Cover Image: Veterans' 1-280 Glass City Skyway, Toledo, Ohio, 612-ft twin cable-stayed spans with 403-ft pylon. The top 196 ft of the pylon features four sides of glass enveloping LED light fixtures that allow an array of as many as 16.7 million color combinations at night. The bridge construction involved 185,000 cubic yards of concrete, 1.9 million lb of post-tensioning strands, and 32.6 million lb of mild steel reinforcement. The bridge was opened in June 2007. (Photos courtesy of Ms. Linda Figg, President and CEO, FIGG, Tallahassee, Florida. Owner: Ohio Department of Transportation. Designer: FIGG. Contractor: Fru-Con.)

Contents

Preface.....	xiii
Acknowledgments.....	xv
Editor-in-Chief.....	xvii
Contributors.....	xix
1 Concrete Constituent Materials <i>Sidney Mindess</i>	1-1
1.1 Introduction	1-1
1.2 Portland Cement.....	1-2
1.3 Modified Portland Cements.....	1-9
1.4 High-Alumina Cement.....	1-10
1.5 “Green” Cements	1-11
1.6 Performance of Different Cements in Concrete.....	1-11
1.7 Water.....	1-12
1.8 Water/Cement Ratio	1-12
1.9 Aggregates.....	1-14
1.10 Reinforcement.....	1-21
1.11 Durability Considerations.....	1-23
References	1-26
2 Mineral Admixtures <i>V.M. Malhotra</i>	2-1
2.1 Fly Ash	2-1
2.2 Blast-Furnace Slag.....	2-18
2.3 Silica Fume	2-29
2.4 Highly Reactive Metakaolin	2-38
References	2-42
3 Chemical Admixtures <i>David P. Whitney</i>	3-1
3.1 Introduction to Chemical Admixtures.....	3-1
3.2 Retarding Admixtures.....	3-2
3.3 Water-Reducing Admixtures.....	3-3
3.4 High-Range, Water-Reducing Admixtures.....	3-5
3.5 Accelerating Admixtures.....	3-7
3.6 Air-Entraining Admixtures	3-10
3.7 Antifreezing Admixtures	3-12
3.8 Antiwashout Admixtures.....	3-13
3.9 Shrinkage-Reducing Admixtures	3-14
3.10 Polymer Modifier Admixtures	3-14
3.11 Alkali-Silica Reaction Prevention Admixtures	3-18
3.12 Conclusion	3-18
References	3-18
4 Long-Term Effects and Serviceability <i>Edward G. Nawy and Hani Nassif</i>	4-1
4.1 Creep and Shrinkage Deformations in Concrete.....	4-1
4.2 Creep Deformations in Concrete	4-2
4.3 Creep Prediction	4-6
4.4 Shrinkage in Concrete	4-10
4.5 Strength and Elastic Properties of Concrete vs. Time	4-16
4.6 Serviceability Long-Term Considerations.....	4-18

4.7	Long-Term Shrinkage and Temperature Reinforcement Controlling Cracking between Joints in Walls and Slabs of Liquid-Retaining Structures	4-34
4.8	Autogenous Shrinkage in Early-Age Concrete	4-35
	Acknowledgments	4-35
	References	4-37
5	Properties and Performance of Normal-Strength and High-Strength Concrete <i>Steven H. Kosmatka</i>	5-1
5.1	Introduction	5-2
5.2	Workability, Bleeding, and Consolidation	5-2
5.3	Mixing, Transporting, and Placing Concrete.....	5-6
5.4	Permeability.....	5-10
5.5	Carbonation	5-10
5.6	Early-Age Characteristics and Strength.....	5-12
5.7	Density.....	5-16
5.8	Abrasion Resistance	5-17
5.9	Volume Change and Crack Control.....	5-20
5.10	Deformation and Creep	5-21
5.11	Concrete Ingredients	5-22
5.12	Proportioning of Concrete Mixtures.....	5-31
5.13	Hot and Cold Weather Concreting	5-32
5.14	Control Tests	5-33
5.15	Freeze–Thaw and Deicer Scaling Resistance.....	5-34
5.16	Sulfate-Resistant Concrete.....	5-35
5.17	Corrosion Protection.....	5-37
5.18	Alkali–Silica Reaction	5-39
5.19	Heat-Induced Delayed Expansion	5-42
5.20	Self-Consolidating Concrete	5-43
5.21	Related ASTM Standards.....	5-43
	References	5-44
6	Design and Placement of Concrete Mixtures	6-1
	Part A. Design of Concrete Mixtures <i>Edward G. Nawy</i>	6-2
6.1	General.....	6-2
6.2	Selection of Constituent Materials.....	6-2
6.3	Mixture Proportioning for High-Performance, Normal-Strength Concrete (Cylinder Compressive Strength Limit 6000 psi).....	6-9
6.4	Mixture Proportioning for High-Performance, High-Strength Concrete (Cylinder Compressive Strength Exceeding 6000 psi).....	6-18
	Part B. Applications and Constructability <i>Jaime Moreno and John Albinger</i>	6-30
6.5	Applications and Constructability with an Emphasis on High-Strength, High-Performance Concrete	6-30
6.6	Job-Site Control.....	6-41
6.7	Testing.....	6-41
	Acknowledgments	6-43
	References	6-43
7	Design and Construction of Concrete Formwork <i>David W. Johnston</i>	7-1
7.1	Introduction	7-2
7.2	Types of Formwork.....	7-5
7.3	Formwork Standards and Recommended Practices.....	7-17
7.4	Loads and Pressures on Formwork	7-23
7.5	Formwork Design Criteria	7-27
7.6	Formwork Design	7-35
7.7	Slab-Form Design Example	7-38
7.8	Wall-Form Design Example.....	7-43

Preface

A great need has existed for an in-depth handbook on concrete construction engineering and technology that can assist the constructor in making correct technical judgments in the various areas of constructed systems. This *Handbook* is intended to fill this very need. This edition is completely updated and includes ten new chapters written by leading experts on various topics dealing with the state of the art in several newly developed areas of concrete construction and design engineering. All chapters treat their particular subjects with extensive detail and depth of discussion, a feature that is lacking in any comparable texts. Also, each chapter provides selected references for the user to consult for further research beyond the scope of the *Handbook*. The topics covered here are state-of-the-art statements regarding what the design engineer and the constructor should know about concrete, the most versatile material of the 21st century. These topics can be grouped into five categories:

1. *Latest advances in engineered concrete materials*, including concrete constituents, high-performance concretes, the design of mixtures for both normal- and high-strength concretes, and special concrete applications such as architectural concrete
2. *Reinforced concrete construction*, including recommendations on the vast array of types of constructed facilities, long-term effects on behavior and performance such as creep and shrinkage, construction loading effects, formwork and falsework proportioning, and automation in construction
3. *Specialized construction*, such as prestressed concrete construction in buildings and transportation facilities; construction and proportioning of structures in seismic zones (including the latest provisions of the 2006 International Building Code on the design of structures in high-seismicity zones); masonry construction; heavy concrete construction, such as roller-compacted concrete; and concrete marine structures, such as offshore platforms concrete
4. *Design recommendations for high performance*, including deflection reduction in buildings, proportioning of concrete structural elements by the latest ACI 318-08 Building Code, prefabricated precasting, geotechnical and foundation engineering, nondestructive evaluation of long-term structural performance, and structural concrete repair, retrofit, and rehabilitation
5. *Specialized topics on new materials*, such as engineered concrete composites, geopolymer concrete, equipment for concrete building construction, joints in concrete structures, design of precast seismic bracing systems, detailed design of fiber-reinforced polymers (FRP), and aesthetics in long-span bridge construction

The 37 contributors to this new edition of the *Handbook* are leading authorities in the field, with a combined professional practice of at least 1200 years. All of them are national or international leaders in research, design, and construction. This *Handbook* is the only publication in this category that has in a single chapter a summary of all concrete design expressions in accordance with the latest ACI 318-08 Building Code for flexure, shear, torsion, strut-and-tie design of corbels and deep beams, compression, long-term effects, slender columns, and development of reinforcement. Both PI (in.-lb) and SI formats are provided. A design office will be able to quickly review all of the latest requirements for structural concrete. This *Handbook* should enable designers, constructors, educators, and field personnel to produce the best and most durably engineered constructed facilities. It is for these professionals that this *Handbook* was written in the hope that the wealth of the most up-to-date knowledge embodied in this comprehensive work will provide, in this dynamic century, vastly better, more efficient, and longer enduring constructed concrete.

Acknowledgments

I consider myself lucky to have had the chance to work with such outstanding world-class experts in developing this *Handbook*. My gratitude and thanks are extended to all of the authors, who, busy as they are, have shared their vast experience gained from extensive years of engineering and construction practice at the highest levels. Acknowledgment and thanks are due to the American Concrete Institute for permitting unrestricted use by the various authors of its vast technical resources of publications and to Prentice Hall/Pearson Education (Addison Wesley Longman) for permitting me to use material originally published in my three textbooks with them. Thanks are also due to Linda Figg for her input to the handsome jacket of the *Handbook* and to Christy Gray, of her staff, for developing its several versions.

Deep appreciation and gratitude are extended to the staff at Taylor & Francis for the hard work required to bring to fruition this second edition of such a major text: Nora Konopka, Publisher, who has always been considerate, decisive, and supportive throughout the lengthy development of this edition of the *Handbook* and the previous edition; Joseph Clements, Acquisitions Editor, for his valuable input and cooperation; Theresa Delforn, Production Manager, for her initial work on the manuscript; Jill Jurgensen, Production Coordinator, for her critical input; and Christine Andreasen, Project Editor, for keeping the production process on track. Thank you, too, to the compositor, Sarah Nicely Fortener, Nicely Creative Services.

