{H_2O}}{P_{HCl}^2} \right) \quad (25.22)$$

In a closed system, the initial amount of HCl is B atm. Then two molecules of HCl gives one molecule of $FeCl_2$ and one molecule of H_2O .

$$P_{HCl} = B - 2P_{FeCl_2} + P_{H_2O} = P_{FeCl_2} \quad (25.23)$$

and

$$\Delta G_{h,c}^0 = -RT \ln \left(\frac{P_{\text{FeCl}_2}}{(B - 2P_{\text{FeCl}_2})^2} \right) \quad (25.24)$$

25.20 CURVED INTERFACES

The equation given by Thompson and Freundlich (the Thompson-Freundlich equation) relates the concentration in equilibrium with a curved surface to that in equilibrium with an infinite flat surface.

$$RF \ln \left(\frac{c_a}{c_{pi}} \right) = \frac{2E}{a} \frac{M}{\rho} \quad (25.25)$$

where c_a is the concentration at the curved interface, c_{pi} is the concentration at planar interface, M is the molecular weight, E is the interfacial energy, and ρ is the density. Thus, the concentration in equilibrium with a curved surface differs from that for a flat surface. This result is not just due to the reduction of surface area. This phenomenon is known as the Gibbs-Thompson effect.

CHAPTER SUMMARY

The key idea for solid-state reactions and phase transformations is that they occur by the movement of interfaces no matter what phase is involved. A phase transformation can occur by one interface moving; but even if a reaction starts at one interface, we have two interfaces as soon as a reaction product forms. When either a solid-state reaction or a phase transformation occurs, the system is not in equilibrium, and the equilibrium phase diagrams can serve only as a guide to what the final product will be. Diffusion of point defects is an essential feature in solid-state reactions, but understanding the kinetics of these processes is not necessarily straightforward because the diffusion coefficients change as the composition of the phase changes (the Darken equation). The situation can be even more complex if the structure of the reaction product is also new and if misfit dislocations form at the phase boundary. The use of slip casting to explain the physical basis of parabolic reaction kinetics is extremely instructive and builds on a real ceramic process. Like slip casting, many phase transformations in ceramics involve the transfer of water or a gas phase. The setting of cement and the corrosion of TBCs are two such examples.

PEOPLE AND HISTORY

Schmalzried, Hermann (1932–). An exception to the rule. Formerly a postdoctoral student with Carl Wagner, Hermann has been a mentor and inspiration to many of the current generation of researchers in the field of solid-state reactions in ceramic systems and is profusely thanked by the authors.

Wagner, Carl (1901–1977). He was born in Leipzig and died in Göttingen. He wrote the seminal text with Schottky and laid the foundations for understanding corrosion and reactions between oxides.

EXERCISES

- Two cubes (400 μm long on each side) of NiO and Al_2O_3 are reacted at 1,600°C. Assuming that the reaction takes place without significant movement of electrons or oxygen and that a reaction layer is produced that is 100 μm thick, what are the respective thicknesses of the remaining NiO and Al_2O_3 ?
- Given the densities of some of the polymorphs of SiO_2 , should it be possible to convert β -cristobalite to some of the other forms by applying pressure? Briefly explain the reasoning behind your answer and indicate to which of the four forms, if any, the transformation might occur.
- Calcium carbonate (CaCO_3) exists in two polymorphic forms: calcite and aragonite. The standard state enthalpy of calcite is $-1,207.37$ kJ/mol, and that of aragonite is $-1,207.74$ kJ/mol. The entropies of aragonite and calcite under the same conditions are 88 J mol $^{-1}$ K $^{-1}$ and 91.7 J mol $^{-1}$ K $^{-1}$, respectively. What is the stable polymorph at 25°C and 1 atm? Is there a temperature above which the other polymorph would be the equilibrium phase? If so, what is that temperature? If not, why not?
- You want to prepare a sample of mullite by reacting alumina and silica powders. If the activation energy is 210 kJ/mol and the reaction is 10% complete at 1,400°C, how long would it take to convert 50% to mullite at 1,400°C and at 1,500°C? How do you determine that 50% has indeed been converted?

- 25.5 You place two perfect crystals of alumina and magnesia in contact with flat (0001) and (111) surfaces in contact. What orientation do you choose to produce the fast reaction when you heat these to 1,400°C for 1 h? You make the assumption that oxygen does not move during this heat treatment, but this cannot be strictly true. Explain.
- 25.6 You react two samples of alumina and magnesia at 1,400°C for 1 h. This time the MgO is a perfect single crystal, but the alumina is 100-nm grain size polycrystalline material. Does the reaction proceed more quickly or more slowly on average?
- 25.7 Explain the geometry of the precipitates in Figure 25.5 and the defects they contain.
- 25.8 Consider Figure 25.13. What can you determine about the activation energies involved and the diffusion processes?
- 25.9 Consider Figure 25.21. How do you explain the experimental observations in the images in view of the phase diagram and other factors you know about these materials?
- 25.10 Consider Figure 25.24. What can you determine about the energies involved in this reaction?
- 25.11 Imagine the particle in Figure 25.7 growing as the sample is internally reduced. Discuss the diffusion of point defects that must occur.
- 25.12 Draw a schematic to show six atomic planes of Fe₂O₃ and six of NiFe₂O₄ aligned with (0001) and parallel to (111). Label them as if they were hexagonal close-packed (hcp) and face-centered cubic (fcc) crystals and suggest how the hematite might grow in the spinel by exsolution.
- 25.13 Draw a nucleus of the particle of the type shown in Figure 25.5, and then draw it again as it begins to grow. Thereby, suggest when and how the twins might form.
- 25.14 Consider Figure 25.10. Which surface of the sapphire is reacting the fastest, and why do you think this is so?
- 25.15 Determine equation 25.5 for yourself and suggest reasonable values for each of the variables and “constants” for the case of water penetrating through a layer of slip.
- 25.16 A layer of MgO reacts with a layer of Al₂O₃ such that only the cations move. By considering Figure 25.12, show that the spinel grows into the sapphire faster than into the periclase.
- 25.17 Consider equation 25.12 and Figure 25.15. What can you deduce about the average diffusion coefficient?
- 25.18 Consider Figure 25.18B. Explain quantitatively why the spinel nucleates where the grain boundary (GB) meets the substrate surface.
- 25.19 Consider Figure 25.20. Are the three straight lines consistent with one another? (Is T the only factor that is different in the three experiments?)
- 25.20 Consider Figure 25.24. What can you deduce about the dissolution of sapphire in silicate glass?

Processing Glass and Glass-Ceramics

CHAPTER PREVIEW

Glass has changed the world more than any other material. In Chapter 21 we described some of the different types of glass and their properties. In this chapter we will look at the main methods used to fabricate glass products. In terms of the volume of glass that is produced each year, glass processing could be said to be the most important processing method for ceramics. The largest segments of the market are

- Flat glass for windows
- Containers (including bottles, jars, and tableware)

These products are formed using essentially two methods [one is recent (in glass terms) the other has its roots in antiquity]:

- The float glass process
- Blowing

We will also look at some processes that are used to modify glass for specific uses such as the application of thin-film coatings for solar radiation control and tempering and laminating for safety glass. In the last section of this chapter we will examine how glass-ceramics are produced.

This chapter does not cover the processing of some special glass products. For example, the processing of optical fibers is described in Chapter 32, but we introduce the important ideas here. Optical fibers must meet stringent quality requirements. We must understand these requirements to understand why the elaborate processing methods are necessary.

This chapter covers three closely related topics:

- Processing as dictated by applications
- Shaping
- Treating

26.1 MARKET FOR GLASS AND GLASS PRODUCTS

More than half of the total worldwide ceramics market is glass products, accounting for over \$50 billion/year. Figure 26.1 shows the distribution of glass sales. The market for manufactured glass products emphasizes three main types of glass.

- Hollow glass (bottles, drinking glasses, lamp bulbs, glass containers), 35%
- Flat glass (mirrors, windows), 30%
- Fiberglass (includes glass fiber), 17%

Hollow glass includes most of the container glass and tableware we use (i.e., consumer glassware). Table 26.1 lists examples of the applications for these product categories.

26.2 PROCESSING BULK GLASSES

Glass production starts with a mixture of raw materials, which for glass manufacture often contain a high proportion of naturally occurring minerals (e.g., sand and limestone). However, some industrial chemicals, such as

FIGURE 26.1. Percent distribution of glass sales. Total: \$48,260 million.

TABLE 26.1 Glass Product Types and Applications

Glass product type	Applications
Flat glass	Automotive: cars and trucks Architectural: commercial buildings, storefronts Residential: windows, doors, sunrooms, skylights Patterned glass: shower doors, privacy glass Blanks for microscopes and telescopes
Containers/tableware	Beverage Liquor, beer, wine Food Pharmaceutical, drugs Glasses, plates, cups, bowls, serving dishes
Fiberglass and glass fiber	Wool: insulation, filters Textile: plastic or rubber tire reinforcements, fabrics, roof shingles, roll goods reinforcement Optical communications
Specialty glass	Artware, stained glass, lead and lead crystal, lighting TV picture tubes and flat-panel displays, ovenware and stovetops Ophthalmics, aviation, tubing, foamed glass, marbles

sodium carbonate (Na_2CO_3) and alumina (Al_2O_3), are also used. The mixture containing the raw materials in the appropriate amounts is known as the *batch*. The batch contains a mixture of glass formers, modifiers, and intermediates; the amount of each component depends on the application of the final glass product. In Table 26.2 we link the different ways of giving a batch composition and the sources of some of the raw materials.

Batch melting depends on the source of energy, the refractory used to contain the glass, details of the batch, processes occurring during melting, and fining (see Section 26.3).

We must also consider the possibility of oxidation and/or reduction of the glass, homogenization processes, and defect in the glass.

By far the greatest amount of flat glass is soda-lime silicate glass. You must be familiar with the terminology used in the glassmaking industry: soda is sodium oxide (Na_2O), and lime is calcium oxide (CaO). Thus, soda-lime silicate glass consists mainly of Na_2O , CaO , and SiO_2 . Glass manufacturers often use the common names for these oxides, which are not always the generally recognized scientific name. If you are unsure of the composition of a particular mineral, you need to look at its formula.

FLAT GLASS RAW MATERIALS

- Limestone, CaCO_3
- Silica sand, SiO_2
- Soda ash, Na_2CO_3
- Alumina hydrate, $\text{Al}_2\text{O}_3 \cdot 3\text{H}_2\text{O}$
- Burnt dolomite, $\text{CaO} \cdot \text{MgO}$

All manufacturers of flat glass use basically the same formula, but they never actually use the compounds Na_2O or CaO . Values of the components are usually given in wt%. Typical values are 72 wt% SiO_2 , 14 wt% Na_2O , 9 wt% CaO , 4 wt% MgO , and 1 wt% Al_2O_3 . The molecular formula for a glass of this composition can be calculated as follows.

Step 1: divide the wt% of each component in the batch by its molecular weight (MW).

Oxide	wt (g)	MW (g/mol)	wt%/MW (mol)	Ratio
SiO_2	72	60.1	1.20	120
Na_2O	14	62.0	0.23	23
CaO	9	56.1	0.16	16
MgO	4	40.3	0.10	10
Al_2O_3	1	102.1	0.01	1

Step 2: divide each ratio by the smallest ratio in column 4.

This gives the number in column 5.

Step 3: write out the molecular formula for the glass.

The molecular formula of our flat glass is then:

To make the batch, it would not be economical to use only synthesized or pure ingredients. For most glasses, a large proportion of the batch is made up of naturally occurring minerals that have been through a beneficiation process. Table 26.3 shows the typical batch constituents to make the $\text{Al}_2\text{O}_3 \cdot 10\text{MgO} \cdot 16\text{CaO} \cdot 23\text{Na}_2\text{O} \cdot 120\text{SiO}_2$ glass. To determine how much of the raw material we need to add to the batch to obtain the desired amount of oxide in

the final glass, we need to know the fraction of that oxide in the raw material. For the principal raw materials used in glass-making, this fraction is given in column 5 in Table 26.2. For example, during melting, limestone decomposes as follows:

The fraction of CaO (molecular weight 56.1 g/mol) in CaCO₃ (molecular weight 100.1 g/mol) is 0.560, or 56%. Hence, for each kilogram of limestone added to the batch the melt contains only 0.56 kg of CaO. So, using the raw materials listed above, and by bearing in mind the fraction of each oxide provided by each mineral, we can determine the batch composition for a 1 kg melt of flat glass. These are the numbers given in Table 26.3. Note that the lime comes from both burned dolomite and limestone. A batch weighing 2 t can be measured to an accuracy of 0.1%.

Table 26.4 shows where we might actually have to go to obtain these raw materials. [If we are making bottles and jars, the batch likely contains cullet, recycled glass (see Section 37.7)].

After the batch has been thoroughly mixed, it is melted at high temperature to form a homogeneous liquid melt. For small-scale melting of glass, the batch is placed in a crucible. For glass-melting experiments in the laboratory, it is common to use Pt, or a Pt alloy such as Pt-5%Au or Pt-20%Rh crucibles.

These crucibles are very expensive, but they can withstand high temperatures, they do not contaminate the glass melt, and they can be easily cleaned and reused. Other

crucible materials, usually used for larger batch sizes, include silica, alumina, and mullite.

Large-scale industrial production of glass is carried out in continuous furnaces called tanks. Glass-melting tanks are the second largest industrial furnaces after the blast furnaces used in making iron and steel. Figure 26.2 shows the inside of a glass melting tank, and Figure 26.3 shows a glass-melting tank for producing glass containers. The tanks are typically 10–40 m long, 3–6 m wide, and 1.0–1.5 m deep; and they contain over 2 kt of molten glass. (The largest glass-melting furnaces are 100 m long and 13 m wide). The furnace is constructed of alumina/zirconia refractories that can withstand the high temperature and corrosive environment of the melt (see Chapter 9). The life of a tank furnace is about 8 years.

With reference to Figure 26.3:

The batch is loaded into the hopper (1). In industry, the batch-loading compartment is referred to as the “dog-house.” In region (3) the batch begins to melt. The surface temperature of the melt peaks in region (4). During the melting process it’s important to control the homogeneity of the mixture and the oxidation state of the components. Region (5), the throat, divides the furnace into two parts—the melting end and the conditioning, or working, region to the right. In the working region, the melt is cooled down to about 1,300°C, and the glass viscosity increases. The glass travels through narrow tunnels called the forehearth (7), where the temperature is further lowered to 1,000–1,100°C, and on to the forming machines. Depending on the requirements of the forming machines, the glass may be delivered in the form of a continuous stream (as shown in Figure 26.4) or in discrete amounts, called gobs. The viscosity of glass at the working point is 10⁴ dPa·s (see Chapter 21). The regenerative chambers, region (9) are used for preheating the fuel gases and air to increase the combustion efficiency of the furnace.

TABLE 26.3 Batch Composition

Raw material	Oxides supplied	Fraction of oxide	Weight of oxide required (g)	Weight of raw material in batch (g)
Limestone	CaO	0.560	90	61
Silica sand	SiO ₂	1.000	720	720
Soda ash	Na ₂ O	0.585	140	239
Alumina hydrate	Al ₂ O ₃	0.654	10	15
Burnt dolomite	CaO	0.582	90	96
	MgO	0.418	40

Silica sand	Bank sand	Jersey shore
	Sandstone	Allegheny mountains
Soda ash	Trona deposits	Wyoming
Limestone	Dolomite	All over (e.g., Alabama)
Feldspars	In pegmatites	North Carolina
B ₂ O ₃	Borax	California

26.3 BUBBLES

The temperature required to form a glass melt varies with the composition of the batch. Typically, melting temperatures are in the range 1,300–1,600°C. At this stage of the process, the melt may contain many gas bubbles, mainly CO₂ and SO₂, from the dissociation of carbonates and sulfates. Bubbles also come from reactions between the glass melt and the refractories. Gas bubbles (which are known as seeds or blisters if the size is >0.5 mm) are usually undesirable in the final product because they affect its appearance. Bubbles are eliminated during melting by a process known as fining.

Fining can be achieved by increasing the temperature of the molten glass by about 150°C to reduce its viscosity. From Stokes’ law (or by comparing the rise of bubbles in Cola versus liquid soap) we know that the drift velocity of the bubbles toward the surface of the melt is increased as the viscosity of the melt is decreased.

FIGURE 26.2. Inside a typical glass-melting tank.

FIGURE 26.3. Glass-melting tank for producing containers.

FIGURE 26.4. Pouring molten glass into a mold.

Fining is also traditionally achieved by adding fining agents (e.g., Na_2SO_4 or NaCl) to the melt at the end of the melting process. The fining agent decomposes, as shown in equation 26.2, to produce a large quantity of gas bubbles, which coalesce with existing bubbles, increasing their volume and hence taking them to the surface faster.

Arsenic oxide, As_2O_3 , is another fining agent (giving a mixed-valence effect), but it is not as widely used today because it is toxic. The reaction involving arsenic oxide is

DEFECTS IN GLASS MELTS

a little more complicated than that shown for Na_2SO_4 , but the effect is the same. Fining occurs toward the end of region (4) in Figure 26.3. Modern systems also use mechanical bubbleblers.

In some studio glass and tableware, bubbles are introduced intentionally, as illustrated in Figure 26.5.

26.4 FLAT GLASS

Flat glass is not necessarily flat but is generally flatish! Historically, glass windows were not made in the way they are now. There are three basic methods for producing flat glass.

- Rolling
- Drawing
- Float process

The float process is so important to the glass industry that we discuss it separately in the next section. In this section we discuss the formation of flat glass by rolling and drawing. Figure 26.6 shows an example of a method for producing flat glass by rolling. The molten glass flows from the tank furnace over a refractory lip and between a set of water-cooled rollers where it solidifies into a continuous ribbon. The glass ribbon is transported over rollers into a tunnel-like annealing furnace (called a *lehr* in the glassmaking industry). Inside the *lehr*, the glass is first reheated to between 600°C and 800°C . On the way through the *lehr*, the temperature decreases slowly in a carefully controlled manner to minimize the development of internal stresses within the glass.

FIGURE 26.6. Continuous casting of flat glass.

FIGURE 26.7. Principle of drawing from molten glass. (A) Circular rod. (B) Problem of pulling a planar sheet. (C) Use of a *débiteuse* and cooling to allow the formation of a sheet of constant width.

The glass thickness is controlled by a combination of factors.

- Rotational speed of the rollers
- Their spacing
- Glass pull rate

Typical pull rates are $0.5\text{--}5.0$ m/min, producing sheets $3\text{--}15$ mm thick and up to 3.6 m wide.

A drawing process can also be used to produce flat glass. A solid metal plate is dipped into a bath of molten glass and then slowly withdrawn from the melt. This process would present no problems if we were interested in producing a glass rod (Figure 26.7). Producing a planar sheet is problematic because the sheet would neck down to a narrow ribbon. This difficulty is overcome by cooling the sheet as it is drawn; it is passed between two coolers, as shown in Figure 26.7C. These coolers solidify the glass and produce a sheet of fixed width. (We see a similar process used in crystal growth in Section 29.6).

There are several variations on the drawing process. They are illustrated in Figure 26.8, which gives a different view of Figure 26.7.

In the Fourcault process, the glass is drawn through a slot in a clay block (called the *debiteuse* or draw bar). The glass sheet is pulled upward through a system of steel rollers about 7 m high. The sheet at the mouth of the *debiteuse* is cooled at its edges to retain the width. As the glass travels

upward, it is annealed in a vertical lehr. After annealing and cooling, the glass can then be cut into sections.

In the Pittsburgh process, the draw bar is completely submerged, the temperature of the glass is lowered below the meniscus. This modification allows increased drawing rates.

In the Libbey-Owens or Colburn-Libbey-Owens process, the drawn glass sheet is bent through 90° ~1 m above the surface of the bath on a polished chrome-nickel alloy roll; there is no debiteuse. The glass then travels into a horizontal lehr for annealing.

By the mid-1900s, these three processes were responsible for the world's entire production of flat glass, with 72% being made by the Fourcault process, 20% by the Colburn-Libbey-Owens process, and 8% by the Pittsburgh process. These processes have now been replaced almost entirely by the float process.

Plate glass is flat glass that has been ground and polished to have two perfectly plane and parallel faces

with a high quality optical finish. The surface of a flat glass sheet is flattened by grinding it between two cast-iron wheels with sand abrasive and water lubricant. As the grinding progresses, the particle size of the abrasive is decreased, producing a very fine satin surface. The operation is completed by polishing the sheet with a suspension of iron oxide on felt pads; this abrasive is known as rouge because of its color (see Chapter 36). The processing of plate glass can be entirely mechanized, with continuous simultaneous grinding and polishing on both faces. However, the float-glass process has virtually ended this older method of manufacturing plate glass. The quality of float-glass may not be quite as high as that of plate glass, but the cost is considerably lower because of the elimination of the mechanical grinding and polishing operations.

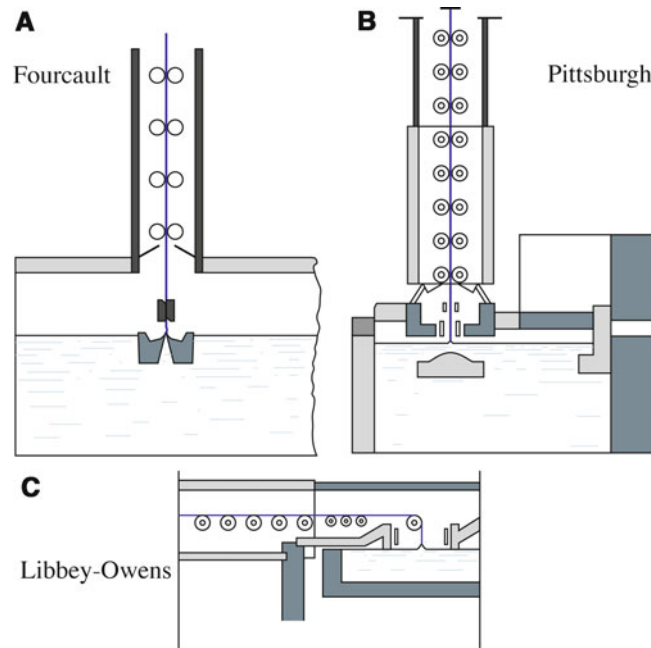

FIGURE 26.8. Drawing processes for window glass. (A) Fourcault. (B) Pittsburgh. (C) Libbey-Owens.

26.5 FLOAT-GLASS

The float process, developed in 1959 by Pilkington in the United Kingdom, revolutionized the flat-glass industry. It is hailed as one of the major inventions of the twentieth century. Worldwide, there are only ~170 float-glass plants, but they have a combined output of 3,000 miles of flat glass, 4–8 ft wide, each day. Annually, these plants produce the equivalent of a ribbon of glass over one million miles long. Over 90% of the world's window glass is produced using the float process.

The float process is shown in Figure 26.9. Molten glass is fed from the furnace between two rollers onto a bath containing molten tin at about 1,000°C (the melting temperature of tin is 232°C). The tin bath is 4–8 m wide and up to 60 m long. Equilibrium between gravitational forces and surface tension produces a sheet of uniform thickness. The equilibrium thickness, h_e , can be calculated using an equation derived by Langmuir.

$$h_e = \left\{ \frac{(\gamma_{Gv} + \gamma_{Gt} + \gamma_{tv})2\rho_t}{g\rho_G(\rho_t - \rho_G)} \right\}^{1/2} \quad (26.3)$$

FIGURE 26.9. Float glass process.

There are three interfacial energy (γ) terms between the different phases: glass (G), air (v), and tin (t); g is the acceleration due to gravity which has a value of 9.806 m/s^2 , and ρ_G and ρ_t are the density of the glass and tin, respectively.

In practice, it is possible to produce glass thicknesses of about 2–20 mm using the float process, depending on the glass viscosity and the drawing speed. At the exit, the temperature of the glass is decreased to $\sim 600^\circ\text{C}$, at which point the tin is still fluid, but the glass can be removed in a “rigid” condition. The glass ribbon leaves the bath and enters the lehr for annealing. The glass leaves the lehr at $\sim 200^\circ\text{C}$, is cooled to room temperature, and cut to size. The main advantage of the float process is the production of planar glass sheets with a high optical quality—the planarity approaches that of plate glass without the need for polishing. Moreover, the output rate is 5–10 times higher than the drawing rate for window glass. About 25 t of finished glass can be produced per hour by the float process.

On the negative side, the equipment requires careful control of the atmosphere above the bath, which must be neutral or slightly reducing to avoid oxidation of the bath, and the maintenance of constant surface tension, which controls the thickness of the sheet. The atmosphere is approximately 90% N, 10% H. The hydrogen ensures that there is an oxygen-free environment, as molten tin is easily oxidized. The glass can itself be affected adversely by the presence of oxygen, which can make the surface appear hazy. Purity and reliability are therefore critical factors in float glass manufacture. Approximately 5 m^3 of hydrogen is required for each ton of glass produced.

26.6 GLASS BLOWING

The classic glassblowing pipes are made from iron tubes about 100–150 cm in length with an opening about 1 cm in diameter. At one end, the tube had a mouthpiece and at the other end a button-like extension. The glassmaker gathers a gob of molten glass on one end then blows through the mouthpiece to form a hollow shape, as demonstrated in Figure 26.10. This process was important historically because by blowing glass with a pipe it was possible not only to produce simple, round shapes but also other thin-walled objects. By blowing the glass into a wooden mold it became possible to produce items with a standard reproducible shape. The glassblowing pipe was also the first step in making flat glass. The glass was blown into a large cylindrical body, cut along its length, and “ironed” flat

while it was still hot and soft. This is known as muffle glass and is still used today to make traditional stained glass.

Today the glassworker’s blowpipe is very similar to the original design and works in the same way. The original blowing technique is used now mainly for specialty glass applications such as glass ornaments and studio-art glass.

To produce hollow glassware for bottles and jars, the original blowing technique has been mechanized. The process starts by forming a blank or pre-form (called a parison) by blowing into or pressing a gob of glass, as illustrated in Figure

26.11. (The hole into the furnace is called the parison-hole; traditionally, the glassblower would gather a glob, or gob, of glass on the blowpipe and roll it to make the parison.) After the initial shaping process, the parison is blown by compressed air to the final shape. With today’s automated techniques, from parison to final product can take less than 10 s.

GLASS THICKNESS

It is instructive to estimate the value of h_e . A reasonable value for the glass/Sn interfacial energy is $\sim 1 \text{ J/m}^2$, the surface free energy of molten tin is 0.68 J/m^2 , the density of Sn is 7.5 g/cm^3 , the surface free energy of a molten soda-lime-silicate glass is 0.35 J/m^2 and the density for a silicate glass is 2.5 g/cm^3 hence h_e is $\sim 9 \text{ mm}$. This calculated value is actually slightly higher than the actual equilibrium thickness, $\sim 7 \text{ mm}$. Remember that we are only using an estimate for the energy of the glass/Sn interface.

- The blow-and-blow process is used to make narrow-neck containers (Figure 26.11A).
- The press-and-blow process is used to make wide-mouth jars (Figure 26.11B).

Figure 26.12 shows the ribbon machine developed in 1926 by Corning for high-speed production of light bulbs. In this process, a stream of molten glass is made into a ribbon by passing it through a pair of rollers. The ribbon passes under a series of blowheads that are attached to a rotating turret (the blowhead turret). Air is puffed into the glass, and the glass begins to take the form of a blown shell. The glass shell is then enveloped by a mold mounted on a rotating turret below the blowhead turret. The shells are blown to their final form while in the mold. The finished shells are cracked away from the ribbon, collected, and carried through the annealer. More than 50 light-bulb shells (in single molds) can be made per second in one machine!

26.7 COATING GLASS

Coated glass also has a long history. Stained glass used in church windows has long used flashed glass, which is clear glass with a coating of a colored glass. Today, we use many other types of coatings, but flashed glass is still used in the glass studio (see Section 26.14).

Normal window glass transmits 75–90% of the incident radiation. We can apply thin coatings to the surface to alter the radiation and heat-transmission characteristics. In architectural applications, coatings on glass are used to reduce the amount of energy needed to heat buildings in the winter and cool them in the summertime. One way to do this is by allowing the transmission of visible light while reducing transmission of infrared (IR) radiation (heat). Such glass would reduce the amount of energy required to air-condition a room in the summer.

One conventional way to achieve reduce the transmission of heat is to add a component to the glass batch that

strongly absorbs in the IR range. When FeO is added to the glass formulation, the product strongly absorbs radiation in the 0.7–2.5 μm range. Because the absorption sharply increases above 0.6 μm , the transmitted visible light has a noticeably green tint, but this can be corrected for to a certain extent by adding other components (commonly Se and Co). A 6 mm thick glass window that contains FeO may absorb ~50% of the total incident radiation but only ~25% of the radiation in the visible part of the electromagnetic spectrum.

Thin films are also used to control the light-transmission characteristics of window glass by reflecting a large amount of IR radiation.

Such films allow higher retention of heat in a room during the winter and thus reduce the energy costs associated with heating. Normal flat glass can be coated with metallic or nonmetallic layers to maintain a high degree of visible-light transmission combined with considerable amount of heat reflection (40–60%). Thin (10–20 nm) metal films of Cu, Ag, and Au are all used commercially; each gives very high reflectivity. The metal layer is deposited using physical vapor deposition (PVD) techniques, such as evaporation and sputtering (see Chapter 27). Metal coatings can also be applied using dipping and spraying techniques, followed by firing to densify the coating (see Chapter 24).

Single-layer and multilayer coatings of oxides are also used to enhance reflectivity in the near-IR spectrum. These coatings work because of optical interference effects and usually have a thickness about one-quarter of the wavelength of the radiation such that the primary wave reflected off the first interface is 180° out of phase with the secondary wave reflected from the second interface. The result is destructive interference of the two waves. Thin films of TiO₂, Ti₃N₄, CrN_x, and Zn₂SnO₄ are all used commercially for this application.

Figure 26.13 summarizes the principles behind solar-radiation control panels. For solar-protective double-glazing, a coated glass pane is combined with an uncoated pane.

Radiation can also be modified using electrochromism. Electrochromism is the production of color by applying an electrical field. Electrochromic compounds such as WO₃ are coated on the glass using a variety of thin film techniques. The point defect reaction is reversible.

When direct current voltage is applied, the optical absorption characteristics of the compound change. The gain/loss of

FIGURE 26.13. Approaches for solar protective double glazing with absorbing and reflecting panes.

MULTILAYER COATING

An example of the effectiveness of a multilayer coating, which works on the interference principle, is the Sb₂S₃/CaF₂ superlattice. For 11 alternating layers of Sb₂S₃ ($n = 2.70$) and CaF₂ ($n = 1.28$), the reflectance is 0.9999 at $\lambda = 1 \mu\text{m}$.

color occurs by the inclusion/elimination of the M⁺ ion. In this case, the M⁺ ion can be H⁺, Li⁺, Na⁺, or Ag⁺. The absorption characteristics of electrochromic materials can thus be tailored for specific applications

simply by adjusting the applied voltage. The new Boeing 787 Dreamliner™ has electrochromic windows.

26.8 SAFETY GLASS

Flat glass often breaks due to impact or to the application of relatively low applied pressure. At most temperatures, the failure occurs in a brittle manner and results in the production of a number of sharp fragments, which, of course, can cause serious injury. Special treatment of the glass can make it less susceptible to breaking and can thus reduce the chance of injury. Hence, the United States and

many other countries require the use of safety glass in buildings and vehicles. There are two forms of safety glass.

- Tempered
- Laminated

Tempered glass (or toughened glass, as it is also often called) is made by quickly heating flat glass to about 150°C above T_g . (Remember: the viscosity at the T_g is $\sim 10^{13}$ dPa·s.) For a soda-lime silicate glass, 150 + T_g is 525–545°C. The glass is then blasted with cold air. The outside of the glass cools much more quickly than the inside. Hence, the inside is still contracting after the surface has already solidified. The result is that the outer surface layer is subject to compression and the inside to tension. This tempering process changes the behavior of the glass when it breaks. For example, when a sheet of tempered glass breaks, the fragments are small and almost regularly shaped with no sharp edges. The principle used in the tempering process is the same as that used to make crackle-glass: the internal stress at the surface is made to be different from that in the bulk.

The other form of safety glass is laminated glass, which consists of two or more glass sheets (usually float glass) joined with a layer of an elastomeric polymer, such as polyvinyl butyral (PVB). The glass layers are bonded to the polymer by a combination of pressure and heating. When laminated glass is broken, the broken pieces of glass are stuck to the polymer, and the broken sheet remains transparent. Car windshields are laminated glass, where the two bonded sheets are both themselves tempered glass. If a stone breaks the windshield when the car is moving, the polymer sheet holds the fragments of glass together so they do not cause injury to the occupants of the car. The side and rear windows of an automobile are routinely made from tempered glass.

The front and rear windows of an automobile are often curved. The flat glass is shaped before the tempering process because the tempered condition would disappear at the bending temperature. One of the advantages of laminated glass over tempered glass is that laminated glass can be processed further; for example, it can be cut and drilled. Bulletproof glass is thick laminated glass (25–60 mm thick) consisting of at least four layers of glass laminated with an elastomeric polymer.

26.9 FOAM GLASS

Usually we don't want glass to contain large numbers of bubbles. We reduce the number of bubbles in the glass melt using the fining process. The opposite approach is used to

make foam glass: additional gases or gas-bearing materials are added to the melt, producing a large quantity of bubbles.

One of the major applications of foam glass is in the manufacture of insulating panels for buildings. Insulating panels made from foam glass can be light, rigid, and good thermal insulators. As usual for porous materials, the thermal property is due to the low heat conductivity of the bubbles (i.e., pores).

- Foam glass is the porous ceramic of the glass world
- Bubbles may be intentionally included in art glass

26.10 SEALING GLASS

Special glasses have been developed that are used as the “glue” usually between another glass and a metal. The main challenge is engineering α while controlling the chemistry and keeping the sealing temperature reasonable.

Borosilicate (alkaline earth/alumina) glass is used to seal glass to W (lighting applications).

Borosilicate (Na) glass is used to seal to Mo.

Borosilicate (K) glass, with a high concentration of B (20% B_2O_3), is used to bond to Kovar. (Westinghouse's trade name for the Fe-Ni-Co magnetic alloy that has α close to that of the glass).

Pb glass is used if electrical insulation of a joint is critical.

26.11 ENAMEL

Ceramic enamel compositions are used for a wide variety of applications, include decorative coatings for glassware and china. In industry, they are used for coating baths, stovetops, etc.—whenever a metal requires a coating that is more durable than paint. It is also used to form colored borders around glass sheets used as automotive windshields. The reason for the colored borders is to enhance the appearance and to decrease the degradation of the underlying

adhesives by ultraviolet (UV) radiation. The enamel compositions consist of a glass frit (a powdered glass), a colorant, and an organic vehicle. The mixture is applied to the required part and then fired to burn off the organic vehicle and to fuse the enamel to the surface of the substrate.

In the art world, enameling is carried out using small furnaces and grams of powdered glass; in industry, square meters of surface can be enameled uniformly. The principle is the same, only the scale differs. A large piece, such as a cast-iron bath, would be shot-blasted to clean it, coated with a ground coat that bonds to the Fe,

CRACKLE GLASS

Crackle glass has been produced for its artistic appearance for over 150 years (perhaps since the sixteenth century in Venice). The glass is heated to $\sim 1,000^\circ\text{C}$ and then plunged into water causing cracks to form across the surface; if reheated and blown further the cracks heal on the interior; a similar effect is produced in glazes.

dried, and heated to nearly 1,000°C. It is then sprinkled with dry enamel frit while still hot and brought back to temperature. Five such coatings of enamel would be routine. The composition of the enamel must be chosen so that it is in compression after cooling. The composition would be modified on curved regions to maintain this compression.

Color is produced similarly for other glass. (We discussed color in glass in Section 21.8). As recently as 1999, the French Consumer Safety Committee considered the safety of the use of UO₂ dye to make enamels for the preparation of jewelry and enameled tiles. Old yellow enamels contained up to 9% UO₂ and frits using nondepleted U are certainly more “radioactive” than those of today. The committee noted that having 50% Pb in the frit might help absorb the radiation, but this increased the toxicity of the frit powder! Hence, safety in enameling is always a concern because the technique uses powders.

26.12 PHOTOCROMIC GLASS

Photosensitive glass is the glass analog of photographic film, where Au or Ag atoms (as halide particles) are affected by the action of light. Such glass is used in printing and image reproduction. Heat treating after exposure to light can cause a permanent change in the glass. Photochromic glass (discovered at Corning in the 1960s), darkens when exposed to light but then returns to its original clear state when the light is removed; hence, it is used in sunglasses or other ophthalmic lenses. The light affects small (~5 nm or a little larger) AgCl_xBr_{1-x} crystals in the glass. The manufacture of photochromic glass requires that the glass is heated to over 1,400°C, shaped, and then annealed again at 550–700°C to allow the small halide crystals to form in the initially homogeneous glass. Large flat glasses are not generally affordable, but the new approach is to use sol–gel processing (see Chapter 22) to form a photochromic layer on conventional preformed glass sheets.

PHOTOSENSITIVE & PHOTOCROMIC

Photosensitive: the glass is sensitive to light.

Photochromic: color is changed by exposure to light.

The principle is that the near-UV radiation generates electron–hole pairs in the halide particles. The electrons are trapped by the interstitial Ag ions, producing Ag colloids on the surface of the halide particle. The activation energy for this process is only 0.06 eV, so the Ag ion moves easily in the halide, plus a small amount of Cu increases the effect by at least an order of magnitude. This is the same process as in photography and is explained by the same Gurney–Mott theory. The metal particles formed in the process are 1–5 nm in size, but the halide must be >5 nm to show the effect; thus, the second annealing *T* is critical.

26.13 CERAMMING: CHANGING GLASS TO GLASS-CERAMICS

Worldwide sales of glass-ceramic products exceed \$500 million dollars a year. The highest volume is in cookware and tableware consumer items (e.g., plates, bowls) and domestic ovens (stovetops and stove windows). In this section we look at how these commercially important ceramics are processed.

Glass-ceramics are formed by controlled crystallization of a glass. They consist of a high density (maybe >95 vol%) of small crystals in a glass matrix. The important feature of the processing of glass-ceramics is that the crystallization must be controlled. As usual, crystallization occurs in two stages.

- First the crystals are nucleated.
- Then they grow.

The rate at which these two processes occur is a function of temperature. We can control the nucleation process by adding a nucleating agent (typically either TiO₂ or ZrO₂) to the glass batch.

ION EXCHANGE

Glass can be strengthened by ion exchange whereby small ions in the surface layer are replaced by larger ions, which put the surface into compression.

Step 1 Rapid exchange of Na⁺ or K⁺ with H⁺ or H₃O⁺ from solution:

This step is usually controlled by diffusion and exhibits $t^{-1/2}$ dependence.

Step 2 Loss of soluble silica in the form of Si(OH)₄, resulting from breaking of Si–O–Si bonds and formation of Si–OH (silanols) at the glass solution interface:

This stage is usually reaction controlled and exhibits a $t^{1.0}$ dependence.

Step 3 Condensation and repolymerization of a SiO₂-rich layer on the surface depleted in alkalis and alkaline-earth cations.

Step 4 Migration of Ca²⁺ and PO₄³⁻ groups to the surface through the SiO₂-rich layer forming a CaO–P₂O₅-rich film on top of the SiO₂-rich layer, followed by growth of the amorphous CaO–P₂O₅-rich film by incorporation of soluble calcium and phosphates from solution.

Step 5 Crystallization of the amorphous CaO–P₂O₅ film by incorporation of OH⁻, CO₃²⁻ or F⁻ anions from solution to form a mixed hydroxyl, carbonate, fluorapatite layer.

Initially, the glass batch is heated to form a homogeneous melt. The shape of the desired object is formed from the glass at the working point by the usual processes, such as pressing, blowing, rolling, or casting. Remember, the viscosity of the glass is $\sim 10^4$ dPa·s at the working point (like honey). After annealing to eliminate internal stresses, the glass object then undergoes a thermal treatment that converts it to a glass-ceramic. The first part of the heat treatment is nucleation. The optimum nucleation temperature generally corresponds to a glass viscosity of 10^{11} – 10^{12} dPa·s. During this step, which may last for several hours, an extremely high density (10^{12} – 10^{15} cm $^{-3}$) of nuclei form. Following nucleation, T is increased to allow growth to occur. The crystal-growth step, like nucleation, may take several hours. The optimum temperature for crystal growth is selected to allow for the maximum development of the crystalline phase without viscous deformation of the object. Figure 26.14 shows the complete processing cycle for a glass-ceramic.

The glass-ceramic process uses the same rapid forming techniques employed in glassworking permitting the economical production of objects with complex shapes or thin walls that are difficult or impossible with other, more traditional, ceramic forming techniques.

The most important and useful glass-ceramic system is the $\text{Li}_2\text{O}-\text{Al}_2\text{O}_3-\text{SiO}_2$ (LAS) family that was first developed at the Corning Company by Stookey. One commercial LAS glass-ceramic is Pyroceram[®], which has β -spodumene ($\text{LiAl}[\text{Si}_2\text{O}_6]$; $\alpha = \sim 10^{-6}/^\circ\text{C}$) as the major crystalline phase.

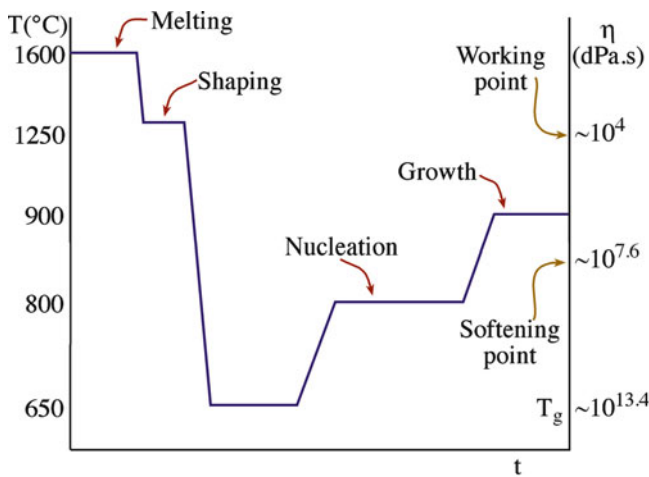

FIGURE 26.14. Processing cycle for a glass-ceramic.

The low α , together with excellent high temperature stability and insensitivity to thermal shock, means that these materials find applications as cookware, benchtops, hot-plate tops, ball bearings, and matrices for fiber-reinforced composites.

If the crystallization temperature is kept $\leq 900^\circ\text{C}$, the crystalline phase that is formed in LAS glass-ceramics is β -quartz. The β -quartz crystals are $< 0.1 \mu\text{m}$ in diameter. Crystal sizes below the wavelength of visible light ($\lambda = 0.7$ – $0.4 \mu\text{m}$), a good match in refractive index between the glass and the crystal phase, coupled with low birefringence result in high transparency. Table 26.5 lists the compositions and applications of some commercial transparent LAS glass-ceramics based on β -quartz.

Application 1: machinable glass-ceramics are derived from the $\text{K}_2\text{O}-\text{MgO}-\text{Al}_2\text{O}_3-\text{SiO}_2$ system containing some fluorine. In Macor[®], the crystalline phase is potassium fluorophlogopite [$\text{KMg}_3(\text{AlSi}_3\text{O}_{10}\text{F}_2)$]. Phlogopite is a mica mineral, and the plate-like mica crystals are randomly oriented in the glass phase, as shown in Figure 18.23. Macor[®] can be machined to precise tolerances (± 0.01 mm) and into intricate shapes using conventional steel tools: they can be drilled, cut, or turned on a lathe.

Application 2: another commercial fluoromica glass-ceramic, called Dicor[®], has been developed for dental restorations. Dicor has better chemical durability and translucency than Macor. It is based on the tetrasilicic mica, $\text{KMg}_{2.5}\text{Si}_4\text{O}_{10}\text{F}_2$, which forms fine-grained ($\sim 1 \mu\text{m}$) anisotropic flakes. Dicor dental restorations are very similar to natural teeth both in hardness and appearance. They are easy to cast using conventional dental laboratory methods and offer significant advantages over traditional metal-ceramic systems.

Application 3: calcium phosphate, $\text{Ca}_3(\text{PO}_4)_2$, glasses can be made into glass-ceramics to form a material resembling the mineral part of bone. As bone is porous, the first step is to produce a foam glass. This is achieved by decomposing carbonate in the glass melt. The foam glass simultaneously undergoes controlled crystallization, transforming it into a porous glass-ceramic. The dimensions of the interconnections between the pores must be sufficient to allow the ingrowth of living bone tissue, which ensures a permanent joint with the surface of the prosthesis.

TABLE 26.5 Base Compositions (wt%) and Applications of Transparent Glass-Ceramics Based on Quartz Solid Solutions

Material	SiO ₂	Al ₂ O ₃	MgO	Na ₂ O	K ₂ O	ZnO	Fe ₂ O ₃	Li ₂ O	BaO	P ₂ O ₅	F	TiO ₂	ZrO ₂	As ₂ O ₃	Commercial application

FIGURE 26.15. Process for making porous glass.

In principle, any glass can be converted to a glass-ceramic by finding a suitable nucleation agent and the appropriate heat treatment. In practice, a number of technical factors (among which is the production of the base glass) limit the choice.

We can use the phenomenon of photosensitivity to make a machinable glass! For example, we could use CorningWare ($\text{Li}_2\text{O}\cdot\text{Al}_2\text{O}_3\cdot\text{SiO}_2$) as the starting material and then add <1 wt% Cu, Ag, or Au. The idea behind the technique is similar to the photochromic glass, but we then leach out the Li_2SiO_3 crystals to leave a high density of small voids in the glass.

- (1) Irradiate glass with UV (Figure 26.15).
- (2) Anneal Au^0 agglomerates (small particles); nuclei for crystalline ceramic Li_2SiO_3 ($2\text{SiO}_2\cdot\text{Li}_2\text{O}$).
- (3) Place in dilute hydrofluoric acid (HF) to dissolve the Li_2SiO_3 (dissolution is 10 times faster than for the glass). This method can produce densities of 3.6×10^4 holes/in².
- (4) Reexpose to UV (no mask) and anneal; all is then polycrystalline (e.g., with 0.001% Au, 0.001–0.03% AgCl, or 0.001–1.00% Cu_2O).

Before leaving the topic, we should mention that this is not the only way to prepare glass-ceramics. Another group of these materials that are used for dentistry go by the label In-Ceram[®]. The material is prepared as a porous crystalline ceramic (alumina, spinel, and zirconia have all been used) and then infiltrated with a La-rich glass. The resulting glass-infiltrated ceramic can be quite translucent, can be colored to match other teeth, and is mechanically tough (for a ceramic). It can be coated with porcelains for improved appearance.

26.14 GLASS FOR ART AND SCULPTURE

Today, the glass art world is very active, with more abstract pieces by Chihuly and others being hung in many public buildings [e.g., the Victoria and Albert

FIGURE 26.16. Chihuly installation at the Victoria and Albert Museum in London.

Museum in London (Figure 26.16)]. Exhibitions travel around the United States and the world. The field is actually much wider than you might imagine.

The glass harp produces the “sound of the universe,” according to Goethe. The musician Gluck gave an entire concert using the glass harp in London in 1746. Sound is when a wine glass “sings”: run your finger around the rim.

The sound is thus produced by making the glass vibrate, rather than by making the air in the container vibrate (like blowing over a

bottle). Benjamin Franklin made a glass armonica. Mozart wrote music for the armonica: he placed glasses inside one another (not touching) and rotated them on a spindle to make playing easy! Galileo actually explained the resonance phenomenon in 1638. The tone depends on the mechanical (elastic) properties of the glass.

Murano, a small island near the city of Venice, was the center of glass-making for many years. The location was chosen to stop glass workers from moving away from the vicinity of Venice. It is still famous for its art glass, and the glass companies provide free boat taxis from the mainland to encourage customers. The millefiore inserts seen in paperweights and glass sculptures, illustrated in Figure 26.17,

MARBLES

Marble King in Virginia makes 10^6 marbles every day.

FIGURE 26.17. Millefiore paperweight showing the different glass canes used.

are usually associated with Murano. Actually, the technique had already been used in the first century CE.

Paté de verre is an art glass made by sintering pieces of glass, including powder, to make objects, particularly with distributions of color that would not be possible if the glass were melted. Essentially, the millefiore glass of Murano is made by this technique but now with larger “particles.” It is now being used by industry for the same purpose. The classical sintering technique for processing ceramic powders is thus being used to produce unique glass objects.

Art glass, usually in the form of figures and vases, became popular in the 1800s with Lalique, Gallé, Daum Frères, Tiffany, and others, as illustrated in Figure 26.18.

Between 1886 and 1936, the father-son team of Leopold and Rudolph Blaschka produced the Harvard glass flowers (shown in Figure 26.19) for use in teaching botany (there are other collections, but this is the best known). Tiffany produced similar specimens for the art market. The idea is that the color of glass does not change with time, and the flowers are three-dimensional. Actually, the Blaschkas used wire, paint (especially in the early years), varnish, and glue to enhance the models at the time. Thus, they are not quite as inert to the atmosphere as hoped, but they are superb examples of lampworking (heating a soda-rich glass and shaping it by pulling and pinching with various tools including tweezers).

In some countries, the best-known form of art glass is the stained-glass window (Figure 26.20). Stained glass has been made using several different techniques since it was first developed in the early twelfth century.

Pot-metal glass is bulk glass that has been colored by adding metal oxides in the usual way (e.g., Cu for red, Fe

FIGURE 26.18. Small vase by Daum Frères.

FIGURE 26.19. Harvard flower.

for green, Co for blue). Because the glass must be thick enough for the window, light transmission was often reduced (making the church dark).

Flash glass is produced by dipping a gob of clear glass into a pot of colored glass. When the glass is then blown, the two layers thin. The colored layer remains only a fraction of the total thickness. If the glass were uniformly colored but not flashed, it would transmit too little light

FIGURE 26.20. Drawing in stained glass.

(old church windows make for dark interiors); if the glass were uniformly colored but thin so as not to decrease the light, it would have insufficient mechanical strength. The layer can be abraded to give variations in color on the one piece of glass. Details in the window images can be drawn on the glass using an iron oxide pigment. The drawing is then fired to incorporate it into the glass.

26.15 GLASS FOR SCIENCE AND ENGINEERING

Lenses have been made using glass since microscopes and telescopes were first invented. When visible light is used, this is still generally the case. For transmitted light, the challenge is usually to minimize absorption; some telescopes, such as that on Mount Palomar, use a very wide, coated glass reflector. The critical factor is now not transmission but thermal expansion.

Stepper lenses are used in producing very-large-scale integration (VLSI) chips using photolithography. The stepper lens is the opposite of an enlarging lens—it shrinks the circuit pattern and prints it onto the semiconductor surface. (The term stepper is used to denote the step-and-repeat exposure system.) In 1997, the line width was 0.25 μm ; now it is around 60 nm. The challenge then is to focus light that has a wavelength much larger than the required resolution.

The Hale Telescope is a 200-in. telescope that was built ~1949 using a Pyrex blank manufactured by Corning Glass works. Schott Glass has since produced a telescope with a dish that is 8.2 m wide; it is made from Zerodur[®], Schott's glass ceramic, using a centrifugal casting process. An interesting link between art and science is the proposal by David Hockney that some of the masters used mirrors and lenses to help compose their paintings. Glass lenses range in size from the end of a fiber used in near-field scanning optical microscopy (NSOM) (see Chapter 10) to the Fresnel plate that was used in lighthouses.

Glass is one of our most important building materials. In 1851, the windows in the Crystal Palace used 300,000 panes, which accounted for 33% of England's annual production of glass. Biosphere 2 (built in the late 1980s) relies entirely on glass to separate the interior from Biosphere 1.

Glass fibers are used in textiles for clothing. The spacesuits used on the Apollo lunar missions were made from glass fiber industrial fabrics.

Glass microspheres are used, for example, in traffic signs and drug delivery. We describe radiotherapy glasses used in the treatment of unoperable cancers in more detail in Chapter 35. The key process is forming uniform glass spheres. We also discuss Bioglass in Chapter 35 but not ceramic cremation tiles for after-life applications.

FORMING MICROSPHERES

1. Glass melting
 - (a) Select chemically pure raw materials (oxides) that do not contain any impurities that would form undesirable radioisotopes during neutron irradiation.
 - (b) Mix raw materials.
 - (c) Melt raw materials to form homogeneous glass.
2. Spheroidization (microsphere formation)
 - (a) Crush glass to particles of desired size.
 - (b) Inject particles into gas-oxygen flame to melt each particle and form solid glass sphere (flame spray powder).
 - (c) Collect microspheres in suitable container.
3. Sizing: screen or separate microspheres into desired size range

Traffic signs and road-marking tape contain spheres that are ~200 μm in diameter and act as microlenses.

In the Ballotini flame drawing process, glass powder is injected into a flame that draws them up a tower until they melt and form spheres (1–60 μm diameter) dropping outside the flame and cooling under gravity. Filaments used to make the biprism for electron holography are made in the laboratory using a variation on the same principle.

CHAPTER SUMMARY

The production of glass is a multibillion dollar industry. The widespread use of glass products has gone hand-in-hand with developments in glass processing. Arguably the most significant development in recent times was the float glass process, which allowed high volume production of very high-quality glass sheets for architectural and transportation applications. Our city skylines certainly are influenced by the use of glass. More recent developments have led to improvements in the energy efficiency of buildings by controlling the transmission and absorption properties of glass. This is part of the “green” revolution in architecture.

Glass processing, which is both industry and art, has its own language. It is necessary to learn that language: in particular frit, cullet, lehr, fining, gob, and ribbon. The processing terms are engineering: floating, rolling, drawing, tempering, laminating, and ceramming.

PEOPLE AND HISTORY

Abbe, Ernst (1840–1905) was a professor of optics who worked with Schott, the glassmaker, and Ziess, the lensmaker, in Jena.

Burne-Jones, Sir Edward Coley (1833–1898) designed stained glass working with William Morris.

Chihuly, Dale (1941–) was born in Tacoma, Washington. In 1971, he co-founded the Pilchuck Glass School in Washington State. His work has been created and displayed throughout the world; most recent exhibition venues are the de Young Museum in San Francisco (2008) and the Museum of Fine Arts in Boston (2011).

Gallé, Émile (1846–1904). A pioneer in the Art Nouveau movement, he used wheel cutting, acid etching, casing (i.e., layers of various glass), including metallic foils and air bubbles. He called his experiments “marquetry of glass.” When you see heavy pieces of deeply coloured, nearly opaque glasses, which use several layers of glass and are then carved or etched to form plant motifs, you think of Gallé.

Lalique, René (1860–1945). One of the creators of Art Nouveau glass. Etched clear glass is a particular trademark.

Littleton, Harvey K. Born 1922 in Corning, NY, he was the University of Wisconsin professor who introduced Chihuly, Lipofsky, and others to glass and began the American Glass Movement.

Owens, Michael (1859–1923) Invented the automatic bottling machine.

Schott, Otto (1851–1935) plus Abbe and Zeiss.

Stookey, S. Donald. Another exception to the rule, he is one of the greatest scientific creators from Corning Glass.

Trancrede de Dolomieu, Guy S. (1750–1801) French professor of mineralogy. The mineral dolomite is named after him.

Zeiss, Carl Friedrich (1816–1888) gave his name to the optics company that was, for many years, based in Jena.

EXERCISES

- 26.1 Describe how cords and stones could be removed.
- 26.2 How much glass in your area is recycled as cullet?
- 26.3 Why did ancient glass batches have so much alkali content?
- 26.4 Why is tin used in the float glass process?
- 26.5 We process the glass to remove bubbles and thus avoid stresses in the glass. Is this statement true or false? Explain your answer.
- 26.6 On ceramming a glass, we produce a density of 10^{15} cm^{-3} nuclei. How far apart are the nuclei, and how does this affect the resulting grain size?
- 26.7 Why has the art of glass produced so much new interest? Is it new? Discuss.
- 26.8 Figure 26.1 shows the distribution of glass sales. Using the Internet or otherwise, compare these with the figures for Al, steel, and Cu. Discuss your results.
- 26.9 Estimate the cost of an automobile’s windows, assuming that they are made from tempered glass.
- 26.10 What are the compositions of some of the common sealing glasses?
- 26.11 How thin can plate glass be, and what determines this value?

- 26.12 A glass sphere is blown and plunged into water that's at 25°C. If the glass is 2 mm thick, how long does it take for the inside surface to cool to $T/2$?
- 26.13 Using the library or otherwise, find the smallest effective density of foam glass. Explain why this composition is chosen for this purpose.
- 26.14 You are told to coat a single sheet of window glass to reflect the most heat. What would you use for the coating, and how thick would the coating be for maximum reflection?
- 26.15 A friend has a piece of cloisonné enamel and thinks it could be very old. She asks for your help in assessing its actual age. Could it be old, and would you be able to help in dating it?
- 26.16 Discuss the reasons for glass artists using *paté de verre* to create a fish sculpture and compare it to the processing of alumina for the same purpose.
- 26.17 Why are the spheres used in road-marking tape $\sim 200 \mu\text{m}$ in diameter?
- 26.18 How does a commercial company make so many marbles each day, and what glass do they use?
- 26.19 Consider Figure 26.1. How do you expect modern technology to change this plot 20 years from now?
- 26.20 If the silica content of the glass in the calculation on page 476 were increased and the Na_2O and CaO wt.% both halved, what would the molecular formula of the glass now be and how would its properties have changed?

Coatings and Thick Films

CHAPTER PREVIEW

The term “thick film” does not just refer to film thickness but, rather, to layers or a coating made by certain processing techniques. Most of the methods that we describe in this chapter involve suspending ceramic particles either in a solution or in a mixture of organic solvents (known as the *vehicle*). It is necessary to remove all the volatile material from the coating to produce a dense adherent ceramic layer. Many of the processes in this chapter are relatively inexpensive (at least compared to those used to produce thin films that we describe in Chapter 28) and simple.

Tape casting is used to produce flat sheets of many different ceramics for applications as substrates, capacitor dielectrics, and fuel cell electrolytes. Some of the techniques described in this chapter (e.g., spin coating) are useful only for producing films on flat substrates. On the other hand, dip coating and electrophoretic deposition can be used to coat complex shapes. We finish by describing how thick film circuits are made. In this application, the ceramic is used as the substrate onto which the films are deposited and as important ingredients of the pastes that are used to form the circuits. The principle of the technology is not difficult, but controlling the processes may be.

All of these techniques are important in industry and you should know the *language* of thick films, such as slurry, slip, and paste.

27.1 DEFINING THICK FILM

A thick film typically has a thickness in the range 10–25 μm ; thin films are usually <500 nm. However, what really distinguishes thick films and thin films—more than just their relative thickness—is the way in which they are produced. Thin films are often deposited using vacuum techniques such as sputtering and molecular beam epitaxy (MBE). We describe these techniques and consider acronyms and hyphens in Chapter 28. Thick films are deposited from a solution or paste, which must be dried and then often sintered to produce the final coating.

There are several advantages of thick film processing.

- Simple
- Easy to automate
- Rapid
- Inexpensive
- Versatile
- Coating of complex substrates

In addition to describing some of the methods used to apply thick ceramic films to a substrate, we also describe

the tape-casting process. Films produced by tape casting are not used as coatings but as self-supporting ceramic sheets (down to 25 μm thick) that are widely used in the production of thick-film circuits.

27.2 TAPE CASTING

Tape casting is used to make flat ceramic sheets having a thickness up to about 1 mm. The process was developed during the 1940s for capacitor dielectrics. The production of ceramic capacitors is still one of the most important applications of tape casting.

In tape casting, a slurry (also called a slip) containing a powdered ceramic together with a complex mixture of solvents and binders is spread onto a moving polymer (e.g., Mylar™) sheet, as shown in Figure 27.1. In the early form of tape casting, the slurry was actually spread onto moving plaster of Paris plates. The use of a polymer sheet was patented in 1961, and since then the process has not significantly changed. The principle of the process

TAPE CASTING

Band casting and the doctor-blade process are other names.

FIGURE 27.1. Tape-casting process.

FIGURE 27.2. Triple doctor blade for producing multilayer tapes.

is essentially identical to spreading plaster on a wall, icing on a cake, or painting.

The thickness of the deposited layer is determined by the height of the doctor blade above the polymer sheet. Multilayer films are possible using the approach illustrated in Figure 27.2. The special feature of the doctor blade is that it produces a very uniform thickness. A typical doctor blade assembly is shown in Figure 27.3. The cast tape is dried, peeled from the polymer sheet, and reeled up to await further processing. At this stage of the process, the tape is flexible because it still contains a high percentage of organics in the form of the polymer binder; it is referred to as being “green.” This term is used to describe any unfired but shaped ceramic.

FIGURE 27.3. Typical doctor blade assembly.

The preparation of the slurry is very important. A slurry formulation used in processing alumina sheets for use as substrates for electronic devices is shown in Table 27.1.

- The solvent controls the viscosity of the slurry, allowing it to be spread on the polymer sheet.
- The binder holds the ceramic particles together until the tape is sintered and must be removed during the sintering process.
- Plasticizers increase the flexibility of the green tape.
- Dispersants (deflocculants) avoid settling of the powder particles.

Dispersants work by a process known as steric hindrance. The long-chain organic molecules, such as those in Menhaden fish oil (a long-chain fatty acid), attach themselves to the ceramic particles, with their long molecular tails pointing outward. This orientation prevents the particles from getting too close together and hence reduces the extent of agglomeration or settling. Manhaden fish oil is a natural product and is widely used in the ceramics industry because it is cheap.

Extensive shrinkage occurs during drying and firing of the tape because of the large volume fraction of organics in the slurry. For example, when the alumina slurry shown in Table 27.1 is cast to a thickness of 1.50 mm, it dries to produce a 0.75 mm green tape (about 50% reduction).

TABLE 27.1 Materials Needed to Prepare Alumina Slurries for Tape Casting

Milling step	Material	Function	wt%
Stage 1: mill for 24 h	Alumina powder	Substrate material	59.6
	Magnesium oxide	Grain growth inhibitor	0.15
	Menhaden fish oil	Dispersant	1.0
	Trichloroethylene	Solvent	23.2
	Ethyl alcohol	Solvent	8.9
Stage 2: add to above, and mill for 24 h	Polyvinyl butyral	Binder	2.4
	Polyethylene glycol	Plasticizer	2.6
	Octyl phthalate	Plasticizer	2.1

FIGURE 27.4. Example of an industrial tape casting machine.

When sintered, the tape shrinks further to a final thickness of about 0.60 mm.

Figure 27.4 shows a commercial tape-casting machine for the continuous production of ceramic tape. These machines range in size from 2 to >35 m in length and from about 100 mm to >1.25 m in width. The size determines the rate at which tapes can be produced. Typical casting speeds are on the order of 0.15 m/min. For quick-drying compositions, the casting speed can be as high as 2 m/min. In industrial production, it is often important to have continuous measurement of the tape thickness. These measurements can be made through a hole in the support plate downstream of the doctor blade. Several different approaches are used commercially: (1) X-ray backscattering from below; (2) X-ray transmission involving instrument heads below and above (a technique commonly used in the aluminum industry to measure thickness of Al plates); or (3) reflecting visible light at an angle from the top surface of the cast tape. The X-ray transmission method is generally preferred because of its greater accuracy.

Figure 27.5 illustrates the production of an integrated circuit (IC) package that uses tape-cast alumina sheets. The green tape can easily be punched to produce holes, or vias, which are an important part of the processing of IC packages. In addition, an ink or paste made of a mixture of metallic powder (tungsten or molybdenum), organic binders, and solvents is screen-printed onto the green tape. The tape is then fired in a wet hydrogen atmosphere to produce a strongly adherent metal layer on the sintered alumina. We describe the screen-printing process in more detail in Section 27.7.

27.3 DIP COATING

A ceramic film can be formed very easily on a substrate by dip coating, as illustrated in Figure 27.6. The starting material usually consists of metal alkoxides, but solutions of metal salts (e.g., nitrates) may be used instead. The substrate, or object to be coated, is lowered into the solution and withdrawn at rates of 10–30 cm/min. It is necessary that the solution wets and spreads over the surface of the substrate, so the contact angle must be low. The final film is obtained after firing the coated object. The advantages of dip coating are:

- It is simple.
- It is inexpensive.
- Complex shapes can be coated.
- Planar substrates can be coated on both sides at once.

The thickness, t , of the liquid film depends on the viscosity, η , of the solution and the speed, V , with which the object is withdrawn from the solution. It is given by:

$$t = 0.944 \left(\frac{\eta V}{\gamma_{lv}} \right)^{1/6} \left(\frac{\eta V}{\rho g} \right)^{1/2} \quad (27.1)$$

where γ_{lv} is the liquid–vapor interfacial energy, ρ is the density of the solution, and g is the acceleration due to gravity. The thickness will, of course, be less in the final fired film due to shrinkage. There are several applications for dip-coated ceramic films, as shown in Table 27.2.

DIP COATING

The high-tech version of the dipping process used to glaze pottery.

FIGURE 27.5. Steps in the production of an integrated circuit package.

27.4 SPIN COATING

Spin coating, like dip coating, starts with a solution that is often a mixture of metal alkoxides. The basic idea is illustrated in Figure 27.7, and there are two variants.

- Static
- Dynamic

In the static spin process, a few volumes of solution are dropped onto the substrate and allowed to spread until they cover most of the surface. Once the liquid has reached a specified diameter, the chuck is accelerated to a predetermined speed, on the order of 20,000 rpm.

In the dynamic spin process, the solution is dispensed onto the substrate surface, which is spinning at a low speed of about 500 rpm. After the liquid has spread, the rotation speed is increased to produce the final film. The dynamic spin process is better for producing uniform coatings on large-diameter substrates.

Spin coating can be used only for single-side coatings and generally is applicable only to fairly simple planar shapes. Also, spinning of very large objects is impractical. The thickness of the coating varies inversely with the angular velocity ($\omega^{-2/3}$) of the spin coater and is proportional to the viscosity of the solution ($\eta^{1/3}$). Spin coating is used widely in industry for forming polymer coatings, in particular for the deposition of photoresist layers prior to patterning of semiconductor devices. Although not widely used for producing ceramic films, spin coating has found some application in forming films of piezoelectric materials for micro-electro-mechanical systems (MEMS).

27.5 SPRAYING

Forming ceramic coatings by spraying is an important industrial process, in particular for applying wear-resistant and thermal-barrier coatings. There are several different

FIGURE 27.6. Simple dip-coating process.

FIGURE 27.8. Thermal spraying with a gas combustion/powder gun.

TABLE 27.2 Applications of Dip-Coated Sol-Gel Preparations

Film use	Composition	Conditions
Mechanical protection	SiO ₂	Multistep process. Alternating dips and firings at >400°C. Increase thickness by 100 nm each cycle
Chemical protection	SiO ₂	Great care in drying. Minimize cracking and crazing
Transparent electrode	In ₂ O ₃ -SnO ₂	Single dip process
Anti-reflecting	Na ₂ O-B ₂ O ₃ -SiO ₂	
Specific absorption	TiO ₂ -SiO ₂ Cr ₂ O ₃ -SiO ₂ Fe ₂ O ₃ -SiO ₂	
Catalytic		Low-temperature gelling <400°C ensures a porous film that has high surface area
Photo-mode	TiO ₂	
Ionic mode	β-Al ₂ O ₃ Ta ₂ O ₅	

FIGURE 27.7. Spin-coating process.

spraying processes. In thermal spraying, illustrated in Figure 27.8, the powder is melted or softened by passing it through an oxyacetylene flame. A variant of the basic thermal spray process, called plasma spraying, utilizes a plasma heat source and is illustrated in Figure 27.9. The plasma temperature is typically >28,000°C, well above that attained in gas combustion processes. The velocity of the plasma/droplet stream that exits the nozzle is usually subsonic, although high-velocity plasma torches with constricted nozzle designs are available. Thermal spray processes are generally suitable for applying any material that melts or becomes plastic in the heating cycle and does not degrade at high temperature.

FIGURE 27.9. Thermal spraying using a plasma arc.

Plasma spraying is widely used in forming wear-resistant coatings on diesel engine components and for producing thermal barrier coatings on metals for gas turbine engines. The efficiency of gas turbine engines depends on the maximum temperature that can be sustained by the rotor blades during continuous operation. Applying a ceramic coating (called a thermal barrier coating) to the metal allows the engine temperature to be increased by 50–200°C without the temperature of the metal increasing significantly. There is a corresponding improvement (up to about 12%) in engine efficiency, with considerable financial savings. Thermal barrier coatings must have the following properties.

- High coefficient of thermal expansion
- Low thermal conductivity
- Chemical stability in the gas turbine environment
- Thermal shock resistance

Yttria-stabilized zirconia (YSZ: ZrO_2 with 6–8 wt% Y_2O_3) has been among the materials investigated for thermal barrier coatings.

Figure 27.10 shows the cross section of such a coating. A Ni-Cr-Al-Y alloy (called the bond coat in Figure 27.10)

provides an adherent interlayer between the metal component and the ceramic coating. Joining metals and ceramics is not a trivial issue, and the approach mentioned here is just one of the methods that we cover in this book.

The source material for spraying can be a solution that is forced through a spray gun onto a heated substrate. In this case, the spraying is not “thermal” and is more akin to paint

FIGURE 27.10. Thermal barrier coating. The relative temperatures in the different parts of the coating are indicated.

SPRAY PAINTING CARS
The paint contains TiO_2 powder.

spraying. The glass industry uses this approach for depositing conductive layers of SnO_2 on glass.

27.6 ELECTROPHORETIC DEPOSITION

Electrophoresis is the movement of charged particles through a liquid under the influence of an external electric field. Electrophoretic deposition, which is very similar to

FIGURE 27.11. Particle electrophoresis cell.

the electrodeposition process used to form metal coatings, can be used to form a ceramic coating up to 0.6 mm thick on a metallic substrate. The substrate forms one of the electrodes in an electrochemical cell, as illustrated in Figure 27.11. The main advantage of electrophoretic deposition is that coatings can be formed on nonplanar objects.

The particles that form the coating are suspended in a liquid, which produces a surface charge on the particles (e.g., by the adsorption of protons). When a particle with charge q is placed in an electric field, E , it experiences a force, F .

$$F = qE \quad (27.2)$$

This force accelerates the particle toward the oppositely charged electrode. The particle also experiences a retarding force due to friction as it moves through the fluid. Recall from Chapter 20 that Stokes' law gives the retarding force due to viscous flow.

$$F = 3\pi\eta dv \quad (27.3)$$

where v is the terminal velocity, which we can write as:

$$v = qE/3\pi\eta d \quad (27.4)$$

In terms of mobility, μ :

$$\mu = v/E = q/3\pi\eta d \quad (27.5)$$

From equation 27.5, we would expect that particle mobility would be increased for small particles in a solution of low viscosity. This assumption is not entirely true. For example, the mobility of Li^+ ions in aqueous solution is lower than that of K^+ ions even though $r_{\text{K}^+} = 133$ pm

FIGURE 27.12. The ζ potential and effective size of a charged particle.

compared to $r_{\text{Li}^+} = 60$ pm. The discrepancy can be accounted for by considering solvation effects. Solvent molecules can cluster around an ion, increasing its effective size. Small ions are the source of stronger electric fields than large ions; hence, solvation is more extensive in the case of small ions, giving them a larger effective size and lower drift velocities. A similar effect can occur for charged ceramic particles moving through a liquid during electrophoretic deposition.

The zeta potential, ζ , illustrated in Figure 27.12, is the potential on the surface of the charged particle moving through the liquid.

For a particle in a dilute electrolyte solution ζ is given by:

$$\zeta = q/2\pi\kappa\epsilon_0 d \quad (27.6)$$

where κ is the dielectric constant of the liquid, and ϵ_0 is the permittivity of a vacuum (a universal constant = 8.85×10^{-12} F/m).

We can now obtain an expression for μ in terms of ζ .

$$\mu = \frac{2\kappa\epsilon_0\zeta}{3\eta} \quad (27.7)$$

For concentrated electrolytes, we use the Helmholtz-Smoluchowski equation to give us the mobility.

$$\mu = \frac{\kappa\epsilon_0\zeta}{\eta} \quad (27.8)$$

The important point from both equations 27.7 and 27.8 is that mobility is proportional to κ . For rapid coating, we want to use a liquid with a high dielectric constant.

TABLE 27.3 Dielectric Constants of Certain Liquids at 25°C and Zero Frequency

Nonpolar molecules		Polar molecules	
Methane	1.70 (at 173°C)	Water	78.54 80.37 (20°C)
Carbon tetrachloride	2.274	Ammonia	16.9 22.4 (-33°C)
Cyclohexane	2.105	Hydrogen sulfide	9.26 (-85°C)
Benzene	2.274	Methanol	32.63
		Ethanol	24.30
		Nitrobenzene	34.82

FIGURE 27.13. Surface charge density and electrophoretic mobility as functions of pH for rutile in aqueous solutions of potassium nitrate.

The advantage of using aqueous solutions is clear—water has a high dielectric constant. Dielectric constants of some other liquids are given in Table 27.3.

Figure 27.13 shows the electrophoretic mobility of TiO₂ particles in aqueous solutions of potassium nitrate (KNO₃). In this plot, σ₀ is the surface charge density, which was measured using the Brunauer, Emmett, and Teller (BET) method. The mobility is a function of the solution pH.

- In acidic solutions, the surface of the TiO₂ particles has a positive charge due to cation adsorption.
- In basic solutions, the powder particles have a negative charge due to the adsorption of anions.

EXAMPLE OF ELECTROPHORETIC DEPOSITION

For β-Al₂O₃ coatings the ceramic powder is suspended in an organic liquid mixture comprising nitromethane (CH₃NO₂) and benzoic acid (C₆H₅CO₂H). The benzoic acid produces a positive charge on the surface of the β-Al₂O₃ particles by adsorption of protons. The particles can be used to coat a negatively charged electrode.

TABLE 27.4 Isoelectric Points of Some Oxides

Material	Nominal composition	IEP
Quartz	SiO ₂	2
Soda-lime silica glass	Na ₂ O-0.58CaO-3.70SiO ₂	2-3
Potassium feldspar	K ₂ O-Al ₂ O ₃ -6SiO ₂	3-5
Zirconia	ZrO ₂	4-6
Apatite	10CaO-6PO ₂ -2H ₂ O	4-6
Tin oxide	SnO ₂	4-5
Titania	TiO ₂	4-6
Kaolin (edges)	Al ₂ O ₃ -SiO ₂ -2H ₂ O	5-7
Mullite	3Al ₂ O ₃ -2SiO ₂	6-8
Chromium oxide	Cr ₂ O ₃	6-7
Hematite	Fe ₂ O ₃	8-9
Zinc oxide	ZnO	9
Alumina (Bayer process)	Al ₂ O ₃	8-9
Calcium carbonate	CaCO ₂	9-10
Magnesia	MgO	12

At pH 5.9, the mobility is zero: this point is referred to as the isoelectric point (IEP). At the IEP, the ζ potential is zero. Table 27.4 shows IEPs for several different oxides. Acidic oxides, such as SiO₂, have low IEPs; basic oxides, such as MgO, have high IEPs.

27.7 THICK FILM CIRCUITS

Thick film circuits are single or multilayer structures produced by depositing a layer, or layers, of a specially formulated paste or ink onto a suitable substrate. Thick film technology began in the early 1960s when DuPont introduced a thick film resistor system for application in miniaturized circuits. IBM used thick film materials in their family of IBM/360 computers. Currently, the worldwide market for thick film circuits and devices is around \$14 billion. Most thick film circuits are still used in electronic applications, such as in computers (Figure 27.14).

FIGURE 27.14. Typical thick film circuit used in a personal computer, showing the different components.

There are three basic classes of thick film material (conductors, resistors, dielectrics), and all have at least one component that is a ceramic. They are supplied in the form of a paste or ink, which contains:

- The functional inorganic component, or components, in the form of a fine powder
- An organic binder, which is used to provide the green strength
- A low-boiling-point organic solvent, which provides the required viscosity to allow the paste to be deposited onto the substrate

27.7.1 Screen Printing and Processing

Thick film materials are deposited onto flat substrates by screen-printing. The origins of screen-printing date back more than 3,000 years when the Chinese used “silk screen” printing to deposit multilayered colored patterns onto fabrics. A similar process is still used today to print designs and logos onto T-shirts.

Figure 27.15 shows a diagram of the screen-printing process. The paste is forced through holes in a screen using a rubber squeegee. The viscosity of the ink is determined by the type and amount of organic solvent added to the formulation. Common solvents include pine oil, terpineol, and butyl carbitol acetate. The ideal thick film paste should have a low viscosity at a high shear rate produced when the squeegee traverses the screen so that material transfer onto the substrate occurs. The viscosity should remain low for a short time after the squeegee passes. The screen then snaps off of the substrate so the printed film is level to fill in the unevenness from the screen wires. The viscosity should then increase rapidly to a very high value to prevent spreading of the deposited film.

The equipment used to deposit thick film pastes is similar to that used in printing T-shirts; but for electronic applications, much higher precision in the placement of material and thickness control is required. It is possible to

FIGURE 27.15. Screen-printing process for depositing thick film circuits. The ink is forced through the screen, which then snaps away, leaving a film on the substrate.

FIGURE 27.16. Typical thick film circuit firing profile.

produce circuit lines having a width of 5 μm and a thickness of 5 μm . After printing, the substrates (coated with the wet paste) are moved to a drying oven, where the low boiling organic solvents are removed. The circuit lines still contain the organic binder, which gives the green strength to the deposited film.

The choice of binder is as important as the choice of solvent. The binder contributes to the overall rheological properties of the paste but must also be removed completely during firing. Ethyl cellulose is a common binder for air-fired materials. Binders for firing in inert or reducing atmospheres must be chosen carefully to avoid leaving a carbon residue in the fired film. Suitable choices include nitrocellulose and copolymers of ethylene and vinyl acetate.

The furnace is a belt furnace with a well-defined temperature profile, as shown in Figure 27.16. The peak temperature is at 6–10 min, during which time the inorganic components sinter together and bond to the substrate.

TABLE 27.5 Properties of Different Substrate Materials (AlN Sublimes)

Property	Units	96% Al ₂ O ₃	BeO	AlN
Thermal conductivity	W m ⁻¹ K ⁻¹	15–20	230–260	120–210
Coefficient of thermal expansion (RT ^a –400°C)	10 ⁻⁶ /°C	7.2	8.3	4.3
Electrical resistivity	Ω·cm	> 10 ¹⁴	> 10 ¹⁴	> 10 ¹⁴
Dielectric constant (RT at 1 MHz)	Unitless	9.4	6.7	8.6
Dielectric loss (RT at 1 MHz)	Unitless	0.0001	0.0003	0.0002
Dielectric strength	kv/mm	15	10	15
Density	g/cm	3.75	2.85	3.3
Melting temperature	°C	2,030	2,530	2,300
Modulus of rupture	MPa	358	280	280–350

Modulus of elasticity	GPa	303	345	331

^aRT room temperature.

27.7.2 Substrates for Thick Film Circuits

Substrates for thick film circuits generally have to satisfy the following requirements.

- Uniform surface (surface roughness of 20–40 μm is typical)
- Minimum distortion or bowing (0.010–0.22 cm/cm)
- Ability to withstand processing temperatures of up to 1,000°C
- Tight dimensional tolerances (±0.07–0.10 mm size; ±0.02–0.10 mm thickness)
- Strong
- High thermal conductivity
- High electrical resistivity
- Chemical compatibility with paste constituents
- Low dielectric constant
- Inexpensive

Alumina (96% Al₂O₃ with 4% of a glass containing MgO, CaO, and SiO₂) is the most common substrate material because it meets, to an acceptable degree, all of the above requirements. The substrates themselves are frequently made by tape casting, which we described in Section 27.2.

When a circuit is used in conditions where a significant amount of heat is transferred through the substrate but the thermal conductivity of alumina is not high enough, alternative materials may be used. For many years, the only alternative to Al₂O₃ was beryllia (BeO). The disadvantages of BeO are its cost and high toxicity in both vapor and powder form, as encountered in processing. Aluminum nitride (AlN) is another option and has not only a high thermal conductivity but is closely matched in the coefficient of thermal expansion to silicon in the temperature range 25–400°C (α_{Si} = 4.0 ppm/°C; α_{AlN} = 4.3 ppm/°C). The three substrates are compared in Table 27.5.

Although the properties of AlN make it very well suited for electronic packaging, there have been several problems in commercializing it.

- Most commercial AlN substrates have thermal conductivities ~170 W m⁻¹ K⁻¹, which is considerably lower than the theoretical thermal conductivity of 320 W m⁻¹ K⁻¹.
- AlN powder costs more than four times that of alumina powder.
- The adhesion of pastes designed for alumina is low on AlN unless the surface is preoxidized prior to deposition.

27.7.3 Thick Film Conductors

The general requirements for thick film conductors are:

- Low electrical resistivity
- Good adhesion to the substrate
- Good line definition

In addition, there may be the following considerations.

- Ability to be wire bonded or soldered for external connections
- Resistant to electromigration
- Compatibility with other thick film components, such as resistors and dielectrics
- Acceptable cost

The functional material in a thick film conductor is a metal. The important metals and alloys used in thick film conductors, together with some of their characteristics, are listed in Table 27.6.

There are two mechanisms for achieving adhesion of the metal film to the substrate.

- Frit bonding. A small amount (2–10%) of glass powder is added to the paste formulation. During firing, the glass softens, wets the substrate, and penetrates into the metal network to develop an interlocking structure. The most common glasses used in frit-bonded

TABLE 27.6 Metals and Alloys Used in Thick Film Conductors

Metal alloy	Principal features
Ag	\$. Highest conductivity. Ag ion migrates. Tarnishes. Seldom used in microcircuits. Migrates through glass and between conductors
Pd-Ag	\$\$\$. Pd inhibits migration but lowers conductivity
Pt-Ag	\$\$\$. Smaller quantity of Pt replaces palladium in the binary alloy
Au	\$\$\$\$. Highly conductive and chemically inert. Reliable bonds to Au wire. High solubility in common solders makes soldering difficult
Pd-Au	\$\$\$\$. Compared with Au, the solubility in solder is reduced but conductivity is impaired
Pt-Au	\$\$\$\$. Reliable solderable alternative to Au; not as conductive
Cu	\$. High conductivity. Fire in reducing atmospheres to achieve excellent solderability
Ni	\$. Can fire in air but not solderable from the furnace

\$ lowest cost; \$\$\$\$ highest cost

conductors are lead borosilicates (e.g., 63 wt% PbO–25 wt% B₂O₃–12 wt% SiO₂).

- Reactive bonding. A small amount (0.1–1.0%) of CuO or CdO is added to the paste formulation. During firing, the oxides react with the alumina substrate to form a copper or cadmium spinel, CuAl₂O₄ or CdAl₂O₄, respectively.

Frit bonding is the most common method, but there are several advantages of reactive bonding. First, very small amounts of additive are needed, which means that the electrical resistivity of the conductor is kept as low as possible. Second, the surface of the conductor is nearly pure metal, which enhances the attachment of thin Au or Al wires during wire bonding. Some thick film conductor compositions are termed “mixed-bonded” and contain a glass frit together with a mixture of oxides.

27.7.4 Thick Film Resistors

The functional phase in thick film resistors is a mixture of electrically conducting (or semiconducting) ceramic powders, such as ruthenium dioxide (RuO₂), bismuth ruthenate (Bi₂Ru₂O₇), lead ruthenate (Pb₂Ru₂O₆), and Ag-Pd-PdO mixtures for use in air-fired pastes; and tantalum nitride (TaN) is used for nitrogen-fired pastes. The resistance of thick film resistors is specified in terms of sheet resistance, which has units of ohms/square (Ω/□).

The concept of sheet resistance is illustrated in Figure 27.17A, which shows a sheet resistor of length *l*, width *w*, and thickness *d*, having a resistance, *R*, given by:

$$R = \frac{\rho l}{dw} \quad (27.9)$$

where ρ is the resistivity. If the resistor is square in shape, as in Figure 27.17B, then $l = w$ and equation 27.9 becomes:

SHEET RESISTANCE
Depends only on the thickness of the resistor and its resistivity.

FIGURE 27.17. Sheet resistance.

$$R = \frac{\rho}{d} \quad (27.10)$$

For a given material and thickness, all square sheets have the same resistance independent of the size of the square. The resistance of such squares is known as the sheet resistance. Figure 27.17C shows a complex thick-film resistor configuration, but the resistance can easily be determined by dividing it into squares, counting the number of squares per strip, and multiplying by the sheet resistance.

Thick film resistors are available with sheet resistance values in the range from 0.1 to 10.0 MΩ/□. By blending different quantities of conductive material and an electrically insulating glass, the resistivity is controlled. For a high sheet resistance

FIGURE 27.18. Typical resistance versus temperature profiles for thick film resistors.

formulation, the ratio of conductor to glass would be about 70:30.

An important parameter for thick film resistors is their temperature coefficient of resistivity (TCR), which is a measure of how much the resistance changes with temperature. It is defined as the slope of the change in resistance ($\Delta R/R$) versus temperature, as illustrated in Figure 27.18. The TCR limits specified for a particular formulation are the slopes of the two lines passing through the reference points on the curve that bound the resistance deviation. Typically, the reference temperature is 25°C , and the temperature range is -55°C to $+125^{\circ}\text{C}$. TCR values for thick film resistors are typically less than ± 100 ppm/ $^{\circ}\text{C}$.

Resistor patterns are designed so the average value of the fired resistor is lower than the required value. The final resistor is then trimmed using a laser, or an abrasive jet, to remove material and increase the resistance to within $\pm 1\%$ of the desired value.

27.7.5 Thick Film Dielectrics

Dielectrics are used in several difficult applications in thick film circuits.

- To isolate circuit lines in multilayer structures
- As a dielectric layers in thick film capacitors
- To encapsulate circuit components

For multilayer applications, the functional material is commonly a glass or a glass-ceramic. It must have a low dielectric constant and be thermal expansion-matched to the substrate to prevent stresses that can cause the substrate to bow. The film must also be stable as it may be subjected to many firing cycles during fabrication of a multilayer structure.

For thick film capacitor applications, the dielectric composition contains a material with a high dielectric constant, such as barium titanate. Encapsulants are used to protect resistors from harmful environmental conditions (e.g., high humidity, reactive organic solvents) and to protect silver-containing conductors from silver migration. The glass is chosen so that it can be fired at low temperatures to avoid significant refiring of the thick film resistors (which would change their resistance values). Typical firing temperatures for encapsulant glasses are $\sim 500^{\circ}\text{C}$. Most glass formulations used in the thick film industry are proprietary. To achieve low softening temperatures, the glass used for encapsulation probably contains a significant amount of either PbO or B_2O_3 .

CHAPTER SUMMARY

The term thick film refers to layers and coatings made by certain processing techniques. Such films are usually not prepared using vacuum conditions. In this chapter, we described most of the techniques that are used to produce thick ceramic films. Some of these processes are extremely simple and inexpensive, such as dip coating, which can be accomplished, at a minimum, with simply a beaker and a pair of tweezers. On the other hand, processes such as thermal spraying require specialized equipment.

We also described tape casting. This process is used to make flat sheets. Although it is a means of shaping and could have been described in the “shaping” chapter, we described it here because it shares a common feature with the other thick film coating methods: it uses a slurry. It also is the process most often used to make ceramic substrates for thick film circuits. Ceramics are a major component of thick film circuits. Even in thick film conductors, ceramics are important in ensuring adhesion between the metal layer and the substrate (which is invariably also a ceramic).

PEOPLE AND HISTORY

Much of the history of this topic is either very old (so no names) or was never known outside the companies where it happened.

Malouin, Paul Jacques (1701–1778) was a French chemist and physicist who had trained in medicine. He first demonstrated dip coating (iron into molten zinc) in 1742. (See Sorel.) He had a laboratory in the Louvre and an apartment in Versailles!

Sorel, Stanislas (1803–1871) of France filed a patent in 1837 for an improved (galvanic paint) process. Dip coating was probably first used for candle-making, but glazing ceramics may still win. Sorel also invented “Sorel cement”—which is stronger than Portland cement but not water-resistant.

EXERCISES

- 27.1 The slurry formulation for tape-casting barium titanate sheets consists of the following ingredients: barium titanate powder, phosphate ester, methyl ethyl ketone, ethanol, acrylic resin, benzyl butyl phthalate, and polyethylene glycol. (1) Explain the function that each of the ingredients has in the formulation. (2) What would be the usual amounts (in wt%) of each of the ingredients in a typical tape-cast formulation?
- 27.2 Explain why shrinkage of a cast tape occurs during drying and firing. Which of the ingredients in the above formulation would you expect to be lost at each stage of the process? Justify your answer.
- 27.3 Of the methods described in this chapter, which one would you choose to produce a uniform 10 μm coating of BaTiO_3 on a 5 cm diameter silicon wafer? Justify your choice.
- 27.4 Of the methods described in this chapter, which one would you choose to produce a uniform 100 μm coating of Al_2O_3 on a 5 mm diameter steel rod? Justify your choice.
- 27.5 Would thermal spraying be a suitable technique for forming thick films of aluminum nitride (AlN)? Explain the reasoning for your answer.
- 27.6 Alumina substrates for electronic packaging usually contain 96% Al_2O_3 and the remaining 4% is a mixture of CaO – MgO – SiO_2 . Why do you think these constituents are added to the alumina? What effect, if any, do you think they would have on the properties of a 96% alumina substrate compared to a 99.5% alumina substrate?
- 27.7 In glass formulations used in thick-film inks, alkali metal constituents are avoided. Why?
- 27.8 Who are the major vendors for thick-film materials?
- 27.9 Rank the thick-film conductors in Table 27.6 in terms of electrical conductivity starting with the most conductive. Is the trend consistent with their cost?
- 27.10 Figure 27.14 shows a thick-film circuit. (1) What is the role of the sealing glass? (2) Why is it green? (3) What properties are important for the sealing glass?
- 27.11 Put some reasonable numbers into equation 27.1 to show that this process can occur within a reasonable time frame to be industrially relevant.
- 27.12 Why do we say 500 rpm is a slow speed, and why would we want to increase it to produce the final film?
- 27.13 By searching the available commercial information, discuss the pros and cons of thermal spraying versus plasma spraying.
- 27.14 Suggest a dimension to add to Figure 27.10. Justify your answer and supply the reference sources.
- 27.15 Put some reasonable values into equations 27.4 and 27.5 to deduce values for v and μ .
- 27.16 How does the zeta potential of 200-nm particles of TiO_2 differ in water and ethanol? How do these values change if the size of the particle is reduced by a factor of 10?
- 27.17 The IEPs for zirconia and ZnO are quite different. Explain this difference.
- 27.18 How can the process described in Figure 27.16 take place at such low temperatures when using Al_2O_3 ?
- 27.19 What is frit bonding? Explore which industries are using this process.
- 27.20 We used to think of Al_2O_3 as an insulator. Now it is a dielectric. What is the difference?

Thin Films and Vapor Deposition

CHAPTER PREVIEW

Thin films are often deposited relatively slowly, so that the growth can be strongly influenced by the substrate, which plays a key role in determining film microstructure and properties. The substrate is much more important in growing thin films than it is for thick films and is a crucial factor if we want to grow oriented (epitactic) films. At the end of this chapter, we describe some of the requirements for the substrate. The growth techniques described in this chapter involve vacuum chambers and are generally expensive, so that thick films are grown by other methods, particularly when epitaxy is not required. Much of this topic is carried over from the semiconductor industry and is often not thought of as ceramic processing. However, without thin films of Si oxide and Si nitride, “Silicon Valley” might still be green fields.