Last, but not least, acknowledgment is due to my wife, Rachel, who has had enduring patience and given unlimited support while I was totally immersed in the development of the *Handbook*.

Edward G. Nawy

Piscataway, New Jersey

Editor-in-Chief

Edward G. Nawy, distinguished professor, Department of Civil and Environmental Engineering, Rutgers, the State University of New Jersey, is internationally recognized for his extensive research work in the fields of reinforced and prestressed concrete, particularly in the areas of serviceability and crack control. He has practiced civil and structural engineering in excess of 50 years and has been on the faculty of Rutgers University almost as long, having served as chairman and graduate director for two terms. He also served two terms on the Board of Governors and one term on the Board of Trustees of the University.

His work has been published in technical journals worldwide and includes over 180 technical papers. He has been a keynote speaker for several international technical conferences and has been the editor of several Special Publication volumes of the American Concrete Institute since 1972. He is the author of several textbooks, including *Simplified Reinforced Concrete*, *Reinforced*

Concrete: A Fundamental Approach, and *Prestressed Concrete: A Fundamental Approach*, all published by Prentice Hall and which have been translated into Spanish, Chinese, South Korean, and Malaysian. He is also the author of *Fundamentals of High-Performance Concrete* (John Wiley & Sons) and has contributed chapters to several handbooks, including the *Handbook of Structural Concrete* (McGraw-Hill) and the *Engineering Handbook* (CRC Press).

Dr. Nawy is an honorary member (formerly Charter Fellow, 1972) of the American Concrete Institute, Fellow of the American Society of Civil Engineers, Fellow of the Institution of Civil Engineers (London), and a member of the Precast/Prestressed Concrete Institute. He has chaired several committees of the American Concrete Institute, including ACI Committee 224 on Cracking and ACI Committee 435 on Deflection of Structures. He is also a member of the ACI–ASCE Joint Committee on Slabs; ACI Committee 340 on the *Strength Design Handbook*, for which he served as the chairman of its Subcommittee on Two-Way Slabs and Plates; and the Technical Activities Committee of the Precast/Prestressed Concrete Institute.

Major awards he has received include the Henry L. Kennedy Award and the Design Practice Award of the American Concrete Institute, as well as Honorary Professorship of the Nanjing Institute of Technology, Nanjing, China. He is a licensed professional engineer in the states of New York, New Jersey, Pennsylvania, California, and Florida; a chartered civil engineer in the United Kingdom and the Commonwealth; a program evaluator for the National Accreditation Board for Engineering and Technology (ABET); a panelist for the National Science Foundation, Washington, D.C.; a university representative to the Transportation Research Board, Washington, D.C.; and a former chairman and subsequently Emeritus Honor member of the TRB Committee on Concrete Materials, National Research Council. He has been an engineering consultant to agencies throughout the United States, particularly in areas of structures and materials forensic engineering. He has been listed in *Who's Who in America* since 1967, in *Who's Who in Engineering*, and in *Who's Who in the World*, as well as in several other major standard reference works.

1.1 Introduction

Portland cement concrete is a composite material made by combining cement, supplementary cementing materials, aggregates, water, and chemical admixtures in suitable proportions and allowing the resulting mixture to set and harden over time. Because hardened concrete is a relatively brittle material with a low tensile strength, steel reinforcing bars and sometimes discontinuous fibers are used in structural concrete to provide some tensile load-bearing capacity and to increase the toughness of the material. In this chapter, we deal with some of the basic constituents: cements, aggregates, water, steel reinforcement, and fiber reinforcement. Chemical admixtures and supplementary cementing materials (often referred to as mineral admixtures) are covered in Chapter 2. It must be emphasized that choosing the appropriate

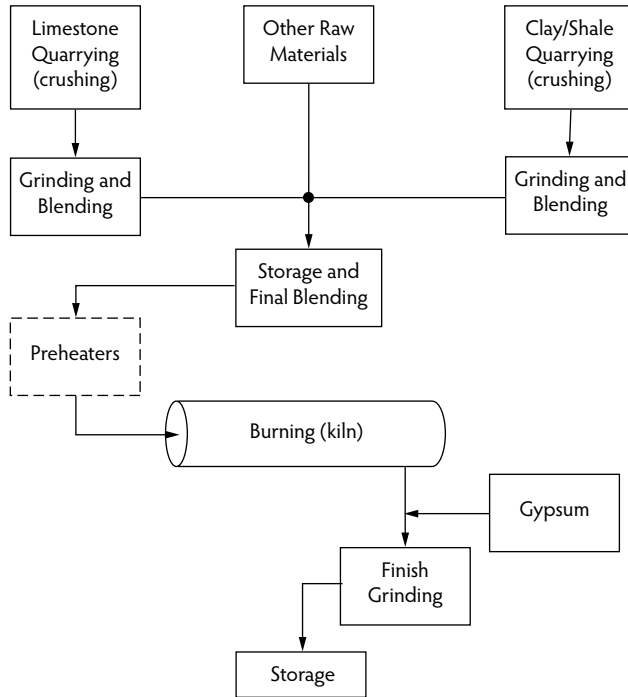

FIGURE 1.1 Schematic outline of Portland cement production.

constituent materials for a particular concrete is a necessary, but not sufficient, condition for the production of high-quality concrete. The materials must be proportioned correctly, and the concrete must then be mixed, placed, and cured properly (Chapter 6). In addition, there must be careful quality control of every part of the concrete-making process. This requires full cooperation among the materials or ready-mixed-concrete supplier, the engineer, and the contractor.

1.2 Portland Cement

Portland cement is by far the most important member of the family of **hydraulic cements**—that is, cements that harden through chemical interaction with water. The first patent for “Portland” cement was taken out in England in 1824 by Joseph Aspdin, though it was probably not a true Portland cement; the first true Portland cements were produced about 20 years later. Since then, many improvements have been made to cement production, leading to the sophisticated, though common, cements that are now so widely available.

1.2.1 Manufacture of Portland Cement

The manufacture of Portland cement is, in principle, a simple process that relies on the use of inexpensive and abundant raw materials. In short, an intimate mixture of limestone (CaCO_3) and clay or silt (iron-bearing aluminosilicates), to which a small amount of iron oxide (Fe_2O_3) and sometimes quartz (SiO_2) is added, is heated in a kiln to a temperature of between 1400 and 1600°C; in this temperature range, the materials react chemically to form calcium silicates, calcium aluminates, and calcium aluminoferrites. The cement production process is shown in Figure 1.1. The raw materials, which are ground to a fineness of less than about 75 μm , are introduced at the top end of an inclined rotary kiln, as shown in Figure 1.2. The kiln is heated by fuel (natural gas, oil, or pulverized coal) that is injected and burned at the lower end of the kiln, with the hot gases passing up through the kiln. Thus, in a period ranging from

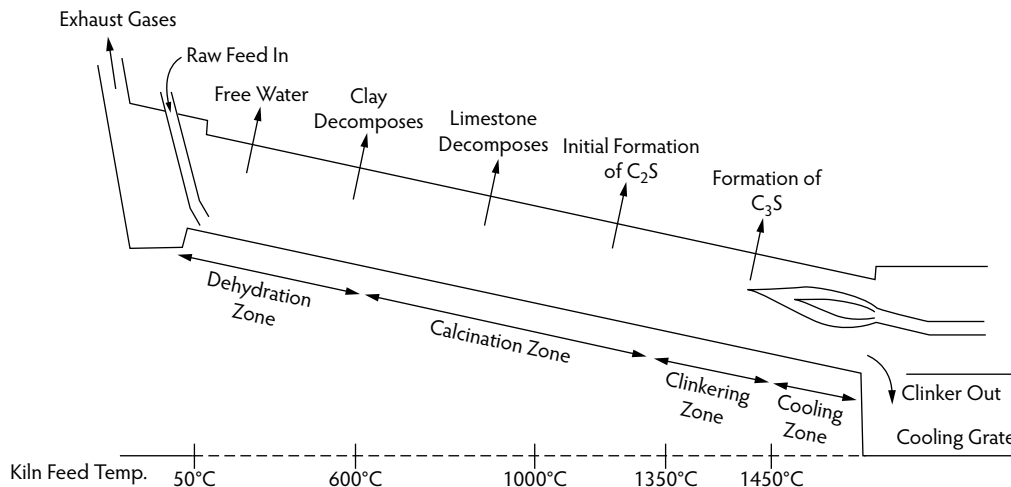

FIGURE 1.2 Schematic outline of reactions in a typical dry-process rotary cement kiln.

about 20 minutes to 2.5 hours, depending on the kiln design, the raw ingredients are subjected to increasingly higher temperatures as they pass through the kiln, and a complex series of chemical reactions takes place. The high-temperature reactions for the formation of cement clinker have been described as follows (Bentur, 2002):

- Decomposition of the clay minerals (~ 500 to 800°C)
- Decomposition of the calcite (~ 700 to 900°C)
- Reactions of the calcite (or lime formed from it), SiO_2 , and the decomposed clays to form $2\text{CaO}\cdot\text{SiO}_2$ (~ 1000 to 1300°C)
- Clinkering reactions at about 1300 to 1450°C to form $3\text{CaO}\cdot\text{SiO}_2$ —a melt of aluminate and ferrite is formed to act as a flux to facilitate the formation of $3\text{CaO}\cdot\text{SiO}_2$ by the reaction between CaO and $2\text{CaO}\cdot\text{SiO}_2$
- Cooling back to ambient temperature, during which time the melt crystallizes to form the ferrite and aluminate phases

As the charge in the kiln moves through the final few feet, its temperature drops rapidly, and it emerges from the kiln as clinker, dark colored nodules about 6 to 50 mm in diameter. This is then cooled and is finally interground with gypsum ($\text{CaSO}_4\cdot 2\text{H}_2\text{O}$), to a particle size of about $10\ \mu\text{m}$ or less. The gypsum is added to control the early hydration reactions of the cement. The ternary phase diagram of the $\text{CaO}\text{--}\text{Al}_2\text{O}_3\text{--}\text{SiO}_2$ system is shown in Figure 1.3 (Bentur, 2002). It may be seen that Portland cement (and, indeed, all other cementitious materials in this system) may have a considerable range of chemical compositions.