28.1 DIFFERENCE BETWEEN THIN FILMS AND THICK FILMS

In the previous chapter we described how thick films of ceramics are produced. The difference between thick films and thin films is not really the thickness of the layer; it is how the layer is formed. In general, thin films are ≤ 500 nm in thickness, whereas thick films may be several tens of micrometers in thickness or even thicker depending on the particular application. Thin films are generally prepared from the vapor phase, whereas for thick films we use a solution or slurry. Furthermore, thin films are often crystallographically oriented in a particular way with respect to the underlying substrate. This orientation relationship, known as epitaxy, is determined by the crystal structures and lattice parameters of the film and the substrate. In general, thick films and coatings have no specific orientation and contain a large number of randomly oriented crystalline grains.

28.2 ACRONYMS, ADJECTIVES, AND HYPHENS

The thinnest thin films are almost exclusively formed from the vapor or gaseous phase and although there are many different deposition techniques they can be divided into two basic classes:

- Physical vapor deposition (PVD)
- Chemical vapor deposition (CVD)

Chemical vapor deposition techniques use either gas phase reactions or gaseous decomposition as the source of material. PVD techniques rely on excitation of a source (sometimes called the target), which is usually solid to produce the necessary material for film formation. In addition to the basic difference in the way that material transfer from the vapor phase to the solid phase is accomplished, there are other differences between CVD and PVD. For example, CVD is often used to produce thicker films (i.e., films >1 μm in thickness). The reason is that the growth rate by CVD is on the order of microns per minute (e.g., 2 $\mu\text{m}/\text{min}$), whereas for PVD techniques the growth rate is often orders of magnitude lower (growth rates in the range 0.01–0.03 $\mu\text{m}/\text{min}$ are typical). There are other differences that become evident as we describe the different techniques in the following sections.

Thin-film technology is replete with acronyms, and several of the main ones we encounter are listed in Table 28.1. MBE (molecular-beam evaporation) is the only acronym that assumes a crystalline structure and alignment of the thin film. Molecular-beam evaporation would be much better, especially when used to grow amorphous films!

We defined epitaxy in Chapter 15. Incidentally, the grammatically correct adjective from epitaxy is epitactic or, better still, epitaxial, but epitaxial has come to be accepted even by the Oxford English Dictionary because it is now so widely used. In many of the deposition techniques, it is not clear where the hyphen(s) should be (if there should be one), but thin-film growth is always the way to grow thin films, and adverbs are never hyphenated to parts of verbs.

TABLE 28.1 Some Common Acronyms in Thin-Film Technology

<i>CVD technique</i>	<i>Chemical vapor deposition</i>	<i>PVD technique</i>	<i>Physical vapor deposition</i>
APCVD	Atmospheric-pressure CVD	MBE	Molecular-beam epitaxy
LECVD	Laser-enhanced CVD	PLD	Pulsed-laser deposition
LPCVD	Low-pressure CVD	IBAD	Ion-beam-assisted deposition
MOCVD	Metal-organic CVD	RE	Reactive evaporation
PECVD	Plasma-enhanced CVD		

28.3 REQUIREMENTS FOR THIN CERAMIC FILMS

There are four general characteristics that we usually want to control when growing ceramic thin films.

- Crystal structure
- Stoichiometry
- Phase
- Surface morphology/topography

We now look at each of these characteristics and explain the rationale behind why they are important. The thin film may be crystalline, often epitactic, or sometimes polycrystalline or amorphous. The reason for requiring crystallinity is that for thin films we often make use of a particular electronic, optical, or magnetic property of the material. These properties are frequently anisotropic. Hence, we want to ensure that the film is crystalline and oriented in the correct way to optimize the desired property. This alignment is best achieved by judicious choice of substrate, and therefore we make use of epitaxy. Many properties of ceramic thin films are affected by the presence of grain boundaries (GBs). In epitactic films, it is often possible to control the types of GB that are produced. Generally, these boundaries are low-angle GBs, but they can be high-angle grain boundaries that may be associated with large distortions.

The correct stoichiometry, or composition, is necessary because for some materials they exhibit the required property only within a certain composition range. An example is the high-temperature superconductors whose structures we described in Chapter 7. For $\text{YBa}_2\text{Cu}_3\text{O}_{6+x}$ (YBCO), the value of the superconducting transition temperature depends on the value of x . When x is close to 1.0, the transition temperature is ~ 90 K. When x is 0.3, the transition temperature is reduced to 30 K. The change in oxygen stoichiometry is associated with a change in the structure of the material. Many technologically important ceramics exist in different crystalline forms. Another example is BaTiO_3 . The ferroelectric form of BaTiO_3 is tetragonal.

The final characteristic is the film surface. In general, we want to have smooth films, but this requirement is not universal and is really based on what we want to do with the film. If the film is part of a multilayer structure (i.e., there are going to be other layers deposited on top), then it is clearly important for the underlying surface to be

smooth. If the film is to be patterned using photolithographic techniques (the same techniques as are used to pattern semiconductor devices), then smooth surfaces are essential. Some properties are dependent upon surface roughness. For example, rough surfaces can contribute strongly to propagation losses in films used for guiding microwave radiation.

From the above discussion, you can see that there are several stringent requirements for ceramic thin films. For this reason, there are numerous techniques that have been used to form such films. Some techniques work better for some materials, whereas other techniques work better for others. We describe some of the techniques used to form ceramic thin films in the following sections, but this is not a comprehensive list.

28.4 CHEMICAL VAPOR DEPOSITION

Chemical vapor deposition involves either:

- Chemically reacting a volatile compound of a material to be deposited with other gases to produce a nonvolatile solid
- Pyrolysis (decomposition) of a compound at high temperature to produce a solid

In either case, the solid forms as a film on a suitably placed substrate. It is important that the reaction takes place only on the substrate surface. If the reaction takes place in the gas stream above the substrate, particulates form. Under these conditions, the film has a low density and a large number of voids. There are several different geometries for a CVD reactor, and some of them are illustrated in Figure 28.1. The substrates are usually placed on a graphite slab, which acts as a susceptor for radiofrequency induction heating. The gases are introduced into the reactor chamber, sometimes in the presence of an inert carrier gas such as argon. As an example of a CVD reaction, consider the formation of SiC from silicon tetrachloride (SiCl_4) and methane (CH_4).

Silicon tetrachloride is a liquid at room temperature and can easily be vaporized (it boils at 57.6°C) and transported to the reactor chamber. Methane can be

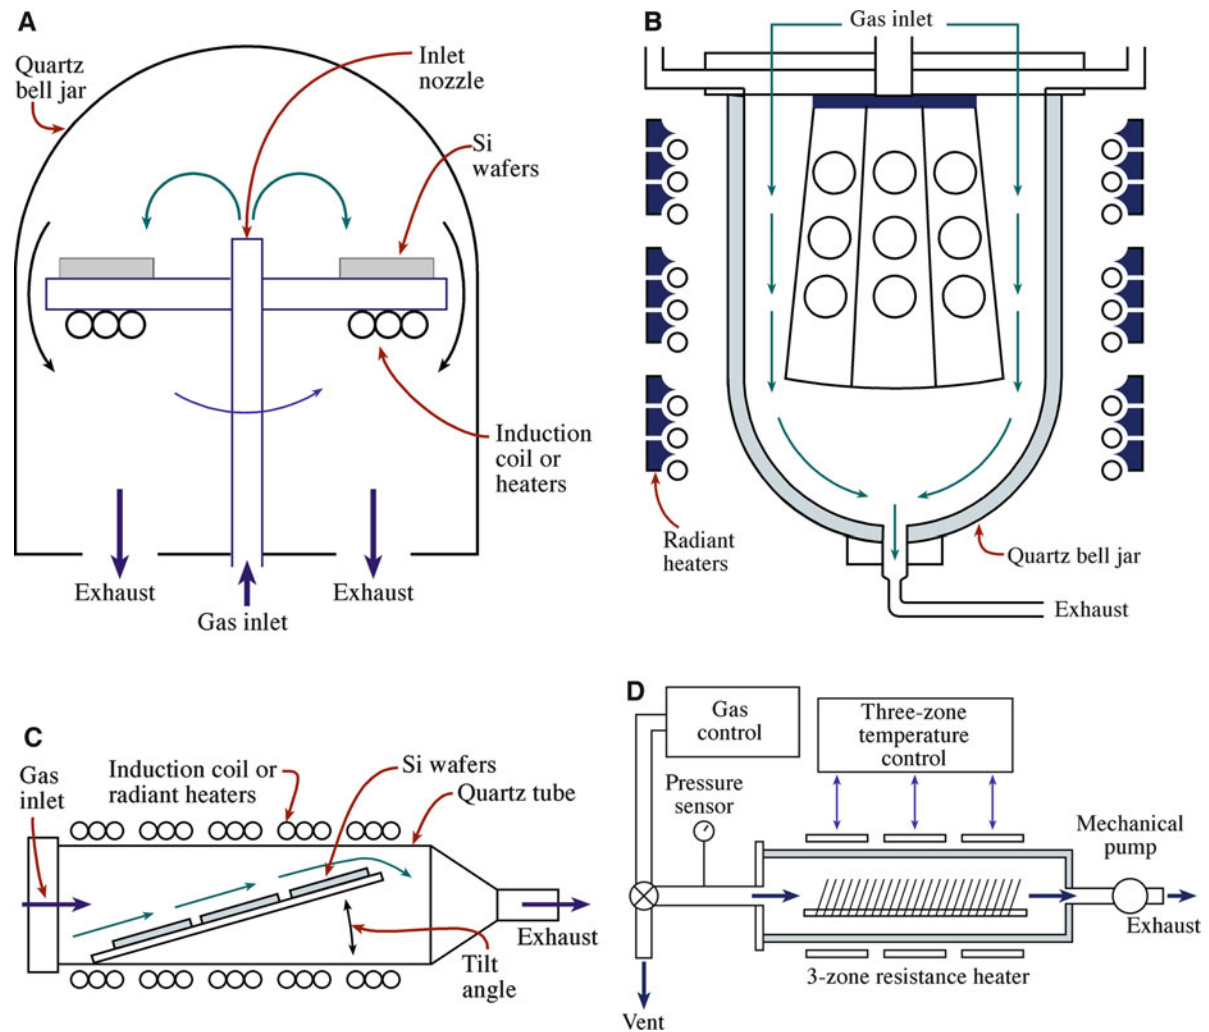

FIGURE 28.1. Examples of chemical vapor deposition (CVD) reactor configurations. (A) pancake, (B) barrel, (C) horizontal, (D) Low-pressure (LP)CVD.

supplied as a high-purity gas directly from a bottle. The reaction between SiCl_4 and CH_4 to produce SiC films occurs at $1,400^\circ\text{C}$. Two aspects of the temperature are important.

- It must be sufficiently high that the reaction occurs.
- If an epitaxial deposit is required, it must be high enough to allow the condensing species to diffuse across the crystal surface to find their required lattice crystal positions.

A variety of oxide, carbide, nitride, and boride films and coatings can be readily prepared by CVD techniques, as shown in Table 28.2. The reacting compounds must exist in a volatile form and must be sufficiently reactive in the gas phase. Examples of other reactions that can be used to produce ceramic films by CVD are given below.

$\text{TiCl}_4 (\text{g}) + \text{CH}_4 (\text{g}) \rightarrow \text{TiC} (\text{s}) + 4\text{HCl} (\text{g})$	$(1,000^\circ\text{C})$
$\text{BF}_3 (\text{g}) + \text{NH}_3 (\text{g}) \rightarrow \text{BN} (\text{s}) + 3\text{HF} (\text{g})$	$(1,100^\circ\text{C})$
$\text{AlCl}_3 (\text{g}) + \text{NH}_3 (\text{g}) \rightarrow \text{AlN} (\text{s}) + 3\text{HCl} (\text{g})$	$(1,000^\circ\text{C})$

Chemical vapor deposition is one of the most important deposition techniques for forming ceramic films and coatings. We described two examples in Chapter 20, where CVD is used in composites. It is used to form SiC fibers by the reaction between CH_3SiCl_3 and H_2 on a tungsten wire. It is also used to form the matrix phase in a ceramic matrix composite (CMC) by a process known as chemical-vapor infiltration. In later chapters, we describe the CVD technique again (e.g., it is used in the formation of optical fibers).

Before we leave this section, there is one additional example of the importance of CVD. All of the electronic grade silicon (EGS) used in the fabrication of silicon wafers is made by CVD. The highest-purity EGS is made by decomposition of silane (SiH_4), which itself can be prepared in extremely high purity. The substrate is an electrically heated U-shaped rod made of single-crystal silicon. The silane decomposes to form silicon, which deposits on the U-shaped rod in the form of a columnar, “feather-like” polycrystalline layer, as shown in Figure 28.2. The overall thickness of this layer can exceed 5 cm, so CVD can be used to produce very “thick” films!

TABLE 28.2 Examples of Ceramic Films and Coatings Produced by CVD

Film	Substrate	Reactants	Deposition temp. (°C)	Crystallinity
Si	Si	Either SiCl ₂ H ₂ , SiCl ₃ H, or SiCl ₄ + H ₂	1,050–1,200	E
		SiH ₄ + H ₂	600–700	P
Ge	Ge	GeCl ₄ or GeH ₄ + H ₂	600–900	E
SiC	Si	SiCl ₄ , toluene, H ₂	1,100	P
AlN	Sapphire	AlCl ₃ , NH ₃ , H ₂	1,000	E
In ₂ O ₃ : Sn	Glass	In-chelate, (C ₄ H ₉) ₂ Sn(OOCH ₃) ₂ , H ₂ O	500	A
ZnS	GaAs, GaP	Zn, H ₂ S, H ₂	825	E
CdS	GaAs, sapphire	Cd, H ₂ S, H ₂	690	A
Al ₂ O ₃	Si	Al(CH ₃) ₃ + O ₂	275–475	A
	Cemented carbide	AlCl ₃ , CO ₂ , H ₂	850–100	A
SiO ₂	Si	SiH ₄ + O ₂	450	A
		SiCl ₂ H ₂ + 2N ₂ O	900	
Si ₃ N ₄	SiO ₂	SiCl ₂ H ₂ + NH ₃	~750	A
SiNH	SiO ₂	SiH ₄ + NH ₃ (plasma)	300	A
TiO ₂	Quartz	Ti(OC ₂ H ₅) ₄ + O ₂	450	A
TiC	Steel	TiCl ₄ , CH ₄ , H ₂	1,000	P
TiN	Steel	TiCl ₄ , N ₂ , H ₂	1,000	P
BN	Steel	BCl ₃ , NH ₃ , H ₂	1,000	P
TiB ₂	Steel	TiCl ₄ , BCl ₃ , H ₂	>800	P

E epitactic, P polycrystalline, A amorphous

28.5 THERMODYNAMICS OF CVD

Thermodynamics tells us if a particular chemical reaction is feasible. However, it does not provide any information about the speed of the reaction or film growth rates. Even when a reaction is thermodynamically possible, if it proceeds at very low rates it is not commercially very useful.

We can calculate the standard free energy, ΔG^0 , of many reactions using tabulations of thermodynamic data. Consider the reaction between TiCl₄ and CH₄.

ELECTRONIC GRADE SILICON (EGS)
 The annual worldwide production capacity is $>10^7$ kg.
 It's all made by CVD.

To find the standard free energy, ΔG_r^0 , for this reaction, we need to consider the standard free energies for forming the reactants and the products from their elements in the standard state at the temperature of interest. If we assume a reaction temperature of 1,200 K, we can look up ΔG^0 for the individual reactions below.

Ti + 2Cl ₂ → TiCl ₄	$\Delta G_1^0 = -610$ kJ
C + 2 H ₂ → CH ₄	$\Delta G_2^0 = 42$ kJ
1/2 H ₂ + 1/2 Cl ₂ → HCl	$\Delta G_3^0 = -102$ kJ
Ti + C → TiC	$\Delta G_4^0 = -171$ kJ

From basic thermodynamics we know:

$$\Delta G_r^0 = \Sigma \Delta G^0 \text{ products} - \Sigma \Delta G^0 \text{ reactants} \quad (28.3)$$

Hence, for the reaction in equation 28.2:

$$\Delta G_r^0 = (\Delta G_4^0 + \Delta G_3^0) - (\Delta G_2^0 + \Delta G_1^0) \quad (28.4)$$

The numbers are

$$\begin{aligned} \Delta G_r^0 &= (-171 + 4(-102)) - (42 - 610) \\ &= -11 \text{ kJ} \end{aligned} \quad (28.5)$$

The negative value of ΔG_r^0 indicates that the reaction proceeds spontaneously at 1,200 K to produce TiC. Consider a similar

calculation at 298 K instead of 1,200 K. The calculated values for ΔG^0 are now:

$\text{Ti} + 2\text{Cl}_2 \rightarrow \text{TiCl}_4$	$\Delta G_1^0 = 718 \text{ kJ}$
$\text{C} + 2 \text{H}_2 \rightarrow \text{CH}_4$	$\Delta G_2^0 = 51 \text{ kJ}$
$1/2 \text{H}_2 + 1/2 \text{Cl}_2 \rightarrow \text{HCl}$	$\Delta G_3^0 = 95 \text{ kJ}$
$\text{Ti} + \text{C} \rightarrow \text{TiC}$	$\Delta G_4^0 = 180 \text{ kJ}$

Therefore, at a temperature of 298 K, the value of ΔG_r^0 is +109 kJ. The positive value of ΔG_r^0 indicates that the reaction between TiCl_4 and CH_4 to form TiC does not proceed spontaneously at room temperature.

If we now consider a generalized chemical reaction between two gases, A and B , to produce a solid C and another gas D .

The equilibrium constant for this reaction is:

$$K = [C]^c [D]^d / [A]^a [B]^b \quad (28.7)$$

where $[\]$ indicates the equilibrium activity of each component of the reaction. As usual, we can take the activity of a pure stable component as unity. Pressures may be used to approximate the activities of the gaseous species; hence:

$$K \approx (pD)^d / (pA)^a (pB)^b \quad (28.8)$$

where (p) is the equilibrium pressure of the reactants and the products. The driving force for growth may be expressed as:

$$\Delta G_r^0 = -RT \ln K \quad (28.9)$$

where R , the gas constant, is $8.314 \text{ J K}^{-1} \text{ mol}^{-1}$.

It is usually desired that the concentration of the volatile reactant species be fairly high so that the transport of reactants to the substrate is very rapid. If the concentration of reactants is too low, it is difficult to produce a reasonable flow of material to the substrate surface. Thus, we want the value of K to be small. Assuming that the reaction to produce TiC was carried out in a closed system (so that the HCl was not being removed), the value of $\ln K$ would be 1.1. [Sometimes the equilibrium constant term is expressed as a logarithm in base 10 (\log) rather than as a natural logarithm, \ln ; then the desired value is $\log K = 0.5$.] When $\ln K$ is very large, the driving force is very large, which tends to produce a polycrystalline film, rather than single crystal epitaxial films. The use of thermodynamics implies that chemical equilibrium has been attained. Although this may occur in a closed system, it is generally not the case in an open system such as a flow reactor, where gaseous reactants and products are continuously introduced and removed.

CVD

This is an empirical method of film growth guided by thermodynamics.

28.6 CVD OF CERAMIC FILMS FOR SEMICONDUCTOR DEVICES

Ceramic films are widely used in the fabrication of semiconductor devices. The two materials that are presently of major interest are silicon dioxide (SiO_2) and silicon nitride (Si_3N_4). These are deposited as thin films using CVD.

SiO_2 films can be deposited with or without dopants. Undoped it has multiple uses.

- Insulating layer between multilevel metallizations (Figure 28.3)
- Implantation or diffusion mask
- Capping layer over doped regions to prevent out-diffusion during thermal cycling

A suitable reaction to produce SiO_2 is the oxidation of silane (SiH_4) at 450°C .

Above 600°C , water vapor is produced.

The SiO_2 film produced by either of the above two reactions is amorphous.

For some applications, we need doped SiO_2 films. Dopant species include boron and phosphorus. Doped oxide films are made by introducing dopant compounds such as phosphine (PH_3) or diborane (B_2H_6) into the gas

FIGURE 28.3. Cross section of multilayer metallization to a polysilicon gate field effect transistor. The contacts to the source and drain are silicides. Tungsten is used to provide vertical interconnects through vias in the oxide layer.

stream along with SiH₄ and an oxygen source. The chemical reactions for phosphorus-doped oxides are:

and

Phosphorus-doped silica films are used as

- Insulators between metal layers
- Device passivation
- Diffusion sources

One application that we describe in a little more detail is the use of phosphorus-doped glass (called P-glass in the semiconductor industry) as an insulator between polysilicon gates and the top metallization in a metal oxide semiconductor field effect transistor (MOSFET). The P-glass is used because steps formed by the polysilicon gate make uniform deposition of the metal film impossible. The P-glass layer is deposited by CVD and then heated until it softens and flows. This process is called reflow. The reflow characteristics depend on the concentration of P in the glass, which is typically 6–8 wt%. Silica doped with both P and B is also used for the reflow process. Typical concentrations are 1–4 wt% B and 4–6 wt% P. The borophosphosilicate glass (BPSG) has the advantage of lower flow temperatures; however, care must be taken to carefully control the dopant concentrations—otherwise, separation of a B-rich phase can occur.

Si₃N₄ layers deposited by CVD are important in the fabrication of certain semiconductor devices. One area is in the so-called LOCOS (local oxidation of silicon) process. This method is used in both bipolar and MOS devices to isolate active device regions. The process works as follows: a layer of Si₃N₄ is deposited on the silicon wafer by CVD either by reacting silane and ammonia at temperatures of 700–900°C:

or by reacting dichlorosilane and ammonia at 700–800°C.

Like the SiO₂ films described earlier, the Si₃N₄ is amorphous. The exposed regions of the silicon wafer are then oxidized while the areas covered by Si₃N₄ are protected. The oxidizing agent cannot diffuse through the Si₃N₄ layer to reach the silicon surface. However, oxidation does occur a small distance below the edges of the silicon nitride layer. If the oxide layer is sufficiently thick, the edges of the nitride film are pushed up and away from the silicon surface. After oxidation the Si₃N₄ layer is removed.

Si₃N₄ layers are also used for passivating Si devices because they act as an extremely good barrier to the diffusion of water and Na. These impurities can cause device metallization to corrode or devices to become unstable.

28.7 TYPES OF CVD

There are several forms of CVD, and each form has its own acronym. If the process takes place at atmospheric pressure (AP) it is referred to simply as CVD or APCVD. In APCVD systems, the gas flow is almost exclusively parallel to the surface. The reactor configurations shown in Figure 28.1 are all examples of configurations used for APCVD.

When lower pressures are used, the operation is low-pressure CVD (LPCVD). The gas pressure is usually in the range 0.5–1.0 Torr for LPCVD reactors, distinguishing it from APCVD systems operating at 760 Torr. In LPCVD reactors, the substrates are mounted vertically.

If a plasma is used to generate ions or radicals that recombine to give the desired film, the process is plasma-enhanced CVD (PECVD). In PECVD, it is possible to use much lower substrate temperatures because the plasma provides energy for the reaction to proceed. A major commercial application of PECVD is the formation of silicon nitride films for passivation and encapsulation of semiconductor devices. At this stage of the fabrication process, the device cannot tolerate temperatures much above 300°C. High temperatures would still be required if crystalline or epitaxial films were required. Many nitrides have been prepared in thin-film form by PECVD, including AlN, GaN, TiN, and BN. A more complete list of films deposited by PECVD is given in Table 28.3.

PECVD has also been used to fabricate carbon nanotubes and other one-dimensional nanostructures, such as boron carbide nanowires and nanosprings. A convenient precursor for boron carbide nanowires is orthocarborane (C₂B₁₀H₁₂).

MOCVD is distinguished from other forms of CVD in that the precursors are metalorganic compounds. MOCVD is widely used in the semiconductor industry but not as widely in forming ceramic films. One example of a ceramic film formed by MOCVD is AlN, where the precursors are trimethyl aluminum (TMAI = Al(CH₃)₃) and ammonia (NH₃).

LECVD (laser-enhanced CVD) uses a laser beam to enhance reactions at the substrate surface. One feature of this technique is that it is possible to “write” materials on the substrate: the deposit is formed only where the scanned light beam hits the substrate.

TABLE 28.3 PECVD Reactants, Deposition Temperatures, Growth Rates

<i>Film</i>	<i>Temp. (K)</i>	<i>Rate (cm/s)</i>	<i>Reactants</i>
a-Si	573	10^{-8} – 10^{-7}	SiH ₄ ; SiF ₄ -H ₂ ; Si-H ₂
c-Si	673	10^{-8} – 10^{-7}	SiH ₄ -H ₂ ; SiF ₄ -H ₂ ; Si-H ₂
C (graphite)	1,073–1,273	10^{-5}	C-H ₂ ; C-N ₂
CdS	373–573	10^{-6}	Cd-H ₂ S
SiO ₂	523	10^{-8} – 10^{-6}	Si(OC ₂ H ₅) ₄ ; SiH ₄ -O ₂ , N ₂ O

Silicon tetrachloride (SiCl ₄)	X				

28.8 CVD SAFETY

Safety issues are particularly important for CVD because many of the source compounds are toxic, and disposal of waste products (e.g., HCl) is often problematic. Additional problems can occur if the reactants are pyrophoric (ignite in contact with air). Table 28.4 lists some of the source gases used in CVD and their potential hazards. Silane is widely used in the semiconductor industry and was the cause of a major explosion and fire at a manufacturing plant in Moses Lake, WA. The incident caused a number of critical injuries and closed the plant for several months.

28.9 EVAPORATION

Experimentally, evaporation is a very simple method for forming thin films. The source is either a liquid or a solid that is heated to produce a flux of atoms or molecules. In general, it is necessary to melt the material if the vapor pressure is $<10^{-3}$ Torr at its melting temperature. Most metals fall into this category, and so liquid sources are used. Some metals reach sufficiently high vapor pressures below their melting temperature (e.g., Cr) and can be used as solids.

Evaporation of metals is generally straightforward because they evaporate either as atoms or as clusters of atoms. On the other hand, most compounds dissociate

when heated, and therefore the vapor composition is different from that of the source. Consequently, the stoichiometry of the deposited film is also different from that of the source. An example of an oxide that dissociates on heating is ZrO_2 .

Films formed directly from evaporation of ZrO_2 tend to be metal-rich. To maintain the desired stoichiometry, it is necessary to perform the evaporation in an oxygen-rich environment. This is called reactive evaporation (RE). A similar approach needs to be used with SiO_2 , GeO_2 , TiO_2 , and SnO_2 .

Some ceramics sublime; that is, they go from the solid to the vapor without dissociation. For example:

Thus, film stoichiometry would be maintained in the deposit. Several oxides behave in this way (e.g., B_2O_3 , GeO , SnO).

For some ceramics, the high sublimation temperatures require special heating sources for evaporation. One such source is a focused electron beam. The process is then called electron beam (or simply e-beam) evaporation.

28.10 SPUTTERING

An example of a simple sputtering system is shown in Figure 28.4. Atoms are dislodged from a solid target through the impact of energetic gaseous ions. The usual sputtering gas is argon, which is ionized, forming a plasma. An argon plasma has a characteristic purple color, which you see during sputter coating of samples for scanning (SEM) and transmission (TEM) electron microscopy analysis. The plasma forms as a result of collisions between energetic electrons in the gas and the argon atoms. The positive Ar^+ ions in the plasma are attracted toward the cathode (the *target*) and the electrons toward the anode (the *substrate*). The energy of the Ar^+ depends on the value of the applied electric field but is sufficient to cause atoms to be ejected from the target surface. When an ion reaches the target, it collects an electron, supplied via the external circuit from the anode; it then becomes a neutral atom that returns to the gas to be reionized. A substrate placed facing the cathode is coated with a film of the material sputtered off the target surface. [If you have any experience with sputter coating samples for electron microscopy, you know that the inside walls of the vacuum chamber also

FIGURE 28.4. Sputtering system.

become coated.] A wide range of ceramics can be deposited by sputtering; some examples are given in Table 28.5.

There are several characteristics of the sputtering process that need to be considered before using this technique for film growth.

- It does not involve melting, and therefore materials with high melting points can be deposited.
- It is a relatively slow process.
- It may be difficult to maintain stoichiometry of a multicomponent target due to different sputtering rates of the constituents.
- When the substrate and target are facing each other (on-axis configuration), the growing film may be damaged by bombardment with energetic species from the plasma.

Ar IN PLASMA FORMATION

Used because of its high mass, which creates a high momentum and more ejected particles from the target.

As with CVD and evaporation, there are various types of sputtering. The process we have described so far is direct-current (DC) sputtering, also called diode

or cathodic sputtering. It is the easiest process to visualize but cannot be used for insulating targets. The two approaches for ceramics are:

- Reactive sputtering—DC sputtering of a metal target in a reactive gas environment. For example, we can make AlN films by sputtering an Al target in either nitrogen or ammonia (mixed in with the working gas, Ar).
- RF sputtering—Uses an alternating radiofrequency (RF) signal between the electrodes. Typical frequencies are 5–30 MHz.

TABLE 28.5 Ceramic Sputtering Targets

<i>Material</i>	<i>Applications</i>
<i>Oxides</i>	
Al ₂ O ₃	Insulation, protective films for mirrors
BaTiO ₃ , PbTiO ₃	Thin-film capacitors
CeO ₂	Antireflection coatings
In ₂ O ₃ -SnO ₂	Transparent conductors
LiNbO ₃	Piezoelectric films
SiO ₂	Insulation
SiO	Protective films for mirrors, infrared filters
Ta ₂ O ₅ , TiO ₂ , ZrO ₂ , HfO ₂ , MgO	Dielectric films for multilayer optical coatings
Yttrium aluminum garnet (YAG), yttrium iron garnet (YIG), gadolinium gallium garnet (GGG, Gd ₃ Ga ₅ O ₁₂)	Magnetic bubble memory devices
YVO ₃ -Eu ₂ O ₃	Phosphorescent coating on special currency papers
YBa ₂ Cu ₃ O ₇	High-temperature superconductors
<i>Fluorides</i>	
CaF ₂ , CeF ₃ , MgF ₂ , ThF ₄ , Na ₃ AlF ₆ (cryolite)	Dielectric films for multilayer optical coatings (e.g., antireflection coatings, filters)
<i>Borides</i>	
TiB ₂ , ZrB ₂	Hard, wear-resistant coatings
LaB ₆	Thermionic emitters
<i>Carbides</i>	
SiC	High-temperature semiconduction
TiC, TaC, WC	Hard, wear-resistant coatings
<i>Nitrides</i>	
Si ₃ N ₄	Insulation, diffusion barriers
TaN	Thin-film resistors
TiN	Hard coatings
<i>Silicides</i>	
MoSi ₂ , TaSi ₂ , TiSi ₂ , WSi ₂	Contacts, diffusion barriers in integrated circuits
<i>Sulfides</i>	
CdS	Photoconductive films
MoS ₂ , TaS ₂	Lubricant films for bearings and moving parts
ZnS	Multilayer optical coatings
<i>Selenides, tellurides</i>	
CdSe, PbSe, CdTe	Photoconductive films
ZnSe, PbTe	Optical coatings
MoTe, MoSe	Lubricants

28.11 MOLECULAR-BEAM EPITAXY

Molecular-beam epitaxy is a technique that has mainly been used by the semiconductor industry for producing thin films of compound semiconductors (e.g., GaAs, InP) used in the fabrication of LEDs, laser diodes, etc. These inorganic semiconductors are ceramics, so it should not be surprising that the technique can also be used to grow other ceramic thin films (e.g., the high-temperature superconductor YBa₂Cu₃O₇). In fact, MBE is ideal for ceramics that have layered structures because it allows precise sequential deposition of single monolayers.

An MBE system is shown in Figure 28.5. The materials to be deposited are usually evaporated from separate furnaces called Knudsen effusion cells, which are bottle-shaped crucibles with a narrow neck. A resistance heater wound around the cell provides the heat necessary to evaporate the material. As in the case of conventional

evaporation, the source may be solid or liquid depending upon its vapor pressure. The rate of deposition of each species is determined by the vapor pressure above the source, which is a strong function of temperature. The temperature of each of the Knudsen effusion cells therefore controls the flux of atoms reaching the substrate.

MBE of semiconductors requires the use of an ultra-high vacuum (UHV) chamber (background pressure 10⁻⁸–10⁻¹⁰ Torr). For oxide ceramics, background pressures of ≤10⁻⁴ Torr are more common. The high-vacuum requirement of MBE presents a problem for the growth of many multicomponent oxides (e.g., the high-temperature superconductors) because most of these compounds require oxygen pressures much higher than this to form. This limitation has been overcome by the use of highly oxidizing gases (e.g., NO₂, atomic O, or O₃) near the surface of the growing film while the background pressure is maintained as low as possible.

FIGURE 28.5. Molecular beam epitaxy system.

FIGURE 28.6. Pulsed-laser deposition system.

PRESSURE

Often quoted in the non-SI units of torr; 1 Torr being equivalent to 1 mmHg. The SI unit for pressure is the pascal, Pa. One Pa is equal to one newton per square meter (N/m^2). To convert between Torr and Pa, simply multiply the pressure in torr by 133.3 to obtain the pressure in Pa ($750 \text{ Torr} = 10^5 \text{ Pa}$).

In addition to the requirement of high-vacuum or UHV environments, the other features of MBE that limit its use are:

- The equipment is expensive ($> \$1$ million), so the value added must be high.
- Deposition rates are low: $\leq 1 \mu\text{m/h}$ is typical.

28.12 PULSED-LASER DEPOSITION

In pulsed-laser deposition (PLD), a laser beam is used to ablate material from a solid target. The experimental arrangement, which is simple, is shown in Figure 28.6. However, the laser–target interactions are very complex and result in the formation of a plume of material (often visible and brightly colored) that contains all the necessary components (often in the correct proportions) for film growth.

PLD GROWTH OF BaTiO_3 THIN FILMS CONDITIONS

Chamber evacuated to $< 5 \mu$ torr
 Pressure during deposition 400 m torr of O_2
 KrF excimer laser $\lambda = 248 \text{ nm}$
 Pulse repetition rate 50 Hz
 Pulse energy 85 mJ
 Target to substrate distance 4 cm
 Substrate temperature 750°C

TABLE 28.6 Excimer Laser Wavelengths

Excimer molecule	Wavelength (nm)
F_2	157
ArF	193
KrCl	222
KrF	248
XeCl	308
XeF	351

Excimer lasers operating in the ultraviolet (UV) range are the lasers of choice for most PLD systems. The operating wavelengths used in commercial systems are shown in Table 28.6. Pulse energies up to 500 mJ are used, with repetition rates up to several hundred hertz.

PLD offers several advantages over other PVD methods.

- The interaction of the laser beam and the target produces a plasma consisting of species having high kinetic energy, which enables epitaxial film growth at low substrate temperatures.
- There is growth of films having complex stoichiometry.
 - The irradiation source is outside the deposition chamber, allowing flexibility. Multiple chambers can use a single laser, and the irradiation source can be easily changed.
 - Relatively high deposition rates ($> 10 \text{ nm/s}$) can be achieved.
 - It is fairly inexpensive.

It also has several drawbacks.

- It is difficult, at present, to cover large substrates uniformly because the plume peaks in the forward direction.
- The technique is line of sight.
- It is difficult to coat a large number of substrates at once.
- Laser–target interactions can result in the deposition of large (micron-sized) particles on the surface of the film. This presents problems if we want to produce multilayer structures.

28.13 ION-BEAM-ASSISTED DEPOSITION

There are two forms of ion-beam-assisted deposition (IBAD). The first is a dual-ion-beam system where one source is used to sputter a target to provide a source of atoms for deposition (the same process we described in Section 28.10). Simultaneously, a second ion beam is aimed at the substrate and bombards the depositing film. In the second configuration, shown in Figure 28.7, an ion source is combined with an evaporation source.

The use of ion bombardment during film growth can modify film properties. For example, IBAD of SiO_2 with 300 eV O_2^+ ions during growth can change the refractive index. It is also possible to:

- Increase film adhesion
- Modify grain shape
- Induce crystallization

FIGURE 28.7. Ion-beam assisted deposition system.

These changes are possible because the incident ion beam may:

- Alter surface chemistry
- Create extra nucleation sites
- Increase the surface mobility of the adsorbed atoms
- Raise film temperature, leading to higher reaction and diffusion rates

28.14 SUBSTRATES

There are many considerations when choosing a substrate for thin-film growth.

- Chemical compatibility. There should be no deleterious reactions between the film and substrate. For the high temperatures ($\geq 700^\circ\text{C}$) used during the growth of many ceramic thin films, this requirement may be quite restrictive.
- Matched coefficient of thermal expansion (α). In cases where the film and substrate are different, it is almost impossible to achieve an exact match in α . A significant difference in α should be avoided because it can cause poor adhesion and cracking of the film. The latter problem is particularly relevant to ceramics, which are often brittle. Brittle materials are particularly weak in tension, and therefore it is better if $\alpha_{\text{film}} < \alpha_{\text{substrate}}$, which puts the film in compression.
- Surface quality. The surface of the substrate is important because it is here that film nucleation and growth occurs. The surface of a single crystal substrate can contain a variety of defects of different sizes, from emergent dislocations, to surface steps, to scratches due to polishing. The defects are important because they can act as preferential sites for nucleation. Figure 28.8 shows the nucleation of islands of Fe_2O_3 at step edges formed in an Al_2O_3 substrate by high-temperature annealing. This type of orientation mechanism is known as graphoepitaxy—where the

FIGURE 28.8. Growth at surface steps.

topography of the substrate surface controls the microstructure of the film.

- **Cleanliness.** It is important to ensure that each substrate is cleaned before film deposition. For example, single-crystal MgO substrates are often packaged in mineral oil prior to shipping to avoid the reaction between the MgO and water vapor, which results in the formation of $\text{Mg}(\text{OH})_2$. The oil can be removed by soaking in acetone. Many laboratories develop their own in-house cleaning procedures. The main steps involve degreasing in organic solvents, possibly followed by a high-temperature anneal.
- **Substrate homogeneity.** In many single-crystal substrates, this is not a problem. In materials that are heavily twinned, however, such as LaAlO_3 and LaGaO_3 , twin boundaries that propagate through the substrate can act as nucleation sites. In bicrystal and polycrystal substrates, the presence and orientation of the grain boundaries affects film microstructure and properties.
- **Thermal stability.** Phase transformations occurring during heating and cooling can result in the generation

of stresses within the film. Perovskite substrates undergo phase transformation.

If we want to form epitaxial films, then we also need to consider:

- **Lattice mismatch.** In semiconductor systems, lattice mismatches of only a few percent or less are desired to reduce the number of dislocations in the film. In ceramic thin films, larger mismatches (generally $<15\%$) are tolerated because higher defect densities in the film are acceptable. In some situations, a certain number of defects are actually beneficial to film properties. (They can provide pinning sites in high-temperature superconductors that can trap magnetic flux lines.)
- **Crystal structure.** A close match in the lattice parameters of the film and substrate is an important requirement for epitaxial growth. There must also be a reasonable number of coincident lattice sites on either side of the interface. Frequently (although not always), this means that the film and substrate should have similar crystal structures. The higher the number of coincident sites, the better is the chance of good epitaxy.

CHAPTER SUMMARY

Thin films of ceramic materials are important both scientifically and commercially. For example, the operation of semiconductor devices relies on thin dielectric layers. In this chapter, we described some of the main techniques used to produce such films. The common feature of all techniques for growing thin films is that we require a vacuum chamber. Deposition may occur at atmospheric pressure (e.g., some versions of CVD), but prior to deposition the chamber was evacuated. The choice of technique is based on several factors, including the type of material being deposited, whether we need an epitaxial layer, and often the cost. The substrate plays an important role in the growth of thin films, and thus we need to know the properties of the substrate and how to prepare it. Some of the techniques we described (e.g., PECVD) are important not only for growing thin films but also in producing nanostructures such as nanowires and nanosprings.

PEOPLE AND HISTORY

Pascal, Blaise (1623–1662) was a French mathematician and philosopher who invented the first digital calculator to help his father, a tax collector. Among his other most notable contributions to mathematics and science was laying the foundation of the theory of probability. The SI unit of pressure, the pascal Pa, is named after him.

Torricelli, Evangelista (1608–1647) was born in Faenza (the home of faence pottery). He invented the barometer and worked in geometry. He died in Florence. The unit of pressure, torr, is named after him.

EXERCISES

- 28.1 What reactive gases would be suitable for forming the following ceramic thin films by reactive sputtering?
(a) Al_2O_3 ; (b) TaN; (c) TiC; (d) CdS.
- 28.2 Name two of the ways that you might use to make sputtering targets.
- 28.3 Thin films can grow by three distinct mechanisms. Name the three mechanisms and explain how they differ.
- 28.4 Why is it often desirable to form thin films at the lowest possible substrate temperature?
- 28.5 What advantages are there, if any, of working at high substrate temperature?

28.6 What reactant gases might you use for making the following films by CVD? (1) ZrC; (2) TaN; (3) TiB₂.

28.7 Consider the data given below:

Reaction	A	B	C
TiCl ₄ = Ti + 2Cl ₂	180,700	1.8	-34.65
2TiN = 2Ti + N ₂	161,700	—	-45.54
SiCl ₄ = Si + 2Cl ₂	155,600	3.64	-43.90
SiC = Si + C	14,000	1.3	-5.68
C + 2 H ₂ = CH ₄	-16,500	12.25	-15.62
½ H ₂ + ½ Cl ₂ = HCl	-21,770	0.99	-5.22
SiO ₂ = Si + O ₂	215,600	—	-41.50

The values of A , B , and C are given for $G^0 = A + B \ln T + CT$ (G^0 in cal.). From these data, determine whether it would be thermodynamically feasible to form the following ceramic films by CVD at a temperature of 850°C. (a) TiN from the nitridation of TiCl₄; (b) SiC from the reaction between SiCl₄ and methane; (c) SiO₂ from the oxidation of SiCl₄.

- 28.8 What technique would you use to produce a 100-nm thin film of AlN on silicon? Explain why you chose your technique and its pros and cons.
- 28.9 What technique would you use to produce a 5-nm thin film of BaBiO₃ on MgO? Explain why you chose your technique and its pros and cons.
- 28.10 Which of the techniques described in this chapter is most suitable for producing thin films on large substrates? What is the largest substrate that can be coated?
- 28.11 We suggest that molecular beam epitaxy is often a misnomer. Discuss this viewpoint with examples. (Always reference your sources.)
- 28.12 If ΔG for the formation of TiC were actually -159 kJ, what would the implications be for the growth of TiC using the method discussed here? Is it particularly important that TiCl₄ is used?
- 28.13 Look up the ΔG values for the reaction in equations 28.10 and 28.11 and explain the reason they are different.
- 28.14 Using the library or other sources, give examples of oxide deposition, using each of the forms of CVD listed in Section 28.7.
- 28.15 Sputtering can be used to grow films of yttrium barium copper oxide (YBCO). Discuss the difficulties and how you would overcome them.
- 28.16 Molecular beam epitaxy can be used to grow oxides. Discuss the state of the art with examples.
- 28.17 Pulsed laser deposition is our favorite technique for growing oxide films. What is the largest substrate currently being used? What are the thickness limitations? Why do we use different lasers for different materials?
- 28.18 Ion-beam-assisted deposition has been referred to as (for example) “MBE with a hammer.” Discuss this statement.
- 28.19 Figure 28.1C shows silicon wafers used as a substrate for deposition in a quartz tube. Do we need to control the pO_2 in this situation?
- 28.20 Figure 28.1C shows a three-zone heater. Give examples of film growth where such a system might be used.

Growing Single Crystals

CHAPTER PREVIEW

Now we describe the important methods used to produce single crystals of ceramic materials. Single crystals are important in many applications, ranging from synthetic gemstones for jewelry to hosts for solid-state lasers. The method that is selected for growing a particular type of crystal depends on several factors. The selection criteria are determined by the properties of the material—whether a suitable solvent can be found; if the solid melts congruently or incongruently, or if it sublimates; and the economic factors, such as the volume of material to be produced and the capital equipment costs. Remember that without the growth of ceramic single crystals, the Si Age would never have happened.

29.1 WHY SINGLE CRYSTALS?

For some applications, ceramic materials must be prepared as single crystals. When used as substrates for thin-film growth [e.g., silicon-on-sapphire (SOS) technology or the growth of superconductor thin films], it is the crystalline perfection of a single crystal that is the important requirement. In optical applications [e.g., the use of ruby and yttrium aluminum garnet (YAG) for laser hosts and quartz and sapphire for optical windows], single crystals are used to minimize scattering or absorption of energy. In piezoelectric materials (e.g., quartz), the optimum properties are obtained in single-domain single crystals. Table 29.1 lists some of the applications that utilize the desirable optical, electrical, magnetic, or mechanical properties of ceramic single crystals.

Because preparing single crystals is, in most cases, a more difficult and expensive process than preparing the same compositions in polycrystalline form, they are often much more expensive than their polycrystalline counterparts. For example, you can buy 99.9% pure MgO powder in small quantities for about \$2 per gram. Single-crystal slices of MgO of the same purity costs about \$300 per gram! The increased cost of the single crystal not only involves the extra processing costs but may also include costs associated with orientating, cutting, and polishing.

When used for jewelry, synthetic single crystals can be more costly than naturally occurring ones. For example, the cost of a gem-grade, faceted, synthetic diamond may cost 10 times that of an equivalent natural diamond. On the other hand, flux-grown emeralds and rubies are about one-tenth the cost of natural stones of comparable quality. (The synthetic stones are often much more perfect than the natural ones). Large single crystals of cubic ZrO₂, which

are used as diamond simulants, are only available as synthetics. In its pure form, the cubic polymorph of zirconia is not stable at room temperature and must be stabilized by the addition of CaO, MgO, or Y₂O₃. The cubic form of ZrO₂ does exist in nature; it was discovered in 1937 as tiny crystals in an amorphized piece of zircon (ZrSiO₄), but it is not abundant.

29.2 BRIEF HISTORY OF GROWING CERAMIC SINGLE CRYSTALS

Although crystal growth is a relatively new industry, we can trace its origin back to 2,500 BCE, when salt was purified by crystallization. Systematic work in crystal growth started in c.1,600 CE with the growth of crystals from aqueous solution and c.1,850 from the melt and the vapor.

Hydrothermal growth. Growth of large single crystals of a ceramic material using the hydrothermal growth method was first demonstrated for α -quartz. This method uses an aqueous solution that is usually heated and pressurized. The growth process closely reproduces the growth of amethyst in nature. The principle is essentially the same as used for growing salt or copper sulfate crystals in high school. Silica is soluble in water, which is where diatoms find their silica. The special feature of hydrothermal growth of quartz is the use of pressure to increase the solubility of SiO₂ in H₂O.

Flux growth. First practiced by French and German chemists and mineralogists in the late 1800s, this technique is also known as molten-salt growth. Flux growth didn't become an important method for forming single crystals until the 1950s. A particularly significant contribution

TABLE 29.1 Uses of Single Crystals

<i>Semiconductor devices</i>	
Diodes	Si, Ge

during this time was the growth of BaTiO₃ single crystals using a KF flux at Bell Telephone Laboratories in New Jersey. These crystals were of interest to Bell Labs for ferroelectric storage elements for digital computers and telephone switching systems. Single crystals were preferred over polycrystalline sintered BaTiO₃ ceramics because the single crystals had a more rectangular hysteresis loop and lower coercive fields. (See Chapter 31 for more on ferroelectric ceramics).

Verneuil, Czochralski, and Bridgman. The Verneuil process, also known as the flame-fusion method, was first described in 1902 by Auguste Verneuil. His original apparatus has been preserved and is in the Museum of Arts and Sciences (Musée des Arts et Métiers) in Paris. This process was used in the early 1900s to make synthetic rubies. Although the initial application for these crystals was in jewelry, their hardness made them suitable for bearings in clocks and watches, which eventually has become their main use. Other methods for growing crystals from the melt followed. Pulling the crystal from the melt was first practiced by Czochralski in 1917. He grew crystals of

low-melting-temperature metals including Sn, Pb, and Zn. Single crystals of Ge and Si were first produced by the Cz method in 1950. This process is now used in the semiconductor industry for preparing very large single crystals of Si; and with some slight modifications, it can be used to produce single crystals of compound semiconductors (e.g., GaAs). The first oxide crystals to be grown extensively by the Cz process were calcium tungstate (CaWO₄), a laser host. Melt growth of single crystals in crucibles was first used by Bridgman, and the method was significantly improved by Stockbarger and became known as the Bridgman-Stockbarger method.

Two melt-growth techniques that have emerged since 1950 are zone refining and the floating zone (FZ) method; some of the thin-film methods discussed in the previous chapter can also be thought of as melt techniques. Zone refining is used to purify single crystals (also for polycrystals). Although zone refining is applicable to all types of single crystal, its use is widespread in the semiconductor industry only where crystal purity is of great concern. The FZ method was first applied to the growth of Si crystals. It has since been used to form single crystals of other ceramics but is mainly limited to high-purity Si.

Although vapor-phase techniques are widely used to make thin films, they are not used extensively in the growth of large single crystals. One of the most interesting vapor-phase methods is the vapor-liquid-solid (VLS) mechanism first identified by Wagner and Ellis. This mechanism allows the growth of thin single-crystal whiskers that can be used as reinforcements in ceramic matrix composites (see Chapter 20). It is also widely discussed regarding the growth of nanotubes, nanowires, and nanosprings.

29.3 METHODS FOR GROWING SINGLE CRYSTALS OF CERAMICS

The growth of single crystals involves one of the following changes of state.

- Liquid (pure or solution) → solid
- Gas → solid

The atomic or molecular species in a fluid are, on average, arranged randomly. During crystal growth, they must move to the correct sites in the ordered structure of the crystalline phase. If crystal growth is too rapid, disordered regions (crystal lattice defects, such as dislocations) are trapped in the crystal or many smaller crystals with varying orientations are nucleated, thereby destroying the desired single-crystal perfection. The growth process involved in producing a single crystal must therefore be slow, and it requires precise control over the growth conditions (e.g., temperature) for prolonged periods.

Several different methods are used commercially to grow single crystals. These methods, which can be divided

TABLE 29.2 Factors Relevant to the Choice of a Growth Technique for Crystal Production

	<i>Equipment investment</i>	<i>Operating costs</i>	<i>Skill needed</i>	<i>Development needed</i>	<i>Range of materials</i>	<i>Growth rate</i>	<i>Crystal perfection</i>
Cz	High	Medium	Medium	Medium	Many	Rapid	High
Bridgman	Low	Medium	Low	Little	Many	Medium	Medium
Verneuil	Medium	Low	High	Little	Some	Rapid	Low
Skull melting	High	Medium	Medium	Medium	Some	Rapid	Medium
Flux	Medium	Medium	Low	Much	Few	Slow	Variable
Hydrothermal	Very high	High	Medium	Much	Few	Slow	Variable
UHP	Very high	High	High	Much	Few	Slow	Variable
Gas phase	Low	Low	Low	Varies	Few	Very slow	Variable

into melt, solution, and vapor-phase techniques, are summarized in Table 29.2. Here, the operating cost does not include the cost of labor; the skill refers only to the difficulty in using the equipment, not in developing the process. The crystal perfection assumes the optimum conditions, not the fastest; and the rate of flux growth depends on the complexity of the reaction—as is the case with growth of emerald.

The method chosen depends on the type of crystal, the application for that crystal, and the required size. The most widely used growth technique is the Czochralski (or Cz) process because it can produce very large dislocation-free crystals of silicon. It is also used to form single crystals of many oxides. For oxides containing more than one cation, the general requirement for forming a crystal by the Cz process is that the material melts congruently. In such cases, crystal growth of compounds by pulling is similar to growing elemental crystals. If the compound melts incongruently, the Cz method can still be used if special precautions are taken, or it may be that an alternative method (e.g., growth from solution or from a flux) must be used.

Most methods of single-crystal growth seek to control the nucleation of the crystalline phase. This is achieved by arranging for the crystal to grow on a “seed” (which is the nucleus). The seed crystal is usually a single crystal of the same composition as the crystal to be grown. It is often oriented in such a way as to facilitate growth of one specific crystalline orientation. In the Bridgman-Stockbarger method, a seed crystal is not used. In that method, advantage is taken of the tendency for crystals to grow more rapidly in one crystallographic direction than in another.

Vapor-phase techniques are not as widely used as growth from the melt or solution because the growth rate is generally slow or only small crystals can be grown. However, two vapor-phase techniques have commercial application: the growth of whiskers or small islands

SINGLE CRYSTAL TERMINOLOGY

A large single crystal in the as-grown form is often referred to as a *boule*, from the French word for ball, or as an *ingot* (which may also be used to describe a polycrystal).

When a boule is cut into flat sections, the single-crystal slices are typically referred to as *wafers*.

When the wafers are cut into small units (usually either square, rectangular, or circular) they are referred to as *substrates* or *windows*.

(e.g., SiC and GaN) by the VLS process and the growth of SiC and nanotubes by sublimation processes.

Many other techniques can be used to produce single crystals; solid-solid phase transformations or growth from gels are modern examples. Although such methods may be useful in the laboratory for

producing small single crystals of ceramics, they are not currently of commercial importance.

29.4 MELT TECHNIQUE: VERNEUIL (FLAME-FUSION)

The Verneuil, or flame-fusion, method is illustrated in Figure 29.1. It is a well-established technique for growing single crystals of oxides that have high melting temperatures. The largest application of the Verneuil method is for the growth of sapphire and ruby.

For growing sapphire crystals, high-purity aluminum oxide powder of a uniform particle size is fed at a controlled rate down a tube, at the end of which the particles are melted by an oxyhydrogen flame. The molten particle then falls into a shallow (~20 μm deep) pool of liquid on top of a seed crystal. The pool of liquid is held on the seed crystal by surface tension. The seed is lowered into the annealing zone of the furnace at the same rate as the new material arrives, thus growing the crystal. The growing crystal cools slowly, helping to reduce strains and minimizing the chance of forming lattice defects. It is always preferable to anneal the crystal from the growing temperature without first cooling to room temperature. If the crystal is first cooled to room temperature and then annealed, it is much more difficult to remove any defects that have formed. Remember that the crystal still contains point defects as these are equilibrium defects at high

FIGURE 29.1. Verneuil technique.

temperature and so cannot easily be annealed out. Because a gas flame and powder are used in the process, trapped pores are common defects.

To produce artificial rubies and sapphires, various transition metal oxides are added to the alumina feed powder. For rubies, 1–3 at% Cr_2O_3 gives the characteristic deep red color. Artificial blue sapphires are obtained when a mixture of 1 at% TiO_2 and 2 at% FeO is added to the feed powder.

One advantage of the Verneuil method is that it does not use a crucible to contain the melt—only a shallow pool of liquid is present throughout the growth process. An important constraint of liquid-to-solid transitions for crystal growth is the reaction of the melt with the container. For crystals with a high melting temperature (a situation we often encounter in ceramics), this constraint becomes especially severe. Even if reactivity is not a problem, it is still difficult to find suitable containers that can withstand very high temperatures without melting or degrading. The other advantages of the Verneuil method are that it is relatively inexpensive and quick. Crystals can easily be obtained

STALAGMITES

The Verneuil technique is related to the growth of stalagmites in nature. Liquid drips (from the stalagmite) onto the stalagmite, but instead of settling there and freezing (like a stalagmite icicle would) some of the mineral content is deposited as the water evaporates.

TABLE 29.3 Some Crystals Grown by Verneuil and Arc-Image Techniques

Material	Common name	Comments	T_M ($^{\circ}\text{C}$)
Al_2O_3	Corundum, sapphire	Growth in a variety of directions; best growth in a cone of directions 60° from c.	2,040
$\text{Al}_2\text{O}_3:\text{Cr}$	Ruby	Verneuil	
MgAl_2O_4	Magnesium-aluminum spinel	Verneuil	2,130
$3\text{Al}_2\text{O}_3 \cdot 2\text{SiO}_2$	Mullite	Verneuil	1,810
CaWO_4	Scheelite	Verneuil	1,530
TiO_2	Rutile	Verneuil	1,830
ZrO_2	Zirconia	Verneuil	2,700
Y_2O_3	Yttria	Verneuil	2,400
MgFe_2O_4	Magnesium (nonstoichiometric) spinel	Arc-image	>1,200
NiFe_2O_4	Nickel ferrite	Arc-image	>1,200

in a matter of hours (typical growth rates are 10^{-2} m/h) compared with the months needed for some solution techniques.

The main disadvantage of the Verneuil process is that there is relatively poor control over the growth parameters, particularly the temperature because of the very small melt volume. As a consequence, the quality of the crystal is often inferior to that obtained by, for example, the Cz

method. Typically, Verneuil-grown crystals have high dislocation densities, which makes them most suitable for applications where such imperfections are not as important (e.g., jewelry or jewel bearings). Very large single crystals cannot be produced by the Verneuil

method. Verneuil-grown boules may be up to 9 cm in diameter. Table 29.3 lists some of the ceramic crystals that have been grown by the Verneuil method. Verneuil sapphire is used as the starting material (crackle) for Cz sapphire.

The FZ method shares many similarities with the Verneuil method. The main difference is that the source is a dense polycrystalline rod of the same composition as the desired single crystal, rather than the free-flowing powder used in the Verneuil method; but it still uses a constrained volume of liquid. The advantage of the FZ method is that, like the Verneuil method, no crucible is used: the material is its own crucible, as shown in Figure 29.2A. A thin region of melt is again held in place by surface tension, this time between two parts of the feed rod. Not having a container removes one possible source of

FIGURE 29.2. (A) Vertical float zone. (B) Arc-image furnace.

contamination; it is for this reason that the FZ method is used to produce high-resistivity silicon. The disadvantages of the FZ method are that it is not as amenable as the Cz method to producing very large high-quality single crystals. For ceramics, the FZ method may use the arc-image heating method to allow us to reach the necessary high temperatures.

29.5 MELT TECHNIQUE: ARC-IMAGE GROWTH

Several techniques for growing single crystals combine aspects of the FZ method and the Verneuil flame fusion method, but the heat source is not a flame. One such “modified” Verneuil growth technique is called arc-image growth. Heat is supplied using a focused light source. Figure 29.2B shows an arrangement of the arc-image growth process. The radiation from the light source is focused by parabolic reflectors and allows us to reach sample temperatures $>2,500^{\circ}\text{C}$. If a controlled or inert atmosphere is needed around the sample, it can be enclosed in a suitable transparent tube (envelope). MgFe_2O_4 , and NiFe_2O_4 have both been grown by this technique. The main advantage of using arc-image heating is that it is easy to provide a clean high-temperature environment with a controllable atmosphere (which is particularly important when Fe cations are involved).

29.6 MELT TECHNIQUE: CZOCHRALSKI

A schematic diagram of the Cz technique is given in Figure 29.3A. The melt is kept at a temperature just above its freezing point; and a seed crystal, rigidly fixed to a rotating tube, is lowered into the surface of the melt. The temperature of the melt is reduced until the molten material begins to freeze onto the seed. Pulling is then started, and more material solidifies onto the crystal as it is withdrawn. The shape of the meniscus is determined by the surface tension of the liquid. The seed crystal is normally rotated as it is withdrawn to average out any thermal asymmetries in the heating elements. This rotation also produces a stirring action, which can help homogenize the melt. At the same time, it accelerates crucible erosion and hence can introduce additional impurities into the melt. In cases where the impurity concentration must be kept to a minimum, the crucible containing the melt and the crystal can be rotated at the same rate and in the same direction! For nonoxide crystals, the whole apparatus is maintained in an inert environment (e.g., Ar). Table 29.4 summarizes the relevant growth conditions that have been used to produce different crystals. A variation is to use a die to produce tubes, fibers, or sheets of sapphire or garnet, as illustrated in Figure 29.3B. Actually, single-crystal tubes can be produced inside single-crystal tubes.

Figure 29.4 shows part of a sapphire boule produced by the Cz process. Sapphire boules can be up to 150 mm in

FIGURE 29.3. (A) Czochralski technique for pulling crystals. (B) Modifications to Czochralski. Compared with the conventional geometry (left).

diameter and 600 mm in length, and they can weigh >40 kg. Most sapphire is grown in the *r*-plane orientation (the growth axis is normal to the *r* plane). If an Si crystal is grown with 300 mm (12 in.) diameter to a length of 0.5 m, the crystal weighs ~82 kg.

To determine the factors that affect the growth rate of the crystal, we need to consider the heat flow in the system. The heat input, q_{in} , to the crystal across the crystal/melt interface is given by the sum of the heat associated with crystallization, q_L , and the heat flow from the melt, q_M .

$$q_{in} = q_L + q_M \quad (29.1)$$

q_L is given by

$$q_L = A\rho_s\Delta H_{fus} \frac{dx}{dt} \quad (29.2)$$

TABLE 29.4 Some Materials Grown by the Cz Technique (for Crystals ~2 cm in Diameter)

Material	T_M (°C)	Crucible	Atmosphere	Pulling rate (mm/h)	Rotation rate (rpm)
Zn	419	Pyrex	Vacuum	400–800	10–30
GaSb	712	Graphite	Hydrogen	50–100	10–30
FeGe ₂	866	Alumina	Vacuum	5–20	20–50

FIGURE 29.4. Sapphire boules grown by the Cz technique: 100–150 mm diameter, 300 mm long.

where A can be considered to be the area of the crystal at the liquid/solid interface. Actually, A is the area of the isotherm that goes through a point in the liquid close to the interface; however very close to the interface this area is approximately the liquid/solid interfacial area. The density of the solid is ρ_s , ΔH_{fus} is the heat of crystallization (fusion), and dx/dt is the rate of growth. To a good approximation, the growth rate can be considered equal to the pulling rate, which from equation 29.2 we can see is inversely proportional to A . Therefore, the faster the crystal grows, the smaller is its diameter.

The heat flow from the melt, q_M , is given by

$$q_M = Ak_L \frac{dT}{dx_L} \quad (29.3)$$

where k_L is the thermal conductivity of the liquid, and dT/dx_L is the thermal gradient in the liquid. q_{in} is also the heat flow down the crystal, which is given by

$$q_{in} = Ak_s \frac{dT}{dx_s} \quad (29.4)$$

where k_s is the thermal conductivity of the crystal, and dT/dx_s is the thermal gradient in the crystal. By substituting equations 29.2, 29.3, and 29.4 into equation 29.1, we find:

$$Ak_s \frac{dT}{dx_s} = A\rho_s \Delta H_{fus} \frac{dx}{dt} + Ak_L \frac{dT}{dx_L} \quad (29.5)$$

Upon rearranging:

$$\frac{dx}{dt} = \frac{1}{\rho_s \Delta H_{fus}} \left[k_s \frac{dT}{dx_s} - k_L \frac{dT}{dx_L} \right] \quad (29.6)$$

If the pulling rate exceeds the value of dx/dt given by equation 29.6, the crystal separates from the melt; if it is less than that given by equation 29.6, then A increases. Figure 29.5 shows the rings that develop around a single crystal as it grows, with dx/dt constantly changing to keep A constant.

According to equation 29.6, the maximum growth rate possible occurs when dT/dx_L approaches 0 (if dT/dx_L becomes negative, the liquid would be supercooled, the interface would advance rapidly, and dendritic growth

FIGURE 29.5. Growth rings on crystal surface: top section of Si crystal after removing seed.

would occur). The maximum growth rate, $(dx/dt)_{max}$, is then given by

$$\left(\frac{dx}{dt} \right)_{max} = \frac{1}{\rho_s \Delta H_{fus}} \left[k_s \frac{dT}{dx_s} \right] \quad (29.7)$$

We can see from equation 29.7 that the value of $(dx/dt)_{max}$ depends on the temperature gradient in the solid. The largest gradients in the solid may be obtained by deliberately introducing large heat leaks from the growing crystal; one method is to water-cool the seed holder. However, the high rates obtained under such conditions are generally not useful because the crystal perfection under such growth conditions is usually not very high. Typically, growth rates for good crystal quality are 10^{-4} – 10^{-2} mm/s; 30–50% slower than the maximum values given by equation 29.7.

The principal advantages of the Cz process are:

- Excellent control over the growth conditions produces very high quality crystals.
- It is relatively fast.
- Very large crystals can be produced.

A particular feature of the Cz process is that it is possible to produce dislocation-free single crystals. As we discussed in Chapter 12, dislocations are not equilibrium defects. Therefore it is, in principle, possible to produce crystals that are free of dislocations. Although a small number of dislocations in a single crystal of most ceramics do not normally present any problems, they must be avoided if we are using the ceramic for its electrical/semi-conducting properties. One way dislocation-free crystals can be achieved is that once growth has started on the seed the diameter of the crystal is slowly reduced to a minimum size. The minimum size is that which can still support the weight of the crystal to be grown (without deforming plastically and multiplying the number of dislocations). Typically, the minimum size is ~3 mm in diameter and 30 mm long; a 3 mm diameter sapphire rod supports ~200 kg. During this period, the crystal-melt surface becomes strongly concave, as illustrated in Figure 29.6, so that dislocations present in the initial seed can glide to the sidewalls of the crystal. Dislocation glide is facilitated if the glide plane makes a large angle to the growth axis. For crystals with the diamond-cubic structure, the glide plane is {111}; for crystals with the rock salt (NaCl) structure, the glide plane is {110} (unless it's not—see Section 17.2). Subsequent growth is slowly modified to give the desired crystal diameter, and a dislocation-free crystal is then pulled. The dislocation density in Cz sapphire boules is typically in the range 10^3 – 10^4 cm⁻².

There are several disadvantages to the Cz process.

- It is applicable only to materials that melt congruently or nearly congruently (see Sections 8.10 and 29.10).

- The melt must be contained in a crucible, a problem for reactive high-temperature melts.
- The capital cost is high. A Cz furnace to produce 8-in. diameter sapphire boules costs \$400,000. For larger boules the furnace can cost \$1 million.

Despite these disadvantages, the Cz technique is the most important crystal-growth technique for producing large high-quality single crystals.

29.7 MELT TECHNIQUE: SKULL MELTING

One of the problems with growing single crystals of ceramic materials is that they often have very high melting temperatures. When molten, they can be extremely corrosive to any crucible. In skull melting, the melt is contained within a frozen shell of the material itself—the material acts as its own crucible. In perhaps the first application of the skull melting process, the technique was combined with crystal pulling to produce single crystals of manganese ferrite. Later (1961), the same method was successfully applied to the growth of single crystals of sapphire and YAG. [The technique is also known as induction skull melting (ISM) and is used for casting Ti and Ti alloys—for the same reason.]

The most important economic application of the skull melting technique for ceramics has been the production of cubic zirconia ($T_M = 2,700^\circ\text{C}$), which is manufactured at rates in excess of 300 t (1.5 billion carats) per year. Cubic zirconia is the best of the diamond simulants; and the growth of large (centimeter size) crystals became feasible only with the use of the skull melting technique (Figure 29.7). The zirconia powder, containing some small pieces of Zr metal, is contained in a water-cooled assembly and heated by means of high-frequency induction heating (see Section 9.6). The Zr metal is used to couple with the high-frequency radiation. Once the temperature has reached $1,100^\circ\text{C}$, the

FIGURE 29.6. Neck-down and flare-out geometries for growing dislocation-free crystals.

FIGURE 29.7. Skull melting process.

FIGURE 29.8. Bridgman-Stockbarger technique.

zirconia becomes electrically conducting and acts as a susceptor. The material close to the water-cooled walls remains solid, thus forming a dense sintered shell, or “skull.” The rest of the zirconia liquefies. To induce crystallization, the melt is lowered slowly (~1 cm/h) from the heating coil, as shown in Figure 29.7B. Crystal growth begins at the base of the melt, and large columnar crystals (up to ~7 cm long) can be produced.

The cost of cubic ZrO_2 crystals varies, depending on supply and demand. The selling price for single crystals is only ~\$0.50 g^{-1} . This makes them a low-cost commodity material for the gem trade and necessitates large-scale production to make the process economically feasible. However, once the crystals have been oriented, cut, and polished for use as substrates for thin-film growth (e.g., high-temperature superconductors), the equivalent cost is ~\$150 g^{-1} [~\$50 for a single $1.0 \times 1.0 \times 0.05$ cm thick (100) oriented substrate].

29.8 MELT TECHNIQUE: BRIDGMAN-STOCKBARGER

The Bridgman-Stockbarger technique is illustrated in Figure 29.8. The powdered charge is melted in a crucible, which is often a refractory metal: Pt, Ir, or Mo. It is a

TABLE 29.5 Typical Conditions for Bridgman-Stockbarger Growth

Crystal	T_M ($^{\circ}C$)	Growth rate (mm/h)	Crucible
Al_2O_3	2,037	2–8	Molybdenum
ZnS	1,850	0.5–2	Silica supported by graphite

K	63.7	1–4	Stainless steel coated with paraffin
Ar	–189.2	0.7–1.5	Mylar

PTFE polytetrafluoroethylene.

necessary requirement of this technique that the melt does not significantly react with the crucible. The furnace is designed such that there is a sharp drop in temperature just below the bottom tip of the crucible in its initial position.

The crucible is lowered (typically at a rate of 1–30 mm/h) so that the tip enters the colder zone, causing the nucleation of crystals. The crystals grow fastest in particular crystallographic directions, and those crystals growing at angles greater than half the cone angle terminate at the walls of the cone. Only those crystals oriented so that the growth is favored in the axial direction persist into the bulk of the charge as the crucible is lowered into the cooler zone. As a result, the upper part of the crucible finally contains either a single crystal or a few large crystals. One of the problems associated with the Bridgman-Stockbarger method occurs if the crystal expands on freezing (this happens in covalently bonded crystals Si and Ge—as it does with ice). The crucible acts as a constraint on the growing crystal, and the expansion usually leads to large stresses, which can result in the introduction of dislocations and low-angle grain boundaries (GBs) and even cause the crucible to burst. It is difficult to produce single crystals with dislocation densities $<10^4$ cm^{-2} by this technique. There are other geometries for the Bridgman-Stockbarger technique. One configuration is the horizontal configuration, where the crystal is grown horizontally in a boat.

The Bridgman-Stockbarger method has been used primarily in the growth of alkali halides and alkaline-earth halides (e.g., LiF and CaF_2). Table 29.5 summarizes some of the other crystals that have been grown by this method. This table is by no means complete; indeed, several thousand different crystals have been reported. In many cases, the furnace tube is filled with an inert gas to protect the charge and crucible. If the crystal is volatile, and the crucible is silica or Pyrex[®], the crucible may also be sealed.

29.9 MELT TECHNIQUE: HEM

The heat-exchange method (HEM), also known as the Schmid-Viechnicki method, is best known for its use in growing large crystals of sapphire. Sapphire crystals of 34 cm diameter and 65 kg in weight are grown in a production facility, up from the initial 20 cm diameter and 20 kg weight. (These values should be compared to a maximum diameter of 15 cm for Cz growth). Sapphire is particularly challenging because it is essential to use low thermal gradients during growth and cool down to prevent cracking of the boule. The furnace is represented in Figure 29.9. The furnace has several special features.

- Heat extraction and input can be controlled independently.
- The boule can be annealed in situ after growth.
- Nothing moves mechanically.

In the Heat-Exchange Method technique, the Mo crucible, the seed, the melt, and the growing crystal are all located in the heat zone. Heat is removed using a W He-gas heat exchanger and is thus a temperature gradient technique (TGT). The technique uses directional solidification of the melt from a seed that is in contact with the heat exchanger placed at the base of the crucible. The furnace elements melt the sapphire crackle, and control the temperature of the

liquid. The temperature of the seed is allowed to increase to melt back its surface; and then growth begins by lowering the temperature of the seed and the melt. Crystallization is a three-dimensional process. The whole process takes about 72 h and is followed by a similar annealing period. Growth of (0001) boules is most difficult because the solid/liquid interface is convex toward the liquid in the HEM process, which increases solidification stresses. The situation can be remedied by carefully controlling the temperature gradients. The resultant boule has a flat top surface, making a large fraction suitable for preparing windows, etc.

Fluorite crystals for use in ultraviolet (UV) ($\lambda = 193$ nm) and vacuum UV (VUV) ($\lambda = 157$ nm) lithography up to 20 cm diameter have been grown using a modified TGT, which is another variation on the directional solidification approach to crystal growth. The inner diameter of the high-purity graphite crucible used is 300 nm. An interesting feature of this method is the use of 2 wt% PbF_2 to scavenge oxygen impurities. Blocks of the $\text{CaF}_2/\text{PbS}_2$ mixture are pressed into the crucible with a (111) seed at the bottom. The vacuum is kept at $\sim 10^{-3}$ Pa with a graphite lid on the crucible to minimize vaporization; and the thermal gradient can be controlled by changing the position of the crucible in the furnace or adjusting the flow of cooling water to the bottom of the crucible support. Crystals of CaF_2 up to 250 mm diameter can also be grown by the Bridgman method. In either case, a temperature of $\sim 1,500^\circ\text{C}$ is used for the growth.

FIGURE 29.9. Heat-exchange (Schmid-Viechnicki) method.

29.10 APPLYING PHASE DIAGRAMS TO SINGLE-CRYSTAL GROWTH

An important consideration in the crystal growth of oxides containing several cations is whether the melting is congruent or incongruent. The discussion in this section builds on that in Section 8.10. If the compound melts congruently, crystal growth proceeds easily. For example, the crystal could be grown by the Cz method in a way that is similar to growth of an elemental crystal.

Crystals of lithium niobate, LiNbO_3 , can be readily grown using the Cz process. Its large nonlinear optical coefficients have led to an intense interest in this material. Figure 29.10 shows part of the $\text{Li}_2\text{O}-\text{Nb}_2\text{O}_5$ phase diagram. The congruent melting temperature is not exactly at the stoichiometric composition but is at 51.4 mol% Nb_2O_5 . Solidifying a melt of the composition 48.6% Li_2O and 51.4 mol% Nb_2O_5 can produce a high-quality single crystal, but the cation stoichiometry is not 1:1. To obtain stoichiometric $\text{Li}_{1.00}\text{Nb}_{1.00}\text{O}_3$, it is necessary to cool a melt containing excess Li_2O . For example, referring back to Figure 29.10, a melt of composition 55 mol% Li_2O and 45 mol% Nb_2O_5 solidifies below $\sim 1,200^\circ\text{C}$, producing a stoichiometric solid. During growth of the crystal, the melt becomes depleted of Nb. To counteract this loss, it is necessary to ensure that the melt is homogenized by stirring; if a large melt volume is used and a moderately sized crystal is grown, the composition change is small.

As we noted in Section 8.10, pure cubic BaTiO_3 cannot be grown from a melt of that composition because, as shown in Figure 8.23, the hexagonal phase is in equilibrium with the liquid at the solidification temperature ($1,618^\circ\text{C}$). The hexagonal phase transforms to the cubic phase at $1,460^\circ\text{C}$, but the phase change is very slow; thus,

the hexagonal phase can persist at room temperature. The hexagonal form of BaTiO_3 is not ferroelectric. Its structure contains the required TiO_6 octahedra, but the linking of the octahedra is different from that found in cubic BaTiO_3 . In cubic BaTiO_3 the octahedra share corners; in hexagonal BaTiO_3 , some of the octahedra share faces.

Cubic BaTiO_3 can, however, be grown from a melt composition containing 35 mol% BaO and 65 mol% TiO_2 , which solidifies below $1,460^\circ\text{C}$, the temperature below which the cubic form is stable. The melt is held just above its solidification temperature, a seed crystal is dipped into its surface, and the crystal is pulled from the melt at a rate of 0.5–1.0 mm/h. The seed crystal is rotated during growth so the liquid near the crystal does not become depleted of Ba. Only a fraction of the melt can be obtained as single-crystal BaTiO_3 because the whole of it solidifies, forming a mixture of cubic BaTiO_3 and $\text{Ba}_6\text{Ti}_{17}\text{O}_{40}$, when the BaO content falls to about 32 mol%.

If the desired compound melts incongruently, it is often easier just to use a technique such as flux growth to obtain single crystals.

FIGURE 29.10. Part of the Nb_2O_5 - Li_2O phase diagram.

FIGURE 29.11. Silver-lined laboratory hydrothermal autoclave, about 35 cm long.

29.11 SOLUTION TECHNIQUE: HYDROTHERMAL

In the hydrothermal method, single crystals are grown from an aqueous (hydro) solution. Although many crystals have been grown hydrothermally, α -quartz crystals are the only ones that are produced on a large scale. For this reason we describe the method used for growing large α -quartz crystals, although the system used for other materials (including emerald and ruby) is very similar. An important feature is that the low-symmetry form of quartz is produced directly because the temperature is low.

Pure finely divided particles of mineral quartz are placed at the bottom of a tall cylindrical autoclave that is 80% filled with a basic solution (e.g., 0.5 M NaOH). Suitably oriented seed crystals of α -quartz are held in wire frames near the top of the autoclave.

Thermometers allow temperature control within the chamber. The seed crystals are usually naturally occurring quartz because it usually has a very low dislocation density. The base of the autoclave is kept at 400°C ; in this section, the quartz fragments dissolve, so it's called the *dissolving* section. The top of the autoclave, which is called the *growth* section, is maintained at a temperature some 40°C cooler than that of the dissolving section. The $\alpha - \beta$ transition in quartz occurs at 573°C . For highly perfect single crystals, growth should be carried out below the transition temperature. The solution at the bottom of the autoclave saturates and moves by convection to the growth zone, where the seed crystals are located. In the growth zone, the solubility is lower, the solution becomes supersaturated, and material is deposited onto the seed crystals. Figure 29.11 illustrates an autoclave used for

hydrothermal growth. The baffle shown in the lower half of the autoclave is a perforated metal disk separating the dissolving and growth sections and helping to localize the temperature differential. For piezoelectric applications, the principal faces of the seed crystals are {0001}, and the crystals grow at ~1 mm/day in both <0001> directions, producing crystals weighing over a kilogram in a few weeks. Figure 29.12 shows some hydrothermally grown α -quartz crystals. Table 29.6 lists other ceramic single crystals grown by the hydrothermal method and includes the experimental conditions used.

AUTOCLAVE

A thick-walled vessel, usually made of steel, which allows us to carry out reactions under pressure and at high temperatures. (The original definition implied a self-closing vessel with internal pressure sealing its joints; the closure is now made externally).

FIGURE 29.12. Hydrothermally grown quartz crystals. Note the colorless seed and the Pt support wires at the top.

TABLE 29.6 Examples of Hydrothermally Grown Crystals

Crystal	Solvent	Growth zone temp (°C)	Dissol. zone temp (°C)	Pressure or degree of fill
α -SiO ₂	1 N Na ₂ CO ₃	360	400	80%

FIGURE 29.13. Hydrothermal ZnO nanorods seen nearly end on.

29.12 SOLUTION TECHNIQUE: HYDROTHERMAL GROWTH AT LOW TEMPERATURE

Low temperatures are suitable for nanowires etc. because they don't have to grow very large! An example is the growth of ZnO nanorods. The early stage of growth on a sapphire substrate is shown in Figure 29.13. The principle of the synthesis is the hydroxylation of Zn^{2+} ions in an aqueous solution in the presence of hexamethylenetetramine [HMTA: $(CH_2)_6N_4$].

The hydrolysis reactions are

This promotes the hydroxylation of Zn^{2+} ions in solution to form dissolved complexes, which are precursors to nucleation of the ZnO precipitate phase.

Though this synthesis route has been used for the synthesis of ZnO nanorods in solution, crystal growth can occur on substrates when they are exposed to the vapor phase above a dilute aqueous solution containing 0.025 M $Zn(NO_3)_2$ and 0.025 M HMTA maintained in the range 70–90°C for 1–3 h.

Pb WARNING

If the temperature is much above 1,350°C PbO is reduced to Pb and this can alloy with the platinum crucible!

29.13 SOLUTION TECHNIQUE: FLUX GROWTH

Crystals of many ceramics can be obtained by cooling a solution of the required compound in a suitable flux or solvent (serving the role of water in Section 29.11). The common fluxes include KF, PbO, and PbF_2 . The flux is selected to give minimum contamination.

- PbO and Bi_2O_3 are good fluxes for the growth of oxides because Pb and Bi are such large atoms they don't fit into many lattices.
- Alkali metal ions do not fit well into many lattices either because the sizes or the charges are wrong.

To illustrate the flux-growth process for growing single crystals we look at three examples.

Yttrium iron garnet ($Y_3Fe_5O_{12}$, or YIG) is ferromagnetic. Approximately 52.5 mol% PbO, 44 mol% Fe_2O_3 , and 3.5 mol% Y_2O_3 are mixed together in a Pt crucible and heated to 1,250–1,350°C. After the melt has homogenized, it is cooled at a rate of $0.5^\circ C h^{-1}$. The solidified melt contains crystals of Fe_2O_3 , $PbFe_{12}O_{19}$, and the required $Y_3Fe_5O_{12}$. The mixture is crushed and digested in nitric acid to free the crystals from the flux. In any flux-growth process, it is important to have a solvent that dissolves the flux but does not affect the desired crystals. The crystals are separated magnetically at temperatures above and below the appropriate Curie temperatures. The garnet crystals are equiaxed and can also be picked out of the crushed mixture visually.

$BaTiO_3$ crystals have been prepared using a KF flux containing 30% $BaTiO_3$. The mixture is homogenized at 1,150–1,200°C for about 8 h. The temperature is then lowered to 900°C and the flux poured off. The $BaTiO_3$ crystals are allowed to cool in the furnace to room temperature. A characteristic feature of flux-grown $BaTiO_3$ crystals is that they form pairs of triangular plates ("butterfly twins") as shown in Figure 29.14. The cooling rate determines the plate thickness, making it possible to form thin sheets directly, without them having to be cut from larger single crystals. In some cases, a small amount of iron, about 0.2 wt. % Fe_2O_3 , is added to the starting mix. Iron assists in the formation of large area plates. However, a small amount of Fe^{3+} is then incorporated in the $BaTiO_3$ lattice on Ti^{4+} sites. The charge difference is compensated for by the replacement of an equivalent number of O^{2-} ions by F^- ions.

Although many details of the process used are kept secret, *emeralds* ($Be_3Al_2(SiO_3)_6$) can be produced by dissolving BeO, Al_2O_3 , and SiO_2 in a Li_2O-MoO_3 flux using an arrangement shown in Figure 29.15.

Emeralds can grow to ~60 g in 10–12 months. Synthetic rubies can be produced using a PbF_2 flux; rubies can grow to 600 g in 8 months. The synthetic

FIGURE 29.14. Butterfly twins in BaTiO₃.

crystals are ~10% of the price of natural ones. The chief commercial manufacturer of emerald and ruby in the United States is Chatham in San Francisco, which produces 20% (1 t/year) of the worldwide production of

TABLE 29.7 Fluxes Used for the Growth of Ceramics

Material	Flux

synthetic emeralds and about 70% (700 kg/year) of the worldwide production of flux-grown rubies.

The main advantage of the flux-growth method is that it can be used for a wide variety of materials. Single crystals of materials that undergo phase transitions, melt incongruently, or have a high vapor pressure at their melting temperature can all be grown using flux growth. The major disadvantages are:

- Impurities may be trapped in the crystal.
- Growth is slow compared to melt-growth methods.
- Growth of very large crystals is not possible.

For these reasons, flux growth is a useful research tool for growing small crystals (typical crucible volumes between 50 and a few hundred cubic centimeters), but it is not used widely for the production of industrial single crystals apart from gemstones. Many ceramics have been produced as single crystals by the flux-growth process. The literature contains a large amount of information about suitable fluxes for several thousand materials. Table 29.7 gives a few examples.

29.14 SOLUTION TECHNIQUE: GROWING DIAMONDS

In addition to their importance in jewelry, diamonds also have important industrial applications, such as in diamond-impregnated cutting tools and as abrasives. The world's use of diamonds is about 26 t (26 Mg) per year, of which about 16 t are synthetic. The synthetic diamond industry is a \$1 billion/year business.

The carbon phase diagram is shown in Figure 8.7. You can see that diamond is, in fact, the metastable form of C under ambient conditions, with graphite being the stable form. Diamond is stable at pressures as low as 1 GPa if the temperature is $\sim 25^\circ\text{C}$, although the rate of the transformation is extremely slow if the pressure is lower. However, diamonds can be synthesized from graphite at very high temperature ($\sim 3,300\text{ K}$) and very high pressure ($\sim 13\text{ GPa}$). A more practical method involves the use of a solution (the flux again) and shares similarities with the other solution methods described above.

The credit for the first synthesis of diamond goes to Bundy et al. of the General Electric Company, although Swedish company ASEA may have synthesized diamond in early 1953. In each case, the product was diamond grit suitable for grinding and polishing uses. In 1970, researchers at GE succeeded in synthesizing large (up to about 1 ct in weight) single-crystal diamonds. The arrangement for growing large diamonds is shown in Figure 29.16. The pyrophyllite (a hydrous aluminum silicate) tube is inserted into a ring of tungsten carbide through which the

FIGURE 29.16. Chamber for diamond growth.

hydraulic pressure is applied. Pyrophyllite is used because at high temperature and under high pressure it extrudes to form a gasket that bonds well to the tungsten carbide pistons and seals the tube to maintain the applied pressure. Heating is achieved by passing an electric current through the tube. The temperature gradient within the tube is such that the center is $10\text{--}30^\circ\text{C}$ hotter than the ends. The carbon source (any carbon-containing compound may be used, even peanuts) is dissolved in the solvent, often Ni, Fe, or an Ni-Fe alloy. The solvent forms a thin film on the surface of the seed, and transport of carbon from the source to the crystal takes place by temperature-difference solution growth (similar to what happens in the hydrothermal process). The diamond seed crystals favor the formation of diamond instead of graphite. Growth rates depend on the solvent and the orientation of the seed crystal but are 3–5 mm per day.

29.15 VAPOR TECHNIQUE: VLS

The vapor-liquid-solid (VLS) mechanism was first used to grow Si whiskers. (Other whiskers were identified some years earlier). The catalyst-mediated whisker-growth process is illustrated in Figure 29.17 for the growth of SiC whiskers. The process begins with melting a solid catalyst particle (e.g., steel), so that it forms a liquid ball on a suitable surface (in this case, a graphite slab). The ball forms a liquid interface between the growing SiC whiskers and the vapor phase. Carbon (in the form of methane CH_4) and silicon (in the form of SiO) in the vapor feed are extracted by the liquid catalyst, which becomes supersaturated. Crystal growth occurs by precipitation from the supersaturated liquid at the solid/liquid interface. Whiskers produced by the VLS process characteristically have a spherical cap. One of the drawbacks of the VLS process is that it is extremely slow. This leads to high production costs and limited availability, which together combine to make the whiskers extremely expensive ($\$800\text{ kg}^{-1}$ in 1994).

FIGURE 29.17. Vapor-liquid-solid (VLS) process for growing SiC whiskers.

Also, although SiC has been classified as a nonhazardous material, there are health concerns associated with very small whiskers. This problem may be even more important with the increasing production of the smaller whiskers known as nanowires and nanotubes.

The VLS mechanism has been identified in the growth of other ceramic whiskers, including Al_2O_3 , BeO, and B_4C . It is proposed as a method for producing nanotubes and is often assumed to be the principal feature of such growth processes.

29.16 VAPOR TECHNIQUE: SUBLIMATION

Single-crystal SiC is of interest for a number of applications, including high-temperature electronic devices and blue-light-emitting diodes. For these applications, the preparation of large high-quality boules is necessary from which individual wafers can be sliced. At atmospheric pressure SiC sublimates, so single crystals cannot be produced by melt growth techniques such as the Cz process. However, a sublimation technique has been developed that can produce boules up to 30 mm in diameter. The cross section of a reaction chamber is shown in Figure 29.18. A seed crystal and a polycrystalline source material are placed at opposite ends of a cylindrical container, along which a temperature gradient of $10\text{--}20^\circ\text{C}/\text{cm}$ is established ($2,300\text{--}2,500^\circ\text{C}$ at the source and $2,100\text{--}2,200^\circ\text{C}$ at the seed). SiC sublimates from the

FIGURE 29.18. Modified sublimation process for SiC single crystals.

source, and the products condense onto the cooler seed. The process is carried out at a low argon pressure (200 Pa), allowing boules 20 mm in length and up to 30 mm in diameter to be produced at a rate of about 4 mm/h.

The SiC wafers produced from the boules are very expensive. A single SiC wafer 30 mm in diameter and 0.3 mm thick can cost upward of \$3,000. By comparison, a Si wafer of this size costs less than \$20.

29.17 PREPARING SUBSTRATES FOR THIN-FILM APPLICATIONS

Conversion of the boule into polished substrates requires several operations. The exact number and type of steps involved in this process depends on the material involved and the application for the substrates. The following sequence would be typical for the preparation of single-crystal substrates of ceramics.

- The top and bottom (sometimes called the *seed* and *tang* ends, respectively) of the boule are removed using a diamond-tipped saw.
- The surface orientation of the boule is determined by an X-ray method (typically Laue back-reflection). The boule is mounted in such a way that when it is cut the slices have the desired surface orientation.
- Wafers are sliced from the boule using a diamond-tipped saw or a set of diamond-coated wires. When the wire saw is used, many slices can be cut in one run (like slicing a hard-boiled egg). The substrate thickness essentially depends on the slicing operation, although the final value depends on subsequent polishing operations.
- The wafers are polished (see Section 18.12).
- The wafers are diced up to produce individual substrates of the desired size. In some cases, the substrates are cut so that the edge is aligned along a particular crystallographic orientation. This orientation is also set by X-ray methods.

29.18 GROWING NANOWIRES AND NANOTUBES BY VLS AND NOT

There is great interest in growing single crystals that are <100 nm in one, two, or three dimensions. The techniques being used are variations on those listed above but deserve separate mention because of the special features involved. The detailed mechanisms involved in the growth are not fully understood. The essential feature is that the “substrate” is small.

The technique that has probably attracted most attention is VLS. The VLS method is an extension of that used by Wagner and Ellis to grow the original Si whiskers, which were actually nanowires. VLS growth of Si required

FIGURE 29.19. (A) Graphene sheet illustrating how carbon nanotubes are formed. (B) TiO_2 nanotubes. (C) IrO_2 nanotubes and (D) IrO_2 nanotubes.

a catalyst particle, but not all wire growth requires a heterogeneous catalyst. We can grow arrays of ZnO wires by depositing islands of catalyst on a substrate and providing a vapor so that the wires grow where the catalyst particle is. Why “Not” in the section title? In some cases, it appears that the catalyst is solid throughout the process. In other similar processes there is no catalyst. Nature grows rutile and asbestos fibers.

Carbon nanotubes started the excitement in nano, although the Nobel Prize was awarded for the buckyball (see Chapter 7). We can construct these nanotubes by rolling the sheet of graphite shown in Figure 29.19A (known as a graphene sheet) and joining the sides. Now we can join the sheets so that A meets B (the armchair configuration), or C meets D (the zigzag configuration), but we can also make A meet E. The vector AE is known as the chiral vector, and the angle BAE is the chiral angle. You can see that this corresponds to the formation of a screw dislocation that runs along the tube and really does have a hollow core! The chirality is then a twist, reminding you of the GB. Then we could wrap other sheets around the first (not necessarily of identical construction). The tubes

can be grown by several methods, including arc-discharge and pulsed-laser deposition. Both methods can produce quite large quantities; it has been claimed that tons of high-quality nanotubes can be produced (which will be needed for the space elevator!). For technological applications, we might prefer to grow arrays of aligned tubes. We can do this using Fe-oxide particles as the catalyst and 9% acetylene in N_2 as the feedstock; the growth temperature need be only $\sim 600^\circ\text{C}$. Such aligned structures can already be grown from the pores of mesoporous SiO_2 , on glass substrates, porous Si, porous alumina, etc. Ni catalysts have been used with plasma-assisted chemical vapor deposition (CVD) at 660°C . We can use the C nanotubes themselves as templates (or substrates) to grow tubes (or wires) of other materials.

We can now grow tubes of many ceramics. The array of TiO_2 nanotubes shown in Figure 29.19B were grown from a Ti foil placed in an electrolyte of 0.5% hydrofluoric acid in water using a Pt cathode. The anodization voltage was kept at ~ 20 V, and this structure was produced in ~ 45 min. The sample was cleaned in pure water and sintered at up to 880°C , transforming the

as-grown anatase to rutile. The resulting material has many possible applications (it resembles MCM-41 structurally) because it has all the chemical properties of rutile. The nanotubes of IrO_2 in Figure 29.19C have a square

cross section because they are single crystals with sides parallel to $\{001\}$ planes. We can grow nanotubes of other oxides such as MgO and NiO and nanotubes of nonoxides such as BN .

CHAPTER SUMMARY

Many methods can be used to grow single crystals of ceramic materials. To produce large crystals, the methods can be classified as melt growth, solution growth, or vapor growth. Solution growth requires that a suitable solvent can be found for the material. Because it is possible to find a solvent for most materials (the literature contains solvents for several thousand materials), solution-growth techniques are applicable to a very wide range of ceramics. Melt-growth techniques generally require that the material melts congruently or nearly congruently—so knowledge of the phase diagram for the material is important. This fact alone eliminates many materials from consideration. The significant advantage of melt-growth techniques is that, particularly in the case of the Cz method, very high quality crystals can be produced. Vapor growth is generally used only for producing single crystal of ceramics (e.g., SiC) that can't be made by either melt or solution techniques or for growing crystals.

Many of the methods used for thin-film growth are producing single crystals: the emphasis in this chapter is that the crystals “stand alone.”

PEOPLE AND HISTORY

Bridgman, Percy Williams was born in Cambridge, Massachusetts in 1882 and joined the faculty of Harvard University in 1908. He is most well known for his research on the effects of high pressure on materials. He was awarded the Nobel Prize in Physics in 1946 “for the invention of an apparatus to produce extremely high pressures, and for the discoveries he made therewith in the field of high pressure physics.” Bridgman made contributions to many fields, including crystallography, and devised a method of growing single crystals, which bears his name. He died in 1961.

Czochralski, Jan was born in 1885 in Kcynia, which is now in Poland. He was the eighth child of a carpenter. He went to Berlin to study chemistry in 1904, and by 1910 he was working on the processing of Cu . The story is that in 1913 he was writing up his notes on a study of crystallizing metals while sitting next to a crucible with molten Sn . Absentmindedly, instead of dipping his pen in the inkpot, he dipped it in the crucible and withdrew it quickly. He observed then a thin thread of solidified metal hanging at the tip of the nib. His observation led to a new crystal growth technique, which he published in 1917. He died in 1953.

Geim, Andre (1958–) and *Konstantin Novoselov* (1974–) won the 2010 Nobel Prize for Physics for their groundbreaking work with graphene (see Figure 29.19A). They cleverly (and carefully) extracted graphene from a piece of graphite using nothing more than Scotch tape. Graphene is, of course, a ceramic and offers many exciting possibilities for future applications. Geim and Novoselov are both at the University of Manchester in the United Kingdom.

Verneuil, August Victor Louis (1856–1913) was a French chemist who reported his method for growing ruby in 1902.

EXERCISES

- 29.1 Describe the Verneuil method for producing ruby. What are the advantages and disadvantages of this process?
- 29.2 Briefly describe how ruby could be produced by the Czochralski (Cz) process. Under what situations, if any, would it be preferable to use the Cz process rather than the Verneuil process for ruby growth?
- 29.3 Why are crystals of cubic zirconia grown by the skull melting technique?
- 29.4 There are several different geometries for the Bridgman-Stockbarger method. Comparing the vertical and horizontal geometries, what are the advantages and disadvantages of each?
- 29.5 Knowledge of phase diagrams is very important for understanding the growth of single crystals from the melt. Using the case of BaTiO_3 , explain the considerations involved when producing single crystals of incongruently melting solids using melt growth techniques such as the Cz method.
- 29.6 Why are flux growth methods widely used in the production of synthetic gems? Are there any disadvantages that you can think of in using these methods for this particular application?

- 29.7 A company wishing to start producing single crystals of AlN has called you in as a consultant. What advice would you give them concerning the type of methods that would be suitable?
- 29.8 Draw up a list of as many different substrate materials as you can that have been used in the growth of thin films of high-temperature superconductors. In your list make note of the surface orientation (if it is given) and the surface condition (was it polished, cleaned, annealed, etc.) of the substrate.
- 29.9 Using the information you gathered for question 29.8, add to your list one method that could be used to produce each type of single crystal from which the substrates were obtained.
- 29.10 By carefully reviewing the literature, present a detailed discussion of the method of growing diamond using the “flux” method. You should give quantities, diagrams, and references.
- 29.11 Hydrothermal growth is being used extensively to produce small particles. Discuss why and give examples of applications in the last year (with references, of course).
- 29.12 What has hydrothermal growth to do with natural amethyst gemstones?
- 29.13 Sapphire can be grown by the Verneuil or Czochralski method. Why is the latter better than the former, and why is the former much more widely used.
- 29.14 If the Verneuil technique resembles stalagmite growth, why is there no technique corresponding to stalagmite growth?
- 29.15 Why would you use the arc-image technique to grow certain crystals, and why is it not widely used?
- 29.16 Can ruby be grown by a hydrothermal technique? If so, discuss the chemistry involved.
- 29.17 Imagine the boule in Figure 29.4 as it grew. What did it weigh? How does this compare to the largest Si crystals that are grown by the same technique?
- 29.18 Propose a crystallographic reason for the butterfly twins in Figure 29.14.
- 29.19 Why do the emeralds in Figure 29.15 have flat tops, and how can this technique be justified when it is so slow?
- 29.20 The vapor-liquid-solid (VLS) technique is being widely used today for growing nanowires. Give illustrations of five different materials that have been grown in this way in the past 2 years. (Give the references, of course).

Part VII

Properties and Applications

Conducting Charge or Not

CHAPTER PREVIEW

Ceramics show the widest range of electrical properties of any class of material. At one extreme, we have high-temperature superconductors, which have no resistance to an electrical current. At the other extreme, we have electrical insulators. Ceramic superconductors have not yet fulfilled many of the expectations and predications for useful applications, whereas insulating ceramics are used for a number of critical applications such as packages for integrated circuits. Without the use of insulating ceramics, the development of powerful personal computers would not have been so rapid. Between the two extremes, there are ceramics that behave very much like metals, and there are the semiconductors, which are all ceramics. Ceramics with metal-like conductivity are used as electrodes and in thick-film resistors. Semiconductors (e.g., SiC) are important for high-temperature electronics. In this chapter we explain why ceramics show such a diverse range of electrical properties. The important concepts are related to our earlier discussion of bonding and energy bands.

In some ceramics, the only species that can move in an applied electric field are the ions in the structure. Generally, the movement of ions is slow; but in a class of ceramics called fast ion conductors, they can move very rapidly. In cubic zirconia, the diffusion of oxygen ions at high temperature is particularly fast, and this ceramic is used as the electrolyte in solid oxide fuel cells. Fuel cells are becoming a key part of a diverse energy plan for the twenty-first century.

We begin by describing the conduction mechanisms in ceramics and look at some specific applications. We finish by describing one of the most fascinating developments in ceramics—high-temperature superconductors.

30.1 CERAMICS AS ELECTRICAL CONDUCTORS

Ceramics are usually thought of as electrical insulators, and indeed a great many of them are. Since the first uses of electricity, it has been necessary to have good electrical insulators to isolate current-carrying wires. The expansion of the electrical industry and, in particular, the use of the electric telegraph required enormous numbers of porcelain insulators for telegraph poles. From 1888, ceramics based on steatite began to be used for the same purpose. Today, ceramics are still used to provide insulating supports in the power lines that crisscross the country.

The distinction that some materials are electrical conductors and others are insulators had been made in the eighteenth century. Although historically the insulating properties of ceramics have often been one of their most important properties, many ceramics are actually very good electrical conductors, and

some are even superconductors. Ceramics show the broadest range of electrical properties of any of the classes of material. The values of electrical conductivity for ceramics vary over an enormous range of values—over 24 orders of magnitude!—as shown in Figure 30.1.

Table 30.1 lists the important parameters that are used in discussions of electrical conductivity. As we've done elsewhere in this book, we stick to SI units (unless there is a good reason for not doing so, such as the use of eV for band gap energies). If another system is widely used, the appropriate conversion factor is given. Electrical conductivity is, in general, a tensor of the second rank. Fortunately, the electrical properties of materials can largely be understood by assuming that they are isotropic, and σ is simply a scalar.

The conduction mechanisms in ceramics can be quite complex and may involve the movement of electrons, holes, ions, and in some cases are “mixed,” where more than one type of charge carrier

ELECTRIC TOWN

In 1881 Godalming became the first town in the world to have a public electricity supply.

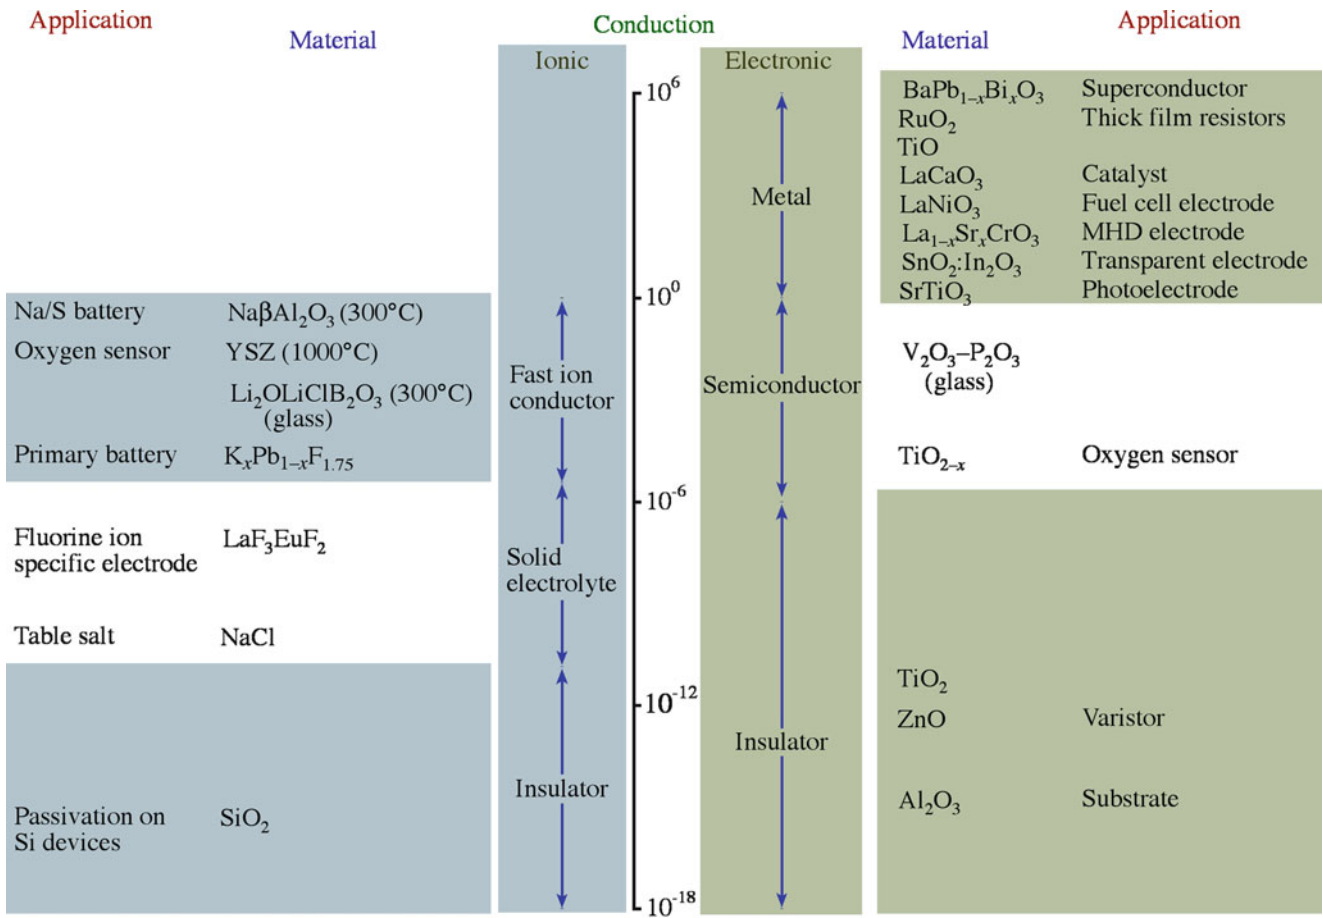

FIGURE 30.1. Range of conductivities of ceramics.

TABLE 30.1 Terms and Units Used

Parameter	Definition	Units/value	Conversion factor
E_g	Band gap energy	eV	1 eV = 1.602×10^{-19} J (eV is a much more convenient unit for E_g)
E_f	Fermi energy		
σ	Conductivity	S/m	1S = $1 \Omega^{-1}$
I	Current	A	
J	Current density	Cm $^{-2}$ s $^{-1}$	
v	Drift velocity	m/s	
ξ	Electric field strength	V/m	
μ	Mobility	m 2 V $^{-1}$ s $^{-1}$	Subscripts e and h are used to represent electron and hole mobility, respectively. The units are the same in both cases.
R	Resistance	Ω	
ρ	Resistivity	Ω .m	
V	Voltage	V	
q	Electron charge	1.602×10^{-19} C	Sometimes e
t	Transference number	Dimensionless	
K	Boltzmann constant	1.381×10^{-23} J/K	
T	Temperature	K or °C	
T_c	Critical temperature for superconductivity	K	0 K = -273° C

is responsible for current flow. In the case of ceramic superconductors, the current is carried by electron pairs (Cooper pairs). Hence, this is really very different and is discussed separately.

In comparing values of σ and ρ , it is useful to remember the simple relationship between them

$$\sigma = \frac{1}{\rho} \quad (30.1)$$

30.2 CONDUCTION MECHANISMS IN CERAMICS

Electrical conductivity is given by

$$\sigma = nq\mu \quad (30.2)$$

The importance of equation 30.2 is that it applies to all materials, and it shows that the two factors affecting σ are:

- Number of charge carriers, n
- Their mobility, μ

When we consider the effect of variables such as composition, structure, and temperature on σ , what we are concerned with is their effect on n and μ .

If more than one type of charge carrier is contributing to σ , then we can define a partial conductivity for each. For example, if σ were due to the movement of electrons and cations with a charge Z , then:

For electrons:

$$\sigma_e = \mu_e(n_e q) \quad (30.3)$$

For cations:

$$\sigma_+ = \mu_+(n_+ Zq) \quad (30.4)$$

Total:

$$\sigma_{\text{tot}} = \sigma_e + \sigma_+ \quad (30.5)$$

If a ceramic is an electron conductor (i.e., $t_e = 1$), then to determine n we need to know E_g . We usually consider the three situations shown in Figure 30.2, where the band gap is either (1) zero, (2) narrow, or (3) wide.

The real band structure of a material is actually a complex three-dimensional shape. Even so, these simple representations can be used to illustrate many of the important electronic properties of materials. When E_g is zero, as

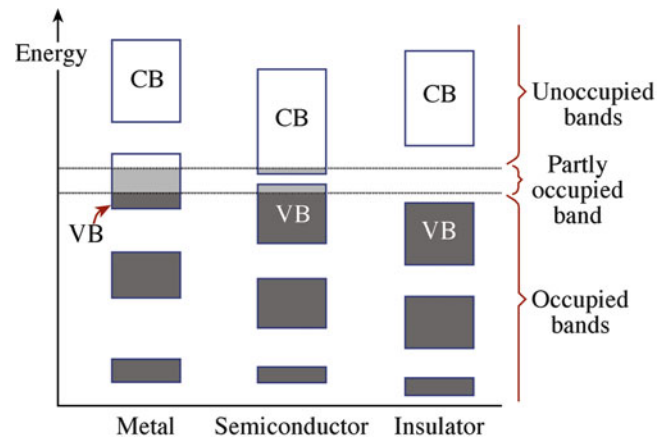

FIGURE 30.2. Electron energy bands in solids. The valence band (VB) and conduction band (CB) are indicated.

TRANSFERENCE NUMBER

The transference or transport number is the fraction of σ_{tot} contributed by each charge carrier.

For electrons $t_e = \sigma_e / \sigma_{\text{tot}}$

For cations $t_+ = \sigma_+ / \sigma_{\text{tot}}$

Table 30.2 lists examples of t .

in the case of most metals, there are free electrons present at any temperature above 0 K. The total number of free electrons is equal to the number of valence electrons per atom multiplied by the number of atoms in the metal.

E_g in a metal is not exactly zero, but it is very small. For example, if we have a metal crystal consisting of 10^{23} atoms, and the width of the energy band is 1 eV, then the separation between the energy levels would be only 10^{-23} eV (1.6×10^{-42} J). This would be the minimum

TABLE 30.2 Transference Numbers of Cations, Anions, and Electrons or Holes in Several Materials

amount of energy required to excite an electron into a vacant level.

A narrow band gap is usually defined as being in the range of 0.02 to about 2.5 eV. When E_g is toward the lowest end of this range, there are a significant fraction of electrons in the conduction band. Materials with a narrow band gap are what we usually refer to as semiconductors.

- Silicon $E_g = 1.12$ eV
- Gallium arsenide $E_g = 1.42$ eV

Both Si and GaAs are ceramics.

Materials with a wide band gap (>2.5 eV) are considered to be electrical insulators because the probability of an electron being in the conduction band at room temperature is extremely small. However, the probability is not zero, so we should think of these materials as wide-band-gap semiconductors. SiC ($E_g = 2.6$ – 3.0) is an example of a wide-band-gap semiconductor and is used in sensors in aircraft and fuel cells that can operate in hostile environments at temperatures up to 600°C , where conventional silicon-based electronics cannot function.

Band gap energies for a number of ceramics are listed in Table 30.3.

30.3 NUMBER OF CONDUCTION ELECTRONS

This section follows on directly from Section 4.8. The number of electrons in the conduction band, n_i , is:

$$n_i = \int_{E_c}^{E_{\text{top}}} N_c(E)f(E)dE \quad (30.6)$$

- $N_c(E)dE$ is the density of states in the conduction band and represents the number of energy levels over which the electrons can be distributed (i.e., the number of allowed energy states).
- $f(E)$ is the Fermi-Dirac function, giving the probability of an electron being in the conduction band.

$$f(E) = \left[\frac{1}{1 + \exp\left(\frac{E-E_f}{kT}\right)} \right] \quad (30.7)$$

The evaluation of n_i is quite straightforward if we make the following assumptions.

1. $E-E_f \gg kT$. This is often the case because at room temperature $kT \sim 0.025$ eV and $E-E_f$ is usually >5 eV. We can now omit the $+1$ in equation 30.7. [We are in effect replacing Fermi-Dirac statistics by Boltzmann statistics].
2. The excited electrons occupy states near the bottom of the conduction band. Under these conditions, they behave as free particles for which the state distribution function is known.
3. The upper limit of the integration in equation 30.6 is taken as ∞ because the probability of occupancy of a state by an electron rapidly approaches zero as the energy increases through the band.

Under these assumptions, we can write:

$$n_i = N_c \exp\left(-\frac{E_c - E_f}{kT}\right) \quad (30.8)$$

E_f lies midway between E_c and E_v in an intrinsic material (i.e., one that has virtually no impurities); and because $N_c \sim 10^{25} \text{ m}^{-3}$ we can simplify equation 30.8 as:

$$n_i = N_c \exp\left(-\frac{E_g}{2kT}\right) \sim 10^{25} \exp\left(-\frac{E_g}{2kT}\right) \quad (30.9)$$

The important things to remember from this series of equations are that:

- n depends on E_g and T .
- As we increase T , we increase n .

30.4 ELECTRON MOBILITY

As electrons move through a solid under the influence of ξ , they experience a number of collisions (in a process called scattering) that decreases μ . There are three scattering mechanisms.

- **Phonon.** This is the major factor affecting μ (of both electrons and holes). A phonon is the quantum unit of lattice vibrational energy (described later in Chapter 34). The higher the temperature, the greater is the vibrational amplitude of the atoms in the lattice and the greater are the number of phonons. As a result, scattering increases, and μ decreases with increasing temperature.

$$\mu \propto T^{-m} \tag{30.10}$$

- **Electron–electron.** At room temperature, the mean distance between electron–electron collisions is about 10 times that of electron–phonon collisions, so electron–phonon scattering is dominant.
- **Polaron.** This mechanism occurs only in ionic crystals and involves the interaction between the electron and the ions in the crystal. The electron can cause local distortion of the lattice known as a polaron, as illustrated in Figure 30.3. When the interaction is sufficiently strong (small polaron), the electron may be trapped at a particular lattice site, reducing μ and decreasing σ .

30.5 EFFECT OF TEMPERATURE

For a material where $E_g = 0$ (i.e., one in which n does not vary significantly with T), σ decreases linearly with increasing temperature because of the decrease in μ .

$$\sigma \propto \frac{n}{T^m} \tag{30.11}$$

FIGURE 30.3. Illustration of (A) Large polaron of radius R , formed in a metal oxide MO. (B) Small polaron, showing the distortion of the lattice around an electron trapped at a metal.

For materials where $E_g > 0$ (i.e., materials that we would class as semiconductors or insulators), σ rises with T because of the temperature dependence of n , as shown by equation 30.9.

$$\sigma \propto \exp\left(-\frac{E}{2kT}\right) \tag{30.12}$$

Figure 30.4 shows the typical T dependence of σ for the three broad classes of electrical behavior.

Because it is possible to make practical use of the variation in σ or ρ with T , it is often beneficial to classify materials based on this variation. (From a practical point of view, we usually consider changes in ρ rather than changes in σ). The temperature dependence of resistivity may be expressed by an empirical equation:

$$\rho_2 = \rho_1[1 + \alpha_R(T_2 - T_1)] \tag{30.13}$$

ρ_1 is the resistivity at T_1 , and ρ_2 is the resistivity at T_2 . The parameter α_R is known as the temperature coefficient of resistivity, or TCR. For materials where $E_g = 0$, the TCR is typically positive. These materials are called PTC (positive temperature coefficient) materials. Most materials that show semiconducting or insulating properties are negative temperature coefficient (NTC) materials. Some ceramics (e.g., BaTiO_3), which do have

FIGURE 30.4. Conductivity variations with temperature for the different classes of electrical conductor. The shading indicates the range of values at room temperature.

energy band gaps, are actually PTC materials. This type of behavior has nothing to do with conduction across the band gap but is actually a grain boundary (GB) effect.

30.6 CERAMICS WITH METAL-LIKE CONDUCTIVITY

The general electrical characteristics of metals are:

- $\sigma \geq 10^4$ S/m
- $t_e = 1$
- $n = 10^{22} - 10^{23}$ cm⁻³
- $d\sigma/dT$ is small and negative

Remember that Ω^{-1} (ohm⁻¹) is S (siemens). Some ceramics (e.g., TiO, VO) show metallic-like electronic conductivity where the conduction is due to the movement of free electrons. To explain this behavior, we consider the example of TiO.

TRANSITION METALS

Transition metals have partially filled d orbitals.

TiO has a structure based on rock salt, with vacancies in both the metal and oxygen sublattices. One-sixth of the titaniums and one-sixth of the oxygens are missing, as illustrated in Figure 30.5. The 2p orbitals from the oxygen atoms form a filled valence band. The bands formed by the 4s and 4p orbitals on the Ti are at a much higher energy. The metal d orbitals form a band below that of the metal s and p orbitals, as illustrated in Figure 30.6.

The divalent titanium ion, Ti²⁺, in TiO has two 3d electrons, so the metal d band shown in Figure 30.6 is partially filled. It is this partially filled band, which resembles the energy level diagram for a metal shown in Figure 30.2, that leads to metallic conductivity in TiO. Looking at Figure 30.6, it is easy to see why titanium

dioxide, TiO₂, is an insulator. In the formation of the Ti⁴⁺ ion, both the two 4s electrons and the two 3d electrons are given up to form oxygen ions. So the 3d band (the conduction band in the solid) is empty at $T = 0$ K. The band gap, E_g , in TiO₂ is 3 eV. This is a relatively small E_g for an insulator and indicates some covalent character in the Ti–O bond.

ELECTRON CONFIGURATIONS

Ti	1s ² 2s ² 2p ⁶ 3s ² 3p ⁶ 3d ² 4s ²
Ti ²⁺	1s ² 2s ² 2p ⁶ 3s ² 3p ⁶ 3d ²
Ti ⁴⁺	1s ² 2s ² 2p ⁶ 3s ² 3p ⁶

Why aren't MnO, CoO, and NiO—which are also monoxides of the first row transition metals and have the rock salt structure—metallic-like conductors?

To answer this question, we need to consider the interaction between the d orbitals and the formation of the d band in metal oxides. In the rock salt structure, the d_{xy} , d_{yz} , and d_{xz} orbitals (collectively known as the t_{2g} orbitals) on adjacent metal atoms overlap. The extent of the overlap is less than it would be in the pure metal because in the oxides the metal atoms are not nearest neighbors. Consequently, the d bands are narrower than they would be for the metal. (We are referring to the widths of the bands themselves, not the size of the band gap). As we go across the first row transition elements (from Ti to Ni), there is an increase in nuclear charge and a corresponding contraction in the size of the d orbitals. As the d orbitals become smaller, the extent of overlap decreases and the 3d band becomes narrower, eventually forming a localized state, as illustrated in Figure 30.7.

Some oxides of the second and third row transition elements also exhibit metallic-like properties (e.g., ReO₂, ReO₃). In these compounds, the metal electron energy

FIGURE 30.5. Structure of TiO (A) The (100) plane (B) The (200) plane. Both showing the absence of alternate ions along $\langle 110 \rangle$ directions. The resultant superlattice has a monoclinic unit cell as indicated by the shaded region.

FIGURE 30.6. Energy bands of a transition metal oxide: (A) d band empty; (B) metallic oxide with d band partially filled.

FIGURE 30.7. Electronic energy levels of some 3d monoxides, deduced from spectroscopic measurements. The energy zero has been taken as the top of the oxygen 2p valence band.

FIGURE 30.8. Temperature dependence of the electrical conductivity of several electronically conducting oxides.

levels of interest are the 5d, rather than the 3d, as in the case of the first row transition metals.

Figure 30.8 shows the σ versus temperature behavior for several oxides. For some of the oxides we've already mentioned (e.g., ReO_3 , TiO , CrO_2 , ReO_2), $d\sigma/dT$ is small and negative, just like it is for most metals.

30.7 APPLICATIONS FOR HIGH- σ CERAMICS

There are many applications for ceramics that have metal-like conductivity. We look at two examples.

- Resistors
- Electrodes

30.7.1 Resistors

The requirements for most resistors are that they are:

- Ohmic
- Small TCR

Components with R in the range 10^3 – $10^8 \Omega$ are the major requirements of the electronic industry. These are fabricated from electronically conducting ceramics with σ in the range 10^5 – 10^6 S/m . Resistance is not an intrinsic property of a material. It is influenced by the specimen configuration (i.e., its thickness and length). The relationship between R and σ is:

$$R = \frac{l}{\sigma A} \quad (30.14)$$

where A is the cross-sectional area of the specimen perpendicular to the direction of the current flow, and l is the distance between the two points at which the voltage is measured. To make a $10^5 \Omega$ resistor of length 10 cm from a material with $\sigma = 10^6 \text{ S/m}$ would require a cross-sectional area of 10^{-12} m^2 . Using a strip with a $1 \mu\text{m}^2$ cross section would be possible but is not usually economically feasible. There are two methods that are used to make high-resistance components using high σ ceramics.

1. Increase the aspect ratio (length to width) of the conductive layer by patterning
2. Mix the conductive phase with a highly resistive one

Thin film resistors usually make use of the first approach. For example, thin films ($\sim 10 \text{ nm}$ thick) of indium tin oxide (ITO) are deposited onto glass, or sometimes steatite, substrates by sputtering or chemical vapor deposition (CVD). After deposition, the films are patterned to achieve a large aspect ratio. If the substrate is in the form of a rod, a spiral groove is cut into the film.

Thick film resistors are made by diluting a conductive oxide with an electrical insulator, such as glass. (The practical aspects of thick film processing were described in Chapter 27). Ruthenium dioxide (RuO_2) and mixed metal oxides containing ruthenium (e.g., $\text{Bi}_2\text{Ru}_2\text{O}_7$) are widely used as the conducting component. These oxides have σ in the range 10^5 – 10^6 S/m . The glass is usually a lead borosilicate of composition typically (in wt%)

FIGURE 30.9. Electrical characteristics of RuO₂ thick film resistors.

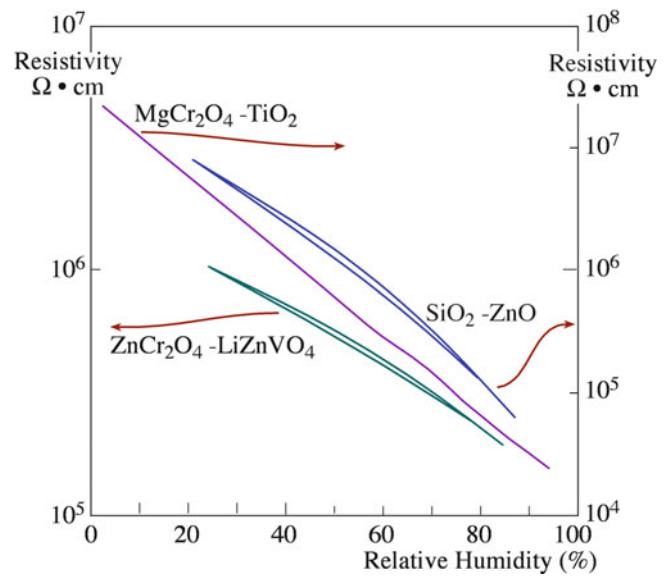

FIGURE 30.10. Electrical response of three ceramic humidity sensors at room temperature and 1 kHz.

52PbO-35SiO₂-10B₂O₃-3Al₂O₃. The final thickness of the resistor after processing is the range of 10–15 μm. The resistors normally give high resistivities and negative TCRs for low concentrations of the conductive component and low resistivities and positive TCRs for high concentrations, as shown in Figure 30.9. This behavior is the result of a combination of the positive TCR of the conductive particles and the negative TCR of the regions between them.

The distribution of the conductive particles and the contact between them also determines the resistance of the deposited film. Final resistance values are obtained either by sand blasting, where the thickness of the film is reduced, or by laser trimming, to increase the effective length of the resistor. These procedures would be performed after the resistor has been fired but before application of the protective glaze coating.

30.7.2 ELECTRODES

High-σ ceramics are used as electrodes in a number of applications.

- Fuel cells
- Humidity sensors
- Displays

The question we need to ask ourselves again is: what's special about ceramics?

Temperature stability LaCrO₃ was developed in the 1960s for electrodes in magnetohydrodynamic (MHD) generators where the electrode had to withstand temperatures up to 2,000°C and the corrosive potassium atmosphere in the generator. LaCrO₃ has a melting

temperature of 2,500°C and σ = 100 S/m at 1,400°C. MHD generators are now of little interest, but LaCrO₃ has been used as an electrode in solid oxide fuel cells. LaCrO₃ has the perovskite structure that we described in Chapter 7.

Porous In humidity and gas sensors, the electrode must be electrically conductive, produce a porous coating (to allow the vapors to reach the sensor), and stable in the sensing environment. RuO₂ is used as an electrode in humidity sensors. One example of the sensing element is a solid solution of TiO₂ in MgCr₂O₄. This type of sensor is used in microwave ovens, where it detects the rapid rise in humidity corresponding to the onset of cooking. There is a fall in ρ when the ceramic is exposed to humid atmospheres, the result of dissociation of water molecules.

Several other materials have been developed for humidity sensors, and the electrical responses of three different ones are shown in Figure 30.10.

Transparent. For applications where a transparent electrode is required, metals are completely unsuitable. Metals, because of their very small E_g , can absorb all wavelengths of visible light and are, as a result, opaque in the visible part of the electromagnetic spectrum. Only metal layers <1 μm are transparent. A ceramic used as a transparent electrode is indium tin oxide (ITO). A typical electrode composition is 90In₂O₃-10SnO₂. Transparent electrodes are important for many electro-optic devices, liquid crystal displays (LCDs), light-emitting diodes (LEDs), and solar cells.

30.8 SEMICONDUCTING CERAMICS

Semiconductors have a small E_g , as shown in Figure 30.2. In semiconductors, σ is proportional to n and μ (for both electrons and holes). In general, there are three ways free electrons and holes may be generated in ceramics.

- Excitation across the band gap (*intrinsic* semiconductors)
- Introduction of impurities/dopants (*extrinsic* semiconductors)
- Departures from stoichiometry (*nonstoichiometric* semiconductors)

Most oxide semiconductors are either doped to create extrinsic defects or are annealed under conditions in which they become nonstoichiometric.

30.8.1 Intrinsic Semiconductors

For every electron that is excited into the conduction band, a hole is produced in the valence band.

The number of electrons in the conduction band is

$$n = N_c \exp\left(-\frac{E_g}{2kT}\right) \quad (30.16)$$

Similarly, the number of holes in the valence band is

$$p = N_v \exp\left(-\frac{E_g}{2kT}\right) \quad (30.17)$$

The densities of states are given by

$$N_c = 2 \left(\frac{2\pi m_e^* kT}{h^2}\right)^{3/2} \quad (30.18)$$

and

$$N_v = 2 \left(\frac{2\pi m_h^* kT}{h^2}\right)^{3/2} \quad (30.19)$$

where m_e^* and m_h^* are the effective masses of the electrons and holes, respectively. For many ceramics, m_e^* and m_h^* are not known, and we make the (often incorrect) assumption that $m_e = m_e^* = m_h^*$, where m_e is the rest mass of the electron.

If we use the subscript i to denote intrinsic carrier concentrations, we can write:

$$n_i = p_i \quad (30.20)$$

and

$$np = n_i p_i = n_i^2 \quad (30.21)$$

Therefore

$$n_i = (N_c N_v)^{1/2} \exp\left(-\frac{E_g}{2kT}\right) \quad (30.22)$$

If $N_c = N_v$, then:

$$n_i = N_c \exp\left(-\frac{E_g}{2kT}\right) \quad (30.23)$$

The intrinsic conductivity is given by:

$$\sigma_i = qn_i(\mu_e + \mu_h) \quad (30.24)$$

Equation 30.24 is similar to equation 30.2, but we are now considering μ_e and μ_h .

The intrinsic conductivity of many pure oxide semiconductors is generally very low because of their large E_g compared to Si and GaAs. To illustrate this point, we compare the room temperature conductivities of Cu_2O (a semiconducting ceramic $E_g = 2.1$ eV) and GaAs (a III-V semiconductor $E_g = 1.4$ eV).

The largest applications for semiconductors use extrinsic material. The entire electronic materials industry is built around doped silicon. However, there are applications that require intrinsic semiconductors. One such application is X-ray detectors used on transmission (TEMs) and scanning (SEM) electron microscopes for chemical analysis. Unfortunately, it is essentially impossible to produce pure silicon. Even electronic grade silicon contains small amounts of boron (a p-type dopant). To create “intrinsic” material, a dopant is added that produces an excess of electrons, which combine with the holes formed by the residual boron. The process involves diffusing lithium atoms into the semiconductor. Ionization of the lithium produces electrons that recombine with the holes. It is possible to produce germanium crystals with much higher purity, and intrinsic Ge detectors are used on some TEMs.

30.8.2 Extrinsic and Nonstoichiometric Semiconductors

An extrinsic semiconductor contains impurities that are present either accidentally, or, as is most often the case, they have been intentionally added. The effect of these impurities on the energy band diagram is that they introduce additional energy levels into the band gap, as illustrated in Figure 30.11. These new energy levels are often close to the band edges.

If the impurity level is just above the valence band, the impurity is an “acceptor” because it can accept electrons, leaving holes in the valence band.

MOBILITIES OF ELECTRONS AND HOLES
 In ceramics these depend upon their interaction with the lattice. Typical values are very small ($\leq 0.1 \text{ cm}^2 \text{V}^{-1} \text{s}^{-1}$), which is orders of magnitude lower than in Si and GaAs.

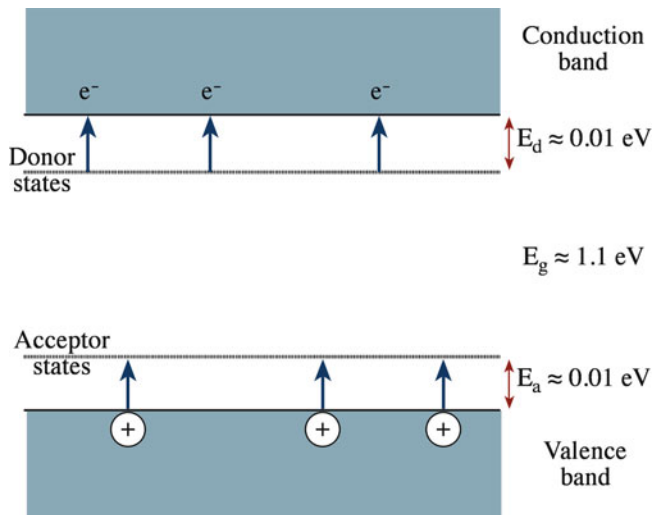

FIGURE 30.11. Effect of doping on band structure.

WORKED EXAMPLE

1. Calculate N_c and N_v (equations 30.18 and 30.19)

(density of states)

Cu_2O we'll assume $m_e^* = m_h^* = 9.11 \times 10^{-32} \text{ kg} \Rightarrow$

$$N_c = N_v = 2.49 \times 10^{19} \text{ cm}^{-3}$$

GaAs $m_e^* = 0.067m_e = 6.10 \times 10^{-32} \text{ kg}$, $m_h^* =$

$$0.48 m_e = 4.37 \times 10^{-31} \text{ kg} \Rightarrow N_c = 4.31 \times 10^{17} \text{ cm}^{-3} \text{ and } N_v = 8.26 \times 10^{18} \text{ cm}^{-3}$$

2. Calculate n_i (equation 30.23)

$$\text{Cu}_2\text{O } n_i = 45.11 \text{ cm}^{-3}; \text{ GaAs } n_i = 2.85 \times 10^6 \text{ cm}^{-3}$$

3. Calculate of σ (equation 30.24)

The last parameters we need before we can calculate the n_i are μ_e and μ_h . In ionic solids these values are often not well known, but are several orders of magnitude lower than for the covalent semiconductors.

$$\text{Cu}_2\text{O } \mu_e = 0.2 \text{ cm}^2\text{V}^{-1}\text{s}^{-1} \text{ and } \mu_h = 0.1 \text{ cm}^2\text{V}^{-1}\text{s}^{-1}.$$

(Reasonable estimates.) GaAs see Table 30.4

$$\text{Cu}_2\text{O } \sigma = 2.17 \times 10^{-18} \text{ S/cm}; \text{ GaAs } \sigma = 5 \times 10^{-9} \text{ S/cm}$$

These are room temperature values for “pure” materials.

If the impurity can supply electrons into the conduction band, it is a “donor,” and the level is located just below the bottom of the conduction band. If the impurity acts as an electron donor, the semiconductor is known as n-type because the electrons (or negatively charged species) are the majority charge carriers. If the impurity acts as an electron acceptor, the semiconductor is known as a p-type semiconductor because holes (or positively charged species) act as the majority charge carriers.

At low temperatures, the number of charge carriers is determined by the donor and acceptor ionization energies. At sufficiently high temperatures, full ionization of the impurities is achieved; and the carrier densities become

TABLE 30.4 Mobilities of Various Semiconductors

independent of temperature. This region is called the “exhaustion” or “saturation” region. At even higher temperatures, the thermal energy is enough to excite electrons across the energy band gap; and the material behaves like an intrinsic semiconductor. These three regions are shown in Figure 30.12.

Nonstoichiometric semiconductors are very similar to extrinsic semiconductors and can really be considered together. The main difference is that the electronic defects, rather than being due to impurity atoms, are the result changes in the stoichiometry of the crystal. We still use the designations n-type and p-type to describe to majority charge carrier; and the defect adds levels into the band gap that lead to increased levels of conductivity, particularly at room temperature and below.

30.9 EXAMPLES OF EXTRINSIC SEMICONDUCTORS

30.9.1 Zinc Oxide: An n-Type Semiconductor

In Section 11.7, we described the results of heating ZnO in Zn vapor. The excess Zn atoms occupy interstitial sites. One electron is produced for every Zn interstitial, as shown using the Kröger-Vink notation.

FIGURE 30.12. Temperature dependence of σ for an extrinsic semiconductor. The dashed lines show the individual contributions of n and μ to σ .

The requirement of electroneutrality means that the concentration of interstitials is equal to the concentration of electrons.

$$[Zn_i] = [e'] = Kp_{Zn}^{1/2} \quad (11.14)$$

Because σ depends on the number of charge carriers, it is proportional to the zinc vapor pressure.

$$\sigma \propto p_{Zn}^{1/2} \quad (30.25)$$

The oxygen dependence can be considered in a similar way and gives:

$$[Zn_i] = [e'] = Kp_{O_2}^{-1/4} \quad (30.26)$$

Now σ varies with the oxygen partial pressure, as shown in the log-log plot in Figure 30.13.

$$\sigma \propto p_{O_2}^{-1/4} \quad (30.27)$$

Figure 30.14 shows the energy band diagram for $Zn_{1+x}O$, illustrating the positions of the donor levels. E_1 and E_2 are the first and second ionization energies for Zn. At low temperatures, the electrons would not be excited into the conduction band and would be localized at the donor level. As the temperature is raised, the fraction of electrons in the conduction band increases. At a sufficiently high temperature, all the impurity atoms are ionized.

30.9.2 Copper Oxide: A p-Type Semiconductor

If we start with stoichiometric Cu_2O and remove a copper atom to form a copper vacancy, the charge balance requires formation of a hole, as shown using the Kröger-Vink notation.

FIGURE 30.13. Effect of oxygen pressure on electrical conductivity of ZnO.

FIGURE 30.14. Energy levels in $Zn_{1+x}O$.

For a possible second ionization state:

The above processes are shown on an energy band diagram in Figure 30.15.

We can also consider hole to form by the production of vacancies on the cation sublattice when p_{O_2} is increased. The overall reaction can be represented as:

FIGURE 30.15. Energy levels in a deficit semiconductor such as Cu_{2-x}O .

FIGURE 30.16. Conductivity of Cu_2O as a function of p_{O_2} .

(You may recognize equation 30.30 as being similar to equation 11.8).

Using the same approach that we used for ZnO, we can obtain a relationship between p_{O_2} and σ .

$$\sigma \propto [h^{\cdot}] = K(T)^{1/4} p_{\text{O}_2}^{1/8} \quad (30.31)$$

Experimentally, as illustrated in Figure 30.16, σ is found to be proportional to $p_{\text{O}_2}^{1/7}$, which is in reasonable agreement with equation 30.31.

There are many examples of impurity semiconductors, and a partial list is given in Table 30.5.

30.10 VARISTORS

A varistor is used in an electric circuit as a protection against large voltage pulses (i.e., a surge protector). They are particularly important in protecting microelectronic

FIGURE 30.17. Typical current–voltage (I - V) characteristics for a ZnO varistor.

devices. ZnO is the most widely used and important material for varistors.

Under normal operating conditions, a small current flows through the varistor. If the voltage rises above some threshold value (as, for example, the result of a voltage spike in the power supply), a large current flows through the varistor to ground before it can damage the circuit. To operate in this way, a varistor must have a highly nonlinear I - V relationship, as shown in Figure 30.17.

- At low applied voltages, the varistor behaves in an ohmic manner (i.e., there is a linear I - V relationship).
- When the applied voltage reaches a threshold value known as the breakdown voltage, a large current flows, following a power law.

$$I \propto V^\alpha \quad (30.32)$$

The exponent α is used as a figure of merit for the varistor and can be as high as 70 for ZnO, although values in the range 25–45 are more typical. For SiC, $\alpha \sim 5$.

A significant difference between a varistor and a diode is that varistors can be used in both AC and DC circuits. Compare the plot shown in Figure 30.17 with what would be seen for a Zener diode.

The microstructure of a ZnO varistor is the key to its operation. Grains of about 15–20 μm in diameter are separated by a Bi-rich intergranular film (IGF) that varies in thickness from 1 nm to 1 μm, as illustrated in Figure 14.38. Varistor action is a result of a depletion region formed on either side of the IGF. To explain varistor behavior, we use an approach very similar to that used to describe Schottky barriers in metal–semiconductor junctions.

Figure 30.18A shows an energy level diagram for two ZnO grains separated by an IGF. The bismuth that segregates to the GB results in the formation of acceptor levels. The way that the bismuth dopants produce these sites is not well understood, but possibly they stabilize acceptor defects such as Zn vacancies at the GB. At equilibrium, the Fermi levels on each side of the boundary must line up, as shown in Figure 30.18B. This is required because at equilibrium the probability of occupation of any quantum level must be independent of position. When this occurs, the conduction and valence bands bend, resulting in an energy barrier (height $e\phi$) at the GB. Conduction band electrons must surmount this energy barrier for conduction to occur. When a potential is applied across the varistor, the size of the energy barrier is reduced. Conduction is provided by thermal activation of electrons across the barrier (at low fields) or tunneling (high fields). At the breakdown voltage the energy barrier is zero, and a massive increase in electrical conduction occurs.

FIGURE 30.18. Proposed band diagram for two semiconducting ZnO grains separated by an IGF. (A) Location of acceptor sites in the IGF. (B) At equilibrium. Application of a potential decreases the barrier height.

Varistor breakdown is reversible; and if the applied voltage is decreased below the breakdown value, the varistor returns to ohmic behavior. The breakdown voltage is typically in the range of tens to hundreds of volts.

- Single crystal silicon diodes (avalanche or Zener) are used only for low-voltage applications.
- ZnO varistors are used for both low- and high-voltage applications.

30.11 THERMISTORS

Thermally sensitive resistors (thermistors) have high TCs, produced by one of the following mechanisms.

1. Excitation across the band gap—intrinsic semiconductor behavior resulting in an exponential decrease in ρ over a wide temperature range (NTC).
2. A structural phase transformation causing a change from semiconducting behavior to metallic conduction causing a large decrease in ρ over a small temperature range (NTC).
3. A change in the conductivity of the GB, which produces a large increase in ρ over a small temperature range (PTC).

In semiconductors (e.g., SiC), where NTC behavior is expected, ρ varies with T according to:

$$\rho(T) = \rho_{\infty} \exp(B/T) \quad (30.33)$$

ρ_{∞} is approximately independent of temperature, and B is a constant related to the energy required to excite the electrons into the conduction band. By differentiation, we can obtain an expression for α .

$$\alpha_R = d\rho/\rho dT = -B/T^2 \quad (30.34)$$

α_R is usually expressed either as a percentage change in resistivity (e.g., $-3\%K^{-1}$) or in terms of parts per million (ppm) changes per degree change in temperature (e.g., ppm/ $^{\circ}C$). Table 30.6 shows the properties of thermistors based on Mn_3O_4 with partial replacement of the Mn by Ni, Co, and Cu.

NTC materials are used in many applications either to sense temperature or to respond to changes in temperature. One application is temperature sensors to measure the temperature of the cooling water in an automobile engine.

The behavior of PTC materials is very different from NTC materials. Commercial PTC devices rely on the changes associated with the ferroelectric Curie temperature (θ_c). Typical PTC behavior is shown in Figure 30.19. In regions AB and CD, the material is showing NTC

TABLE 30.6 Properties of Thermistor Compositions Based on Mn₃O₄ at 25°C

behavior, but at the Curie temperature (θ_c) there is a large positive change in ρ .

Polycrystalline lanthanum-doped BaTiO₃ (BLT) is an example of a PTC material. The effect is associated with GBs and is not observed in single crystals. At the GB, there is a potential barrier (ϕ) preventing electron movement from one grain to an adjacent one (very similar to that caused by the IGF in ZnO). The GB resistance, R_{gb} is:

$$R_{gb} \propto \exp(\phi/kT) \quad (30.35)$$

Above θ_c :

$$R_{gb} \propto \exp\left[N\left(1 - \frac{T_{cw}}{T}\right)\right] \quad (30.36)$$

where N is a temperature-independent constant for the particular material and includes specific details about the electronic structure of the grain boundary, and T_{cw} is the Curie-Weiss temperature ($\sim\theta_c$).

30.12 WIDE-BAND-GAP SEMICONDUCTORS

Wide-band-gap semiconductors refer to materials that have a band gap of about 2–5 eV. At present, one of the most interesting wide-band-gap semiconductors is SiC, which has E_g of 2.4–5.1 eV. These materials are important because they can be used at much higher temperatures than Si or GaAs. This is because the thermal generation of electron–hole pairs is much lower. SiC exists in a number of different polytypes, each having different properties, as shown in Tables 30.7 and 30.8.

30.13 ION CONDUCTION

Ion movement can make a major contribution to σ , particularly if the material has a large E_g . Conductivity resulting from ion migration is important in several ceramics. It is also the major conduction mechanism in ionic salts such as the halides.

When we describe the mobility of ions we often use the absolute mobility, B :

$$B = \frac{v}{F} = \frac{v}{zeE} \quad (30.37)$$

where v is the drift velocity, and F is the applied force (which in this case is the electrical potential i.e., $F = Zq\xi$, where Z is the charge on the ion).

B is related to μ .

$$\mu = ZqB \quad (30.38)$$

Substituting equation 30.38 into equation 30.2 gives:

$$\sigma = nZq^2B \quad (30.39)$$

FIGURE 30.20. Potential energy barrier to ion movement. (A) In the absence of an applied field. (B) With an applied field. E_A is the activation energy, and a is the jump distance between ion sites.

The absolute mobility, and hence σ , is directly related to the diffusion coefficient, D , through the Nernst-Einstein equation.

$$D = kTB \quad (30.40)$$

The diffusion coefficient is given by an Arrhenius equation, which means that there is an activation energy that must be overcome for the ions to move through the material, as illustrated in Figure 30.20. We can then give σ in terms of D , which is what we did in Section 11.15.

$$\sigma = \frac{ne^2D}{kT} \quad (11.53)$$

Factors that contribute to ionic mobility are:

- Size. It's easier to move a small ion than a large one.
- Charge. A highly charged ion polarizes and is polarized by ions of opposite charge as it moves past them. This increases E_A .
- Lattice geometry. Some structures contain channels that facilitate the ion movement. A large number of vacant lattice sites can help.

30.14 FAST ION CONDUCTORS

Materials that show exceptionally high ionic conductivity are referred to as “fast ion” conductors or “superionic” conductors. The conductivities are comparable to those of electrolyte solutions but are still low compared with metal-like electron conductivity. There are two important types of fast ion conductor.

1. β -Aluminas (e.g., nonstoichiometric aluminates)

- $\text{Na}_2\text{O} \cdot 11\text{Al}_2\text{O}_3$ (β -alumina)
- $\text{Na}_2\text{O} \cdot 8\text{Al}_2\text{O}_3$ (β' -alumina)
- $\text{Na}_2\text{O} \cdot 5\text{Al}_2\text{O}_3$ (β'' -alumina)

They all have a layer structure, as illustrated earlier in Figure 7.12, that comprises spinel blocks of close-packed O^{2-} ions with Al^{3+} in tetrahedral and octahedral interstices. Planes containing Na^+ and O^{2-} ions separate the spinel blocks. It is within these planes that the mobility of the Na^+ ions is high. The conductivity is highly anisotropic; it is high within the Na^+ -containing planes and negligible in the perpendicular direction.

2. Cubic stabilized zirconia stabilized usually with either CaO or Y_2O_3

These materials have oxygen ion transport numbers very close to 1.0. To understand how they are able to conduct large oxygen ions, it is necessary to consider their defect structure. The correct composition of an oxide with the fluorite structure oxide would be MO_2 . The addition of CaO to ZrO_2 , for example, drops the metal to an oxygen ratio below 2.0, and the formula of the oxide becomes $\text{Ca}_x\text{Zr}_{1-x}\text{O}_{2-x}$. As we showed in Section 11.7, the Ca^{2+} ions substitute for Zr^{4+} ions, and we have compensating oxygen vacancies. For each substitutional Ca^{2+} , we must create one anion vacancy. The result of this enormous defect population is to greatly increase the diffusion coefficient for oxygen—to the extent that this material becomes a very fast oxygen-ion conductor.

Stable ceramics that have completely ionic conductivity can be used as solid-state electrolytes. Two examples are the Na-S battery and the solid oxide fuel cell.

30.15 BATTERIES

A battery operates on the principle of the Galvanic cell: a chemical reaction is used to produce electricity. The materials that are involved in the reaction form the electrodes, and the reaction takes place by the passage of ions through an electrolyte. The formation of ions during the chemical reaction involves the transfer of electrons to or from the electrodes. In a galvanic cell, they are not allowed to pass through the electrolyte but must travel around an external circuit, driven by a potential difference created between the electrodes. It is the electron movement through the external circuit that can be used to do the work.

β -Alumina is used as an electrolyte in high-energy-density Na-S batteries. The concept of a battery based on the reaction of Na and S was first proposed in 1967 as an alternative to the conventional lead-acid battery. The Na and

FIGURE 30.21. “Central sulfur” cell. Typically, the electrolyte tube is some 300 mm long and 30 mm in diameter.

S are separated by a membrane of β -alumina, usually in the form of a closed-end thin-walled tube, as shown in Figure 30.21. It is often convenient to place the S inside the β -alumina tube because the ceramic has far superior corrosion resistance than that of the mild steel outer casing. On connection to the external circuit, the Na gives up electrons, forming Na^+ ions. These diffuse through the β -alumina to react with the S to produce the sulfide according to the reaction:

The reverse reaction occurs on recharging. The cell runs at about 300°C with both Na and S in the liquid state. The cell reaction is extremely energetic, and the heat required to maintain the cell at its operating temperature is readily supplied by the cell reaction itself.

Despite being used by Ford Motor Company in a series of test vehicles, the disadvantages of the Na-S battery, not least its cost (\sim \\$50,000 each), have limited its adoption for electric vehicle applications.

A different application proposed for Na-S batteries is for spacecraft. Because electrical power systems make up a major part of a spacecraft’s weight, and batteries are typically the largest component of the power system, it is critical to improve the efficiency of spacecraft batteries.

TABLE 30.9 Efficiency of Various Batteries

Type	Efficiency (Wh/kg)
Nickel-cadmium (Ni-Cd)	7–50
Nickel-metal hydride (Ni-H)	20–100
Sodium-sulfur	75–200

Battery efficiency is measured in terms of specific energy, or watt-hours of energy output per kilogram of battery weight (Wh/kg). The values for several batteries are given in Table 30.9. In 1996, an Na-S battery was flight tested during a space shuttle mission. Although cost is not such an issue with spacecraft as it is with automobiles, there are still technological challenges in using Na-S batteries. One of these challenges is producing a suitable casing. Steel containers, even with protective coatings, can easily be dented or scratched, leading to corrosion and rapid failure.

Because of recent interest in an increasing use of energy generated from renewable sources (e.g., wind, solar) and balancing supply and demand in a “smart grid,” the performance values offered by the Na-S battery have once again made it an important option as an energy storage technology. The theoretical specific energy of a Na-S cell is \sim 800 Wh/kg, which is higher than the actual

values that have been achieved to date. The high energy efficiency and good cycle life also make Na-S batteries more attractive than some of the alternatives. The U.S. Department of Energy has recently invested more

than \\$7 million in Na-S battery technology through its Advanced Research Projects Agency–Energy (ARPA-E) program.

OTHER USES OF CERAMICS IN BATTERIES

Hg battery— HgO is the cathode.

Ni-Cd battery—hydrated NiO ($\text{NiOOH}\cdot\text{H}_2\text{O}$) is the cathode.

Li battery— MnO_2 is the cathode.

30.16 FUEL CELLS

A fuel cell—another example of a galvanic cell—supplies electrical energy in the same way as a battery. The essential difference between the two types of cell is that the electrodes of a fuel cell do not deteriorate chemically. Therefore, if a fuel cell is fed a constant supply of fuel, it supplies continuous electrical energy. The fuel is hydrogen or a hydrogen-rich source (e.g., methanol, formic acid).

The first practical fuel cell was developed in the 1950s at Cambridge University in the United Kingdom. The cell used Ni electrodes and an alkaline electrolyte. Pratt and Whitney further modified the alkaline fuel cell (as it was called in the 1960s) for NASA’s Apollo program. The cells were used to provide on-board electrical power and drinking water for the astronauts. The alkaline fuel cell proved

TABLE 30.10 Fuel Cells and Their Applications

Fuel cell	Electrolyte	Anode fuel	Cathode gas	Operating temp. (°C)	Applications
Alkaline fuel cell (AFC)	KOH solution	H ₂	O ₂	60–90	Spacecraft, submarines
Proton exchange membrane fuel cell (PEMFC)	Proton conductive polymer membrane	H ₂	O ₂ (in air)	60–90	Transportation vehicles, stationary power plants, cogeneration plants, portable power supplies
Direct methanol fuel cell (DMFC)	Proton conductive polymer membrane	Methanol	O ₂ (in air)	90–120	Transportation vehicles, stationary power plants, cogeneration plants, portable power supplies
Phosphoric acid fuel cell (PAFC)	Phosphoric acid	H ₂	O ₂ (in air)	200	Stationary power plants, cogeneration plants
Molten carbonate fuel cell (MCFC)	Molten alkaline carbonate	H ₂ , CH ₄ , or coal gas	O ₂ (in air)	650	Stationary power plants, cogeneration plants
Solid oxide fuel cell (SOFC)	Ceramic solid electrolyte	H ₂ , natural gas, coal gas	O ₂ (in air)	600–1,000	Stationary power plants, cogeneration plants

successful but was an order of magnitude too expensive for terrestrial applications and demanded pure hydrogen and oxygen to operate.

Table 30.10 lists the different types of fuel cell that are being investigated together with some of their potential applications. Fuel cells are one of the leading research topics at the present time, with the goal of reducing the dependence on fossil fuels and associated problems of global warming.

There are two types of fuel cell that use ceramics.

- Molten carbonate fuel cell (MCFC)
- Solid-oxide fuel cell (SOFC)

The main difference between the two types is the electrolyte. The MCFC uses a molten carbonate immobilized in a porous LiAlO₂ matrix. The SOFC uses a ceramic membrane of cubic stabilized zirconia. An illustration of the operation of a SOFC is shown in Figure 30.22.

The cell reactions are:

A single fuel cell supplies a DC voltage of <1 V. If larger voltages are required, the cells must be stacked together in series. Commercially voltages up to ~200 V can be attained. The current produced is proportional to the area over which the reaction occurs. The best fuel cells at present provide a maximum current density of 0.5–2.0 A/cm².

MCFCs and SOFCs can be made by assembling individual plate cells into stacks, just like the design of the original voltaic pile. For SOFCs producing 5–200-kW ceramic plates, 150–300-mm squares are required. This requirement presents a problem because it is difficult to produce large, thin, flat, dense plates of ceramics. Siemens-Westinghouse developed an alternative tubular design; it is straightforward to extrude long tubes (see

FIGURE 30.22. Simple representation of a solid-oxide fuel cell using cubic zirconia.

Section 23.9). The disadvantage of the tube design is that it has high thermal inertia and a long warming time.

Fuel cells offer significant advantages over many other power sources. They are:

- Silent
- Low maintenance
- Efficient (they are not limited to the Carnot efficiency—i.e., the maximum theoretical efficiency that can be obtained from an engine employing combustion)
- Nonpolluting (the product is distilled water)

These advantages are the reasons for the continued research efforts. However, the jury is still out on whether fuel cell technology can be made commercially viable. (At the present time it is not).

A similar principle used in the SOFC can be applied to oxygen sensors for applications including monitoring of automobile exhaust emissions to increase engine efficiency and reduce emissions. You can compare Figure 11.17 with Figure 30.22 to see the similarities. Oxygen control is also important in several metallurgical processes, such as gas carburizing and the bright annealing of stainless steel.

30.17 CERAMIC INSULATORS

More typically we think of ceramics as being good electrical insulators, and there are many ceramics that have $\rho > 10^{14} \Omega\text{cm}$. Examples of common ceramic insulators include:

- Aluminum oxide (Al_2O_3)
- Mullite ($3\text{Al}_2\text{O}_3 \cdot 2\text{SiO}_2$)
- Forsterite ($2\text{MgO} \cdot \text{SiO}_2$)
- Beryllium oxide (BeO)
- Aluminum nitride (AlN)

In an electrical insulator, there is a wide energy gap between the bottom of the conduction band and the top of the valence band. Figure 30.23 shows the energy band diagram for MgO. The valence band is formed by the 2p energy levels of oxygen (O^{2-} ions), and the conduction band is formed from the empty 3s orbitals of the Mg^{2+} ions. The energy band gap is $\sim 8 \text{ eV}$, and the concentration of thermally excited electrons in the conduction band of MgO

FIGURE 30.23. Energy band diagram for MgO.

is low right up its melting point, $2,800^\circ\text{C}$. MgO is therefore an excellent high-temperature insulator.

Very wide energy band gaps ($>6 \text{ eV}$) are associated with compounds that have high fractions of ionic character in their bonding. Ions have a stable noble gas electron configuration. To excite an electron from the valence band to the conduction band involves making the electron configuration of the ions different from those of the noble gases. This process is energetically unfavorable.

In general, compounds with wide band gaps:

- Have predominantly ionic bonding
- Consist of atoms (ions) of low Z

Some ceramics having large values of E_g are listed in Table 30.3. No entirely satisfactory relationship has been established between the ionic character of the bond and the atom size on E_g . In a homologous series of oxides, such as the oxides of the alkaline-earth metals, E_g increases with increasing ionic potential, ϕ , of the cation, as shown in Figure 30.24.

In a series of isoelectronic compounds (i.e., compounds with an identical total number of electrons) E_g increases with increasing ionic character of the interatomic bond, as shown in Figure 30.25. Understanding this relationship is quite straightforward. As the fraction of covalent character in a bond increases, the electrons in that bond are more equally shared; hence, electron transfer becomes easier.

The presence of point defects in the lattice can be viewed as being donor or acceptor species in the same

FIGURE 30.24. Effect of bond ionicity on E_g for metal oxides MO ($\phi = Z/r$).

FIGURE 30.25. Correlation of E_g and the electronegativity difference.

FIGURE 30.26. Defect levels in MgO.

way that we considered defects in semiconductor crystals. Figure 30.26 shows another version of an energy band diagram for MgO. This time the estimated defect energy levels are included. If the crystal contains oxygen vacancies (i.e., it has been reduced) they can become ionized.

Notice that the Kröger-Vink notation is useful for describing this process. The energy for ionization is 0.5 eV and can be represented as a level just below the bottom of the conduction band—the oxygen vacancy is behaving as a donor.

The oxygen vacancy can become doubly ionized,

The energy for this second ionization process is ~ 2 eV and can be represented as another donor level.

In a similar way, we can represent acceptor sites within the band diagram for MgO as being due to the oxidation of MgO (i.e., the introduction of magnesium vacancies and corresponding holes). The following reactions show the origin of the acceptor levels:

and

The energies for these two processes are 0.5 and ~ 1.5 eV, respectively. Even though these ionization energies are relatively small compared to the band gap, the concentration of these defects is extremely low. Even at temperatures $> 2,000^\circ\text{C}$, the number of cation and anion vacancies in MgO is only about one per billion lattice sites.

The addition of substitutional and interstitial point defects can also introduce additional energy levels. Using MgO as our example let's consider the incorporation of Al_2O_3 . There are two defect reactions we can envision.

and

In equation 30.46, the incorporation of Al into Mg sites is compensated for by the formation of a magnesium vacancy. This type of incorporation is termed ionically compensated because an ionic defect has compensated for the charge difference. The second reaction, given by equation 30.47, is electronically compensated because electrons (or in some cases holes) are compensating for the charge difference resulting from the substitution of a divalent cation for a trivalent one. Acceptor levels are introduced by ionic compensation, and electronic compensation corresponds to the introduction of donor levels in the energy gap.

Combining equations 30.46 and 30.47, we can write:

Stoichiometric oxides such as MgO are very difficult to reduce, and hence the reaction represented by equation 30.48 is strongly to the right throughout all accessible ranges of temperature and oxygen activity. Even highly doped compositions are not electrically conductive at room temperature. The defects with a positive effective charge are donors; they have given up an electron to become ionized positively relative to the perfect lattice site. Correspondingly, defects with negative effective charge are acceptors, having accepted electrons relative to the perfect lattice.

Dislocations are defects that also create additional energy levels within the band gap. They act as acceptors, as shown in Figure 30.27. Note that the dislocation-acceptor levels are usually in the upper half of the band gap. Dislocations are particularly deleterious to the behavior of semiconductors. One of the main factors that limited the increase in the size of silicon wafers has been the necessity to grow dislocation-free single crystals. At the beginning of the semiconductor industry in the 1960s, wafer sizes were limited to 2-in. diameters; now, 18-in. diameter wafers are possible because of better control of the growth parameters.

To understand why dislocations act as acceptors, consider the illustration of a dislocation in silicon shown in Figure 12.11. The dislocation creates dangling bonds, which act as electron traps to satisfy the requirement of each silicon atom to achieve a noble gas electron configuration.

FIGURE 30.27. Effect of dislocations on the energy band diagram of a semiconductor.

Ceramics with high ρ are important for a number of applications, many of which utilize more than just the high ρ . Other properties—e.g., high strength, stability at elevated temperature, high thermal conductivity, hermeticity (impervious to the environment)—are also important.

One application that you may be familiar with is the use of alumina ceramics as the insulator in spark plugs. The insulator must be able to withstand a peak voltage of about 10 kV at each spark discharge, a pressure pulse of about 10 MPa, and thermal radiation from the combustion temperature, which is typically 2,000°C. This combination of requirements can be met only by a ceramic.

A very visible application of ceramic insulators is as power line insulators. For this application, the strength of the ceramic is very important because the insulator supports a considerable weight. The insulator must also be resistant to weather damage and to absorption of water, which can lead to arcing. One ceramic used for this application is porcelain. A typical porcelain composition would lie in the following ranges: clays [e.g., kaolinite $Al_2(Si_2O_5)(OH)_4$, 40–60 wt.%], flux [e.g., orthoclase $(KAlSi_3O_8)$, 15–25 wt.%], and quartz or bauxite filler, 30–40 wt.%. The porcelain is known as a “silicious porcelain” if quartz is used as the filler and an “aluminous porcelain” if bauxite is used.

The above applications are visible uses for ceramic insulators. The two applications that we’re going to emphasize next may not be ones that immediately come to mind when you think of ceramic insulators, but they are extremely important. In fact, the development of personal computers and other electronic devices owes much to the use of insulating ceramics.

30.18 SUBSTRATES AND PACKAGES FOR INTEGRATED CIRCUITS

Substrates and packages for integrated circuits (ICs) are the largest applications for ceramic insulators. The following properties are required.

- High ρ
- High thermal conduction
- Low dielectric constant
- Hermetic

Three ceramics are usually used for this application.

- Al_2O_3
- BeO
- AlN

TABLE 30.11 Physical Properties of Substrate Materials

Property	96% Al ₂ O ₃	99.5% Al ₂ O ₃	BeO	AlN	Mullite	Glass-ceramics
Density (g/cm ³)	3.75	3.90	2.85	3.25	2.82	2.5–2.8
Flexural strength (MPa)	400	552	207	345	186	138
Thermal expansion from 25–500°C (10 ⁻⁶ /°C)	7.4	7.5	7.5	4.4	3.7	3.0–4.5
Thermal conductivity at 20°C (Wm ⁻¹ °C ⁻¹)	26	35	260	140–220	4	4–5
Dielectric constant at 1 MHz	9.5	9.9	6.7	8.8	5.4	4–8
Dielectric loss at 1 MHz (tan δ)	0.0004	0.0002	0.0003	0.001–0.0002	0.003	>0.002

Alumina ceramics dominate, but there are important reasons why BeO and AlN are used in certain applications. Table 30.11 compares the properties of these three ceramics and some others that have also been used as substrates and packages. BeO and AlN are used in situations where high thermal conductivity is needed. Heat removal from power electronics and from integrated circuits is determined mainly through the substrate; one factor that influences the heat transfer rate is the thermal conductivity of the substrate material. Effective thermal management is important in improving the reliability of electronic devices.

AlN has a theoretical thermal conductivity of 320 W m⁻¹ K⁻¹, and values as high as 285 W m⁻¹ K⁻¹ have been experimentally measured for single crystals. Commercial AlN substrates are available with a thermal conductivity up to about 200 W m⁻¹ K⁻¹ at room temperature. The thermal expansion of AlN (3.9 × 10⁻⁶ K⁻¹) from room temperature to 500 K is very similar to that of silicon (3 × 10⁻⁶ K⁻¹) over the same temperature range, which helps to avoid cracking due to thermal misfit stresses between substrate and device. This consideration is particularly important for large silicon chips. AlN also does not have the inherent toxicity problems that are associated with BeO.

30.19 INSULATING LAYERS IN INTEGRATED CIRCUITS

Layers of SiO₂ have several uses in the production of silicon ICs.

- Device isolation
- Isolation of multilevel metallization
- Surface passivation
- Gate oxide in metal oxide semiconductor (MOS) structures
- Barrier layer during dopant incorporation

SiO₂ layers can be obtained by direct oxidation by one of the following reactions.

Dry oxidation

Wet oxidation

Dry oxidation is slow but produces a uniform, relatively defect-free layer that is electrically very reliable. Wet oxidation is more frequently used for masking operations because the growth rate is quicker; however, the layers are not as uniform as those produced by dry oxidation.

The oxide layer formed on the silicon surface is what is known as a protective oxide. The growth rate initially follows a linear rate law; that is, the oxide thickness, *x*, increases linearly with time, *t*.

$$x \propto t \quad (30.51)$$

For the two processes the activation energies are:

$$E_A = 1.96 \text{ eV for wet oxidation}$$

$$E_A = 2.0 \text{ for dry oxidation}$$

These values are close to the energy required to break the Si–Si bond, 1.83 eV.

After a layer of approximately 100 nm has formed, the growth kinetics follow a parabolic rate law: the oxide thickness increases with the square root of time.

$$x \propto \sqrt{t} \quad (30.52)$$

Diffusion through the oxide layer follows an Arrhenius law (equation 3.13).

$$E_A = 1.24 \text{ eV for dry oxidation}$$

$$E_A = 0.71 \text{ eV for wet oxidation}$$

These activation energies are close to those for the diffusivity of oxygen and water vapor through fused silica, respectively. Fused silica has a structure very similar to that of thermal SiO₂.

When very thin SiO₂ layers are required—such as a gate oxide in a MOS-field effect transistor (MOSFET) or when an SiO₂ layer is required as an insulating layer between layers in a multilevel device—the chemical vapor deposition (CVD) process is used. The dielectric is

an active component of the storage capacitor in dynamic RAMs, and its thickness determines the amount of charge that can be stored (see Chapter 31).

In a complementary MOS (CMOS) device, oxidation of polysilicon is necessary for electrical isolation. A thermal oxide can be produced on polysilicon in a manner similar to that produced on single-crystal silicon.

30.20 SUPERCONDUCTIVITY

There are two properties that a material must possess to be considered a superconductor.

1. $\rho = 0$
2. $B = 0$ (described in Chapter 33)

Zero resistivity is observed in a superconductor at all temperatures below a critical temperature, T_c , as illustrated in Figure 30.28. At T_c the material changes from a state of normal conduction to the superconducting state. In the superconducting state, an induced current flows indefinitely: without loss. This behavior has been demonstrated experimentally, where a current has been run through a closed ring of a superconducting metal for over 2½ years without any measurable decay.

Superconductivity has been observed in *all* classes of materials: metals, ceramics, and polymers. Of all the elements in the periodic table, only 27 are known to become superconducting under ordinary pressure. Niobium is the element with the highest T_c , 9.2 K, whereas for tungsten T_c is only 0.0154 K. An interesting fact is that

FIGURE 30.28. Plot of ρ versus T for a superconductor.

metals having the highest σ (e.g., Cu, Ag, Au) are not superconducting, even at extremely low temperatures if at all. It is the poorer electrical conductor metals that make the better superconductors, albeit still at very low temperatures. Low-temperature superconductors (LTSC) have T_c values up to about 20 K. High-temperature superconductors (HTSC) are usually defined as having a T_c above the boiling temperature of liquid nitrogen.

The BCS theory (after Bardeen, Cooper, and Schrieffer) provides an explanation for superconductivity at low temperatures. The theory is complicated, but the basis is that there exists an attractive force between electrons that have about the same energy. This force causes them, under the right circumstances, to move in pairs. These are the so-called Cooper pairs. The criterion for superconductivity is that this attraction should be greater than the natural repulsion between like charges. T_c corresponds to the binding energy needed to hold the Cooper pairs together in the superconducting state.

The origin of the attractive force is that in a lattice of positive ions an electron attracts the positive ions toward itself. In this region, the lattice is slightly denser, as shown in Figure 30.29. To a passing electron the local lattice distortion appears as an increase in positive charge density, and it is attracted toward it. The two electrons pair up in this way through their interaction with the lattice.

If the lattice is vibrating through thermal effects, pairing is not possible; but at very low temperatures, where the vibration amplitude is small, the attractive force can be dominant. The electrons are held together by a binding energy of only about 10^{-4} eV. The separation of the electrons in the pair (called the coherence length) for most LTSCs is 100 nm. Interatomic spacings are on the order of 0.3 nm, so two bound electrons can be as far apart as 300 lattice spaces. The large coherence length means that defects such as dislocations, GBs, and impurities are too small to have much effect on superconducting behavior.

FIGURE 30.29. Lattice distortion around a free electron, which leads to the formation of Cooper pairs.

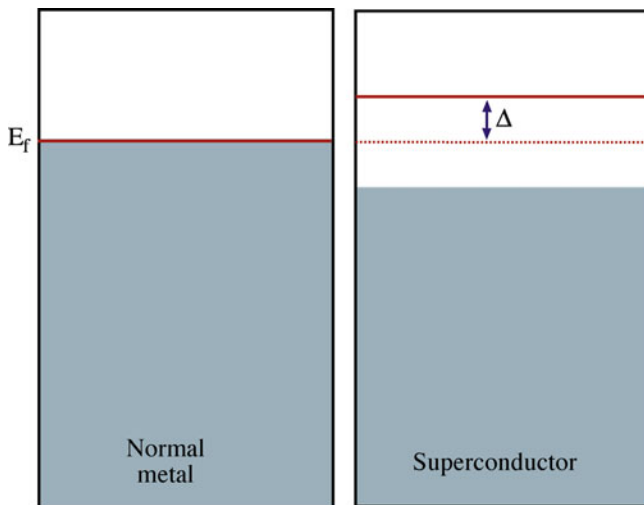

FIGURE 30.30. Band diagram for a superconductor.

The existence of these bound electron pairs alters the energy band diagram for a superconductor by introducing a small gap at E_F , known as the superconducting gap, Δ . The difference in the band structure of a material in the superconducting state and in the nonsuperconducting state is illustrated in Figure 30.30. The energy of this gap corresponds to the binding energy of the electron pairs. An energy 2Δ is needed to break a Cooper pair. The relation between Δ and T_c is given by the BCS theory.

$$2\Delta = 3.5 kT_c \quad (30.53)$$

- For LTS $\Delta \sim 1$ meV
- For HTS $\Delta \sim 1\text{--}10$ meV

The BCS theory predicts an ultimate limiting value for T_c of 30 K for electron pairing via lattice vibrations (phonons). This limit was enough to stop many researchers pursuing careers in superconductivity. Clearly, the BCS theory, in its entirety, cannot be applicable to HTSCs where $T_c \gg 30$ K. In these materials, pairing of the electrons occurs, but the mechanism that allows this pairing needs to be determined.

30.21 CERAMIC SUPERCONDUCTORS

The earliest nonmetallic superconductors were NbO and NbN. Both materials have the rock salt crystal structure. What was significant about the discovery of superconductivity in these materials (they are of no practical use) is that they linked the phenomenon to

CHEVREL PHASES

Complex forms of MoS_2 having the general formula $\text{M}_x\text{Mo}_6\text{X}_8$, where M is a metal and X a chalcogen. PbMo_6S_8 has the highest T_c of the Chevrel phases ($T_c = 15$ K). They are named after French scientist Roger Chevrel.

TABLE 30.12 Critical Temperatures of some Ceramic Superconductors

Compound	T_c (K)
$\text{La}_{2-x}\text{M}_x\text{CuO}_{4-y}$ M = Ba, Sr, Ca $x \sim 0.15$, y small	38
$\text{Nd}_{2-x}\text{Ce}_x\text{CuO}_{4-y}$ (electron doped)	30

$\text{R}_1\text{Ba}_2\text{Cu}_{2+m}\text{O}_{6+m}$ R: Y, La, Nd, Sm, Eu, Ho, Er, Tm, Lu	
$m = 1$ (123)	92
$m = 1.5$ (247)	95
$m = 2$ (124)	82
$\text{Bi}_2\text{Sr}_2\text{Ca}_{n-1}\text{Cu}_n\text{O}_{2n+4}$	
$n = 1$ (2201)	~ 10
$n = 2$ (2212)	85
$n = 3$ (2223)	110
$\text{Tl}_2\text{Ba}_2\text{Ca}_{n-1}\text{Cu}_n\text{O}_{2n+4}$	
$n = 1$ (2201)	85
$n = 2$ (2212)	105
$n = 3$ (2223)	125

ceramics and cubic crystal structures.

Superconductivity in a multicomponent oxide was first observed in SrTiO_3 . Although T_c was determined to be only 0.3 K, SrTiO_3 has the very important perovskite structure, which we showed in Chapter 7 is the structural building block of all presently known HTSCs.

The beginning of HTSC started in 1986 with the discovery of superconductivity in the compound $\text{La}_2\text{BaCuO}_4$, which has $T_c \sim 8$ K. This discovery was of monumental importance because the classic BCS theory for superconductivity predicted a maximum value of T_c of only 30 K! Many more HTSCs were simply obtained by systematic substitution of elements into the basic perovskite unit. Certainly in the early days, many scientists said that research on HTSCs was more akin to cooking than any area of science!

The elements yttrium and lanthanum are interchangeable in terms of chemical properties (they are in the same group in the periodic table), although they differ in size. The same is true of strontium and barium in group II of the periodic table. The idea behind substitution of the large element for a smaller element was based on observations that T_c could be raised under an applied pressure. It was thought that substitution of a larger element for a smaller

one might produce an internalized pressure effect. Table 30.12 lists some of these compounds and their T_c .

Tables 30.13 compares properties of HTSCs and LTSCs. In the table, v_F is the velocity of propagation of conduction electrons through crystal.

TABLE 30.13 Comparison of Superconductors in the Normal State

Material	No. of conduction electrons (10^{21} cm^{-3})	Fermi velocity (v_F) (10^6 m/s)	Mean free path (λ_e) (nm)	ρ (@ 100 K) ($\mu\Omega\text{cm}$)	χ (nm)
Al	180	2.0	130	0.3	1,600
Nb	56	1.4	29	3	38
LSCO	5	0.1	~5	~100	~1.5
YBCO	7	0.1	~10	~60	~1.0

- The obvious difference is T_c . The fact that $T_c \sim 10^2\text{K}$ means that the binding energy is $\sim 10 \text{ meV}$, as compared to $<1 \text{ meV}$ in LTSCs.
- The ceramics have higher ρ than metals at 100 K, but ρ is comparable to some of the best ceramic electrical conductors (e.g., CrO_2 , TiO).
- For HTSC, χ is only $\sim 1.0 \text{ nm}$, which means that the pairing behavior is almost on an atomic scale, and the superconducting properties are dependent on atomic scale defects. (Compare χ to the width of a dislocation or GB). Such defects therefore scatter the electron pairs and reduce the critical current density. For metals, χ is large (e.g., $\chi = 1.6 \mu\text{m}$ in pure Al; $\chi = 38 \text{ nm}$ in pure Nb).
- χ is anisotropic. For YBCO, $\chi_{ab} \sim 1.5 \text{ nm}$ and $\chi_c \sim 0.4 \text{ nm}$. A major problem with HTSCs is to find a crystal defect that pins the flux vortices but does not disrupt current flow.

FIGURE 30.31. I - V characteristics of a Josephson junction.

We showed the structures of HTSC in Chapter 7. Superconductivity essentially takes place within the CuO_2 planes. The Cu-O chains can be considered a “charge-reservoir,” which is needed to transfer charge into the CuO_2 planes. Charge carriers are added by doping, such as adding oxygen to $\text{YBa}_2\text{Cu}_3\text{O}_6$, which enters the compound as O^{2-} and forms Cu-O chains. To maintain charge balance, electrons are removed from the Cu-O planes, and the remaining holes are mobile (hence conduction); and they form Cooper pairs below T_c .

In LTSCs, Cooper pairs with a charge of $-2e$ are responsible for current flow. In most of the HTSCs the Cooper pairs have a positive charge, $+2e$. In other words, they are positive holes, and the charge transfer process can be written as

One of the consequences of a hole-hopping process involving a two-dimensional array of copper ions is that the superconducting current is very anisotropic. Hopping tends to occur between copper ions that have the smallest separation from each other (i.e., those in the plane). The distance between copper ions on adjacent planes is much larger than within the planes; hence, charge hopping between planes is much less efficient.

There are many potential applications for HTSCs, but actual realization has in many cases not occurred. The major problem is being able to fabricate the ceramics into useful and usable shapes. Ceramics are inherently brittle, and this alone makes the fabrication of long wires and tapes extremely difficult. These would be essential for domestic and industrial power transmission (some limited progress has been made in this area, as we describe in Chapter 37). The low χ also makes practical applications more difficult to achieve because we have to be concerned about defects.

The most likely route to widespread practical application is to use the HTSC in the form of a thin film and utilize the Josephson effect. The original observation of this effect was made using a junction consisting of two superconductors separated by a very thin insulating layer ($\sim 1 \text{ nm}$). In thin films the “insulating” region can be orientation changes across a GB, as we showed in Figure 14.37.

The current–voltage (I - V) characteristics of a Josephson junction are very nonlinear, as shown in Figure 30.31. The key features are:

- When $V = 0$, a direct current flows.
- When a small voltage is applied, $I = 0$.
- At V_c , the electrons are no longer paired and normal electron tunneling occurs with associated resistive losses.

FIGURE 30.32. Effect of incident microwave radiation on the I - V characteristics of a Josephson junction.

If a Josephson junction is irradiated with microwaves of frequency f , the I - V behavior shows a series of steps, called Shapiro steps, as shown in Figure 30.32. These steps correspond to supercurrents across the junction when the condition for the absorption of microwave photons is satisfied (this is called the AC Josephson effect). A similar behavior is seen when we expose the junction to a magnetic field. We describe how Josephson junctions can be used to detect very small magnetic fields in Chapter 33.

CHAPTER SUMMARY

We can explain the wide range of electrical properties shown by ceramics by considering their electron band structure. Some oxides show metallic-like levels of conductivity, consistent with either a partially filled valence band or a small E_g . These materials are used as electrodes and conductors. Most ceramics fall into the category of having a medium-to-wide E_g . Semiconducting ceramics are used in a variety of sensors. The most important application is to “sense” anomalous voltages. As with the more familiar Si and GaAs, which are also ceramics, the conductivity of all semiconductors can be changed by doping. Unlike Si and GaAs, we can use stoichiometry changes to modify σ . Ceramics having the largest E_g usually show a significant degree of ionic bonding, and any conductivity is mainly associated with ion transport. The important technological example is cubic ZrO_2 , which is the electrolyte in solid oxide fuel cells. Fuel cells comprise one of the key components of a “hydrogen economy.” We finished this chapter with superconductors. The structure of these materials is already familiar from Chapter 7 and the importance of GBs as weak links from Chapter 14.

PEOPLE AND HISTORY

Bardeen, John (1908–1991) received the 1972 Nobel Prize in Physics along with Cooper and Schrieffer for the BCS theory. It was his second Nobel Prize! He won his first in 1956 for his role in the invention of the transistor.

Cooper, Leon Neil (1930–) received the Nobel Prize in physics with Bardeen and Schrieffer for the BCS theory. Cooper pairs are named after him.

Drude, Paul Karl Ludwig (1853–1906) He was a German physicist who developed a theory for electron conduction. Drude’s theory provided an atomistic basis for understanding electron motion in metals and ceramics. In its original version, it contained several inaccuracies, which were corrected by the application of quantum mechanics.

Grove, Sir William Robert Grove was a British scientist who in 1839 discovered the principle on which fuel cells are based. His cell, which comprised two Pt electrodes both half immersed in dilute H_2SO_4 —one electrode fed with O_2 the other with H_2 —was not a practical method for energy production.

Onnes, Heike Kamerlingh (1853–1926) was a Dutch physicist who succeeded in liquefying helium in 1908 and discovered superconductivity in mercury in 1911. He wrote at the time: “Mercury has passed into a new state, which on account of its extraordinary electrical properties may be called the superconducting state.” He received the Nobel Prize in Physics in 1913.

Schrieffer, John Robert (1931–) received the Nobel Prize in physics with Bardeen and Cooper for the BCS theory.

EXERCISES

- 30.1 Using Table 30.2, explain the following: (a) Why do t_+ and t_- change for NaCl as the temperature is increased from 400°C to 600°C. (b) How would you expect these numbers to change if the temperature was increased further to 700°C? (c) Why is t_e zero?
- 30.2 At what temperature would the probability of finding an electron in the conduction band of diamond be the same as the probability of finding an electron in the conduction band of silicon at 25°C?
- 30.3 Using appropriate sketches, compare the ion arrangements in the electrical conductor TiO shown in Figure 30.5 to those in the electrical insulator MgO.
- 30.4 In glasses containing alkali metal oxides such as Na₂O, the current is carried almost entirely by the alkali metal ion. (a) What is the transference number for alkali metal ions in this case? (b) Sketch the potential energy barrier for ion transport (i.e., redraw Figure 30.20 for a glass). (c) Why does your figure look different from Figure 30.20?
- 30.5 Calculate the probability of an electron being in the conduction band of MgO at a temperature of 2,000°C.
- 30.6 The Hope diamond exhibited at the Smithsonian Institution in Washington, DC is a striking blue. Would you expect this stone to be electrically conducting? Explain how you arrived at your answer. Make sure to mention any assumptions you make.
- 30.7 What is the high-temperature superconductor (HTSC) that currently has the highest T_c ? Are there any practical problems related to the use of this material?
- 30.8 In ZrO₂ (fluorite structure), ion conduction is the result of anion motion. (a) In Li₂O (antifluorite structure), would you consider the anions or cations to be more mobile? (b) How might you increase ion conductivity in Li₂O? In both cases explain how you arrived at your answer. (c) Now repeat (a) and (b) for MgO.
- 30.9 GaN is a wide-band-gap semiconductor. (a) What is E_g for GaN? (b) Describe some possible applications for GaN.
- 30.10 Dislocations have been shown to decrease the mobility of electrons in a semiconductor. Using the illustration of a dislocation in Figure 12.11, explain why you think they have a detrimental effect on μ .
- 30.11 Explore the literature to find evidence for the existence of the small polaron and the large version. List some of the materials you find, the size of the polaron, and how it is detected.
- 30.12 Have TiO and VO actually been prepared and measured? How is the charge on the cation measured in these oxides?
- 30.13 We note that ceramics are used as electrodes in fuel cells, humidity sensors, and displays. By exploring the library or otherwise, find examples of each and discuss why/how each one works.
- 30.14 Indium tin oxide (ITO) changed many people's idea of a ceramic material. How was this composition deduced, why does it "work," and what is the structure of commercial ITO films?
- 30.15 We note that the entire electronics industry is built around doped Si. Why not doped Ge, especially when the first transistor used Ge, not Si.
- 30.16 There is a condition preceding equation 30.52. What do you think is different when the oxide layer is thinner than 100 nm. (Explain your reasoning and quote references if you look them up).
- 30.17 As devices decrease in size, silicon oxide is not a good enough dielectric, so other materials (e.g., strontium barium titanate, hafnium oxide) are considered. Summarize the current status of these oxide applications.
- 30.18 A philosophy question: Discuss what it means when we say superconductivity has been observed in all classes of materials.
- 30.19 Using the literature, expand on the statement "Chevrel Phases" and explain why we might be interested in these materials.
- 30.20 More difficult: Figure 30.29 refers to a lattice distortion leading to the formation of Cooper pairs. What are Cooper pairs, and how do they relate to this figure.

Locally Redistributing Charge

CHAPTER PREVIEW

In this chapter, we describe ceramic dielectrics. A dielectric is by definition an electrical insulator (ρ is high, E_g is large). That means that dielectric behavior is a property associated with certain ceramics and polymers but not a property associated with metals. We begin with a background section. You may have covered some of this material before but perhaps not thinking specifically of ceramics.

Dielectrics in the context of this chapter are more than just passive insulators. For example, in BaTiO_3 and related perovskites, structural changes create permanent electric dipoles that cause the material to become polarized. Polarization allows, among other things, the material to store large amounts of charge: a prerequisite for a capacitor. Without dielectrics, computers can't function; some of today's biggest challenges for the electronics industry concern dielectrics more so than the semiconductor.

The key topics in this chapter are:

- Dielectrics are polarizable: the separated charges cause an electric field that we characterize by the dielectric constant.
- Dielectrics can be self-polarizing: this is the ferroelectric effect. These ceramics are used in capacitors because of their high dielectric constant.
- The dimensions of a dielectric may change when it is polarized: this is the piezoelectric effect and is used in micro-electro-mechanical systems (MEMS), sonar, and medical ultrasound imaging.
- The spontaneous polarization of a dielectric depends strongly on temperature; this is the pyroelectric effect that we use for infrared (IR) detection (e.g., intruder alarms, thermal imaging).

31.1 BACKGROUND ON DIELECTRICS

All materials contain electrically charged particles. At a minimum, these are the electrons and protons that are part of the constituent atoms. Many ceramics also contain ions, which are charged. In a dielectric, charges have limited mobility, and they move only when they have enough energy to overcome their inertia. When an insulator receives a charge, it retains that charge, confining it within the localized region in which it was introduced. On the other hand, a conductor allows charge to flow freely and redistribute itself within the material. The distinction between conductors and nonconductors (and it's not always a clear one) arises from the relative mobility of charge within the material.

The terms “dielectric,” “nonconductor,” and “insulator” are often used interchangeably, although we often specify dielectrics as materials that are not only electrically insulating but also have a high dielectric constant, κ .

Table 31.1 lists the important parameters we meet in this chapter and their units.

31.1.1 Polarization Mechanisms

Even though no charge is transferred when a dielectric is placed in an electric field there is a redistribution of charge, which occurs by the formation and movement of electric dipoles. There is an associated dipole moment, μ , having both magnitude and direction:

$$\mu = qd \quad (31.1)$$

where d is the separation of the positive and negative ends of the dipole. The dipole direction is, by convention, taken to point from the negative end to the positive end.

When a dielectric material is placed in an electric field, the induced dipoles and any permanent dipoles become

TABLE 31.1 Terms and Units Used to Describe Dielectric Behavior

Parameter	Definition	Units/value	Conversion factor
C	Capacitance	F, farads	$1 \text{ F} = 1 \text{ C/V} = 1 \text{ A}^2 \text{ s}^4 \text{ kg}^{-1} \text{ m}^{-2}$

ξ	Electric field strength	V/m	
C	Curie constant	K	

aligned. The material is now polarized, and the polarization (or dipole moment per unit volume) is given by:

$$P = Nqd \quad (31.2)$$

where N is the number of dipoles.

There are four possible polarization mechanisms in a dielectric.

- Electronic
- Ionic
- Dipolar (also called molecular or orientation)
- Interfacial (also called space charge)

These mechanisms are each illustrated in Figure 31.1.