The above description of the production of Portland cement represents a considerable simplification of what really occurs, in that it overlooks several important factors:

- Because of the nature of the raw materials, about 5 to 8% impurities are present in the clinker, the exact type and amount of which depend on the particular raw material sources. These impurities include sodium and potassium oxides (from the clay), sulfates (from the fuel), magnesium (from the limestone), manganese, iron, potassium, titanium, and perhaps others as well.
- The mineral phases formed are not pure but are doped with various other ions, depending on the exact chemistry of the raw feed.
- The different mineral phases are not in the form of separate grains; each cement particle generally contains several phases.

FIGURE 1.3 Ternary phase diagram of the CaO–Al₂O₃–SiO₂ system. (Adapted from Bentur, A., *J. Mater. Civ. Eng.*, 14(1), 2–22, 2002.)

The precise details of the chemistry of cement are not particularly important for ordinary concretes, whose properties (in both the fresh and hardened states) can be predicted reasonably well based on the aggregate grading, the cement content, and the water/cement (w/c) ratio. This permits us to design normal concrete mixes with little regard to the source and composition of the particular cement being used; however, for high-performance concretes, these details can be of vital importance, as such concretes will invariably contain both mineral and chemical admixtures and in particular superplasticizers (also known as high-range water reducers). The behavior and durability of these much more complex mixtures can be greatly affected by the minor components of the cement and by the cement mineralogy and composition. The problems of cement–superplasticizer incompatibility and other adverse admixture interactions can create difficulties in finding satisfactory mix designs for concretes for some special applications.

The chemical composition of Portland cement is customarily reported in terms of the **oxides** of the various elements that are present, using the shorthand notation given in Table 1.1. Using this notation, the typical compound composition of ordinary Portland cement may be given as shown in Table 1.2. The characteristics of these compounds when cement is hydrated are indicated in Table 1.3. It can be seen that the two calcium silicates are primarily responsible for the strength that the cement will develop upon hydration. The C₃A can lead to durability problems when the concrete is in contact with soils or groundwater containing sulfates. By making relatively small changes in the relative proportions of raw materials, one can bring about relatively large changes in the relative proportions of the principal compounds of Portland cement. In North America, this has led to the specification of five types of Portland cement, as indicated in Table 1.4. It is thus possible, to a considerable degree, to tailor cements for particular applications, as long as the quantities required are sufficiently large to be economically feasible. For example, special cements have been formulated for very high-strength concretes and for particular durability considerations.

TABLE 1.1 Shorthand Notation for the Oxides in Portland Cement

Oxide	Shorthand Notation	Common Name	Typical Weight Percent in Ordinary Cement
CaO	C	Lime	63
SiO ₂	S	Silica	22
Al ₂ O ₃	A	Alumina	6
Fe ₂ O ₃	F	Ferric oxide	2.5
MgO	M	Magnesia	2.5
K ₂ O	K	Alkalis	0.6
Na ₂ O	N		0.4
SO ₃	\bar{S}	Sulfur trioxide	2.0
CO ₂	\bar{C}	Carbon dioxide	—
H ₂ O	H	Water	—

TABLE 1.2 Typical Compound Composition of Ordinary Portland Cement

Chemical Formula	Shorthand Notation	Chemical Name	Weight Percent
3CaO·SiO ₂	C ₃ S	Tricalcium silicate	50
2CaO·SiO ₂	C ₂ S	Dicalcium silicate	25
3CaO·Al ₂ O ₃	C ₃ A	Tricalcium aluminate	12
4CaO·Al ₂ O ₃ ·Fe ₂ O ₃	C ₄ AF	Tetracalcium aluminoferrite	8
CaSO ₄ ·2H ₂ O	C \bar{S} H ₂	Calcium sulfate dihydrate (gypsum)	3.5

TABLE 1.3 Contribution of Cement Compounds to the Hydration of Portland Cement

Compound	Reaction Rate	Heat Liberated	Contribution to Strength
C ₃ S	Moderate	High	High
C ₂ S	Slow	Low	Low initially; high later
C ₃ A + C \bar{S} H ₂	Fast	Very high	Low
C ₄ AF + C \bar{S} H ₂	Moderate	Moderate	Low

TABLE 1.4 Approximate Chemical Compositions of the Principal Types of Portland Cement

ASTM Designation	Common Name	Percent by Weight					Fineness ^a
		C ₃ S	C ₂ S	C ₃ A	C ₄ AF	C \bar{S} H ₂	
Type I	Ordinary	50	25	12	8	5	350
Type II	Modified	45	30	7	12	5	350
Type III	High early strength	60	15	10	8	5	450
Type IV ^b	Low heat	25	50	5	12	4	300
Type V	Sulfate resistant	40	40	4	10	4	350

^a Blaine fineness (m²/kg).

^b Now rarely produced; replaced with blends of Portland cement and fly ash.

The hydration reactions of Portland cement do not involve the complete dissolution of the cement grains; rather, the reactions take place between water and the exposed surfaces of the cement particles. As a result, the fineness of the cement will have a considerable effect on its rate of reaction, as this will determine the surface area exposed to water. Clearly, more finely ground cements will hydrate more rapidly, but they give rise to higher rates of heat liberation during hydration, the consequences of which are discussed later.

1.2.2 Hydration of Portland Cement

The hydration reactions that take place between finely ground Portland cement and water are highly complex, because the individual cement grains vary in size and composition. As a consequence, the resulting hydration products are also not uniform; their chemical composition and microstructural characteristics vary not only with time but also with their location within the concrete. The basic characteristics of the hydration of Portland cement may be described as follows:

- As long as the individual cement grains remain separated from each other by water, the cement paste remains fluid.
- The products of the hydration reactions occupy a greater volume than that occupied by the original cement grains.
- As the hydration products begin to intergrow, setting occurs.
- As the hydration reactions continue, additional bonds are formed between the cement grains, leading to strengthening of the system.

1.2.2.1 Chemistry of Hydration

The principal products of the hydration reactions, which are primarily responsible for the strength of concrete, are the calcium silicate hydrates that make up most of the hydrated cement. They are formed from the reactions between the two calcium silicates and water. Using the shorthand notation of Tables 1.1 and 1.2, these reactions may be written as:

In reality, calcium silicate hydrate is a largely amorphous material that does not have the precise composition indicated in Equation 1.1. It is thus more often referred to merely as C–S–H so no specific formula is implied. The reactions of Equation 1.1 are highly exothermic. These reactions, and the others described below, occur first on the surfaces of the finely divided cement; as the surface layers react, water must diffuse through the hydration products to reach still unhydrated material for the reactions to proceed. The reactions will continue, at an ever-decreasing rate, until either all of the water available for hydration is used up or all of the space available for the hydration products is filled.

In the absence of the gypsum that is interground with the Portland cement clinker, the C_3A would react very rapidly with the water, leading to early setting (within a very few minutes) of the cement, which, of course, is highly undesirable. In the presence of gypsum, however, a layer of **ettringite** forms on the surface of the C_3A particles which slows down the subsequent hydration:

As the gypsum becomes depleted by this reaction, the ettringite and the C_3A react further:

The monosulfoaluminate is thus the stable phase in concrete.

The ferrite phase is much less reactive than the C_3A , so it does not combine with much of the gypsum. Its reaction may be written as:

FIGURE 1.4 Compressive strength development of the pure cement compounds.

(A, F) means that A and F occur interchangeably in the so-called hexagonal hydrates, but the ratio A/F need not be the same as that in the parent compounds. These hydrates derive their name from the fact that they tend to occur in thin, hexagonal plates. The tetracalcium aluminate hydrate is structurally related to monosulfoaluminate; the ferric–alumina hydroxide is amorphous.

It must be emphasized again that the chemical formulae presented in Equations 1.1 to 1.4 are only approximate. There may be as much as 5% of various other impurities in the raw materials used to make cement (K_2O , Na_2O , MgO , etc.), and these atoms also find their way into the structure of the hydration compounds, so the pure phases represented above are rarely found in that form. In general, this has little effect on the mechanical properties of hardened cement or concrete; however, the impurities may have a considerable effect on the durability of the concrete and on interactions between the cement and modern chemical admixtures.

1.2.2.2 Development of Hydration Products

The hydration reactions described above occur at quite different rates, so the rates of strength development and the final strengths achieved by the various hydration products vary widely (Figure 1.4). Most of the strength comes from the hydration of the calcium silicates. The C_3S hydrates more rapidly than the C_2S and so is responsible for most of the early strength gain. The aluminate and ferrite phases hydrate quickly but contribute little to strength. The course of the hydration of Portland cement is best described by reference to Figure 1.5, in which the hydration process is divided into five stages on the basis of the amount of heat being liberated. The first stage lasts only a few minutes; the heat liberated is due mostly to the wetting and early dissolution of the cement grains. In the second, or induction stage, which may last for several hours, there is very little hydration activity, and the cement paste remains fluid. The beginning of the hydration of C_3S marks the start of the third stage, during which both initial set and final set occur, due to the production of the hydration products and the development of a solid microstructural skeleton. Stage four is marked by the hydration of the C_3A after depletion of the gypsum. Finally, in stage five, the rate of reaction slows as long as water is present, and the skeleton developed in stage three is filled in and densified by additional hydration products.

FIGURE 1.5 Rate of heat evolution during the hydration of Portland cement.

1.2.2.3 Mechanical Properties of Hydration Products

What determines the mechanical properties of the hardened cement is not so much the chemical details of the hydration reactions but the physical microstructure that is developed as a result of these reactions. As a continuous matrix of C–S–H is formed, the porosity of the system is reduced, and it is this reduction in porosity that is largely responsible for the gain in strength with an increasing degree of hydration. Of course, in addition to the C–S–H, the hardened matrix also contains the still unhydrated residues of the cement grains, relatively large crystals of calcium hydroxide, and monosulfoaluminate crystallites, but the latter two are more important for durability than for strength considerations. Here, we focus on the resultant porosity of the system. Pores may exist in hydrated Portland cement over a wide range of sizes. They may generally be classified into the following size ranges:

Micropores, which are <2.5 nm

Mesopores, which are 2.5 to 100 nm (0.1 μm)

Macropores, which are >100 nm

If, however, we adopt the simplified model of pore structure first suggested by Powers (1958), it is possible to relate the strength of the hardened paste to its porosity. Powers subdivided pores into two types. Gel pores, with a diameter of <10 nm, are an intrinsic part of the microstructure of the hardened paste, whereas capillary pores, >10 nm in diameter, represent the spaces in the hardened paste that were originally filled with mixing water and have not been completely filled by the various hydration products. The larger the amount of mixing water used, therefore, the greater the volume of capillary pores; the volume of gel pores is largely independent of the amount of mixing water. It is possible to calculate the volume fraction of the pores and the solid fraction in terms of two parameters: the original water/cement (w/c) ratio and the degree of hydration (α), which is the fraction of cement that is hydrated and ranges from 0 to 1. The following equations were originally determined empirically by Powers and are still often used:

$$\text{Volume of total hydration products} = 0.68\alpha \text{ cm}^3/\text{g of original cement (including gel pores)} \quad (1.5)$$

$$\text{Volume of unhydrated cement} = 0.32(1-\alpha) \text{ cm}^3/\text{g of original cement} \quad (1.6)$$

$$\text{Volume of capillary pores} = [w/c - 0.36\alpha] \text{ cm}^3/\text{g of original cement} \quad (1.7)$$

$$\text{Volume of gel pores} = 0.16\alpha \text{ cm}^3/\text{g of original cement} \quad (1.8)$$

$$\text{Capillary porosity (relative volume of capillary pores)} = \frac{w/c - 0.36\alpha}{w/c + 0.32} \quad (1.9)$$

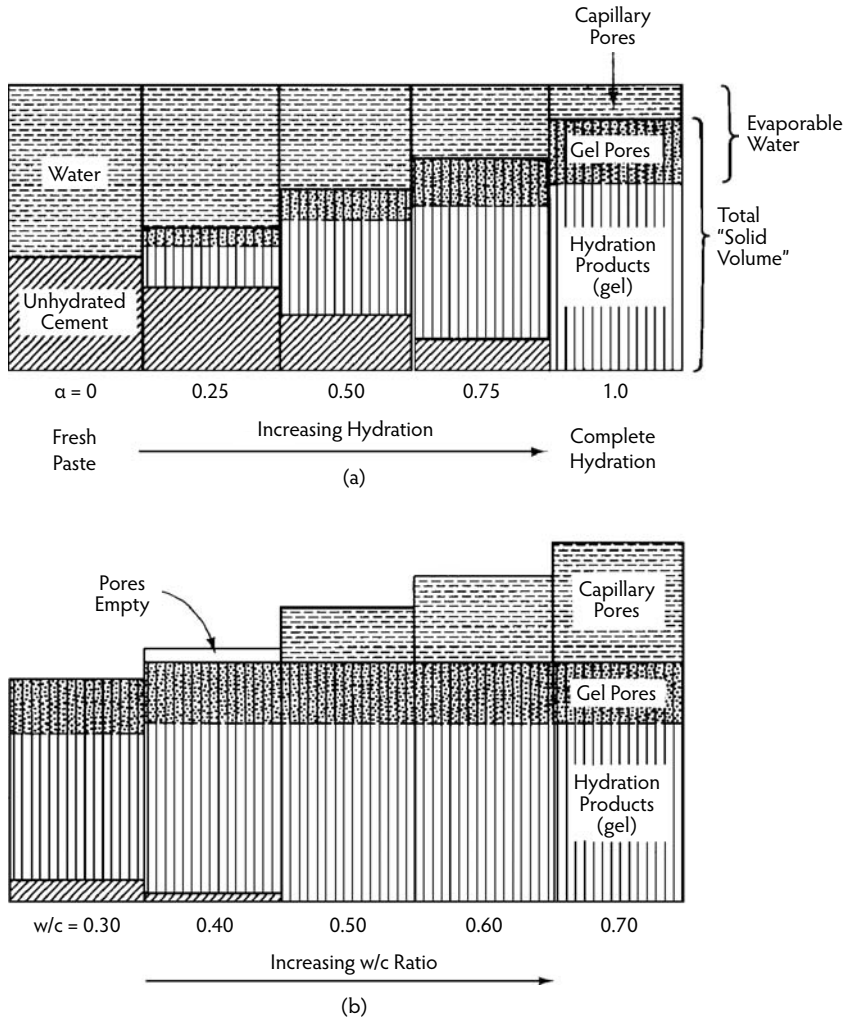

FIGURE 1.6 Volume relationships among the hydration products of hydrating Portland cement pastes: (a) constant w/c ratio = 0.50; (b) increasing w/c ratio ($\alpha = 1.0$).

These volume relationships can be seen more clearly in Figure 1.6, in terms of the degree of hydration and w/c ratio. From the above, it may be seen that the w/c ratio essentially controls the capillary porosity, which in turn controls the permeability and strength of the hardened paste. This is the basis of the w/c ratio law on which most mix design procedures are based. To produce high-strength, low-permeability concretes, it is thus necessary to use a low w/c ratio and to ensure a high degree of hydration by following proper curing procedures.

1.3 Modified Portland Cements

Increasingly, modern concretes contain a blend of Portland cement and other cementitious materials. When other materials are added to Portland cement at the time at which the concrete is batched, they are referred to as **mineral admixtures**, which are described in detail in Chapter 2; however, there are also *hydraulic cements*, which are produced either by forming other compounds during the burning process or by adding other materials to the clinker and then intergrinding them. The common types of such modified cements are described in the following sections.

1.3.1 Portland Pozzolan Cements

Portland pozzolan cements are blends of Portland cement and a pozzolanic material (see Chapter 2). The role of the pozzolan is to react slowly with the calcium hydroxide that is liberated during cement hydration. This tends to reduce the heat of hydration and the early strength but can increase the ultimate strength of the material. These cements tend to be more resistant to sulfate attack and to the alkali–aggregate reaction.

1.3.2 Portland Blast-Furnace Slag Cements

Ground granulated blast-furnace slag (GGBFS), which is a byproduct of the iron and steel industry, is composed largely of lime, silica, and alumina and thus is a potentially cementitious material. To hydrate it, however, it must be activated by the addition of other compounds. When the GGBFS is to be activated by lime, the lime is most easily supplied by the hydration of the Portland cement itself. Slags may be present in proportions ranging from 25 to 90%. They react slowly to form C–S–H, which is the same product that results from the hydration of the calcium silicates. In general, because they react more slowly than Portland cement, slag cements have both lower heats of hydration and lower rates of strength gain. On the other hand, they have an enhanced resistance to sulfate attack. When the GGBFS is to be activated with calcium sulfate (CaSO_4), together with a small amount of lime or Portland cement, the material is known as **supersulfated cement**. This cement is available mostly in Europe, where it is used for its lower heat of hydration and its resistance to sulfate attack.

1.3.3 Expansive Cements

Expansive cements were developed to try to offset the drying shrinkage that concrete undergoes. This is particularly important when the concrete is restrained against contraction or when it is to be cast against mature concrete in repair situations. In both cases, severe cracking may occur as a result of the shrinkage. Expansive cements are based on the formation of large quantities of ettringite during the first few days of hydration; however, they are little used today, in large part because it is very difficult to control (or predict) the amount of expansion that will take place for a particular concrete formulation.

1.4 High-Alumina Cement

A number of non-Portland inorganic cements are available, but by far the most important is high-alumina cement (also known as calcium–aluminate cement). It was developed originally for its sulfate-resistant properties but was subsequently used structurally because of its high rate of strength gain. Its use has been limited by structural problems due to the loss of strength that can occur in certain circumstances, which has led to several disastrous structural collapses. High-alumina cement (HAC) is about 60% CA, 10% C_2S , and 5 to 20% C_2AS (gehlenite), with 10 to 25% various minor constituents. When this material hydrates, much depends on the temperature:

These reactions take place rapidly, so HAC reaches about 75% of its ultimate strength in one day. Unfortunately, C_2AH_8 and CAH_{10} are transformed to C_3AH_6 at temperatures above 30°C , particularly in moist conditions. This leads to a considerable loss in strength, because C_3AH_6 has a smaller solid volume

TABLE 1.5 Comparison of Mix Proportions for 25-MPa Concrete

Component	Conventional Concrete		HVFA Concrete	
	By Mass (kg/m ³)	By Volume (m ³)	By Mass (kg/m ³)	By Volume (m ³)
Cement	307	0.097	154	0.049
Fly ash	—	—	154	0.063
Water	178	0.178	120	0.120
Entrapped air (2%)	—	0.020	—	0.020
Coarse aggregate	1040	0.387	1210	0.449
Fine aggregate	825	0.318	775	0.299
Total	2350	1.000	2413	1.000

Source: Adapted from Mehta, P.K., *Concrete Int.*, 24(7), 23–28, 2002.

than the other two calcium aluminate hydrates, causing a large increase in porosity. This loss in strength can be minimized if a low w/c ratio (<0.40) is used, but because of difficulties in predicting or controlling strength loss HAC is now not used structurally. Rather, it is used primarily for refractory purposes because of its good high-temperature properties.