31.1.1.1 Electronic

When an electric field is applied to an atom, there is displacement of the electrons relative to the nucleus. The electrons concentrate on the side of the nucleus near the positive end of the field. The atom acts as a temporarily induced dipole. This effect occurs in all materials (because all materials contain atoms), but the magnitude is small because d is very small. Typical displacements are ~ 1 am, giving $\mu \sim 1.6 \times 10^{-37}$ C.m. Electronic polarization is the only possible mechanism in pure materials that are covalently bonded and do not contain permanent dipoles (e.g., diamond, silicon).

31.1.1.2 Ionic

Ionic polarization, which occurs when an ionically bonded material is placed in an electric field, is common in many ceramics (e.g., MgO, Al₂O₃, NaCl). The bonds between the ions are elastically deformed. Consequently, the charge

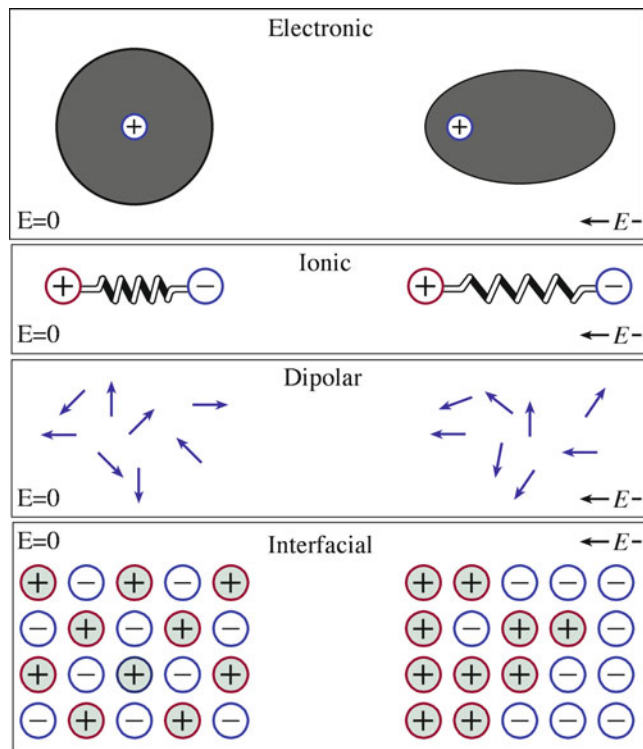

FIGURE 31.1. Different polarization mechanisms in a solid.

is minutely redistributed. Depending on the direction of the field, the cations and anions move either closer together or farther apart. These temporarily induced dipoles cause polarization and may also change the overall dimensions of the material. The dipole moment is usually small because, once again, the displacements involved are very small. Typically, the ion displacements are only 10–100 am.

31.1.1.3 Dipolar

Dipolar polarization is generally uncommon in ceramics because most of the permanent dipoles cannot be reoriented without destroying the crystal structure. However, there are some very important exceptions, and it is these materials that form a large part of this chapter. The prototypical example is barium titanate, whose structure is shown in Figure 7.2. At room temperature, the octahedrally coordinated Ti^{4+} ion is displaced slightly from its ideal symmetric position, causing the crystal structure to become tetragonal and permanently polarized. When an alternating electric field is applied to a crystal of barium titanate, the Ti^{4+} ion moves back and forth between its two allowable positions to ensure that the polarization is aligned with the field.

31.1.1.4 Interfacial

A charge may develop at interfaces (e.g., grain or phase boundaries and free surfaces) normally as a result of the presence of impurities. The charge moves on the surface when the material is placed in an electric field. This type of polarization is not well understood, although it has considerable practical interest because most real materials and, in particular, many ceramics are not pure.

The total P for the material is then the sum of all the individual contributions:

$$P = P_{\text{electronic}} + P_{\text{ionic}} + P_{\text{dipolar}} + P_{\text{interfacial}} \quad (31.3)$$

31.1.2 Relating P and κ

The dielectric constant is an important materials property. It is a measure of the ability of an insulating material to store charge when subjected to an electric field. As you might expect, it is directly related to P .

POLARIZATION MECHANISMS

A note: In some texts you'll find that the polarization mechanism occurring in BaTiO_3 is described as dipolar in others as ionic. We prefer the former because BaTiO_3 contains permanent dipoles (a condition of dipolar polarization) that are being oriented in an electric field. Although the permanent dipoles in BaTiO_3 are the result of ion displacements, the term ionic polarization refers to the movement of any ions in an electric field (whether the material has a permanent dipole or not).

We can develop an equation relating P and κ by beginning with a simple parallel plate capacitor. From electromagnetic theory we know that the total charge per unit area of capacitor plate, D_0 , is proportional to the applied electric field ξ . The constant of proportionality is ϵ_0 .

$$D_0 = Q/A = \epsilon_0 \xi \quad (31.4)$$

If we now place a dielectric between the parallel plates we write:

$$D = \epsilon \xi \quad (31.5)$$

where D is also known as the dielectric displacement and represents the extra charge that can be stored because of the presence of the dielectric. Therefore, we can rewrite equation 31.5 as:

$$D = \epsilon_0 \xi + P \quad (31.6)$$

By substituting equation 31.5 into equation 31.6, we obtain:

$$\epsilon \xi = \epsilon_0 \xi + P \quad (31.7)$$

By simple rearrangement we can write:

$$P = (\kappa - 1)\epsilon_0 \xi = \chi \epsilon_0 \xi \quad (31.8)$$

χ is a measure of the ratio of the bound charge/free charge (i.e., P/Q). For dielectrics that polarize easily, κ is large; and, in turn, a large quantity of charge can be stored.

Table 31.2 lists κ for a range of materials. Many ceramics and glasses have κ in the range of 4–10. Polarization is electronic only in covalent ceramics (e.g., diamond) and is a combination of electronic and ionic in

TABLE 31.2 Dielectric Constants of Various Ceramics

Material	κ at 1 MHz	Material	κ at 1 MHz
Diamond	5.5–6.6	Al_2O_3	8.8
SiO_2	3.7–3.8	MgO	9.6
NaCl	5.9	BaTiO_3	3,000
Mica	5.4–8.7	Pyrex glass	4.0–6.0
Soda-lime glass	7.0–7.6	TiO_2	14–110

High-lead glass	19	Vycor glass	3.9

materials such as MgO. Some ceramics, in particular BaTiO₃ and other titanates and zirconates, have very large κ due to their permanent dipole moments.

31.1.3 Frequency Dependence of Polarization

When a dielectric is placed in an alternating electric field, the dipoles attempt to maintain alignment with the field. This process requires a finite time, which is different for each polarization mechanism. At the relaxation frequency, the dipoles are only just able to reorient themselves in time with the applied field. At this frequency, the dielectric is “lossy,” and energy is lost in the form of heat. The dielectric loss is maximum when the frequency of the external field coincides with the relaxation frequency of a given polarization mechanism. This is the principle behind the microwave oven. We operate at the relaxation frequency of water molecules, and the heat generated warms the food.

At frequencies above the relaxation frequency, the dipoles are no longer able to keep up with changes in the applied field. The contributing polarization mechanism becomes effectively “frozen” and no longer contributes. Figure 31.2 shows the variation of polarization with frequency for a hypothetical material that exhibits all of the four polarization mechanisms.

FIGURE 31.2. Frequency dependence of polarization.

REAL AND IMAGINARY COMPONENTS OF ϵ

The permittivity under an alternating field can be represented mathematically as the sum of real (ϵ') and imaginary (ϵ'') parts

$$\epsilon = \epsilon' - j\epsilon'' \quad (\text{B1})$$

In an alternating electric field the phase angle of the electric flux density lags behind that of the electric field due to the finite speed of polarization. The delay angle δ is

$$\tan \delta = \epsilon''/\epsilon' \quad (\text{B2})$$

The electric power loss per unit time (also called the dielectric loss) is proportional to $\tan \delta$. Typical values are given in Table 31.3.

- At optical frequencies, only electronic polarization is operative.
- Dipolar and ionic contributions are small at high frequencies because of the inertia of the molecules and ions. The peaks occurring at $\sim 10^{13}$ and $\sim 10^{15}$ Hz are due to resonance effects, where the external field is alternating at the natural vibrational frequency of the bound ions or electrons, respectively.

31.1.4 Dielectric Strength

A dielectric is able to withstand a certain applied electric field strength before it breaks down and current flows. High dielectric strengths are important in applications where the thickness of the material is small (e.g., in capacitors). Values of dielectric strength for several ceramics are given in Table 31.4. Note the very high value of mica—one of the reasons it was used in early ceramic disk capacitors.

31.1.5 Nonlinear Dielectrics

Nonlinear dielectrics have permanent dipoles that interact to give polarization in the absence of an applied electric field. These materials are the ferroelectrics. The topic

shares many similarities with ferromagnetism, described in Chapter 33. For example, above a critical temperature, the Curie temperature θ_c , the spontaneous polarization is destroyed by thermal disorder. A plot of P versus ξ is shown in Figure 31.3 and demonstrates hysteresis. This behavior is similar to that produced by a ferromagnet when it is cycled through an alternating magnetic field. The description is based on the domain structure of ferroelectrics.

When the dipoles in a crystal are randomly oriented, there is no net P . When a field is applied, the dipoles begin to line up with the electric field. The total dipole moment changes either by the movement of the walls between domains or by the nucleation of new domains. Eventually,

the field aligns all of the dipoles, and P_s is obtained. When all the dipoles are aligned in the same direction, the material is “poled.”

When the field is subsequently removed, a remnant polarization P_r exists due to the coupling between adjacent dipoles. The material is permanently polarized in the absence of an electric field. This property is key to ferroelectricity.

When the direction of ξ is reversed, the dipole orientation switches to become aligned with the new field direction. As the strength of the reverse field is increased, P_s eventually occurs with the opposite polarization. As the field alternates, a hysteresis loop is produced. The area contained within the loop is related to the energy required to cause the polarization to switch directions. Linear dielectrics (which is most of them) do not show significant hysteresis in an alternating electric field.

There is a structural requirement for ferroelectricity. There are a total of 32 different symmetry point groups, 21 of which do not possess a center of symmetry. Ferroelectrics are part of a small subgroup of noncentrosymmetric crystals. Related properties are piezoelectricity and pyroelectricity. Dielectrics belonging to all but one of the groups of noncentrosymmetric crystals are piezoelectric. Pyroelectric crystals form another subgroup of 10 types of crystal having especially low symmetry, as shown in Table 31.5.

- All ferroelectrics are pyroelectric and piezoelectric.
- All pyroelectrics are piezoelectric.
- All piezoelectrics are not pyroelectric.
- All pyroelectrics are not ferroelectrics.

31.2 FERROELECTRICITY

Ferroelectrics exhibit an electric dipole moment in the absence of an external electric field. The direction of the dipole moment may be switched by application of an alternating field. This property of polarization reversal and remanence cannot be predicted simply by looking at the structure of a material; it must be determined experimentally.

Ferroelectricity is a property that is not only associated with ceramics, certain polymers, such as polyvinylidene fluoride (PVDF), and copolymers between PVDF and trifluoroethylene are ferroelectric. PVDF is a semicrystalline polymer. The crystalline conformation has an orthorhombic unit cell (mm2).

A ferroelectric crystal consists of regions called domains. Within each domain the polarization is in a common direction, but in adjacent domains the polarization is in a different direction, as illustrated in Figure 31.4. The net polarization then depends on the difference in the volumes of the two domain orientations. If the volumes are equal, the material does not exhibit a net polarization. By etching in a suitable chemical, we can see the domain structure. This is analogous to the process we described in Section 12.3 to reveal dislocations.

Domain walls separate adjacent domains and are transition regions where the direction of polarization changes. They have a width on the order of one lattice parameter (~0.2–0.3 nm), but this varies with temperature and crystal purity. This is less than one hundredth as thick as the Bloch walls between magnetic domains in ferromagnets (see Chapter 33). Figure 31.5 illustrates a domain wall in a ferroelectric. There are actually two types.

- 90° wall — polarization vectors in adjacent domains at right angles
- 180° wall — polarization vectors in adjacent domains are antiparallel

The wall energy is of the order of 10 mJ/m². You can compare this value to typical grain boundary (GB) energies that are 0.1–0.3 mJ/m² for low-angle boundaries, 0.5–0.6 J/m² for high-angle tilt boundaries, and 0.8–0.9 J/m² for high-angle twist boundaries. As a consequence, it is, in general, easier to move domain boundaries than it is to move GBs.

Ferroelectricity depends on temperature. Above θ_c , ferroelectric behavior is lost, and the material becomes paraelectric. The change from the ferroelectric to the nonferroelectric state is accompanied either by a change in crystal symmetry (e.g., as in BaTiO₃) or by an order–disorder transition, such as in the organic ferroelectric compound triglycine sulfate (TGS).

The relative permittivity shows a characteristic peak at T_{cw} , as shown in Figure 31.6, and falls off at higher temperatures following the Curie-Weiss law.

$$\epsilon_r - 1 = \chi = C / (T - T_{cw}) \quad (31.9)$$

Curie constants and Curie temperatures for several ferroelectric ceramics are given in Table 31.6.

- For ferroelectrics that undergo a first-order transition [e.g., BaTiO₃, (Ba,Sr)TiO₃, PbTiO₃, KNbO₃], $T_{cw} < \theta_c$. A first-order transition involves a discontinuous change in P with T .
- For ferroelectrics that undergo a second-order transition (e.g., TGS, Rochelle salt, dihydrogen phosphate), $T_{cw} \sim \theta_c$. The change in P is continuous for a second-order transition.

FIGURE 31.5. A 180° domain wall. The width is ~0.2–0.3 nm.

31.3 BaTiO₃: THE PROTOTYPICAL FERROELECTRIC

Barium titanate (BaTiO₃) was the first ceramic in which ferroelectric behavior was observed and is probably the most extensively investigated of all ferroelectrics. Its discovery made available κ s up to two orders of magnitude greater than had been known before. This property was very soon utilized in capacitors, and BaTiO₃ remains the basic capacitor dielectric in use today (although not in its pure form). There are several reasons why BaTiO₃ has been so widely studied.

- Relatively simple crystal structure
- Durable
- Ferroelectric at room temperature ($\theta_c = 120^\circ\text{C}$)
- Easily prepared as a polycrystalline ceramic, single crystal, or thin film

31.3.1 Structure and Structural Transformations

Above θ_c , the unit cell of BaTiO₃ is cubic (point group $m\bar{3}m$), with the ions arranged as shown in Figure 7.2.

Recap: Each Ba²⁺ is surrounded by 12 nearest-neighbor oxygen ions; each Ti⁴⁺ has six oxygen ion neighbors. Together, the Ba²⁺ and O²⁻ ions form a face-centered cubic (fcc) arrangement, with Ti⁴⁺ fitting into the

octahedral interstices. The octahedral site is actually expanded because of the large Ba²⁺ ions ($r_{\text{Ba}^{2+}} = 0.136 \text{ nm}$). The Ti⁴⁺ ion is quite small ($r_{\text{Ti}^{4+}} = 0.064 \text{ nm}$), giving a radius ratio with oxygen ($r_{\text{Ti}^{4+}}/r_{\text{O}^{2-}}$) of 0.44. This value is close to the limiting value (≥ 0.414) for a coordination number of 6. The result is that the Ti⁴⁺ often finds itself off-centered within its coordination octahedron. This is why it is sometimes referred to as the “rattling” titanium ion (think back to Pauling’s rules). The direction of off-centering may be along one of the 6 $\langle 001 \rangle$ directions or along one of the 8 $\langle 111 \rangle$ directions or 12 $\langle 110 \rangle$ directions.

At temperatures $>\theta_c$, the Ti⁴⁺ has no fixed unsymmetrical position, and hence there is no permanent dipole moment. The crystal is paraelectric; it can be polarized only while in an applied electric field.

On cooling BaTiO₃ below θ_c , the structure spontaneously changes to the tetragonal form (point group $4mm$) with a dipole moment along the c axis, as shown in Figure 31.7. The magnitude and direction of the ion displacements accompanying this transformation are given in the figure.

FIGURE 31.6. Relative permittivity of a ferroelectric as a function of temperature.

FIGURE 31.7. [100] Projection of BaTiO₃ shows ion displacements below θ_c (not to scale).

TABLE 31.6 Curie Temperatures and Curie Constants for Several Ferroelectric Ceramics

Ceramic	Structure	θ_c (K)	C (10^4 K)	Oxide	Structure	θ_c (K)	C (10^4 K)

KNbO ₃	Perovskite	712	27.0				

FIGURE 31.8. BaTiO₃ polymorphs show the direction of polarization.

FIGURE 31.9. Experimental measurements of lattice parameters of BaTiO₃ as a function of temperature. (Note the change in volume at each transition and the hysteresis in the lattice parameters).

There are other structural transformations that occur in BaTiO₃, as shown in Figure 31.8.

- Below 0°C, the unit cell is orthorhombic, with the polar axis parallel to a face diagonal. Application of an electric field along [011] causes the domains to adopt this direction of Ti⁴⁺ off-centering.
- Below -90°C, the structure is rhombohedral, with the polar axis along a body diagonal. The Ti⁴⁺ is off-centered along [111].

Because these transformations both occur below room temperature, they are not commercially important.

The phase changes that occur in BaTiO₃ are characterized by an expansion of the original cubic lattice in the direction of spontaneous polarization and a contraction in the perpendicular direction. The temperature dependence of the lattice parameters of BaTiO₃ in the four phases is shown in Figure 31.9.

CALCULATION OF THE DIPOLE MOMENT FOR BaTiO₃

Using equation 33.1 we need to consider the distances that the Ti⁴⁺ and O²⁻ ions are displaced from their regular (cubic) lattice positions (assuming the position of the Ba²⁺ ions is fixed). The charge is the product of q and the ion charge. The dipole moments are then

$$\begin{aligned} \mu(\text{Ti}^{4+}) &: (1.602 \times 10^{-19}\text{C})(4)(0.06 \times 10^{-8}\text{cm}) \\ &= 3.84 \times 10^{-28}\text{C}\cdot\text{cm} \end{aligned}$$

$$\begin{aligned} \mu(\text{O}^{2-}\text{-top}) &: (1.602 \times 10^{-19}\text{C})(2)(0.09 \times 10^{-8}\text{cm}) \\ &= 2.88 \times 10^{-28}\text{C}\cdot\text{cm} \end{aligned}$$

$$\begin{aligned} \mu(\text{O}^{2-}\text{-side}) &: (1.602 \times 10^{-19}\text{C})(2)(0.06 \times 10^{-8}\text{cm}) \\ &= 1.92 \times 10^{-28}\text{C}\cdot\text{cm} \end{aligned}$$

Now we need to include the number of each of the types of ions per cell. There is a single Ti⁴⁺/cell, there is one top-face O²⁻/cell, and two side-face O²⁻/cell.

The total dipole moment per unit cell is

$$\begin{aligned} \mu &= \mu(\text{Ti}^{4+}) + \mu(\text{O}^{2-}\text{-top}) + 2\mu(\text{O}^{2-}\text{-side}) \\ &= 1.056 \times 10^{-27}\text{C}\cdot\text{cm} \end{aligned}$$

31.3.2 Properties of BaTiO₃

Barium titanate is ferroelectric and, by implication, also pyroelectric and piezoelectric. The characteristic of a ferroelectric is that it is polarized in the absence of an applied electric field, and the direction of polarization can be

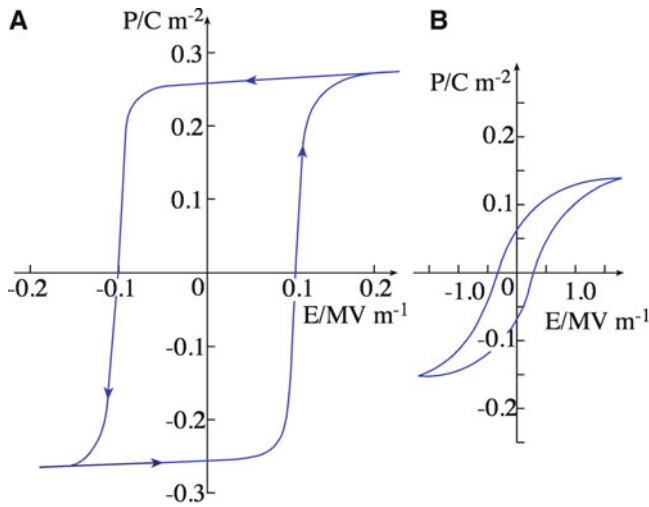

FIGURE 31.10. Hysteresis loops for BaTiO₃. (A) Single-domain single crystal. (B) Polycrystalline ceramic.

FIGURE 31.11. Growth of a ferroelectric domain in a field, ξ .

reversed. Figure 31.10 shows a rectangular hysteresis loop for a single-domain single crystal of BaTiO₃. This loop was obtained at room temperature using a 50-Hz supply. E_c is 0.1 MV/m, and P_s is 0.27 C/m².

In tracing out the hysteresis loop, both 180° and 90° changes in domain orientation take place. The almost vertical portions of the loop are due to reversal of the spontaneous polarization as antiparallel 180° domains nucleate and grow, as illustrated in Figure 31.11. This process corresponds to the Ti⁴⁺ moving from one of its off-center sites along the c axis to the other site. There is a potential barrier to this movement, as indicated by Figure 31.12.

The motion of domain walls in ferroelectrics is not simple. In an electric field, a 180° wall in BaTiO₃ appears to move by the repeated nucleation of steps by thermal fluctuations along the parent wall. Domains misoriented by 180° tend to switch more easily than 90° domain walls because no net physical deformation is required; domains misoriented by 90° are inhibited from changing orientation by the strain that accommodates switching c - and a -axes.

The almost horizontal portions of the hysteresis loop represent saturated states, in which the crystal is single domain during a cycle. Defects and internal strains within the crystallites impede the movement of domain walls. Domain wall mobility has been found to decrease with

FIGURE 31.12. Potential energy wells for Ti⁴⁺ as a function of displacement within the octahedral site.

FIGURE 31.13. Hysteresis loops for BaTiO₃ as a function of temperature.

time (even without applied mechanical or electrical stress or thermal changes). This is due to internal fields associated with charged defects, redistribution of lattice strains, and accumulation of defects at domain walls.

The hysteresis loop of a polycrystalline BaTiO₃ ceramic has a higher E_c and lower P_r than the single crystal.

The size of the hysteresis loop also depends on temperature, as shown in Figure 31.13. At low temperatures, the loops are fatter and E_c is greater, corresponding to a larger energy required to domain reorientation. At higher temperatures, E_c decreases until at θ_c no hysteresis remains and the material becomes paraelectric.

Figure 31.14 shows the temperature dependence of the dielectric constant of single-crystal BaTiO₃. The high value of κ appears over a very short temperature range, close to θ_c and far from room temperature. For this reason, pure BaTiO₃ is not particularly useful as a dielectric. Ideally, κ must be:

- High at room temperature
- Stable over as wide a temperature range as possible

There are several approaches that can be used to increase lower θ_c and increase κ at room temperature.

- Form a solid solution with an isostructural compound (see Section 31.4)
- Reduce the grain size, as shown in Figure 31.15

FIGURE 31.14. (A) Dielectric constant and (B) spontaneous polarization of single-crystal BaTiO₃ as a function of temperature. (Compare to Figure 31.9).

FIGURE 31.15. Effect of grain size on the dielectric constant of BaTiO₃.

- Induce mechanical stresses (compressive or tensile) in thin films because of differences in lattice parameter between the film and the substrate (e.g., θ_c for BaTiO₃ thin films on MgO and on Pt are lower than for bulk material).

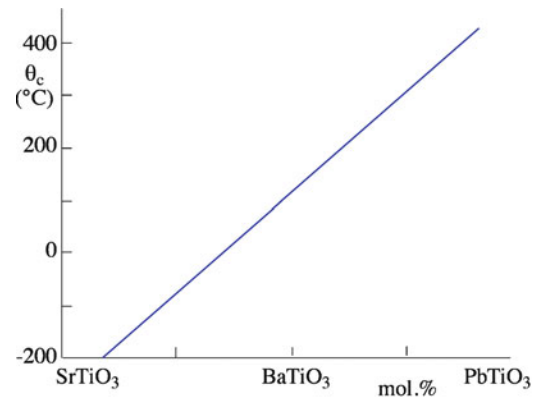

FIGURE 31.16. Effect of substitution on θ_c for BaTiO₃ solid solutions with SrTiO₃ and PbTiO₃.

TABLE 31.7 Some Other Ferroelectric Ceramics

Compound	θ_c (°C)
SrTiO ₃	-245
PbTiO ₃	490
KNbO ₃	435
KTaO ₃	-260
Cd ₂ Nb ₂ O ₇	-85
PbNb ₂ O ₆	570
LiNbO ₃	1,200

31.4 SOLID SOLUTIONS WITH BaTiO₃

BaTiO₃ is rarely used in its pure form because, as we mentioned in the previous section, the high κ occurs only over a very short temperature range that is far from room temperature. Solid solutions with an isostructural compound can broaden θ_c as well as shift it to lower temperatures. One important solid solution phase is that formed between BaTiO₃ and SrTiO₃. These solid solutions are often referred to as BST. Solid solutions of BaTiO₃ and PbTiO₃ lead to an increase in θ_c over that of pure BaTiO₃. The effect on substitution of either Sr²⁺ or Pb²⁺ for Ba²⁺ in BaTiO₃ is shown in Figure 31.16.

31.5 OTHER FERROELECTRIC CERAMICS

Table 31.7 lists some other ferroelectric ceramics. This table does not include the large number of solid solution phases that are ferroelectric. Many ferroelectric ceramics have the perovskite structure above θ_c , but this is not a prerequisite. For example, LiNbO₃ has the ilmenite (FeTiO₃) structure, and Cd₂Nb₂O₇ has the pyrochlore structure (the mineral pyrochlore is CaNaNb₂O₆F).

31.6 RELAXOR DIELECTRICS

BaTiO₃ and most related compositions show little change in dielectric properties with frequency until the gigahertz range is reached. Relaxor dielectrics are a class of perovskite ferroelectrics that show significant changes in κ and $\tan \delta$ with frequency. The classic high- κ relaxor is lead magnesium niobate (PbMg_{1/3}Nb_{2/3}O₃, or PMN), which was first synthesized in the late 1950s.

In addition to the high κ of many relaxor compositions, they also have a broad peak in permittivity versus temperature, even in the absence of additives and even in the form of single crystals. This behavior is attributed to nanoscale (~10 nm)-ordered regions, which are too small to yield the sharp phase transition of normal ferroelectrics. As a result, spontaneous polarization and associated ferroelectric properties are retained over a very broad temperature range. Another attractive feature of relaxors is that dense polycrystalline ceramics are achievable at relatively low sintering temperatures ($\leq 900^\circ\text{C}$), which allows a significant reduction in the amount of Pd used in Ag-Pd metallizations for electrodes in multilayer capacitors (see Section 31.7).

One of the difficulties with most relaxor compositions containing Pb and Nb is that they have a tendency to form the lower κ pyrochlore-type rather than perovskite structures. The pyrochlore-type phase found in PMN has the composition Pb_{1.83}Nb_{1.71}Mg_{0.29}O_{6.39}. It has a room temperature κ of 130 and is paraelectric.

There are a whole range of lead-containing relaxors based on lead zinc niobate (PZN), lead iron niobate (PFN), lead iron tungstate (PFW), and solid solutions with each other and with BaTiO₃ (BT), PbTiO₃ (PT), and SrTiO₃ (ST). Some of the solid-solution phases are PMN-PT, PMN-PT-PZN, PMN-PZN, PFN-PFW, PFN-PMN, and PFW-PT.

31.7 CERAMIC CAPACITORS

Capacitance is defined as the total charge stored by the capacitor divided by the applied potential.

$$C = Q/V \quad (31.10)$$

It depends on the:

- Dielectric between the conductors
- Area of each conductor, A
- Separation between them, d

For a parallel plate capacitor in a vacuum

$$C = \epsilon_0 A/d \quad (31.11)$$

When a dielectric is present, polarization occurs and permits additional charge to be stored. The ability of the dipoles in the dielectric to polarize and store charge is reflected by ϵ :

$$C = \epsilon A/d \quad (31.12)$$

or in terms of κ :

$$C = \kappa \epsilon_0 A/d \quad (31.13)$$

There are three main types of capacitor.

- Ceramic
- Paper or polymer film
- Electrolytic (aluminum or tantalum)

Frequency ranges where these capacitor types are usable and the capacitance values of each type are shown in Table 31.8. Ceramic capacitors occupy about 30% of the total capacitor market, with sales of over 80 billion discrete units per year.

We can distinguish three basic types of ceramic capacitor.

- Film capacitors used in memory devices
- Single-layer discrete capacitors, usually disk capacitors
- Multilayer chip capacitors (MLCCs)

Each of these types is described separately. Film capacitors that are used in memory devices are integrated with the other circuit components. On the other hand, disk capacitors and MLCCs are discrete components.

31.7.1 Categories of Ceramic Capacitor Dielectric

Ceramic capacitors are generally classified into three types based on their properties.

TABLE 31.8 Frequency and Capacitance Ranges for Capacitor Types

Capacitor	Maximum useable frequency (Hz)	Range of capacitance values (μF)
Mica	10 G	0.1– 10^{-6}
Paper/polymer	10 G	100 – 10^{-6}
Ceramic	10 G	10^3 – 10^{-6}
Al electrolytic	10 k	10^6 –0.1
Ta electrolytic	10 k	10^3 –0.1

Class 1 or *NPO* These have $\kappa < 15$ and are mainly used for electrical insulation, such as substrates, power line insulators, and spark plug insulators. Medium κ class 1 capacitors are used in:

- High-power transmitter capacitors in the frequency range 0.5–50 MHz because of their low $\tan \delta$
- Stable capacitors for general electronic use in the frequency range 1 kHz to 100 MHz because of the stability of capacitance with temperature
- Microwave resonant cavities operating at 0.5–50 GHz because of their stability and low $\tan \delta$

Class 2 These are high dielectric constant ceramics based on BaTiO_3 . The two main subclasses are *Z5U* and *X7R* after the scheme shown in Table 33.5 that was devised by the Electronics Industries Association (EIA) in the United States for specifying the variability of capacitance with temperature in the range of practical interest (Table 31.9). For maximum capacitance, θ_c is shifted close to room temperature and broadened. Shifters form solid solution phases with BaTiO_3 . Depressor additives result in broadening of the peak and then concentrate at the grain boundaries (GBs). Compositions and properties of some *Z5U* and *X7R* dielectrics are shown in Tables 31.10 and 31.11, respectively.

Class 3 These are based on either BaTiO_3 or SrTiO_3 (usually *X7R* type) and have very high “apparent” dielectric constants ($\kappa = 50,000\text{--}100,000$), which are achieved by producing either a surface layer on the grains or at the GBs that is electrically insulating whereas the grains themselves are conducting or semiconducting. This can be achieved in two ways.

- The ceramic is first heated to high temperature (900–1,000°C) under reducing conditions (usually a H_2/N_2 mixture) that makes it semiconducting, and then the surface layer is reoxidized by heating in oxygen at a lower temperature.

TABLE 31.9 EIA Coding of Class 2 Capacitors

Code	Temperature range (°C)	Code	Capacitance change (%)
X7	–55 to +125	D	±3.3
X5	–55 to +85	E	±4.7
Y5	–30 to +85	F	±7.5
Z5	+10 to +85	P	±10
		R	±15
		S	±22
		T	+22 to –33
		U	+22 to –56
		V	+22 to –82

TABLE 31.10 Composition and Properties of Z5U Dielectrics

Component	Composition (wt%)			Role
	1	2	3	
BaTiO_3	84–90	65–80	72–76	Base material
CaZrO_3	8–13	—	—	Shifter
MgZrO_3	0–3	—	—	Depressor
SrTiO_3	—	7–11	5–8	Shifter
CaTiO_3	—	7–11	4–6	Depressor
BaZrO_3	—	7–11	7–10	Shifter
CaSnO_3	—	—	2–4	Shifter
Other oxides (e.g., Nb_2O_5)	1–3	8–13	0–3	Acceptors
κ (25°C, 1 kHz)	5,700–7,000	5,500–6,500	11,500–13,000	
$\tan \delta$	≤0.03	≤0.03	≤0.03	

TABLE 31.11 Composition and Properties of X7R Dielectrics

Component	Composition (wt%)			Role
	1	2	3	
BaTiO_3	90–97	85–92	86–94	Base material
CaZrO_3	2–5	4–8	—	Shifter
BaCO_3	0–5	—	—	Stoichiometry adjuster
SrTiO_3	—	3–6	—	Shifter
Bi_2O_3	—	—	5–10	Depressor, flux
Other	2–5	1–4	2–6	
κ (25°C, 1 kHz)	1,600–2,000	1,800	1,400–1,500	
$\tan \delta$	<0.025	<0.025	<0.015	

- The GBs can be made insulating by diffusing a low-melting-point mixture of metal oxides, such as CuO, MnO, and Bi₂O₃. The very thin (<10 nm) insulating layers and the high GB area produces very high capacitances.

The properties of these dielectrics are similar to those in class 2, but their working voltages are 2–25 V. The big advantage is that simple disk capacitors can be produced with large capacitances, >1 μF.

31.7.2 Disk Capacitors

Figure 31.17 shows an example of a ceramic disk capacitor. Disc diameters range from 2 to 30 mm, and dielectric thicknesses are 50 μm to 2 mm.

These capacitors are common but from a practical standpoint can store only a limited amount of charge. To increase the storage capacity, it would be necessary to increase the overall size or decrease the distance between the plates. The first option would make the component too bulky. The second option would increase the possibility of dielectric breakdown.

The first disk capacitors used mica sheets. Mica has very high dielectric strength (see Table 31.4) and can readily be cleaved into thin sheets. Nowadays, disk capacitors are made from BaTiO₃-based compositions using traditional ceramic processing methods. The powder is mixed with 5–10 vol.% of an organic binder and pressed into a disk. Alternatively, they can be punched from extruded ribbon or tape. The green ceramic is then sintered at 900–1,300°C in air to produce a dense material. After

FIGURE 31.17. Ceramic disc capacitor.

sintering, Ag paint is applied to the major surfaces, and the disks are briefly refired at 600–800°C. Tinned copper wires are soldered to the metallized ceramic disk before the whole assembly is immersed in a polymer (usually an epoxy resin).

Disk capacitors are made using all classes of capacitor dielectric, allowing a wide range of capacitances.

- 0.1–1,000 pF using class I dielectrics
- 1,000–100,000 pF using class II dielectrics
- 0.1–2.0 μF using class III dielectrics

31.7.3 Multilayer Chip Capacitors

The largest class of ceramic capacitors produced, in number and in value, is the MLCC. More than 80 billion “chips” are manufactured worldwide each year.

Figure 31.18 shows several MLCCs and their structures. The external dimensions range from

MLCC ADVANTAGES

- Small
- Inexpensive
- Good frequency response
- Can be surface mount
- High capacitance
- Easy to make

FIGURE 31.18. (A) Ceramic multilayer chip capacitor. (B) Electrode structure.

1.25 × 1.0 × 1.0 mm thick up to 6.0 × 6.0 × 2.25 mm thick. The interelectrode spacing is typically about 20 μm. Capacitance values have been produced from 1 pF up to 300 μF. Class 1 and class 2 dielectrics are mainly used for MLCCs. Increased performance has been obtained using relaxor dielectrics, such as lead iron niobate (PFN) and lead magnesium niobate (PMN).

31.7.4 Fabricating MLCCs

There are several different ways to make MLCCs. The basic steps are:

- Preparing the slurry. The slurry may contain up to 35 vol.% of liquid. Water-based slurries containing a latex binder are often used, although for some powder formulations an organic based slurry is required.
- Tape casting.
- Drying.
- Cutting of dried sheets into typically 15-cm squares.
- Screen printing Ag-Pd electrodes. The cost of the electrode materials is a big concern. In fact, the noble metals account for more than half the cost price of MLCCs. Alternative nonprecious metals such as copper and nickel have been used. A different approach to reducing cost of metallization is the “fugitive” electrode process. The electrodes are made of carbon, which is removed during sintering in air. The remaining cavities are then pressure-infiltrated with either molten lead or a tin-lead alloy to produce the electrodes.
- Stacking the electroded sheets.
- Laminating.
- Dicing.
- Burning out the binder. This step of the process must be very carefully controlled. There is a lot of binder to be removed, and if burnout is too rapid the sheets may delaminate.
- Sintering. Typical sintering temperatures are 1,200–1,400°C in air. If nonprecious metals are used, the furnace atmosphere must be very carefully controlled to avoid oxidation. Atmospheres of N₂ and H₂ + N₂ have been used.
- Application of external electrodes. The ends of the chips can be dipped into an Ag-Pd ink. Pure Ag can be used (which is cheaper), but it must be coated with Ni to increase solder leach resistance and then by Sn to maintain solderability.

31.8 CERAMIC FERROELECTRICS FOR MEMORY APPLICATIONS

An important potential application for ferroelectrics is their incorporation as thin films into dynamic random access memories (DRAMs). The majority of the memory

in a computer is DRAM. Information is stored in millions of tiny capacitors, each representing a single bit. The capacitors used in DRAM chips are fabricated directly onto the silicon substrate.

The dielectrics currently used in DRAMs are:

- SiO₂, which can be produced by thermal oxidation of Si
- A combination of SiO₂ and Si₃N₄, (which is often referred to as “ONO” because the dielectric consists of alternating layers of SiO₂ and Si₃N₄)

The bottom electrode is the doped (often n-type) silicon substrate; the top electrode is either polysilicon or aluminum. The limitation of both SiO₂ and Si₃N₄ is that they have low κ.

The dielectric constant of SiO₂ is 3.9. A 100 nm thick SiO₂ film yields a capacitance of 3.4 × 10⁻¹⁶ F/μm² (31 fF/μm²).

The dielectric constant of Si₃N₄ is 6. A 100-nm Si₃N₄ film yields a capacitance of 53 fF/μm².

To push memory densities beyond 64 Mbits using SiO₂ or ONO dielectrics, it has been necessary to develop very complicated three-dimensional structures such as trench capacitors.

Being able to use a dielectric with a large κ would allow a decrease in the required surface area, avoid stacking and trenching, and allow planar configurations. Such configurations are easier and cheaper to fabricate and provide high production yields.

Thin films of BST have been the most widely studied dielectric for ferroelectric DRAMS. The highest capacitance reported for a BST dielectric is 145 fF/μm², which was achieved with a 20-nm film of a material having κ = 325. Prototype BST capacitor DRAMS were first reported in 1995 but have not been widely used commercially because of the advances in other storage technologies.

31.9 PIEZOELECTRICITY

Piezoelectricity—pronounced P (the letter) A (the letter) zow (like toe)—is a reversible property possessed by a select group of materials that don’t have a center of symmetry. When a dimensional change is imposed on the dielectric, polarization occurs and a voltage or field is created. This is the direct effect. When an electric field is applied to a dielectric, polarization may change its dimensions. This is the inverse effect, also called electrostriction. Dielectric materials that display this reversible behavior are piezoelectric.

The ξ produced by the stress *T* is:

$$\xi = gT \quad (31.14)$$

The strain, S , produced by ξ is:

$$S = d\xi \quad (31.15)$$

where d and g are piezoelectric coefficients related through Young's, \mathcal{E} .

$$\mathcal{E} = 1/gd \quad (31.16)$$

- High d coefficients are desirable for dielectrics that are utilized in motional or vibrational devices, such as sonar and transducers in ultrasonic cleaners.
- High g coefficients are desirable for dielectrics used to produce voltages in response to mechanical stress, such as in gas igniters.

The equations of state that describe a piezoelectric crystal in regard to its electric and elastic properties are, in their general form:

$$\text{Direct effect } D = dT + \epsilon^T \xi \quad (31.17)$$

$$\text{Inverse effect } S = s^\xi T + d\xi \quad (31.18)$$

The only new variable here is s , the material compliance (inverse of stiffness). The superscripts in equations 31.17 and 31.18 denote the parameters that are held constant. For example, s^ξ is the compliance at constant ξ .

When written in matrix form, these equations relate the properties to the crystallographic directions. For ceramics and other crystals, the piezoelectric constants are anisotropic. For this reason, they are expressed in tensor form. The directional properties are defined by the use of subscripts. For example, d_{31} is the piezoelectric strain coefficient where the stress or strain direction is along the 1 axis and the dielectric displacement or electric field direction is along the 3 axis (i.e., the electrodes are perpendicular to the 3 axis). The notation can be understood by looking at Figure 31.19.

Another important parameter of a piezoelectric is the electromechanical coupling coefficient, k , which is a measure of the ability of the material to convert electrical energy to mechanical energy or vice versa.

For the direct effect:

$$k^2 = \frac{\text{mechanical energy converted to electrical energy}}{\text{input mechanical energy}} \quad (31.19)$$

FIGURE 31.19. Notation of axes for piezoelectric ceramic.

For the indirect effect:

$$k^2 = \frac{\text{electrical energy converted to mechanical energy}}{\text{input electrical energy}} \quad (31.20)$$

STRESS AND STRAIN

We use S for the strain and T for the stress (not ϵ and σ , which are more typical) to avoid possible confusion with permittivity that is almost always represented by ϵ

Because the conversion of electrical energy to mechanical energy (or vice versa) is always incomplete, k^2 is always <1 , and so k is also <1 . Values of k in piezoelectric ceramics range

from 0.1 to 0.9, as shown in Table 31.12. Rochelle salt is the classic example of a piezoelectric because k is so large.

TABLE 31.12 Properties of Some Piezoelectric Ceramics

Material	Piezoelectric coefficient (10^{-12} C/N)	Electromechanical coupling factor (k)
Quartz (X cut)	$d_{21} = 2.25$ $d_{33} = 2.3$	0.10
BaTiO ₃	$d_{31} = -75$	0.48
PZT	$d_{33} = 374$	0.67
Lead metaniobate	$d_{33} = 85$	0.42
Lithium niobate	$d_{33} = -1$	
	$d_{15} = 68$	0.40
Rochelle salt (45° X cut)	$d_{14} = 870$	0.78

31.10 LEAD ZIRCONATE-LEAD TITANATE SOLID SOLUTIONS

Solid solutions between lead zirconate (PbZrO_3) and lead titanate (PbTiO_3) are known by the acronym PZT and are the most widely used of all piezoelectric ceramics.

Lead zirconate is orthorhombic at room temperature: $a = 0.588$ nm, $b = 1.176$ nm, and $c = 0.820$ nm. It is antiferroelectric, with $\theta_c = 231^\circ\text{C}$. The dipoles due to the displacement of the Zr^{4+} ion from the center of the octahedral site are in opposite directions in adjacent unit cells so that the net P is zero.

Lead titanate is isomorphous with BaTiO_3 , with $a = 0.390$ nm and $c = 0.415$ nm. It is ferroelectric at room temperature with a $\theta_c = 495^\circ\text{C}$ (the highest known value among perovskite ferroelectrics).

The PZT phase diagram is shown in Figure 31.20. The significant feature of this phase diagram is the morphotropic phase boundary (MPB) at a composition where the PZ:PT ratio is almost 1:1. At an MPB, there is an abrupt change in the structure with the composition at a constant temperature. PZT compositions near the MPB have both high k and high κ , as shown in Figure 31.21. This is where commercial PZT compositions are chosen.

The PZT ceramics often contain dopants (in the range 0.05–5.0 at.%) to modify the properties of the material for specific applications.

Examples

Donors (e.g., replacing Zr^{4+} with Nb^{5+} or replacing Pb^{2+} with La^{3+}). To maintain electroneutrality, the addition of these dopants is usually compensated for by the formation of Pb^{2+} vacancies. Donors enhance domain reorientation, and materials produced with these additives are characterized by rectangular hysteresis loops, low E_c , high P_r , high κ , maximum k , high $\tan \delta$, high elastic compliance, and reduced aging. Typical applications are in areas where high sensitivity is required, such as hydrophones, sounders, and loudspeakers.

Acceptors (e.g., replacing Zr^{4+} with Fe^{3+} , with the concomitant formation of oxygen vacancies). Domain reorientation is limited, and hence acceptor additives lead to poorly developed hysteresis loops, lower κ , low $\tan \delta$, low compliance, and high aging rates. Typical applications are in high-power devices, such as sonar and ultrasonic transducers.

Isovalent (e.g., replacing Pb^{2+} with Ba^{2+} or Sr^{2+} or replacing Zr^{4+} with Sn^{4+}). The substituting ion is of the same valence and approximately the same size as the replaced ion. Solid-solution ranges with these additives are usually quite high and may result in lower θ_c . Hysteresis loops may be poorly developed without additional additives. Other properties include lower $\tan \delta$, low compliance, and higher aging rates. These ceramics are used in high-drive applications such as torpedo guidance.

FIGURE 31.20. Lead zirconate titanate (PZT) phase diagram.

FIGURE 31.21. Dielectric constants and coupling coefficients for PZT compositions near the morphotropic boundary.

The PZT ceramics can be made by normal powder-processing methods. The main difficulty is the high volatility of PbO . To retain as much PbO as possible, sintering may be performed, with the component surrounded by a lead-rich powder such as PZ and enclosed in a lidded crucible. Even with these precautions, there is usually some (typically 2–3%) loss of PbO , which is compensated for by adding additional PbO to the starting batch. A note about safety: lead is toxic, and exposure to lead compounds has a cumulative effect. It is therefore necessary that evaporation is controlled.

31.11 APPLICATIONS FOR PIEZOELECTRIC CERAMICS

Applications for piezoelectric ceramics utilize one of the two piezoelectric effects.

Direct effect – Voltage is produced by means of compressive stress.

Inverse effect – An applied ξ produces small movements. In an alternating field, the piezoelectric vibrates.

31.11.1 Direct Effect

The first commercial piezoelectric BaTiO₃ devices were phonograph pickups marketed by Sonotome Corporation in the mid-1940s. They used a so-called bimorph design, where an electrode layer separated two strips of the piezoelectric material. Bimorphs are no longer used for this application because they don't produce high enough quality sound reproduction, and most people use CDs now.

The direct effect is used in high-voltage spark generation for some gasoline engine ignition systems and manually operated gas lighters. In the latter example, which are widely used to ignite natural gas water heaters and other gas-fired domestic appliances, lever-amplified hand pressure generates the voltage. Two electroded piezoelectric cylinders are placed back to back, and a force applied to the cylinders generates a spark across the electrodes. It is important that the force is applied quickly; otherwise, the voltage generated disappears as the charge leaks away. Typical spark energies are ~3 mJ.

31.11.2 Indirect Effect

Actuators are an important and growing market for piezoelectric ceramics. In applications requiring precise mechanical control, there is a need for a variety of types of actuator. Examples include the positioning of circuit components during the fabrication of integrated and positioning of lenses and mirrors in precise optical equipment. They are also used as positioners for atomic force microscopes and scanning tunneling microscopes.

The natural resonance frequency of a piezoelectric crystal may be used as a frequency standard. Quartz is the material of choice. Quartz crystal resonators provide highly stable crystal-controlled clocks and watches

FIGURE 31.22. Medical ultrasound image using ceramic piezoelectric transducers (scale is in centimeters).

(constant to 1 part in 10⁹) and control fixed frequencies in communications equipment. Other resonant uses include selective wave filters and transducers for sound generation, as in sonar. PZT ceramics also dominate the market for resonators for ultrasonic cleaners and drilling devices.

Piezoelectric transducers are key components in medical ultrasound imaging and are used both as the acoustic source and the detector (pulse-echo technique). The uses for ultrasound are numerous and include examination of a fetus in the mother's womb, as shown in Figure 31.22, and, at high resolution imaging, intravascular structures. PZT is the ceramic of choice for this application mainly

because it has a high κ and is inexpensive compared to some of the other options, such as polymer piezoelectrics.

**MEDICAL ULTRASOUND IMAGING
FREQUENCY RANGES**

Abdominal, obstetrical, and cardiological applications:
2–5 MHz

Pediatric and peripheral vascular applications:
5–7.5 MHz

Small objects (e.g., the eye), intracardiac and intravascular applications:
10–30 MHz

As in other forms of microscopy, a higher frequency (lower λ) gives better resolution;
~50 μm at 30 MHz

31.12 PIEZOELECTRIC MATERIALS FOR MEMS

Micro-electro-mechanical systems are devices capable of sensing and responding to a mechanical or an electrical stimulus. One common MEMS device that is in commercial production is the miniature accelerometer (a device used to control deployment of an automobile airbag). Ferroelectric and piezoelectric ceramics are materials that fit well into the field of MEMS because of their combined and related electrical/mechanical properties. It is not a necessary requirement that the ceramic

FIGURE 31.23. Steps in the production of a micro-electro-mechanical system cantilever. (A) Create trench by etching. (B) Deposit SiO_2 layer by plasma-enhanced chemical vapor deposition. (C) Deposit Si_3N_4 followed by polysilicon. (D) Deposit the piezoelectric film on an electrode/diffusion barrier system. (E) Pattern and etch. (F) Apply metal contacts and sacrificial etch.

is both ferroelectric and piezoelectric, but if it is ferroelectric the polycrystalline material can be used because it can be poled before use. In nonferroelectric piezoelectric materials such as ZnO , it is necessary to use single crystals with a single domain orientation.

The most widely studied ceramics for MEMS applications are the PZTs because of their high κ and high k . Thin films of PZT have been used in the fabrication of a range of different MEMS and can be integrated with silicon IC processing methods. Figure 31.23 illustrates some of the process steps used to fabricate a cantilever beam microsensors, such as an accelerometer. The actual processing sequence requires over 50 individual steps.

The PZT films can be prepared using physical vapor deposition (PVD) methods such as sputtering, chemical vapor deposition (CVD), and solution processing. Vapor deposition provides uniform films with good step coverage and use methods that are standard in microfabrication facilities. However, there is often a problem with obtaining films of the correct stoichiometry because of the high vapor pressure of PbO . Solution techniques such as sol-gel

processing are simple, inexpensive, and give good stoichiometry control, but they result in poor step coverage.

31.13 PYROELECTRICITY

Pyroelectric materials exhibit spontaneous polarization that is a strong function of temperature because the dipole moments vary as the crystal expands or contracts. It was

PYROELECTRICS

LiTaO_3 (single crystal)	$p = 230 \mu\text{Cm}^{-2}\text{K}^{-1}$
$(\text{Sr},\text{Ba})\text{Nb}_2\text{O}_6$ (single crystal)	$p = 550 \mu\text{Cm}^{-2}\text{K}^{-1}$
PZT (polycrystalline)	$p = 380 \mu\text{Cm}^{-2}\text{K}^{-1}$

observed in the mineral tourmaline in the seventeenth century. Pyroelectricity occurs in organic crystals such as triglycine sulfate (TGS), ceramics such as LiTaO_3 , and polymers such as PVDF.

The electric field that develops across a pyroelectric crystal can be extremely large when it is subjected to a small change in temperature, T . A pyroelectric coefficient, p , can be defined as the change in D due to a change in T .

$$p = \frac{\partial D}{\partial T} \quad (31.21)$$

For example, a crystal with a typical pyroelectric coefficient of $10^{-4} \text{ C m}^{-2} \text{ K}^{-1}$ and $\kappa = 50$ develops a field of 2,000 V/cm for a 1 K temperature change.

31.14 APPLICATIONS FOR PYROELECTRIC CERAMICS

Pyroelectric ceramics can be used to detect any radiation that produces a change in the temperature of the crystal but are generally used for IR detection. Because of their extreme sensitivity, a temperature rise of less than one-thousandth of a degree can be detected. This property finds application in devices such as intruder alarms, thermal imaging, and geographical mapping.

MEMS APPLICATIONS USING PIEZOELECTRIC THIN FILMS

- Accelerometers
- Acoustic sensors
- Infrared detectors
- Hot-wire anemometers
- Microvalves
- Micropumps
- Stepper motors

CHAPTER SUMMARY

The uses of dielectrics range from capacitors for storing charge to ultrasound imaging for medical applications. We separate “dielectrics” from “insulators,” which we described in the previous chapter, because dielectrics have permanent electric dipoles. If the resultant polarization is spontaneous, we have ferroelectrics. This field is essentially exclusively ceramics. Although some polymers are ferroelectric, they do not find as wide use as ceramics. Also, metals can't be ferroelectric because the charge is not localized.

The requirement of a permanent dipole moment limits useful dielectrics to a select few crystal structures. Therefore, the topic of crystallography is once again important, but we can't predict ferroelectricity by considering crystal structure alone. The most important of the ferroelectric crystals are perovskites. By now you should be gaining an appreciation for the significance of this crystal structure, and we still have some important magnetic perovskites to describe in Chapter 33.

PEOPLE AND HISTORY

Hankel, Wilhelm Gottlieb (1814–1899) (father of Herman Hankel) proposed the word piezoelectricity in 1881. He taught for 10 years in Halle and then moved to Leipzig in 1849 where he was Professor for 40 years. His thesis was titled “De thermoelectricitate crystallorum”. Pierre and Jacques Curie had discovered piezoelectricity in 1880.

Seignette, Pierre (1660–1719) He was a French pharmacist who first prepared Rochelle salt in c.1675. In the early literature, the phenomenon of ferroelectricity was more often referred to as “Seignette-electricity” or “Rochelle-electricity.”

Valasek, Joseph (1897–1993) discovered ferroelectricity in the 1920s during an investigation of the anomalous dielectric properties of Rochelle salt, $\text{NaKC}_4\text{H}_4\text{O}_6 \cdot 4\text{H}_2\text{O}$. Rochelle salt is named after the town of La Rochelle (France), where it was first prepared. Valasek was on the faculty at the University of Minnesota from 1919 until he retired in 1965.

Von Hippel, Arthur Robert (1898–2003) reported the ferroelectric properties of BaTiO_3 in 1946. Since then, over a hundred pure materials and many more mixed crystal systems that are ferroelectric have been found. He was on the faculty of MIT from 1936 until he retired in 1964. His starting salary was only \$3,500 per year, and he is reported to have sold textbooks to pay for medical bills for his children. The Materials Research Society has named one of its major awards in recognition of von Hippel's contribution to “dielectrics, semiconductors, ferromagnetics, and ferroelectrics.”

EXERCISES

- 31.1 What technique would you use to obtain the data shown in Figure 31.9?
- 31.2 Explain why the hysteresis loops of single crystal and polycrystalline BaTiO_3 shown in Figure 31.10 have different E_c and P_s . Would you expect this behavior?
- 31.3 What would be the appropriate Electronics Industries Association (EIA) code for a capacitor that is required to have a capacitance at room temperature that changes by no more than $\pm 4.7\%$ in the temperature range -55°C to $+125^\circ\text{C}$?
- 31.4 (a) The dielectric strength of lead glass has been measured at two temperatures, 25°C and 200°C . The values obtained are 0.25 MV/cm and 0.05 MV/cm , respectively. Explain why these values are different. (b) A similar study was performed using a 100 nm thick Al_2O_3 film that had been obtained by anodizing Al. The dielectric breakdown was measured to be 16 MV/cm . Why is this value so much higher than that for the polycrystalline Al_2O_3 ceramics listed in Table 31.4?
- 31.5 Describe how you would expect the polarization of the following ceramics to vary as a function of frequency. Start at 1 MHz and go up to visible light frequencies. (a) Diamond. (b) Al_2O_3 . (c) BaTiO_3 . (d) MgO . (e) AlN .
- 31.6 Explain the trend in the hysteresis loops shown in Figure 31.13. Sketch the situation at 150°C .
- 31.7 A parallel plate capacitor is required to store a charge of 50 C at a potential of 5 kV . The separation between the electrodes is 500 m . Determine the plate area if the following dielectrics are used. (a) mica. (b) MgO . (c) BaTiO_3 . (d) Al_2O_3 .
- 31.8 Estimate the polarization of diamond. Diamond has a diamond-cubic structure with $a = 0.357 \text{ nm}$.

- 31.9 Estimate the polarization of MgO. MgO has a rock salt structure with $a = 0.421$ nm.
- 31.10 Write out, using the Kröger–Vink notation, the effect of the donor and acceptor additions described in Section 31.10.
- 31.11 Summarize in your own words the four types of polarization encountered in ceramics.
- 31.12 Memorize the dielectric constants of diamond, NaCl, BaTiO₃, Pyrex, and TiO₂. Give a reason for why you want to remember each of them.
- 31.13 Explain using the concept of a parallel plate capacitor why we want a high dielectric constant to store charge.
- 31.14 Explain what you mean by the dielectric strength of quartz. Why does high-voltage porcelain have a low dielectric strength?
- 31.15 When would you want a high dielectric loss and when would you want it to be low?
- 31.16 What is a ferroelectric, and why are these materials so important today? Give five devices that use them.
- 31.17 Barium titanate is the prototypical ferroelectric. It is not the best ferroelectric, but it is widely used today. Why? Calculate the dipole moment in barium titanate, showing all the equations you use and any assumptions you make.
- 31.18 Why is lithium niobate such an interesting material, and when might you use it? Does it have any drawbacks?
- 31.19 Calculate the capacitance of a 100 nm thick SiO₂ capacitor.
- 31.20 Summarize the pros and cons of PZT. List its uses and why we are urgently seeking replacements for it.

Interacting with and Generating Light

CHAPTER PREVIEW

In this chapter, we examine four key properties of ceramic materials, all of which we can classify as *optical*. (1) Ceramics can be transparent, translucent, or opaque for one particular composition. (2) The color of many ceramics can be changed by small additions: additives, dopants, or point defects. (3) Ceramics can emit light in response to an electric field or illumination by light of another wavelength. (4) Ceramics can reflect and/or refract light. Here, we discuss why these effects are special for ceramics and how we make use of them.

The optical properties of ceramics result in some of their most important applications. In their pure form, most dielectric single crystals and glasses are transparent to visible light. This behavior is very different from that of metals and semiconductors, which unless they are very thin ($<1\ \mu\text{m}$) are opaque. Many ceramics and glasses also show good transparency to infrared radiation. This property has led to the use of glasses for optical fibers for high speed communications.

We can produce polycrystalline ceramics that are highly transparent. The ability to make translucent and transparent polycrystalline ceramics was developed in the 1960s, when it was discovered that small additions of MgO to Al_2O_3 powder could produce a fully dense ceramic by sintering. This product is widely used in streetlights (the golden glow).

If a transparent ceramic or glass is doped (e.g., by addition of transition metals ions), the material becomes colored. We discuss the different types of colors that can be produced in ceramics. The doping of Al_2O_3 with Cr^{3+} produces ruby, which is used as an optical cavity in a solid-state laser. The ruby laser was the first solid-state laser. There are now many more examples of solid-state lasers using colored ceramics and glasses as the optical cavity. We describe how solid-state lasers work and the different wavelengths of radiation that can be produced.

Phosphors produce light as a result of excitation by, for example, electron irradiation. Again, we're using doped ceramics for this application because doping changes the electronic band structure of the ceramic.

32.1 SOME BACKGROUND FOR OPTICAL CERAMICS

32.1.1 Electromagnetic Spectrum: Terminology and Units

Table 32.1 lists some of the major terms, and their units, that we meet in this chapter. It also lists the important physical constants that are needed to describe the optical properties of materials. The electromagnetic spectrum embraces a wide range of wavelengths, from the very short γ rays to the long radio waves.

The portion of the spectrum that the human eye can detect is quite small. To put this in context, the full electromagnetic spectrum is shown in Figure 32.1. Radiation with a single wavelength is referred to as monochromatic; λ and f are related through c .

$$f = \frac{c}{\lambda} \quad (32.1)$$

λ AND COLOR

UV is short λ .
 Blue is 390 nm.
 Green is 550 nm.
 Red is 770 nm.
 IR is long λ .

The frequency never changes regardless of the density of the medium through which the monochromatic light passes; however, the velocity of propagation and λ do

change. For a high-density medium such as glass, the velocity is lower than it would be in a vacuum, and consequently λ is proportionally smaller. (A dense medium has a lower c). The light waves are retarded because of the interaction of the electromagnetic radiation and the electrons of the atoms that make up the material.

TABLE 32.1 Terms and Units Used in Optics

Parameter	Definition	Units/value	Conversion factor
λ	Wavelength	m	$1 \text{ \AA} = 10^{-10} \text{ m}$
f	Frequency	Hz	
v	Velocity	m/s	
n	Refractive index	Dimensionless	
Δn	Birefringence	Dimensionless	
c	Speed of light	$2.998 \times 10^8 \text{ m/s}$	
R	Reflected light	Dimensionless	Ratio given by equation 32.6
T	Transmitted light	Dimensionless	Ratio given by equation 32.2
E_g	Bandgap energy	eV	$1 \text{ eV} = 0.1602 \text{ aJ}$
I	Intensity	cd	
ϵ_0	Permittivity of a vacuum	$8.85 \times 10^{-12} \text{ F/m}$	See also Section 31.1
R_∞	Molar refractivity		Directly proportional to electronic polarizability (see Section 31.1)
N_0	Avogadro's number	$6.022 \times 10^{23} \text{ mol}^{-1}$	
r_c	Linear EO coefficient	m/V	
R	Quadratic EO coefficient	m^2/V^2	
P	Polarization	C/m^2	See also Section 31.1
E_c	Coercive field	V/m	

EO electro-optic.

32.1.2 The Nature of Light

Maxwell's equations describe how an electromagnetic wave originates from an accelerating charge and propagates in free space with a speed of $2.998 \times 10^8 \text{ m/s}$. An electromagnetic wave in the visible part of the spectrum may be emitted when an electron changes its position relative to the rest of an atom, involving a change in dipole moment. Light can also be emitted from a single charge moving at high speed under the influence of a magnetic field: because the charge follows a curved trajectory, it is accelerating and, as a consequence, radiating. (The same principle is used to produce high-energy X-rays at a synchrotron).

An electromagnetic wave in free space comprises an electric field \mathbf{E} and a magnetic induction field \mathbf{B} that lie in mutually perpendicular directions in a plane normal to the wave propagation direction as shown in Figure 32.2. Remember: a dielectric material reacts to electromagnetic radiation because the opposite electrical charges are displaced in opposite directions; this dielectric property is the underlying reason for refraction and absorption in glass.

32.1.3 Absorption and Transmission

The classical description of the absorption of electromagnetic radiation by materials is to say that it occurs by two basic mechanisms.

- *Electronic transitions:* Electrons are excited from the valence band into unfilled energy states in the conduction band.
- *Absorption:* The light excites vibrational and rotational vibrating modes in the dielectric because it is associated with an oscillating electric field.

For a single-phase material, we can express the fraction of light transmitted, T , as:

$$T = I/I_0 = \exp(-\beta x) \quad (32.2)$$

FIGURE 32.1. Electromagnetic spectrum. The visible region has been expanded for clarity. It is actually a very small part of the spectrum.

FIGURE 32.2. Polarization of light.

where I is the transmitted intensity, I_0 is the intensity of the incident light, x is the optical path length (the thickness as seen by the light beam), and β is the absorption coefficient. Equation 32.2 is a mathematical representation of Lambert's law, which simply says that the fraction of light that is transmitted by a material does not depend on the intensity of the incident light. The parameter β varies with λ ; this variation is important because it causes color when light is transmitted. If the absorption is due to a particular dopant ion, then equation 32.2 is modified by setting β equal to ϵC , where C is the concentration of the absorbing ion, and ϵ is the absorption per unit concentration. This is the Beer-Lambert law. In real life, we also have scattering by defects in the bulk or at the surface.

Ultraviolet (UV) absorption corresponds to electronic transitions from the filled valence band to the unfilled conduction band: the larger E_g is, the greater is the range of transparency in the UV spectrum. Infrared (IR) absorption occurs by elastic vibrations.

32.1.4 Refraction

Refraction is the phenomenon that is responsible for making lenses work. The ratio of the velocity of light in a vacuum to that in any other medium is known as the refractive index, n . Expressed mathematically, n is given by the simple equation:

$$n = \frac{c}{c_m} \quad (32.3)$$

where c_m is the velocity of light in the material (the medium). Because c_m is always less than c , values of n are always greater than unity and range from 1.0003 (air) to approximately 3.0 for very dense solids. Clearly, n is not a constant for any ceramic because it depends on c_m ; n is a function of λ . The variation of n with λ produces a dispersion of the light.

$$\text{Dispersion} = dn/d\lambda \quad (32.4)$$

The ability of a substance to refract, or "bend," light waves is sometimes described as refraction. Those crystals having one unique axis (optic axis) along which the index of refraction is different from that along the other orthogonal axes are known as uniaxial birefringent crystals. The magnitude of the difference between the two indices of refraction is referred to as the birefringence, or simply Δn . It is defined as

$$\Delta n = n_e - n_o \quad (32.5)$$

where n_e is the index of refraction of a light wave vibrating in a plane parallel to the optic axis but traveling in a direction perpendicular the optic axis; n_o is the index of refraction of a wave vibrating parallel to either of the other axes and traveling in the direction of the optic axis; o is the ordinary ray; and e is the extraordinary ray.

The value of the birefringence may be positive or negative. Glass can't be birefringent because it's isotropic. Ceramics from all noncubic crystal systems do show birefringence.

Ceramic applications of refraction are numerous: from the glass spheres used in road signs to the sparkle in diamonds. The trilobite eye made use of refraction in calcite (see Section 32.16).

32.1.5 Reflection

The amount of light reflected from a surface of a material in air is determined by the refractive index of the reflecting medium. At normal incidence, the fraction, R , of light reflected (in medium 1) from the interface between two dielectric materials (1 and 2) is given by Fresnel's equation.

$$R = (n_2 - n_1)^2 / (n_2 + n_1)^2 \quad (32.6)$$

For air ($n_1 \sim 1$) and "optical" glass ($n_2 \sim 1.5$), R is $\sim 4\%$, whereas lead-crystal glass ($n_2 \sim 2.1$) gives an R of $\sim 13\%$. Equation 32.6 is very important when we use dielectrics as antireflection coatings (ARCs); then we have to consider two interfaces. The thickness of the films and the nature of the reflecting surface are also important. Ceramic applications of reflection are numerous but are often linked to refraction.

32.2 TRANSPARENCY

Dielectrics generally show good transmission in the visible part of the electromagnetic spectrum, as shown in Figure 32.3. In the UV spectrum, absorption corresponds to electronic transitions from the filled valence band to the unfilled conduction band. Ceramics with large values of E_g

FIGURE 32.3. Comparison of the frequency variation of absorption for metals, semiconductors, and dielectrics. The visible region of the spectrum is shaded.

are transparent to shorter UV wavelengths. In the IR, absorption by elastic vibrations is the result of loss of transparency. This absorption occurs at longer wavelengths for materials that contain large ions held together by weak interatomic forces: large ions and weak bonds lead to low frequencies (i.e., small f , which implies a large λ and thus a long wavelength). Transparency in the microwave and radiofrequency (RF) region is critical for radomes, which house the guidance system on missiles. Ceramics are the only materials that are suitable for this application.

32.3 REFRACTIVE INDEX

Refraction is the bending of a beam of light when it enters a dielectric. The physical reason this occurs is that the velocity of light is different inside the dielectric. We're used to this happening in water or glass, but in crystals the situation can be more complex when the crystals are anisotropic. The classic example is calcite, which is illustrated in Figure 32.4.

The refractive index of several ceramic materials is given in Table 32.2. We've seen that the value of n is a function of λ . It normally decreases as λ increases, and this trend is illustrated for a range of ceramics in Figure 32.5A, B. The reason for this behavior is that colorless solids and glasses have characteristic frequencies in the UV range, where they become opaque. For example, the important characteristic frequencies for glasses occur at $\lambda \approx 100$ nm. The dispersion as a function of λ for several ceramics is shown in Figure 32.6. Dispersion is important in creating "fire" in gemstones (see Chapter 36). Several factors influence n .

- **Ion size.** Materials containing large ions have large values of n because large ions are more easily polarized than small ions. The Lorentz-Lorentz

TABLE 32.2 Refractive Indices of Some Glasses and Crystals

Glass composition	Average refractive index	Birefringence
From orthoclase (KAlSi_3O_8)	1.51	
From albite ($\text{NaAlSi}_3\text{O}_8$)	1.49	
From nepheline syenite	1.50	
Silica glass, SiO_2	1.458	
Vycor glass (96% SiO_2)	1.458	
Soda-lime-silica glass	1.51–1.52	
Borosilicate (Pyrex) glass	1.47

FIGURE 32.4. Birefringence in calcite.

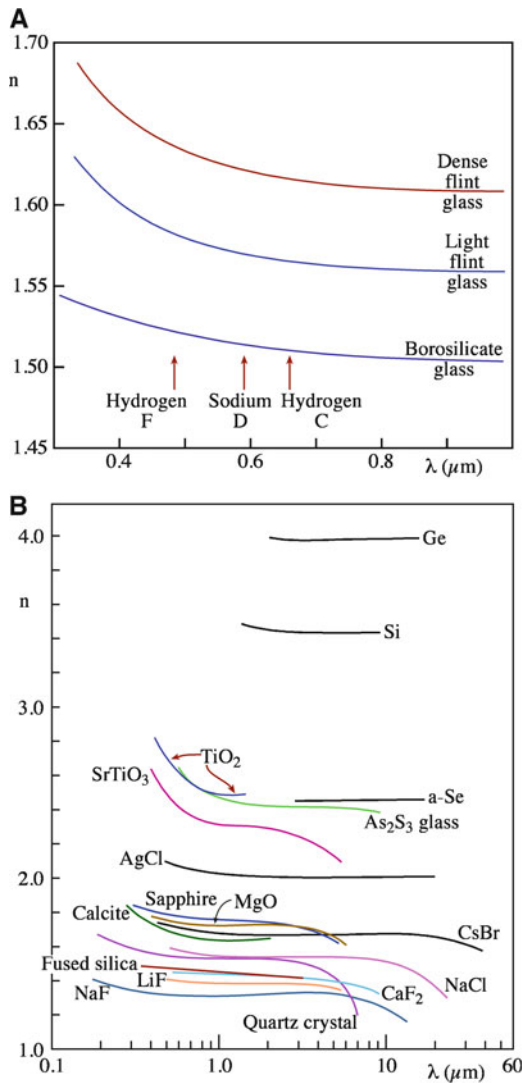

FIGURE 32.5. (A) Change in n with λ for several commercial glasses. (Hydrogen F, Sodium D, and Hydrogen C refer to specific light sources that have $\lambda = 589$, 486, and 656 nm, respectively). (B) Change in n with λ for several ceramics and glasses.

equation quantifies the relationship between polarizability, α , and n

$$\alpha = \frac{3\epsilon_0}{N_0} \frac{n^2 - 1}{n^2 + 2} \frac{M}{\rho} = \frac{3\epsilon_0}{N_0} R_\infty \quad (32.7)$$

where M is molar weight, and ρ is density.

The refractive index of SiO₂ glass can be raised adding GeO₂. This has important implications in the fabrication of optical fibers (see Section 32.11).

- **Structure.** Less-dense polymorphs of a particular material have a more open structure and thus a lower n than their denser counterparts. We can illustrate this with the case of SiO₂, which can exist as a glass or in several crystallographic forms: $n_{\text{glass}} = 1.46$, $n_{\text{tridymite}} = 1.47$, $n_{\text{cristobalite}} = 1.49$, $n_{\text{quartz}} = 1.55$.

FIGURE 32.6. Dispersion as a function of wavelength for a number of ceramics. (Inset) Classic illustration of dispersion: a prism separating white light into its spectral components.

- **Crystallographic direction.** Glasses and crystals with a cubic structure are optically isotropic. In all other crystal systems, n is higher along close-packed directions.
- **Stress.** The application of tensile stress to an isotropic material causes an increase in n normal to the direction of the applied stress and decreases n along the stressed direction. The situation is the exact opposite if a compressive stress is applied. The change of n with applied stress is known as *stress birefringence*.

32.4 REFLECTION FROM CERAMIC SURFACES

Using equation 32.6, we can determine the reflectivity from the surface of various ceramics and glasses. The reflectivity is about 4% from a surface with $n = 1.5$, and about 10% for a surface with $n = 1.9$. A high reflectivity is often important for aesthetic reasons. The high reflectivity, $R = 13\%$, of lead “crystal” glass—glass that contains a high amount of PbO—is due to its high refractive index, $n = 2.1$ (the reflectivity being more than twice that of normal silicate glasses). High reflectivity is important for gemstones, where it affects the brightness and sparkle of the stone. This is partly achieved by the cutting skills of the jeweler but also because gemstones have high values of n . The refractive index of diamond is 2.4.

FIGURE 32.7. Effect of surface roughness on reflectivity.

FIGURE 32.8. How antireflection coating works.

High reflectivity for glazes and enamels is also important and can be achieved by using glass formulations with a high PbO content, although it is important to test the formulation carefully to make sure that high concentrations of Pb don't leach out into food and beverage items. (Hence, there is a protocol for the leach-testing of glazes; see Section 2.5).

The reflectivity of a glaze or enamel is reduced if the surface is rough. Roughness causes considerable diffuse reflection from the surface, as illustrated in Figure 32.7.

- Specular reflection is light reflected at a single angle (conventional reflection).
- Diffuse reflection occurs when light is reflected through a range of different angles.

In some situations we don't want high reflectivity. In fact, we want to minimize the reflectivity as far as possible. One very effective way of reducing the reflectivity of a glass surface is to coat it with an antireflection (AR) coating (giving an ARC). A good ARC can cut the percentage of light reflected from $>5.0\%$ to $<0.2\%$. One example is the purple ARC you see on binocular and camera lenses. If you look in a catalog for optical

equipment, it often says if the lens has an ARC applied. The principle behind how an ARC works is illustrated in Figure 32.8. The coating is applied to the glass surface so its thickness is one-quarter of the wavelength of the incident light. For an ARC optimized for green light ($\lambda = 530 \text{ nm}$), which is in the center of the electromagnetic spectrum (and where the eye is most sensitive), the thickness of the ARC should be about 130 nm ($0.13 \mu\text{m}$). Light reflected from the top surface of the coating is exactly out-of-phase with light reflected from the glass surface, so there is destructive interference and no net reflected beam. Magnesium fluoride (MgF_2) is a widely used ARC material and is usually applied to the glass surface by a physical vapor deposition (PVD) process such as evaporation. A single layer of MgF_2 ($d = \lambda/4$) reduces the reflectance of glass from about 4% to a bit more than 1% over the visible spectrum. Antireflective coatings are also applied to glass for architectural applications to help with radiation control (see Section 26.8).

32.5 COLOR IN CERAMICS

First, a reminder: we discussed colorants in history throughout Chapter 2, F centers in crystals in Section 11.9, and the origins of color in glass in Section 21.8. There is also more on color in Chapter 36.

A LIGAND

Any molecule or ion that is bonded to a metal ion.

Most dielectric ceramics and glasses are colorless because of their large E_g . They become colored when energy states are added within the band gap. These new levels allow electron transitions to occur within the visible part of the electromagnetic spectrum.

The most common way to color a ceramic is by adding transition metals (TMs), particularly Ti, V, Cr, Mn, Fe, Co, and Ni where the 3d is partly filled.

To explain how the addition of a TM to a colorless ceramic makes it colored, we use the ligand field theory. In ceramics, the most common ligand is oxygen, the O^{2-} ion. To understand the behavior of a TM once it is placed in a ligand field, we need to consider the shapes of the d orbitals (see Figure 3.2). There are five of them, and they are designated d_{xy} , d_{xz} , d_{yz} , $d_{x^2-y^2}$, d_{z^2} . In a free ion, all the d orbitals are degenerate (i.e., they have the same energy). However, when the ion is put into a crystal, the energy of the d orbitals is affected by the ligands.

Consider the case of the Ti^{3+} ion, which contains only a single 3d electron. If the Ti^{3+} ion is in an octahedral site (i.e., it is surrounded by six anions arranged at the corners of an octahedron) the energy of the $d_{x^2-y^2}$ and d_{z^2} orbitals is raised relative to the free Ti^{3+} ion because of repulsion from the surrounding anions. The energy of the other three orbitals is lowered, as illustrated in Figure 32.9A.

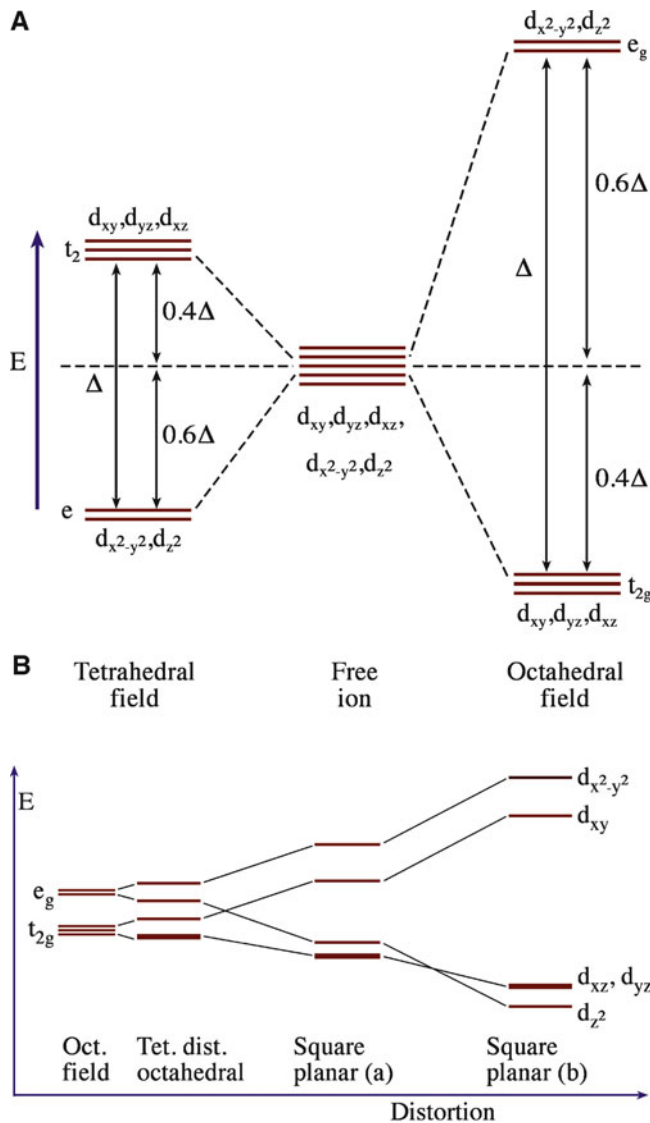

FIGURE 32.9. (A) Splitting of the d orbitals in a ligand field. (B) Splitting of d orbitals in a distorted octahedral ligand field in corundum.

If the Ti^{3+} ion were placed in a tetrahedral site (i.e., it is surrounded by four anions arranged at the corners of a tetrahedron), the energy of the $d_{x^2-y^2}$ and d_{z^2} orbitals is lowered with respect to the d_{xy} , d_{xz} , d_{yz} orbitals. The total splitting for d orbitals is in the range of 1–2 eV, being lower for the case of a tetrahedral ligand field than for an octahedral field. Hence, absorption of light, associated with electronic transitions between the lower and upper d levels, generally occurs in the visible or near-IR regions of the spectrum.

The situation is actually a little more complicated if we consider corundum because the octahedral sites are slightly distorted. This distortion produces further splitting of the energy levels, as illustrated in Figure 32.9B.

We can use a similar argument to show how the addition of rare earth (RE) elements, with incomplete f shells, also causes color. Table 32.3 shows the colors produced by

TABLE 32.3 Optical Absorption of Rare-Earth Ions in Oxide Glasses

Ion	No. of f electrons	Color
Ce^{3+}	1	Green
Pr^{3+}	2	Green
Nd^{3+}	4	Violet
Sm^{2+}	6	Green
Eu^{2+}	7	Brown
Dy^{2+}	10	Brown
Ho^{3+}	10	Yellow
Er^{3+}	11	Pink

the addition of RE ions to oxide glasses. RE ions tend to color glass less strongly than do TM ions, and the spectra usually consist of a large number of weak bands.

Other sources of color in ceramics are:

- Farben (F) centers in alkali halides, which result from heating in alkali vapor. An F center in metal halides consists of a halide ion vacancy that has trapped an electron. This process creates additional energy levels between the valence band and the conduction band. A similar situation is found in MgO heated in Mg vapor: the F center consists of two electrons trapped at an oxygen vacancy. F centers are one example of so-called color centers. There are other types of possible color centers in ionic materials involving electrons and holes (see Section 11.9).
- Defects produced by X-ray or neutron bombardment. Irradiation of colorless quartz crystals with X-rays result in the formation of a dark brownish gray to black color of “smoky quartz.” Coloration is due to the formation of a color center, a hole color center this time. If the smoky quartz is heated to several hundred degrees centigrade, it becomes clear again.
- Defect states produced as a result of nonstoichiometry. This occurs in, for example, TiO_2 and ZrO_2 .

32.6 COLORING GLASS AND GLAZES

To color glass, TM oxides or RE oxides are added to the glass batch. Color is produced through selective light absorption by the TM or RE ion, which is incorporated into the glass structure. The mechanism essentially uses a solution approach to coloring. The color results when the absorbing ion removes light of certain wavelengths, so we see the complementary color in transmission.

Uses for colored glass include not only the obvious stained glass windows and Tiffany lampshades but also the glazes used to seal and decorate cups and pots. Adding Pb to make X-ray-absorbing glass is essentially the same process/motivation: the intent is to absorb the X-rays.

32.7 CERAMIC PIGMENTS AND STAINS

We color ceramics using inorganic pigments and stains that are relatively insoluble in the ceramic they are coloring. They should also be unaffected chemically and physically. This is not same approach as we use for glass.

Table 32.4 shows the types of environment and temperatures that ceramic pigments must withstand. The colorant may be mixed directly with the ceramic body (this is called a body stain). An example is the coloring of house bricks—not all house bricks are the same color. If the stain is used to produce a glaze, then actually we are coloring a glassy phase and coating the ceramic. An example of this approach is the glazing of sanitaryware and tiles (coloring whitewares). There are several classification systems for ceramic pigments. One of the most widely used is that drawn up by the Color Pigments Manufacturers Association (CPMA) formerly the Dry Color Manufacturers Association (DCMA) in the United States. This system provides a structural classification of pigments, as summarized in Table 32.5. A total of 14 classes of pigment and over 50 broad pigment subcategories cover all the principal mixed-metal oxide pigments manufactured today. However, it does not cover the full range of possible pigments. For example, nonoxide compounds, such as the Cd-based pigments, are not included.

In the CPMA classification, one commercially important class of pigment is the zircon pigments. Zircon is zirconium silicate. The first patent for a zircon-based pigment was issued in the 1930s. Zircon pigments fall into two categories.

- Lattice type. The dopant ion substitutes for a Zr^{4+} ion in the zircon lattice [e.g., vanadium blue (V^{4+} substituting for Zr^{4+}) and praseodymium yellow (Pr^{4+} substituting for Zr^{4+})].
- Encapsulated type. Discrete particles of the colorant are trapped inside zircon crystals (e.g., the iron coral pink, where very fine particles of red Fe_2O_3 particles are incorporated in zircon crystals).

A different important class of pigments is the family of cadmium pigments. These are substitutional solid solutions between CdS and CdSe (both end members have the same crystal structure). Cadmium sulfide has a band gap $E_g = 2.6$ eV. This provides absorption of violet and some blue but none of the other colors, leading to a yellow color. CdSe has $E_g = 1.6$ eV and is black. When CdSe is added to CdS, the band gap of the material decreases and the color changes. This process is analogous to what we do in doping the III-Vs used to make light-emitting diodes (LEDs) (see Section 32.12).

The achievable colors range from the yellow of CdS, through orange to bright red and maroon as the percentage of CdSe is increased (Table 32.6). (The red is known as selenium ruby). The red color is particularly significant because, for now, the only other additive that can produce the red color in glass is the metal Au. The stability of the selenide pigment is somewhat limited; it oxidizes at $650^\circ C$ with a resultant loss of color. However, if the pigment is encapsulated in a zircon matrix, it has the properties of zircon and is stable to at least $1,300^\circ C$ and is relatively inert in many environments.

PIGMENTS

Much of the information is covered in the patent literature. Zircon–vanadium blue was one of the most significant innovations in color technology for several decades. Seabright was also responsible for the praseodymium yellow and the zircon-iron coral pink.

TABLE 32.4 Ceramic Environments for Colors

Temp ($^\circ C$)	Environment	Colorant type	Use
700–900	Molten leaded/unleaded borosilicate glass	Enamel or overglaze colors	Tableware, tile decoration
900–1,000	Molten lead/unleaded borosilicate or alkali borosilicate glasses	Low-temperature glaze stains, underglaze colors, colored pellets and granules	Tableware, wall and floor tiles
950–1,200	Siliceous bodies	Body stains, brick surface colorants, colored pellets and granules	Tableware, floor tiles, fancies, bricks
1,100–1,350	Molten alkali/lime glasses	Glaze stains	Tableware, tiles, sanitary ware

TABLE 32.5 CPMA Classification of Mixed-Metal Oxide Inorganic Pigments

Pigment system, CPMA No.	Main components	Color
I. Baddeleyite 1-01-4	Zr-V	Yellow
II. Borate 2-02-1	Co-Mg	Red–blue
III. Corundum-hematite 3-03-5	Cr-Al	Pink
IV. Garnet 4-07-3	Ca-Cr-Si	Green
V. Olivine 5-08-2	Co-Si	Blue
VI. Periclase 6-09-8	Co-Ni	Gray
VII. Phenacite 7-10-2	Co-Zn-Si	Blue
VIII. Phosphate 8-11-1	Co-Ni	Gray
IX. Priderite 9-13-4	Ni-Ba-Ti	Primrose
X. Pyrochlore 10-14-4	Pb-Sb	Yellow
XI. Rutile-cassiterite 11-15-4	Ni-Sb-Ti	Yellow
XII. Sphene 12-25-5	Cr-Sn-Si	Pink
XIII. Spinel 13-26-2	Co-Al	Blue
XIV. Zircon 14-42-2	Zr-Si-V	Blue

TABLE 32.6 Colors in the CdSe-CdS System

CdSe (mol%)	CdS (mol%)	Color
12.6	87.4	Orange
20.0	80.0	Orange-red
36.0	64.0	Light red
43.0	57.0	Dark red
49.0	51.0	Brown
54.5	45.5	Dark brown

A problem, of course, with Cd-containing pigments (like Pb in glass) is the toxicity of Cd. In some countries (e.g., Sweden), the use of Cd is prohibited. There is increasing pressure worldwide to reduce the use of potentially harmful or toxic species such as Cd and Pb; and there is a growing need for developing suitable alternatives. Even if these additives can be managed during processing, it is difficult to control them during recycling; legislation can be aimed at the initial use (to protect the worker) or at recycling (e.g., so that heavy metals no longer enter the water supply).

32.8 TRANSLUCENT CERAMICS

Polycrystalline ceramics are often opaque even though the single crystal may be transparent and E_g is large. We can also make glass that is not clear or is even opaque. The loss of transparency is due to scattering of the incident light, which can have several possible causes as illustrated in Figure 32.10.

FIGURE 32.10. Mechanisms for loss of transparency due to scattering. Details of the individual defects are described in Chapters 12–15.

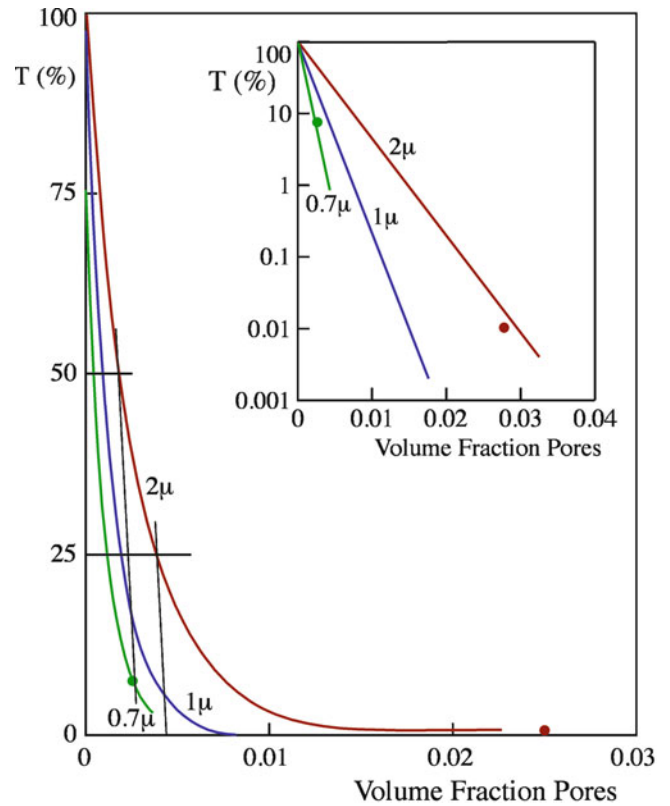

FIGURE 32.11. Effect of porosity on the transparency of polycrystalline alumina.

- *Porosity.* The transmission decreases markedly with small increases in porosity, as shown in Figure 32.11. When the pore size is close to the λ of visible light, the scattering is maximized. This scattering can be engineered by controlling the sintering conditions or by hot pressing. Table 32.7 shows examples of processing conditions, which have been shown to produce translucent ceramics.
- *Differences in n .* In general, light scattering can occur at grain boundaries (GBs) where refractive indices are discontinuous; this possibility is especially easy for noncubic (i.e., anisotropic) structures. A similar situation can occur in multiphase materials, such as ceramics densified by liquid-phase sintering, where there may be an intergranular film (IGF). Matching refractive indices between different phases can reduce scattering losses. This approach is used in making high-quality bone china.
- *Grain size, r .* The effect of grain size on scattering is shown in Figure 32.12. Scattering is maximum when r is close to λ of visible light. For grain sizes smaller than the wavelength of the incident radiation, the scattering increases with r and is proportional to λ^{-4} . Scattering decreases rapidly as r increases; and for large r , it reaches a constant value.

The oldest glass objects in museums are opaque. Frosted glass appears to be opaque because light is scattered at the surface.

TABLE 32.7 Sintering Additives and Conditions of Various Translucent Ceramics

Ceramic	Sintering additive (wt%)	Transmissivity (%)	λ (μm) and specimen thickness (mm)	Sintering conditions
Al_2O_3	MgO (0.25)	40–60	0.3 ~ 2.0 (1.0)	$T = 1,850\text{--}900^\circ\text{C}$ $t = 16$ h Atmosphere: H_2
	Y_2O_3 (0.1) MgO (0.05)	70	0.3 ~ 1.1 (0.5)	$T = 1,700^\circ\text{C}$ $t = 5$ h Atmosphere: H_2
	MgO (0.05)	40	~0.9	$T = 1,700^\circ\text{C}$ $P = 0.06$ Pa
	Y_2O_3 , La_2O_3 , ZrO_2 (0.1 ~ 0.5), MgO (0.55~1.0)	80	Visible light (~1)	$T = 1,700^\circ\text{C}$ Atmosphere: H_2
	MgO (0.05)	85–90	Visible light (0.75)	$T = 1,725\text{--}1,800^\circ\text{C}$ $t = 17\text{--}30$ h Atmosphere: H_2

FIGURE 32.13. (A) Construction of a sodium-vapor lamp. (B) An actual lamp.

32.9 LAMP ENVELOPES

An important application of transparent ceramics is found in the familiar high-intensity yellow streetlights that are common along major highways. These lamps are known as sodium-vapor lamps because during operation they contain sodium vapor that is being heated to a high temperature. Figure 32.13 shows the construction of a typical sodium-

vapor lamp. The plasma temperature inside the lamp is $3,700^\circ\text{C}$, and the lamp envelope reaches a peak temperature of $1,200^\circ\text{C}$; the sodium-vapor pressure is ~ 100 Torr. The requirements for the envelope material are therefore very stringent: it has to be transparent to visible light, stable at high temperature, and contain the corrosive Na

TABLE 32.8 Fundamental Properties of Candidate Lamp-Envelope Materials

Property	Al ₂ O ₃	Y ₂ O ₃	MgO	3Al ₂ O ₃ ·2SiO ₂	MgAl ₂ O ₄	Y ₃ Al ₅ O ₁₂
E _G (eV)	7.4	5.6	>5	≥5	>5	>5

α (10 ⁻⁶ K ⁻¹ ; 300–1,300 K)	8.2	7.9	13.5	5.3	9.0	8.6
Strength (MPa)	310	150	206	270	184	410
ε (GPa)	405	164	307	220	277	290
k at 300 K (W m ⁻¹ K ⁻¹)	29	13	25	6	15	13
R _{TS}	2,707	1,508	1,242	1,389	1,077	2,137
T _M (K)	2,323	2,737	3,073	2,101	2,408	2,243
Vapor pressure (Pa at 1,500 K)	3 × 10 ⁻⁹	1 × 10 ⁻¹⁰	2 × 10 ⁻⁵	2 × 10 ⁻⁵	2 × 10 ⁻⁶	—
Relative emissivity (~λ _{0.75}) (μm)	5.56	7.9	8.2	4.0	5.7	5.8

plasma. It needs to be inexpensive because about 16 million units are made each year. The sodium-vapor lamp was made possible by the development of very dense ceramic envelopes that did not contain any light-scattering porosity. The addition of small amounts of magnesia (MgO) allows us to sinter a compact of fine Al₂O₃ powder to theoretical density—free of porosity.

Table 32.8 compares the properties of Al₂O₃ to some of the other materials evaluated as candidate lamp-envelope materials. In addition to satisfying the materials selection criteria given above, Al₂O₃ has a significant advantage over the other materials listed in Table 32.8 because it has superior thermal shock resistance.

32.10 FLUORESCENCE

Fluorescence occurs when light that is incident on a specimen causes the emission of light of another color; the effect is shown in Figure 32.14. The effect is most dramatic when the incident light is UV (and the observer is in a darkened room), but it also occurs with other wavelengths. Short-wavelength UV is 254 nm; long-wavelength UV is 300–388 nm (IR would be >780 nm). The wavelength of the emitted radiation is longer than that of the illuminating light; this is known as Stokes' law of fluorescence.

FIGURE 32.14. Fluorescent minerals.

Therefore, the energy of the emitted light is lower, with the difference in energy causing heating in the sample. Many naturally occurring minerals show fluorescence, but only some are spectacular.

Calcite, halite (with Mn)	Red
Fluorite, Opal	Green
Adamite	Yellow/green
Willhemite	Green
Scheelite	Blue
Scapolite	Yellow

Scapolite has a complicated crystal structure and forms by alteration of plagioclase feldspars. Incidentally, diamond, sapphire, and ruby all fluoresce; but as with the materials noted above, the color depends on the UV wavelength used. A given specimen can also show different colors depending on the distribution of impurities. Trace elements can be included in synthetic gemstones to make them fluoresce and thus be easily identifiable.

Phosphorescence. UV radiation excites electrons to a higher energy state. When the UV is removed, decay to the ground state usually takes seconds but can take years. A material that phosphoresces for 12 h would have many uses (see Section 32.12).

Flash is the initial color produced when a UV lamp is first directed at certain fluorescent samples. The emitted wavelength then changes as exposure continues.

Thermoluminescence. This is essentially fluorescence caused by heating a mineral to allow electrons that are trapped in high-energy states to drop back to the ground state. Heating chlorophane, a variety of fluorite, can produce a green light but only once.

Triboluminescence. Light can be produced by rubbing or striking a ceramic. Fracturing mica or rubbing a sphalerite crystal causes light emission.

Cathodoluminescence. Instead of UV radiation, this luminescence is produced by irradiating the sample with electrons (and therefore usually occurs in a vacuum).

This is the phenomenon used in cathode ray tubes (CRTs) (including old TV screens) that were coated on the inside with a ceramic phosphor.

32.11 BASICS OF OPTICAL FIBERS

Light is transmitted from one end of an optical fiber to the other by total internal reflection (TIR), as illustrated in Figure 32.15. Modern optical fibers use a composite construction with a core of refractive index, n_1 , and a cladding with a lower refractive index, n_2 , such that $(n_1 - n_2)$ is typically in the range 0.005–0.05. Light remains in the fiber when the critical angle of incidence, i_c , is met or exceeded. To determine i_c , we make use of Snell's law (which can be derived from Maxwell's equations).

$$n_2/n_1 = \sin i/\sin r \quad (32.8)$$

At i_c , the angle of refraction, r , must be 90° , so we can write:

$$n_2/n_1 = \sin i_c/\sin 90^\circ = \sin i_c/1 \quad (32.9)$$

The requirement for TIR sets a limit on the angle of the light incident on the fiber that is trapped in the core of the fiber. This condition is expressed in terms of the numerical aperture (NA) of the fiber, defined as the sine of the acceptance angle for incident radiation.

$$\sin i_c = (n_2^2 - n_1^2)^{1/2} \quad (32.10)$$

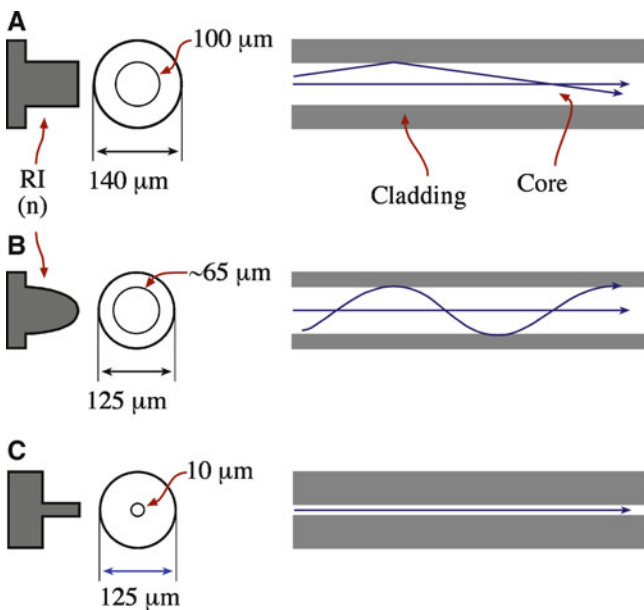

FIGURE 32.15. Total internal reflection along an optical fiber. (A) Step index fiber. (B) Graded index fiber. (C) Single mode fiber. Plot on left is variation of RI ($=n$)

Although light can be transmitted along a glass fiber in air, there are large losses due to scattering arising from surface defects on the fiber. The most important optical fibers consist of a high-purity glass core encased in equally high-purity cladding. In most cases, the cladding is glass, but polymer claddings are also used when a suitable glass cladding is not available or when it is important to reduce costs.

Kao and Hockham suggested the concept of sending optical signals along glass fibers in 1966. Initiated at the Standard Telecommunications Laboratory (STL) in the United Kingdom, optical fibers were crossing the Atlantic Ocean by 1988 and the Pacific Ocean by 1996 (but STL had disappeared). The first low-loss fibers were made at the Corning Glass Works. The fibers were made by a chemical vapor deposition (CVD) process known as outside vapor-phase oxidation (OVPO) and produced an early fiber with a loss of 20 dB/km (which means that 1% of the light remains after traveling 1 km).

32.11.1 Materials

- Processing: How to make the fibers
- Applications: How they work and what goes wrong
- Materials: Which glasses to choose

There are four classes of glass optical fiber.

1. *Pure fused silica* and doped silica glasses are used for telecommunications because of the requirement of very low transmission loss over long distances. They now form the backbone for trunk transmission in most developed countries and in undersea intercontinental routes; many millions of kilometers have been installed throughout the world. For applications in laser surgery, pure silica-based glass fibers are used as they have low transmission loss at $1.06 \mu\text{m}$ and have high strength and durability.
2. *Multicomponent oxide* glasses, such as $\text{Na}_2\text{O}-\text{CaO}-\text{SiO}_2$ (NCS) and $\text{Na}_2\text{O}-\text{B}_2\text{O}_3-\text{SiO}_2$ (NBS), are used for applications requiring light transmission over short distances, such as in image bundles, optical faceplates on CRTs, and IR imaging devices. The glass is of lower optical quality than silica glass but can be processed in bulk by conventional melting techniques and is relatively cheap.
3. *Fluoride glasses* based on $\text{ZrF}_4-\text{BaF}_2-\text{LaF}_3-\text{AlF}_3-\text{NaF}$ (ZBLAN) have been widely investigated because they have potentially very low losses. The ultimate attenuation has been calculated to be $\sim 10^{-2}$ dB/km at $2.5 \mu\text{m}$. Heavy-metal fluoride glasses are made by melting together high-purity fluoride powders at $\sim 800^\circ\text{C}$ and casting preforms. The impurity levels ($\sim 10-1,000$ ppb) have meant that the very low losses have not yet been achieved.
4. *Chalcogenide glasses* based on AsGeS have been investigated. The raw materials used to make these

glasses are volatile, so the glasses are usually made in sealed silica ampoules in a rocking furnace. The resulting glass is reasonably stable and can be machined into preforms or drawn in a fiber from the melt.

32.11.2 Fabrication

Three methods are used to make glass optical fibers

- Double crucible method
- Rod-in-tube method followed by drawing
- CVD techniques to make preforms followed by drawing

The double crucible method and the rod-in-tube method are used primarily for higher-loss fibers made from multicomponent glasses, such as those used in imaging bundles. Pure fused silica and doped silica fibers are drawn from a preform that has been made using a CVD process.

Double-crucible method: The glasses for the core and cladding are made by melting together the constituent oxides (or fluorides) and then pulling the fiber. This technique is suitable for glasses that have low working temperatures (<1,200°C), such as NBS and NCS glasses.

Rod-in-tube method: A preform consisting of a rod of the core glass is formed inside a tube of the cladding glass. The preform can be made either by drawing a rod of core glass and a tube of cladding glass from the melt or by machining a rod and tube from bulk glass. The preform is then drawn into fiber by elongation in a furnace. Glass is drawn into a fiber when the viscosity is in the range 10^3 – 10^5 dPa.s. The drawing process, which is normally performed vertically downward, is a balance between the downward viscous forces, and the surface tension of the molten region.

Several variations of the CVD process are used to make preforms.

- MCVD—modified chemical-vapor deposition
- OVD—outside vapor deposition
- VAD—vapor axial deposition

The MCVD process was developed by Bell Laboratories in the United States and became the standard method. The other processes are very similar except for the details of the geometry. The MCVD process is illustrated in Figure 32.16. The cladding is a tube of pure silica that is mounted in a special lathe. The core, which must have higher n than the cladding, is formed inside the tube by the following reactions.

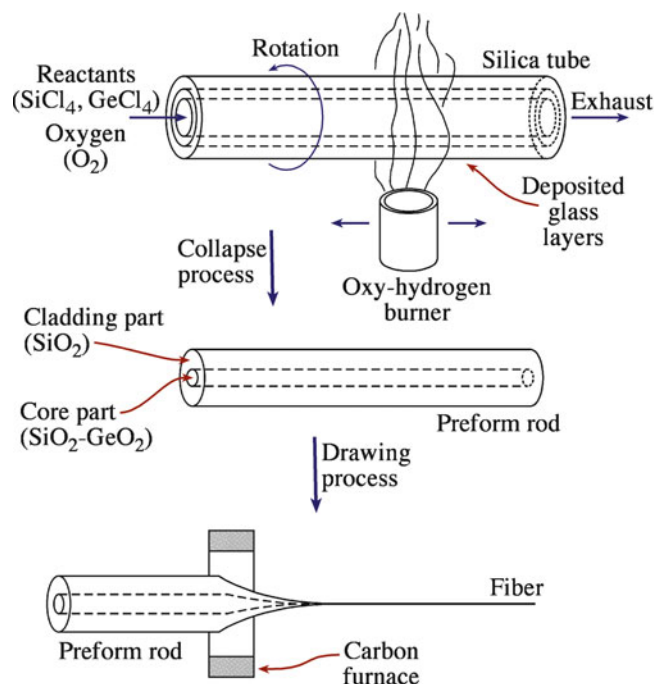

FIGURE 32.16. Steps in the metal oxide chemical vapor deposition process for forming optical fiber preforms.

and

The burners that traverse the tube heat the vapors and oxidize the halides. Glass particles are deposited on the wall of the tube and are remelted to give clear glassy layers. The deposition rate is typically 1 g/min. When sufficient deposit has been achieved, the tube is collapsed to give a preform. The GeO_2 has the effect of raising n . Adding 10 mol% GeO_2 to pure SiO_2 raises n by 0.012. By varying the ratio of GeCl_4 to SiCl_4 in the gas stream with time, it is possible to produce graded-index fibers.

32.11.3 Drawing the Preform

The preform is drawn in a carbon-resistance furnace or zirconia induction furnace; these furnaces can provide the required temperature (>2,000°C) while still having a reasonable operating life. The temperature required for drawing optical fibers is much greater than that for conventional glass fibers because of their higher purity (the cladding is pure SiO_2). The furnace is mounted in a tall tower, with a preform feed-screw mounted above. Drawing is achieved using a capstan, with the fiber being wound onto a drum that can hold several kilometers of fiber. A coating applicator is mounted above the capstan, and fibers are coated online with a polymer to give mechanical protection. Drawing speeds of >10 m/s are possible in production; the drawing speed is mainly limited by the stability of the polymer coating process. A single preform can yield up to

FIGURE 32.17. Fiber drawing tower.

FIGURE 32.18. Loss spectrum for fibers.

100 km of fiber. A typical fiber-drawing apparatus is represented in Figure 32.17.

Silica fibers may be joined in an electric arc. The two ends are aligned and the arc struck. The fibers are fed toward each other at a controlled rate so they are fused with minimal distortion of the core; joint losses can be very low (<0.1 dB). We then have to polish the ends of the fiber.

32.11.4 Operation

An important characteristic for optical fibers is loss or attenuation. Attenuation in fibers is normally measured in decibels per kilometer (dB/km). The optical loss, in decibels, measured over 1 km is written as $10 \log I_{in}/I_{out}$, where I_{in} and I_{out} are the input and output optical power.

The optical signal can be attenuated primarily by two factors.

- **Absorption.** Photons interact with electronic and vibrational transitions in the glass in the UV and IR regions, respectively. In the UV region, absorption is due to electronic transitions across the bandgap. Absorption occurs at shorter wavelengths for a larger bandgap. In the IR region, absorption is due to coupling of the electromagnetic field to lattice vibrations.
- **Scattering.** Fluctuations in composition and density of the glass occur as it cools down below T_g ; the resulting

scattering is a form of Rayleigh scattering. We can describe the intrinsic loss, L , mathematically by:

$$L = A \exp(e/\lambda) + B \exp(-g/\lambda) + C\lambda^{-4} \quad (32.13)$$

where A , B , C , e , and g are constants characteristic of the glass. These loss mechanisms combine to give a loss spectrum, as shown in Figure 32.18. For silica, the minimum loss of 0.15 dB/km occurs at a wavelength of 1.55 μm . ZBLAN is a fluoride glass with even lower loss, 0.02 dB/km at 2.55 μm . These losses are theoretical minima and difficult to achieve in practical situations.

There are many extrinsic sources of loss.

- Absorption caused by transition metal impurities (e.g., Fe, Cu)
- Absorption caused by the OH group
- Scattering caused by defects in the glass, such as particulate contamination and bubbles
- Scattering caused by manufacturing defects, such as changes in the fiber diameter along its length and frozen-in stresses

The minimum loss in commercial silica fibers used for optical communications is typically 0.2 dB/km at 1.55 μm . In fluoride fibers, the lowest reported loss is 0.4 dB/km at 2.35 μm .

TABLE 32.9 Applications of Various Phosphors

Applications	Excitation methods	Phosphors	Color
Color TV	18–27 kV e-beam	ZnS: Ag, Cl	Blue
		ZnS: Cu, Au, Al	Green
		Y ₂ O ₂ S: Eu	Red
CRT	1.5–10.0 kV e-beam	Zn ₂ SiO ₄ : Mn	Green
Electron microscope	50–3,000 kV e-beam	(Zn,Cd)S: Cu, Al	Green
Numerical display	~20 kV e-beam	ZnO	Green

Solid-state lasers	Visible light (near UV to near-IR)	Y ₃ Al ₅ O ₁₂ : Nd (YAG)	IR

32.12 PHOSPHORS AND EMITTERS

When a material is placed in an electric field or irradiated with light, it may itself radiate light: either electric or optical energy is absorbed, and optical energy is then radiated. A material that exhibits this phenomenon is called a phosphor, and the light radiated is called luminescence (see Section 32.10). Luminescence can be fluorescence or phosphorescence. The difference is the time for which emission occurs.

- Fluorescence occurs very quickly $<10^{-8}$ s.
- Phosphorescence is slow emission over ~ 1 s or even longer.

Table 32.9 lists the applications of various phosphors.

Light-emitting diodes and III-V lasers are devices that use a direct-bandgap semiconductor to convert electrical energy into visible light. They have long been used for materials with $E_g \sim 1$ eV (the familiar red), and now GaN (with a wider bandgap, large ν , smaller λ) gives us a blue emitter.

NOTATION

$^4I_{11/2}$ is an example of a term symbol having the form $^{2S+1}L_J$, which is used to describe arrangements of electrons in orbitals. The superscript is $2S + 1$ where S is the overall spin $S = \sum m_s$. The symbol is the overall $L = \sum m_l$. The subscript is a quantum number, J , that considers spin-orbit coupling, J has values from $L + S$, $L + S - 1$, to $|L - S|$.

FIGURE 32.19. Components of a ruby laser.

32.13 SOLID-STATE LASERS

The word “laser” was originally an acronym for “light amplification by the stimulated emission of radiation;” now it’s just a word—so there is no capitalization. A laser produces coherent (in phase) monochromatic (single λ) radiation. A laser consists of an active medium, called the optical cavity, which in the case of a solid-state laser is an insulating crystal or glass containing a specific dopant. The optical cavity is typically 10 cm long and 1 cm in diameter. One end is coated to form a partially transparent mirror, and the other end is fully reflecting. Operation of the laser is based on electronic excitation of the active medium using a pump source, which is usually a flash lamp or flash tube, as shown in Figure 32.19, or another laser. The excited electrons relax back to the ground state by emitting light. As light is reflected to and fro between the mirrors, it is amplified.

The two most important solid-state lasers are classes of dopant in solid-state lasers are the:

Ruby laser, which uses a single crystal of Al_2O_3 containing about $1.6 \times 10^{19} \text{ Cr}^{3+}/\text{cm}^3$. The active electronic states are d levels of the Cr^{3+} .

Nd-YAG laser, which uses a single crystal of $\text{Y}_3\text{Al}_5\text{O}_{12}$ containing $1.4 \times 10^{20} \text{ Nd}^{3+}/\text{cm}^3$. The active electronic states are the f levels of Nd^{3+} .

The properties of the ruby and Nd-YAG laser are summarized in Table 32.10. The Cr^{3+} transition is a three-level system: the laser transition returns the electrons to the ground state. The emission occurs in the red part of the visible spectrum ($\lambda = 694$ nm).

TABLE 32.10 Characteristics of Typical Solid-State Laser Crystals

Crystal	Active center	Concentration of active centers (cm^{-3})	Spontaneous fluorescence lifetime	Wavelength
Ruby	Cr^{3+}	1.6×10^{19}	3 ms	694.3 nm
YAG: Nd	Nd^{3+}	1.4×10^{20}	230 μs	1.061 μm , 1.064 μm , 1.839 μm (77 K), 0946 μm (77 K), 1.318 μm
NaF-(F_2^+)	(F_2^+) color center	2×10^{17}	40 ns	Tunable, 0.99–1.22 μm
$\text{Nd}_{0.5}\text{La}_{0.5}\text{P}_5\text{O}_4$	Nd^{3+}	2×10^{21}	150 μs	1.05 μm

FIGURE 32.20. Four-level system for lasers.

The Nd^{3+} transition is a four-level system: emission occurs near 1.06 μm , and the terminating state lies above the ground state. The four-level system is shown in Figure 32.20.

Doped oxide glasses are also used as the optical cavities in solid-state lasers. A wide range of dopants and glasses can be used, as indicated by Table 32.11. The advantages of using glass as a laser medium is that glass is optically isotropic and producible in a variety of sizes and shapes of high optical quality. In addition, its chemical composition can be varied to tailor laser parameters for specific applications. However, because the thermal conductivity of glass is usually poor compared to their crystalline counterparts, glass lasers are limited to pulsed and low-average power operation. Crystalline lasers are more appropriate for continuous and high-average power operation.

32.14 ELECTRO-OPTIC CERAMICS FOR OPTICAL DEVICES

32.14.1 Electro-Optic Effect

By applying an E field, the optical properties, especially n , of electro-optic (EO) materials can be changed. Many transparent solids and liquids show EO effects, but only a few of them are useful for practical applications.

If an electro-optic ceramic is noncentrosymmetric, then δn is proportional to E .

Examples of such materials include piezoelectric crystals and some poled ferroelectric ceramics; this is known as the linear, or Pockels, effect. If the material is initially centrosymmetric, then δn is proportional to E^2 ; this is known as the quadratic, or Kerr, effect. Such materials include isotropic crystals, unpoled ferroelectric ceramics, and all liquids.

POLING

The process of polarizing a ferroelectric material by applying a high electric field for a short time.

We saw in Section 32.1 that EO materials are birefringent: that is, they have two orthogonal optic axes that are characterized by different indices of refraction, Δn , which is referred to as birefringence in equation 32.5. The value of Δn may be positive or negative. If an E field is applied parallel to one optic axis, then one refractive index is changed with respect to the other. As a result, Δn is changed, and the state of polarization of light propagating through the material is altered. Quadratic EO materials are not generally birefringent unless they are subjected to a properly aligned E field.

The general relationship between Δn and E is:

$$\Delta n = n^3(r_c E + R E^2) \quad (32.14)$$

Table 32.12 lists the values of r and R for several EO ceramics. The higher the EO coefficient, the lower is the applied voltage necessary to perform a particular function.

A brief note on grammar: We have chosen to hyphenate the term electro-optic. However, you may also see it

frequently written as electrooptic. We prefer the hyphenated form because it helps in pronunciation. Optoelectronic is slightly different.

32.14.2 Solid Solutions in the PLZT System

The most important EO ceramics are solid-solution phases in the $\text{PbZrO}_3\text{--PbTiO}_3\text{--La}_2\text{O}_3$ system, known collectively as polarized lead-lanthanum-zirconate-titanate (PLZT) materials.

- The general chemical formula is $\text{Pb}_{1-x}\text{La}_x(\text{Zr}_z\text{Ti}_{1-z})_{1-x/4}\text{O}_3$.
- The structure of PLZT is based on the perovskite, ABO_3 (see Section 7.3).

The linked network of oxygen octahedra has B ions ($\text{Ti}^{4+}, \text{Zr}^{4+}$) occupying the sites within the oxygen octahedra (B sites) and A ions ($\text{Pb}^{2+}, \text{La}^{3+}$) situated in the

FIGURE 32.21. Polarized lead-lanthanum-zirconate-titanate (PLZT) phase diagram. A, memory; B, linear; C, quadratic.

interstices (A sites) created by the linked octahedra. When off-valent ionic substitutions are made into this structure (e.g., La^{3+} for Pb^{2+}), electrical neutrality is automatically maintained by the creation of A-site or B-site vacancies.

The PLZT phase diagram at room temperature is shown in Figure 32.21. The compositions are specified by three successive numbers (e.g., 8.5/65/35), which represent, from left to right, the La, Zr, and Ti atomic concentrations as a percentage.

Ferroelectric PLZT ceramics possess crystalline phases that belong principally to the tetragonal and rhombohedral crystal systems. These materials are classified as uniaxial because they have two or more crystallographically equivalent directions lying in a plane that is, respectively, perpendicular to the fourfold or sixfold axis. They are also optically negative (i.e., $n_e - n_o < 0$), with Δn values typically ranging from about -0.018 to near zero. These values

are low because of the low distortion of the unit cell. In their FE state, the polar c -axis is typically only about 1% longer than the a -axis, which is why domain reorientation is easy in these materials. Domain reorientation produces a change in the optical properties. The magnitude of the

PLZT COMPOSITION
When expressed as 8.5/65/35, the PLZT contains 8.5 at. % La and the Zr/Ti ratio is 65/35.

TABLE 32.13 Transparent Electro-Optic Ceramics

Composition	Notation	Composition	Notation
(Pb,La)(Zr,Ti)O ₃	PLZT	(Pb,La)(Hf,Ti)O ₃	PLHT
(Pb,Ba,Sr)(Zr,Ti)O ₃	PBSZT	(Pb,Sn)(In,Zr,Ti)O ₃	PSIZT

(Pb,La,Li)(Zr,Ti)O ₃	PLLZT	(Sr,Ba)Nb ₂ O ₆	SBN

observed EO effect is dependent on both the strength and direction of the E field.

PLZT ceramics display optically uniaxial properties on both a microscopic scale and a macroscopic scale once polarized. The optic axis coincides with the polarization. The macroscopic or effective birefringence is designated by $\overline{\Delta n}$. On a macroscopic scale, $\overline{\Delta n}$ is equal to zero before electrical poling and has some finite value after poling depending on the composition and the degree of polarization. The $\overline{\Delta n}$ value is an important quantity because it is related to the optical phase retardation, Γ , of the material.

The phenomenon of optical phase retardation in an EO poled ceramic that occurs when entering linearly polarized monochromatic light is resolved into two perpendicular components c_1 and c_2 . Because of the different refractive indices, n_e and n_o , the propagation velocity of the two components are different and result in a phase shift, or “retardation.” Γ is a function of both $\overline{\Delta n}$ and the path length t .

$$\Gamma = \overline{\Delta n} t \quad (32.15)$$

Although at the present time PLZT is the most important EO ceramic, there are other transparent ceramics that exhibit EO characteristics; some of them are listed in Table 32.13. Many of these ceramics are based on solid solutions in the PZT system and are structurally related to PLZT. Notable exceptions are the niobates, such as KTN (potassium tantalum niobate or $\text{KTa}_{1-x}\text{Nb}_x\text{O}_3$ with $x \sim 0.35$), which are also based on the perovskite structure. NTT has shown n for KTN changing by a factor of $20\times$ the change produced in LiNbO_3 using an applied field of 60 V/mm^2 (achieved by applying 1.2 V across a $20\text{-}\mu\text{m}$ sample), but the limiting factor is the growth of high-quality crystals.

32.14.3 Electro-Optic Characteristics of PLZT Ceramics

Depending on composition, PLZT ceramics display one of the three major electro-optic characteristics, shown in Figure 32.22.

Memory. The P versus E hysteresis loop is narrow, indicating low E_c . This characteristic occurs for the rhombohedral ferroelectric (FE) phase, a typical composition being $8/65/35$. The EO memory effect depends on the fact that $\overline{\Delta n}$ can be set to different values by applying (and removing) an E field. Once set, $\overline{\Delta n}$ remains constant as long

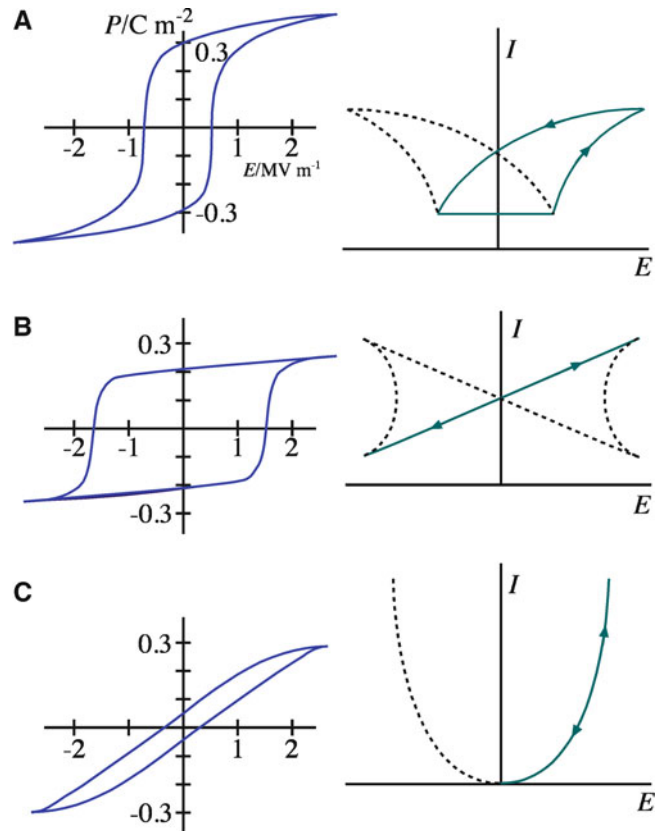

FIGURE 32.22. Electro-optic characteristics of PLZT. (A) Memory. (B) Linear. (C) Quadratic. I is the light output versus applied field E . (See A, B, and C in Figure 32.21).

as $E = 0$. The variation of $\overline{\Delta n}$ is usually plotted in terms of the normalized remnant polarization P_r/P_R because P_r is an easily measured parameter that depends on domain switching. Intermediate remnant states can be achieved by removing the applied E field prior to reaching E_c .

Linear (Pockels effect). This effect is characterized by a square hysteresis loop having a large E_c . It occurs for tetragonal type compositions at the PbTiO_3 -rich end of the solid solution range, such as $8/36/60$. $\overline{\Delta n}$ is linear with E ; from a practical point of view, grain size has a very significant effect on the linearity.

Quadratic (Kerr effect). A slim hysteresis loop with zero or very low P_r is obtained between the FE and paraelectric (PE) compositions; a typical composition is $9.5/65/35$. At room temperature, they are essentially cubic, but the application of E enforces a transition to the rhombohedral or tetragonal FE phase, and the optical anisotropy increases with E^2 .

32.14.4 Making Transparent PLZT Ceramics

The primary requirement for a ceramic to be useful as an EO material is that it is transparent. In single-crystal form, ferroelectric materials possess high optical transparency and useful EO properties. In the form of polycrystalline

ceramics, they can also possess such properties if special precautions are taken during processing. To create a transparent ceramic, it is necessary to limit the amount of sources that can lead to light scattering (the main culprits were discussed in Section 32.5). Hot pressing can produce a high-density product with low porosity. If the pore size is reduced to a value less than the wavelength of light ($\lambda_{\text{yellow}} \sim 0.5 \mu\text{m}$), the pores have only a minor scattering effect. The presence of impurities can be reduced by using high-purity starting materials or by preparing the powders by a sol-gel process using metal alkoxides (see Chapter 22). The use of liquid or solution techniques also helps to ensure good intermixing between the various components. As noted above, for noncubic materials, light scattering can occur at GBs, where refractive indices are discontinuous. In PLZT ceramics the optical anisotropy is reduced by doping with La, which brings the ratio between c and a lattice parameters close to unity.

32.14.5 Applications Using PLZT Electro-Optic Ceramics

There are several applications for EO ceramics and two basic modes of operation for EO devices.

- *Transverse*—The E field is applied in a direction normal to the light propagation direction.
- *Longitudinal*—The E field is applied along the light direction.

Linear materials are used primarily for high-speed modulation of the intensity, amplitude, phase, frequency, or direction of a light beam. Quadratic materials are used principally for light valves and shutters.

Here we briefly describe five applications for PLZT ceramics.

- *Flash goggles* for use by military pilots to prevent them being blinded by a very bright flash! The arrangement consists of three components, as illustrated in Figure 32.23. Under normal illumination, the PLZT plate allows the plane of polarization to be turned by 90° when a voltage of $\sim 800 \text{ V}$ is applied to the interdigitated gold electrodes. The light passes through the analyzer and into the pilot's eyes. An intense flash of light is detected by a photodiode that forms part of the circuit connected to the PLZT plate and removes the voltage applied to the electrodes. The plane of polarization of the incident light is not rotated, and the analyzer blocks most of the light. The switching times are $\sim 100 \mu\text{s}$, and transmission ratios are 1,000:1. For this application, the PLZT is a slim-loop quadratic material, typical composition 9.2/65/35, with almost zero birefringence when $E = 0$.

This application uses an arrangement similar to that used for a voltage-controlled color filter. Now a variable voltage is used that determines what part of

FIGURE 32.23. Operation of flash goggles and the interdigitated electrode arrangement.

FIGURE 32.24. Basic layout of a PLZT reflective display.

the visible spectrum is blocked. When the applied voltage is zero, no light is transmitted. At a voltage where the green light is retarded by $\lambda/2$, “white” light is transmitted (i.e., green plus part of everything else). Further increases in the voltage produce conditions where the blue is extinguished, resulting in the transmission of yellow light (i.e., red and green are transmitted). In a similar way, voltage conditions can be reached where either the red or the green is excluded, and the resulting colors are transmitted. Again, the PLZT is of the slim-loop quadratic variety.

- *Displays*. PLZT elements can be used in reflective displays, as shown in Figure 32.24. P_1 and P_2 are polarizers that are set up in the parallel position. When no voltage is applied to the indium tin oxide (ITO) electrodes, light passes through both polarizers and the PLZT plate and is reflected from the reflecting surface into the eye. If a voltage ($\sim 200 \text{ V}$) is applied to

FIGURE 32.25. Image storage device using a field-induced polarized PLZT film.

the PLZT, the light experiences a retardation of $\lambda/2$ and is extinguished at P_2 . The activated segments appear dark against a light background. The PLZT is again of the 9.5/65/35 type, so it has a slim-loop quadratic. PLZT displays are much more expensive and require much higher operating voltages (>100 V) than the liquid crystal variety, but they offer faster switching times. The main applications are in military and automotive markets.

- *Image storage.* Figure 32.25 shows a storage device using PLZT that operates on the basis of light scattering by domain boundaries in the unpoled material. The PLZT is of the memory type, with a composition 7/65/35 and a grain size of ~ 4.5 μm . To start, the device is uniformly irradiated, and the PLZT is poled to P_r . The image to be stored is focused on the photoconductive film (e.g., CdS or ZnS), and a voltage (~ 200 V and opposite to that of the poling voltage) is applied across the transparent electrodes. This causes regions of the ferroelectric to become depoled. We can then read the image by passing light through the plate and focusing the unscattered light so it passes through an aperture and onto a film. Regions that have become depoled scatter the light to a greater extent than the poled regions. Repoling the PLZT can erase the display.

- *Thin-film optical switch.* Optical signals in telephone systems are routed by first converting them to their electronic equivalents, switching them electronically, and then reconverting them to the optical form. Thin-film optical switches allow the process of switching to be done optically, avoiding the need for electronic conversion. An example of a thin-film optical switch using PLZT is shown in Figure 32.26. The PLZT layer can be deposited on the sapphire substrate by a variety of methods, including sputtering, CVD, and sol-gel. The lattice mismatch between the (0001) plane of sapphire and the (111) plane of the PLZT is quite small ($\sim 2\%$), and this facilitates the formation of an epitaxial layer with the planar relationship, $(0001)_{\text{s}} \parallel (111)_{\text{PLZT}}$.

When there is no voltage applied to the metal electrodes, light entering at 1 exit at 3. If a large enough

FIGURE 32.26. Example of a PLZT thin film optical switch on sapphire.

voltage V is applied, the total internal reflection (TIR) of the light occurs between the electrodes, causing the signal to now exit at 4. TIR occurs because the voltage reduces n . The critical angle for TIR is

$$\theta_c = \sin^{-1}(1 - 0.5n^2RV^2) \quad (32.16)$$

The change in n causing TIR is regarded as being due to the Kerr effect. If we use a 9/65/35 quadratic PLZT with $R = 380 \text{ nm}^2/\text{V}^2$, $n = 2.5$, and a 2° angle between the guides (i.e., $\theta_c = 88^\circ$) then the switching voltage is only 1.4 V.

32.15 REACTING TO OTHER PARTS OF THE SPECTRUM

So far we have concentrated on how ceramics interact with light in the UV, visible, and IR parts of the spectrum. This emphasis is because these interactions are often the most useful and the ones that we are likely to notice. The response of ceramics to γ -rays is becoming of increased interest because of their use for radiation detectors (primarily aimed at locating radioactive material that might be used for “dirty bombs”). Ceramics have long been used for detecting high-energy radiation. One example is Tl-doped NaI used as a scintillation detector on early X-ray diffractometers. The goal is to make lower-cost devices that can be portable, for example incorporated into pagers and cell phones.

The basic requirements of a scintillator for γ -rays are:

- High light yield (>20 k photons generated per incident γ ray).
 - A fast response time (<100 ns).
 - High density and high Z .
 - Scintillation λ matches that of the light sensor (usually a Si diode or photomultiplier).

Ce-doped YAG (which is yellow) is one ceramic that meets these requirements and the estimated cost for single crystals is $< \$0.05 \text{ mm}^{-3}$.

32.16 OPTICAL CERAMICS IN NATURE

We use many of the concepts introduced in this chapter when we discuss gemstones in Chapter 36. Nature does make use of these concepts in surprising ways. Figure 32.27 shows the eye of a trilobite.

Trilobites have existed for over 300 million years. The eye shown here is an array of calcite crystals, which direct the light to a point. Thus, at least some of the trilobites could see because their eyes were inorganic crystals. We may think of this as being an oddity because the trilobites are extinct

FIGURE 32.27. Trilobite eye.

ECHINODERMATA

A group of animals that includes sea urchins and sea stars, one of which is the brittlestar (*Ophiocoma wendtii*).

(although they did survive for ~200 million years). However, it has now been shown that brittlestars use a similar structure to detect light. The scanning electron microscopy (SEM) image in Figure 32.28 shows an array of calcite lenses on the surface of the dorsal arm plate. The cross section through one of these lenses demonstrates how the light is focused on the nerve and even how the spherical aberration is corrected.

FIGURE 32.28. Brittlestar lens. (A) Plan view of an array. (B) Cross section.

32.17 QUANTUM DOTS AND SIZE EFFECTS

The CdSe-CdS solid solution is interesting because we can achieve different colors by changing the ratios of the two components, as we showed in Table 32.6. This is an example of bandgap engineering that has been used in the ceramic pigment industry for decades. At the nanoscale level, we can change color by changing the particle size (i.e., different size nanoparticles of the same material produce different colors). A quantum dot (QD) is simply a nanoparticle of a semiconductor (e.g., Si, Ge) or something with a bigger bandgap (e.g., CdSe, CdS). Figure 32.29 shows a collection of solutions containing CdSe QDs where the particle size increases from left to right. A longer growth time produces larger nanoparticles: the emission

FIGURE 32.29.

wavelength is shifted to red as the particles get bigger. In Chapter 37, you can see an application for QDs.

CHAPTER SUMMARY

At the simplest level, the optical properties of ceramics are so critical to society because glass is transparent, diamonds are not opaque, the development of television required phosphors, and nearly all lighting has depended on glass; also, the future of communications relies on glass fibers and periodic amplifiers, etc. Microscopy developed using glass lenses and led to our understanding of biology. We tend to use color when glazing (there are no patterns otherwise). The general idea is that light affects and is affected by the electrons in the ceramic, and this interaction is determined by the bonding in the ceramic. The interaction actually causes the speed of light to change inside a ceramic. The key properties of the material are then described by average quantities such as the dielectric constant and the refractive index. Crystallography comes in again because many ceramics are anisotropic; one particularly well-known case is calcite.

PEOPLE AND HISTORY

Coble, R.L. (Bob) developed Lucalox[®], a transparent polycrystalline alumina (Al_2O_3) ceramic, at the GE Laboratory in Schenectady in 1961. GE is still a major supplier of lamp envelopes, but Sylvania, Osram, and others also manufacture the envelopes now. (He was also interested in sintering).

Maxwell, James Clerk (1831–1879) developed the electromagnetic wave theory of light.

Seabright, Clarence A in the United States, was one of the key contributors to the development of ceramic pigments: (1948) Ceramic Pigments, U.S. Patent 2,441,367; (1961) Yellow Ceramic Pigments, U.S. Patent 3,012,898; (1965) Iron Ceramic Pigment, U.S. Patent 3,166,430.

van Royen, Willebrod Snell (1581–1626), the Dutch scientist who first described Snell's law; the derivation is given in standard textbooks on electromagnetism (Panofsky and Phillips 1961) or optics (Born and Wolf 1970).

EXERCISES

- 32.1 Why have we used this title for the chapter rather than calling it "Optics"?
- 32.2 Explain why BaTiO_3 is a linear electro-optic material below T_C but a quadratic electro-optic material above T_C .
- 32.3 Polarized lead-lanthanum-zirconate-titanate (PLZT) ceramics belonging to either the tetragonal or rhombohedral crystal systems are classified as optically uniaxial. Which other crystal system or systems are also optically uniaxial?
- 32.4 Several methods have been used to produce PLZT thin films. Try to find as many methods as you can and discuss the pros and cons of each.
- 32.5 Prior to the development of transparent alumina ceramics, the material of choice for the lamp-envelope market was silica-based glass. Explain why such materials are not suitable for use in the sodium-vapor lamp but dominate the incandescent, fluorescent, and electric discharge lamp-envelope markets.
- 32.6 With the increasing demand for optical fiber communication systems, new glass and fiber processing methods are being investigated. One such example is the sol-gel route for silica fibers. What advantages do you think the

sol–gel route would offer over the present chemical vapor deposition (CVD) processes? Can you think of any disadvantages of the sol–gel route?

- 32.7 The single crystals required for solid-state lasers are often made by the Czochralski process. Describe the advantages and disadvantages of using this process for producing single crystals of ruby and yttrium aluminum garnet (YAG).
- 32.8 Explain briefly why the transparency range of single-crystal NaCl is much greater than for single-crystal MgO.
- 32.9 Why are house bricks different colors? (You can answer this in 2 min or 2 h.)
- 32.10 How is the numerical aperture (NA) of a fiber linked to the NA of a camera lens?
- 32.11 What causes refraction in glass?
- 32.12 Did Beer and Lambert work together to come up with their law, and why are they linked to Bouguer?
- 32.13 “Refraction in ceramics is the most important phenomena in the development of biomedical engineering.” Discuss and criticize this statement.
- 32.14 Noncubic ceramics are birefringent. Explain why this is important for transparent polycrystalline alumina nose cones.
- 32.15 Discuss what the eye shown in Figure 32.27 and the lens in Figure 32.28 have in common and how you might use this idea in a new product.
- 32.16 The price of Ce-doped YAG is given in Section 32.15. How does this compare to the cost of commercial sapphire?
- 32.17 In Section 32.14 we get a bit carried away with PLZT-based devices. Are there environmental concerns with these materials? If so, what is being done to address them?
- 32.18 Is Si an electro-optic material? Discuss and reference your sources.
- 32.19 The topic of phosphors and emitters is dealt with very briefly but has enormous potential economic value. Explore the current literature and summarize the most active areas for research and development and how this relates to solid-state lighting.
- 32.20 We mention Nd-YAG lasers, but Nd is also used as a dopant in glass for laser applications. Explore why and what type of glass is used.

Using Magnetic Fields and Storing Data

CHAPTER PREVIEW

If you were asked to give an example of a magnetic material, instinctively you would probably say iron. A good example, but in its pure form iron is not a very useful magnet. Ceramics can be magnetic too, and they were the first magnets known to humans. About 600,000 t of ceramic magnets are produced each year making them, in terms of volume, commercially more important than metallic magnets. The largest market segment is hard ferrites (permanent magnets), which are used in a range of applications including motors for electric toothbrushes and windshield wipers in automobiles, refrigerator door seals, speakers, and stripes on the back of the ubiquitous credit and ATM cards. Soft ferrites can be magnetized and demagnetized easily and are used in cell telephones, transformer cores, and now to a somewhat lesser extent magnetic recording. Ferrite is a term used for ceramics that contain Fe_2O_3 as a principal component.

Magnetism has probably fascinated more people, including Socrates and Mozart (listen to *Così fan tutte*), over the years than any other materials property. For over 4,000 years the strange power of magnets has captured our imagination. Yet, it remains the least well understood of all properties. In this chapter we start by describing some of the basic characteristics of magnetic materials, often that they contain one of the first row transition metals: Fe, Co, or Ni. The electron arrangement in the third level of these atoms is key. The manganates are a very interesting class of magnetic ceramic. Although they are not new, the recent discovery that they exhibit colossal magnetoresistance (just like the giant magnetoresistance observed in metal multilayers only *much* bigger) has renewed interest in these materials. Structurally, the manganates are very similar to the high-temperature superconductors (HTSCs). The similarity may be more than coincidental.

33.1 BRIEF HISTORY OF MAGNETIC CERAMICS

Applications of magnetism began with ceramics. The first magnetic material to be discovered was lodestone, which is better known now as magnetite (Fe_3O_4). In its naturally occurring state, it is permanently magnetized and is the most magnetic mineral. The strange power of lodestone was well known in ancient times. In c.400 BCE, Socrates dangled iron rings beneath a piece of lodestone and found that the lodestone enabled the rings to attract other rings. They had become magnetized. Even earlier (~2,600 BCE), a Chinese legend tells of the Emperor Hwang-ti being guided into battle through a dense fog by means of a small pivoting figure with a piece of lodestone embedded in its outstretched arm. The figure always pointed south and was probably the first compass. The term lodestone was coined by the British from the old English word *lode*, which meant to *lead* or *guide*.

Figure 33.1 shows an ancient Chinese compass. The spoon or ladle was carved out of lodestone and rests

on a polished bronze plate. The rounded bottom of the spoon swivels on the plate until it points south. Although this compass has been found to work, it was used apparently for quasi-magical rather than navigational purposes.

Magnetite is found in many parts of the world and is an important iron ore used for steel-making. The word magnet comes from the Greek word *magnes*, which itself may derive from the ancient colony of Magnesia (in Turkey). Magnetite was mined in Magnesia 2,500 years ago. Today, large deposits of magnetite are found at Kiruna in Sweden and in the Adirondack region of New York.

Commercial interest in ceramic magnets really started in the early 1930s with the filing of a Japanese patent describing applications of copper and cobalt ferrites. In 1947, J.L. Snoeck of N.V. Philips Gloeilampenfabrieken performed a detailed study of ferrites; and the following year, Louis Néel published his theory of ferrimagnetism. This latter study was particularly important because most of the ceramics that have useful magnetic properties are ferrimagnetic. The first commercial ceramic magnets were produced in 1952 by researchers at the Philips

FIGURE 33.1. Ancient Chinese compass.

Company—the same company that introduced the compact audiocassette in 1963.

33.2 MAGNETIC DIPOLES

The Danish physicist Hans Christian Oersted discovered that an electric current (i.e., moving electrons) gives rise to a magnetic force. In an atom, there are two possible sources of electron motion that can create a magnetic dipole and produce the resultant macroscopic magnetic properties of a material. Magnetic dipoles are small internal magnets with north and south poles.

- Orbital motion. Equivalent to a small current loop generating a very small magnetic field. The direction of the magnetic moment is along the orbit axis, as illustrated in Figure 33.2A.
- Spin. Origin of the fourth quantum number, m_s that we used in Chapter 3. The magnetic moment is along the spin axis, as shown in Figure 33.2B and is either up ($m_s = +1/2$) or in an antiparallel, down direction ($m_s = -1/2$).

The magnetic moment due to electron spin is, when present, dominant over that due to orbital motion. Table 33.1 lists

FIGURE 33.2. Generation of atomic magnetic moments. (A) By electron orbital motion around the nucleus. (B) By electron spin around its axis of rotation.

values of μ_{ion} calculated for some first row transition metal ions using equation Box 33.3. You can see that, in general, the calculated values agree well with the experimental values. This agreement shows that we are justified in considering only the contribution of the spin magnetic moment to the overall magnetic moment.

When an electron orbital in an atom is filled (i.e., all the electrons are paired up), both the orbital magnetic moment and the spin magnetic moment are zero.

33.3 BASIC EQUATIONS, WORDS, AND UNITS

Table 33.2 lists the important parameters we meet in this chapter and their units. The situation regarding units is more complicated for magnetism than almost any other

property. The reason is that some of the older units, in particular the oersted (Oe) and the gauss (G), are still in widespread use despite being superseded, in the SI system, by A/m and T, respectively.

The properties of most interest to us in the description of magnetic behavior are:

- μ
- χ

These terms are, of course, related to each other and by considering the role of H to macroscopic measures such as M and B .

The usual starting point to arrive at

MAGNETIC MOMENTS

The fundamental magnetic moment is the Bohr magneton, μ_B , which has a value of $9.27 \times 10^{-24} \text{ A}\cdot\text{m}^2$.

The orbital magnetic moment, μ_{orb} , of a single electron is

$$\mu_{\text{orb}} = \mu_B \sqrt{l(l+1)} \quad (\text{Box 33.1})$$

l is the orbital shape quantum number (see Chapter 3)

The spin magnetic moment of an electron is

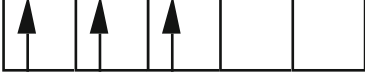

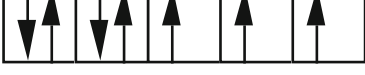

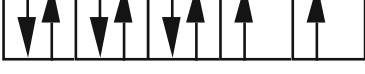

$$\mu_s = 2\mu_B \sqrt{m_s(m_s+1)} \quad (\text{Box 33.2})$$

In ceramics where the magnetic behavior is due to the presence of transition metal ions with unpaired electron spins in the 3d orbital the magnetic moment of the ion due to electron spin, μ_{ion} , is

$$\mu_{\text{ion}} = 2\mu_B \sqrt{S(S+1)} \quad (\text{Box 33.3})$$

$$S = \sum m_s.$$

TABLE 33.1 Magnetic Moments of Isolated Transition Metal Cations

Cations	Electronic configuration	Calculated moments using equation Box 33.3	Measured moments (μ_B)
Sc ³⁺ , Ti ⁴⁺	3d ⁰ 	0.00	0.0
V ⁴⁺ , Ti ³⁺	3d ¹ 	1.73	1.8
V ³⁺	3d ² 	2.83	2.8
V ²⁺ , Cr ³⁺	3d ³ 	3.87	3.8
Mn ³⁺ , Cr ²⁺	3d ⁴ 	4.90	4.9
Mn ²⁺ , Fe ³⁺	3d ⁵ 	5.92	5.9
Fe ²⁺	3d ⁶ 	4.90	5.4
Co ²⁺	3d ⁷ 	3.87	4.8

expressions for μ and χ is to consider a coil of wire in a vacuum, as illustrated in Figure 33.3A. A current, I , passed through the wire generates a magnetic field H .

$$H = IN \quad (33.1)$$

where N is the number of turns of wire per meter. The magnetic induction or magnetic flux density, B , is related to H by:

$$B = \mu_0 H \quad (33.2)$$

where μ_0 is a universal constant.

TABLE 33.2 Terms and Units Used in Magnetism

Parameter	Definition	Units/value	Conversion factor
H	Magnetic field strength	A/m	$1 \text{ A/m} = 4\pi \times 10^{-3} \text{ Oe (Oe)}$
H_c	Coercive field	A/m	
H_{cr}	Critical field	A/m	
M	Magnetization	A/m	
B	Magnetic flux density	T	$T = \text{Wb/m}^2 = \text{kg/A}^{-1} \text{ s}^2$ $= \text{V/sm}^2 = 10^4 \text{ G (G)}$
μ_0	Permeability of a vacuum	$4\pi \times 10^{-7} \text{ H/m}$	$1 \text{ H} = 1 \text{ J s}^2\text{C}^{-2}$
μ	Permeability	H/m	$1 \text{ H/m} = 1 \text{ Wbm}^{-1}\text{A}^{-1}$
μ_r	Relative permeability	Dimensionless	
χ	Susceptibility	Dimensionless	
μ_{ion}	Net magnetic moment of an atom or ion	Am^2	
μ_s	Spin magnetic moment	Am^2	
μ_{orb}	Orbital magnetic moment	Am^2	
μ_B	Bohr magneton	$9.274 \times 10^{-24} \text{ Am}^2$	
θ_c	Curie temperature	K	$0 \text{ K} = -273^\circ\text{C}$
θ_N	Néel temperature	K	
T_c	Critical temperature for superconductivity	K	
C	Curie constant	K	

FIGURE 33.3. Generation of a magnetic field by (A) current flowing in a coil of wire in a vacuum. (B) With a material present.

When a material is placed inside the coil, as shown in Figure 33.3B, it becomes “magnetized.” The magnetic moment produced in the material by the external field changes B .

$$B = \mu_0 H + \mu_0 M \tag{33.3}$$

where M represents the response of the material to H , which is linear, and the ratio gives:

$$\chi = M/H \tag{33.4}$$

By simple substitution we get:

$$B = \mu_0(1 + \chi)H \tag{33.5}$$

B/H is then the permeability.

$$B/H = \mu_0(1 + \chi) = \mu \tag{33.6}$$

The ratio of the permeabilities gives us the relative permeability.

$$\frac{\mu}{\mu_0} = 1 + \chi = \mu_r \tag{33.7}$$

There are many qualitative similarities between magnetic parameters and those we used to describe dielectrics in Chapter 31. In the former case, the material is responding to an applied magnetic field, and in the latter case it is responding to an applied electric field.

- H and the electric field strength ξ (V/m). Both are the external driving force, which causes the orientation of either magnetic or electric dipoles, resulting in magnetization or polarization, respectively.
- B and the polarization P (C/m²). Both correspond to the total field after dipole orientation.
- χ and dielectric constant, κ . Dimensionless “constants” that describe the magnitude of a material’s response to

the applied field. They are both properties of a material and depend on the types of atoms, the interatomic bonding, and the crystal structure.

- μ_0 and the permittivity of a vacuum ϵ_0 are constants. They are reference values to establish the strength of a material's response to H or ξ , respectively.

The similarities described above are not surprising. In both cases, we are concerned with the relationship between an external field and the dipoles within a material. Despite these similarities, the physical nature of the dipoles and their origin is very different. In the case of a dielectric, the dipoles are electric; there is a separation of positive and negative charges. These dipoles can be permanent or induced. In a magnetic material, the dipoles are, of course, magnetic in origin and due to electron motion.

A note on terminology: In most materials science textbooks, as we've done here, H is defined as the magnetic field or the applied magnetic field, and B as the magnetic flux density. In many physics textbooks, B is referred to as the magnetic field and H is often ignored. This convention is adopted for purely historical reasons, but it does have the advantage of reducing the number of terms we need to consider. Also, H has nothing to do with

χ AND μ

Susceptibilities are generally used when the response to an applied magnetic field is weak (of interest only to physicists!). Permeabilities are used when the response is large—of great interest to engineers!

MAXWELL EQUATIONS

The magnetic, electric, and optical properties of a material are all related mathematically through the Maxwell equations.

a material, whereas B is a measure of the response of a material to an applied magnetic field. Another point to note is that B and H are both vector quantities; and because the magnetic properties of a material are anisotropic (different along different directions in the crystal), they should actually be represented by a second-rank tensor.

33.4 FIVE CLASSES OF MAGNETIC MATERIAL

There are five main types of magnetic behavior, and they can be divided into two general categories.

- Induced
- Spontaneous

Table 33.3 summarizes the properties of the five classes. We can find examples of each in ceramics.

33.5 DIAMAGNETIC CERAMICS

Most ceramics are diamagnetic. The reason is that all the electrons are paired during bond formation; and, as a result, the net magnetic moment due to electron spin is zero.

TABLE 33.3 Magnetic Classification of Materials

Class	Critical temperature	χ	Temperature variation of χ	Spontaneous magnetization	Structure on atomic scale
Diamagnetic	None	-10^{-6} to -10^{-5}	Constant	None	Atoms have no permanent dipole moments.
Paramagnetic	None	$+10^{-5}$ to $+10^{-3}$	$\chi = C/T$	None	Atoms have permanent dipole moments. Neighboring moments do not interact
Ferromagnetic	θ_C	Large (below θ_C)	Above θ_C , $\chi = C/(T - \theta)$, with $\theta \approx \theta_C$	Below θ_C , $M_s(T)/M_s(0)$ against T/θ_C follows a universal curve; above θ_C , none	Atoms have permanent dipole moments. Interaction produces parallel alignment
Antiferromagnetic	θ_N	As paramagnetic	Above θ_N , $\chi = C/(T \pm \theta)$, with $\theta \neq \theta_N$, below θ_N , χ decreases, anisotropic	None	Atoms have permanent dipole moments. Interaction produces antiparallel alignment
Ferrimagnetic	θ_C	As ferromagnetic	Above θ_C , $\chi \approx C/(T \pm \theta)$, with $\theta \neq \theta_C$	Below θ_C , does not follow universal curve; above θ_C , none	Atoms have permanent dipole moments. Interaction produces antiparallel alignment; moments not equal

TABLE 33.4 Magnetic Susceptibilities for Several Diamagnetic Materials

Material	$\chi (\times 10^{-6})$
Al ₂ O ₃	-37.0
Be	-9.0
BeO	-11.9
Bi	-280.1
B	-6.7
CaO	-15.0
CaF ₂	-28.0
C (diamond)	-5.9
C (graphite)	-6.0
Cu	-5.5
Ge	-76.8
Au	-28.0
Pb	-23.0
LiF	-10.1
MgO	-10.2
Si	-3.9
Ag	-19.5
NaCl	-30.3

Table 33.4 lists χ for several diamagnetic materials. Cu, Au, and Ag are diamagnetic even though their atoms have unpaired valence electrons. When the atoms combine to form the metal, the valence electrons are shared by the crystal as a whole (to form the electron gas). On average, there are as many electrons with $m_s = +1/2$ as with $m_s = -1/2$.

Most diamagnetic ceramics are of no commercial significance and of little scientific interest, at least not for their magnetic behavior. The one exception is the ceramic superconductors, which are perfect diamagnets below a critical magnetic field.

33.6 SUPERCONDUCTING MAGNETS

When a superconductor in its normal (i.e., nonsuperconducting) state is placed in a magnetic field and then cooled below its critical temperature, the induced magnetization, M , exactly opposes H . Therefore, from equation 33.3, we can write

$$B = 0 \quad (33.8)$$

FIGURE 33.4. Magnetization behavior of type I and type II superconductors as a function of applied field.

The net effect is that the whole of the magnetic flux appears to have been suddenly ejected from the material, and it behaves as a perfect diamagnet. This phenomenon is known as the Meissner effect and is usually demonstrated by suspending a magnet above a cooled pellet of the superconductor.

LONDON PENETRATION DEPTH
 Although there is no magnetic field in the bulk of a superconductor it does penetrate below the surface to a depth of between 0.2 and 0.8 μm .

CRITICAL MAGNETIC FIELDS FOR YBCO

H_{c1} (T)	$c \sim 0.1$	$a,b \sim 0.01$
H_{c2} (T)	$c \sim 50$	$a,b \sim 200$

|| c field along c axis of unit cell
 || a,b field in the basal plane
 These H_{c2} values are enormous. The world's most powerful magnet is about 40 T.

There is an upper limit to the strength of the magnetic field that can be applied to a superconductor without changing its diamagnetic behavior. At a critical field H_{cr} the magnetization goes toward zero, and the material reverts to its normal state. For most elemental superconductors, M rises in magnitude up H_{cr} and then abruptly drops to zero—type I behavior.

A few elemental and most compound superconductors, including all HTSCs, exhibit type II behavior. Above a certain field, H_{c1} , magnetic flux can penetrate the material

without destroying superconductivity. Then, at a (usually much) higher field, H_{c2} , the material reverts to the normal state. These two behaviors are compared in Figure 33.4.

When a type II superconductor is in the “mixed” state, it consists of both normal and superconducting regions. The normal regions are called vortices, which are arranged parallel to the direction of the applied field. At low temperature, the vortices are in a close-packed arrangement and vibrate about their equilibrium positions in the same way that atoms in a solid vibrate. If the temperature is high enough, the vortex motion becomes so pronounced that the arrangement randomizes and the vortex lattice “melts.” Defects in the material can trap or pin vortices in place, and higher temperatures are then needed to cause “melting.” Pinning is of considerable practical importance

because it enables higher currents to flow through the material before the superconductivity is lost.

One of the most exciting potential applications of the Meissner effect is magnetic levitation (maglev) for advanced high-speed transportation. Pilot maglev trains that can reach speeds of more than 550 km/h have already been developed in Japan, and other countries have plans to develop maglev train services. The first U.S. maglev train was scheduled for the campus of Old Dominion University in Virginia with plans to complete construction by 2003, but the project has suffered continuing major setbacks since then.

Although ceramic superconductors have not been used for the generation of large magnetic fields because it is difficult to form them into long wires, they have been made into superconducting quantum interference devices (SQUIDs). The essential component of a SQUID is the Josephson junction, a thin (~1 nm) insulating layer between two superconductors through which weak supercurrents consisting of Cooper pairs can tunnel without an applied voltage. The insulating barrier can be a deposited thin film; or in the case of some of the ceramic superconductors, a high-angle grain boundary (GB), such as that shown in Figure 14.37, works well.

A SQUID can be used to detect very small (~10⁻¹⁵ T) changes in *B*. When a Josephson junction is exposed to a magnetic field, steps are produced in the current–voltage (*I*-*V*) behavior. This is similar to what happens when the junction is irradiated with microwaves (as we showed in Chapter 30). Each step corresponds to a quantum change in *B*. Uses for SQUIDs include:

- Detecting small changes in magnetic field strength at the earth's surface that can then be related to the underlying geological structure (e.g., thickness of the crust, movement of magnetic poles over time).
- Magnetic imaging using scanning SQUID microscopy. Allows local magnetic fields to be measured at the surface of a sample.
- Searching for submarines. When a submarine moves through the water, the metal hull slightly disturbs the Earth's magnetic field and this small distortion can be measured.
- Imaging the human brain by detecting small magnetic fields produced as a result of the currents due to neural activity, an area of research called magnetoencephalography (MEG) that is being used to study epilepsy.

33.7 PARAMAGNETIC CERAMICS

The magnetic moment is due to unpaired electron spins. Magnetic susceptibilities are positive (as shown in Table 33.5) because the magnetic moments line up with

TABLE 33.5 Magnetic Susceptibilities for Several Paramagnetic Materials

Material	χ ($\times 10^{-6}$)
Al	+16.5
Ca	+40.0
Ce	+2,450
CeO ₂	+26.0
Cr	+180
Cr ₂ O ₃	+1,965
Li	+14.2
Mg	+13.1
Na	+16.0
Ti	+153.0
TiO ₂	+5.9

REFERENCE POINTS

$B = 10^{-12}$ T at the Earth's surface
The human body produces a magnetic field of ~10⁻¹⁰ T

H, and this leads to an increase in *B*. However, adjacent magnetic dipoles essentially behave independently; there is no interaction between them.

It is this lack of an interaction that separates paramagnetic materials from ferromagnets.

Most first row transition metals (e.g., Ti, Cr) are paramagnetic because they have unpaired electrons in their third orbitals (see Table 33.1). The number of unpaired electrons per atom is determined using Hund's rule (see Section 3.5).

Nontransition metals (e.g., Na) may be paramagnetic due to the alignment of the spin moment of some of the valence electrons with the applied field. This effect, known as Pauli paramagnetism, is much weaker than that due to unpaired third electrons and involves electrons moving into a higher energy level and changing their spin direction. This process can happen only if the gain in magnetic energy is more than the energy needed for electron promotion. Some oxides containing transition metal or rare earth ions (e.g., CeO₂, Cr₂O₃) are also paramagnetic.

The temperature dependence of paramagnetic susceptibility is shown in Figure 33.5 and follows the Curie law.

$$\chi = \frac{C}{T} \quad (33.9)$$

There are no commercial applications for paramagnetism.

33.8 MEASURING χ

The most straightforward way to obtain χ is the classical Gouy method. The material, in the form of a rod, is attached to one arm of a sensitive balance. It is then placed between the poles of a magnet. If the sample is paramagnetic, its energy is lower when it is inside the magnetic field, and so there is a force, *F*, drawing it into the field.

FIGURE 33.5. How χ varies with temperature (T) for a paramagnetic solid. Insets. Direction of the magnetic dipoles in the solids.

If the sample is diamagnetic, its energy is less if it is outside the field, and so F is in the opposite direction.

Qualitatively, the sign of χ can be determined by whether the force on the sample (the apparent weight change measured by the balance) is positive or negative. We can quantify the value of χ using equation 33.10.

$$F = \frac{1}{2} A \chi H^2 \quad (33.10)$$

where A is the cross-sectional area of the sample.

A strong magnet has a large χ value.

Other methods can be used to determine magnetization and susceptibility, but all rely either on measuring the force exerted on the sample by the magnetic field (as in the Gouy method) or on detecting currents induced in a circuit placed close to the magnetic material. The main disadvantage of the Gouy method is that it requires quite a large sample (~grams).

33.9 FERROMAGNETISM

The origin of ferromagnetism, like paramagnetism, is the presence of unpaired electron spins. However, in a ferromagnetic material, there is an interaction between adjacent dipoles. Of the first row transition metals, only Fe, Co, and

FIGURE 33.6. Slater-Bethe curve showing the magnitude and sign of J as a function of D/d .

Ni are ferromagnetic. Why is Cr paramagnetic not ferromagnetic? The reason is due to a quantum mechanical exchange interaction between the third orbitals on adjacent atoms, which is represented mathematically by the exchange integral, J . If $J > 0$, there is an interaction between adjacent magnetic dipoles, causing them to line up, and the material is ferromagnetic (below the Curie temperature, θ_C). If $J < 0$, adjacent dipoles are antiparallel, and the material is antiferromagnetic (below the Néel temperature, θ_N).

The magnitude and size of J depends on the interatomic separation, D , and the diameter, d , of the electron orbital under consideration, as shown in Figure 33.6 (the Slater-Bethe curve) for the case of the third orbital of Fe, Co, and Ni.

The term D can be determined simply by looking up the atomic radius of the element and doubling it (e.g., for Fe, $r = 0.124$ nm and $D = 0.248$ nm). The value of d can be estimated using equation Box 33.2 in Section 3.2. For the third orbitals of Fe, $r = 0.159$ nm. Hence, D/d is 1.56, as shown in Figure 33.6.

The term J is more difficult to determine. It is related to the overlap of the electron orbitals and involves integrating the products of the wave functions for the electron orbitals on adjacent atoms. If there is significant overlap of the third orbitals, by the requirements of the Pauli exclusion principle the spins must be antiparallel ($J < 0$). If the separation is too large, there is no appreciable interaction. However, in the case of iron, cobalt, and nickel, the exchange interaction is large, and positive and the electron spins are parallel.

The magnetic susceptibility of a ferromagnetic material varies with temperature (Figure 33.7A), according to the Curie-Weiss law.

$$\chi = C/(T - \theta_c) \quad (33.11)$$

You may recognize this type of variation as being very similar to an order-disorder transition. Above θ_C , the

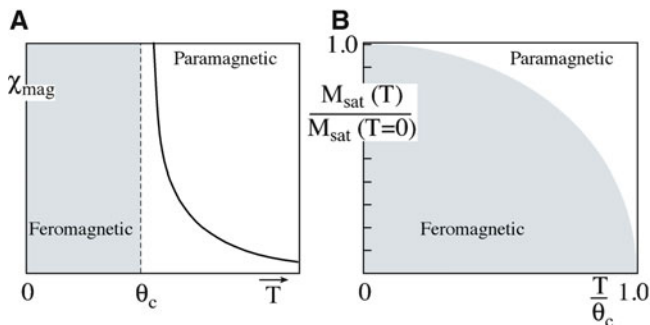

FIGURE 33.7. (A) How χ varies with T . (B) How M varies with T for a ferromagnet.

FIGURE 33.8. How χ varies with T for an antiferromagnetic material. At θ_N , it becomes paramagnetic.

material becomes paramagnetic because of randomization of the spin magnetic moments. M decreases from its maximum value at 0 K and vanishes at θ_C , as shown in Figure 33.7B.

Chromium dioxide (CrO_2) is, at present, the most important ferromagnetic ceramic. It is used as the magnetic medium in audio and video recording tapes. In this application, the CrO_2 is not in the pure form but is usually doped to improve its properties.

CrO_2 has the rutile (TiO_2) structure (Figure 6.11). The Cr^{4+} ions are located at the corners of the unit cell, and there is a distorted CrO_6 octahedron in the center. The lattice parameters are $a = 0.437$ nm and $c = 0.291$ nm. CrO_2 does not occur in nature and is usually manufactured by thermal decomposition of CrO_3 at $\sim 500^\circ\text{C}$ under high pressure (>200 MPa) in the presence of water.

33.10 ANTIFERROMAGNETISM AND COLOSSAL MAGNETORESISTANCE

In an antiferromagnet there is exact cancellation of the magnetic moments. We can think of an antiferromagnetic material as consisting of two ferromagnetic lattices where the spin magnetic moments are equal in magnitude but

FIGURE 33.9. Overlap between Ni d_{z^2} orbitals and O p_z orbitals in Ni.

opposite in direction. Above θ_N , the antiferromagnetic spin alignments are randomized, and the material becomes paramagnetic. The temperature dependence of the magnetic susceptibility is shown in Figure 33.8.

The following oxides are antiferromagnetic.

They all have the rock salt (NaCl) structure, and magnetic dipoles on adjacent $\{111\}$ planes are antiparallel. The magnetic interaction between the cations occurs indirectly through the oxygen ions and is known as a “superexchange” interaction. Along $\langle 100 \rangle$ there is overlap of the Ni d_{z^2} orbitals and the O p_z orbital, as illustrated in Figure 33.9. The Pauli exclusion principle governs the spin direction in the overlapping orbitals; and, as a result, the adjacent Ni ions have opposed spins.

We have direct evidence of the orientation of the spin magnetic moments in antiferromagnetic materials from neutron diffraction studies. Neutrons have a magnetic dipole moment. In neutron diffraction, the neutron beam is responding not only to atom positions but also to their magnetic moments. (X-rays give us information on atom positions and electron distribution.) Above θ_N , the neutron diffraction pattern consists of reflections due to the periodic arrangement of the crystal structure. Below θ_N , extra reflections appear in the pattern because the neutrons are “seeing” two sets of cations, with different magnetic moments. The magnetic unit cell is therefore twice the size of the crystallographic unit cell, as shown in Figure 33.10.

Antiferromagnetism is not limited to oxides with the rock salt structure. The following antiferromagnets have the corundum structure.

Although the ceramics we have mentioned so far in this section have no applications that use their magnetic properties, there are a range of manganate ceramics in the $\text{La}_{1-x}\text{A}_x\text{MnO}_3$ ($0 \leq x \leq 1$; A = Sr, Ca, Ba) system that are antiferromagnetic and exhibit colossal magnetoresistance (CMR). CMR is where the resistance drops

FIGURE 33.10. Comparison of structural and magnetic unit cells of NiO.

dramatically in an applied magnetic field. It is related to, but much greater than, giant magnetoresistance (GMR), found in multilayers of ferromagnetic and nonferromagnetic metals (e.g., {Co/Cu}_x30). In these structures, there is an interaction between the ferromagnetic layers that can cause antiferromagnetic ordering of magnetic moments in adjacent layers. Thus, individually each Co layer is ferromagnetic, but the multilayer structure is actually antiferromagnetic. The extent of the interaction depends on the thickness of the nonferromagnetic layer and H . All current hard disk drives make use of this technology.

The manganates have the layered perovskite structure similar to that found in the yttrium barium copper oxide (YBCO) superconductor (see Section 7.16). This similarity is particularly interesting and may lead to increased understanding of both types of material. The nature of the interactions in the manganites is complicated. They show a metal-insulator transition and a ferromagnetic-antiferromagnetic transition associated with CMR.

33.11 FERRIMAGNETISM

In a ferrimagnet, the magnetic moments of one type of ion on one type of lattice site in the crystal are aligned antiparallel to those of ions on another lattice site. Because the magnetic moments are not of the same magnitude, they only partially cancel each other, and the material

ZnFe₂O₄
 In ZnFe₂O₄ (Fe^{III}(Zn^{II}Fe^{III})O₄) all the magnetic Fe³⁺ are on octahedral sites and are separated by a plane of O²⁻ ions. The material is antiferromagnetic because the super-exchange interaction involving the two Fe³⁺ ions resembles that shown in Figure 33.9.

has a net M . Ferrimagnetism has several similarities to ferromagnetism in that the cooperative alignment between magnetic dipoles leads to a net magnetic moment even in the absence of an applied

field. Ferrimagnetism is lost above θ_c . The difference between ferromagnetism, antiferromagnetism, and ferrimagnetism in terms of the spin alignments is illustrated in Figure 33.11.

The easiest way to consider what happens in a ferrimagnet is to look at the prototypical ferromagnetic material, magnetite. Magnetite has the inverse spinel structure (see Section 7.2). The formula can be written as Fe^{III}(Fe^{II}Fe^{III})O₄ (i.e., in the classic spinel form AB₂O₄). The Fe²⁺ ions and half of the Fe³⁺ ions are in octahedral sites; the other half of the Fe³⁺ cations are in tetrahedral sites. The spins of the Fe ions on the octahedral sites are parallel but of a different magnitude. The spins of the Fe ions on the tetrahedral sites are antiparallel to those in the octahedral sites. The situation is illustrated in Figure 33.12, which shows 1/8 of the magnetite unit cell. The alignment of the spins is the result of an exchange interaction involving the O²⁻ ions. The antiparallel alignment of the Fe³⁺ ion in the octahedral site and the Fe³⁺ ion in the tetrahedral site is usually explained by a superexchange reaction similar to that used to explain antiferromagnetism.

A mechanism to account for the parallel spin alignment between the Fe³⁺ in the octahedral site and the octahedrally coordinated Fe²⁺ was proposed by Zener and is called the “double exchange” mechanism. The idea is that an electron

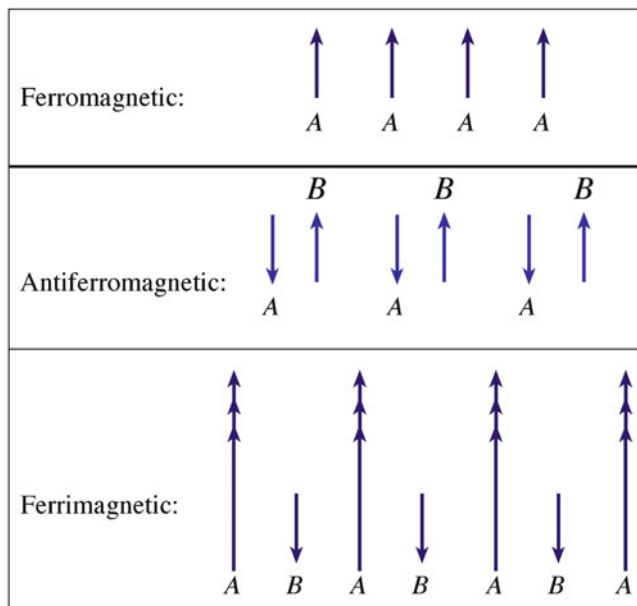

FIGURE 33.11. Comparison of dipole alignments in ferromagnetic, antiferromagnetic, and ferrimagnetic materials.

from the Fe^{2+} ion ($3d^6$) is transferred to the oxygen in the face-centered position of the subcell shown in Figure 33.12. At the same time, there is transfer of an electron with parallel spin to the Fe^{3+} ion. The process, illustrated in Figure 33.13, shares similarities with the electron-hopping model of conduction in transition metal oxides. (Note: a

FIGURE 33.12. Subcell of magnetite shows the location of Fe ions and their spin moments.

requirement of Zener's model is that the cations have different charges).

Ferrimagnetic ceramics have the spinel (almost exclusively inverse), garnet, or magnetoplumbite structure. Table 33.6 lists some examples of ferrimagnetic spinels and their properties. The magnetic moments in this table were calculated taking into account only the number of unpaired 3d electrons; units are Bohr magnetons, and the minus sign denotes an antiferromagnetic coupling.

The most important and widely studied magnetic garnet is yttrium iron garnet (YIG), which has the formula

FIGURE 33.13. Double exchange interaction in magnetite.

$Y_3Fe_2(FeO_4)_3$ [remember garnet is $Ca_3Al_2(SiO_4)_3$]. We can write the formula of YIG as $Y_3^cFe_2^aFe_3^dO_{12}$, where the superscripts refer to the type of lattice site occupied by each cation. The cell shown in Figure 33.14 is actually one of the eight subcells that form the YIG unit cell, which contains 160 atoms. In the subcell, the a ions are in a body

centered cubic (bcc) type arrangement, with the c and d ions lying on the cube faces. Each a ion is in an octahedral site, each c ion is on a dodecahedral site, and each d ion is on a tetrahedral site, as illustrated in Figure 33.14.

The net magnetic moment in YIG, as in other ferrimagnetic ceramics, arises from an uneven contribution from antiparallel spins; the magnetic moments of the a and d ions are aligned antiparallel, as are those of the c and d ions. For every two Fe^{3+} on a site, there are three Fe^{3+} ions on d sites, giving a measured magnetic moment of $\sim 5 \mu_B$.

The mineral magnetoplumbite has the approximate composition $PbFe_{7.5}Mn_{3.5}Al_{0.5}Ti_{0.5}O_{19}$. The commercially important ferrimagnetic ceramic barium hexaferrite ($BaO \cdot 6Fe_2O_3$) is isostructural with magnetoplumbite. The crystal structure of $BaO \cdot 6Fe_2O_3$ is shown in Figure 33.15. The hexagonal unit cell is very large and contains 64 atoms. Magnetization is easiest along the c -axis. Also shown in Figure 33.15 is a simplified representation of the spin magnetic moments of the Fe^{3+} ions in $BaO \cdot 6Fe_2O_3$. The actual arrangements are more complicated.

There is a range of hexagonal ferrimagnetic ceramics containing BaO. These are usually classified based on their chemical formula.

- M-type compounds, $(MO)(Fe_2O_3)_6$ e.g., $(BaO)(Fe_2O_3)_6$
- W-type compounds, $(BaO)(MO)_2(Fe_2O_3)_8$ or M_2W —e.g., $(BaO)(CoO)_2(Fe_2O_3)_8$
- Y-type compounds, $(BaO)_2(MO)_2(Fe_2O_3)_6$ or M_2Y —e.g., $(BaO)_2(MnO)_2(Fe_2O_3)_6$

e.g., $(\text{BaO})_4(\text{ZnO})_2(\text{Fe}_2\text{O}_3)_{18}$

33.12 ESTIMATING THE MAGNETIZATION OF FERRIMAGNETS

We can estimate saturation values of M and B by knowing the crystal structure and lattice parameter of the material and the orientation of the spin magnetic moments. We illustrate this approach for magnetite. The magnetic moments of each type of ion are summarized in Table 33.7. The Fe^{3+} ions interact antiferromagnetically, and the net magnetic moment is due only to the Fe^{2+} ions. Using equation B3, we can calculate the magnetic moment of an Fe^{2+} ion as $4.9 \mu_B$. There are eight Fe^{2+} ions per unit cell, so the total magnetic moment per cell is $8 \times 4.9 = 39.2 \mu_B$.

M is therefore

$$39.2[\mu_B] \times 9.27 \times 10^{-24}[\text{Am}^2 \mu_B^{-1}] / (0.837 \times 10^{-9}[\text{m}])^3 = 6.17 \times 10^5 \text{ A/m}$$

which is in fairly good agreement with the measured value of $5.3 \times 10^5 \text{ A/m}$.

B is

$$B_S = \mu_0 M_S = 4\pi \times 10^{-7} \times 6.17 \times 10^5 = 0.78 \text{ T}$$

This value is close to the measured value of 0.6 T.

An interesting characteristic of both these values is that if the classical value of the spin magnetic moment is taken for Fe^{2+} (i.e., $4 \mu_B$) then both M and B are closer to the measured values. Even though for isolated cations, equation B3 provides much better agreement with experimental data. The reason for this discrepancy is not obvious.

TABLE 33.7 Magnetic Properties of Fe in Magnetic Ceramics

Fe^{3+}	1	Oct.	↑	5	5
Fe^{3+}	1	Tet.	↓	5	-5

33.13 MAGNETIC DOMAINS AND BLOCH WALLS

A ferromagnetic or a ferrimagnetic material is divided into many small regions or domains. Pierre Weiss was the first to recognize the presence of magnetic domains, and therefore they are often named after him. Within each domain the direction of magnetization is the same. When the material is in its unmagnetized state, the net magnetization is zero; that is, there are as many domains magnetized in one direction as there are in the antiparallel direction. This situation is illustrated for several different domain structures in Figure 33.16. The energy of the material is lowered when the domains are smaller. For the configurations shown in Figure 33.16, the overall energy decreases from left to right. The triangular domains are called closure domains and complete the magnetic flux path with the solid; this also lowers the overall energy.

In the boundary region between the different domains there is a gradual change in magnetic dipole orientation, as illustrated in Figure 33.17. The boundary regions are

FIGURE 33.16. Examples of domain structures, each with zero net magnetization.

FIGURE 33.17. Change in magnetic dipole orientation through a domain wall. All moments lie in the plane of the wall.

FIGURE 33.18. Magnetic domains on the basal surface of a hexagonal ferrite, $\text{Co}_2\text{Ba}_2\text{Fe}_{28}\text{O}_{46}$, revealed by the Bitter technique.

FIGURE 33.19. Domain pattern in a YIG thin film revealed by the Faraday effect.

known as domain walls or Bloch walls after the man who did much of the early work on this subject. The thickness of the domain wall is a tradeoff between the requirement for a small angle between adjacent spins that would necessitate a thick wall and the tendency for the magnetic dipoles to be aligned with a specific crystallographic orientation, requiring a thin wall.

DOMAIN WALL
Typically the domain wall has a thickness of about 100 nm and an energy of $\sim 10^{-3} \text{ J/m}^2$.

There is also a domain structure in antiferromagnetic materials, with walls separating each domain.

- In S walls, the magnetization direction is rotated across the wall.
- In T walls, there is a change in orientation characteristic of twinning.

33.14 IMAGING MAGNETIC DOMAINS

There are many different ways to image magnetic domain structures in a material. All the “microscopy” techniques we described in Chapter 10 can be used, although in some cases deviations from the usual operating procedure are necessary to obtain the desired images. It is also possible to use X-ray topography to study magnetic domains. In this section, we briefly describe three techniques: the oldest, one of the newest, and the trickiest.

33.14.1 Visible Light Microscopy

Examination of a magnetic material by simple visible light microscopy (VLM) does not reveal any information about the domain structure because the direction of magnetization does not change the appearance of the surface in any way. Transmitted light requires that the specimens are transparent, so very thin ($<0.1 \mu\text{m}$) samples must be used.

The first approach, known as the Bitter technique, “decorates” the domain boundaries with magnetic particles suspended in a liquid. The particles are

attracted to where the domain boundaries intersect the surface, and this allows the domain pattern to be observed. The Bitter technique is applicable to all types of magnetic material, but specimen preparation is important to avoid introducing surface strains that can distort the domain structure. A Bitter pattern obtained in the hexagonal ferrite $\text{Co}_2\text{Ba}_2\text{Fe}_{28}\text{O}_{46}$ is shown in Figure 33.18.

An alternative means of observing magnetic domain structures by VLM is to use polarized light. Domains magnetized in opposite directions rotate the plane of polarization in opposite senses. Using an appropriate analyzer, it is possible to vary the intensity of the light coming from each domain and produce corresponding intensity changes in the image. The effect of M on the transmitted light intensity is called the Faraday effect. The Faraday effect in a thin film of a substituted YIG, $(\text{BaTb})_3(\text{FeGa})_5\text{O}_{12}$, is shown in Figure 33.19.

The effect of M on the reflected light intensity is known as the Kerr effect. The polar Kerr effect refers to the situation where the sample has a component of M normal to the surface and normal incidence illumination is used. The longitudinal Kerr effect is used when M is parallel to the surface and the illumination is oblique.

33.14.2 Magnetic Force Microscopy

Magnetic force microscopy (MFM) is closely related to scanning tunneling microscopy (STM) and atomic-force

FIGURE 33.20. Magnetic force microscopy of a magnetized pattern on a hard drive.

microscopy (AFM). In MFM, the tip is coated with a ferromagnetic thin film that detects magnetic force variations on the sample surface. The tip is scanned over the surface of the sample (it does not actually touch) as in STM. Interactions between magnetic domains in the sample and the ferromagnetic coating result in a force on the tip, which depends on the orientation of the domains. Different orientations produce a different force, and this is how the different magnetized regions can be determined. Figure 33.20 illustrates how an MFM image of a magnetic tape would appear. The bright and dark stripes in the center of the image are regions where the direction of magnetization is different.

33.14.3 Transmission Electron Microscopy

Because electrons are charged, they experience a force—the Lorentz force—as they move through a magnetic field. This force causes them to be deflected by a small angle. The deflections are in different directions in different domains. The domain walls cannot be imaged under normal bright-field imaging conditions, but they can be seen by either underfocusing or overfocusing the image (Fresnel images) or by displacing the objective aperture (Foucault images).

33.15 MOTION OF DOMAIN WALLS AND HYSTERESIS LOOPS

When an external magnetic field is applied to a ferromagnetic or ferrimagnetic material, the domain boundaries begin to move. They move in such a way that domains

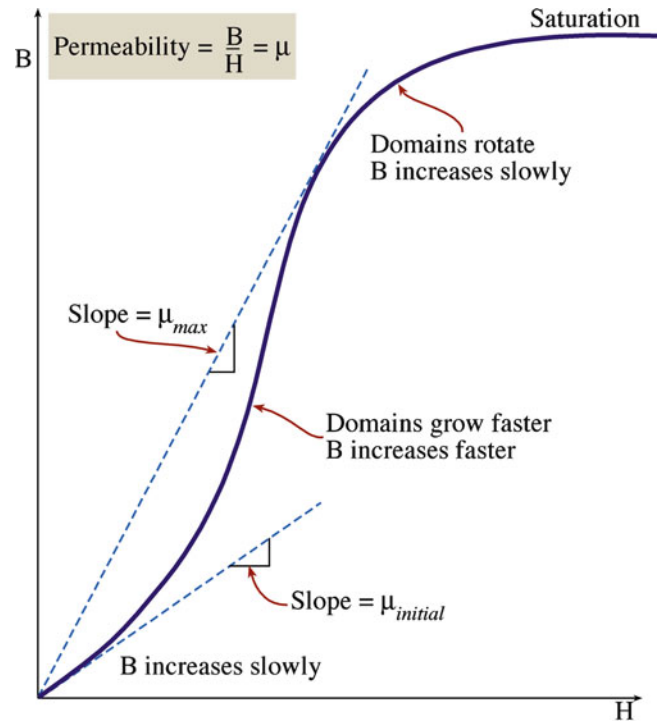

FIGURE 33.21. Effect of H on B . The ratio is μ .

where the magnetization direction is aligned with H grow at the expense of the unaligned domains. The change in B with H is shown in Figure 33.21. Initially, the movement of the domain walls is reversible, and B increases only slightly with increasing H . As the field increases, the favorably oriented domains grow more easily, and μ increases. At very large H , the unaligned domains rotate; and saturation is reached in which all the domains are aligned in the same direction.

When the field is removed, there is resistance to domain wall motion, preventing reorientation of the domains. As a result, there is residual magnetization, known as remanence (B_r), and the material acts as a permanent magnet.

If H is then applied in the opposite direction to that originally used, the domains grow with an alignment in the new direction. A certain field called the coercive field, H_c , is needed to completely randomize the domains. Further increases in H eventually align the domains to saturation in the new direction. The behavior of a ferromagnetic or a ferrimagnetic material in an alternating magnetic field is shown in Figure 33.22. The size of the hysteresis loop (i.e., the values of B_r and H_c) vary from material to material.

- When H_c is small (typically $< 10^3$ A/m), the material is a *soft* magnet.
- When H_c is large (typically $\gg 10^3$ A/m), the material is a *hard* magnet.

Hard and soft do not have any connection to the mechanical properties of the material. There are examples of metals and ceramics that exhibit hard and soft behavior.

FIGURE 33.22. Variation of B as H alternates. Insets. Domain structure at various points along the hysteresis curve.

33.16 HARD AND SOFT FERRITES

The important ferrimagnetic ceramics form three groups depending on their crystal structures, as summarized in Table 33.8. When we are considering possible applications, it is more useful, at least to the engineers who are designing and building magnetic components, to specify the materials as hard or soft. These designations, as we mentioned in Section 33.15, are based on the size of the B - H hysteresis loop (i.e., on the difficulty in reversing the direction of magnetization for the material). Hysteresis loops for hard and soft magnetic materials are compared in Figure 33.23.

Convention: Magnetic oxides that contain Fe^{3+} ions are called ferrites. This terminology does not distinguish

TABLE 33.8 Classes of Magnetic Ceramic		
Structure	Composition	Applications

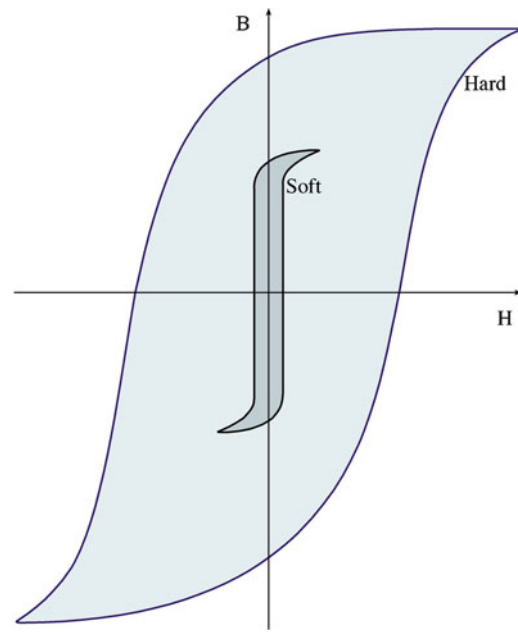

FIGURE 33.23. Comparison of the size and shape of hysteresis loops for hard and soft magnets.

between the crystal structures; don't confuse it with the chemical name. We often say that ferrites contain Fe_2O_3 as a principal component.

33.16.1 Hard Ferrites

Hard ferrites, which are used to fabricate permanent magnets, must have large:

- H_c
- B_r

To satisfy these requirements, it is necessary to use materials with crystal structures that exhibit a large magnetic anisotropy and to prevent the growth and rotation of magnetic domains (by, for example, controlling the grain size so that each grain becomes a single domain). Barium ferrite and oxides with the magnetoplumbite structure are the preferred choice.

Philips introduced ferrite magnets commercially in 1952 under the trade name Ferroxdure. About 550,000 t of hard ferrites are produced annually (>95% of the hard magnet market). This is more than metallic magnets. There are a number of reasons why ferrite magnets are commercially so important, not least of which is that the raw materials are relatively cheap and widely available and the manufacturing processes are simple.

Hard ferrite magnets are found in:

- Starter motors in automobiles
- Loudspeakers
- Rotors for cycle dynamos

TABLE 33.9 Properties of Several Hard Magnets

Material	Composition (wt%)	B_r (T)	H_c (A-turn.m ⁻¹)	$(BH)_{max}$ (kJ/m ²)	θ_c (°C)	ρ ($\Omega.m$)

Table 33.9 compares some of the important properties of hard ferrites with hard metal alloy magnets (e.g., alnico) and high-energy ($BH \geq 80 \text{ kJ/m}^3$) rare earth magnets (e.g., SmCo₅).

33.16.2 Soft Ferrites

The prime requirement for a soft ferrite is that a high M can be produced using a small H . This means that soft ferrites should have:

- High μ
- Low H_c

Soft ferrites therefore have narrow hysteresis loops. During changes in field direction, the domains are rapidly and easily realigned with the changing magnetic field. Consequently, domain wall motion and/or magnetization rotation must be easy. Domain wall motion is particularly sensitive to the microstructure of the material; and characteristics such as grain size and GB structure, the presence of inclusions or pores within the grains, impurity levels, and stresses all reduce domain wall motion. Porosity is particularly common in many sintered ceramics, and ferrites are certainly no exception. As a result, magnetization rotation plays an important role in reaching B_s . Soft ferrites should also have high electrical resistivities (not a

TABLE 33.10 Properties of Several Soft Magnets

Material	Composition (wt%)	μ_i	B_s (T)	Hysteresis loss/cycle (J/m ³)	ρ ($\Omega.m$)
Iron	99.95Fe	150	2.14	270	1.0×10^{-7}

Ferroxcube A	48MnFe ₂ O ₄ , 52ZnFe ₂ O ₄	1,400	0.33	~ 40	2,000
Ferroxcube B	36NiFe ₂ O ₄ , 64ZnFe ₂ O ₄	650	0.36	~ 35	10^7

problem for most ceramics!) because this limits eddy current losses.