1.5 “Green” Cements

The concrete industry is the largest user of natural resources in the world and thus has a considerable environmental impact. Each ton of Portland cement requires about 1.5 tons of raw material for its production. This industry is not only energy intensive but is also a major contributor of greenhouse gases, in the form of CO₂. Each ton of Portland cement that is produced involves the release into the atmosphere of about one ton of CO₂. Indeed, according to Mehta (1999), the cement industry is responsible for about 7% of global CO₂ emissions; thus, there is considerable interest now in developing cements that are more environmentally friendly. One such cement (CEMROC), based on blast-furnace slag, has recently been described by Gebauer et al. (2005). This cement, produced by Holcim in Europe, is reported to show close to zero CO₂ emission during its production (only about 100 pounds per ton of cement). It is similar to the supersulfated cement described above and is particularly well suited for use in structures exposed to aggressive environments. Other cements of this general type will almost certainly be developed in the future. Another (and simpler) approach is to use much greater proportions of fly ash in concrete. A great deal of development is being conducted on what is referred to as *high-performance, high-volume fly ash concrete* (Malhotra, 2002; Malhotra and Mehta, 2002). Such concretes may be defined as:

- Containing at least 50% fly ash by mass of the cementing materials
- Having a Portland cement content of less than 200 kg/m³
- Having a water content of less than 130 kg/m³
- Having a water/cementing materials ratio of less than 0.35

These concretes reach their full strength potential rather more slowly than conventional concretes, but the end result is a low-permeability, durable concrete. A comparison of the mix proportions for conventional and high-volume fly ash concretes is given in Table 1.5 (Mehta, 2002).

1.6 Performance of Different Cements in Concrete

The compositions of each of the five American Society for Testing and Materials (ASTM) types of cements may vary widely from cement to cement, due to variations in locally available raw materials, kiln design, burning conditions, and so on. Their fineness may also be quite variable. As a result, their cementitious properties may also vary widely. In some regions, for example, it may not be possible to find a commercially available cement for the production of very high-strength (>100 MPa) concrete.

FIGURE 1.7 Relative compressive strengths of concretes made with different cements. (Adapted from U.S. Bureau of Reclamation, *Concrete Manual*, 8th ed., U.S. Bureau of Reclamation, Washington, D.C., 1975.)

Because most cements contain about 75% by weight of calcium silicates and undergo the same hydration reactions, though perhaps at different rates, their ultimate performances in concrete are similar, as shown in Figure 1.7. Here, the major differences are in the rate of strength gain and in the heat of hydration.

1.7 Water

Although the water itself is often not considered when dealing with materials that go into the production of concrete, it is an important ingredient. Typically, 150 to 200 kg/m³ of water is used. The old rule of thumb for water quality is “If you can drink it, you can use it in concrete,” although good-quality concrete can be made with water that is not really potable. Indeed, more bad concrete is made by using too much drinkable water than by using the right amount of undrinkable water. The tolerable limits for various common impurities in mixing water are given in Table 1.6. When in question, the suitability of the water is determined by comparing the strength of concrete made with the suspect water to the strength of concrete made with a known acceptable water.

1.8 Water/Cement Ratio

For brittle ceramic materials, including cementitious systems, the strength has been found to be inversely proportional to the porosity. Often, an exponential equation is used to relate strength to porosity; for example,

$$f_c = f_{c0}e^{-kp} \quad (1.11)$$

TABLE 1.6 Tolerable Levels of Some Impurities in Mixing Water

Impurity	Maximum Concentration (ppm)	Remarks
Suspended matter (turbidity)	2000	Silt, clay, organic matter
Algae	500–1000	Entrains air
Carbonates	1000	Decreases setting times
Bicarbonates	400–1000	400 ppm for bicarbonates of Ca or Mg
Sodium sulfate	10,000	May increase early strength but reduce later strength
Magnesium sulfate	40,000	
Sodium chloride	20,000	Decreases setting times, increases early strength,
Calcium chloride	50,000	reduces ultimate strength, and may lead to corrosion
Magnesium chloride	40,000	of reinforcing steel
Sugar	500	Affects setting behavior

where f_c is the strength, f_{c0} is the intrinsic strength at zero porosity, p is the porosity, and k is a constant that depends on the particular system. Equations such as this do not consider the pore-size distribution, the pore shape, and whether the pores are empty or filled with water; thus, they are a gross simplification of the true strength vs. porosity relationship. Nonetheless, for ordinary concretes for the same degree of cement hydration, the strength does indeed depend primarily on the porosity. Because the porosity, in turn, depends mostly on the original w/c ratio, mix proportioning for normal-strength concretes is based, to a large extent, on the w/c ratio law articulated by D.A. Abrams in 1919: “For given materials, the strength depends only on one factor—the ratio of water to cement.” This can be expressed as:

$$f_c = \frac{K_1}{K_2^{(w/c)}} \quad (1.12)$$

where K_1 and K_2 are constants, and w/c is the water/cement ratio by weight.

In fact, of course, given the variability in raw materials from concrete to concrete, the w/c ratio law is really a family of relationships for different mixtures. As stated by Gilkey (1961a):

For a given cement and acceptable aggregates, the strength that may be developed by a workable, properly placed mixture of cement, aggregate, and water (under the same mixing, curing, and testing conditions) is influenced by the: (a) ratio of cement to mixing water; (b) ratio of cement to aggregate; (c) grading, surface texture, shape, strength, and stiffness of aggregate particles; and (d) maximum size of aggregate.

Thus, in some cases, simple reliance on the w/c ratio law may lead to serious errors. It should be noted that many modern concretes contain one or more mineral admixtures that are, in themselves, cementitious to a greater or lesser degree; therefore, it is becoming more common to use the term **water/cementitious material ratio** to reflect this fact rather than the simpler water/cement ratio.

For ordinary concretes, the w/c ratio law works well for a given set of raw materials, because the aggregate strength is generally much greater than the paste strength; however, the w/c ratio law is more problematic for high-strength concretes, in which the strength-limiting factor may be the aggregate strength or the strength of the interfacial zone between the cement and the aggregate. Although it is, of course, necessary to use very low w/c ratios to achieve very high strengths, the w/c ratio vs. strength relationship is not as straightforward as it is for normal concretes. Figure 1.8 shows a variety of water/cementitious material vs. strength relationships obtained by a number of different investigators. A great deal of scatter can be seen in the results. In addition, the range of strengths for a given w/c ratio increases as the w/c ratio decreases, leading to the conclusion that, for these concretes, the w/c ratio is not by itself a very good predictor of strength; a different w/c ratio “law” must be determined for each different set of materials.

1.9 Aggregates

Aggregates make up about 75% of the volume of concrete, so their properties have a large influence on the properties of the concrete (Alexander and Mindess, 2005). Aggregates are granular materials, most commonly natural gravels and sands or crushed stone, although occasionally synthetic materials such as slags or expanded clays or shales are used. Most aggregates have specific gravities in the range of 2.6 to 2.7, although both heavyweight and lightweight aggregates are sometimes used for special concretes, as described later. The role of the aggregate is to provide much better dimensional stability and wear resistance; without aggregates, large castings of neat cement paste would essentially self-destruct upon drying. Also, because they are less expensive than Portland cement, aggregates lead to the production of more economical concretes. In general, aggregates are much stronger than the cement paste, so their exact mechanical properties are not considered to be of much importance (except for very high-strength concretes). Similarly, they are also assumed to be completely inert in a cement matrix, although this is not always true, as will be seen in the discussion on the alkali–aggregate reaction. For ordinary concretes, the most important aggregate properties are the particle grading (or particle-size distribution), shape, and porosity, as well as possible reactivity with the cement. Of course, all aggregates should be clean—that is, free of impurities such as salt, clay, dirt, or foreign matter. As a matter of convenience, aggregates are generally divided into two size ranges: **coarse aggregate**, which is the fraction of material retained on a No. 4 (4.75-mm) sieve, and **fine aggregate**, which is the fraction passing the No. 4 sieve but retained on a No. 100 (0.15-mm) sieve.

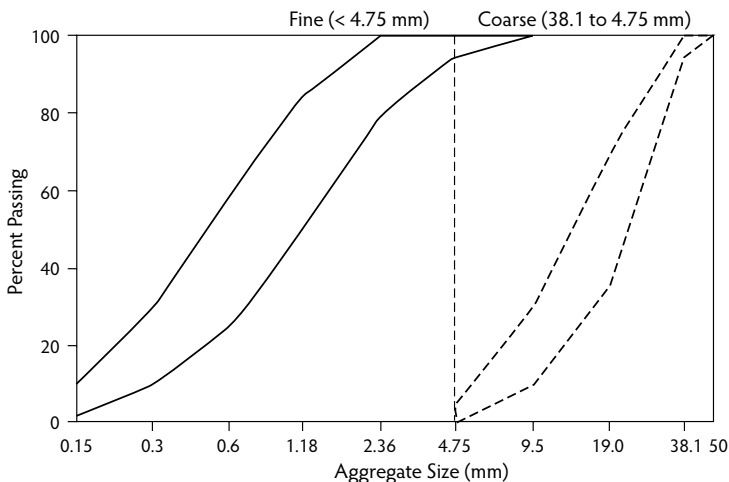

FIGURE 1.9 ASTM grading limits for fine aggregate and for coarse aggregate with a maximum particle size of 38.1 mm.

1.9.1 Particle Shape and Texture

Ideally, to minimize the amount of cement paste required to provide adequate workability of the fresh concrete, aggregate particles for ordinary concrete should be roughly equidimensional with relatively smooth surfaces, such as most natural sands and gravels. Where natural sands and gravels are unavailable, crushed stone may be used. Crushed stone tends to have a rougher surface and to be more angular in shape. As a result, it tends to require rather more cement paste for workability. Whether using natural gravels or crushed stone, however, either flat or elongated particles should be avoided, as they will lead to workability and finishing problems.

1.9.2 Particle Grading

The **particle-size distribution** in a sample of aggregate, referred to as the *grading*, is generally expressed in terms of the cumulative percentage of particles passing (or retained on) a specific series of sieves. These distributions are most commonly shown graphically as **grading curves**. Examples of such curves are given in Figure 1.9, which shows the usual North American grading limits for fine aggregate and for a particular maximum size (38.1 mm) of coarse aggregate. Such grading limits have been determined empirically. They are intended to provide a fairly dense packing of aggregate particles, again to minimize the cement paste requirement; however, no ideal aggregate grading exists that can be derived theoretically. In practice, one can provide good concrete with quite a range of aggregate gradings. Although the continuous type of grading described in Figure 1.9 is the most common, other types of grading are sometimes used for special purposes; for example, **gap grading** refers to a grading in which one or more of the intermediate size fractions is omitted. This is sometimes convenient when it is necessary to blend different aggregates to achieve a suitable grading. Such concretes are also prone to segregation of the fresh concrete. **No-fines concrete** is a special case of gap-graded concrete in which the fine aggregate (<4.75 mm) is omitted entirely to produce a porous, lighter weight concrete that, for example, may allow water to drain through it. For fine aggregates, the particle-size distribution tends to be described by a single number, the **fineness modulus (FM)**, which is defined as:

$$FM = \frac{\sum (\text{cumulative \% retained on standard sieves})}{100} \quad (1.13)$$

where the standard sieve sizes are No. 100 (0.15-mm), No. 50 (0.30-mm), No. 30 (0.60-mm), No. 16 (1.18-mm), No. 8 (2.36-mm), and No. 4 (4.75-mm). An example of the calculation of the fineness

TABLE 1.7 Calculation of Fineness Modulus

Sieve Size	Weight Retained	Weight Percent Retained	Cumulative Weight Percent Retained
#4	30	3	3
#8	100	10	13
#16	195	19.5	32.5
#30	200	20	52.5
#50	260	26	78.5
#100	215	21.5	100.0
			$\Sigma = 279.5$

Note: Sample weight 1000 g; fineness modulus (FM) = $(279.5/100) = 2.80$.

modulus is shown in Table 1.7. Normally, the FM should fall between 2.3 and 3.1 (higher values imply a coarser material). The value of the FM is required for mix design purposes. (Also see Chapter 6 of this handbook, which discusses the proportioning of concrete mixtures.)

1.9.3 Aggregate Moisture Content

Aggregates can hold water in two ways: absorbed within the aggregate porosity or held on the particle surface as a moisture film. Thus, depending on the relative humidity, recent weather conditions, and location within the aggregate stockpile, aggregate particles can have a variable moisture content. For the purposes of mix proportioning, however, it is necessary to know how much water the aggregate will absorb from the mix water or how much extra water the aggregate might contribute. Figure 1.10 illustrates four different moisture states:

- *Oven-dry (OD)*—All moisture is removed by heating the aggregates in an oven at 105°C to constant weight.
- *Air-dry (AD)*—No surface moisture is present, but the pores may be partially full.
- *Saturated surface dry (SSD)*—All pores are full, but the surface is completely dry.
- *Wet*—All pores are full, and a water film is on the surface.

Of these four states, only two (OD and SSD) correspond to well-defined moisture conditions; either one can be used as a reference point for calculating the moisture contents. In the following discussion, the SSD state will be used. Now, to determine how much water the aggregate may add to or take from the mixing water, three further quantities must be defined:

- The *absorption capacity (AC)* represents the maximum amount of water the aggregates can absorb. From Figure 1.10, this is the difference between the SSD and OD states, expressed as a percentage of the OD weight:

$$AC = \frac{W_{SSD} - W_{OD}}{W_{OD}} \times 100\% \quad (1.14)$$

where W represents weight. It should be noted that, for most common aggregates, the absorption capacities are of the order of 0.5 to 2.0%. Absorption capacities greater than 2% are often an indication that the aggregates may have potential durability problems.

- The *effective absorption (EA)* refers to the amount of water required for the aggregate to go from the AD to the SSD state:

$$EA = \frac{W_{SSD} - W_{AD}}{W_{SSD}} \times 100\% \quad (1.15)$$

FIGURE 1.10 Moisture states of aggregates.

To calculate the weight of the water absorbed (W_{abs}) by the aggregate in the concrete mix:

$$W_{abs} = (EA)W_{agg} \quad (1.16)$$

- The *surface moisture* (SM) represents water in excess of the SSD state, held on the aggregate surface:

$$SM = \frac{W_{wet} - W_{SSD}}{W_{SSD}} \times 100\% \quad (1.17)$$

Thus, the extra water added to the concrete from the wet aggregates will be:

$$W_{add} = (SM)W_{agg} \quad (1.18)$$

1.9.4 Lightweight Aggregates

Lightweight aggregates, which can be either natural or synthetic materials, are characterized by a high internal porosity. Ordinary concrete has a unit weight of about 2300 kg/m^3 , but lightweight concretes with unit weights as low as 120 kg/m^3 can be produced, although they are accompanied by a significant decrease in concrete strength. Natural lightweight aggregates include pumice, scoria, and tuff; however, most lightweight aggregates are synthetically produced. The most common such lightweight aggregates are made from expanded clay, shale, or slate. The raw material is either crushed to the desired size or ground and then pelletized; it is then heated to 1000 to 1200°C . At these temperatures, the material **bloats** (or puffs up) due to the rapid generation of gas produced by the combustion of the small amounts of organic material that these particles generally contain. (The process is similar to that of popping popcorn.) Other materials, such as volcanic glass (perlite), calcium silicate glasses (slags), or vermiculite, can similarly be bloated. Lightweight aggregates tend to be angular and irregular in shape and can be quite variable. They will also tend to have high porosities, leading to a considerable potential for absorbing water from the mix; hence, mix design with lightweight aggregates is much more of a trial-and-error procedure than with normal-weight aggregates. Lightweight concretes made with these aggregates may be classified as shown in Figure 1.11. The properties of different types of lightweight concrete are described in Table 1.8. It should be noted that, despite the high porosity and relative weakness of the aggregate, it is not a problem to reach strengths as high as 40 MPa. To do this, lower w/c ratios are required for lightweight concretes than are required for ordinary concretes of the same strength. Although a general relationship exists between strength and density of the concrete, it can be seen in Figure 1.12 that this relationship depends on the particular aggregate used.

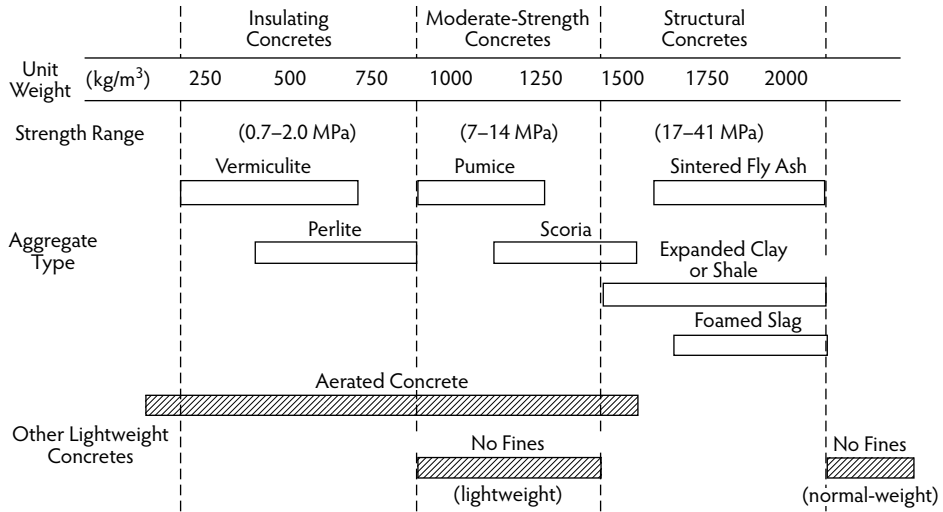

FIGURE 1.11 Classification of lightweight concretes.

TABLE 1.8 Properties of Some Lightweight Concretes

Type of Lightweight Concrete	Type of Aggregate	Aggregate Density (kg/m ³)	Concrete Density (kg/m ³)
Aerated	—	—	400–600
Partially compacted	Expanded vermiculite and perlite	5–240	400–1150
	Foamed slag	480–960	960–1500
	Sintered pulverized-fuel ash	640–960	1100–1300
	Expanded clay or shale	560–1040	950–1200
Structural lightweight aggregate concrete	Foamed slag	480–960	1650–2050
	Sintered pulverized-fuel ash	640–960	1350–1750
	Expanded clay or shale	560–1040	1350–1850

FIGURE 1.12 Average density vs. compressive strength relationships. (Adapted from Short, A. and Kinniburgh, W., *Lightweight Concrete*, 3rd ed., Applied Science Publishers, London, 1978.)