Soft ferrites are generally used in applications where the direction of H is frequently changing, such as high-frequency inductors and transformers and magnetic elements in microwave components. There are plenty of household examples of where soft ferrites are used.

- Magnetic recording and data storage media
- Transformer cores in telephones
- Numerous applications in radios and televisions, such as line transformers, deflection coils, tuners, rod antennas
- Electromagnetic shielding in smartphones

Table 33.10 compares some of the relevant properties of metal and ceramic soft magnets. Spinel ferrites based on the (Mn,Zn,Fe)O₄ system are examples of commercially important soft magnets. The market for soft ferrites is

about 50,000 t per year. These are usually marketed under the trade name Ferroxcube.

Garnets also tend to be soft magnets but are not as widely used as the cubic ferrites: they are more expensive. There was a great deal of interest in the late 1960 and 1970s regarding magnetic garnets for use in bubble memory. A magnetic bubble is a small (ranging from about 0.05 μm up to 10 μm) cylindrical region that has M in the opposite direction to H .

A bubble memory is nonvolatile, which means that once information is stored it remains even when the power is removed (just like current hard drives). Bubble memories used a thin layer (usually about 4 μm) of a magnetic garnet (a typical formulation being $\text{Y}_{2.6}\text{Sm}_{0.4}\text{Ga}_{1.2}\text{Fe}_{3.8}\text{O}_{12}$) deposited by liquid phase epitaxy onto a substrate of gadolinium gallium garnet (GGG). The strain induced by the lattice misfit and differences in coefficient of thermal expansion between the two garnets result in an anisotropic axis normal to the film.

By the mid-1970s, most of the large electronic companies were working on bubble memories, and by the late 1970s there were several commercial products. By the 1980s, the bubble memory market was dead. One of the reasons was the introduction of larger, faster hard drives.

33.17 MICROWAVE FERRITES

When a magnetic field is applied to a spinning electron, it precesses around the field direction in much the same way that a spinning top precesses around the direction of gravitational field. In ferromagnetic and ferrimagnetic materials the electron spins are coupled, and the magnetization vector, M , precesses around the field direction, as shown in Figure 33.24. The interaction between electromagnetic

waves and the precessing spin magnetic moments in the ferrite has been used to make waveguides for microwaves. Microwaves are electromagnetic radiation with frequencies in the range 1–300 GHz ($\lambda = 30 \text{ cm}$ to 3 mm). As they travel along the waveguide, their behavior is modified.

An important example is known as Faraday rotation, which involves rotation of the plane of polarization of a plane wave as it travels through the waveguide. A plane-polarized wave is equivalent to two circularly polarized waves, polarized in opposite senses (i.e., a right-polarized and a left-polarized component). Each component interacts very differently with the precessing spins and encounters different permeabilities, which affect the velocities of the two waves. The left component is retarded relative to the right, causing a clockwise rotation of the plane of polarization.

The most direct application of Faraday rotation is to use waveguides in the same way that polarizers and analyzers are used in light optics: to accept or reject plane polarized waves.

There are several different types of microwave device. Isolators allow transmission of microwave radiation in one direction (they are used to prevent unwanted reflected signals). Gyrotors are used to rotate the plane of polarization. There are other, more complicated devices, such as phase shifters and circulators. Garnets are widely used in microwave engineering because their properties can be tailored for the specific application. A garnet that is currently used in radar phase shifters is $\text{Y}_{2.66}\text{Gd}_{0.34}\text{Fe}_{4.22}\text{Al}_{0.68}\text{Mn}_{0.09}\text{O}_{12}$.

Microwave ferrites are used in radar-absorbing paint, which is used to make planes such as the F-117 Nighthawk and the B-2 Spirit “stealthy.”

33.18 DATA STORAGE AND RECORDING

Magnetic recording is a major technology for electronic information mass storage. Its presence is ubiquitous in audio- and videocassette tapes, floppy disks, computer hard disks, credit cards, etc. The magnetic audio recorder was invented in 1898. Video recorders were first introduced in 1955 primarily for use by broadcasters before they became widely available for commercial use. Now magnetic recording equipment has spread to almost every household, with sales exceeding \$50 billion per year.

Magnetic recording materials such as magnetic tapes and floppy disks are collections of very fine magnetic particles supported on a flexible polymer such as polyethylene terephthalate (PET). The basic features of magnetic recording are illustrated in Figure 33.25. A minute part of the magnetic tape is magnetized by a signal from a magnetic head, and data are stored in a form of the magnetization direction. The properties of the material used for this purpose are quite specific.

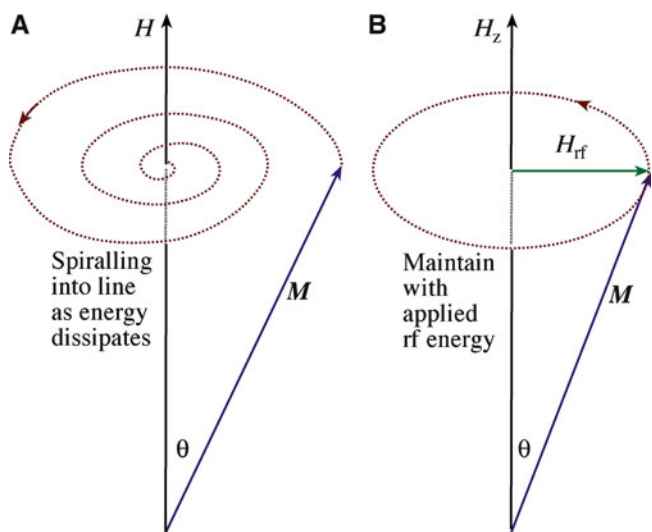

FIGURE 33.24. Precessional motion of magnetization vector.

FIGURE 33.25. Principal features of longitudinal recording.

TABLE 33.11 Physical and Magnetic Properties of Magnetic Particles

Magnetic Particle	Particle Length (μm)	Aspect ratio	Specific surface area (m^2/g)	H_c (kA/m)	B_s (T)	θ_c ($^\circ\text{C}$)
$\gamma\text{-Fe}_2\text{O}_3$	0.3–0.6	10	20–30	20–32	0.5	675
Co- $\gamma\text{-Fe}_2\text{O}_3$	0.3–0.4	10	20–30	30–70	0.5	400
CrO_2	0.2–0.7	10–20	24–40	30–50	0.5	113
Fe (metal)	0.2–0.4	~6	40–50	75–130	2.0	770

- H_c must be high enough to maintain magnetization but sufficiently low to allow stored data to be erased.
- Chemically stable.
- Small ($<1 \mu\text{m}$), uniformly distributed acicular particles.
- Uniform distribution of particles.
- Cheap.

Three types of ceramic particles are currently used as magnetic media: $\gamma\text{-Fe}_2\text{O}_3$, Co- $\gamma\text{-Fe}_2\text{O}_3$, and CrO_2 . Their properties are given in Table 33.11. Iron oxide particles were first used in magnetic recording in the 1930s and now account for 90% of this market. The standard method for making $\gamma\text{-Fe}_2\text{O}_3$ involves dehydrating goethite ($\alpha\text{-FeOH}$) to hematite ($\alpha\text{-Fe}_2\text{O}_3$), followed by reducing the hematite to magnetite (Fe_3O_4), and finally oxidizing the magnetite to maghemite ($\gamma\text{-Fe}_2\text{O}_3$).

Various experimental modifications have been made to the process over the years to produce $\gamma\text{-Fe}_2\text{O}_3$ particles that have the required shape and uniformity for use as magnetic media. The $\gamma\text{-Fe}_2\text{O}_3$ particles typically have lengths in the range 100–700 nm and aspect ratios up to 10. H_c of $\gamma\text{-Fe}_2\text{O}_3$ is at the low end of the useful range for magnetic recording. As a result, it is more useful at recording signals in the low-frequency range. Cobalt-modified $\gamma\text{-Fe}_2\text{O}_3$ particles were developed to increase

H_c . These particles were widely used in audiocassette tapes (before the advent of CDs and iPods) and also on some videocassette tapes. The reason for the higher H_c is not well understood.

The process for producing chromium dioxide (CrO_2) particles for magnetic media was developed by the DuPont Company in the 1960s. Because of the higher uniformity in size and shape of the particles, CrO_2 tends to have a much higher H_c than $\gamma\text{-Fe}_2\text{O}_3$. This makes CrO_2 more suitable for high-density recording. It also has a high M , giving a large range of response and thus high-quality reproduction. The small particle size and the very uniform particle size distribution mean that CrO_2 tapes have much lower noise (less background hiss on audio tapes; less “snow” on video pictures). Chromium dioxide is widely used in tapes for videocassettes and for professional audiotapes. The drawbacks of CrO_2 are:

- Low θ_c
- Toxicity
- Abrasive to some types of recording head
- Magnetic properties degrade slowly with time

The main drawback that prevented its more widespread use in audiotapes is that it is more expensive than $\gamma\text{-Fe}_2\text{O}_3$.

Ferrites can be used to store a considerable amount of information but in many applications are being replaced by optical information storage such as CDs and DVDs.

Magnetic materials are used in the read and write heads of magnetic storage drives. The most significant change since the beginning of this technology and the use of conventional recording heads using magnetic inductance was the introduction of magnetoresistance (MR) and then GMR recording heads. They allowed data to be stored

more densely and read more quickly. GMR is now used in most modern hard drives. Ceramic CMR materials may produce the next big change. In CMR, the resistance does not change by a few percent but by orders of magnitude. Applications

for these materials are being developed.

The use of barium ferrite for high-density recording applications has been investigated because it is chemically stable and can have $H_c \sim 480 \text{ kA/m}$. The hexagonal particles can, in principle, be oriented with their c-axis normal to the tape surface, as shown in Figure 33.26. This is known as a perpendicular medium and can give very high recording densities. Hexagonal ferrites are used in the magnetic strips on credit cards and ATM cards. In these applications, we want the data to be permanent.

MAGHEMITE

The name *maghemite* was first suggested in 1927. It is a combination of the first syllables of *magnetite*, which has the same structure, and *hematite*, which has the same composition.

FIGURE 33.26. Principle of perpendicular recording.

FIGURE 33.27. Virus-induced nano-assembly of magnetic nanoparticles.

33.19 MAGNETIC NANOPARTICLES

Magnetic ceramic nanoparticles are becoming of increasing interest in a number of areas. One of these areas is using them for the location and detection of viruses: a viral nanosensor. The approach is illustrated in Figure 33.27. Iron oxide particles (~50 nm in diameter) with a dextran coating are covered with antibodies. The antibodies are

chosen for a specific virus (e.g., herpes simplex virus or adenovirus). When these specially coated nanoparticles are then exposed to the virus they form clusters that would be large enough to be visible on a nuclear magnetic resonance or magnetic resonance imaging scan. This approach has already been demonstrated in the laboratory using viral particles in solution. The idea is that it might eventually be used to detect viruses in human body fluid or tissue.

CHAPTER SUMMARY

In this chapter, we described the different magnetic properties of ceramics. Most ceramics are diamagnetic, a very weak and commercially unimportant property. The most important magnetic properties of ceramics arise because of the presence of unpaired electron spins, primarily in the 3d orbitals of Fe. Ferrites, a class of magnetic ceramics containing Fe_2O_3 , are used in a wide variety of applications, and their production constitutes a multibillion dollar industry. Ferrites can be classified according to their structure, and there are three structural types: spinel or cubic ferrites, garnets, hexagonal ferrites. The cubic ferrites, of which $\gamma\text{-Fe}_2\text{O}_3$ (maghemite) is the most ubiquitous example, are soft magnetic materials, and hence the direction of magnetization

(continued)

CHAPTER SUMMARY (*continued*)

can be changed relatively easily in an alternating magnetic field. Maghemite was used extensively in audiotapes and floppy disks (which have now largely been replaced by iPods and CDs). The magnetic garnets are used in microwave applications, including as ingredients on radar-absorbing paint for stealthy airplanes. The hexagonal ferrites (e.g., $\text{BaO} \cdot 6\text{Fe}_2\text{O}_3$) are hard, or permanent, magnetic materials. They are more difficult to demagnetize. Barium hexaferrite is used in many applications, from small electric motors in automobiles, to the magnetic seal on a refrigerator, to the magnetic strip on your credit card. Manganates, which have the technologically important layered perovskite structure, exhibit a property called colossal magnetoresistance and offer potential in a number of technologies from read/write heads in magnetic recording, sensors, and spin-polarized electronics.

PEOPLE AND HISTORY

Bitter, Francis (1902–1967) was born in Weehawken, NJ. In 1931, he discovered a method for visualizing magnetic domains. In 1934, he joined the Department of Mining and Metallurgy at MIT (where he spent most of his career) and helped establish a high field magnet laboratory. During World War II, he worked in England on methods to demagnetize German mines in the English Channel. His work after the war led to the establishment of the National Magnet Laboratory, which after his death was renamed the Francis Bitter National Magnet Laboratory.

Bloch, Felix (1905–1983) was born in Zurich, Switzerland. He received his Ph.D. in 1928 from the University of Leipzig, where he worked with Heisenberg. Upon Hitler's rise to power, Bloch left Europe and came to the United States, where he accepted a position at Stanford University. He was awarded the 1952 Nobel Prize in Physics for the development of the NMR technique.

Curie, Pierre (1859–1906) was born in Paris. In 1895, he obtained his Doctor of Science degree and was appointed Professor of Physics at the Sorbonne. In his early studies on crystallography, together with his brother Jacques, he discovered the piezoelectric effect. Later, he turned his attention to magnetism and showed that the magnetic properties of a given substance change at a certain temperature (the Curie temperature). He was awarded the Nobel Prize in Physics in 1903 (together with his wife Marie) for their work in radioactivity. On April 19, 1906 he was killed in a street accident in Paris.

Josephson, Brian David (1940–) was born in Cardiff, Wales. He discovered the Josephson effect while a 22-year-old graduate student at the University of Cambridge. He won the Nobel Prize in Physics in 1973 for his discovery.

Lenz (pronounced *lents*), *Heinrich Friedrich Emil* (1804–1865) was born in Dorpat, Russian Empire (now Tartu, Estonia) and formulated his eponymous law of electromagnetism in 1833. He participated in a round-the-world expedition in 1823–1826 and made extremely accurate measurements of the properties of seawater.

London, Fritz (1900–1954) was born in Breslau, Germany (now Wroclaw, Poland). He fled Nazi Germany in 1933 and came to the United States in 1939, where he became naturalized in 1945. Together with his younger brother Heinz, he formulated the London equations of superconductivity.

Meissner, Walter and his graduate student *Robert Ochsenfeld*, both Germans working in Berlin, discovered in 1933 that a superconducting material repels a magnetic field—behaving as a perfect diamagnet. The effect became known as the Meissner (or Meissner-Ochsenfeld) effect.

Oersted, Hans Christian (1777–1851) was a Danish physicist and philosopher. He demonstrated the fundamental relationship between electricity and magnetism on July 21, 1820 during a lecture on electricity at the University of Copenhagen. He showed that a compass needle is deflected when a wire carrying an electric current is placed near it. In addition to his work in electricity and magnetism, Oersted was the first to prepare pure metallic aluminum (1825).

Weiss, Pierre Ernest (1865–1940) was born in Mulhouse in the Alsace region of eastern France. He proposed the domain theory of ferromagnetism in 1907 while working at the Polytechnic Institute in Zurich.

Giant magnetoresistance was discovered in 1988. *Colossal magnetoresistance* was discovered in 1993.

EXERCISES

- 33.1 Diamagnetism is present in all materials. Why do we not usually need to consider its contribution when we determine χ for a paramagnetic material using a Gouy balance?
- 33.2 You are given a sample of a ceramic powder that you believe to be paramagnetic. You have access to a Gouy balance. Explain how you would determine χ for your powder and what possible sources of error there might be.

- 33.3 In Section 33.4 we said that there are two general categories of magnetic behavior. Assign each of the five main types of magnetic response—diamagnetism, paramagnetism, ferromagnetism, antiferromagnetism, ferrimagnetism—into one of the two categories. Explain briefly how you arrived at your assignments.
- 33.4 Al_2O_3 , BeO, diamond, MgO, NaCl, and Si are all diamagnetic. Explain this observation.
- 33.5 You perform experiments using a Gouy balance on sintered rods of Al_2O_3 , BeO, CeO_2 , and TiO_2 . What sign would you expect to obtain for χ for each material? Would you get a different result if you replaced the oxide with its corresponding metal?
- 33.6 How would the magnetic properties of magnetite change if it were a normal spinel?
- 33.7 Sketch the position of the atoms in the perovskite unit cell that you would expect for the colossal magnetoresistant (CMR) compound $\text{La}_{0.5}\text{Ca}_{0.5}\text{MnO}_3$.
- 33.8 Compounds in the $\text{La}_{1-x}\text{A}_x\text{MnO}_3$ system contain both Mn^{3+} and Mn^{4+} ions and are collectively called “manganites.” Is the use of this term correct scientific usage? Briefly explain your answer.
- 33.9 Liquid phase epitaxy (LPE) was used to form thin garnet films for magnetic bubble memories. Describe the basic principles behind this technique. Would sputtering or evaporation be good alternative techniques for such films? Explain how you arrived at your answer.
- 33.10 Compare the energy and width of domain boundaries with values for grain boundaries. Based on the values you obtain, discuss the relative ease of movement of the two types of boundary.
- 33.11 We make a statement about finding examples of each type of magnetic material in ceramics in Section 33.4. Give two such examples for each type.
- 33.12 In Table 33.5, Cr_2O_3 has a particularly large value. How has this property been used commercially?
- 33.13 What is the origin of the London penetration depth? Does it have any implication, positive or otherwise, for magnetic ceramics?
- 33.14 Explain to a nonscientist the meaning of magnetic susceptibility of a diamagnetic ceramic and why it is larger for NaCl than for LiF.
- 33.15 Explain to a nonscientist the meaning of magnetic permeability and compare numerical values for several different ceramic materials.
- 33.16 Colossal magnetoresistance is a topic of much current interest. Why is this so? How does it relate to ceramics, and why do we say “colossal”?
- 33.17 Explain how the image in Figure 33.18 was produced. How do we know that the lines labeled “domain walls” are such?
- 33.18 Explain how the image in Figure 33.19 was produced and what it tells you about the material.
- 33.19 Explain in words why the curves in Figure 33.23 have been labeled “hard” and “soft” and put typical values on the B and H axes (with correct units).
- 33.20 Magnetic nanoparticles are mentioned in Section 33.19. What is the state of the art? Discuss.

Responding to Temperature Changes

CHAPTER PREVIEW

Heat is essentially the vibration of atoms in a material. Consequently, thermal properties reflect the type and strength of interatomic bonding and the crystal structure. The important thermal properties of any material are:

- Heat capacity
- Coefficient of thermal expansion
- Thermal conductivity

Thermal properties of ceramics differ from those of metals whenever the presence of free (conduction) electrons is involved, such as in thermal conductivity. However, heat transfer by phonon (lattice vibration) transport can in some cases be more effective than through the movement of electrons. We describe melting and vaporization of ceramics, as the temperatures for these transformations tends to be high. This can be critical in certain applications, such as the tiles on the space shuttle, but presents problems during processing. It should also be obvious by now that heat affects many of the properties of ceramics, such as Young's modulus, electrical conductivity, magnetic behavior, and dielectric constant. There are major applications that utilize the varied thermal properties of ceramics: from high thermal conductivity substrates for electronic packaging to enormous mirror blanks for telescopes that have "zero" expansion.

34.1 SUMMARY OF TERMS AND UNITS

Table 34.1 lists the important parameters we meet in this chapter and their units. The SI unit of temperature is kelvin (K), but as you have realized by now °C is often used in presenting data in materials science. As we mentioned in Chapter 1, the numerical value of a temperature difference or temperature interval expressed in °C is equal to the numerical value of the same temperature difference or interval when expressed in K. This point is worth remembering when you compare coefficients of thermal expansion or thermal conductivities for different materials.

34.2 ABSORPTION AND HEAT CAPACITY

When a solid absorbs an amount of heat, dq , its internal energy, E , rises by an amount dE where:

$$dE = dq \quad (34.1)$$

The increase in internal energy is largely due to the increased vibrational amplitude of the atoms about their equilibrium positions. This vibrational motion represents

the thermal energy of the solid. There are other mechanisms for heat absorption, but they are either negligible or absent entirely. However, we list them here and very briefly describe them because they relate to some concepts that have been described in earlier chapters, such as point defects.

- *Rotational*—This is important in liquids and gases where the molecules are free to rotate, but this contribution is negligible in solids.
- *Electronic*—Absorption by conduction electrons is very small, but it can be used to provide information about the electronic structure of a solid—so from that point of view it is useful.
- *Defect formation*—Formation of Frenkel and Schottky defects can contribute usually only at high temperatures.
- *Phase transformation*—This is absorption by structural, magnetic, and ferroelectric transformation in certain materials.

Heat capacity is a measure of the amount of energy required to raise the temperature of a material. At room temperature, the specific heat capacity of many ceramics is 0.75–1.0 J g⁻¹ K⁻¹. For example, granite (an igneous silicate rock) has a specific heat capacity of 0.79 J g⁻¹ K⁻¹

TABLE 34.1 Summary of Terms Used to Describe the Thermal Properties of Materials

Definition	Units/value
α Linear coefficient of thermal expansion	$^{\circ}\text{C}^{-1}$ or K^{-1}
C_v Heat capacity at constant volume	J/K
c_v Molar heat capacity at constant volume	$\text{Jmol}^{-1}\text{K}^{-1}$
C_p Heat capacity at constant pressure	J/K
c_p Molar heat capacity at constant pressure	$\text{Jmol}^{-1}\text{K}^{-1}$
ΔS_f Entropy of fusion	$\text{Jmol}^{-1}\text{K}^{-1}$ or $\text{Jg}\cdot\text{atom}^{-1}\text{K}^{-1}$
ΔS_v Entropy of vaporization	$\text{Jmol}^{-1}\text{K}^{-1}$ or $\text{Jg}\cdot\text{atom}^{-1}\text{K}^{-1}$
k Thermal conductivity	$\text{Wm}^{-1}\text{K}^{-1}$
T_b Boiling temperature	$^{\circ}\text{C}$ or K
T_m Melting temperature	$^{\circ}\text{C}$ or K
R_{TS} Thermal shock resistance	W/m
θ_D Debye temperature	$^{\circ}\text{C}$ or K
R Gas constant	$8.314 \text{ Jmol}^{-1}\text{K}^{-1}$

at 25°C , which means that it takes about 0.8 J of energy to raise the temperature of 1 g of granite by 1 K. Water has a specific heat capacity of $4.184 \text{ J g}^{-1} \text{ K}^{-1}$ at 25°C , a value that is more than five times greater than that of granite. This difference is crucial in regulating the earth's temperature. It takes five times more energy to increase the temperature of water by 1 K than it does to increase the temperature of granite. If the earth's surface were composed entirely of rock (i.e., there were no oceans) then daytime temperatures would be extremely high. The oceans also help limit the temperature drop at night because they have absorbed more energy during the day, which is released at night. If the earth had no oceans, temperature swings between day and night would be very large.

When referring to heat capacity, and in particular when you consult various other sources, it is necessary to be a little bit careful about terminology. Here are the definitions of all the terms you're likely to meet.

- **Heat capacity.** The amount of heat required to change the temperature of an object by one kelvin. The units of heat capacity are J/K.
- **Specific heat capacity.** The amount of heat required to change the temperature of 1 g of a substance by 1 K. The units of specific heat capacity are $\text{Jg}^{-1} \text{ K}^{-1}$.
- **Molar heat capacity.** The amount of heat required to change the temperature of 1 mol of a substance by 1 K. The units of molar heat capacity are $\text{Jmol}^{-1} \text{ K}^{-1}$.

In the literature you find that "heat capacity" is often used to describe all three terms, but it is usually obvious from the units given what term is actually

HEAT CAPACITY

For most ceramics heat capacity reaches $3nR$ by $1,000^{\circ}\text{C}$; n is the number of atoms per formula unit.

FIGURE 34.1. Heat capacity of some ceramics as a function of temperature.

the correct one to use. The next term is really the confusing one. Fortunately, it is not used now but it does occur from time to time in some of the older literature, so beware.

- **Specific heat.** The ratio of the heat capacity of a substance to the heat capacity of water. This term is a unitless ratio and was used when the heat capacity of water was unity. In the SI system of units, the heat capacity of water is not 1.

Heat capacities of solids are always functions of temperature, as illustrated for several ceramics in Figure 34.1. Note that the units are $\text{J}\cdot\text{g}\cdot\text{atom}^{-1} \text{ K}^{-1}$. At absolute zero, the internal energy of a solid is minimum, and the heat capacity is zero. As the temperature is raised, the heat capacity increases and is indicative of the various mechanisms by which energy is absorbed. The heat capacity approaches a classical limit of $3R$ ($\sim 25 \text{ Jmol}^{-1} \text{ K}^{-1}$) at a sufficiently high temperature that differs from one solid to another. This limit is the Dulong-Petit law. The crystal structure and composition of a material do not appreciably affect heat capacity, but n does: for example, c_p is $3R$ for Cu but $6R$ for MgO.

The temperature at which the heat capacity becomes constant, or only slightly varying with temperature, is the Debye temperature, θ . Values of θ are typically in the range $T_m/5$ – $T_m/2$ and depend on:

- Bond strength
- \mathcal{E}
- T_m

For example, in diamond, where the covalent bonds are very strong, θ is $\sim 2,000 \text{ K}$. On the other hand, the value of θ_D for NaCl is 281 K .

Abrupt changes in heat capacity are observed over a narrow temperature range when a material undergoes a structural transformation or some

FIGURE 34.2. Heat capacity of SiO₂ as a function of temperature.

other change in order. The example shown in Figure 34.2 is for quartz (a polymorph of SiO₂), which undergoes a displacive $\alpha - \beta$ phase transformation at 573°C. Similar changes in heat capacity occur in glasses at the glass transition temperature, T_g , because of the increase in configurational entropy in the liquid. Anomalous heat capacities are also associated with the alignment of magnetic dipoles in ferromagnetic materials and the alignment of electric dipoles in ferroelectrics.

The heat capacity of a material can be calculated, depending on the temperature range of interest, using one of two equations. At very low (cryogenic) temperatures:

$$c_p \cong c_v = K \left(\frac{T}{\theta_D} \right)^3 + \gamma T \quad (34.2)$$

where K is a constant equal to $1,940 \text{ J mol}^{-1} \text{ K}^{-1}$, and γ is the electronic heat capacity coefficient. Values of θ_D and γ are tabulated in several lists of thermodynamics properties. These values are generally widely available for metals but somewhat more obscure for most ceramics. The overall contribution of equation 34.2 to the heat capacity of a material is small and is really of importance only if you wish to obtain a fundamental understanding about the nature of a material or if you are designing systems to operate at cryogenic temperatures.

At high temperature (usually above room temperature), heat capacities can be calculated using the empirical relation:

$$c = a + bT + cT^{-2} \text{ J mol}^{-1} \text{ K}^{-1} \quad (34.3)$$

where a , b , and c are “constants” that have been tabulated for a wide range of materials.

34.3 MELTING

One of the very useful properties of many ceramics is their high T_m , as shown in Table 34.2. This property makes ceramics without equal for application at high temperature, such as refractories and thermal barrier coatings. There is a direct correlation between T_m and bond strengths. Also, ceramics with the highest values of T_m tend to have a significant fraction of covalent character to their bonding, as shown in Table 34.3; this table is calculated using equation 4.24 and values of Pauling electronegativities given in Figure 3.4. However, T_m does not correlate directly with the fraction of covalent character of the bond or the ionic potential (ϕ) of the cation, as shown for the oxides of the alkaline earth elements in Table 34.4, which are calculated in the same manner. (The values of ionic radii are given in Table 4.6.)

Compounds with very high fractions of ionic character to their bonds (e.g., alkali halides NaCl and LiF) tend to have lower values of T_m than their corresponding oxides. The reason is the greater ionic charges (e.g., O^{2-} rather than Cl^-) involved, and hence the stronger electrostatic attraction. We can illustrate this point for the two compounds Li₂O and LiF. Bond energies for ionic compounds can be obtained using equation 34.1 (this is simply the Born-Landé equation given in Chapter 4 written for a single bond).

$$E_{\text{bond}} = \frac{Z_1 Z_2 e^2}{4\pi\epsilon_0 r_0} \left(1 - \frac{1}{n} \right) \quad (34.4)$$

For Li₂O we have $r_{\text{Li}^+} = 0.068 \text{ nm}$ and $r_{\text{O}^{2-}} = 0.140 \text{ nm}$, so $r_0 = 0.208 \text{ nm}$. Taking $n = 10$ and substituting into equation 34.4, we get a value of $E_{\text{bond}} = 1.997 \times 10^{-18} \text{ J}$.

For LiF we have $r_{\text{Li}^+} = 0.068 \text{ nm}$ and $r_{\text{F}^-} = 0.133 \text{ nm}$, so $r_0 = 0.201 \text{ nm}$. Taking $n = 10$ and substituting into equation 34.4, we get a value of $E_{\text{bond}} = 1.033 \times 10^{-18} \text{ J}$.

So we would expect Li₂O to have a higher T_m than LiF; and if you look at Table 34.2, you’ll see that for Li₂O $T_m = 1,570^\circ\text{C}$ whereas that for LiF $T_m = 848^\circ\text{C}$.

The entropy difference between the solid and the liquid at T_m is:

$$\Delta S_f = \frac{\Delta H_f}{T_m} \quad (34.5)$$

Values of ΔS_f are shown in Table 34.2. They are positive because the liquid is always more disordered than the solid, but they vary considerably from the empirical prediction known as Richard’s rule. Richard’s rule holds fairly well for many elements (e.g., Au, Ti, Pb, Na, K, B) but not for compounds.

TABLE 34.2 T_m and ΔS_f for Selected Ceramics

<i>Compound</i>	T_m (°C)	ΔS_f (Jmol ⁻¹ °C ⁻¹)	<i>Compound</i>	T_m (°C)	ΔS_f (Jmol ⁻¹ °C ⁻¹)

We can consolidate the values in Table 34.2 with Richard's rule by considering the processes involved when a compound, AB , melts. Overall melting reaction:

This reaction can be broken down into two steps. First,

$$\frac{1}{x+y}A_xB_y(s) = \frac{1}{x+y}A_xB_y(l) \quad (34.7)$$

which gives ΔS_2 and corresponds to a hypothetical melting process where the compound retains its ordered structure in the liquid phase. This step is followed by:

which gives $\Delta S_3 = \Delta S_m$ and represents disordering of the compound in the liquid to form a random solution. For this latter step, the entropy change is given by the "entropy of mixing," which is:

$$\Delta S_m = -R[X_A \ln X_A + X_B \ln X_B] \quad (34.9)$$

where X_A and X_B are the atom fractions of A and B, respectively. For our particular example, we can write the entropy of mixing as:

$$\Delta S_3^0 = -R \left[\frac{x}{x+y} \ln \left(\frac{x}{x+y} \right) + \frac{y}{x+y} \ln \left(\frac{y}{x+y} \right) \right] \quad (34.10)$$

The entropies associated with each of the melting reactions given above are related as follows.

$$\Delta S_1 = \Delta S_2 + \Delta S_3 \quad (34.11)$$

We now apply this approach to a real compound, MgO.

The entropy of fusion for MgO, given in Table 34.2, is $\Delta S_f = 12.9 \text{ J g-atom}^{-1}\text{C}^{-1}$ (i.e., $\Delta S_1 = 12.9 \text{ J g-atom}^{-1}\text{C}^{-1}$). The entropy of mixing, ΔS_3 , can be calculated from equation 34.7 as:

$$\Delta S_3^0 = -8.314 \left[\frac{1}{2} \ln \left(\frac{1}{2} \right) + \frac{1}{2} \ln \left(\frac{1}{2} \right) \right]$$

$$= -8.314 \ln \left(\frac{1}{2} \right) = 5.76 \text{ Jg.atom}^{-1}\text{K}^{-1} \quad (34.12)$$

which, using equation 34.11, gives the entropy for the hypothetical melting reaction of $7.14 \text{ J g-atom}^{-1}\text{C}^{-1}$. This value, which is closer to Richard's rule, does not consider a mixing contribution but only the vibrational change on melting such as occurs for an element. By assuming that, we can apply Richard's rule as shown above that it is possible to determine ΔS_1 (ΔS_f) where such values are not available in the literature and hence obtain ΔH_f .

RICHARD'S RULE
 $\Delta S_f = 8.4 \text{ J g.atom}^{-1} \text{K}^{-1}$

34.4 VAPORIZATION

Most ceramics have very high T_b . Consequently, their vapor pressures are negligible at room temperature and become appreciable only at high temperature. Also, very few ceramics vaporize without molecular change. The result is that the vapor composition is usually not the same as that of the original liquid or solid. A practical consequence is that when we try to grow ceramic thin films by evaporation as described in Chapter 28, the film may have a different stoichiometry than that of the source. Some of the phenomena that can occur when compounds evaporate are shown in Table 34.5.

In many multicomponent oxide ceramics, the vapor pressure of each component may be different. This effect is particularly noticeable in lead-containing compounds, such as lead zirconium titanate (PZT), an important piezoelectric ceramic. PZT contains PbO, ZrO₂, and TiO₂ in the form of a solid solution. PbO is significantly more volatile than the other two oxides (Table 34.6). As a result, if PZT films are heated during processing, significant Pb loss can occur, leading to a change in film stoichiometry and dramatically different properties. If Pb loss is to be avoided, special precautions must be taken. For example, we can compensate for Pb loss by making our starting films Pb-rich.

34.5 THERMAL CONDUCTIVITY

At all temperatures, the atoms in a solid are vibrating about their equilibrium positions with a set of characteristic frequencies, ν , with values as high as 10^{12} Hz at room temperature. The energies of the lattice vibrations are quantized and given by:

$$E = \left(n + \frac{1}{2} \right) h\nu \quad (34.13)$$

TABLE 34.5 Possible Reactions During the Evaporation of Compounds

Reaction type	Chemical reaction	Examples	Comments
Evaporation without dissociation	$\text{MX}(s \text{ or } l) \rightarrow \text{MX}(g)$	SiO, B ₂ O ₃ GeO, SnO, AlN CaF ₂ , MgF ₂	Compound stoichiometry maintained in deposit

TiO ₂	1,640	~1,300
ZrO ₂	2,700	~2,200

where n is an integer, which is zero at 0 K; and h is Planck's constant. At absolute zero, the atoms have $E = hv/2$: the zero point energy. If the solid is heated, E increases in integer steps of hv ; and, similarly, if the solid is cooled, the vibrational energy decreased in steps of hv . You can see immediately that there is a similarity between this process and the absorption or emission of light (*photons*). Thus, the name *phonon* is used as the quantum unit of lattice vibrational energy.

Wave-particle duality applies equally to phonons as it does to photons. Thus, phonons possess the characteristics of both waves and particles. In ceramics, the conduction of heat is primarily due to the movement of phonons. When a ceramic is heated, we can think in terms of an increase in the number of phonons. When there is a temperature difference, phonons move from the high temperature end, where their concentration is high, to the lower temperature end, where they are fewer. The driving force is the concentration gradient, just as it is in the diffusion of matter. The rate of heat flow, dq/dt , is

proportional to the temperature gradient, dT/dx , where the constant of proportionality is the thermal conductivity, k .

$$\frac{dq}{dt} = -kA \frac{dT}{dx} \quad (34.14)$$

where A is the cross-sectional area normal to the direction of heat flow.

Thermal conductivity depends on three factors:

- Heat capacity C
- Average particle velocity, v
- Mean free path of a particle between collisions, l

From the kinetic theory of gases, the thermal conductivity of an ideal gas is:

$$k = \frac{1}{3}Cvl \quad (34.15)$$

Debye (in 1914) applied equation 34.15 to phonon conduction to describe thermal conductivity in dielectric solids. Then, C is the heat capacity of the phonons, v is the phonon velocity, and l is the phonon mean free path.

Phonon conduction in ceramics is very different to that found in metals, where the free electrons are the source of the thermal conductivity. The mobility of phonons is usually significantly lower than that of electrons because they are scattered by lattice vibrations (i.e., other phonons). Consequently, ceramics generally

VIBRATIONAL AMPLITUDES

In a solid may be as large as 0.02–0.03 nm.

v AND l FOR ELECTRONS AND PHONONS

For electrons in a metal at room temperature, $v \sim 10^6$ m/s and $l \sim 10$ nm.

For phonons in a ceramic at room temperature, $v \sim 10^3$ m/s and $l \sim 1$ –4 nm.

Phonon mean free path greatly increases with decreasing temperature; it's ~ 10 μm at 20 K.

TABLE 34.7 Thermal Conductivity of Some Ceramics

Material	k ($W m^{-1} K^{-1}$)	Material	k ($W m^{-1} K^{-1}$)
Al_2O_3	30.0–5.0	Spinel ($MgAl_2O_4$)	12.0
AlN	200.0–280.0	Soda-lime-silicate glass	1.7

SiO ₂	1.4	Si ₃ N ₄	25.0
Cordierite (Mg-aluminosilicate)	4.0	Forsterite	3.0

have low thermal conductivities. However, the phonon mechanism can be very effective, and it is often a surprise to realize that the thermal conductivity of some ceramics is actually higher than that of metals! At temperatures above ~50 K, diamond has the highest thermal conductivity of any known material. The thermal conductivity of gem-quality diamond is in the range 2,000–2,500 $Wm^{-1} K^{-1}$ at room temperature, whereas that of copper is 400 $Wm^{-1} K^{-1}$. Values for the room temperature thermal conductivity of some selected ceramics are given in Table 34.7.

Ceramics having high thermal conductivities generally share the following characteristics.

- Strong interatomic bonding
- Simple crystal structure
- Comprised of light elements that are close together in the periodic table

From Table 34.7 you can see that BeO and AlN are examples of ceramics with high thermal conductivity, and both of these materials satisfy the conditions given above.

Figure 34.3 shows the thermal conductivity of single-crystal alumina as a function of temperature. At very low temperatures, the mean free path, l , of the phonons becomes comparable to the size of the specimen, and k depends mainly on the heat capacity, which increases as T^3 . The thermal conductivity reaches a maximum at some low temperature (~40 K in this case). As the temperature increases, k decreases because there are more phonons around to collide with and more chances of a scattering event taking place. The interactions between phonons was first described by Rudolf Peierls (1929), who identified two types of scattering processes.

- Umklapp (from the German *umklappen*, which means “flipping over”)
- Normal

The normal process has no effect on the thermal resistance. On the other hand, the umklapp process leads to an increase in thermal resistance with temperature given by:

FIGURE 34.3. Thermal conductivity of single-crystal aluminum oxide over a wide temperature range.

FIGURE 34.4. Inverse phonon mean free paths for several crystalline oxides and vitreous silica.

$$l \propto \frac{1}{T} \tag{34.16}$$

Eventually, l decreases to a value close to the interplanar spacing; and k , due to phonon transport, becomes temperature-independent. The temperature variation of l for several ceramics is shown in Figure 34.4.

At high temperatures, part of the thermal energy may also be transferred by radiation. The radiant energy conductivity, k_r , is given by:

$$k_r = \frac{16}{3} \sigma n^2 T^3 l_r \tag{34.17}$$

σ is the Stefan-Boltzmann constant, n is the refractive index, and l_r is the mean free path of the photons responsible for radiant heat transfer.

Some single crystals and glasses have good transparency in the visible and infrared (IR) parts of the electromagnetic spectrum, and l_r can become large. In most polycrystalline ceramics, l_r is very short because of absorption and scattering, mainly due to the presence of pores. For opaque materials, $l_r \sim 0$, and radiation transfer is negligible except at very high temperatures.

At the other extreme, when l_r is very large, there is no interaction with the material; and radiation heat transfer becomes a surface effect. The contribution of k_r to the overall thermal conductivity becomes significant only when l_r is small compared with the sample size but large compared with atomic dimensions.

In ceramics with mobile electrons or holes, there is a third mechanism that can contribute to the thermal conductivity. The electronic thermal conductivity k_e is:

$$k_e \propto \exp\left(-\frac{E_g}{kT}\right) \quad (34.18)$$

where E_g is the band gap energy, and k is Boltzmann's constant.

In most ceramics, the electronic contribution to the overall thermal conductivity is negligible. However, it can be significant in electrically conducting and semiconducting ceramics, such as SiC, TiC, and graphite.

34.6 MEASURING THERMAL CONDUCTIVITY

There are several methods available to measure k , but no single one is appropriate for all ceramics because of their wide range of thermal conductivities. The laser flash method, illustrated in Figure 34.5, is one of the most

FIGURE 34.5. Laser flash method used for measuring thermal conductivity of ceramics.

popular. In this technique, a laser pulse is used to rapidly heat one face of the ceramic, which is in the form of a thin plate. A typical laser would be a Nd:glass laser producing radiation with $\lambda \sim 1,060$ nm. The energy of each laser pulse is ~ 15 J. An IR detector measures the temperature of the face remote from the laser. The time taken for the peak in the temperature profile to reach the remote face of the sample and the reduction in the peak temperature are measured. These measurements provide us with the thermal diffusivity, D_{th} , and the heat capacity, c_p . If the density, ρ , of the ceramic is known, then k can be obtained using:

$$k = \rho c_p D_{th} \quad (34.19)$$

The measurements can be performed at room temperature or at a range of higher temperatures by enclosing the sample in a furnace.

34.7 MICROSTRUCTURE AND THERMAL CONDUCTIVITY

As we mentioned in Chapter 1, thermal conductivity depends on microstructure. Anything that changes the local atomic arrangement or induces elastic strains in the lattice decreases k .

- **Impurities.** The presence of impurities disrupts the normal lattice arrangement. As temperature increases, the effect of the impurity becomes less because l approaches the dimensions of the unit cell. The effect on k is illustrated for solid solutions in the isomorphous system MgO–NiO in Figure 34.6.
- **Porosity.** The thermal conductivity of air is only $0.026 \text{ Wm}^{-1} \text{ K}^{-1}$, significantly less than most crystalline ceramics. Consequently, ceramics containing a high volume fraction of porosity have low values of k . This property is used to good effect in designing materials for thermal insulation, such as the tiles used on the outside of the space shuttle to protect it during reentry into the earth's atmosphere. The tiles consist of a porous mat of SiO_2 fibers, as we showed earlier in Figure 15.19. The SiO_2 provides the high strength and high melting temperature requirements of the tile, and the porous microstructure ensures a very low k .
- **Grain size.** The mean free path of phonons at room temperature is significantly smaller than typical grain sizes in ceramics. As a result, the phonon scattering at grain boundaries is not important in reducing k in most practical applications. Figure 34.7 shows the temperature dependence of k for CaF_2 , TiO_2 , and Al_2O_3 in single crystalline and polycrystalline form. The deviation in the relative thermal conductivities at higher temperatures is due to the contribution from photon conductivity.

- Dislocations.** A dislocation consists of a core where the structure and density of the material is altered. Around the core there is a long-range strain field. Both these regions can cause phonon scattering.

$l \sim 3 \text{ nm}$ at 200°C
 $l \sim 0.6 \text{ nm}$ at $1,000^\circ\text{C}$
 $a_{\text{MgO}} = 0.421 \text{ nm}$

MgO

The thermal resistance associated with dislocations is proportional to the dislocation density. There is no theory that so far accounts entirely satisfactorily for

the magnitude of phonon scattering by dislocations. If you want to delve into some of the theories that have been proposed, much of the original work has been discussed by Nabarro (1987).

Most practical ceramics are multiphase materials, where each constituent, in general, has a different k . The value of k for the heterogeneous material is dependent on the amount and distribution of the different phases.

There are three idealized kinds of phase distribution where equations have been derived to estimate k of the bulk material; they are illustrated in Figure 34.8, with examples summarized in Table 34.8.

For parallel slabs with heat flow parallel to the phase boundary:

$$k_m = V_1 k_1 + V_2 k_2 \quad (34.20)$$

where V_1 and V_2 are the volume fractions of the two phases.

For parallel slabs with heat flow perpendicular to the phase boundary:

$$k_m = \frac{k_1 k_2}{V_1 k_2 + V_2 k_1} \quad (34.21)$$

For a continuous major phase:

$$k_m = k_c \left[\frac{1 + 2V_d \left(1 - \frac{k_c}{k_d}\right) / \left(2\frac{k_c}{k_d} + 1\right)}{1 - V_d \left(1 - \frac{k_c}{k_d}\right) / \left(\frac{k_c}{k_d} + 1\right)} \right] \quad (34.22)$$

where k_c is the thermal conductivity of the continuous phase, k_d is the thermal conductivity of the dispersed phase, and V_d is the volume fraction of the dispersed phase.

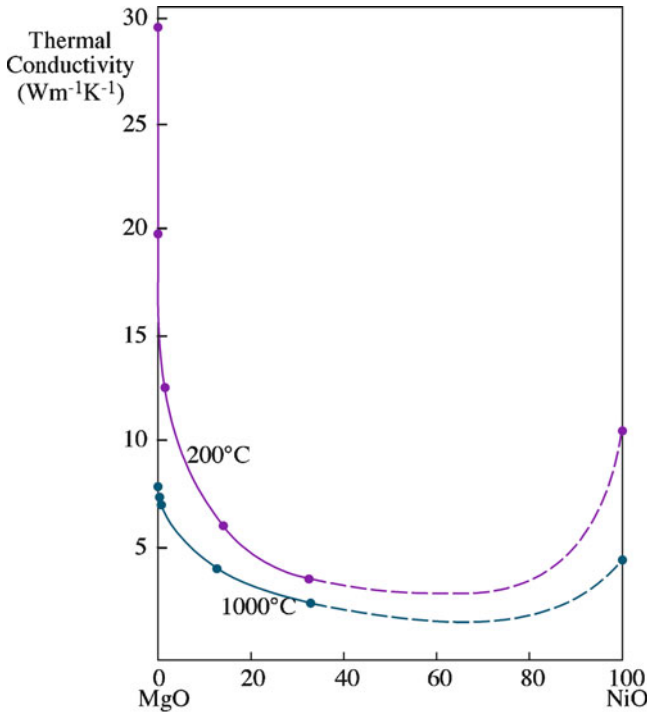

FIGURE 34.6. Thermal conductivities of solid solutions in the MgO–NiO system.

FIGURE 34.7. Comparison of the thermal conductivity of single-crystal (sc) and polycrystalline (pc) ceramics.

34.8 USING HIGH THERMAL CONDUCTIVITY

One of the most important applications for high- k ceramics is as substrates and packages for electronic devices, as shown in Figure 34.9. Due to the complexity and density of modern electronic devices, efficient thermal management is important. Removal of heat from the semiconductor is essential to prevent thermally induced damage.

Alumina (96 wt% Al_2O_3) is the most commonly used substrate material. It has a thermal conductivity in the range $15\text{--}20 \text{ Wm}^{-1} \text{ K}^{-1}$. The higher- k alternatives are AlN, SiC, and BeO. Aluminum nitride is the most promising because it combines a high k and high electrical

FIGURE 34.8. Three models for the distribution of two phases in a material. (A) Parallel slabs. (B) Continuous matrix phase, discontinuous particulate dispersion. (C) Large isolated grains separated by a continuous minor phase.

TABLE 34.8 Goes with Figure 34.8

resistivity (unlike SiC), is nontoxic (unlike BeO), and has a coefficient of thermal expansion closely matched to Si in the temperature range 25–400°C. Theoretically, AlN has $k = 320 \text{ W m}^{-1} \text{ K}^{-1}$. However, in polycrystalline AlN, k is typically in the range 50–200 $\text{W m}^{-1} \text{ K}^{-1}$. One of the reasons that commercially available materials show a wide range in k and values lower than predicted by theory is the presence of impurities, mainly oxygen. When oxygen replaces nitrogen, an aluminum vacancy is formed. We can represent this process using the Kröger-Vink notation (we gave the details of this notation in Chapter 11).

The aluminum vacancy leads to phonon scattering because its scattering cross section, Γ , for phonons is large: Γ is proportional to the relative difference in mass between the original site occupant and the new site occupant.

$$\Gamma \propto \frac{\Delta M}{M} \quad (34.24)$$

Aluminum has an atomic weight of 27, and the vacancy has zero weight. For our example, $\Delta M/M$ is one. When an N atom is replaced by O on the anion sublattice, $\Delta M/M = 0.1$. As a result, the scattering cross section is smaller.

FIGURE 34.9. Ceramic pin-grid-array package (96 %-pure Al_2O_3) with multilayer Au metallization.

We can reduce the oxygen content in polycrystalline AlN by adding rare earth or alkaline metal oxides (e.g., Y_2O_3 and CaO) to the initial powder. During sintering, the additive reacts with the oxide coating on the AlN grains, forming a liquid. The liquid helps in densification (as described in Section 24.7) and also acts as an oxygen “getter,” removing Al_2O_3 from the bulk of the grains. During cooling, the liquid concentrates mainly at triple points, leaving mostly clean and sharp AlN–AlN GBs, as shown in Figure 1.4.

The record-high thermal conductivity of diamond makes it an obvious choice for consideration as a substrate for high-power electronic devices. One method that has been successful in producing diamond films is chemical vapor deposition (CVD). The CVD diamond films are polycrystalline but can still have $k > 2,000 \text{ W m}^{-1} \text{ K}^{-1}$. The high cost of diamond films still precludes their widespread use.

34.9 THERMAL EXPANSION

We know from our everyday experiences that when we heat most materials they expand and when we cool them they contract. The linear coefficient of thermal expansion, α , indicates how much the dimensions of a solid change with temperature

$$\alpha = \frac{\Delta l}{\Delta T l_0} \quad (34.25)$$

Δl is the change in the length of the sample, l_0 is the original length, and ΔT is the temperature interval.

Figure 34.10 shows a typical bond-energy curve. At 0 K, the atoms are separated by the equilibrium spacing, r_0 , which corresponds to the minimum in the bond-energy curve. The atoms are in their lowest vibrational energy state, corresponding to the zero point energy, $h\nu/2$, and possess the minimum amplitude of vibration, x_0 . When the solid is heated, its energy increases, as shown by the horizontal lines in Figure 34.10. The width of the trough in the bond-energy curve represents the average vibrational amplitude of the atoms for a specific energy (or temperature). The average distance between the atoms is represented by the mean position along this line. A solid expands when heated because the bond-energy curve is asymmetric. If the curve was symmetric (the dashed curve in Figure 34.10) the average vibrational amplitude would increase with increasing temperature, but there would be no increase in the interatomic separation.

As we described in Chapter 4, the shape of the bond-energy curve depends on the strength and type of the interatomic bonding.

FIGURE 34.10. Typical bond-energy curve.

FIGURE 34.11. Plot of an average coefficient of thermal expansion versus melting temperature for many ceramics.

- The greater the bond strength, the deeper and narrower is the trough in the bond-energy curve and the smaller is the value of α .
- The more ionic the bonding, the more asymmetric is the curve. Ionically bonded materials, in general, have higher values of α than covalently bonded ones.
- As melting temperature increases, α decreases, as shown in Figure 34.11.

AN EXAMPLE—MgO

$\alpha = 13.5 \times 10^{-6} \text{ }^\circ\text{C}^{-1} = 13.5 \text{ ppm}/^\circ\text{C}$

$\alpha(^\circ\text{C}^{-1}) \times 10^6 = 13.5; \alpha(10^6 \text{ }^\circ\text{C})^{-1} = 13.5$

Heating MgO from 25°C to 50°C ($\Delta T = 25^\circ\text{C}$) increases a (0.421 nm at 25 °C) by only 0.14 pm.

Values of α for various ceramics are given in Table 34.9. For most ceramics, α is about $3\text{--}15 \times 10^{-6} \text{ }^\circ\text{C}^{-1}$. As α is a function of temperature—usually increasing with increasing temperature, as shown in Figure 34.12—a

mean value is often quoted for a particular material over a stated temperature range. Table 34.8 shows the mean values as well as the temperature ranges over which these values are applicable. Most values of α found in the literature are room temperature values; and from a practical point of view, it would be incorrect to use these values when considering an application for a different temperature range.

34.10 EFFECT OF CRYSTAL STRUCTURE ON α

Cubic crystals such as MgO are isotropic because they have uniform thermal expansion along the three crystallographic axes. Single crystals of noncubic structures are anisotropic and have different values of α along different crystallographic directions. Some examples are given in Table 34.10. In a polycrystalline sample of an anisotropic material such as Al_2O_3 , α would be intermediate between the single-crystal values for each of the different orientations.

Some silicate minerals, such as quartz (SiO_2) and cordierite ($\text{Mg}_2\text{Al}_4\text{Si}_5\text{O}_{18}$), have very low coefficients of thermal expansion (for cordierite, α is actually negative along

the *c* axis!). This property is attributed to the very open three-dimensional structure of many silicates. Cordierite is a ring silicate made up of [SiO₄]⁴⁻ tetrahedral, as we described in Chapter 7. During heating, thermal energy can be absorbed by rearrangement of these tetrahedral units by tilting or rotating.

Structural changes that occur in a ceramic during heating can also produce a change in α . An example is shown in Figure 34.13 for BaTiO₃. Similar changes are seen in the crystalline forms of SiO₂. Displacive phase transformations usually produce sudden changes in α . Reconstructive phase changes, which involve bond

breaking, usually occur more slowly and are often characterized by hysteresis.

34.11 THERMAL EXPANSION MEASUREMENT

The usual method of measuring α is to record mechanically the change in length of a test piece as it is heated in an instrument called a push-rod dilatometer, which is illustrated in Figure 34.14. The data obtained are plotted

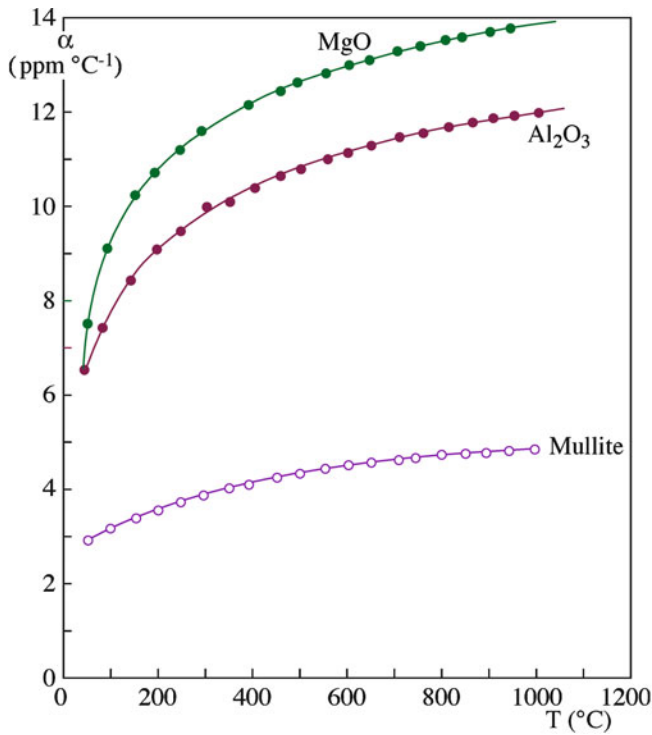

FIGURE 34.12. Thermal expansion coefficients versus temperature for some ceramic oxides.

TABLE 34.10 Thermal Expansion Coefficients for Some Anisotropic Crystals ($\alpha \times 10^{-6} \text{ } ^\circ\text{C}^{-1}$)

Crystal	Normal to <i>c</i> -axis	Parallel to <i>c</i> -axis
Al ₂ O ₃	8.3	9.0
Al ₂ TiO ₅	-2.6	+11.5

C (graphite)	1.0	27.0

as $\Delta l/l_0$ versus temperature, as shown in Figure 34.15. The slope of a line at any temperature is α . Accuracies of commercial dilatometers can be as good as 0.5%.

A typical plot of $\Delta l/l_0$ versus temperature for a commercial silicate glass is shown in Figure 34.16. The sudden increase in α in the temperature range 500–600°C is associated with the change from the glassy state to the supercooled liquid (i.e., T_g). The temperature range over which this change occurs depends not only on the glass composition but also on the thermal history of the glass and the rate of heating (remember T_g is not an absolute value). The decrease in length at about 700°C corresponds to the dilatometric softening temperature (T_d), which is due to viscous flow of the sample under the stresses imposed by the dilatometer. Measurement of α for a glass should always be done on well-annealed samples.

FIGURE 34.13. Coefficient of thermal expansion of BaTiO₃ as a function of temperature.

FIGURE 34.14. Double push-rod differential dilatometer.

34.12 IMPORTANCE OF MATCHING α s

Thermal expansion plays a key role when two or more materials are combined in situations where they are subjected to changes in temperature. Consider the situation illustrated in Figure 34.17. On heating, material 1 (with the higher α) experiences a compressive stress during heating, whereas material 2 (with the lower α) experiences tensile stresses. On cooling back down, material 1 is in tension,

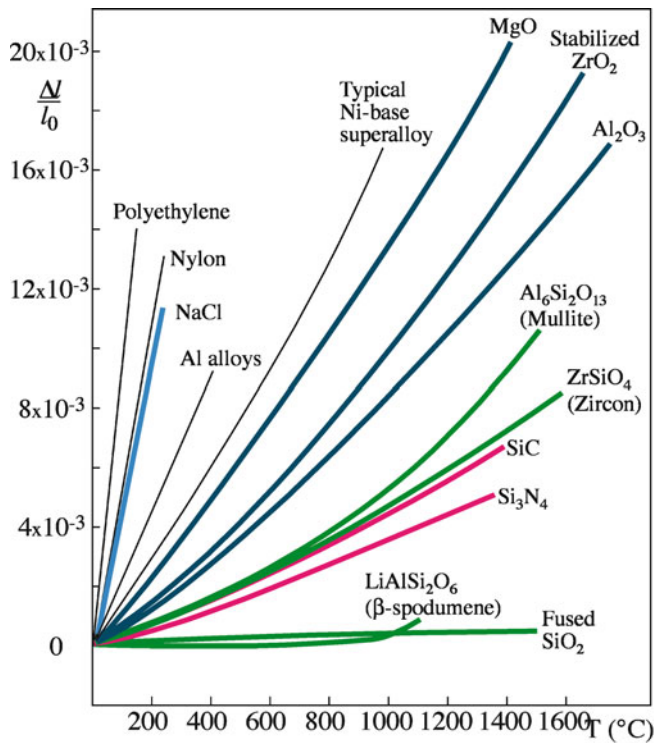

FIGURE 34.15. Thermal expansion characteristics of several polycrystalline ceramics.

FIGURE 34.16. Typical data for thermal expansion of a commercial silicate glass.

whereas material 2 is in compression. These stresses can lead to:

- Bowing
- Delamination
- Cracking

FIGURE 34.17. Stresses generated in a layered structure due to differences in α .

FIGURE 34.18. Artistic cracking in a glaze as a result of stresses generated due to differences in α .

Here are some important examples.

- *Glazes on ceramics.* Most types of pottery and whiteware are coated with a glaze for both aesthetic reasons and to make the body impermeable to liquids. The glaze (like most glasses) is strong in compression yet weak in tension. Typical compressive stresses in a glaze are on the order of 70 MPa. If tensile stresses are generated, they can cause cracking of the glaze, as illustrated in Figure 34.18.
- *Metal-to-ceramic bonding.* In the packaging of semiconductor devices, it is often necessary to join a ceramic (the substrate on which the “chip” is mounted) to a metal (the lead frame that provides connections to and from the outside world). The most common substrate material is a 96% wt% Al_2O_3 ceramic ($\alpha = 7.2 \times 10^{-6} \text{ }^\circ\text{C}^{-1}$). The Kovar metal alloys (e.g., 29% Ni, 17% Co, 54% Fe; $\alpha = 5.1 \times 10^{-6} \text{ }^\circ\text{C}^{-1}$) were developed to have α s as close as possible to that of alumina.
- *Glass-to-metal seals.* In incandescent lamps, the tungsten wire coil is fused to the glass lamp bulb to form a vacuum tight seal. The best seal is achieved when the

glass and metal have similar values of α . Tungsten has $\alpha = 4.5 \times 10^{-6} \text{ }^\circ\text{C}^{-1}$. A typical glass composition for matching with W is an alkali alumina borosilicate (72.9 SiO_2 , 4.5 Al_2O_3 , 14.5 B_2O_3 , 3.5 Na_2O , 2.4 K_2O , 1.2 BaO), which has $\alpha_{20-300^\circ\text{C}} = 4.5 \times 10^{-6} \text{ }^\circ\text{C}^{-1}$.

- **Porcelain-enameled metals.** Porcelain enameling is an established technology for bonding a coating of glass onto ferrous metal objects (e.g., stoves). The coefficient of thermal expansion of the glass must be closely matched to that of steel ($\alpha_{1,025 \text{ steel}} = 16 \times 10^{-6} \text{ }^\circ\text{C}^{-1}$).
- **Thin films.** Differences in α between a thin film and a substrate can lead to film stress. In a thin film (where the thickness of the film is considerably less than that of the substrate), the thermal stress, σ_f , in the thin film is

$$\sigma_f = \frac{(\alpha_s - \alpha_f)\Delta T E_f}{(1 - \nu_f)} \quad (34.26)$$

α_f and α_s are the coefficients of the normal expansion of the film and substrate, respectively; E_f is the Young's modulus of the film; and ν_f is the Poisson ratio.

EXAMPLE OF THERMAL STRESS

Determine the thermal stress in a TiC coating deposited onto 1025 stainless steel by CVD at $1,000^\circ\text{C}$

$$\begin{aligned} \alpha_{1025 \text{ steel}} &= 16 \times 10^{-6} \text{ }^\circ\text{C}^{-1} & \alpha_{\text{TiC}} &= 8 \times 10^{-6} \text{ }^\circ\text{C}^{-1} \\ E_{\text{TiC}} &= 450 \text{ GPa} & \nu_{\text{TiC}} &= 0.19 \end{aligned}$$

Substitution into equation 34.26 gives

$$\sigma_f = 1.67 \text{ GPa at } 0^\circ\text{C}$$

34.13 APPLICATIONS FOR LOW- α

Glass-ceramics, such as the lithium-alumino-silicates (LASs), can be designed to have very low, in fact near zero, α s over a wide temperature range, making them particularly suitable as supports for telescope mirrors. Telescopes are precise optical instruments, and the resolution is very sensitive to the alignment of the mirrors and

other optical components. Support materials with low α values minimize thermally induced strains. A commercial glass ceramic that is used for this application is known as Zerodur[®]. In addition to the very low α , Zerodur is stable up to 800°C and insensitive to thermal shock. The world's largest optical mirror is located at the Paranal Observatory in the Atacama Desert in Chile. The mirror, which is made of a polished Zerodur base coated with aluminum, is 8.2 m in diameter with a surface area of $> 50 \text{ m}^2$.

34.14 THERMAL SHOCK

Thermal shock resistance is the ability of a material to withstand failure due to rapid changes in temperature. Ceramics and glasses are much more likely to develop thermal stress than metals because:

- They generally have a lower k .
- They are brittle.

Rapid cooling of a ceramic or a glass is more likely to inflict thermal shock than heating because the induced surface stresses are tensile. Also, as you know, crack formation and propagation from surface flaws are more probable when the imposed stress is tensile.

The thermal shock resistance (R_{TS}) of a material can be estimated using:

$$R_{\text{TS}} = \sigma_f k / (E\alpha) \quad (34.27)$$

where σ_f is the fracture stress [which for ceramics is often taken as the flexural strength or modulus of rupture (MOR)], and E is Young's modulus. For high thermal shock resistance, we want a ceramic with:

- High σ_f
- High k
- Low E
- Low α

Values to calculate R_{TS} for several ceramics are given in Table 34.11. As an example, the R_{TS} of SiC is $2.3 \times 10^4 \text{ W/m}$, whereas that of Al_2O_3 is 740 W/m .

TABLE 34.11 Comparison of Thermal Shock Parameters for a Number of Ceramics^a

Material	MOR (MPa)	E (GPa)	α ($10^{-6} \text{ }^\circ\text{C}^{-1}$)	$k \text{ Wm}^{-1}\text{K}^{-1}$	R_{TS} (Wm^{-1})
SiAlON	945	300	3.0	21	22,050
Hot-pressed Si_3N_4	890	310	3.2	15–25	13,458
Reaction-bonded Si_3N_4	240	220	3.2	8–12	2,727
SiC (sintered)	483	410	4.3	84	23,012
Hot-pressed Al_2O_3	380	400	9.0	6–8	633
Hot-pressed BeO	200	400	8.5	63	3,706
PSZ	610	200	10.6	2	575

^aPoisson's ratio was taken to be 0.25 for all materials

Ceramics such as SiC and Si₃N₄, which also have high R_{TS} , are the most useful for components that are loaded at high temperature.

Silica glass (SiO₂) has an R_{TS} of 5.27×10^3 W/m. Addition of other components to the glass lowers both E and increases α , hence decreasing R_{TS} . Soda-lime-silicate glasses, such as those used for holding beverages, are very susceptible to thermal shock, as you have probably found out at one time or another, because of their high $\alpha = 9.2 \times 10^{-6} \text{ }^\circ\text{C}^{-1}$. Modification of R_{TS} can most easily be accomplished by changing α . The other parameters in equation 34.27 don't vary significantly with glass composition. If the CaO and Na₂O contents

are reduced and B₂O₃ is added, a borosilicate glass is formed. This is known as Pyrex™ glass ($\alpha = 3.3 \times 10^{-6} \text{ }^\circ\text{C}^{-1}$), which is much more resistant to thermal shock. Most cookware and the majority of laboratory glassware is Pyrex. From a practical point of view, a soda-lime-silicate glass fails if the temperature difference is $\geq 80^\circ\text{C}$ (pouring boiling water into a glass beaker can certainly crack it). Pyrex glass can withstand temperature differences of 270°C before failure. Glass-ceramics, with their extremely low α , have very high thermal stress resistance (TSR) and can withstand temperature changes of $>1,000^\circ\text{C}$.

CHAPTER SUMMARY

The thermal properties of ceramics, like many of their other physical properties, vary over a very wide range. A good example is that of thermal conductivity. Diamond, a ceramic material, has the highest known thermal conductivity, whereas the thermal conductivity of a multiphase ceramic such as partially stabilized zirconia is three orders of magnitude lower. Thermal properties of ceramics are dominated primarily by the nature of the interatomic bonding (bond strength and ionicity). In practical ceramics, we of course have to consider the presence of defects, impurities, and porosity, as they all affect thermal properties.

PEOPLE AND HISTORY

Debye, Petrus (Peter) Josephus Wilhelmus (1884–1966) was born in The Netherlands and became a naturalized American citizen in 1946. In 1912, he proposed the idea of quantized elastic waves, called phonons. From 1940 to 1952 Debye was Professor of Chemistry at Cornell University. He won the Nobel Prize in Chemistry in 1936.

Thomson, William (Lord Kelvin) (1824–1907) Scottish mathematician and physicist born in Belfast, Ireland. He proposed his absolute scale of temperature in 1848. During his lifetime he published more than 600 papers and was elected to the Royal Society in 1851. He is buried in Westminster Abbey next to Isaac Newton.

EXERCISES

- 34.1 Why do we use this title rather than the usual “Thermal Properties”?
- 34.2 Show that equation 34.4 gives energy in units of J.
- 34.3 The melting temperature of MgO is 3,073 K, whereas that of NaCl is 1,074 K. Explain the reason for this difference.
- 34.4 Consider the structure of graphite. Would you expect the thermal conductivity to be the same parallel to the basal plane and perpendicular to the basal plane? If not, why not?
- 34.5 (a) Would you expect the thermal conductivity of crystalline quartz to be higher or lower than that of fused quartz? (b) Would you expect the differences in k to increase or decrease with increasing temperature? Explain the reasoning behind your answers.
- 34.6 Using the criteria given in Section 34.5, rank the following ceramics in order of increasing thermal conductivity: B₄C, UO₂, TiO₂, and Si₃N₄. Explain the reasoning for your ranking.
- 34.7 Why is thermal transfer by radiation important only at high temperatures?
- 34.8 An AlN ceramic substrate contains 0.05 vol% porosity. Calculate the thermal conductivity of the ceramic at room temperature.
- 34.9 Which has the greater effect on the thermal conductivity of an AlN ceramic: 0.05 vol% porosity or 0.5 vol% of an Y₃Al₅O₁₂ second phase?
- 34.10 Would hot pressing or reaction bonding be the best method to produce Si₃N₄ components for applications in which sudden changes in temperature occur? Explain how you arrived at your answer.

- 34.11 Would the alkali alumina borosilicate glass given in Section 34.12 be a good choice to glaze a mullite crucible? If not, would you be better off using a soda-lime-silicate glaze or a pure silica glaze?
- 34.12 Use “book values” to compare the numerical heat capacities of the four ceramics in Figure 34.1. How can it rise above 3R?
- 34.13 The box on page 644 gives values for v and l for a ceramics and a metal. Why are they so different?
- 34.14 Explain why there is a variation in the data >800 K in Figure 34.3. Why there is a sharp maximum in this curve at low temperature?
- 34.15 Explain why the curves in Figure 34.4 are different for each material. Are there any trends? What materials would be used to obtain these curves? Explain your reasoning.
- 34.16 What conclusions can you deduce from the plot of α versus T in Figure 34.11?
- 34.17 The thermal expansion coefficients in Figure 34.12 all increase with temperature. Discuss what this means. In rare cases α can be negative. How can this happen, and could the phenomenon have useful applications?
- 34.18 What can you deduce from Figure 34.18? This requires real thought!
- 34.19 Zerodur is used at the Paranal Observatory. Could a similar material be used for the platter of a hard drive instead of glass? Explain your reasoning carefully.
- 34.20 Imagine you deposit a thin film of rock salt-structured oxide A (lattice parameter a) on a substrate of oxide B (lattice parameter $1.1a$) at 700°C . You then find that the thin film is in tension when it cools to room temperature. Explain what is happening.

Ceramics in Biology and Medicine

CHAPTER PREVIEW

Bioceramics are ceramics used for the repair and reconstruction of human body parts. As you can imagine, there are many applications for bioceramics; currently, the most important is in implants, such as alumina hip prosthesis. Alumina is classified as an inert bioceramic because it has very low reactivity in the body. On the other hand, bioactive materials have the ability to bond directly with bone. The advantages are:

- Earlier stabilization of the implant
- Longer functional life

However, bioactive ceramics are relatively weak compared with common implant metals and high-strength ceramics such as alumina and zirconia. As a result, they are often used as coatings, relying on the mechanical strength and toughness of the substrate. An important bioactive ceramic is hydroxyapatite (HA). Natural bone is a composite in which an assembly of HA particles is reinforced by organic collagen fibers. HA-reinforced polyethylene composites have been developed in an attempt to replicate the mechanical behavior of bone.

You can appreciate a major problem with this topic when you realize you can't replace bone if you don't understand why bone has such incredible mechanical properties. Therefore, if you work in this field, you must learn about biology.

35.1 WHAT ARE BIOCERAMICS?

A comprehensive definition of a biomaterial was provided at the National Institutes of Health (NIH) Consensus Development Conference on the Clinical Applications of Biomaterials in the United States.

A biomaterial is any substance, other than a drug, or combination of substances, synthetic or natural in origin, which can be used for any period of time, as a whole or as a part of a system which treats, augments, or replaces any tissue, organ, or function of the body.

This definition was significantly simplified in 1986 at the European Society for Biomaterials Consensus Conference

Biomaterial—a non-viable material used in a medical device intended to interact with biological systems.

A bioceramic is defined as a ceramic used as a biomaterial (which is great if you know what a ceramic is). The field of bioceramics is relatively new; it didn't exist until the 1970s. However, many bioceramics are not new materials. One of the most important is Al_2O_3 , which we first met as a constituent of many traditional ceramic products. Bioceramics are typically

classified into subgroups based on their chemical reactivity in the body. The subgroups are listed in Table 35.1, and their relative reactivities are compared in Figure 35.1.

If a nearly inert material is implanted into the body, the body initiates a protective response that leads to encapsulation by a nonadherent fibrous coating about 1 μm thick. Over

time this leads to complete isolation of the implant. A similar response occurs when metals and polymers are implanted. In the case of bioactive ceramics, a

bond forms across the implant/tissue interface, which mimics the body's natural repair process. Bioactive ceramics such as HA can be used in bulk form but are often used as part of a composite or as a coating. Resorbable bioceramics, such as tricalcium phosphate (TCP), actually dissolve in the body and are replaced by the surrounding tissue. It is an important requirement, of course, that the dissolution products are not toxic. As in the case of HA, TCP is often used as a coating rather than in bulk form. It is also used in powder form (e.g., for filling space in bone).

Figure 35.2 shows a number of clinical uses of bioceramics. They go from head to toe and include repairs

PROSTHESIS

A prosthesis is an artificial replacement for a part of the body.

TABLE 35.1 Classification Scheme for Bioceramics

Nearly inert bioceramics
Examples: Al_2O_3 , low temperature isotropic (LTI) carbon; ultra-LTI carbon; vitreous carbon; ZrO_2
Tissue attachment: mechanical
Bioactive ceramics
Examples: HA; bioactive glasses; bioactive glass-ceramics
Tissue attachment: interfacial bonding
Resorbable bioceramics
Examples: tricalcium phosphate (TCP); calcium sulfate; trisodium phosphate
Tissue attachment: replacement
Composites
Examples: HA/autogenous bone; surface-active glass ceramics/PMMA; surface-active glass/metal fibers; polylactic acid (PLA)/carbon fibers; PLA/HA; PLA/calcium/phosphorus-based glass fibers
Tissue attachment: depends on materials

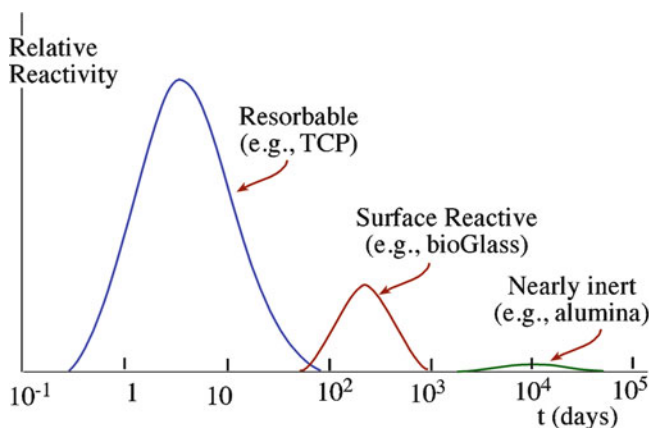

FIGURE 35.1. Relative reactivity of the different classes of bioceramic. TCP tricalcium phosphate.

to bones, joints, and teeth. These repairs become necessary when the existing part becomes diseased, damaged, or just simply wears out. There are many other applications of bioceramics, including pyrolytic carbon coatings for heart valves and special radioactive glass formulations for the treatment of certain tumors. We describe these two applications toward the end of this chapter. In the next section we look at the advantages and disadvantages of ceramics as biomaterials compared to the use of polymers and metals. We note that nanomaterials show interesting possibilities for such applications but may pose health problems in other situations.

35.2 ADVANTAGES AND DISADVANTAGES OF CERAMICS

In the selection of a material for a particular application we always have a choice. Materials selection is a critical part of any component design process and is especially important for implants and other medical devices.

The three main classes of material that we can select from for a load-bearing application are metals, polymers, and ceramics. Table 35.2 is a comparative list of the significant physical properties of different biomaterials

FIGURE 35.2. Illustration of the head-to-toe clinical uses for bioceramics.

from each of the three classical material classes. Table 35.3 compares the behavior of these different classes relevant to their potential use as implants.

The main advantage of ceramics over other implant materials is their biocompatibility: some are inert in the physiological environment, whereas others have a controlled reaction in the body. The main disadvantages of most bioceramics are:

- Low toughness (which can affect reliability)
- High \mathcal{E} (which can lead to stress shielding; see Section 35.3)

One of the main ways of increasing the toughness of ceramics is to form a composite. The ceramic may be the reinforcement phase, the matrix, or both. An example of a

TABLE 35.2 Significant Physical Properties of Different Biomaterials

Material	Density (g/cm ³)	UTS (MPa)	Compressive strength (MPa)	ϵ (GPa)	K_{Ic} (MPa·m ^{1/2})	Hardness (Knoop)	α (ppm/°C)	Fracture surface energy (J/m ²)	Poisson's ratio	k (Wm ⁻¹ K ⁻¹)

TABLE 35.3 General Comparison of Materials for Implants

Material class	Advantages	Disadvantages
Polymers	Resilient Tough Easy to fabricate Low density	Weak Low ϵ Not usually bioactive Not resorbable
Metals	Strong Wear resistant Tough Easy to fabricate	Can corrode in physiological environment High ϵ High density Not usually bioactive Not resorbable
Ceramics	Biocompatible Wear resistant Certain compositions lightweight	Low tensile strength Difficult to fabricate Low toughness Not resilient

polymer-matrix composite (PMC) reinforced with a bioceramic is polyethylene (PE) reinforced with HA particles. The toughness of the composite is greater than that of HA; and, as we see in Section 35.6, ϵ is more closely matched to that of bone. Bioceramics are also used as coatings on metal substrates. An example is bioactive-glass coating on stainless steel, which utilizes the strength and toughness of steel and the surface-active properties of the glass.

35.3 CERAMIC IMPLANTS AND THE STRUCTURE OF BONE

The requirements for a ceramic implant depend on what role it is to play in the body. For example, the requirements for a total hip prosthesis (THP) are different from those for a middle ear implant. However, there are two basic criteria.

The ceramic should be compatible with the physiological environment.

Its mechanical properties should match those of the tissue being replaced.

Most bioceramic implants are in contact with bone. Bone is a living material composed of cells and a blood supply encased in a strong composite structure. The composite consists of collagen, which is flexible and very tough, and crystals of an apatite of calcium and phosphate, resembling calcium HA; we proceed here as if it is HA. It is the HA component that gives bone its hardness. The acicular apatite crystals are 20–40 nm in length and 1.5–3.0 nm wide in the collagen fiber matrix. Two of the various types of bone that are of most concern in the use of bioceramics are:

- Cancellous (spongy bone)
- Cortical (compact bone)

Cancellous bone is less dense than *cortical* bone. Every bone of the skeleton has a dense outer layer of compact bone covering the spongy bone, which is in the form of a honeycomb of small needle-like or flat pieces called trabeculae. Figure 35.3 shows a longitudinal section of a long bone. The open spaces between the trabeculae are filled with red or yellow bone marrow in living bone. Because of its lower density, cancellous bone has a lower \mathcal{E} and higher strain-to-failure than cortical bone, as shown in Table 35.4. Both types of bone have higher \mathcal{E} than soft connective tissues, such as tendons

and ligaments. The difference in \mathcal{E} between the various types of connective tissues ensures a smooth gradient in mechanical stress across a bone, between bones, and between muscles and bones.

STRESS SHIELDING
This occurs when a high- \mathcal{E} implant material carries nearly all the applied load.

The mechanical properties of the implant are clearly very important.

Figure 35.4 compares \mathcal{E} of various implant materials to those of cortical and cancellous bone.

- \mathcal{E} of cortical bone is 10–50 times less than that of Al_2O_3 .
- \mathcal{E} of cancellous bone is several hundred times less than that of Al_2O_3 .

If the implant has a much higher \mathcal{E} than the bone it is replacing, then a problem called *stress shielding* can occur. Stress shielding weakens bone in the region where the applied load is lowest or is in compression. (Bone must be loaded in tension to remain healthy). Bone that is unloaded or is loaded in compression undergoes a biological change that leads to resorption. Eliminating stress shielding by reducing \mathcal{E} is one of the primary motivations for the development of bioceramic composites.

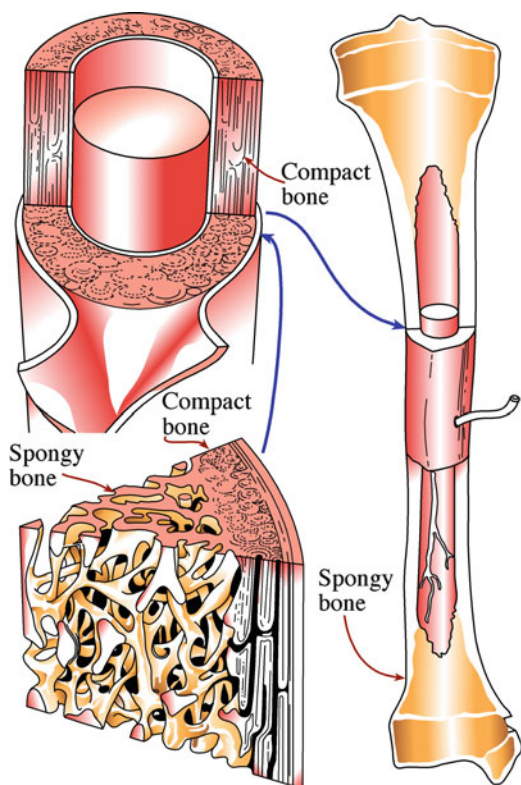

TABLE 35.4 Mechanical Properties of Skeletal Tissues

Property	Cortical bone	Cancellous bone	Articular cartilage	Tendon
Compressive strength (MPa)	100–230	2–12		
Flexural strength (MPa)	50–150	10–20	10–40	80–120

35.4 ALUMINA AND ZIRCONIA

Al_2O_3 and ZrO_2 are two nearly inert bioceramics. They undergo little or no chemical change during long-term exposure to body fluids. High-density, high-purity (>99.5%) alumina is used in a number of implants, particularly as load-bearing hip prosthesis and dental implants. More than one million hip prostheses were projected to have been performed using an alumina ball for the femoral-head component. Figure 35.5 shows three femoral components of total hip prostheses (THPs) with alumina balls. The U.S. Food and Drug Administration (FDA) approved the use of alumina in this type of application in 1982.

Although some alumina dental implants are made from single crystals, most alumina implants are very fine-grained polycrystalline Al_2O_3 . These are usually made by pressing followed by sintering at temperatures in the range 1,600–1,800°C. A small amount of MgO (<0.5%) is added, which acts, as we've seen already, as a grain growth inhibitor and allows a high-density product to be achieved by sintering without pressure. Table 35.5 lists the physical characteristics of Al_2O_3 bioceramics. The International Standards Organization (ISO) requirements are also given. The most current ISO standard relating to alumina for implants is ISO 6474: 1994, Implants for Surgery—Ceramic Materials Based on High Purity Alumina. The ISO is the international agency specializing in standards at the highest level. Individual countries also have their own standards organizations.

An important requirement for any implant material is that it should outlast the patient. Because of the probabilistic nature of failure in ceramics, it is not possible to provide specific and definite lifetime predictions for each individual implant. This was the approach that we discussed in Section 16.14. [See the discussion of Figure 16.27, a diagram showing applied stress versus probability of time to failure (SPT) for medical-grade

FIGURE 35.5. Medical-grade alumina used as femoral balls in total hip prostheses. The schematic shows how the femoral ball fits into the socket.

alumina.] It shows, as you might expect, that increased loads and longer times increase the probability of failure. Results from aging and fatigue studies show that it is essential that Al_2O_3 implants be produced with the highest possible standards of quality assurance, especially if they are to be used in orthopedic prostheses in young patients.

Although alumina ceramics combine excellent biocompatibility and outstanding wear resistance, they have only moderate

flexural strength and low toughness. This limits the diameter of most alumina femoral head prostheses to 32 mm. Zirconia ceramics have higher fracture toughness, higher flexural strength, and lower \mathcal{E} than alumina ceramics, as shown in Table 35.2. However, there are some concerns with ZrO_2 .

There is a slight decrease in flexural strength and toughness of zirconia ceramics exposed to bodily fluids. The reason is associated with the martensitic transformation from the tetragonal to the monoclinic phase. A similar transformation has been observed to occur in aqueous environments.

The wear resistance of zirconia is inferior to those of alumina. In ceramic/ceramic combinations, the wear rate of zirconia can be significantly higher than that of alumina. In combination with UHMWPE (ultra-high-molecular-weight polyethylene) excessive wear of the polymer occurs.

Zirconia may contain low concentrations of long half-life radioactive elements, such as Th and U, which are difficult and expensive to separate out. The main

BIOMEDICAL APPLICATIONS OF Al_2O_3

There are many other applications of alumina as an implant material including knee prostheses, ankle joints, elbows, shoulders, wrists, and fingers.

A MOIETY

A moiety is a group of atoms that forms a distinct part of a large molecule.

TABLE 35.5 Physical Characteristics of Al_2O_3 Bioceramics

Property	Commercially available high alumina ceramic implants	ISO standard 6474
Alumina content (wt%)	>99.7	≥99.51
$\text{SiO}_2 + \text{Na}_2\text{O}$ (wt%)	<0.02	<0.01
Density (g/cm^3)	3.98	≥3.94
Average grain size (μm)	3.6	<4.5
Hardness (Vickers, HV)	2,400	>2,000
Bending strength (MPa, after testing in Ringer's solution)	595	>450

concern is that they emit α -particles (He nuclei) that can destroy both soft and hard tissue. Although the activity is small, there are questions concerning the long-term effect of α radiation emission from zirconia ceramics.

35.5 BIOACTIVE GLASSES

Bioactive materials form an interfacial bond with surrounding tissue. Hench and Andersson gave the following definition.

A bioactive material is one that elicits a specific biological response at the interface of the material, which results in the formation of a bond between tissues and the material.

The first and most thoroughly studied bioactive glass is known as Bioglass[®] 45S5 and was developed at the University of Florida. Bioglass[®] 45S5 is a multicomponent oxide glass with the composition (in wt%): 45% SiO₂, 24.5% Na₂O, 24.4% CaO, and 6% P₂O₅.

The majority of bioactive glasses are based on the same four components, and all current bioactive glasses are silicates. However, the structure of Bioglass[®] 45S5 is different from that of the silicate glasses we described in Chapter 7. Bioactive glasses have a random, two-dimensional sheet-like structure with low density. This is a result of the relatively low SiO₂ content. (You can compare the bioglass composition with that of other silicates given in Table 21.6). Bioglass is mechanically weak and has low fracture toughness. Both these properties are related to the glass structure.

Bioactive glasses can readily be made using the processes developed for other silicate glasses. The constituent oxides, or compounds that can be decomposed to oxides, are mixed in the right proportions and melted at high temperatures to produce a homogeneous melt. On cooling, a glass is produced. Because bioactive glasses are going to be used inside the body, it is necessary to use high-purity starting materials; and often the melting is performed in Pt or Pt alloy crucibles to minimize contamination.

Bioactive glasses have certain properties that are relevant to their application in the body.

Advantages:

There is a relatively rapid surface reaction that leads to fast tissue bonding. There are five reaction stages on the glass side of the interface. The reaction rates and mechanisms at each of the five stages have been determined by Fourier transform infrared (FTIR) spectroscopy. Bonding to tissue requires a further series of reactions that are, at present, not as well defined. The bonding process starts when biological moieties are adsorbed onto the SiO₂-hydroxycarboapatite layer.

E is in the range 30–35 GPa, close to that of cortical bone (see Figure 35.4)

Disadvantages:

They are mechanically weak. Tensile bending strengths are typically 40–60 MPa.

The fracture toughness is low.

As a result of this combination of properties bioactive glasses are not found in load-bearing applications; rather, they are used as coatings on metals, in low-loaded or compressively loaded devices, in the form of powders,

FIGURE 35.6. (A) Middle ear cavity and the auditory ossicles. (B) Ear implants.

and in composites. The first successful use of Bioglass[®] 45S5 was as a replacement for the ossicles (tiny bones) in the middle ear. The position of these bones is illustrated in Figure 35.6.

Cone-shaped plugs of bioactive glasses have been used in oral surgery to fill the defect in the jaw created when a tooth is removed. Bioactive glass implants have also been used to repair the bone that supports the eye (the orbital socket).

In powder form, bioactive glasses have been used in the treatment of periodontal disease and for the treatment of patients with paralysis of one of the vocal cords. When mixed with autologous bone they have been used in maxillofacial reconstruction (i.e., mixed with natural bone to rebuild a jaw).

35.6 BIOACTIVE GLASS-CERAMICS

We know that glass-ceramics are produced by ceramming a glass (see Chapter 26), converting it to a largely crystalline form by heat treatment. Several glass-ceramic compositions are bioactive. Their behavior in the body is very similar to that of the bioactive glasses; that is, they form a strong interfacial bond with tissue.

Cerabone[®] A-W is a glass-ceramic containing oxyfluorapatite (A) and wollastonite (W).

Ceravital[®] is primarily now used in middle ear operations. Bioverit I[®] is a class of bioactive machinable glass.

Cerabone[®] A-W is a glass-ceramic produced by crystallization of a glass of composition (in wt%), 4.6 MgO, 44.7 CaO, 34.0 SiO₂, 6.2 P₂O₅, 0.5 CaF₂. The crystalline phases are oxyfluoroapatite [Ca₁₀(PO₄)₆(O,F)₂] (the A phase) and β-wollastonite (CaO·SiO₂), the W phase. These phases precipitate out at 870°C and 900°C, respectively. The composition of the residual glassy phase is (in wt%) 16.6 MgO, 24.2 CaO, and 59.2 SiO₂. The properties of A-W glass ceramic are shown in Table 35.2. The applications include vertebral prostheses, vertebral spacers, and iliac crest prostheses.

Ceravital[®] refers to a number of different compositions of glasses and glass-ceramics that were developed in the 1970s in Germany for biomedical applications. The only field in which Ceravital[®] glass-ceramics are clinically used is replacement of the ossicular chain in the middle ear. In this application, the mechanical properties of the material are sufficient to support the minimal applied loads.

Bioverit I[®] consists of two crystalline phases in a glass matrix. The key crystalline component that makes this glass-ceramic machinable is mica. We have already described the idea behind machinable glass-ceramics in Section 18.10. For bioactivity, the other crystalline phase is apatite. The type and amounts of each phase depends on the initial glass composition. Table 35.6 shows the typical

TABLE 35.6 Composition Range (wt%) of Bioverit[®] Glass Ceramics

Constituent	Composition range	Composition 1	Composition 2
SiO ₂	29.5–50.0	30.5	38.7
MgO	6–28	14.8	27.7
CaO	13–28	14.4	10.4
Na ₂ O/K ₂ O	5.5–9.5	2.3/5.8	0/6.8

P ₂ O ₅	8–18	11.4	8.2
TiO ₂	Additions	—	1.9

composition range of Bioverit I[®] glass-ceramics. Composition 1 produces fluorophlogopite mica and apatite. Composition 2 produces tetrasilicic mica and apatite. There are several clinical applications of bioactive machinable glass-ceramics, such as spacers in orthopedic surgery and middle ear implants.

35.7 HYDROXYAPATITE

The apatite family of minerals has the general formula A₁₀(BO₄)₆X₂. In HA, or more specifically calcium hydroxyapatite, A = Ca, B = P, and X = OH. The mineral part of teeth and bones is made of an apatite of calcium and phosphorus similar to HA crystals. Natural bone is ~70% HA by weight and 50% HA by volume.

Hydroxyapatite is hexagonal (space group is P6₃/m) with *a* = 0.9432 nm and *c* = 0.6881 nm. The hydroxyl ions lie on the corners of the projected basal plane and occur at equidistant intervals [one half of the cell (0.344 nm)] along columns perpendicular to the basal plane and parallel to the *c* axis. Six of the ten Ca²⁺ ions in the unit cell are associated with the hydroxyls in these particular columns. One group of three Ca²⁺ ions describing a triangle, surrounding the OH group, is located at *z* = 0.25; the other set of three is at *z* = 0.75. The six phosphate (PO₄)³⁻ tetrahedra are in a helical arrangement from levels *z* = 0.25 to *z* = 0.75. A network of (PO₄)³⁻ groups provides the skeletal framework that gives the apatite structure its stability. (Complicated but certainly crystalline and very natural!)