TABLE 1.9 Physical Properties of Some Heavyweight Aggregates

Material	Chemical Composition	Relative Density	Granular Bulk Density (kg/m ³)
Goethite	Fe ₂ O ₃ · H ₂ O	3.5–3.7	2100–2250
Limonite	Impure Fe ₂ O ₃	3.4–4.0	2100–2400
Barytes	BaSO ₄	4.0–4.6	2300–2550
Illmenite	FeTiO ₃	4.3–4.8	2550–2700
Magnetite	Fe ₃ O ₄	4.2–5.2	2400–3050
Hematite	Fe ₂ O ₃	4.9–5.3	2900–3200
Ferro phosphorus	Fe ₂ O ₃ · P ₂ O ₃	5.8–6.8	3200–4150
Steel	Fe (scrap iron, steel punchings)	7.8	3700–4650

1.9.5 Heavyweight Aggregates

Heavyweight aggregates are used to make heavyweight concretes, with unit weights ranging from about 2900 to 6000 kg/m³. Such concretes are used primarily for radiation shielding, but they are sometimes used to make counterweights as well. Natural heavyweight aggregates include materials such as goethite, limonite, barite, illmenite, magnetite, and hematite, with specific gravities (SGs) ranging from about 3.5 up to about 5.3, leading to concretes with unit weights up to about 4100 kg/m³. For higher unit weight concretes, synthetic materials such as ferrophosphorous (SG 5.8 to 6.8) or scrap iron and steel punchings (SG 7.8) can be used, with resulting concrete unit weights of up to 6100 kg/m³. The physical properties of some heavyweight aggregates are shown in Table 1.9. High-density aggregates are good attenuators of gamma rays and of fast neutrons, hence their use in radiation shielding. Although heavyweight concretes can be proportioned in much the same way as ordinary concretes, the aggregates tend to be harsh and have a tendency to segregate from the rest of the mix. As a result, both higher than usual cement contents and a higher ratio of fine to coarse aggregates are recommended.

1.9.6 Aggregate Durability

It is generally assumed that aggregates are inert in concrete, but this is often not true, so their durability must also be considered.

1.9.6.1 Soundness

Soundness refers to the ability of aggregates to withstand cyclic volume changes due to wetting and drying or freezing and thawing without deteriorating. Rocks that are susceptible to wetting and drying cycles are rare, so soundness generally refers to freeze–thaw resistance. Aggregates will deteriorate if high internal stresses are developed when water absorbed within the aggregate freezes. This deterioration, in turn, depends on the size, porosity, permeability, and degree of saturation of the aggregate. For most aggregates, the critical size above which unsoundness develops is greater than the maximum size normally used in concrete; however, for some sedimentary rocks (chert, graywacke, sandstone, shale, and poorly consolidated limestone), the critical size can be less than 25 mm. The most susceptible rocks are those that have a relatively high absorption (porosity), greater than 2%, combined with a very fine pore structure (low permeability) so the freezing water cannot easily be expelled from the aggregate. If aggregates are unsound, this can lead to surface pop-outs and to D-cracking in pavements and slabs.

1.9.6.2 Alkali–Aggregate Reaction

A large number of failures have resulted from expansions caused by reactions between certain types of siliceous aggregates and the alkalis (K₂O and Na₂O) contained in the cement. The types of rocks that are likely to participate in these reactions include siliceous limestones, cherts, shale, flint, volcanic glasses, opaline rocks, quartzite, sandstone, and some granites and schists. In some cases, these expansive

TABLE 1.10 The Alkali–Silica Reaction

Reaction Step	Reaction	Consequences
1	Release of alkali ions during cement hydration	Increased alkalinity of water in the pores (pore solution)
2	Initial hydrolysis of the reactive silicates in the alkaline pore solution: $K(Na)OH + SiO_2 \rightarrow K_2O(Na_2O)-SiO_2-H_2O$, amorphous alkali silicate gel	Aggregate integrity destroyed
3	Swelling of alkali silicate gel as it imbibes water	Localized cracking
4	Liquefaction of alkali silicate gel as it imbibes more moisture	Liquid gel expelled through the cracks

reactions, which are first manifested by extensive surface cracking, occur within a few years after the concrete has been cast. In other cases, however, damage may not appear until 15 to 20 years after construction.

The factors that control the rate and extent of the alkali–aggregate reaction are (1) the nature of the reactive silica, (2) the amount of reactive silica, (3) the particle size of the reactive material, (4) the amount of alkali available, and (5) the amount of available moisture. Regardless of the specifics of the cement and the aggregate, however, the alkali–silica reaction progresses through the steps indicated in Table 1.10. Step 1 is controlled by the alkali content of the cement. Any real control of the reaction potential must be taken at this step, either by avoiding reactive aggregates or by keeping the alkali content of the cement quite low ($Na_2O + 0.6K_2O \leq 0.60$). Step 2 depends on the exact form of the silica and determines the rate at which the reaction will take place. It is at Step 3 that the damage occurs as the alkali–silicate gel imbibes water and swells, cracking the matrix. Step 4 mostly produces the visible signs of the reaction. It should be noted that Steps 3 and 4 will not occur if the concrete is kept dry.

If low-alkali cements are not available in a particular region (because the raw materials used to produce the cement are themselves too high in alkali content), a useful strategy is often to replace some of the cement with a pozzolanic material (such as fly ash) that contains no alkalis at all, to reduce the total alkali content of the cementitious materials to an acceptable level. Although pozzolanic materials contain silica in a reactive form, the silica is very finely divided and reacts very quickly with the alkalis. Harmful expansions do not occur because the resulting alkali–silicate gel is distributed throughout the cementitious matrix, so the expansions are distributed. The worst case is to have relatively small volumes of reactive aggregates in large pieces scattered throughout the concrete; this localizes and concentrates the expansions, leading to severe cracking.

1.9.6.3 Alkali–Carbonate Reaction

Expansive reactions can also occur between the alkalis in the cement and certain dolomitic limestones ($MgCO_3/CaCO_3$) that contain some clay. Not all dolomitic limestones are subject to this reaction; those that are have the following features: (1) very small crystals of $MgCO_3$, (2) presence of considerable fine-grained calcite, (3) abundant interstitial clay, and (4) dolomite and calcite crystals uniformly distributed in the clay matrix. The expansive reaction is:

This reaction is still not fully understood. The alkali–carbonate reaction can also be controlled by keeping the alkali content of the cementitious material very low ($<0.40\%$). Unlike the case of the alkali–silica reaction, pozzolanic materials in this case cannot control the alkali–carbonate reaction.

1.10 Reinforcement

1.10.1 General

Plain concrete is a brittle material, with low tensile strength and strain capacities; hence, reinforcement has to be used to balance this deficiency. Main bar reinforcement is used in tensile zones to enhance the capacity of concrete elements so the structural beam or slab will be able to withstand high loads and deform adequately without brittle failure. Chapter 27 of this handbook details the ACI 318 design equations for proportioning reinforced concrete members. Another method that can increase the tensile capacity of plain concrete within a structural bar-reinforced section is the use of fiber reinforcement. The use of **fiber-reinforced concrete** (FRC) has steadily increased since the early 1960s, as has the use of **fiber-reinforced plastics** (FRPs).

1.10.2 Fiber Reinforcement

The role of the fibers is not to increase strength, although modest strength increases may occur. Rather, the role of discrete, discontinuous, randomly oriented fibers is to bridge the cracks that develop in concrete either as it is subjected to environmental changes (such as drying) or as it is loaded. If the fibers are strong enough, stiff enough, and present in sufficient quantity and develop sufficient bonds with the cementitious matrix, they will serve to keep the crack widths small and will permit the FRC to withstand significant stresses over a relatively large strain capacity in the post-cracking (or strain-softening) stage. In other words, by bridging the cracks that develop, the fibers can provide a considerable amount of post-cracking ductility. This is often referred to as **toughness**. The toughness may be defined in terms of the area under the load vs. the deflection curve. The stress is transferred from the matrix to the fibers in two ways:

- At early stages of loading, the stress is transmitted from the matrix to the fibers through an elastic shear-transfer mechanism, which, however, has only a small effect on the limit of proportionality or first-crack stress of the FRC.
- After the initial cracking, and at more advanced stages of loading, debonding along the fiber–matrix interface occurs, and frictional slip becomes the process controlling the stress transfer. The degree of frictional slip affects both the ultimate strength and strain of the FRC. At this stage, the fibers may increase the strength of the FRC by transferring loads and stresses across the cracked matrix. In addition, and more importantly, they may increase the toughness of the FRC by providing energy absorption mechanisms related to the pullout processes of the fibers. Chapter 22 of this handbook gives an in-depth treatment of this subject for both FRC and FPC concretes.

1.10.3 Steel Reinforcement

Typically, steel reinforcement used in concrete has yield strengths in the range of 275 to 550 MPa (40,000 to 80,000 psi). For all these steels, the modulus of elasticity is in the range of 200×10^6 MPa (29×10^6 psi). The bar sizes in the United States range from No. 3 to No. 18 deformed bars. In slabs, the use of welded wire fabric is more prevalent. Table 1.11 and Table 1.12 give the properties of most commonly used bars for concrete reinforcement. Table 1.13 gives standard wire fabric reinforcement for one-way and two-way slabs and plates. These tables are derived from the ASTM Standards. The bar deformations shown in Figure 1.13 are in accordance with ASTM A 616.