Substitutions in the HA structure are possible. Substitutions for Ca, PO₄, and OH groups result in changes in the lattice parameter as well as in some of the properties of the crystal such as solubility. If the OH⁻ groups in HA are replaced by F⁻, the anions are closer to the neighboring Ca²⁺ ions. This substitution helps to further stabilize the structure and is proposed as one of the reasons that fluoridation helps reduce tooth decay, as shown by the study of the incorporation of F into HA and its effect on solubility. Biological apatites, which are the mineral phases of bone, enamel, and dentin, are usually referred to as HA. Actually, they differ from pure HA in stoichiometry,

TABLE 35.7 Comparative Composition, Crystallographic, and Mechanical Properties of Human Enamel, Bone, and HA Ceramic

composition, crystallinity, and other physical and mechanical properties, as shown in Table 35.7. Biological apatites are usually Ca-deficient and are always carbonate-substituted: (CO₃)²⁻ for (PO₄)³⁻. For this reason you sometimes see biological apatites referred to as carbonate apatite and not as hydroxyapatite or HA.

For use in biomedical applications, HA is prepared in one of two forms: dense or porous. We now discuss how these two forms are produced and some of the applications for each.

The methods used to produce *dense HA* are ones that we've already encountered in Chapter 23. The simplest is to dry-press HA powder. Mold pressures are typically 60–80 MPa. The powder may also be mixed with a small amount of a binder. Suitable binders are 1 wt% cornstarch and water, steric acid in alcohol, or low-molecular-weight hydrocarbons. After pressing, the green ceramic is sintered in air. Sintering temperatures are up to 1,300°C, with dwell times at peak temperature of several hours.

TABLE 35.8 Applications for Dense HA Ceramics

Application	Form
Augmentation of alveolar ridge for better denture fit	Blocks
Orthopedic surgery	Blocks
Target materials for ion-sputtered coatings	Blocks
Filler in bony defects (dental and orthopedic surgery)	Particles
Plasma-sprayed coatings on metal implants	Particles
Filler in composites and cements	Particles

By using hot-pressing techniques, we can achieve densification at much lower temperatures (900°C vs. 1,300°C). The use of lower sintering temperatures not only saves on energy costs but prevents the formation of other calcium phosphate phases (e.g., TCP), which usually form when HA is sintered at temperatures >900°C.

Hot isostatic pressing (HIPing) has also been used to form HA ceramics. HIPing results in products with more uniform densities than those obtained by uniaxial pressing and higher compressive strength.

The disadvantage of both hot pressing and HIPing is the equipment costs.

There are many applications for dense HA in both block form and as particles, as listed in Table 35.8. One important application is replacements for tooth roots following extraction. The implants help minimize alveolar ridge resorption and maintain ridge shape following tooth loss, which affects millions of people.

The particular advantage of *porous HA* is that it permits ingrowth of tissue into the pores, providing biological

fixation of the implant. The minimum pore size necessary is ~100 μm. When used as a bone graft substitute, porous HA should mimic the framework (or stromal component) of the bone. The ideal microstructure for regeneration of cortical bone is an interconnected porosity of 65%, with pore sizes ranging from 190 to

230 μm. The ideal graft substitute for cancellous bone would consist of a thin framework of large (500–600 μm) interconnected pores.

Several methods have been used to produce porous HA ceramics. Remember that historically much of ceramic processing was concerned with trying to produce components that are fully dense. Therefore, to produce porous components, particularly where we need to control pore size. Often requires ingenuity and a rethink. We discussed porous ceramics in Section 23.15, so here we just point out special features for producing porous HA ceramics.

DENSE HA

Porosity <5 vol%
Pore size <1 μm diameter
Grain size >0.2 μm

RESORPTION

Resorption is the process of reabsorbing biological material.

Sinter HA powders
 Make a cement
 Use a natural template

Sinter HA powders, or a mixture of suitable reactant powders, with naphthalene particles that volatilize during heating to create an interconnected porous network. Similar approaches have been used to produce foam glass (see Section 26.9) and in the fugitive electrode method of producing multilayer chip capacitors (MLCCs) (see Section 31.7).

By mixing water-setting HA *cements* with sucrose granules, porosity can be created when the sucrose is dissolved prior to the cement setting. One example of an HA cement is that obtained by the following reaction in an aqueous environment.

The *natural-template method* was developed in 1974. It can produce porous HA powders. A suitable template was found to be the calcium carbonate (CaCO_3) skeleton of reef-building corals, such as those found in the South Pacific. The reaction to produce HA involves a hydrothermal exchange reaction of carbonate groups with phosphate groups, which can occur via the following chemical reaction.

The HA structure produced by this exchange reaction replicates the porous marine skeleton, including its interconnected porosity. HA grown on *Porites* and *Goniopora* coral skeleton templates can be used to mimic the stroma of cortical bone and cancellous bone, respectively.

35.8 BIOCERAMICS IN COMPOSITES

The main reason for forming composites is to improve the mechanical properties, most often toughness, above that of the stand-alone ceramic. For bioceramic composites, we often are trying to increase K_{IC} and decrease \mathcal{E} .

The first bioceramic composite was a stainless steel fiber/bioactive glass composite made of Bioglass® 45S5 and AISI 316L stainless steel. The composite was made by first forming a preform of the discontinuous metal fibers, then impregnating it with molten glass, and finally heat-

treating the composite to develop the desired mechanical properties.

For effective stress transfer between the glass matrix and the reinforcing metal fibers when the composite is under load, there must be a strong glass–metal bond. This requires that the glass wet the metal surface during processing. Wetting is achieved by oxidizing the metal fibers before they are immersed in the glass. Chemical analysis across the glass/metal interface showed that there is Fe diffusion from the oxide into the glass and Si diffusion from the glass into the oxide. The composition gradient across the interface indicates chemical interaction between the two phases, which leads to improved adhesion.

Assuming that the fibers are aligned in the direction of the applied load, and that there is good adhesion with the matrix such that the elastic strains are equal in both components, we can write:

$$\sigma_c = \sigma_f V_f + \sigma_m V_m \quad (35.3)$$

where the subscripts c, f, and m refer to the composite, fiber, and matrix, respectively; and V is the volume fraction of each phase. If we assume 45 vol% of steel fibers, that $\sigma_f = 530$ MPa, and that $\sigma_m = 42$ MPa, then $\sigma_c = 262$ MPa. This value, which is close to experimentally measured values, represents significant strengthening above that of the glass alone.

One of the potential problems associated with forming composites is that of mismatch in α between the two components, which is significant for glass and steel. For reinforcing fibers where the difference in α with the glass

phase is even greater than that with steel (e.g., Ti), it is necessary to change the composition of the glass to lower its α .

Other current bioceramic composites of interest are:

- Ti-fiber-reinforced bioactive glass
- ZrO₂-reinforced A-W glass
- TCP-reinforced PE
- HA-reinforced PE

Hydroxyapatite-reinforced PE is a good illustration of where a composite can have properties that are not available in a single material. These composites were developed as bone replacement that would have a matched modulus, be ductile, and be bioactive. Figure 35.7 shows how, by increasing the volume fraction of HA to 0.5, a composite can be achieved with \mathcal{E} in the range of that of cortical bone. When the volume fraction of HA in the composite is increased above about 0.45, the fracture mode changes from ductile to brittle. For clinical applications, a volume fraction of 0.4 has been found to be optimum. The

FIGURE 35.7. Effect of the volume fraction of HA on E and strain to failure of HA-reinforced polyethylene composites in comparison to cortical bone.

HA-reinforced PE composite is designated commercially as HAPLEX™, and several thousand patients have received middle ear implants made from this material. The technology was granted regulatory approval by the FDA in the United States in 1995.

35.9 BIOCERAMIC COATINGS

Applying a glass or ceramic coating onto the surface of a substrate allows us to have the best of both worlds. We have the bulk properties of the substrate and the surface properties of the coating. The three main reasons for applying a coating are:

1. Protect the substrate against corrosion
2. Make the implant biocompatible
3. Turn a nonbioactive surface into a bioactive one

We can list four substrate-coating combinations:

1. Ceramic on ceramic
2. Glass on ceramic
3. Ceramic on metal
4. Glass on metal

Bioceramic coatings are often used on metallic substrates, where the fracture toughness of the metal is

combined with the ability of the coating to present a bioactive surface to the surrounding tissue. The use of a bioceramic coating on a metal implant can lead to earlier stabilization of the implant in the surrounding bone and extend the functional life of the prosthesis. Under the proper conditions, a cementless prosthesis should remain functional longer than a cemented device, in which stability is threatened by fracture of the bone cement.

The important ceramic coatings are HA and TCP. We described the structure and properties of HA, a bioactive ceramic, in some detail in Section 35.6. TCP is a resorbable bioceramic. It occurs in two polymorphs: α -whitlockite and β -whitlockite. The β form is the more stable. When TCP is implanted into the body it eventually dissolves and is replaced by tissue. The role of resorbable bioceramics is to serve as scaffolding, permitting tissue infiltration and eventual replacement. Essentially, this is the same function as bone grafts. TCP has been clinically applied in many areas of dentistry and orthopedics. Bulk material, available in dense and porous forms, is used for alveolar ridge augmentation, immediate tooth root replacement, and maxillofacial reconstruction. However, because bulk TCP is mechanically weak, it cannot be used in load-bearing applications. Therefore, TCP is often used as a coating on metal substrates.

The most widely used method for applying coatings of HA and TCP is plasma spraying. We already described this technique in Section 27.5; it is one of the methods used to produce thermal barrier layers. Plasma spraying uses a plasma, an ionized gas, that partially melts the HA particles and carries them to the surface of the substrate. For HA coatings, the starting material is pure 100% crystalline HA particles in the 20–40- μm range. One of the advantages of plasma spraying is that the substrate remains at a relatively low temperature (generally $<300^\circ\text{C}$; the plasma temperature may exceed $10,000^\circ\text{C}$!) so the mechanical properties of the metal are not compromised. The coating thickness typically averages 40–60 μm with a residual porosity $<2\%$. HA coatings prepared by plasma spraying typically contain considerable amounts of amorphous calcium phosphate and small amounts of other crystalline phases. Heat-treating the coating can increase crystallinity and improve the adhesion to the substrate. However, this process is not usually done because of economic factors and concerns about the adverse effects it might have on the mechanical properties of the substrate.

In addition to plasma spraying, other methods have been used to apply HA coatings.

- Electrophoretic deposition when line-of-site deposition is not possible
- Sputtering when very thin coatings are needed
- HIPing when we need a very dense material

Electrophoretic deposition (see Section 27.6 for a description of the technique) can be used to coat porous

surfaces that cannot be completely coated by line-of-sight techniques such as plasma spraying. However, the adhesion of the HA particles to the substrate and each other is weak, and high-temperature sintering after deposition is usually necessary.

Sputtering has been used to produce thin (1 μm) HA coatings. The deposited films are amorphous because the sputtered components don't possess enough kinetic energy to recombine in a crystalline form. Heat treatment at 500°C is enough to crystallize the amorphous film. Durability of thin sputtered films in the body has not yet been demonstrated.

HIPing is a technique we met earlier but not in the context of forming films. If a metal implant is coated with HA particles, then HIPing can be used to form a dense adherent coating. To achieve a uniform application of pressure on the HA particles, an encapsulation material (e.g., a noble metal foil) is necessary. As we mentioned earlier, HIPing allows the use of lower sintering temperatures than pressureless techniques; as a result, there is less chance of altering the microstructure or mechanical properties of the metal substrate.

There are several requirements for HA coatings used for prosthetic devices.

- Correct crystalline phase
- Stable composition
- Dense
- Good adhesion to the substrate
- High purity
- No change to the substrate

Plasma-sprayed coatings often contain a mixture of crystalline and amorphous phases, which may be undesirable. The adhesion of plasma-sprayed HA coatings to metal substrates is principally mechanical, and so surface roughness of the substrate plays an important role.

Bioactive glass coatings are also important for implant devices. These are usually applied by one of the following techniques.

- Enameling
- Flame spraying
- Dip coating

Flame spraying is similar to plasma spraying except that the carrier gases are not ionized, and the temperatures are considerably lower than in plasma spraying. In dip coating, the metal implant is preoxidized to provide a suitable surface for wetting the molten glass. The heated metal is then dipped into the molten glass.

Enameling is a traditional method of applying glass coatings and uses a particulate form of the glass called a frit, which is formed when molten glass is quenched in water. The resulting coarse particles of the frit are ground to a fine powder, which is applied to the metal substrate by painting, spraying, or dipping. The coated article is then

heated to soften the glass and form a uniform coating. In traditional enameling, the adhesion between the glass and metal is improved by using what enamellers call a "ground coat." This is a mixture of metal oxides that react chemically with both the metal and the glass, enabling formation of a chemical bond. However, this approach has not proved to be successful with bioactive glasses, and alternative approaches are being used.

35.10 RADIOTHERAPY GLASSES

Radioactive yttrium aluminosilicate (YAS) glasses have been used to provide in situ irradiation of malignant tumors in the liver. Although primary liver tumors are relatively rare in the United States (about 3,000–4,000 deaths per year; 1.2 million worldwide), they are almost always lethal. Most of these tumors are inoperable due to various medical complications. Irradiating the tumors inside the body allows the use of large (>10,000 rad) localized doses of radiation directly to the tumor while minimizing damage to surrounding healthy tissue. This procedure represents an important tool in treating this disease.

YAS glasses are particularly suitable because they are:

- Not toxic
- Easily made radioactive
- Chemically insoluble while the glass is radioactive

The sol-gel process has been used to produce high-purity YAS glass spheres, shown in Figure 35.8. The radioactive isotope produced when the YAS glass spheres are irradiated is ^{90}Y , a β -emitter with a half-life of 64.1 h. The average penetration of β -particles (electrons) in human tissue is 2.5 mm (maximum penetration ~10 mm). For the radioactive material to reach the site of the tumors, between 1 and 15 million microspheres are injected into the hepatic artery, which is the primary blood supply for

FIGURE 35.8. Lithium calcium borate glass microspheres produced by passing through a flame at 1,400°C.

the target tumors. Treatment time is 2–4 h. The microspheres are 15–35 μm in diameter, and this allows the blood to carry them into the liver, but they are too large to pass completely through the liver and enter the circulatory system. The microspheres concentrate in the tumor because it has a greater than normal blood supply. There they irradiate it with β -particles. Because the half-life of ^{90}Y is 64.1 h, the radioactivity decays to a negligible level in about 3 weeks.

Although the use of radiotherapeutic glass spheres in treating liver cancer is still at a relatively early stage, the results appear promising. The commercially available product, called TheraSphere™, made by MDS Nordion, is approved in the United States and Canada for treating patients with inoperable liver cancer. Other medical applications for these glass spheres have been considered, such as the treatment of cancers of the kidney and brain.

35.11 PYROLYTIC CARBON HEART VALVES

Carbon is an important bioceramic. It combines outstanding biocompatibility and chemical inertness. Carbon exists in many forms, and we've already met some of these forms in earlier chapters. The most important form of carbon for biomedical applications is a type of pyrolytic graphite known as the low-temperature isotropic form (LTI carbon).

The LTI is an example of what are referred to as turbostratic carbons. These have a disordered structure based on graphite (and thus are also called turbostratic graphite). In turbostratic carbon, the ABABA stacking sequence is disrupted through random rotations or displacement of the layers relative to each other. The individual LTI carbon crystallites are only ~ 10 nm in size and are arranged randomly in the bulk material. This microstructure leads to the material having isotropic mechanical and physical properties, unlike graphite where the properties are highly anisotropic. The density and mechanical properties of LTI are influenced by the number of carbon vacancies in each of the layers and distortions within each plane. The densities range from $1,400 \text{ kg/m}^3$ up to a theoretical maximum of $2,200 \text{ kg/m}^3$.

High-density LTI carbons are the strongest bulk form of turbostratic carbon; we can increase their strengths further by adding Si. The material then consists of discrete submicrometer β -SiC particles randomly dispersed in a matrix of roughly spherical micrometer-size subgrains of pyrolytic carbon; the carbon itself has a "subcrystalline" turbostratic structure, with a crystallite size typically

FIGURE 35.9. LTI pyrolytic carbon-coated heart valves.

< 10 nm. This is analogous to the microstructure produced during precipitation hardening of metals.

A chemical vapor deposition (CVD) process (see Section 28.4) involving the co-deposition of carbon and SiC is typically used to produce the LTI-Si alloys. Two possible reactions are:

Decomposition of propane:

Decomposition of methyltrichlorosilane

The articles to be coated are suspended within a fluidized bed of granular particles, usually ZrO_2 . The reactions take place in the range $1,000$ – $1,500^\circ\text{C}$, and the products coat the components as well as the ZrO_2 particles.

One of the major applications for LTI carbon is in making prosthetic heart valves, as shown in Figure 35.9. This is one of the most demanding applications

for biomaterials. The first use of LTI carbon in humans as a prosthetic heart valve was in 1969. The majority of artificial heart valves currently use Si-alloyed LTI pyrolytic carbon.

35.12 NANOBIOCERAMICS

There are many books on the uses of nanoparticles, and there are hundreds of research papers on this topic. There are also many papers discussing the toxicity of these materials. The asbestos fibers linked to respiratory illness have widths < 250 nm; amphibole (red or blue asbestos)

LTI
Low T refers to the forming $T < 1500^\circ\text{C}$. For ceramics 1500°C is not a high T .

FIGURE 35.10. Microbarcodes from Corning. The cylindrical bars are typically 100 μm long and 20 μm in diameter.

fibers are ~ 75 to ~ 240 nm wide, thus definitely counting as nanoparticles.

Examples of a microbarcode made by Corning are shown in Figure 35.10. The information is coded into the small glass bars so that they fluoresce. The pattern can then be read by illuminating the glass with ultraviolet (UV) radiation; otherwise, it is not only too small to see but the information would not be detected.

The magnetite crystals we discussed in Chapter 33 are used by nature in ways we don't fully understand, but they appear to allow certain species to detect the earth's magnetic field and use it to navigate.

Functionalized magnetic nanoparticles can be used as drug carriers to target specific abnormalities in the body, such as tumor cells. The particles can be directed using an externally applied magnetic field. In hyperthermia treatment, a ferrite or other magnetic material produces localized heating in the presence of an alternating magnetic field. The implanted nanomaterial and the surrounding area heat up, and this kills the targeted cancerous cells. A clinical study in Germany using prostate cancer patients showed that localized temperatures as high as 48.5°C could be obtained with a magnetic field strength of 4 kA/m. Cell death usually begins around 41°C , and necrosis (rapid death) occurs above 50°C (a healthy body temperature is 37°C).

TiO₂ nanoparticles are used in sunscreen to protect the skin from UV radiation. The particles used for this application are typically 10–100 nm in diameter and block both UVA (320–400 nm) and UVB (290–320 nm) irradiation. There is some concern that these nanoparticles (and those of ZnO) are so active that they might catalyze the breakdown of DNA, but they do not appear to penetrate the outer layers of the skin. The positive aspect of this is the potential for using these same TiO₂ nanoparticles for photo-killing malignant cells—known as photodynamic therapy. TiO₂ and ZnO particles are actually being coated

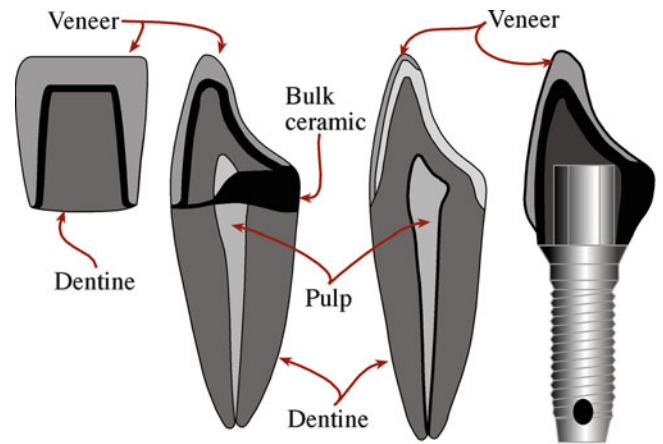

FIGURE 35.11. Tooth restoration.

with silica so the particle surface is more inert (a use for core-shell nanoparticles).

35.13 DENTAL CERAMICS

The feldspathic porcelains (porcelain based on feldspar) are used as the veneer to “cap” the front of a tooth for cosmetic reasons; these veneers are ~ 500 μm thick. Today, this material is mainly replaced by glass, although the name may not have changed. Leucite is added to modify the thermal expansion coefficient. Dicor is the glass-ceramic developed by Corning for constructing replacement teeth. The

tooth is cast as a glass using a lost-wax mold and then cerammed. Alumina has also been used to form the tooth although porosity causes failure during “use.” One way to improve this is to infiltrate the alumina with a lanthanum-containing glass (known commercially as In-Ceram). The different restorations are shown in Figure 35.11.

DENTAL RESTORATIONS

- Feldspathic veneers
- Porcelain jacket crowns (PJC)s

35.14 BIOMIMETICS

The topic of biomimetics was actually mentioned earlier but not using the new name. The principle underlying the development of biomimetics is “learning from nature.” Biomimetics can potentially lead to an enormous subset of ceramics. Not only are the materials important, their topology and microstructure are also special. The aim is to mimic natural materials that have special behaviors but to do it with “better” (i.e., ceramic) materials.

Shells (especially the abalone shell). Biological materials deposit inorganic layers. The abalone shell consists of layers of aragonite with ~5 wt% organic material (e.g., protein) between the layers to toughen it. A schematic cross section and a scanning electron microscopy (SEM) image of the aragonite layers are shown in Figure 35.12.

Coral. Used in the manufacture of bone grafts “as harvested” or after processing. It is a natural porous ceramic and can be converted to porous HA (see Section 35.7). Surgeons in the United States perform ~500,000 bone grafts each year.

Petrified wood. A natural material is infiltrated by a ceramic.

Petrified wood provides a good illustration of the surprising potential of biomimetics in a way that is analogous to the conversion of coral. Wood can be intentionally converted into biomorphic, microcellular SiC-based ceramics using a reactive melt-infiltration process or, more specifically, liquid-Si infiltration (LSI). The images in Figure 35.13 illustrate the possibility: the microstructure of the resulting composite depends on the nature of the wood used. Beech, pine, and rattan produce very different microstructures; and they are, of course, different in cross

FIGURE 35.12. (A) Schematic of the abalone shell. (B) Abalone slabs.

section and longitude. In this example, the infiltrating liquid was a molten Si-M alloy (Mo, Ta, Ti, and Fe were explored as the metal, M). For Mo, this produces a MoSi_2/Si composite. The LSI technique has been used previously to produce SiC and Si_3N_4 ; the special feature here is the biomimetic structure produced by the wood.

FIGURE 35.13. Wood converted into ceramics by a reactive melt-infiltration process.

CHAPTER SUMMARY

Bioceramics is a relatively new field and an increasingly important one. Bioceramics are implanted into the human body to replace existing parts that have become diseased, damaged, or worn out. More than one million hip prostheses using alumina components have been implanted. Alumina is a very important bioceramic because it is biocompatible—it doesn't produce any adverse reactions in the body. One of the disadvantages of alumina is that it is also an example of what is termed a nearly inert bioceramic: it doesn't allow interfacial bonding with tissue. When bioactive ceramics and glasses are implanted into the body, they undergo chemical reactions on their surface, leading to strong bond formation. The most important bioactive ceramic is HA, which is very similar to the mineral part of teeth and bones. HA is brittle and mechanically weak; but if it is combined with a polymer, we can produce a composite that is ductile and has E close to that of bone. HA and other bioactive ceramics and glasses are often used as coatings on metal supports. This allows the excellent mechanical properties of the metal to be combined with the biocompatibility of ceramics. Another ceramic material that is used in the form of a coating is pyrolytic carbon. The application here is artificial heart valves, which is a very demanding materials application: reliability is critical. We concluded the chapter with a brief discussion of biomimetics (which is related to bionics, etc.) and emphasized that this will become a large field in itself, but you must understand the materials to take full advantage of this potential.

PEOPLE AND HISTORY

Duchateau, Alexis (1714–1792) was the pharmacist in Paris who made the first porcelain dentures in ~1770.

Dubois de Chémant, Nicolas (1753–1824) wrote a dissertation on artificial teeth describing the advantages using mineral paste to make replacement teeth. He escaped to England from the French Revolution and later obtained porcelain paste from Wedgwood.

Gluck, Themistocles (1853–1942) is generally regarded as the inventor of artificial biomaterials (ivory was a favorite).

Hench, Larry (born 1938) developed Bioglass[®] in 1969. He is Emeritus Professor of Materials at Imperial College, London.

Hippocrates (460–370 BCE). One of his aphorisms can be translated as: those diseases which medicines do not cure, iron cures; those which iron cannot cure, fire cures; and those which fire cannot cure, are to be reckoned wholly incurable. Modern hyperthermia treatment uses ferrite nanoparticles to locally generate heat.

EXERCISES

- 35.1 Briefly compare and contrast the suitability of metals, ceramics, and polymers for use in biomedical applications. In your answer, consider the following factors: biocompatibility, mechanical properties, and ease of processing.
- 35.2 Alumina (Al_2O_3) ceramic implants are required to have a small grain size ($<4.5 \mu\text{m}$). (a) Why do you think a small grain size is important? (b) How does the addition of MgO to the powder mixture help to keep the grain size small? (c) Are there any other ways that could be used to limit the extent of grain growth?
- 35.3 Explain why tetragonal zirconia polycrystal (TZP) and Mg-partially stabilized zirconia (PSZ) ceramics have higher toughness than alumina ceramics.
- 35.4 The Weibull modulus of an alumina bioceramic is given as 8.4. (a) What does a value of $m = 8.4$ imply? (b) For an implant made out of a metal, the value of $m \sim 100$. What implications would this have for lifetime predictions for the metal component compared to the alumina component? (c) How does the value of m affect the design of a component for a load-bearing application?
- 35.5 The composition of Bioglass[®] 45S5 is 45% SiO_2 , 24.5% Na_2O , 24.4% CaO , and 6% P_2O_5 . (a) Classify each of the oxide constituents of 45S5 as either network formers, modifiers, or intermediates. (b) What would the composition of Bioglass[®] 45S5 be in mol%? (c) Explain briefly how the structure of 45S5 differs from the silicate glasses described in Chapter 7 and what implications this difference has on the properties of 45S5.
- 35.6 The substitution of ions in the hydroxyapatite (HA) structure can change the lattice parameters of the unit cell. Explain how you think the substitution of Ca^{2+} for the following ions would change both the a and c lattice parameters: Sr^{2+} , Ba^{2+} , Pb^{2+} , Mg^{2+} , Mn^{2+} , and Cd^{2+} .

- 35.7 According to ASTM Standards [American Society for Testing and Materials (1990) Annual Book of ASTM Standards, Section 13, F 1185–1188], the acceptable composition for commercial HA is a minimum of 95% HA, as established by X-ray diffraction (XRD) analysis. Describe how XRD can be used to determine phase proportions in a mixture.
- 35.8 We mentioned that in steel fibers/bioactive glass composites it was important that there was chemical interaction between the two components to ensure stress transfer during loading. We have just formed a bioceramics company and want to hire you as a consultant. We want you to determine whether such interactions have occurred in a composite we have just made. What analytical technique or techniques would you use for your evaluation? Explain the reasoning behind your answer and some of the pros and cons of the technique or techniques you chose.
- 35.9 One of the advantages of plasma spraying for producing HA coatings on metallic implants is that the substrate temperature can be kept relatively low. What possible mechanisms can lead to a loss in the mechanical strength of a metal if it is exposed to high temperatures? (You can limit your discussion to the cases of Ti alloys and stainless steel).
- 35.10 Explain why the mechanical properties of turbostratic carbons such as LTI are different from those of graphite. Both are forms of carbon and are chemically identical.
- 35.11 We can use several definitions of a biomaterial. Discuss at least three that have been proposed and explain why you prefer the one given here.
- 35.12 Explain why HA and TCP behave differently in the body.
- 35.13 Name the two main types of bone. Say where they are found in the body and why.
- 35.14 Why is stress shielding a problem for prostheses?
- 35.15 Why is alumina used as the femoral ball, and why is so much work aimed at improving this device?
- 35.16 What is a bioactive ceramic, and why has Bioglass been so successful?
- 35.17 Discuss the composition and structure of Cerabone and explain why it was so designed.
- 35.18 Write down the general formula for HA and state its percentage in bone by weight and volume. How does its structure relate to its properties?
- 35.19 Discuss why thermal spraying is the preferred method for producing HA and TCP coatings.
- 35.20 Summarize and justify five uses for nanobioceramics.

Minerals and Gems

CHAPTER PREVIEW

We begin this chapter by explaining why we're including gems in a text on ceramics. Gems have been intimately linked with many developments in the use of ceramics or have been the motivation for what has become a leap forward in ceramic processing or application. We saw earlier how the efforts by August Verneuil in the early 1900s to produce synthetic ruby lead to an industry that produces 2×10^5 kg of single-crystal Verneuil sapphire each year. Similarly, flux-growth techniques and hydrothermal quartz owe much to the desire to create gems. Gemstones use some special properties of ceramics: they can be transparent but with a range of colors; they scatter light (the sparkle); the valuable ones are generally very stable (the less valuable have often been treated—actually, most gemstones have been processed in some way). We discuss the well-known gems and a few of the lesser known (for their special features). The most important gems are diamond, ruby, sapphire and emerald. However, many other gems that are less well known may often be more valuable. Incidentally, the weight of a gemstone is usually given in carats (5 ct = 1 g). We also use this chapter to summarize the links between some preceding topics, including history. If a friend hands you a blue (or red, yellow, green, colorless) faceted sparkling stone and asks you to identify it (because you studied ceramics), what do you do or say? So when you read this chapter, keep asking yourself—what ceramic science is involved here?

36.1 MINERALS

Mining and mineral engineering are not always popular topics today. Many gemstones and mineral specimens are found during mining operations. The bulk of the minerals are then processed by physical or chemical means. Ceramists should have some knowledge of mineral processing because it can be the clue to understanding why certain impurities are present in powders used to produce high-tech ceramics (hence our discussion of raw materials in Chapter 19), but minerals and gemstones have many commercial, in addition to decorative (ornamental), uses.

Grinding is a particularly simple example of physical processing. It has been used to make pigments, early cosmetics, and the ingredients for the potter's slip. It is a key step in modern ore processing (see Chapter 19), but it has been used for centuries to make powders.

Grind hematite to produce the red pigment *ochre*.

Grind cinnabar to produce the major component of *vermillion*.

Crush lapis lazuli like the Persians did to make *ultramarine*.

Grind azurite like the ancient Egyptians did to produce the blue pigment *azure*.

Grind tin oxide like the Romans did to make a white cosmetic paste.

Be cautious about using ground *talc* on your body.

Of course, grinding is also the principle of the abrasives industry. Powders may be made by grinding or used for grinding/polishing, as we discussed in Section 18.12.

A crystal of galena was used in the cat's whisker radio (in the "point-contact" diode); Cu wire was slowly moved across the galena crystal to tune the device. Thin slices of tourmaline crystals were used in making the pressure gauges that measured the power dissipated by the first atom bomb explosions (tourmaline is piezoelectric).

Chalcedony is "noncrystalline" quartz. Examples of chalcedony are agate, jasper, and carnelian; they form by hydrothermal growth—hence the banding you see on stones in museum shops. The color depends on the impurities, and not much impurity is needed (it can easily be changed/dyed). We discuss flint and opal separately, although they are closely related. Flint tools, like obsidian tools, were used thousands of years ago. Flint consists of fine-grain silica (the black color is caused by trapped carbon) and fractures like obsidian, producing sharp edges that are ideal for cutting.

Alabaster, gypsum ($\text{CaSO}_4 \cdot 2\text{H}_2\text{O}$) and plaster of Paris ($2\text{CaSO}_4 \cdot \text{H}_2\text{O}$) are all calcium sulfate (the last of these has been treated to produce the hemihydrate). Fine-grain gypsum is easily carved: fractures do not propagate far. Alabaster ornaments were made in Assyria (Iraq) before 2,000 BCE and plaster of Paris was used by the Egyptians in ~3,000 BCE in making mortar.

NATURAL GLASS THREAD

Pele's hair (the Hawaiian goddess of volcanoes, not the footballer) consists of natural threads of basalt glass often containing crystals of olivine. Like obsidian and pumice it forms in volcanic eruptions.

One challenge is to identify a particular gemstone.

The scientist's way: use X-ray diffraction (XRD), X-ray energy dispersive spectroscopy (XEDS), wavelength dispersive spectrometry (WDS), or a comparable technique for chemical analysis.

The gemologist's way: use the refractive index or the thermal and/or electrical conductivity.

The difference, of course, is that the gemologist must often identify the gemstone in the field (in the home, in the mine, or really in the field) without taking the sample to the laboratory. With experience, you can, for example "feel" if a stone is a good thermal conductor.

Some questions you might be asked:

- Is this stone really diamond not cubic zirconia (CZ), white sapphire, or even moissanite?
- Why is the Black Prince's ruby so dark? (It's in the English Crown Jewels, and it's not a ruby.)
- Is this stone peridot or green glass? (If you can't tell, need you care?)
- Is this natural turquoise? (Probably, but the better question is: has it been treated?)
- Are there defects in my emerald? (Yes.)
- Is natural emerald better than synthetic emerald? (Synthetic is usually more perfect.)
- Should I wash my opal with water or with alcohol? (No.)

The questions emphasize the need for techniques to aid the eye in examining these materials or the need to understand the structure and chemistry of gemstones when handling them.

36.2 WHAT IS A GEM?

Gems are often characterized as expensive sparkling stones. The value is not necessarily as obvious as we might hope. Even so, you can spend significant money on gems.

A gem can be real (natural), synthetic (grown in the laboratory or factory), or a simulant (one material made to look like another).

Gems can provide a link between ceramics, geology, crystallography, mechanical testing, solid-state, physical, and inorganic chemistry, and electrical engineering. They provide the ceramist with many challenges, such as, identify this ceramic (gem) without removing it from the gold band it's set in. Table 36.1 lists some of the best-known gemstones with some of their special features.

TABLE 36.1 Gemstones

Hard and resistant to chemicals	<i>Chrysoberyl</i> , BeAl_2O_4 <i>Corundum</i> , Al_2O_3 <i>Quartz and chalcedony</i> , SiO_2 <i>Spinel</i> , $\text{MgO} \cdot \text{Al}_2\text{O}_3$
Gem carbonates (not so hard)	<i>Calcite</i> , CaCO_3 <i>Malachite</i> , $\text{Cu}_2(\text{OH})_2\text{CO}_3$ <i>Rhodochrosite</i> , MnCO_3
Gem phosphates (not so hard)	<i>Apatite</i> , $\text{Ca}_5(\text{F}_2\text{Cl})(\text{PO}_4)_3$ <i>Turquoise</i> , a complex hydrated phosphate of copper and aluminum

36.3 IN THE ROUGH

The traditional mining of gemstones is illustrated in Figure 36.1. Because many mines are in less developed countries and very small stones can be very valuable, the mining tends to rely on manual labor. Open mines such as the one shown here are inexpensive to establish and in many cases have not changed in centuries. Miners then and now often have to endure brutal conditions. The following quotation, which is believed to be dated about 1830 BCE describes the conditions suffered by Egyptian turquoise miners in the Sinai.

[The Pharaoh] dispatched the Seal-Bearer of the God, the Overseer of the Cabinet, and Director of *Lances*, Hor-ur-Re, to this mining area. This land was reached in the 3rd month of the second season [June, an almost unbearably hot season in Sinai], although

FIGURE 36.1. Open cast mining in the Magok region of Myanmar (Burma).

it was not at all the season for coming to the mining area. The Seal-Bearer of the God says to the officials who may come to this mining area at this season:

Let not your faces flag because of it. Behold ye, Hat-Hor [Egyptian goddess of the Sinai mines] turns it to good. I have seen (it so) with regard to myself. I came from Egypt with my face flagging. It was difficult, in my experience, to find the (proper) skin for it, when the land was burning hot, the highland was in summer, and the mountains branded an (already) blistered skin. When the day broke for my leading to the camp, I kept on addressing the craftsmen about it: "How fortunate is he who is in this mining area!" But they said: "Turquoise is always in the mountain, but it is the (proper) skin which has to be sought at this season. We used to hear the like, that ore is forthcoming at this season, but, really, it is the skin that is lacking for it in this difficult season of summer!"

Examples of gemstones *in the rough* are shown in Figure 36.2; many of these natural stoned show have shapes that are determined by their crystallography. Sources of sapphire, ruby, emerald, and diamond are given in Table 36.2. Sapphire tends to grow with a hexagonal shape, as seen in these images; the best-quality natural sapphire is shaped like a double hexagonal pyramid. Many of the harder gemstones (especially diamonds, sapphires, and garnets), are found in rivers, where they have been deposited after removal from their native (natural) softer matrix.

Some specimens of natural gemstones are much larger than you might think. Just to remind you: amethyst *cathedrals* and *wheels* are the results of natural hydrothermal growth. The cathedrals can be >2 m tall.

36.4 CUTTING AND POLISHING

Idar-Oberstein started polishing agates in the 1800s and is now a center for polishing gemstones. Antwerp and Amsterdam have been the centers for diamond cutting for many years, although much of this trade is now carried out in Asia. The basic processes are the saw and the polishing wheel. The saw is tipped with SiC, alumina, or diamond for precision work. Originally, the polishing pads used jeweler's rouge, but they now use various compounds including Syton™, alumina, zirconia, and ceria. For most polishing, the process used actually has both a chemical and mechanical component and is thus known as chemical/mechanical polishing (CMP). The professional polisher uses a dop stick and wheel. In the diamond trade, this has been partly automated using a tripod device (not unlike the tripod used for polishing transmission electron microscopy, or TEM, samples) to replace, or to help steady the hand of, the polisher; these are illustrated in Figure 36.3.

There are numerous books describing the shapes produced by polishers of gemstones. Figure 36.4 shows the main parts of a faceted stone to illustrate the terminology. For faceted stones, the upper part is called the crown and consists of the table and the bezel. The girdle separates the crown from the pavilion, which is also called the base or the back. If a face is polished on the pavilion parallel to the table, it's called the culet. If you can see straight through the stone from the table through the culet, then the stone has a window. The shape of a brilliant-cut diamond is designed so that the light is all reflected back to the source placed directly in front of it—the pavilion facets act as

mirrors. The term *en cabochon* refers to the shape (a cabochon—e.g., a skull) shown in the lower part of Figure 36.4, which is essentially a nonfaceted stone.

The {111} plane of diamond is the hardest plane to polish, which is why diamonds were initially left with {111} surfaces

FIGURE 36.4. Different regions of polished (cut, faceted) stones and two cross sections of cabochons. T table, C culet, G girdle.

FIGURE 36.3. Equipment used for polishing gemstones.

and just the tip was polished off. Small, naturally occurring octahedral crystals of diamond are quite common.

Carving minerals and gemstones is an old art. An example of a rock crystal goblet is shown in Figure 36.5. Old jade statues, fluorite bowls, and alabaster figures are museum pieces, but new ones are still being produced. The challenge in carving the harder minerals and gemstones is simply that they are hard and you reduce the weight of the stone as you carve it.

36.5 LIGHT AND OPTICS IN GEMOLOGY

The gemologist judges diamonds by the four C's: color, clarity, cut, and carat (weight). Here, cut may actually mean cleave followed by polish. You would rather avoid cutting a

FIGURE 36.5. Examples of natural mineral specimens that have been shaped: (A) Buddha in garnet; 45 mm tall. (B) Rock-crystal bowl (~150 mm diameter).

stone because that wastes material. Remember, 1 carat is 0.2 g (about the weight of a carat—a small seed used in ancient Egypt as a unit of weight). As diamonds can be expensive, you may also encounter points (100 points in 1 ct).

The important optical properties that contribute to the attractiveness associated with precious gems are:

Color. Color is one of the main features we consider when choosing a gemstone. There are many different reasons for these colors (e.g., Cr makes emerald green and rubies red).

Refractive index. The higher the value of the refractive index (n or RI) of a properly cut gem, within limits, the more light returns to the eye of the viewer, resulting in brilliance, sometimes also termed life or liveliness. Diamond has a particularly high value of $n = 2.417$.

Dispersion. The dispersion is usually given as the difference in n for the b and g Fraunhofer solar spectrum lines. The Fraunhofer lines serve as reference markers across the spectrum. The b line is in the green part of the spectrum, and the g line is in the violet. The dispersion is 0.044 for diamond, one of the highest values for a natural gemstone. Dispersion causes rays of light to be split into their colored components, which then emerge in slightly different directions to produce what the trade calls *fire*.

We discuss the causes of color in gemstones separately, but the point to remember here is that color is determined by the wavelength of the light, λ , and the n of a crystal depends on λ (dispersion). Table 36.3 gives examples of

Al_2O_3 , α -alumina	1.761, 1.769	KCl (sylvite)	1.49

FIGURE 36.6. (A) Portable jeweler's refractometer for measuring the critical angle. (B) Optics of determining the critical angle using the refractometer.

the n values of minerals and related materials, which are determined by measuring the critical angle on a hand-held refractometer (Figure 36.6) or a bench-top goniometer-style refractometer (Figure 36.7). Not all materials are transparent to visible light when they are too thick (i.e., we think of them as being opaque). Sphalerite, for example, is a grey crystal, but it is an orange gemstone with an n of 2.36.

Absorption. The other factor that is particular to different materials is the optical absorption. The absorption spectrum can easily distinguish different gems. Although laboratory instruments are best, gemologists can use a hand-held spectrometer. Hematite is gray unless the light passes through it, in which case it appears red (hence its name). A streak of hematite appears red for the same reason; hematite with powder on the surface appears red. The reason for the red color is that hematite absorbs blue light. Two types of absorption spectrometer are used: one based on prisms and the other using a diffraction grating (both are shown in Figure 36.8). The wavelengths that are absorbed are well defined and are characteristic of both the doping (if it colors the stone) and the matrix itself, as illustrated in Figure 36.9, where you can see stones with the same color clearly differentiated.

Facets. The faceted gemstone is ideally shaped to optimize its sparkle, which is simply saying we want to maximize the amount of light that is reflected back to the observer, as shown in Figure 36.10. The objective of faceting, then, is to make the most of internal reflection. Note that the facets that you see on most gemstones are not crystallographic planes; the gemologist essentially never uses XRD to orient the sample!

FIGURE 36.8. (A) Photograph of a spectrometer. (B) The prism spectrometer. (C) The absorption spectrometer.

FIGURE 36.9. Spectra from different minerals.

Immersion. A simple method for estimating the refractive index is to use liquid immersion. The stone is immersed in a series of liquids of known refractive index (values of the n values for different liquids are given in Table 36.4). The idea is that the gemstone “disappears” when placed in a

liquid that has the same n (Figure 36.11). The principle is that there is no longer a change in refractive index at the surface of the stone, so that even if it is faceted it does not reflect light internally. Of course, the technique is not good if the solvent can penetrate the stone or dissolve any filler.

Reflection. A more accurate method for determining the n of a gemstone is to measure the critical angle (the Brewster angle, θ_B) for reflection using a reflectometer. The principle is that the refractive index of a material is given by

$$n = (\sin \theta_I) / (\sin \theta_E) \quad (36.1)$$

Here the angle is defined as the angle to the normal ($\theta_I =$ incident angle; $\theta_E =$ exit angle). In the reflectometer, we place the gemstone in contact with a prism, the n of which is chosen to be large. We then adjust the incident angle until it is θ_B and deduce the n of the stone from equation 36.2.

$$n_{\text{gemstone}} = n_{\text{prism}} \times \sin \theta_B \quad (36.2)$$

Figure 36.6B illustrates the optics of the reflectometer.

Pleochroism. When the n of a crystal varies with the direction in which light travels through it, the absorption can be different in different directions. The crystal then shows a different color when viewed in different directions, which gives another method for identifying the crystal. If there are two distinct directions, the crystal is said to be dichroic (tetragonal, trigonal, and hexagonal crystals). Iolite (cordierite, $\text{Mg}_2\text{Al}_4\text{Si}_5\text{O}_{18}$) and tanzanite [the purple form of zoisite, $\text{Ca}_2\text{Al}_3(\text{SiO}_4)_3(\text{OH})$] are two of the best-known examples. Crystals can show three colors: orthorhombic, monoclinic, and triclinic crystals are trichroic. Pleochroic means either dichroic or trichroic. The dichroscope (Figure 36.12) is a simple handheld device that is used to estimate the dichroism of a gemstone. It uses a crystal of calcite to separate the polarized rays and then compares them side-by-side to see how the color differs. Calcite has strong double refraction. You have to rotate the stone because dichroism is not present when viewed along the optic axis. In the laboratory, you might use the polarizing visible light microscopy (VLM) instead of the handheld device.

36.6 COLOR IN GEMS AND MINERALS

We treat color separately for the different minerals and just add a few notes here. The importance of dopants is clear from Table 36.5. There are several different causes of color in gemstones. Most are associated with local trapped charges.

- Metal ions can give up an electron, which may remain trapped locally. Tavorite is green because of the V^{3+} , but the same ion causes tanzanite to be purple.

FIGURE 36.10. Origin of the sparkle in gemstones: total internal reflection.

Monobromobenzene	1.56
Bromoform	1.60
Monoiodobenzene	1.62
α -Monobromophthalene	1.66
Methylene iodide	1.74

FIGURE 36.11. Determining the shadow patterns when stones are immersed in methyl iodide or liquid of another n . Different liquids are given in Table 36.4.

- When we have two metal ions in different oxidation states, we can have intervalence charge transfer. The interplay between Fe^{2+} and Ti^{4+} causes the blue in blue sapphire and blue kyanite, but it also makes dravite brown. Mn^{2+} and Ti^{4+} combine to cause elbaite to be yellow.
- Instead of using a reactor or other source of radiation, natural ionizing radiation can excite electrons in a crystal. Fluorite can be red, green, or purple due to natural irradiation. The same irradiation can cause topaz to be brown (see below).
- The arrangement of defects (as in labradorite feldspar) or of grains (as in opal) can cause diffraction of the light.

- The mineral may be a semiconductor, as in the case of sphalerite.

Blue. The common blue stones are sapphire, lapis, and irradiated topaz. Less common gemstones include blue

FIGURE 36.12. Dichroscope for estimating the dichroism of a stone and the optics on which it is based.

TABLE 36.5 Transition Element Dopants and Color

Titanium	Blue sapphire (with iron), blue zoisite (tanzanite)
Vanadium	Grossular garnet (tsavorite), green vanadium beryl, synthetic corundum (alexandrite simulant), some synthetic emeralds, blue/violet sapphire
Chromium	Ruby, emerald ^a , red spinel, pyrope garnet, chrome grossular garnet, demantoid garnet, uvarovite garnet ^b , chrome diopside, green jadeite, pink topaz, alexandrite, hiddenite
Manganese	Rhodochrosite ^b , rhodonite ^b , spessartite garnet ^b , rose quartz, morganite variety of beryl, andalusite
Iron	Sapphire, sinhalite ^b , peridot ^b , aquamarine, blue and green tourmaline, enstatite, amethyst, almandine garnet ^b
Cobalt	Synthetic blue and green spinel, synthetic blue quartz (except for a rare blue spinel, cobalt is not found in any natural transparent gemstone); cobalt glass
Nickel	Chrysoprase, synthetic green and yellow sapphires
Copper	Diopside, malachite ^b , turquoise ^b , synthetic green sapphire

^aIn UK and Europe only beryl colored by chromium may be described as emerald.
^bIdiochromatic gemstones.

diamond, although such stones could be common if irradiated more often.

Green. The green stones include emerald, malachite, and both uvarovite and tsavorite garnets.

Red. The red stones include ruby and both pyrope and almandite garnet (almandine).

FIGURE 36.13. (A) Combined effect of incorporation of Ti and Fe in sapphire. The distance between the dopant cations is 0.265 nm. (B) Corresponding energy band diagram for the excitation shows how a gemstone with blue coloration is obtained by absorption.

Yellow. Yellow stones are less common but include citrine, yellow sapphire, and yellow diamond.

The color of *ruby red* and *emerald green* is the result of a transition metal in a ligand field (see Section 32.5). In both cases, the coloring ion is Cr^{3+} substituting for an Al^{3+} ion. Ruby is red corundum (Al_2O_3) containing about 1% Cr_2O_3 . The Cr^{3+} ion, which is only a little larger than Al^{3+} , is easily accommodated into the corundum structure. The five 3d orbitals in the Cr^{3+} ion split in the distorted octahedral ligand field. This is a slightly more complicated case than for the simple octahedral ligand field we described in Section 32.5 and involves further splitting of the 3d levels, as shown in Figure 32.9. Nevertheless, absorption of selected values of λ in the visible spectrum is due to electron transitions. Absorption is strongest in the green and violet and least in the red and blue; this gives ruby its red color with a slight purple overtone. In emerald, the color is again due to the Cr^{3+} ion replacing Al^{3+} in a distorted octahedral arrangement very similar to that in corundum. Emerald without the chromium impurity is beryl, which has the chemical formula $3\text{BeO} \cdot \text{Al}_2\text{O}_3 \cdot 6\text{SiO}_2$ or $\text{Be}_3\text{Al}_2\text{Si}_6\text{O}_{18}$. Because of the presence of the other constituents (it's a ring silicate), the overall bonding is a little weaker and the ligand field is less strong. As a result, the splitting of the energy levels is different, with strong absorption occurring in the yellow-red and violet regions and strong transmission in the blue-green.

For *sapphire blue*, the color results from a charge transfer mechanism. Sapphire shares the corundum structure with ruby, but the impurities are now small amounts of both iron and titanium oxides. Both Fe^{2+} and Ti^{4+} take the place of Al^{3+} in the corundum structure. If they are present on adjacent sites, as shown in Figure 36.13, an interaction

between them becomes possible. In this configuration, there is enough overlap of the d_z^2 orbitals of the two ions that it is possible for an electron to transfer from the Fe^{2+} ion to the Ti^{4+} ion as follows.

The energy of the combination on the right side of equation 36.3 is 2.11 eV higher than that on the left side, as shown in Figure 36.13. If light of this energy falls on blue sapphire, it is absorbed while producing the charge transfer shown in equation 36.3. You can produce the blue color by doping with Ni or Co, but the mechanism is different.

36.7 OPTICAL EFFECTS

Chatoyancy. The scattering of light by aligned fibers or channels within a matrix gives the optical effect seen in the minerals cat's eye and tiger-eye; the effect is termed chatoyancy. The crystals are cut *en cabochon*, with the long axis parallel to the fibers because you don't need the internal reflection from the surfaces. Tiger-eye (or tiger's eye) is quartz that contains oriented fibers of crocidolite. The mineral started as crocidolite (a form of asbestos) and was partly replaced by silica, which then becomes the matrix to the crocidolite fibers. This effect is shown together with others caused by interference in Figure 36.14.

Precious, or oriental, cat's eye is the rarest and most highly prized form of chrysoberyl; it is a green mineral called cymophane. The chatoyant effect is due to parallel arrays of pores.

Asterism. This term refers to the star effect that can occur in sapphires, rubies, and garnets. The effect is illustrated for sapphire, where it is often the strongest (Figure 36.15). In this case, aligned precipitates in the single crystal cause the optical effect. Because sapphire has a threefold axis, the precipitates reproduce this symmetry by aligning along particular directions giving the sixfold star. In black sapphire, the needles are hematite; in essentially all other sapphires, they are rutile. Some star sapphires from Thailand contain both hematite and rutile (sometimes called silk because they are so fine) and show 12-fold stars. In star garnets and diopside, the star shows fourfold symmetry. In garnet, the crystals lie at 90° along [001] directions; in diopside, they lie at 73° to one another.

Iridescence. The best known form of iridescence is opalescence. The reason opals show different colors when viewed in different directions is that the silica spheres are just the right dimensions to diffract light, as illustrated in Figure 36.16.

Labradorescence and adularescence (shiller). These are two forms of iridescence caused by planar interference in a transparent mineral. Labradorite is a plagioclase

FIGURE 36.14. Chatoyancy: scattering of light by aligned fibers or precipitates.

feldspar named after the Labrador Peninsula in Canada; spectrolite is a special feldspar found in Finland. Labradorescence results from the presence of lamellar intergrowths inside the crystal; two phases of slightly different composition separate out as the mineral cools. The interference occurs when light is reflected from the different interfaces. The color we see (illustrated in Figure 36.17) depends on the effective thickness of the layers and thus on the viewing angle. Moonstone is transparent feldspar that shows this effect. The planar defects in these feldspars are actually lamellar twin boundaries arising from chemical twinning.

36.8 IDENTIFYING MINERALS AND GEMS

Because many gemstones appear quite similar, which is why they can be simulated, it is important to be able to distinguish the real from the synthetic or from the simulant. If you have scanning electron microscopy (SEM) available, the latter task is not a problem; but usually this is not the case in the field (or the shop). The basic tests are for thermal conductivity, optical properties, and mechanical

FIGURE 36.15. Asterism: effect of precipitates oriented along several different directions, giving rise to the star in star sapphire.

properties. Using a mechanical test to characterize a material that you don't want to damage is clearly tricky, so the use of hardness measurements is directed more toward minerals than gemstones.

36.8.1 Hardness (Toughness)

Indentation has been discussed in Section 16.3. Although these tests could be used for gemstones, they are not, except as a calibration. The Mohs scratch hardness scale

FIGURE 36.16. Origin of opalescence: Bragg scattering of light from a surface of ordered spheres. Best known in opals.

FIGURE 36.17. Laboradite causes an iridescence due to scattering by twin planes in the feldspar crystal.

is much more popular because the principle is to test what the stone does scratch, not what scratches the stone.

The Mohs hardness test (the word scratch is assumed) is almost a nondestructive test. The hardness of a gemstone is usually referred to as its Mohs hardness. As this *hardness* value is determined by a scratch test, it is not actually a *hardness*. The scale has many drawbacks, including the fact that it is not linear, it does not necessarily relate to wear resistance, and it damages the specimen—so it's not ideal for polished stones.

Table 36.6 gives Mohs hardness values for the *Gem Scale* and for some other materials as a comparison. (Note that in Chapter 16 we consider the extended version as defined by Ridgeway but it is not nearly so widely used in the gem industry). The table also includes a “relative” hardness scale. Remember that minerals are anisotropic, so the Mohs hardness of kyanite is ~4.5 when scratched parallel to the long axis and ~6.5 when scratched perpendicular to the long axis. Incidentally, this material is not

TABLE 36.6 Classical Mohs Hardness Scale for Gems

Mohs #	Classic Abs #	Classic mineral	Other materials
1	1	Talc	Pencil lead (graphite)
2	3	Gypsum	Your fingernail (2.2)
3	9	Calcite	Chalk (3), gold (2.5–3.0), dolomite (3.5–4.0), ZnS (3)

CZ	5
Glass	1

^aMean value between *c* axis and *z* axis directions

confused with kaolinite using this test because the latter has a Mohs hardness of 2.0–2.5.

An additional problem in using mechanical tests for minerals is that many tend to cleave. Wear (or abrasion) might be a better test, but it's more difficult for the gemologist.

36.8.2 Thermal Conductivity

The thermal conductivity of gemstones provides a useful way of identifying a mineral in the field. Table 36.7 lists values used for gemstones. The common assumption is that gemstones are poor conductors of heat. Diamond is actually a much better thermal conductor than Cu. The measurement of thermal conduction of gemstones is particularly attractive as a test because it can be applied to stones that

FIGURE 36.18. Pocket-size instrument for measuring thermal conductivity.

are already mounted (e.g., in a ring). The instrument supplies the heat, and the sink is either the ring or another part of the device. The device shown in Figure 36.18 measures the change in temperature of its tip when the tip is placed in contact with the gemstone. When testing the poorer thermal conductors, the temperature of the tip is allowed to fall until it reaches a first set value, when the subsequent decrease to the next set value is timed—much like taking a blood pressure reading.

36.9 CHEMICAL STABILITY (DURABILITY)

Gemstones are usually thought of as being chemically stable. Some are; some are certainly not. Opal contains a significant amount of water; if this water is removed, the opal fractures and degrades. Emeralds are slightly different in that they usually already contain many fractures that have been filled with oil or polymer. If this filler is removed—for example, by cleaning with a solvent—the fracture may extend. Even though the diamond in an engagement ring is durable, the 18 k gold setting holding it in place may not be, especially if it is exposed to chlorine-containing liquids, such as in a swimming pool or hot tub.

36.10 DIAMONDS, SAPPHIRES, RUBIES, AND EMERALDS

Why diamond? Yes, it's hard, but it is its optical qualities (and great advertising) that have made it so popular. The refractive index of diamond is 2.42, whereas rutile (once proposed as a diamond simulant) and moissanite (now being used as such) have refractive indices of 2.6/2.9 and 2.65/2.69, respectively, so they do not have the best optical properties (for internal reflection).

Diamonds can now be synthesized to weigh more than 0.6 g (3 ct). This is an art in regard to the color and clarity. The production of gem-quality synthetic diamonds (see Section 29.14) gives a deep yellow color. Colored diamonds tend to be more valuable than colorless ones simply because they are more rare. The Dresden green diamond weighs 40.70 ct and is the largest known green diamond in the world. Natural red, pink, and yellow diamonds can also command prices of near \$1 million per carat. The danger is that diamonds can also be artificially

colored by irradiating them; diamond was perhaps the first irradiated gem. Blue B-doped diamond is a semiconductor, whereas blue irradiated diamond is still an insulator. A concentration of 10^{-6} B in diamond gives it a deep blue color as seen in the Hope diamond. A B-doped diamond fluoresces under ultraviolet (UV) light and continues to glow for minutes afterward.

Diamonds are actually mined in large quantities in South Africa and Russia, with newer sources in Sierra Leone and northeast of Yellowknife in Canada's Northwest Territories. Natural diamonds are created 150 km beneath the earth's surface and are transported to the surface by volcanic activity. The Kimberley Pipe is the remains of such volcanic activity. A pipe is a carrot-shaped volcanic neck; there is a cluster of 11 pipes at Kimberley—they are about 1.2 billion years old. The largest kimberlite pipe is now the Premier Mine at Cullinan, which produces 1.6 million ct annually. The original location of kimberlite is now known as Kimberley's "Big Hole."

Nitrogen causes both synthetic and natural (e.g., the Tiffany Yellow) diamonds to be yellow. A Florida company has up to 200 diamond-making growth chambers, each weighing about 4,000 lbs (cost ~\$50,000 each). Each chamber can produce eight 3-ct rough stones per month. A little history: a team of five Russian scientists in Novosibirsk, Siberia, managed to create gem-quality diamonds at the relatively low pressure of 60,000 atm. in 1989, which avoids the high pressure of the so-called GE process used to make industrial diamond. Carter Clarke, an American entrepreneur, paid \$57,000 in 1996 for a "diamond-growth chamber" during a business trip to Russia; the chamber was the size of a washing machine. He then founded Gemesis.

For some time, mixtures of H_2 and natural gas have been used for chemical vapor deposition (CVD) growth of diamond-like carbon (DLC) films. It is now possible to use this technique to grow diamond seed crystals to produce clear, perfect, colorless diamonds. Diamonds grown by the high-pressure methods are invariably doped and thus colored. One company, Apollo, has used the technique to grow 1-ct diamonds.

Examples of famous diamonds are listed in Table 36.8. One feature that is obvious when you think about it: these gemstones were all cut from much larger rough stones. When first extracted from the Premier Mine near Pretoria, the *Cullinan* diamond weighed 0.621 kg. It was later cut into 9 major gemstones (the largest 2 being in the list and shown in Figure 36.19) and 96 other stones. The *Hope* diamond, thought to be from the Kollur Mine in Golconda, India, was first cut into a triangular $112\frac{3}{16}$ -carat stone. In 1673, it was recut to give a $67\frac{1}{8}$ -carat stone and then presumably cut again

TABLE 36.8 Famous Diamonds

Name	Weight	Notes
Hope	45.52 ct	Blue due to B doping L = 25.60 mm, W = 21.78 mm, D = 12.00 mm In the Smithsonian
Koh-I-Noor (Mountain of Light)	105.60 ct	Originally 186 carats Tower of London
Cullinan I (Great Star of Africa)	530.20 ct	Original rough Cullinan Diamonds 3,106 ct Tower of London (10 × 6 × 5 cm)
Cullinan II (Lesser Star of Africa)	317.40 ct	In the British Imperial Crown Tower of London
The Regent	140.50 ct	In the Louvre
The Centenary	273.85 ct	Found in 1986 (de Beers Centenary). Rough wt. 599 ct. In the Tower of London
The Tiffany Yellow	128.51 ct	Found in De Beers mine, Kimberly 1887. Rough weight 287.42 ct Still at Tiffany's in New York

to give the current 45.52 ct. We say "presumably" because the diamond disappeared for 20 years following looting after the French Revolution in 1792 (the current Hope could indeed fit inside the old Hope). The *Presidente Vargas* was found in the Rio Santo Antonio in Minas Gerais and weighed 726.6 metric carats ($56.2 \times 51.0 \times 24.4$ mm) but was cut into 29 separate stones.

Figure 36.20 shows the different facets found on natural diamonds; all these shapes just involve {001} and {111} surfaces. Modern diamond faceting does not need to take into account the crystallography because, as a face-centered cubic (fcc) crystal, diamond is structurally quite isotropic.

DIAMOND MINE

Production began in 2003 in Lac de Gras 300 km north east of Yellowknife; it may be the richest diamond lode in the world. It has estimated reserves of 30 million tons and yields over 3 ct per ton of ore (more than three times the world average). In 2009, 5.6 million ct were extracted valued at over US\$ 1.3 billion.

FIGURE 36.19. Two examples of blue diamonds. Both were cut from the same Cullinan rough diamond.

FIGURE 36.20. Different diamond shapes produced by diamonds faceting on three different crystallographic planes while keeping the same symmetry.

TABLE 36.9 Beryl ($\text{Be}_3\text{Al}_2\text{Si}_6\text{O}_{18}$)

Name	Color	Dopant	
Beryl	Blue	Cr	
Emerald	Green	Cr or V	
Aquamarine	Blue/light green	Fe	
Morganite (rose beryl)	Pink	Mn	Also in red beryl
Heliodor	Gold-yellow	Fe	
Goshenite	None		

36.10.1 Sapphire and Ruby

Sapphire and ruby are both mainly Al_2O_3 . If the stone is red, it is called ruby; if it's any other color, it is called sapphire or fancy sapphire. There are many ways to produce the color, as summarized in Section 36.6. Ruby is Cr-doped, whereas the blue gemstones contain the Fe-Ti complex (see Section 36.7).

Sapphires can be colored by diffusing in dopants. Co gives blue, and Be gives yellow. Doping with Be is quite new; the Be diffuses much more quickly than Co and can penetrate the whole crystal, so there are no telltale effects at the facets. The process involves surrounding the sapphire with chrysoberyl (BeAl_2O_3) powder and heating to $\sim 1,300^\circ\text{C}$.

36.10.2 Emerald and Beryls

The mineral is generally referred to as beryl and is found in several forms, as summarized in Table 36.9. Commercially, the mineral beryl is the principal source of Be. Beryl occurs in three forms: emerald, aquamarine, and precious beryl (everything else); this is somewhat analogous to the naming of sapphires. Some precious beryls do have their own names in the gem trade. In the field, gemologists use the Chelsea filter specifically to identify emeralds. The Chelsea filter is a dyed gelatin film designed to transmit the red but absorb the green; through it, emeralds appear red. The filter became less useful when synthetic emeralds became common.

The formula is $\text{Be}_3\text{Al}_2\text{Si}_6\text{O}_{18}$ (with up to 1 H_2O); it has $n = 1.595$. The crystal structure is hexagonal and is composed of sixfold rings of SiO_4 tetrahedra, which make up

FIGURE 36.21. Emerald cut in the classical style that minimizes the likelihood of fracture.

the Si_6O_{18} unit. It cleaves along both $\{10\bar{1}0\}$ and (0001) faces; fractures on these planes do not need to break Si-O bonds. Actually, cleavage is so easy that essentially all natural emeralds contain fractures. The so-called emerald cut, shown in Figure 36.21, has the corners removed; it was developed to minimize the likelihood of fracture (while maximizing the size of the stone).

Synthetic emerald can be grown by the flux method or hydrothermally (like synthetic quartz and natural emeralds), as shown in Figure 29.15, and is much more perfect. The largest natural single crystal of gem-quality aquamarine was found in Minas Gerais and weighed 110.5 kg. In one form of aquamarine known as *Maxixe*, the blue is enhanced by irradiation, but the color is not permanent. The coloring of morganite can often be improved by heating the gem to $>400^\circ\text{C}$. The same treatment can change green beryl into blue aquamarine. The likely effect is that the process reduces Fe^{3+} to Fe^{2+} . Not included in Table 36.9 are Co and Ni doping, which produces pink/violet and pale green, respectively.

36.11 OPAL

Natural opal was deposited in fissures in rocks or fossilized (silicified) wood from water-based solutions at relatively low temperatures, as illustrated in Figure 36.22. *Precious opal* consists of perfect arrays of identical spheres of SiO_2 , as shown in the SEM image in Figure 36.23. The spheres

FIGURE 36.22. Natural opal in a vein.

FIGURE 36.24. Polished precious opal.

FIGURE 36.23. Scanning electron microscopy image of a Gilson opal.

have a radius of ~ 300 nm, so arrays of the spheres look like crystals (three-dimensional diffraction gratings) to incident visible light. Thus, the light is diffracted (in the actual “reflection” Bragg geometry), which is why we see different colors when viewing the opal from different directions. The spheres can be amorphous or partially crystalline. Not all opal shows these colors because the term opal refers to any material made up of such SiO_2 spheres; other examples are common opal or fire opal. A key component of opal is the included water, which is typically present at 3–9 wt.% but may be as much as 20 wt.%. It is a little tricky to polish opal (a fine example is shown in Figure 36.24), partly because you mustn’t remove the water and partly because it is quite soft. Opal thus has much in common with chalcedony, another form of fine-grain quartz.

FIGURE 36.25. Amethyst crystals from a section of a cathedral. The crystals were initially inside the geode.

Opals are synthesized commercially, as we saw in Chapter 28. Because the structure is quite open, it is easy to diffuse a dye into the matrix to change the overall color. We can produce inverse opals in a similar way using latex spheres instead of SiO_2 and then various sols such as TiO_2 instead of the dye. When the impregnated polymer is burned out, the inverse opal has potential as a photonic band gap material. The last point reminds us that opal was the first photonic material; we are now exploring how we can exploit this natural phenomenon using synthetic materials.

36.12 OTHER GEMS

Quartz crystals are known by several different names. The colorless form is known as rock crystal. Amethyst is single-crystal quartz. The crystals grow naturally by a hydrothermal process and are found as cathedrals and wheels, as shown in Figure 36.25. The purple color can be caused by Fe that is in the excited 4+ state due to natural (or artificial) irradiation or Mn. The Fe concentration is probably in the range 20–40 ppm. Smoky quartz is gray

also due to irradiation, but the dopant is probably Al^{3+} . When heat-treated, the stones become yellow-orange-brown and are known as citrine. Rhinestones were originally quartz pebbles collected from the River Rhine. The lesson is that each of these forms of quartz grew by natural hydrothermal processes and were then “treated” by nature (or humans).

Topaz is a silicate with the general formula $\text{Al}_2\text{SiO}_4(\text{F}_2\text{OH})_3$. It is the hardest silicate, testing at 8 on the Mohs scale. The crystal structure is unusual. It is orthorhombic, consisting of chains of AO_6 octahedra linked together with SiO_4 tetrahedra. Cleavage is parallel to the basal plane as there are no Si-O bonds crossing this plane. It is found in a variety of shades of blue and the Imperial Yellow. Figure 36.26 shows a natural single crystal. Color is

produced either by high-energy neutron irradiation in a nuclear reactor or in a gamma cell (in Brazil they use ^{60}Co to produce γ -rays) or with a *linear accelerator* (linac), producing a high-energy electron beam. The stones may be radioactive for some time after processing (a few weeks for the sky blue produced by the linac; several months for the London blue produced with neutrons). One story concerns a gem dealer who was surprised to find that the gems in his pocket were still hot. Gamma radiation can produce both yellow and blue centers, giving a brown color; the yellow can be annealed out at $\sim 450^\circ\text{C}$, leaving the blue, which lasts a lifetime (but may not be an heirloom).

Tourmaline is another mineral that can show many colors because it can contain different cations, some of which are listed in Table 36.10. This table is quite new and still being developed. For example, the Y ion in dravite can be replaced by Mn(II) or V(II); Mn doping can be as high as 9 wt.% and makes tourmaline pink. Some cations tend to share the Y site, compensating charge. Color variation is especially known for the variant watermelon tourmaline, which is naturally pink in the interior and green on the outside, as illustrated in Figure 36.27. As always, we have to be careful because electron irradiation can change

FIGURE 36.26. Topaz. Examples of irradiated rough, natural imperial topaz and a huge natural single crystal.

TABLE 36.10 Tourmalines							
Species	X	Y ₃	Z ₆	T ₆ O ₁₈	V ₃	W	Color
Elbaite	Na	Li _{1.5} Al _{1.5}	Al ₆	Si ₆ O ₁₈	(OH) ₃	(OH)	
Dravite	Na	Mg ₃	Al ₆	Si ₆ O ₁₈	(OH) ₃	(OH)	
Chromdravite	Na	Mg ₃	Al ₆	Si ₆ O ₁₈	(OH) ₃	(OH)	
Schorl	Na	Fe(II) ₃	Al ₆	Si ₆ O ₁₈	(OH) ₃	(OH)	Black
Olenite	Na	Al ₃	Al ₆	Si ₆ O ₁₈	O ₃	F	
Buergerite	Na	Fe(III) ₃	Al ₆	Si ₆ O ₁₈	O ₃	F

Rossmannite	Ca	LiAl ₂	Al ₆	Si ₆ O ₁₈	(OH) ₃	(OH)	
Foiteite	vac	Fe(II) ₂ Al	Al ₆	Si ₆ O ₁₈	(OH) ₃	(OH)	

FIGURE 36.27. Watermelon tourmaline.

yellow-brown tourmaline into pink tourmaline. The terms red tourmaline and blue tourmaline have now replaced the names rubellite and indicolite because they are not distinct minerals. Natural crystals of schorl can be >15 cm inches long. Tourmaline is an unusual crystal in that it has true threefold symmetry; the space group is R3m with $a = 1.594$ nm and $c = 0.7138$ nm, but the actual values of a and c depend on which cations are present. Commercially, this mineral is a principal source of boron. We mentioned the piezoelectric property earlier; it is strongest along the c -axis but quartz is now used more often except in special pressure sensor applications.

*Spinel*s are less common gemstones but sometimes quite famous even if known by another name. The Black Prince's Ruby (5 cm long) and the Timur Ruby (polished but not faceted, 361 ct) in the English imperial state crown are both spinels. The largest known natural spinel crystal weighed 104 g (520 ct). Although the spinel structure can accommodate wide variations in chemistry, most spinel gemstones are actually naturally doped $MgAl_2O_4$. One variation is gahnite, the zinc aluminate spinel, $ZnAl_2O_4$. The best known spinel, magnetite ($FeFe_2O_4$), is not very attractive as a gemstone. Synthetic spinels can be doped in many colors and have the advantage over synthetic sapphire that they are more nearly isotropic.

Garnet crystals are some of the older popular gemstones and a special class of mineral (much like spinel). The crystal structure is able to accommodate many different cations, which then produce different colors. All those shown in the box are natural silicates, although several synthetic garnets are now available; synthetic garnets produced for gemstones are usually doped yttrium aluminum garnet (YAG).

All natural garnets have the general formula $R_3M_2(SiO_4)_3$, where R is Ca, Mg, Fe(II), or Mn; M is Al, Fe(III), or Cr. They form two groups.

- Pyralspites
- Ugrandites

Natural garnets are rarely pure. Natural almandines usually contain Ca, Mg, and Fe^{3+} so they denote the end-member garnets. We then use whichever name most closely matches the composition we have. There is then a whole extra array of names. Rhodolite lies between pyrope and almandite; tsavorite is a green variation of grossular; demantoid (the most valuable garnet) and the black melanite are andradite garnets. Pyrope is also known as Bohemian garnet and was the favorite red stone in the 1700s and 1800s but can look very

FIGURE 36.28. As grown crystal of rare-earth-doped cubic zirconia.

FIGURE 36.29. Single-crystal of rare earth (RE)-doped synthetic cubic zirconia that has been cut and polished.

similar to almandite. Almandite is Dana's name for almandine, which is also known as precious garnet and was probably called alabandine (after the ancient Turkish city of Alabanda) by Pliny, so the two names are used interchangeably.

Cubic zirconia is a special case in that it is ubiquitous as a synthetic gemstone; an example of an as-grown stone is shown in Figure 36.28 and a polished and faceted stone in Figure 36.29. Naturally occurring zirconia is rare and then only as the monoclinic baddeleyite.

Peridot is better known as the mineral olivine. The gemstones usually have a composition close to $(Mg_{0.9}, Fe_{0.1})_2 SiO_4$ and have a unique green color. Peridot was mined for 3,500 years on the island of Zabargad (St. John's Island) in the Red Sea near Aswan, Egypt. The largest cut peridot (319 ct) was found on this island.

Alexandrite is a variety of chrysoberyl. It is special

SILICATE GARNETS

Pyralspites: named according to the dominant R cation present:
 Mg^{2+} : *Pyrope* [$Mg_3Al_2(SiO_4)_3$]
 Fe^{2+} : *Almandine* [$Fe_3Al_2(SiO_4)_3$]
 Mn^{2+} : *Spessartine* [$Mn_3Al_2(SiO_4)_3$]
 The dominant M cation in these garnets is Al; usually with Fe^{3+}
Ugrandites (calcic garnets with R = Ca): named after the dominant M cation.
 Cr^{3+} : *Uvarovite* [$Ca_3Cr_2(SiO_4)_3$]
 Al^{3+} : *Grossular* [$Ca_3Al_2(SiO_4)_3$]
 Fe^{3+} : *Andradite* [$Ca_3Fe_2(SiO_4)_3$]

because absorption is so different in two directions. When viewed along the different crystallographic axes, its color changes from red to orange-yellow to emerald-green. In daylight the color is green; in artificial light it is red.

Tanzanite is a purple variety of zoisite. Most stones are green when mined and become purple when heat-treated. The stone is particularly interesting (valuable) because it is only found in one place. It is quite hard (Mohs 6.5–7.0), can be essentially perfect, and is pleochroic.

36.13 MINERALS WITH INCLUSIONS

Inclusions in gemstones are quite common and are often used as an indication that the stone is *natural*. The best-known gems with inclusions are the star stones, where the stone can be sapphire, garnet, etc. Perfect star sapphires can now be synthesized.

Quartz crystals containing a hematite *seed* and the rutile needles are particularly interesting. You can also see hematite needles in quartz. When considering the origin of such

FIGURE 36.30. Rutile growing in hematite. This combination often causes patterns in quartz crystals.

structures, you should know that the same arrangement of seed and needles occurs without the quartz matrix, as shown in Figure 36.30. The name *cat's eye* originally referred to chrysoberyl, which contains inclusions, but the effect is seen in many other gemstones as well.

36.14 TREATMENT OF GEMS

Two methods that are widely used to enhance the color of gemstones are irradiation and heating, usually in that sequence. Table 36.11 summarizes some of the heat and irradiation treatments that have been used. The reason for treating (processing) gemstones is invariably to enhance their appearance and thus increase their value. We review the general features of the different treatments and the science behind them here but refer you to the sections on particular materials for discussions of the details. All irradiated samples are heated.

Heating. Sapphires. Over-heating can cause good stones to become so dark that they are not transparent. Most citrine is produced by heating amethyst. This process can also occur naturally.

Irradiation. Topaz is sold as Swiss blue, London blue, etc. In all cases, the material has been irradiated and heated.

Composite stones can be constructed by joining different stones, as illustrated in Figure 36.31. One of these methods is essentially equivalent to making a bicrystal with an amorphous (polymer) intergranular layer.

Filling cracks with oil, polymer, or glass is commonplace. The different procedures produce a similar result, the difference being mainly how long it takes until the result degrades. The extreme example of this is the transformation of turquoise chalk to something that looks like the *real thing*, as shown in Figure 36.32. In 2004, some highly priced rubies were found to have had internal fractures filled with Pb-containing glass (chosen to match the *n*).

TABLE 36.11 “Treatment” of Gems: Its Effectiveness and “Publicity”

Treatment	Stable?	Detectable?	Disclosure?
Aquamarine turned from green to blue by heat	Yes	No	No
Zircon heated to turn colorless or blue	Virtually all	No, but these colors are very rare in nature	No
Sapphire or ruby heated to remove silk	Yes	Usually	Yes
Sapphire heated to modify or develop a blue color	Yes	Usually	Yes
Topaz turned blue by irradiation	Yes	No	Explained
Topaz or sapphire irradiated to a yellow or brown color	No	No, only fact of fading	Explained
Beryl irradiated: Maxixe-type blue color	No	Yes	Yes
Turquoise or opal impregnated with a colorless stabilizer	Usually	Usually	Yes
Emerald or ruby impregnated with a colorless substance	Variable	Yes	Yes
Beryl or emerald impregnated or coated with color	No	Yes	Yes
Sapphire impurity diffused to produce a surface color or surface asterism	Yes/No	Yes	Yes
Fracture-filled diamond	Yes/No	Yes	Yes

FIGURE 36.31. Different methods of simulating (faking) gemstones by forming composites (e.g., bicrystals).

Lasers are used to drill channels into diamonds to remove internal blemishes, afterward filling the hole with glass having a similar n . This is a variation on the technique is used to created three-dimensional images inside glass blocks for use as decorations. In either process,

a pulsed laser is focused on a small area at the required location in the crystal and then pulsed to create an internal fracture (in the glass model) or ablating material (in the gemstone). This process is illustrated in Figure 36.33.

FIGURE 36.32. Examples of turquoise (A) before and (B) after processing. Both samples are real turquoise. An old method of infiltration to modify the properties of a material is common for turquoise.

FIGURE 36.33. Laser etching to remove inclusions in a gemstone.

How effective *diffusion* is depends on the rate of diffusion. If the intention is to improve the color of a gemstone, then you want the color to be uniform throughout the stone.

FIGURE 36.34. Diffusion to modify the color of a gemstone.

Hence, after diffusion, the stone should be equilibrated for a long period to remove the concentration gradient. This equilibration would take too long for the gem trade, so the dopant has a concentration profile peaking at the surface. You diffuse dopant into the cut stone because otherwise the surface region has a different color when you facet it. In the case of Co, which produces a blue color in sapphire, diffusion is slow so that the facets have a color different from that of the bulk. The color difference is particularly obvious at the facet junctions, as shown in Figure 36.34.

36.15 THE MINERAL AND GEM TRADE

There are many interesting international aspects to the history of gems. Economies of countries have been based on gem production. Though not usually as bad as precious-metal mines, the effect of gem mines on the environment can be very negative. The Kimberley Mine is always associated with “Big Hole,” which by 1914 when work on it stopped was the largest man-created excavation in the world, having a depth of 215 m, a surface area of ~17 ha, and a perimeter of ~1.6 km; 22.5 million tons of earth were excavated to produce 2,722 kg of diamonds. In the 1990s and later, the diamond trade in Sierra Leone became associated with raising funds to fund ongoing wars. The stones were referred to as “blood diamonds,” and international organizations tried to minimize the trade in these stones. Now these diamonds account for 0.2% of diamonds sold, down from a peak of 4%.

It is often very difficult to reach the mines in Myanmar (Burma), but historically Magok is the center of the ruby-producing region. Many gemstones are exported through Thailand, which is a worldwide center for processing (cutting and polishing) gemstones.

In Brazil, the most important production area for gems and minerals in Minas Gerais. It is a more remote region of Brazil but with a growing industrial presence.

BLOOD DIAMONDS IN POP CULTURE

Diamonds from Sierra Leone by Kanye West won a 2006 Grammy for Best Rap Song.

Blood Diamond starring Leonardo DiCaprio and Jennifer Connelly was released by Warner Brothers in 2006.

FarCry2 a 2008 video game set in a Central African country in the midst of civil war uses diamonds as currency.

The book *Diamonds in the Shadow* by Caroline B. Cooney (Delacorte Books for Young Readers, 2007) involves a refugee family smuggling blood diamonds into the United States from Africa.

In 2010 war-crimes trial of Liberian leader Charles Taylor, supermodel Naomi Campbell admits he gave her “dirty rocks.”

In India, the major source of talc is located in the Dagota District. The talc is prepared by crushing boulders that have been produced in the soapstone mines.

Mining is threatening the existence of the Indian tiger (see Section 37.6).

The history of De Beers and the diamond trade has been covered in several books, so we do not examine it here except to say that it makes for a fascinating story. It surprises some to hear that diamonds are not rare. One aspect of the diamond business is that the stones are very portable and easily can be made unrecognizable. The company De Beers is now based in Amsterdam and Antwerp. A new development is to use a laser to inscribe each diamond with a code number after it has been faceted (another “modification” using lasers). The diamonds from Canada’s Northwest Territories have a laser-inscribed polar bear and are known as “Polar Bear Diamonds”.

There are, of course, many other uses of gemstones, including jewel bearings for watches and other precision machinery; but here we have concentrated on their use in decoration and the science behind the preparation of the gemstone from the rough. There is also a worldwide trade in mineral specimens such as you may see in museums that can be priced in excess of \$100,000.

CHAPTER SUMMARY

The topic of this chapter is unusual in a ceramics textbook. It is an example of real-world ceramics, where mineralogy, chemistry, physics, materials science, art, and commerce meet.

PEOPLE AND HISTORY

Cullinan, Sir Thomas owned the mine where, in 1905, the world’s largest diamond was found.

De Beer, Johannes Nicholas and *Diederik Arnoldus* are brothers who owned the farm that became the Kimberley “Big Hole.”

Mohs, Fredrich (1773–1839) introduced the term “scratch hardness” in 1826. He was born in Gernrode/Harz Germany, studied at the University of Halle and at Freiberg. He later worked in Austria.

Moissan, Ferdinand Frederic Henri (1852–1907) discovered naturally occurring SiC in 1905 in a meteorite from the Diablo Canyon in Arizona (USA). He developed the electric furnace, which he used to make carbides and prepare pure metals. He received the Nobel Prize in 1906 for successfully isolating fluorine (1886).

Winston, Harry (1896–1978) A key figure in the diamond trade, he opened his business in New York City in 1932. In 1958, he donated the Hope Diamond to the Smithsonian.

EXERCISES

- 36.1 What are the lines in Figure 36.9?
- 36.2 In Figure 36.11 the stones are immersed in a liquid. Why is this liquid chosen? Show that the observations are what you would expect.
- 36.3 What can you deduce regarding the size, shape, and alignment of the particles causing the stars in Figure 36.15?
- 36.4 Explain the phenomenon of labradorescence seen in Figure 36.17.
- 36.5 What is the common flaw found in natural emeralds? Explain your answer from a crystallographic point of view.
- 36.6 If you had a good means for measuring thermal conductivity, would you prefer such a test to Mohs’ scratch test? How sensitive would your apparatus need to be? We can use a handheld tester to distinguish diamond and moissanite. How is this fact connected to the electronics industry?
- 36.7 Why must you be particularly careful when polishing opal? How is opal related to today’s electronics industry?
- 36.8 What do the stabilization of turquoise, the treatment of emerald, and ZnO varistors have in common?
- 36.9 Diamond has a high n and is also a very hard material. (a) Are these two features linked? (b) If so, explain why SrTiO₃ has a higher n but is not as hard.

- 36.10 Explain, using your knowledge of ceramic processing, how you might take turquoise powder and turn it into a gemstone.
- 36.11 We answered the question: is this turquoise natural? Clarify the answer.
- 36.12 When asked how to wash an opal, we answered: “No.” Why?
- 36.13 Diamonds have now been found in Zambia. Where else are they found worldwide?
- 36.14 Diamond is known for its sparkle. Which gemstones sparkle more? Why are they less valuable than diamond?
- 36.15 Watermelon tourmaline ranges in color from green to pink. Did the color affect its use as a piezoelectric? Explore and discuss.
- 36.16 You can make green tanzanite purple, white turquoise “blue,” and colorless topaz blue. What are you doing in each case, and how does each one relate to more technologically relevant ceramics?
- 36.17 Beryllium can be diffused into sapphire to produce a yellow color that is quite rare in nature. How would you, as a ceramist, show that it had been doped?
- 36.18 Talc has been used for many years. Discuss how its crystal structure influences its use.
- 36.19 Natural garnet occurs in many different colors. So does synthetic cubic zirconia. Discuss what features these two materials have in common to facilitate this coloration.
- 36.20 Why can we say that opal was the first photonic material?

Energy Production and Storage

CHAPTER PREVIEW

One of the grand challenges for the twenty-first century is to produce sufficient clean energy for the world's growing population and to meet the increasing demand among rapidly developing countries. Annual world energy consumption now exceeds 500×10^{18} J (500 exajoules) and, according to the U.S. Energy Information Administration (EIA), is projected to exceed 650×10^{18} J by 2025. China and India lead the growth in energy demand. Although our current energy needs are met largely through the consumption of fossil fuels, future clean energy technologies rely heavily upon developments in materials science. In this chapter, we look at areas where ceramics are playing an important and, in some cases, defining role in energy generation and the related issue of energy storage. As an example, the yearly supply of energy from the sun to the earth is 3×10^{24} J; that is 10^4 times the energy we currently consume. However, we don't see much energy being generated from solar radiation (it is responsible for generating less than 0.1% of the electrical energy used in the United States). The challenge is making solar cells more efficient and cheaper. Ceramics are critical components of a number of different solar cell technologies. In dye-sensitized solar cells, TiO_2 , a ceramic with a wide band gap, is used as the porous support structure for the light-absorbing material, which could be ceramic quantum dots. The term "quantum dot" should make you realize that "nano" is important in energy applications for ceramics. Nanomaterials are used for both the anode and cathode in lithium-ion batteries. In the case of the cathode, the material is nanopowder LiFePO_4 . This is a phospho-olivine, which takes us back to Chapter 7, where we described the olivine crystal structure.

37.1 SOME REMINDERS

Ceramic materials are an essential component of devices for production and storage of energy. Some of the topics covered in this chapter are summarized in Table 37.1. In many cases, a more efficient and cleaner process can be designed through the use of catalysts, or better catalysts. The problem is that the catalyst may change during use, and it is very difficult to see what is actually happening on the catalyst surface during the reaction.

As you search through the literature, you can find papers written in many different units, with the SI units of the Joule now being the standard. The conversion between these units is summarized in Table 37.2.

37.2 NUCLEAR FUEL AND WASTE DISPOSAL

Uranium dioxide (UO_2) has been important as a nuclear fuel since the mid-1950s and is obtained from its major ore, uraninite. After leaching the ore, an impure uranium

concentrate called "yellowcake" is precipitated out of solution. Yellowcake, which is actually brown or black rather than yellow, is typically made up of 70–90% U_3O_8 with some UO_2 and UO_3 also being present. The price of uranium is currently about \$100/kg (the peak was in 2007 when it reached over \$260/kg). The United States uses about 25 kt of uranium oxide each year, most of which is imported from Canada and Australia.

Before use in a nuclear reactor, U_3O_8 is converted into UF_6 gas. Then, using either diffusion or centrifugal processing, $^{235}\text{UF}_6$ is separated from $^{238}\text{UF}_6$. The ^{235}U -enriched gas is reacted to form UO_2 powder, which is pressed into pellets. These pellets are loaded into zirconium alloy tubes, making the fuel rods. A 1,000-MW reactor "burns" 25 t of UO_2 per year, and a kilogram of fuel costs about \$900. Thus, a 1,000-MW reactor consumes about \$22.5 million of UO_2 annually. In the United States there are presently about 100 operable nuclear reactors (over 400 worldwide), producing 21% of the countries electrical power. The number of operable reactors has decreased since it reached its peak in 1990, but there is some interest in reviving the nuclear industry

TABLE 37.1 Energy Production Using Ceramics

Source	How?	Problem	What's special?
Fossil fuels	Combustion	Limited resources CO ₂ emitters Polluting	Ceramics for catalysts and catalyst supports (e.g., cracking and reforming) See Chapter 38
Bio-based fuels	Combustion	Need catalysts Various compositions Contain O	Ceramics for catalysts and catalyst supports
Nuclear	Radioactive decay	Storage	UO ₂ fuel Synroc and glass for storage
Solar	Electronic transitions	Low efficiency High cost	Support structures for dye-sensitized cells Ceramic quantum-dots Thin films Mixed oxidation states
Environment	Mechanical vibrations	Low power High cost	Piezoelectrics One-dimensional (1D) nanomaterials

because it is a zero “green-house emission” technology and because it does not consume limited resources of fossil fuels.

One of the major problems with increasing nuclear reactor capacity is what to do with the spent fuel. There are two current approaches.

- Reprocessing (adopted by United Kingdom, France, Germany, Japan, China, India)
- Storage (adopted by United States, Canada, Sweden)

In Europe, spent fuel is frequently reprocessed, which involves dissolving the fuel elements in nitric acid. Because plutonium is created in the fission process, reprocessed fuel contains both radioactive U and Pu and is referred to as mixed-oxide (MOX) fuel.

The remaining liquid after Pu and U are removed is high-level waste (HLW), containing about 3% of the spent fuel. It is highly radioactive and continues to generate a lot of heat. This waste must be immobilized; and because of the presence of radioisotopes with long half-lives, it must be immobilized for tens of thousands of years. Ceramics are key materials in this process.

The major requirements for waste immobilization are:

- The radioactive elements must become immobilized in the crystal or glass structure.
- The leaching rate of radioactive elements must be low.
- The cost must be acceptable.

URANIUM OXIDE

One uranium oxide fuel pellet (about the size of a dime) contains as much energy as 17,000 cubic feet of natural gas, 1,780 lb of coal or 149 gal of oil.

TABLE 37.2 Energy Conversion

1 eV	1.60217653 × 10 ⁻¹⁹ J
1 J	1 Newton-metre (N.m)
1 foot-pound force	1.3558 J
1 British thermal unit (Btu)	~1,055 J
1 horsepower-hour	2.6845 MJ
1 calorie	4.184 J
1 Wh	3.6 kJ
1 erg	10 ⁻⁷ J
1 erg/cm ²	1 mJ/m ²

Note that the Newton meter is also the unit of torque: use the Joule instead. The Btu depends on the temperature! The mJ/m² is the energy unit from grain boundaries. You encounter Wh even on your electricity bill.

The main method of solidifying HLW not already contained in spent fuel rods is to “vitrify” it into a borosilicate glass and cast it into stainless steel cans for ultimate burial. Vitrification of civil HLW first took place on an industrial scale in France in 1978. A year’s worth of HLW from a 1,000-MW reactor can be stored in about 26 m³.

A second-generation immobilization material, “synroc,” is in development. This synthetic rock, based on mixed titanate phases (e.g., zirconolite, hollandite, or perovskite), incorporates the HLW elements into its crystal structure, yielding excel-

lent chemical stability. Synroc features leach rates more than an order of magnitude lower than borosilicate glass.

An initially unforeseen issue in putting radioactive material, particular heavy α -emitters, into crystalline materials is that the radiation can disrupt the atomic arrangement within the crystal structure enough to cause it to become amorphous. The technique used to analyze the extent of the lattice disruption was nuclear magnetic resonance (NMR) (see Section 10.10). Figure 37.1 shows examples of NMR spectra from a number of samples. In each case, the sharper peak in the spectrum arises from Si atoms in crystalline regions (or domains), and the broader peak at lower frequency (more negative parts per million values) is from Si atoms in amorphous regions. The results predicted that the crystalline structure of zircon (ZrSiO₄) incorporating ²³⁹Pu would become amorphous after only 1,400 years. Although this seems like a very long time, remember that these radioactive materials have to be immobilized for about 250,000 years!

In terms of phase transformations, the α -radiation causes a crystalline-to-amorphous transformation. So the thermodynamically stable phase is being replaced by a metastable phase. In earlier chapters, such as in Section 26.13, we were interested in crystallizing glasses

FIGURE 37.1. Increasing cumulative α -radiation doses cause substantive changes in the local structure around silicon atoms as amorphization of the crystals progresses. (A) Undamaged zircon. (B) UG40, a zircon with $1.2 \times 10^{18} \alpha/g$. (C) Cam26, a zircon with $2.9 \times 10^{18} \alpha/g$. (D) Ni12, a zircon with $7.1 \times 10^{18} \alpha/g$.

to form glass-ceramics (i.e., amorphous-to-crystalline transformations).

Whether the final HLW is vitrified material from reprocessing or entire spent fuel assemblies, it needs eventually to be disposed of safely. This means that it should not require any ongoing management after disposal. Although final disposal of HLW will not take place for some years, preparations are being made for sites for long-term disposal. One of these is Yucca Mountain in Nevada. Another is the Waste Isolation Pilot Plant near Carlsbad in New Mexico, which has been the source for rock salt—hence the mines. The United States may already have ~ 100 t of Pu to store.

The depository in Morsleben, Germany—another rock salt mine—was closed for nuclear-waste storage in 1998: the domes of the salt mines have been reinforced with salt-concrete ($480,000 \text{ m}^3$ since 2003) with another $4,000,000 \text{ m}^3$ needed to temporarily stabilize the lower levels of the mines. The cost to date is 2.2 billion euros. The follow-up question is: where is the rest stored? The example of Morsleben shows that creating structures that can survive 30 years (the Morsleben site began storing nuclear waste in 1971) is difficult enough, but imagine the challenges creating structures that survive intact for thousands of years!

FUEL EFFICIENCY

Calculations by Boeing have shown that a SOFC APU would use 40% less Jet-A fuel than a conventional APU (in-flight) and 75% less fuel when the plane is on the ground.

FIGURE 37.2. Solid oxide fuel cell (SOFC) auxiliary power unit (APU) designed for the tail cone of the Boeing 787. The fuel cell would operate on Jet-A fuel or bio-based aviation fuels.

37.3 SOLID OXIDE FUEL CELLS

In Section 30.16 we introduced the topic of solid oxide fuel cells (SOFCs), which use an oxygen-ion-conducting ceramic membrane. Why do we want to look at this technology again in Chapter 37? There are many advantages of SOFCs; and despite the fact that they are not in widespread use, there are several potentially important applications that could be realized in the next several years. SOFCs have the potential to be a key power-generation technology in the future because:

- They have high electrical efficiency ($\sim 60\%$).
- They can operate over all output ranges from kilowatts to megawatts.
- They can run on many fuels: they are not limited to hydrogen, like proton-exchange membrane (PEM) fuel cells.

One exciting area that is being investigated for SOFCs is to replace the gas-turbine auxiliary power unit (APU) in the tail cone of commercial airplanes, such as the Boeing 737 and the new Boeing 787 “Dreamliner” (Figure 37.2). To offset the increase in weight, the fuel cells would have to run directly on Jet-A fuel, which is the kerosene-based fuel for commercial airplanes, and eventually on next-generation bio-based aviation fuels. The benefits would be that the fuel cells would have much greater efficiency than the gas turbine engines, enabling a “more electric” airplane, and NO_x emissions and other pollutants would be reduced making the airport environment cleaner and healthier.

A key requirement is to develop a catalyst that can be used on the fuel side (the anode) of the SOFC, which is both resistant to coke formation (carbon build up that blocks the active sites of the catalyst) and is tolerant to high sulfur concentrations (Jet-A can contain 500–1,000 ppm of S). Conventional Ni-based catalysts quickly deactivate under Jet-A fuel reforming environments. A small number of ceramics have been shown to be active catalysts for reforming hydrocarbons and resistant to coke formation and sulfur poisoning. One example is molybdenum dioxide (MoO₂).

The catalytic activity of MoO₂ can be explained in terms of the Mars-van Krevelen mechanism, which involves the consumption of oxygen ions provided by the oxygen sublattice with the purpose of sustaining the redox cycles taking place on the catalyst surface. The Mars-van Krevelen mechanism is illustrated in Figure 37.3 and described by the reaction equations 37.1 and 37.2 (these equations represent the partial oxidation of *n*-dodecane, which is a component of Jet-A fuel).

Partial oxidation of fuel using lattice oxygen

Partial oxidation of catalyst using atmospheric oxygen

Molybdenum dioxide is an unusual transition metal oxide because of its high metallic-like electronic conductivity (we showed the temperature dependence of electronic conductivity of a number of ceramics in Figure 30.8). In bulk samples, σ has been measured to be 1.1×10^4 S/cm at 300 K. The high electronic conductivity means that MoO₂ could be used as an anode in direct Jet-A SOFCs (i.e., where the sole fuel feed is Jet-A; there is no separate fuel reformer). MoO₂ has also been studied as a possible anode material for lithium-ion batteries. In this application, good electronic conductivity is also important.

37.4 PHOTOVOLTAIC SOLAR CELLS

The basic idea of the solar cell is to use light to create excitons (electron–hole) pairs and then separate these charge carriers to produce an electric current.

In Chapter 28, we studied how to deposit the thin films that are critical for the high-efficiency cells; in Chapter 29, we discussed growing the thin single crystals. Chapters 30–32 concern charge transport and generating light. These five chapters form the basis of making thin-film solar cells. Inexpensive solar cells use polycrystalline Si,

which can be produced in large quantities in fluidized bed reactors. More efficient, but more expensive, single-crystalline material can be used for roof installations, for farms, traffic, and literally in the field. SolarWorld uses 8-in.-diameter Czochralski-grown Si, lines up 16 ingots at a time, and cuts near-6-in. squares. Sixty of these squares are used for one panel. Using single-crystal Si means less electron–hole recombination at defects [grain boundaries (GBs)] and thus higher efficiency.

The highest efficiency ever achieved with a solar cell to date is 42.3%. A value of 41.0% was obtained using a Boeing-Spectrolab multijunction GaAs cell consisting of multiple layers, as shown in Figure 37.4. The layers are deposited using molecular beam epitaxy (MBE) or metal-organic chemical vapor deposition (MOCVD). These cells are much too expensive for large-area applications and are usually placed at the focal point of mirrors or lenses that

FIGURE 37.3. Mars-van Krevelen mechanism.

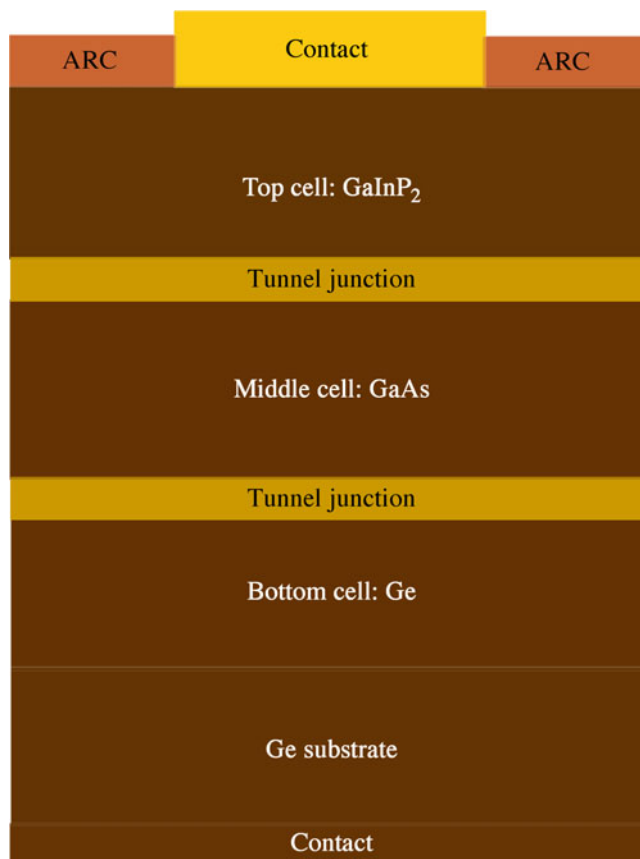

FIGURE 37.4. Spectrolab multijunction solar cell. Sizes up to 32 cm² are possible with this structure.

concentrate the solar light by up to a factor of 1,000 (they're called concentrator cells), or they are used for space applications (e.g., the Mars Exploration Rover), where cost is secondary.

37.5 DYE-SENSITIZED SOLAR CELLS

The dye-sensitized solar cell (DSSC) is a type of photoelectrochemical (PEC) solar cell that uses a hybrid structure consisting of inorganic semiconductors and organic molecules. There are several different geometries. The one shown in Figure 37.5 uses a film of sintered TiO₂ nanoparticles (10–30 nm) on a conducting glass substrate. Dye molecules that absorb sunlight are coated onto the TiO₂ particles. The TiO₂ itself doesn't absorb a significant amount of sunlight; it is a wide band gap semiconductor ($E_g = 3.0$ eV). The dye molecules absorb by electrons moving into excited states. These excited electrons are injected into the TiO₂, which creates positively charged dye molecules. The incident solar energy has created electron-hole pairs. If these pairs are separated, we have a photovoltaic (or solar) cell. The circuit is completed by a liquid electrolyte and transparent electrode. The commercialization of DSSCs has been restricted because of the low efficiencies (at present), short lifetime of the photoelectrode, and the high cost of the device. Table 37.3 compares efficiencies for several different types of solar cell.

There is lots of research around the world to improve the efficiency and lower the cost of DSSCs. An important component is the ceramic electrode. The electrode must be porous with a high surface area and provide a three-dimensional scaffold to hold the dye molecules. Nanomaterials, such as the TiO₂ nanotubes shown in Figure 29.19B, are an alternative to using nanoparticles.

Semiconductor quantum dots (QDs) can replace dyes as the light-harvesting component in DSSCs. The absorption of light produces excitons (electron-hole pairs) in the QD. The electron is injected into the semiconductor oxide support. A hole conductor or electrolyte in the pores of the nanocrystalline oxide film captures the hole. Figure 37.6 shows an example of a QD-sensitized solar cell. The QDs are CdSe, which are attached to ZnO nanowires.

37.6 CERAMICS IN BATTERIES

Developing techniques to store electrical energy efficiently is critical for a number of applications.

- Increasing the lifetime of mobile devices such as laptops and cell phones

ECONOMIC IMPACT

Power interruptions cost US industry about \$80 billion per year. The problem could be solved with better batteries.

FIGURE 37.5. Dye-sensitized nanocrystalline solar cell.

TABLE 37.3 Solar Cell Efficiencies Under AM1.5 Simulated Solar Illumination^a

Type of Cell	Efficiency (%)
Crystalline Si cells	
Single crystal	24
Polycrystalline	20
Thin film	
Cu(In,Ga)Se ₂	20
CdTe	16
Amorphous Si	13
Poly-Si	16

Dye cells (DSSC)	11
Organic cells	5

^aSolar cells are usually characterized according to the International Electrotechnical Commission (IEC) Norm (IEC-904-3, 1989) under standard test conditions, which correspond to 1 kW/m² (100 mW/cm²) direct perpendicular irradiance under a global AM1.5 spectrum at 25°C cell temperature.

- Enabling electric and hybrid-electric vehicles
- Load-leveling (storing energy during periods of low usage and releasing it during peak demand)
- Backup supply to avoid interruptions in delivery from the grid
- Commercialization of renewable resources, such as wind and solar, which are intermittent

In transportation applications, in particular automobiles, and in widespread implementation of renewable energy, low cost and long life are essential for commercial success.

Neither can be obtained with the current battery technology. In this section, we look specifically at lithium-ion batteries (Li-B) because at the present time this is the most widely

FIGURE 37.6. Quantum dot (QD)-sensitized solar cell. An array of ZnO nanowires—grown vertically from an F-doped SnO₂/glass substrate and decorated with CdSe quantum dots—serve as the photoanode. A second F-doped SnO₂/glass substrate, coated with a 10-nm layer of Pt, is the photocathode. The space between the two electrodes is filled with a liquid electrolyte, and the cell is illuminated from the bottom.

TABLE 37.4 Energy Output of Electrochemical Devices and Petroleum

Energy Source	Energy Output (kWh/kg)
Ultracapacitors	0.01
Lithium-ion battery	0.8
Hydrogen fuel cell	1.1
Gasoline	6.0 ^a

^aAssuming 30% combustion efficiency.

researched battery technology and relies on ceramic materials. Table 37.4 compares the energy-storage capabilities of several different technologies with that of gasoline. Another way to compare the performance of energy-storage technologies is to use a Ragone plot, shown in Figure 37.7: values of energy density (Wh/kg) are plotted versus power density (W/kg). (Energy is in Wh and power in W). The Ragone plot was first used in 1968 to compare batteries but is now used to compare any energy-storage device. Note that you also see power density as W/m³ and energy density as Wh/m³.

Franklin’s battery was simply a “battery of capacitors” using glass as the dielectric. Conventional capacitors store low amounts of energy, but that energy can be delivered very quickly; that is, they have a high power density. Fuel cells can have very high-energy densities, particularly if they are operated on liquid fuels such as methanol, but their power density is poor. In between these extremes

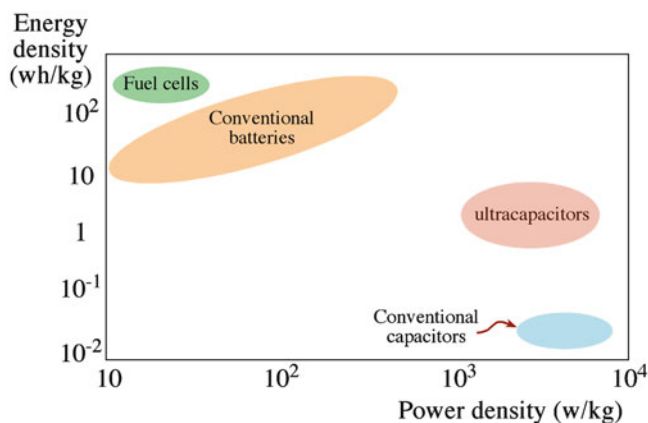

FIGURE 37.7. Ragone plot comparing the power and energy densities for batteries, capacitors, and fuel cells. (Energy is the capacity to do work; power is the rate at which work is done).

TABLE 37.5 Examples of Electrochemical Systems Used in Batteries

Negative electrode	Electrolyte	Positive electrode	Comment
Zn	NH ₄ Cl/ZnCl	MnO ₂	Zinc-carbon battery
Li	Organic	MnO ₂	Lithium battery
Li	Organic	CuO	Lithium battery
Cd	Alkali	NiO	Nickel-cadmium battery (NiCd)
Zn	Alkali	MgO	Mercury battery
Pb	H ₂ SO ₄	PbO ₂	Lead-acid battery
Zn	Alkali	Ag ₂ O	Silver-oxide battery

you can see there are batteries and ultracapacitors. We introduced capacitors in Section 31.7; in Section 37.8 we look at ultracapacitors.

Batteries are generally electrochemical devices; many rely on ceramic oxides, particularly as the positive electrode. The oxides of Mn, Ni, Hg, Ag, and Cu are all currently used. Note that we say “the oxides of” to avoid being specific about the charge state of the cation (usually MnO₂, NiO, and Ag₂O but also NiOOH). Incidentally, the reason batteries are interchangeable (so all AA batteries are the same size and voltage) is due in part to the International Electrotechnical Commission (IEC) and the American National Standards Institute (ANSI).

Table 37.5 summarizes a few of the electrochemical systems used in batteries today.

37.7 LITHIUM-ION BATTERIES

In this section, the focus is lithium-ion batteries, which is the main power source for most rechargeable electronic devices, such as laptops, iPads, and cell phones. An Li-B is so-called because lithium ions (Li⁺) move between the anode and cathode.

FIGURE 37.8. LiC_2 cells. (A) Unit cell. (B) 2×2 Supercell.

In most current Li-Bs, the anode is graphitic carbon with a very high surface area. Carbon reacts with lithium at room temperature to form a compound with the stoichiometry LiC_6 . This is an example of an intercalation compound. The lithium ions occupy regions between the layers of carbon atoms, as shown in Figure 37.8. The hexagonal unit cell ($a = 0.4316 \text{ nm}$; $c = 0.3703 \text{ nm}$) of LiC_6 has alternating layers of Li and C atoms, as shown in Figure 37.8A. We can also represent the structure in terms of the 2×2 supercell (Figure 37.8B). Although carbon is widely used, it suffers from the following limitations.

- If the intercalation rate of Li into C is too low, the lithium ions can plate out as metallic lithium, which could cause a fire.
- The energy density of carbon-lithium anodes is low: 372 mA.h.g^{-1} compared to $>3,000 \text{ mA.h.g}^{-1}$ for silicon.

Two interesting nanostructured ceramics that have been studied as anodes are mesoporous MoO_2 (shown in Figure 37.9) and SnO_2 nanowires. The mesoporous MoO_2 was prepared using a silica template, which was subsequently removed using a dilute hydrofluoric acid (HF) solution. Initial results have shown a reversible lithium storage capacity as high as 750 mA.h.g^{-1} . Another ceramic material that has been proposed as an alternative to carbon-based anodes is SnO_2 . Tin oxide has a lithium storage capacity of 781 mA/hg but has been limited by the large volume change (up to 300%) that accompanies the insertion and removal of lithium. By forming the film as nanostructured columnar grains, the local volume changes; and associated mechanical stresses can be reduced and the cyclability of the material improved. Thus, we use carbon because it works and is cheap, but we need to develop better materials and be able to make those materials in an economical way.

On the cathode side of an Li-B, there is much to interest the ceramist and an opportunity to develop a new material that can increase both the storage capacity and battery lifetime. The requirements for the cathode of an Li-B have been summarized by Whittingham (2008).

OLIVINE

Forsterite is Mg_2SiO_4 . Replace the Mg with Li and Fe and replace Si with P and you have LiFePO_4 an important cathode for lithium-ion batteries.

FIGURE 37.9. Transmission electron microscopy (TEM) images of mesoporous MoO_2 at different magnifications and a typical selected area electron diffraction (SAED) pattern.

- The material must contain a readily reducible/oxidizable ion (e.g., a transition metal).
- The material must react with Li reversibly and without major structural change.
- The material must react with Li with a high ΔG for high voltage.
- The material should react with Li very rapidly on both insertion and removal to give high power.
- The material should ideally be a good electronic conductor to alleviate the need for a conductive additive.
- The material must be economical to produce, environmentally benign, and abundant.

All commercial cathode materials belong to one of two classes.

- Cubic oxides, such as LiCoO_2 (layered rock salt) and LiMn_2O_4 (spinel)
- Phospho-olivines, such as LiFePO_4 (olivine structure was shown in Figure 7.6)

The phospho-olivines are particularly interesting because of the stability of the phosphate group (PO_4). Only under extreme conditions is the olivine structure destroyed, and even then the phosphate group is maintained as lithium phosphate. Because this material is an electrical insulator, it has to be mixed with a conductor,

FIGURE 37.10. Basic structure of an ultracapacitor.

usually carbon, when it is formed into the cathode. To improve the energy-storage capacity, several groups are looking at cation substitutions (e.g., Mn for Fe to form LiMnPO_4). There are still lots of opportunities to improve the performance of Li-B through the use of different materials systems. Also, even with the existing materials, there is a need to be able to develop low-cost, high-volume synthesis methods. This need is particularly true for nanomaterials, such as the nanophosphates being used by A123 Systems, a company that came out of the research done at MIT in the United States.

37.8 ULTRACAPACITORS

From the Ragone plot in Figure 37.7, you can see that ultracapacitors (also called supercapacitors and electrical double-layer capacitors, EDLCs) have very high power densities and energy-storage capacities—exceeding those of conventional capacitors. Whereas Li-B manufacturers (and university researchers) are putting a lot of effort into increasing the power density of Li-Bs, ultracapacitor manufacturers are looking at increasing energy density. Also, because capacitors store charge on the surface, rather than through a chemical reaction, they can be cycled hundreds of thousands of times (i.e., they don't have to be thrown away as frequently as batteries!)

In Section 31.7, we described the structure and properties of conventional capacitors that used ceramics as the dielectric layer. In ultracapacitors, the structure is quite different: high-surface-area carbon is used as the electrodes (aluminum foil is used as a current carrier), and the electrolyte is a liquid, typically acetonitrile.

ELECTRICAL DOUBLE LAYER (EDL)

The first electrical layer is due to the charging of the electrode surface by the applied potential. The second electrical layer is due to ions in the electrolyte being attracted to the surface charge on the electrode. We therefore have a “double” layer on each electrode.

An individual ultracapacitor cell is shown in Figure 37.10. When voltage is applied across the plates, the positive electrode attracts the negative ions in the electrolyte and vice versa. A dielectric separator

(paper works well) that is placed between the electrodes prevents the ions from moving between the two electrodes. The charge is stored on the surface, which is why high surface areas are important. The cell voltages are limited to ~ 3 V to prevent decomposition of the liquid. As the amount of energy that can be stored is very directly related to surface area, the goal is to find lightweight materials with high surface area. Table 37.6 lists surface areas of a number of commercial and experimental carbons, and you can see the close correlation with specific capacitance (up to a point!). Several groups

have proposed replacing activated carbon—which is currently the material of choice—with nanomaterials such as carbon nanotubes and nanoporous carbons. The biggest problem

associated with this at the moment is the high cost of making the nanomaterials and the need to attach them to the aluminum current collector with a suitable binder, which inherently reduces the accessible surface area.

ULTRACAPACITORS ON PLANES

Each Airbus A380 uses 16 ultracapacitors in the emergency doors.

37.9 PRODUCING AND STORING HYDROGEN

37.9.1 Thermochemical Processing

We know it is completely feasible to produce hydrogen using solar energy from the point of view of thermodynamics. The idea is to use thermochemical processing. The

TABLE 37.6 Specific Capacitance and Specific Surface Areas for Different Carbons

Carbon	C_g (F/g)	S_{BET} (m^2/g) ^a	S_{DFT} (m^2/g) ^b	Comments

^bSurface area determined using the differential functional theory (DFT) model.

goal is to convert water (in the form of steam) into its components, hydrogen and oxygen, and then collect the hydrogen for use as a fuel. Simple! The process is particularly exciting because efficiencies of up to 76% should be achievable, which makes it both commercially and environmentally very attractive.

The principle behind the process is to use solar energy to drive a highly endothermic reaction and then produce hydrogen by a subsequent exothermic reaction. This is known as a *two-step water-splitting cycle*. Solar energy in the form of heat is used to reduce the ceramic (a metal oxide). This reduced metal oxide is then reoxidized by removing the oxygen from water, thus producing hydrogen gas. The reduced (lower valence) metal oxide in step I (thermal reduction) could alternatively be a metal carbide, a metal nitride, or even a metal. The second step (oxidation by water) is known as hydrolysis. The limit for step I would be:

If we use FeO in step I, then the temperature must be >1,600 K. However, step II is then spontaneous at a temperature of ~1,200 K.

FIGURE 37.11. TEM image of a silica nanospring for hydrogen storage (on a lacy C film).

Several systems are being explored for this purpose. They include the reduction of ZnO (in some cases enhanced by the presence of C), the reduction of ceria, and the reduction of oxides containing Fe³⁺ (both iron oxide and a range of ferrites).

All that we need to do is to optimize the ceramics and, perhaps the more challenging step, optimize the geometry of the sample to allow repeated cycling (1) without degradation and (2) while allowing easy extraction of the hydrogen. Hence, it's the usual process: improve the design (tailor) of both the material (e.g., powder versus multilayer films or foams) and the reactor itself.

This whole process should remind you of our discussion of phase boundaries (PBs) in Chapter 15 and reactions in Chapter 25. The solar part of this has many similarities to processes that are now being explored for producing lime (the endothermic calcinations of CaCO₃) and other ceramics. Currently, we use fossil fuels for producing cement and lime, which accounts for 5% and 1%, respectively, of the global human-made CO₂ emissions—up to 40% of this is from burning fossil fuels.

37.9.2 Hydrogen Storage

Of all the limitations preventing the achievement of a hydrogen economy, the most significant is hydrogen storage. For transportation applications, storage requirements are particularly stringent and none of the current approaches comes close to meeting targets. Indeed, some of the approaches are actually dangerous. Storing hydrogen on the surface of nanomaterials is an exciting possibility. The idea is again to use the very large surface areas available at the nanoscale. The hydrogen attaches nondissociatively (i.e., as H₂) through weak molecular-surface interactions, such as van der Waals forces. Studies have shown that hydrogen attaches to the surface of carbon nanotubes, but the temperatures don't seem to be ideal for transportation needs. Recently, using glasses for hydrogen storage has been proposed; and, experimentally, hydrogen has been shown to attach to the surface of one-dimensional silica glass nanostructures (e.g., wires, ropes, tubes, springs) at room temperature. Figure 37.11

shows a transmission electron microscopy (TEM) image of a silica nanospring. The only difference, apart from size, between these nanostructures and “bulk” glass fibers appears to be that the surface is more ionic, which may be important for hydrogen attachment. The nanosprings grow by the vapor–liquid–solid (VLS) mechanism described in Chapter 29. The Au catalyst is the dark particle. The deposition process occurs at temperatures as low as 300°C, allowing them to be formed on polymer substrates.

37.10 ENERGY HARVESTING

Kinetic energy (the energy due to motion) can be harvested using piezoelectric-based generators. Piezoelectric ceramics such as lead zirconate titanate (PZT) have been used to make simple cantilever generators, such as the one illustrated in Figure 37.12. A cantilever structure has a PZT film on the top and bottom surfaces of a metal plate. In Figure 37.12, the metal is a strip of brass. The cantilever deflects due to external vibrations (e.g., shaking), which strains the PZT films, generating a charge. The mass at the end of the beam lowers the resonant frequency.

There is a lot of interest in using human-powered energy-harvesting devices for personal generation of energy. We might generate our own electrical energy to power our cell phones and laptops, for example, by simply walking or swinging our arms. Studies have shown that an average-gait-walking human weighing 68 kg produces 67 W of energy at the heel of the shoe. Although it would not be possible to “harvest” all this energy, it should be possible to generate as much as 1.3 W from walking. A group at MIT in the United States put a PZT piezoelectric dimorph into the heel of a Navy work boot that generated energy each time the heel struck the ground. Each event generated an average of 8.4 mW. The maximum power generated from a PZT cantilever generator is about 0.4 mW.

Boeing is developing seats for its commercial airplanes that would harvest the motion of passengers moving in their seats. This energy could be used to power outlets

for laptops and the personal entertainment systems used on long-haul flights. Of course, lightweight materials would have to be used in this application.

An advantage of piezoelectric generators is that they are scalable: to generate more power, individual piezoelectric elements can be combined; to create small localized sources of power, the device dimensions can be scaled down even to the nanoscale so long as the aspect ratio is maintained. ZnO nanostructures such as nanowires and nanobelts (shown in Figure 37.13) are creating lots of interest in nano-piezoelectrics in terms of scavenging energy from the environment, such as wind, friction, and body movement. However, this is a technology that is still in the very early stages of development, and significant engineering challenges need to be overcome before there are commercial products based on these exciting nanomaterials.

ENERGY HARVESTING
Mechanical energy is converted into electrical energy.

37.11 CATALYSTS AND CATALYST SUPPORTS

The final section in this chapter looks at ceramics as catalysts and catalyst supports for emerging energy applications. We briefly introduced this possibility in Section 13.17. Here, we show some specific examples. To maximize reaction rates, it is necessary to have very high surface areas (so we are dealing with nanomaterials). Surface areas are typically hundreds of square meters per gram (a few grams would have the equivalent surface area of several football fields). Table 37.7 lists the dominant catalytic processes for energy conversion that have been

FIGURE 37.12. Cantilever piezoelectric generator.

FIGURE 37.13. TEM image of ZnO nanobelts.

TABLE 37.7 Catalysts, Applications, and Reactor Types

<i>Reaction</i>	<i>Reactants</i>	<i>Major Products</i>	<i>Typical industrial catalyst</i>	<i>Reactor type</i>
Cracking	Petroleum fractions (e.g., straight-chain and cyclic alkanes)	Lighter hydrocarbons (alkanes and alkenes)	Acidic zeolite in matrix of silica-alumina with components to oxidize CO (Pt) and sequester sulfur oxides	Entrained bed
Naphtha reforming	Petroleum-derived naphtha (e.g., straight-chain and cyclic alkanes)	Aromatic compounds, isomerized (branched) alkanes	Pt nanoclusters with another metal (Re, Sn, or Ir) supported on Al ₂ O ₃	Fixed bed or moving bed
Hydrodesulfurization (HDS)	Sulfur-containing compounds in fossil feedstocks (e.g., thiophene, dibenzothiophene)	H ₂ S and hydrocarbons (e.g., butenes, biphenyl)	MoS ₂ nanoclusters promoted with Co and supported on Al ₂ O ₃	Fixed bed (typically trickle bed) or slurry
Hydrodenitrogenation (HDN)	Nitrogen-containing compounds in fossil feedstocks (e.g., quinoline, triglycerides)	NH ₃ and hydrocarbons	MoS ₂ nanoclusters promoted with Ni and supported on Al ₂ O ₃	Fixed bed (typically trickle bed) or slurry
Hydrodeoxygenation (HDO)	Oxygen-containing compounds in coal or biomass-derived feedstocks (e.g., phenol, sugars)	H ₂ O and hydrocarbons (e.g., benzene)	MoS ₂ nanoclusters promoted with Co or Ni and supported on Al ₂ O ₃	Fixed bed or slurry
Water-gas shift	CO + H ₂ O	CO ₂ + H ₂	Iron oxide/chromium oxide or Cu supported on Al ₂ O ₃ with ZnO	Fixed bed
Fischer-Tropsch synthesis	CO + H ₂	Straight-chain alkanes, alkenes, oxygen-containing compounds (e.g., alcohols, aldehydes, ketones)	Bulk iron promoted with alkali metal or Co particles on a support	Fixed bed or slurry
Methanol synthesis	CO + H ₂	Methanol (with CO ₂ and H ₂ O)	Cu supported on Al ₂ O ₃ with ZnO	Fixed bed or possibly slurry

developed for fossil fuels, such as petroleum, natural gas, and coal.

Many catalysts are composite materials consisting of a carrier or support—which may constitute as much as 99% of the total mass but is catalytically inactive—combined with catalytically active components and possibly promoters. Typical ceramic supports include aluminas (e.g., γ -Al₂O₃, η -Al₂O₃), silica gel, zirconia, magnesia, zeolites, and carbon. Aluminas are widely used because they are inexpensive, thermally stable, and durable. As an example, commercial ultra-pure γ -Al₂O₃ (99.99% pure) with a surface area of 70–100 m²/g is available in bulk quantities for <\$15 kg⁻¹. Alumina can also be formed into particles with a wide range of shapes, internal surface areas, and pore size distributions. Table 37.8 lists surface areas for several γ -Al₂O₃ nanosorbents that have been developed for removal of arsenic.

Although, historically, catalysts have been developed for fossil fuel-based processes, more recently biomass sources are being used as reactants. For example, biomass-derived liquids (e.g., soy oil) and even wood

have been converted into syngas (a mixture of CO and H₂) using a hot-flow reactor employing a rhodium catalyst containing cerium oxide supported on an α -Al₂O₃ foam.

CHAPTER SUMMARY

Developing clean energy technology is essential to meet the world's growing demands for energy. For the ceramist, there are amazing opportunities to improve existing technologies and even to create entirely new approaches to energy generation and storage. It is also an opportunity to revisit topics such as mineralogy and see how mineral structures, such as olivine, are enabling brand-new technologies such as high-energy-density lithium-ion batteries. Because many of the next generation approaches to energy generation and storage rely on high surface areas, nanomaterials were a common theme in this chapter.

PEOPLE AND HISTORY

Daniel, John Frederick (1790–1845) was Professor of Chemistry in London. He constructed the Daniel cell using an unglazed ceramic (earthenware) pot to allow ions to flow while keeping the two electrodes (Cu in CuSO_4 and Zn in H_2SO_4) apart—an early ceramic membrane.

Franklin, Benjamin (1706–1790) coined the term “battery” to describe a stack of capacitors that he had constructed! (Named after the artillery battery, which functions more effectively by grouping the components). The capacitors were plates of glass with metal coating on each surface.

Galvani, Luigi (1737–1798), from Bologna, was an early experimentalist using electric charge (hence the word galvanic). He is said to have inspired Volta's invention because Volta disagreed with him!

Grätzel, Michael was born in 1944 in Dorfchemnitz, Sachsen. The dye-sensitized solar cell was invented in Grätzel's laboratory at the Ecole Polytechnique Fédérale de Lausanne in Switzerland. He is the author of over 800 publications and in 2010 received the Millennium Technology Prize (worth 800,000 euros), for development of the dye-sensitized solar cell.

Grove, William Robert (1811–1896), from Wales, used Zn in H_2SO_4 and Pt in HNO_4 , separated by with a porous ceramic pot. He studied Classics at Brasenose, became a lawyer, and then was Professor of Experimental Philosophy (Physics). In 1839 or 1842, he developed the first fuel cell, the Grove cell, using the porous ceramic pot as a membrane.

Mwond, Ludig and Langer, Charles coined the term “fuel cell” in ~1889.

Steele, Brian Charles Hilton (1929–2003) was a pioneer in solid oxide fuel cells (SOFCs). Having worked at Morgan Crucible, he then became Professor at Imperial College and was a founder of Ceres Power and thesis advisor to M.G.N. He emphasized the need to make SOFCs work below 600°C.

Volta, Alessandro (1745–1827), born in Como and later Professor in Pavia, began the development of today's battery with the Voltaic pile. This really was a large pile of pairs of metal plates (alternating of Zn and Ag), which were the electrodes, and cardboard soaked in brine, which was the electrolyte.

The SOFC uses a solid oxide so we should use a hyphen. Usually the hyphen is not used.

SolarWorld traces its roots to Solar Technology International, ARCO Solar, Siemens Solar, and Royal Dutch Shell. It now has a capacity of 500 MW p.a.

EXERCISES

- 37.1 The passage of α -particles through a ceramic are known to cause a few hundred Frenkel defects. What would be the most likely Frenkel defect in zircon? Write this defect using the Kröger-Vink notation.
- 37.2 MoO_2 has been proposed for lithium-ion battery anodes. Describe one synthesis method in the literature that produces nanostructured MoO_2 . What were the noted advantages of this particular nanostructure?
- 37.3 Nanoparticle TiO_2 is the most widely used oxide for dye-sensitized solar cells (DSSCs). Can you identify three other oxides, either from the literature or from thinking about the necessary properties of the electrode, that might be employed instead of TiO_2 .
- 37.4 Figure 37.6 shows CdSe quantum dots (QDs). Give three other materials that might work as QDs for QD-sensitized solar cells. Also, find their band gap energies and compare the values with the band gap of CdSe.
- 37.5 In Table 37.1 we refer to “AM1.5.” What is AM1.5, and why do we use this value to characterize and compare solar cells?
- 37.6 Figure 37.4 shows a multijunction (actually a triple junction) solar cell. The top layer is an antireflective coating. What material or materials would be suitable for this application, and are they ceramics based on our definition in Section 1.1? [Hint: search patents at the United States Patent and Trademark Office (www.uspto.gov), where you can find what is actually used].

- 37.7 One choice for a lithium battery (LiB) anode is graphitic carbon because the Li can intercalate between the graphene layers. Which material or materials in Chapter 6 might, at least from a structural point of view, be possible LiB anodes? Has anyone tried that material, and if so how well did it work?
- 37.8 Using the data in Table 37.3, plot C_g versus S_{DFT} . What do you notice about the relationship between C_g versus S_{DFT} ? What does this tell you about considering surface area as the only variable affecting C_g ?
- 37.9 Figure 37.12 Shows a cantilever piezoelectric generator. If you were designing such a device, how would you propose applying the PZT film to the brass substrate?
- 37.10 Using the Ragone plot in Figure 37.7, mark the specific region of the diagram occupied by lithium-ion batteries. How does this compare to other forms of battery, such as metal hydride and lead acid?
- 37.11 Where are the world's largest deposits of lithium?
- 37.12 There are three major ultracapacitor manufacturers in the world. Name those companies, and find out the size of the total ultracapacitor market.
- 37.13 Ultracapacitors are used on the A380 Airbus and in the Toyota Prius. Find three other applications for ultracapacitors.
- 37.14 MoO_2 has been shown to be effective in reforming bio-based aviation fuels. What is the typical composition of such a fuel? What are the major differences between kerosene-based aviation fuels such as Jet-A and bio-based fuels?
- 37.15 Lead zirconate titanate (PZT) is one type of piezoelectric ceramic that has been used in energy-harvesting devices. Can you find other examples of ceramics used for this application? If not, why not?
- 37.16 Table 37.5 lists the production of methanol from syngas (a mixture of CO and H_2) using a copper catalyst supported on Al_2O_3 with ZnO. Using the literature or the Internet, find out the temperature at which this reaction occurs. Are there other catalysts that have been used for this reaction?
- 37.17 Ceramics are often used as catalyst supports. Find three examples of specific reactions that are catalyzed by catalysts supported on ceramics.
- 37.18 What are the regions of dark contrast (the dark lines) in the transmission electron microscopy image of the ZnO nanobelts? Do you think these lines have any impact on the piezoelectric properties?
- 37.19 The nanostructured aluminas in Table 37.5 were developed to absorb arsenic. Why is it necessary to absorb arsenic?
- 37.20 MSU-X is a commercial mesoporous alumina from Sigma-Aldrich. How much does it cost? What is the main application (or applications) for this material?

In October 2012, A123 filed for bankruptcy

Industry and the Environment

CHAPTER PREVIEW

Throughout this book we have highlighted the engineering applications for ceramics. In the final analysis, the importance of any material is based on what it can be used for. For example, at the present time, high-temperature superconductors (HTSCs) are of research interest but are not commercially important. Because of the unparalleled range of properties shown by ceramics, they find application in a vast number of areas. This last chapter looks at the field from an industrial perspective. Because it is impossible in one chapter to cover every aspect of the multibillion-dollar ceramic industry, we have chosen to focus on a few topics, mainly through examining case studies. One of the exciting prospects for the industry over the next decade is in nanotechnology. Ceramic nanopowders already represent the biggest segment of the nanopowders market and are used for polishing, sunscreens, etc. With the demonstration of the successful growth of ceramic nanowires, nanoribbons, nanosprings, and nanotubes, etc., there exists the potential for even more applications in critical areas such as solar cells, batteries, and hydrogen storage. As we have often done, we begin with some history.

38.1 BEGINNING OF THE MODERN CERAMICS INDUSTRY

In Chapter 2, we described some of the early history of ceramics and their production. The transition to a large-scale manufacturing industry occurred in Western Europe during the eighteenth century as part of the period that became known as the Industrial Revolution. The great porcelain factories established and subsidized by royal patronage at Miessen in Germany and Sèvres in France began to give way to purely commercial products being made in Staffordshire in the north of England. Later, the factories at Miessen and Sèvres began to imitate English designs. They were certainly helped in this area by immigrant workers. Emigration was a concern for the ceramics industry more than many others, such as iron production, because it relied on secret processes, such as specific body and glaze compositions. Once these became known, a worker would become valuable to a competitor.

The development of the Staffordshire area as the prominent pottery center in England was in large part due to the use of coal as a fuel for the kilns. Coal was abundant in this area, as

was (and still is) clay. The proximity of raw materials provided an economic advantage over other rural potteries that were still using the diminishing supply of timber. Staffordshire is a long way from the major metropolitan areas of London, Bristol, and Norwich. Early pictures of Tunstall, one of the six towns that formed the Potteries and in 1910 became absorbed into the city of Stoke-on-Trent, show a town surrounded by hilly countryside.

By the mid-eighteenth century there were many separate potteries employing a large number of workers. A petition presented before the British Parliament in 1763 read:

In Burslem [another of the six towns that made up the Potteries] and its neighborhoods [*sic*] are nearly 150 separate potteries for making various kinds of stone and earthenware, which, together, find constant employment and support for nearly 7,000 people.

In the early days of the pottery industry in England, transport of raw materials in, and products out, was inefficient. The costs of transportation had to be included in the selling price of every article produced. Clearly, quantity production could not be achieved without better transportation.

SÈVRES

Royal Commission: The factory at Sèvres was commissioned to make an 800-piece dinner service for Catherine II of Russia. It took 3 years to complete.

SIX TOWNS: THE POTTERIES

Tunstall, Burslem, Hanley, Stoke-upon-Trent, Fenton, Longton

Master potter and entrepreneur Josiah Wedgwood was instrumental in organizing a potters' association to push for the development of improved roads and a canal system. Wedgwood realized that cheaper and more regular transport meant an even flow of production, less breakage, lower prices, wider markets, and greater sales. Staffordshire potters lobbied successfully for the development of a canal that would link the rivers Trent and Mersey, which was authorized by an Act of Parliament in May 1766. The project was completed in 1772 at a total cost of £300,000. The completion of the Trent-Mersey Canal ensured that Staffordshire would remain the center of English pottery production. A complex web of railway routes followed, and these developments transformed an isolated rural area into a major industrial center.

Wedgwood made contributions in several areas that helped transform the production of pottery into a major industry. He changed the manufacturing process and adopted mechanization that would enable him to increase production while lowering prices; and the increased productivity would help to maintain a stable wage for his employees. He had many ideas about sales and marketing of his products and was the first manufacturer to introduce the "satisfaction-guaranteed-or-your-money-back" policy, which is now an extensively used tool for selling.

Wedgwood was an advocate of free trade, and a commercial treaty with France was welcomed by many of the ceramic manufacturers as a means of stimulating imports. Industries that had not adapted to new technology (e.g., the use of steam) feared the competition of imports. Wedgwood wrote on this issue of the treaty with France:

An exchange of the produce of one nation for the manufactures of another are happy circumstances, and bid fair to make the intercourse lasting; but sensible as I am to the interests of trade, manufacturers and commerce, they all give place to a consideration much superior in my mind to them all. I mean the probability that a friendly intercourse with so near and valuable a neighbour [sic], may keep us in peace with her—may help to do away with prejudices as foolish as they are deeply rooted, and may totally eradicate that most sottish and wicked idea of our being natural enemies . . .

The production of ceramics became an important and growing export industry. Vast quantities of ceramic ware produced in the potteries were exported from the major seaports of London, Bristol, Liverpool, and Hull to America, the West Indies, and all over Europe.

Today, many of the most famous names associated with the Staffordshire Potteries, such as Royal Doulton and Spode, can still be seen. A visit to any department store demonstrates that these names are still associated with some of the highest-quality ceramic tableware. However, most of the Royal Doulton pieces are now made in China, not in the small towns in the Potteries. As with other industries, the ceramic industry has seen much consolidation and acquisition in recent years. Wedgwood merged in 1986 with Waterford Crystal, forming Waterford Wedgwood plc to become the world's largest tableware

company, with sales in excess of \$1 billion. Unfortunately, the company bearing the great name of Wedgwood went into receivership in 2009, and production at its headquarters in Waterford, Ireland shut down with the loss of several hundred jobs. Also in 2009, the Portmeirion Group acquired Spode; and production still takes place in Stoke-on-Trent.

38.2 GROWTH AND GLOBALIZATION

Although the United Kingdom was a traditional leader in the development of ceramics, there were major changes during the latter half of the twentieth century, when Japan became the major producer of ceramics. Rapid transportation routes meant that manufacturing sites no longer needed to be near mineral resources. For example, Japan has no significant domestic energy supplies but is a major industrialized manufacturing nation. One of the significant changes that led to the growth and dominance of Japan was a shift in its business from traditional low value-added basic ceramics to one that has a large component of high value-added. Table 38.1 shows the market for high-technology ceramics as it was in 1980. Japanese companies satisfied about half of the \$4.25 billion demand. In some areas they were dominant, producing over 60% of the worldwide market for integrated circuit (IC) packages and almost 80% of the ferrites. The market for IC packages, which is based on alumina, was established largely by U.S. companies, but there are few remaining that sell on the open market.

The rapid growth in the Japanese production of ferrites in the 1970s and 1980s coincided with a decline in this area in the United States and in Europe. The only serious constraint on the expanded production of ferrites in Japan during this period was a shortage in raw material (secondary iron oxide) caused by weak steel production. In 2011, Japan remains the largest market for advanced ceramics.

TABLE 38.1 1980 Market for High-Technology Ceramics (Excluding Fibers, Nuclear Fuels, Spark Plugs)

<i>Product</i>	<i>Japan</i>	<i>World</i>
Ceramic powders	\$130	\$250
Electronic IC packages/substrates	540	880
Capacitors	325	750
Piezoelectrics	295	325
Thermistor/varistors	125	200
Ferrites	380	480
Gas/humidity sensors	5	45
Translucent ceramics	20	45
Cutting tools: carbide, cermet, coated noncarbide	120	1,000
Structural ceramics (heat and wear resistant)	120	250
Totals	\$2,065	\$4,250

IC integrated circuit.
Markets in millions of dollars.

TABLE 38.2 Challenges Facing the Ceramic Industry According to Percent of Survey Respondants

Environmental standards	39%
Changing markets	33%
Cost of labor	32%
Imports	27%
Health and safety standards	26%
Cost of materials	25%
Quality of labor	20%
Capital for expansion	20%
Quality control	19%
Cost of fuel	19%

Table 38.2 shows some of the challenges that face ceramics companies worldwide. This information was gathered from a survey of over 250 ceramics companies. The major challenges are meeting environmental standards, adapting to changing markets, and labor costs. The ceramics industry, like many others, can establish production facilities where labor costs are lower. For example, KEMET Corporation, based in Greenville, SC, a manufacturer of tantalum electrolytic and multilayer ceramic chip capacitors, has relocated all manufacturing to lower-cost facilities such as in Mexico and China.

38.3 TYPES OF MARKET

As we described in Chapter 1, the ceramics industry is generally divided into six distinct markets.

- Glass
- Advanced ceramics
- Whiteware
- Porcelain enamel
- Refractories
- Structural clay

It is in advanced ceramics that many of the exciting developments are occurring. The 2007, U.S. advanced ceramics market was \$12 billion, and by 2015 it is projected to reach \$16 billion. The global market for advanced ceramics is expected to exceed \$56 billion by 2015. The largest growth segments are electronic ceramics, which includes capacitors, piezoelectrics, and ferrites. In chemical processing and environmental-related applications, ceramics are routinely used for automotive catalyst supports and filters that reduce pollutants in response to regulations on both automobile and industrial emissions.

TABLE 38.3 Types of Ceramic Industry

<i>Activity</i>	<i>Examples</i>
Ceramic powders	SiC for abrasives Nanosized TiO ₂ for sunscreen Bioactive glasses for bone reconstruction Bayer process Al ₂ O ₃ for the production of Al using Hall-Héroult cells
Forming powders into bulk forms	Slip casting of toilet bowls Cz growth of Nd:YAG single crystals AlN sheets by tape casting Glass melting
Fabricating ceramic components	Ceramic chip capacitors Packages for integrated circuits SiC pressure sensors

38.4 CASE STUDIES

As we described in Chapter 1, the ceramics industry covers a wide range of materials and products. We can generally divide the activities of this industry into three distinct categories, as listed with examples in Table 38.3. In this section, we describe in more detail one example of each activity and some current industrial trends.

CERAMIC IC PACKAGES

Together with substrates, ceramic packages compete with polymers but are superior in terms of thermal conductivity and hermeticity and are used in high-reliability applications.

38.4.1 Silicon Nitride Powder

Silicon nitride, Si₃N₄, is not a naturally occurring mineral. All the Si₃N₄ that we use must be synthesized, usually by one of the following methods (more details in Chapter 19).

- Direct nitridation of Si
- Carbothermal reduction of silica in N₂
- Vapor phase reaction of SiCl₄ or silane (SiH₄) with ammonia

The characteristics of the resulting powder that are important to end-users are:

- Particle size and distribution. Powder compacts containing a few coarse particles produce components with significantly reduced strength and toughness (two of the properties we are often trying to maximize). Milling can be used to reduce particle size but often leads to significantly increased costs and the introduction of unwanted contamination.
- Surface area. Affects how easily the powder can be densified during sintering and the final grain size in the sintered component.
- Purity. Depends on the processing route and wide variations are possible. Oxygen on the surface of the

FIGURE 38.1. Schematic showing processing steps in forming Si_3N_4 by LPS. The metal oxide additive (m) would be something like Y_2O_3 and the liquid an oxynitride/silicate.

powders can affect densification; however, we need enough to form the liquid phase during sintering.

- **Structure.** A high $\alpha\text{-Si}_3\text{N}_4$ content is desirable because it favors the conversion to rodlike interlocking $\beta\text{-Si}_3\text{N}_4$ during subsequent processing into bulk components, as illustrated in Figure 38.1.

The cost of Si_3N_4 powders can vary from \$30/kg up to \$150/kg depending on particle size and purity. The high costs of raw material and the subsequent shaping and forming processes have restricted the use of Si_3N_4 . Table 38.4 shows a summary of a cost analysis performed for direct-nitrided Si_3N_4 powder. Most of the cost of the powder is due to the raw materials and the process materials (i.e., the milling media). Si_3N_4 milling media is very expensive; it costs about \$150/kg, compared with alumina or steel media at \$16/kg and \$4/kg, respectively.

Some of the present applications for Si_3N_4 parts include cutting tool inserts, bearings and rollers, refractory parts, cam followers in engines blades, vanes in heat engines, and turbocharger rotors. The advantage of using Si_3N_4 for cutting tool inserts should be clear from Figure 38.2. You may see the units given as surface feet per minute (SFM), which is a measure of the distance covered by a rotating tool (traditionally a saw or lathe now used in wear); the surface foot is a linear foot ($3.28 \text{ SF} = 1 \text{ m}$).

There are several powder manufacturers—primarily in China, Germany, and Japan—producing hundreds of tons of Si_3N_4 . There are currently no U.S. suppliers of Si_3N_4

TABLE 38.4 Summary of Costs for Direct-Nitrided Si_3N_4 Powder

Cost distribution	\$/kg	% of total
By cost element		
Silicon powder	7.49	25.4
Silicon nitride seed powder	1.71	5.8
Capital equipment	0.49	1.7
Direct labor	1.18	4.0
Energy	1.88	6.4
Process materials	16.74	56.8
Total	29.48	100.0
By process step		
Silicon powder	7.49	25.4
Silicon nitride seed powder	1.71	5.8
Direct nitriding	3.30	11.2
Crushing	6.62	29.3
Fine grinding	8.36	28.4
Total	29.48	100.0

powder. GTE, Dow Chemical, and Ford Motor Company developed high-quality Si_3N_4 powders between about 1973 and 1995, but none of these companies is a supplier today.

38.4.2 Ceramic Chip Capacitors

We described the structure of a multilayer chip capacitor (MLCC) in Chapter 31. The MLCCs are used in a large number of products, in particular personal computers and

FIGURE 38.2. Improvements in the rate of metal cutting for various cutting-tool inserts.

FIGURE 38.4. Trends in number (N) of dielectric layers and thickness (Δ) of the dielectric layer.

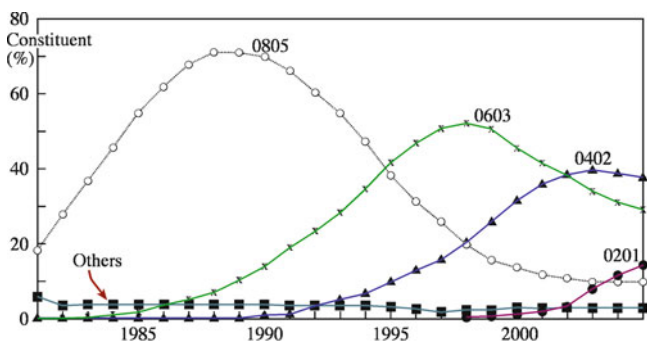

FIGURE 38.3. Multilayer ceramic capacitor-size trends.

cell phones. A typical cell phone may contain 400 MLCCs. The goal is to make smaller components with larger capacitances at a lower cost.

Capacitors are extremely price-competitive because of their relatively simple structure (see Figure 31.19). The following costs are involved.

- Ceramic dielectric. The ceramic capacitor industry uses more than 10,000 t of BaTiO₃-based dielectrics (about 90% of the total produced).
- Metal electrodes are usually precious metal-based.
- Labor costs are particularly important in this industry because of the low value-added costs.

Figure 38.3 shows the trend in the size of MLCCs since 1981. The designations used follow the Electronic Industries Association (EIA) guidelines. In the

EIA CAPACITOR CODE

The size of MLCCs is defined as “llww”: ll is the length of the capacitor and ww is the width, both in thousandths of an inch (a case where Imperial and U.S. units are still widely used in industry!)

Example: 0805 means a capacitor of length 0.080 in (~2 mm) and width 0.050 in (~1.25 mm).

PRECIOUS METAL

In January 2001 Pd prices reached a staggering \$1,000 per troy oz. Currently Pd trades for between \$750–800 per troy oz.

1980s, most MLCCs produced were either 1206 or 0805 (the two largest sizes). By 2000, the 1206 type accounted for less than 10% of the market, and 30% of the market was the 0402 type: a component with a fraction of the area and using much less material. Since 2000, the very small 0201 captured an increasingly larger market share.

The use of lower operating voltages in handheld devices and microprocessors has allowed dielectric layer thickness (Δ) to be reduced; consequently, higher layer counts (N) are possible within the same overall device dimensions, as shown in Figure 38.4. The trends in N and Δ predicted by the arrows at the end of the lines in

Figure 38.4 are consistent with where the industry was in 2011: N > 1,800 and Δ < 1 μm.

You may recall from Chapter 31 that capacitance, C, is given by:

$$C = \epsilon_0 \kappa \frac{A}{d} \quad (31.13)$$

By reducing d and increasing the number of layers (effectively increasing A), it has been possible to expand the capacitance of MLCCs into the tantalum and aluminum electrolytic capacitor range.

The ability to cast thin layers (<3 μm) requires highly disperse, uniform, fine-grained ceramic powders (100–300 nm particle diameter). To achieve these particle sizes, extensive milling may be used, or the powder can be made by solution methods such as using metal alkoxides, as we described in Chapter 22.

A major challenge in the MLCC industry has been to replace the

precious metal electrodes (usually a Pd-Ag alloy) with base metals such as Ni. The MLCC industry accounts for about 75% of the electronic industries' use of palladium.

38.4.3 Nd-Doped YAG Laser Crystals

Yttrium aluminum garnet (YAG) single crystals are the most widely used laser host, with over 100,000 YAG lasers worldwide. The Czochralski process, which we described in Chapter 29, is used to grow single crystals of YAG. Typical growth conditions are pull rates of 0.4 mm/h at temperatures nearing 1,900°C.

One of the most common dopants is Nd^{3+} , which substitutes for yttrium in the crystal lattice. Commercial Nd-doped YAG is regularly produced with Nd concentrations of 0–1.5 substitutional percent (sub %) of yttrium sites. From the chemical formula $\text{Y}_{3-x}(\text{Nd}_x)\text{Al}_5\text{O}_{12}$, the substitutional percent Nd is given by $x/3$. For instance, 1.02 sub% Nd = 0.153 at. % Nd. Few crystals beyond 1.5 sub% Nd are available commercially.

The goal for commercial suppliers is to grow highly doped, large-diameter crystals. Increasing the dopant concentration results in a

higher absorption coefficient, lower fluorescence lifetime, and greater overall laser efficiency. However, raising the Nd concentration increases the frequency of cracking during growth as we showed in Figure 16.1. If fracture occurs during growth, the process must be halted, which results in significant loss of time because a single boule can take 2 months to grow.

One of the causes of fracture has been shown to be small regions of inhomogeneity in the crystal, as shown in the transmission electron microscopy (TEM) image in Figure 38.5. The widely spaced fringes in the image are moiré fringes caused by interference of the electron beam as it passes through two lattices that have different lattice parameters. The particle shown in Figure 38.5 actually has

a larger lattice parameter, corresponding to a local Nd concentration of 2.768%, compared to the matrix, which has an Nd concentration of 1.02% Nd. (There is also a very small misorientation between the particle and the matrix, which affects the spacing of the moiré fringes).

More recently, there has been interest in using nanopowders to make polycrystalline laser hosts, which would avoid the need to use slow single-crystal growth methods.

The problem is keeping the grain size small enough during sintering to maintain transparency.

38.5 EMERGING AREAS

The area of advanced ceramics is exciting as technologies developed in research laboratories and universities become adopted by industry. This market segment shows continued growth offering good employment opportunities for Management Science and Engineering (MS&E) graduates.

In this section we describe three emerging areas: ceramic nanopowders, high-temperature superconductors, and ceramic matrix composites.

38.5.1 Ceramic Nanopowders

Nanotechnology is a “hot” research topic. The field is trendy, popular, and high-tech. Although silica and iron oxide nanoparticles have a commercial history spanning half a century or more, it is really within the last two decades that technologies have been developed for

YAG LASERS

The first application for Nd-doped YAG lasers was in laser range finding. Nonmilitary applications include cutting, welding, and drilling of metals for the automobile industry and in medical and dental procedures.

Ce-DOPED YAG

Ce-doped YAG is a scintillator that can be used to detect γ -rays with a high energy resolution (<4% using ^{137}Cs 662 keV γ -rays). The applications include nuclear threat detection and medical diagnostics using positron emission tomography. Ce-doped YAG is yellow; Nd-doped YAG is purple.

FIGURE 38.5. Moiré fringes observed in a high-resolution transmission microscopy image of an Nd-rich particle in single-crystal YAG.

TABLE 38.5 Current and Emerging Applications for Nanosized Powders

<i>Electronic, optoelectronic, magnetic applications</i>	<i>Biomedical, pharmaceutical, cosmetic applications</i>	<i>Energy, catalytic, structural applications</i>
Chemical–mechanical polishing (CMR) supports	Antimicrobials	Automotive catalyst
Electroconductive coatings	Biodetection and labeling	Ceramic membranes
Magnetic fluid seals	Biomagnetic separations	Fuel cells
Magnetic-recording media	Drug delivery	Photocatalysts
Multilayer ceramic capacitors	Magnetic resonance imaging contrast agents	Propellants
Optical fibers	Orthopedics	Scratch-resistant coatings
Phosphors	Sunscreens	Structural ceramics
Quantum optical devices		Thermal spray coatings
Solar cells		

producing ultrapure nanosized powders of a range of ceramics. The global nanoparticle market, which is dominated by ceramics, is now around \$1 billion. Current applications for ceramic nanoparticles are summarized in Table 38.5.

- Electronic, magnetic, and optoelectronic applications account for 70%. The biggest single use is slurries of abrasive silica particles (50–70 nm) for chemical–mechanical polishing (CMP).
- Biomedical, pharmaceutical, and cosmetic applications account for 18%. Sunscreens use nanosized powders of TiO₂ or ZnO.
- Energy, catalytic, and structural applications account for the remaining 12%. Uses include catalyst supports (e.g., for low-temperature H₂ production), ceramic membranes, fuel cells, and scratch-resistant coatings.

An example of the potential of nanosized ceramic powders in medicine is the demonstration that 5-nm cerium oxide (CeO₂) nanoparticles can prolong the life of brain cells. Usually these cells live for around 25 days in the laboratory, but after a low dose of the nanoparticles they have been shown to survive and function normally for 6 months. The hope is that this approach might one day be used to treat age-related disorders such as Alzheimer’s disease. It was also found that the treated cells had increased protection against damage from ultraviolet (UV) radiation, as shown in Figure 38.6. The implication is that the nanoparticles

NANO

Nanosized ceramic powders have grain sizes on the order of tens of nanometers or less; conventional ceramic particles typically have grain sizes of several microns or more.

FIGURE 38.6. Effect of nanosized cerium oxide particles on the life-span of rat neurons.

mop up free radicals—reactive molecules that damage cells and are known to be involved in aging and inflammation. (Look back at Chapter 35—this is just the beginning, but always remember that perhaps the most dangerous asbestos fibers are “nanoparticles”).

An energy-related application undergoing extensive testing is the use of 10-nm CeO₂ particles as additives to diesel fuel. The CeO₂ nanoparticles catalyze combustion of the fuel. The claim is that they release oxygen to oxidize carbon monoxide and hydrocarbon gases to carbon dioxide and reduce quantities of harmful nitrogen oxides. The result is a cleaner-burning fuel that converts more fuel to carbon dioxide, produces less noxious exhaust, and deposits less carbon on the engine walls.

The market for nanosized powders is much smaller than for conventional ceramic powders, but the cost per kilogram is much greater. Despite progress in scaling up production and reducing costs, nanosized powders remain relatively expensive (often 100 times more than conventional ceramic powders).

There are growing concerns about the impact of nanoparticles on human health and the environment. Inhaling fine quartz particles is known to cause silicosis, a potentially fatal scarring of delicate lung tissue. Fine particles shed from hip and knee replacements as they wear cause inflammation of the surrounding tissues and may result in the implant having to be replaced. Studies where carbon nanotubes were placed directly into the lungs of mice showed that there

was significant damage to the lung tissue. Because many of the potential applications for nanoparticles are in the human body, it is important to determine their safety. It is also necessary to evaluate their environmental impact.

38.5.2 High-Temperature Superconductors

One of the benefits with increasing T_c above 77 K is that liquid nitrogen, rather than liquid helium, can be used as the coolant. Liquid nitrogen is both cheaper and more readily available than liquid helium. You can find the cost of liquid nitrogen described as either less than milk or less than cheap beer! The cost of liquid helium is often likened to fine champagne.

Soon after the discovery of HTSCs and, in particular, the yttrium barium copper oxide (YBCO) compound, there were grand predictions that these materials would revolutionize areas such as a high-speed transportation and power transmission. The applications to date have been a little more modest. Magnetic levitation (maglev) for high-speed transportation has not been achieved with HTSCs but continues to a limited extent with the use of low-temperature materials. The other major application proposed for HTSCs was in power transmission. However, due to the high cost and impracticality of cooling miles of superconducting wire, this has happened only with short “test runs.” In May 2001, about 150,000 residents of Copenhagen, Denmark, began receiving their electricity through superconducting cables. The superconductor chosen for this application was bismuth strontium calcium copper oxide (BSCCO) (see Section 7.16) in the form of a tape wrapped around a flexible duct that carries the liquid N_2 . The remainder of the cable consists of thermal and electrical insulation. In November 2001, commercial power was delivered to about 30,000 homes in Detroit, Michigan using a similar approach.

One area where HTSCs are is poised to make a significant impact is in filters that improve network performance between wireless (cellular) devices and cell sites. Superconductivity avoids a typical trade-off by filtering out interference from adjacent signal bands without hindering the base station’s ability to pick up weak signals. Commercial units using HTSCs are available and have been deployed.

According to estimates by Conectus, the worldwide market for HTSC products is projected to grow to about \$0.5 billion by 2013. It is interesting to compare this projection with the very “bullish” one provided by the same organization and quoted in the first edition of this book! It really goes to show that it is very difficult to accurately predict markets over even short periods of time.

38.5.3 Ceramic-Matrix Composites

Ceramic-matrix composites (CMCs) are being developed to provide an alternative to single-phase ceramic components because of the possibility of designing in

TABLE 38.6 Priority Needs in CMCs to Address Key Challenges Faced by Ceramic Manufacturers and End Users

<i>Key challenges for CMCs</i>	<i>Priority needs to address the challenge</i>
Reduce the cost of precursors	Scale-up/cost reduction of fiber manufacturing Lower-cost interface materials and deposition processes
Improve understanding of failure modes	Basic understanding of interactions between CMC constituents and application environments Micro- and macro-mechanics understanding of interactions of CMC with an applied stress or strain
Increase temperature stability to 1,200–1,500°C	Higher-temperature fibers, matrix materials, and interface coatings Environmental barrier coatings (EBCs) Active cooling designs
Manufacturing scale-up and cost reduction	Larger furnace design and construction Automation/semiautomation of perform fabrication Low-cost tooling Near-net-shape fabrication Low-cost in-process and post-process quality assurance

higher toughness. The most important CMCs will probably be those with continuous fiber reinforcement. We described some of the processing routes in Chapter 20. CMCs are at a relatively early stage of development compared to polymer-matrix composites (PMCs) and metal-matrix composites (MMCs); and significant research is needed if they are to meet their full potential. Table 38.6 lists some of the priorities.

- *Cost:* Nonoxide fibers cost thousands of dollars per kilogram. Oxide fibers, even those that have been commercially available for years, sell for hundreds of dollars per kilogram. The main reason is that production volumes are small. Most fiber-reinforced CMCs utilize a layer between the fiber and the matrix to optimize mechanical properties. The methods used for depositing this layer tend to be expensive and difficult to scale up for production.
- *Understanding failure modes:* We generally want a weak fiber/matrix interface in CMCs. A propagating crack is deflected around the fibers as shown in Figure 38.7 and does not propagate through the fibers. This is a situation opposite to that in PMCs, where we often want a strong interface so that the load is transferred to the stronger fibers.
- *Increase temperature stability:* Fiber-reinforced CMCs have been demonstrated to survive in the severe environment of a gas turbine engine for 2,500 h at temperatures up to 1,200°C. The use of environmental barrier coatings (EBCs), such as oxide layers, on SiC appears to help extend durability, but more research is

FIGURE 38.7. Crack propagation through a fiber-reinforced composite: SiC fiber in calcium aluminosilicate glass.

needed to determine whether they present a long-term solution.

- *Scale-up:* The high price of finished components made from fiber-reinforced CMCs is a major limitation. Reducing materials' costs and increasing production volume would reduce costs substantially. One of the requirements for large-scale manufacturing of CMCs is the development of quick, inexpensive quality control procedures that can be used during production. The main processing defects are voids, density variations, and cracks. X-ray computed tomography (CT) is a powerful technique for this type of investigation, and high-resolution detectors can detect defects as well as resolve features as small as 5 μm (see Chapter 10). However, the technique remains expensive and slow and is not suitable at the present time for in-line process control.

38.5.4 Ceramics as the Enabling Materials

As you've realized from the discussion of capacitors, glass, data storage, etc., ceramic materials are often the critical part of a program or product even if the consumer never sees them.

Sapphire single crystals are grown for use in substrates, as windows, as infrared (IR)-transparent domes, in jewel bearings, as the "glass" on your watch; but there are other applications of these and other single crystals that most of us never see. Large sapphire crystals are being tested for use in the Laser Interferometer Gravitational-Wave Observatory (LIGO) Fabry-Perot interferometer. The aim of LIGO is to study astrophysical gravitational waves. There are two LIGO sites: one in eastern Washington and one in Louisiana. Sapphire should reduce the thermal noise

compared to the fused silica that was initially used. The LIGO requires the crystals to be 35 cm in diameter and 12 cm long, and it uses 5 N-pure alumina powder. The factors studied in assessing the sapphire mirrors for future generations of LIGO include all aspects of the influence of temperature on mechanical properties. The results are compared with the current fused-silica mirrors. In either case, the ceramic is the enabling material and is the topic of very focused research.

38.6 MINING

From the ugliness of an open cast mine, to the health problems of mine workers, to the bitter civil wars fought over mineral resources in Africa, the impact of mining and our search for raw materials are frequently topics in the news media. Many of the ceramic products we use are produced from natural resources. For example, the main component of most glasses is SiO_2 , which comes from sand. The main component of traditional ceramic products such as tableware and bricks is clay, which is available in different grades and is usually extracted by opencast mining. These raw materials are abundant and widespread. Data on the United States Geological Survey (USGS) site is fascinating food for thought and is updated annually.

38.6.1 Talc

A mineral that has caught the attention of environmentalists and conservationists is talc. Talc is used in the production of paper and tiles and as coatings in the motor industry for dashboards and bumpers. However, its main use is in beauty products such as eye shadow, lipstick, body lotions, deodorants, and soaps. Talc is produced from soapstone, which occurs in the form of large subsurface boulders. One concern is that some of the finest powder is obtained from soapstone that is the result of illegal mining in India's Jamwa Ramgarh Wildlife Sanctuary and the neighboring Sariska Tiger Reserve 250 km southwest of Delhi. These sites are considered essential to the revival of the Indian tiger. The current population of Indian tigers is about 3,000, but they are threatened with extinction because of the loss of habitat and prey caused by the mining activities. The other concern is that some studies indicate that talc particles cause tumors in the ovaries and lungs of cancer victims; however, talc often contains asbestos, so all is not clear.

38.6.2 Vermiculite

Vermiculite is a mica-like mineral used as housing insulation and in gardening or even animal feed! Up to 80% of the world's supply

RARE-EARTH ELEMENTS

The REEs are the 15 lanthanides plus scandium and yttrium. They play a major role in the development of a number of advanced materials, including those with applications related to clean energy technology.

FIGURE 38.8. Structure of a solid electrolyte Ta capacitor.

came from Zonolite Mountain in Montana. Workers have a 50% chance of developing health problems relating to lung cancer.

38.6.3 Tantalite

The dielectric in tantalum electrolytic capacitors is tantalum pentoxide (Ta_2O_5), which forms a thin layer on tantalum, as illustrated in Figure 38.8. The benefits of using tantalum capacitors are that they are small, have a wide operating temperature range (-55°C to $+125^\circ\text{C}$), and are very reliable.

Controversy has arisen recently concerning the source of tantalum: the mineral tantalite, which is found in association with niobium as the ore columbite-tantalite (col-tan). A major supply of col-tan is found in the Kahuzi-Biéga Park in the Democratic Republic of Congo. The park is home to the eastern lowland gorilla, one of the most rare animals in the world. As a result of col-tan mining, the gorilla population is being decimated, and the billion-dollar export has funded the Congo's civil war.

38.6.4 Dysprosium Oxide

Dysprosium is one of the rare-earth elements (REEs) and, according to the U.S. Department of Energy, may be the single most critical element for emerging clean-energy technologies. The spot price (August 2011) for 1 kg of dysprosium oxide (Dy_2O_3) was $\sim\$1,500$ —a more than fourfold increase in less than 8 months. The price has increased from only $\$300 \text{ kg}^{-1}$ in 2010. China is the only country with significant known deposits of dysprosium and mines over 90% of the supply of REEs. The most important dysprosium-containing minerals are xenotime, which is mined in Guangdong, and rare-earth laterite, which is mined in Longnan in Jiangxi Province. China imposed an export quota of 30,258 t of REEs in 2010 in response to a demand from the rest of the world for 48,000 t. The mining

of dysprosium (and other REEs) creates two separate environmental problems. First, the REEs often occur together with radioactive elements (e.g., thorium, uranium), which pose significant health risks for miners. Second, the refining process uses toxic acids.

38.6.5 Lithium Carbonate

When you think batteries, you think Li and you would be correct. Lithium-ion battery production represents about 75% of the total portable rechargeable battery market worldwide. Around the world, lithium batteries power most cell phones and laptops (including iPods and iPads), as well as many heavy-duty power tools. In 2009, the United States consumed 1,399 t of Li. That is about 45% below 2007 and 2008 values: use is determined by the economy. Lithium is mined as an ore or brine. Fortunately, lithium ore is found worldwide. Australia is currently the leading producer of lithium mineral concentrates; the spodumene was mainly exported to China to produce lithium carbonate. Major sources of Li are in Bolivia and Chile where mining is having a critical impact on local politics. Comibol (Corporación Minera de Bolivia) expects to produce 30,000 t/year at the

Salar de Uyuni salt flat, which is the world's largest.

Afghanistan may become the largest supplier of lithium, with deposits valued at $\$1$ trillion in 2010. The mineral deposits are scattered throughout the country, including in the southern and eastern regions along the border with Pakistan, which have seen some of the most intense combat in recent years.

38.7 RECYCLING

There are three basic reasons given for recycling.

1. Preserve finite resources
2. Protect the environment
3. Save energy

The raw materials used for glass production are abundant and, unlike many metal ores, are not in any imminent danger of being depleted. Producing glass does involve consumption of large amounts of energy, as shown in Table 38.7. (Glass is the lowest on this list because high-purity sources of SiO_2 are readily available). Table 38.8 shows the total energy involved in producing a 12-oz beverage bottle, including factors such as mining, transportation, etc. The energy savings by recycling and reusing glass containers are also shown in Table 38.8.

TABLE 38.7 Energy Consumption to Extract 1 t of Raw Material from Its Ore or Source

Material	Energy (GJ)
Aluminum	238
Plastics	100
Zinc	70
Steel	50
Glass	20

TABLE 38.8 Energy Consumption per Use for a 12-oz Beverage Container

Container	Energy (MJ)
Aluminum can used once	7.4
Glass bottle used once	3.9
Recycled aluminum can	2.7
Recycled glass bottle	2.7
Refillable glass bottle used 10 times	0.6

Glass recycling has been going on for thousands of years; broken glass was reused in antiquity to make new glass objects. This ancient recycling system makes it difficult for archeologists to determine the provenance of a glass object from its chemical composition alone. A structured recycling program for domestic glass waste started in 1975, initiated by the glassmaking companies.

In Chapter 26 we described the glass-forming process. The initial step is that the batch, which consists primarily of sand, is melted. The temperature required varies with the composition of the batch but is typically in the range 1,300–1,600°C. Adding crushed recycled glass, called cullet, to the melt promotes melting of the sand, permitting the use of reduced furnace temperatures with considerable savings in both raw materials and energy. For example, if a glass batch for beverage-container glass contains 25% cullet, it requires 5% less energy to melt. Although cullet has been used in ratios ranging from 0% to 100% of the glass, 30–60% cullet is the most effective

range. For colored bottles, cullet comprises about 50% of the batch.

One difficulty associated with using recycled glass, particularly from consumer recycling, is the necessity to sort the discarded bottles according to color. In the United States, over 65% of container glass is clear, 25% is brown or “amber,” and 10% comes in different shades of green and occasionally blue and other colors. These percentages do not correspond exactly with the glass contents in domestic waste because of the consumption of imported beverages that come in mostly brown and green bottles. In France, 80% of the glass containers are green. Wine is usually packed in green bottles because it provides better UV protection, but the original reason is that when the wine bottle was invented in England during the seventeenth century it was made of green glass.

Clear glass is the most valuable glass for recycling. Both clear and brown glasses are very sensitive to impurities, so they cannot be mixed with each other or with other types of glass. Green glass, on the other hand,

can accept other glass types without noticeable influence on the color. However, green glass is often the most difficult for the glass manufacturers to use simply because the supply of recycled green glass often exceeds the demand. One application for recycled green glass that is not influenced by color is fiberglass insulation.

It is important that container glass is not mixed with other types of glass product, such as windows, light bulbs, mirrors, and tableware. These glasses have different compositions, as we showed in Chapter 26. Because of problems associated with contamination of recycled glass, the

use of returnable/refillable glass bottles and containers is increasing. Switching to refillable containers can save up to 56% of the energy consumed, reduce water consumption by up to 82%, and decrease materials consumption over 10 times for 35 refills.

Currently, the cost of recycling far outweighs the value of the recyclables. It may take up to five times the amount of money a recyclable product is worth to collect, process, and transport it to a buyer. As a result, the recycling

BOTTLE BANKS

First appeared in the UK in August 1977. There are now over 22,000 bottle bank sites and more than 570,000 t of glass are recycled annually.

GLASS RECYCLING: FACTS AND FIGURES

More than 40 billion glass containers are produced each year in the US.

All glass food and beverage containers can be recycled. Recycling a glass jar saves enough energy to light a 100-W light bulb for 4 h.

Glass constitutes about 6% of US municipal solid waste. Approximately 12 million tons of waste glass food and beverage containers are generated each year in the US.

About 25% of all glass food and beverage containers are recycled in the US.

The average glass bottle contains over 25% recycled glass.

industry is currently driven by consumer demand, not by profit. Many environmental economists point out that in a “sustainable” economic system (one based on the real costs to the environment resulting from the transportation and production of goods and materials) recycling is financially cost-effective. In such a system, the prices of products made from virgin materials would be prohibitive, encouraging manufacturers to use recycled materials instead. However, under such a system, the concept of curbside recycling would become even less cost-effective than it is now due to increasing transportation and energy costs.

Some of the issues that drive the need for recycling in Europe are quite different from those in the United States. One significant difference is population density. Recycling in The Netherlands, which recycles more than 80% of its glass waste, is much more important than in the United States. The population densities are about 372 inhabitants/km² and 27 inhabitants/km², respectively. As the population density increases, the landfilling of wastes, particularly industrial wastes, becomes more difficult and unacceptable for the nearby population. Landfill space has to compete with the land requirements for expanding suburban developments and, in many cases, agricultural land as well.

One recycling issue that is important throughout the developed world is what to do with the approximately 300 million (old fashioned!) TVs and computer monitors that are thrown out each year. The European Union Waste Electrical and Electronic Equipment Directive banned them from being dumped in landfills because the screens contain PbO (added to shield against the X-ray radiation released by the high anode voltage).

CATALYTIC CONVERTERS
Have reduced automobile pollution by more than 1.5 billion tons since 1974

Table 38.9 shows typical compositions of cathode ray tube (CRT) glasses.

To prevent a growing mountain of TVs, one of the plans is to melt down the tubes in a sealed furnace under conditions that would reduce the PbO to Pb. The heavy molten metal would run out of fissures at the base of the furnace, but the molten glass would be retained. The purified glass could then be used for other applications, such as bottles.

The use of recycled glass as an ingredient in concrete is being explored in several locations worldwide.

38.8 AS GREEN MATERIALS

38.8.1 Catalytic Converters

Catalytic converters are used in the exhaust system of automobiles and can reduce emissions of carbon monoxide and hydrocarbons by up to 90%. Carbon monoxide can be transformed into carbon dioxide, and unburned hydrocarbons from the fuel get burned on the metal surfaces. Nitric oxide, one of the main contributors to urban smog, reacts with carbon monoxide to form carbon dioxide and nitrogen gas. These processes are conducted in catalytic converters.

The first catalytic converters used mainly platinum, but now palladium is the predominant catalyst metal. Sixty percent of the palladium manufactured worldwide is used in catalytic converters. Other uses are as the electrodes in MLCCs and other electronic components, and a small amount is used in jewelry (e.g., as an alloying element in white gold).

The metal is dispersed as tiny particles on a supporting framework of a porous ceramic. Because of the requirement of thermal shock resistance, a ceramic with a near-zero coefficient of thermal expansion is required. One such material is cordierite. Figure 38.9 shows an example of a ceramic honeycomb substrate for a catalytic converter. Substrates have been produced with up to 900 cells per square inch and walls with a thickness of 50 μm. These complex shapes are produced by extrusion, a process we described in Chapter 23. The ceramic powder is mixed with a hydraulic-setting polyurethane resin. The mix is extruded into a water bath at a rate of about 2 mm/s. The extrusion rate matches the rate at which the resin cures.

Other requirements for the catalyst substrate are:

- Low cost
- Thermal-mechanical durability
- Lightweight

38.8.2 Diesel-Particulate Filters

Diesel-particulate filters (DPFs) are devices used to remove soot (small carbon particles often down to nanometer sizes) from the exhaust gas of a diesel engine. Cordierite is the most common DPF and looks much like the one shown in Figure 38.9. The difference is that alternate channels are blocked, which means the exhaust gas is forced through the porous walls where the carbon particles collect, as shown in Figure 38.10. Silicon carbide (SiC) is also used as a DPF material. It benefits from a higher melting point than cordierite and is primarily used for stationary diesel applications.

A recent addition to the DPF market is the Dow™ Aerify™, which consists of mullite whiskers grown

FIGURE 38.10. Cordierite or silicon carbide diesel particulate filter. Notice how the gas flow is required to go through the walls of the ceramic.

on the inside of the channels of a cordierite DRF monolith, as shown in Figure 38.11. The DPF is designed for use in both on-road and off-road diesel applications and has the benefit of a low back-pressure, which improves engine performance and fuel efficiency. Mass production of Aerify™ was to begin in 2011.

38.8.3 Carbon Dioxide Utilization

Carbon dioxide (CO₂) is a product of the combustion of fossil fuels such as coal and is also produced by a number of industrial processes, such as the production of iron and steel. Currently, over 30 billion tons of CO₂ is emitted each year from the burning of fossil fuels, and this number is projected to reach 43 billion tons by 2030. Carbon capture and sequestration (CCS) of industrial CO₂ emissions has been proposed as an approach to mitigate its release into the atmosphere. However, CCS remains unproven, costly, and is not likely to be commercially available for decades. Perhaps a better approach is to consider converting CO₂ into useful fuels and chemicals (i.e., thinking of CO₂ as a resource and recycling it). Using a photocatalyst, such

PHOTOCATALYTIC REDUCTION OF CO₂

Several steps in the photocatalytic conversion of CO₂ have been proposed:

1. Absorption of light (usually UV) by the photocatalyst generating an exciton (electron-hole pair):

2. Oxidation (“splitting”) of water:

3. Reduction of carbon dioxide

The possibility of “tuning” the reaction to favor certain products is particularly exciting about this approach.

as TiO_2 suspended in water, CO_2 has successfully been converted to C1 compounds, such as methanol (CH_3OH) and formaldehyde (HCHO), at room temperature. When the initial work was done back in 1979, the connection between anthropogenic CO_2 and global climate change had not been proposed; but now several groups are looking at photocatalytic conversion as an approach toward mitigating CO_2 emissions into the atmosphere. At the present time, the processes are not economical, and the development of improved catalysts is needed.

An alternative approach to utilizing CO_2 is to convert it into calcium carbonate (CaCO_3) or limestone, which can be used in cement production. The basic idea behind this technology was inspired by nature: CO_2 is naturally absorbed into the oceans and converted into stable mineral deposits. Whereas nature can take its time, the process is commercially viable only if it can be sped up. Also, it makes sense as a CO_2 utilization technology only if the energy associated with increasing the kinetics does not generate additional large amounts of CO_2 .

FIGURE 38.11. Scanning electron microscopy image of acicular mullite crystals used to trap carbon “soot” particles from diesel exhausts.

CHAPTER SUMMARY

In this chapter, we described some of the industrial aspects of ceramics. Ceramics make money. Unfortunately, obtaining the raw materials can have some undesirable environmental and societal impacts. The environmental impact of nanomaterials is an issue that has not significantly concerned the ceramics industry yet because no one knows exactly what that impact is. However, as the market for ceramic nanopowders and other nanostructures (e.g., wires and tubes) increases, the environmental concerns will have to be addressed. Many of the “grand challenges” we face as a society—such as producing energy, protecting the environment, and providing health care—require innovative technological solutions. Ceramics can play an important role in these areas. Three key examples that affect us all are nuclear waste immobilization, catalytic conversion, and viral nanosensors. Many ceramic materials are not thought of as ceramics, so the field seems smaller than it really is. For example, molecular sieves are zeolite-based or zeolite-like materials that are used as filters, absorbents, catalysts and catalyst supports. They are among the new ceramic materials, but they are often just left to the chemists. It is important to realize that industry is constantly in a state of flux, so numbers reported here can change from year to year. Indeed, several have changed since the first edition—some up and some down! Also, this chapter reflects a snapshot of an industry at the beginning of the twenty-first century. In a decade, the relative importance of some of the topics we described may have increased, decreased, or disappeared altogether.

PEOPLE AND HISTORY

Cronstedt, Axel Frederik (1722–1765) was the Swedish mineralogist who named zeolites because they are the stones that boil: the water they contain can be removed and replaced without changing the crystal structure.

Darby, Abraham I. (1678–1717) was born in Staffordshire. He patented sand casting in 1708 and invented coke smelting in 1709.

Feynman, Richard (1918–1988) gave his visionary talk in 1959 titled “There’s Plenty of Room at the Bottom.” Since then, nanotechnology has captured the minds and imaginations of many scientists and engineers. A transcript of his nanotechnology talk can be found at <http://www.zyvex.com/nanotech/feynman.html>. Feynman shared the 1965 Nobel Prize in Physics for work on quantum electrodynamics (physics of elementary particles). You can debate which topic was more important—it won’t take long!

Wollaston, William Hyde (1766–1828). He was an English scientist who discovered Pd in 1803 and named it after the asteroid Pallas, found in 1802. The mineral wollastonite is named after him.

EXERCISES

- 38.1 In addition to oxygen, what other impurities might you expect in Si_3N_4 powder?
- 38.2 Why is the extent of Nd substitution in YAG so small?
- 38.3 What companies make the Pd-Ag metallization used for multilayer chip capacitors (MLCCs)?
- 38.4 Do TiO_2 and ZnO play different roles in sunscreen? Which is the best material?
- 38.5 Describe one process that can be used to make CeO_2 nanoparticles.
- 38.6 In the form of a table, compare the cost of conventional (micrometer-sized) ceramic powders with their nano-sized equivalents.
- 38.7 How much glass is recycled in your community (or state)?
- 38.8 Compare the costs of recycling to landfilling for various materials.
- 38.9 Why is the bismuth strontium calcium copper oxide (BSCCO) superconductor the material of choice for superconducting wires?
- 38.10 Find today's price for Pd. Is it higher than when this book was written?
- 38.11 What factors affect the price of Pd?
- 38.12 What is the current price for dysprosium oxide? How has the price changed since the value cited in this book?
- 38.13 Does China still impose export restrictions on rare-earth elements? If so, what are the current restrictions?
- 38.14 List three applications for dysprosium. Do any of these applications use dysprosium as a ceramic, or is it always used as part of a metal alloy?
- 38.15 List all the lanthanide elements. Several of these elements, when they are in the form of oxides, are used as glaze colorants. Praseodymium oxide produces transparent green glazes. What glaze colors are produced by neodymium oxide and erbium oxide?
- 38.16 What are the current catalog prices for neodymium oxide and erbium oxide? What purities are available?
- 38.17 Xenotime is a major mineral source of dysprosium. What is the crystal structure of xenotime?
- 38.18 In addition to China, where are other major reserves of xenotime?
- 38.19 Ce-doped YAG and Nd-doped YAG single crystals are used for a number of applications. We mentioned in Section 38.4 that these crystals are grown by the Czochralski process. Are any other processes used in industry to make Ce-YAG and Nd-YAG? If so, how do they differ from the Czochralski process. If not, why not?
- 38.20 Both cordierite and silicon carbide are used to make diesel particulate filters. In a table, compare the properties of these two ceramics that are relevant to this application.

Details for Figures and Tables

This list summarizes the sources used for images and the origin of data used in tables and diagrams. Where possible, the original source for each figure is given but on many occasions the figures have been so widely used in the literature that the original source is not known to us; in these cases, when new diagrams have been created, no citation is given in this list. We will add information regarding original citations to the web site as it becomes available. Images obtained by our students, postdocs or colleagues in collaborative research with the authors but not published elsewhere are denoted here by the author's initials; those obtained by the authors are not attributed further.

Chapter 1

Figure 1.2

Data from Evans, A.G. and Davidge, R.W. (1969) "Strength and fracture of fully-dense polycrystalline MgO", *Phil. Mag.* **20**, 373. <http://www.tandf.co.uk/journals>

Figure 1.3

Courtesy of Sandia National Laboratory.

Figure 1.4

McKernan, S., MGN & CBC.

Figure 1.5

Data from Kingery, W.D., Bowen, H.K., and Uhlmann, D.R. (1976) *Introduction to Ceramics* 2nd Ed., p. 1008.

Figure 1.6

Data from Moulson, A.J. and Herbert, J.M. (1990) *Electroceramics*, Chapman and Hall, London, p. 215.

Table 1.3

From the NIST Reference on Constants, Units, and Uncertainty (www.physics.nist.gov).

Table 1.4

From *S.I. and Related Units: Quick-Reference Conversion Factors* (1968), compiled by Dryden, I.G.C, BCURA, Leatherhead, Surrey, UK.

Chapter 2

Figure 2.2

Figure 2.9

Data from Ashby, M.F., and Jones, D.R.H. (1986) *Engineering Materials 2*, Pergamon Press, Oxford, p. 192.

Figure 2.10

Data from Ashby, M.F., and Jones, D.R.H. (1986) *Engineering Materials 2*, Pergamon Press, Oxford, p. 192.

Figure 2.11

From the *Travels of Sir John Mandeville*, ink and tempera on parchment, Bohemia, circa 1410. The British Library (MS Add. 24189, f.16), London. Reproduced by permission of the British Library.

Table 2.1

Data from Fergusson, J.E. (1982) *Inorganic Chemistry and the Earth*, Pergamon, Oxford, p. 47.

Table 2.2

Data from Wood, N. (1999) *Chinese Glazes*, A&C Black, London.

Table 2.4

Data from Lechtman, H.N. and Hobbs, L.W. (1986) "Roman concrete and the Roman architectural revolution", in: *Ceramics and Civilization III: High-Technology Ceramics—Past, Present, and Future*, edited by W.D. Kingery, The American Ceramics Society, Westerville, OH, p. 95.

Chapter 3

Figure 3.7

Data from Lupis, C.H.P. (1983) *Chemical Thermodynamics of Materials*, Elsevier Science Publishing, New York, p. 35.

Figure 3.8

Data from Schmalzried, H. (1974) *Solid State Reactions*, Academic Press, New York, p. 109.

Table 3.5

Data from Moore, C.E. (1970), *Ionization Potentials and Ionization Limits Derived from the Analysis of Optical Spectra*, NSRDS-NBS 34, National Bureau of Standards, Washington, D.C. Data on the actinides is from Seaborg, G.T. (1968) *Ann. Rev. Nucl. Sci.* 18, 53 and references therein.

Table 3.6

Data from Berry, R.S. (1969) *Chem. Rev.* **69**, 533 except: ^a Edlen, B. (1960) *J. Chem. Phys.* **33**, 98; ^b Baughan, E.C. (1961) *Trans. Faraday Soc.* **57**, 1863; ^c Ginsberg, A. P., and Miller, J.M. (1958) *J. Inorg. Nucl. Chem.* **7**, 351; ^d Politzer, P. (1968) *Trans. Faraday Soc.* **64**, 2241.

Chapter 4

Figure 4.1a

Data from Sproull, R. (1956) *Modern Physics: A Textbook for Engineers*, Wiley, New York, Figure 7-2 on p. 192.

Figure 4.2

Data from Wachtman, Jr., J.B., Tefft, W.E., Lam, Jr., D.G., and Apstein, C.S. (1961) "Exponential Temperature Dependence of Young's modulus for several oxides," *Phys. Rev.*, **122**, 1754.

Figure 4.3

Data from Wachtman, Jr. J.B., and Lam, Jr. D.G. (1959) "Young's modulus of refractory materials as function of temperature", *J. Am. Ceram. Soc.* **42**, 254.

Figure 4.7

Data from Schoknecht, V.G. (1957) *Z. Naturf.*, **12A**, 983.

Figure 4.19

Data from Bader, R.F.W., Keaveny, I., and Cade, P.E. (1967) "Molecular charge distributions and chemical binding: II. First-row diatomic hydrides, AH", *J. Chem. Phys.* **47**, 3381.

Figure 4.21

Data from Slater, J.C. (1934) *Phys. Rev.* **45**, 794.

Table 4.2

Modified from Van Vlack, L.H. (1964) *Physical Ceramics for Engineers* Addison Wesley Reading MA (1964) p.118.

Table 4.3

Data compiled by Huheey, J.E. (1975) *Inorganic Chemistry: Principles of Structure and Reactivity*, Harper & Row, London, p. 62.

Table 4.4

Data compiled by Huheey, J.E. (1975) *Inorganic Chemistry: Principles of Structure and Reactivity*, Harper & Row, London, p. 61.

Table 4.5

Data from (B-H): Johnson, D.A. (1982) *Some Thermodynamic Aspects of Inorganic Chemistry*, Cambridge; (B-L): Morris, D.F.C. (1957) *J. Inorg. Nucl. Chem.* 4, 8.

Table 4.6

Data from Shannon, R.D. (1976) "Revised effective crystal radii and systematic studies of interatomic distances in halides and chalcogenides," *Acta. Cryst.* **A32**, 751.

Table 4.8

Data compiled by Israelachvili, J.N. (1992) *Intermolecular and Surface Forces*, 2nd Ed., Academic Press, London, p. 186.