One of the problems resulting from permeability of concrete to moisture is the corrosion of the reinforcement. Corrosion can lead to a reduction in the effective cross-sectional area of the steel and a spalling of the concrete above the steel, both of which can lead to severe damage or even failure of a structure or structural element. The mechanisms of corrosion in steel are by now well known. An isolated steel bar will rust spontaneously (Figure 1.14) because different areas of the bar may have different

TABLE 1.11 Reinforcement Grades and Strengths

1982 Standard Type	Minimum Yield Point or Yield Strength (f_y) (psi)	Ultimate Strength (f_u) (psi)

electrochemical potentials and thus set up anode–cathode pairs, with corrosion occurring in localized anodic areas; however, steel corrosion should not occur, even in the presence of moisture and oxygen. This is because the highly alkaline concrete (pH of about 12 to 12.5) causes a passive oxide film to form on the surface of the steel, which prevents corrosion. Only when the pH falls below 11 will the passive iron oxide layer be destroyed, permitting rusting to occur. The pH may be reduced in two ways:

- The calcium hydroxide that is responsible for the high pH can be converted to calcium carbonate by atmospheric carbonation. For good concrete, the depth of carbonation rarely exceeds 25 mm, so adequate cover (25 mm to 40 mm) over the reinforcement should provide adequate protection. For high-permeability concretes or very severe exposures, a thicker cover must be used. Of course, if there are cracks in the concrete, perhaps due to drying shrinkage, CO₂ may penetrate to the steel and initiate corrosion. It has been found empirically, however, that if the crack widths at the surface of the concrete can be kept below 0.025 mm by suitable reinforcing details, then the rate of CO₂ diffusion will be slow enough to avoid extensive corrosion.
- Chloride ions have the capacity to destroy the passive oxide layer even at high pH, and relatively little chloride is required to initiate corrosion. Chloride ions may enter concrete from CaCl₂ used as an accelerating admixture, from seawater, and from the deicing salts commonly used on bridge decks and pavements. This may be particularly severe for prestressing steel, because in this case **stress corrosion** may occur. Whatever the source of the Cl⁻ ions, when a critical concentration of chlorides develops at the level of the steel (0.6 to 1.2 kg Cl⁻ per m³), corrosion will occur.

Several strategies to combat steel corrosion have been developed, but corrosion remains one of the principal concrete construction problems. The most common techniques at this time (apart from making more impermeable performance concrete) are the following:

- Suppression of electrochemical corrosion by using **cathodic protection**. In this technique, an electric current is applied to the rebars (which must be connected electrically) in the direction opposite that of the current flow in spontaneous corrosion. This makes the steel cathodic, preventing corrosion. This technique has been used successfully but is difficult to apply.
- Various corrosion-inhibiting admixtures are now available commercially that serve to maintain the passive oxide film.

TABLE 1.12A Weight, Area, and Perimeter of Individual Bars

Bar Designation Number	Weight per Foot (lb)	1982 Standard Nominal Dimensions

- Epoxy-coated rebars have become more and more common, but this technique has two problems: (1) If the bars are scratched during handling or are bent too severely, then the epoxy coating may be damaged, exposing the steel to corrosion, and (2) the epoxy-coated bars develop substantially less bond with the concrete, and if this issue is not recognized severe structural cracking can occur. New design techniques for epoxy-coated bars are now being developed that address this reduction in bond. More efficient deformation patterns are also being developed.

1.11 Durability Considerations

If concrete is properly designed for the environment to which it is to be exposed and is properly placed and cured, it should last for many decades without costly repairs. This is particularly the case for the modern generation of high-performance concretes; however, concrete is potentially vulnerable to both chemical attack and physical attack. Several of these durability problems (alkali–aggregate reaction and corrosion of reinforcing steel) have already been discussed, while freeze–thaw durability is discussed in Chapter 4 of this handbook. Here, the major consideration is primarily chemical attack.

The single parameter that has the largest influence on durability is the porosity of the concrete (governed by the w/c ratio), because damage due to surface attack of concrete occurs slowly. A dense, well-cured concrete has a permeability similar to that of low-porosity rocks, despite the much higher porosity of the paste, because in such concretes the porosity is discontinuous. This means that, instead

FIGURE 1.14 Schematic of rusting in reinforcing steel.

of the bulk flow that would occur through continuous capillary pores, water can flow only by a much slower molecular diffusion process through micropores. Permeability can be further reduced by the use of silica fume or blast-furnace slag which helps to create an even, more discontinuous pore structure.

1.11.1 Leaching and Efflorescence

Efflorescence consists of salts that are leached out of the concrete by water and are then crystallized on the concrete surface by the subsequent evaporation of the water. Efflorescence due to the leaching of calcium hydroxide from concrete and its subsequent carbonation (to CaCO_3) on the concrete surface is frequently seen as white deposits on the underside of floor slabs in parking garages. Efflorescence itself is primarily an aesthetic rather than a durability problem, but it does indicate substantial leaching in the concrete, which will lead to an increase in porosity and permeability.

1.11.2 Sulfate Attack

Sulfates are often present in groundwaters and in seawater. Chemical attack by sulfates occurs when sulfate ions penetrate into the concrete and react to form gypsum. This is followed by the formation of ettringite, which is accompanied by a volume expansion sufficient to cause cracking of the concrete. This process can continue to complete destruction of the concrete. The principal methods of preventing sulfate attack are to reduce the permeability of the concrete by reducing the w/c ratio or by using a slag or pozzolanic mineral admixture. The use of a sulfate-resistant cement (Type V, with $\leq 5\% \text{C}_3\text{A}$) with a w/c ratio less than 0.45 will minimize the possibility of sulfate attack.

1.11.3 Acid Attack

Because concrete is an alkaline material ($\text{pH} \cong 12.5$), it is susceptible to attack by acids, such as might occur in industrial wastes or near some mining operations. The problem is particularly severe when the acidity is high ($\text{pH} < 4$) and water flow is present. Any acid that forms soluble calcium salts on contact

with concrete is particularly aggressive (hydrochloric, nitric, acetic, sulfuric, and lactic acids). In contrast, for acids that form an insoluble salt (phosphoric, tannic acids), the precipitation of their salts within the capillary pores will slow or even prevent further deterioration.

2.1 Fly Ash

2.1.1 Introduction

Fly ash is a byproduct of the combustion of pulverized coal in thermal power plants. A dust-collection system removes the fly ash, as a fine particulate residue, from combustion gases before they are discharged into the atmosphere (Figure 2.1). The types and relative amounts of incombustible matter in the coal used determine the chemical composition of fly ash. More than 85% of most fly ashes is comprised of chemical compounds and glasses formed from the elements silicon, aluminum, iron, calcium, and

* Scientist Emeritus at CANMET, Natural Resources Canada, Ottawa, Canada; prolific author, editor, and researcher who has received many awards and honors from the ACI, ASTM, and other institutions throughout the world.

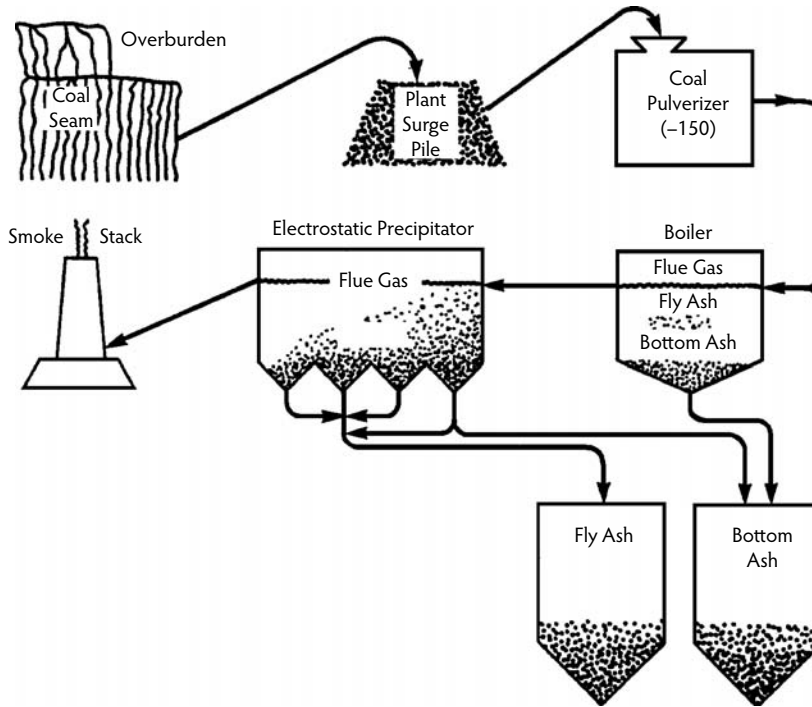

FIGURE 2.1 Schematic of a fossil-fuel plant.

magnesium. Generally, fly ash from the combustion of subbituminous coals contains more calcium and less iron than fly ash from bituminous coal; also, fly ash from subbituminous coals contains very little unburned carbon. Plants that operate only intermittently (peak-load stations) and that burn bituminous coals produce the largest percentage of unburned carbon. Fly-ash particles are typically spherical, ranging in diameter from $<1 \mu\text{m}$ up to $150 \mu\text{m}$.

Fly ashes exhibit pozzolanic activity. The American Society for Testing and Materials (ASTM) (ASTM, 1975) defines a pozzolan as “a siliceous or siliceous and aluminous material which in itself possesses little or no cementitious value but which will, in finely divided form and in the presence of moisture, chemically react with calcium hydroxide at ordinary temperature to form compounds possessing cementitious properties.” Fly ashes contain metastable aluminosilicates that will react with calcium ions, in the presence of moisture, to form calcium silicate hydrates.

The term *fly ash* was first used in the electrical power industry around 1930. The first comprehensive data on the use of fly ash in concrete in North America were reported by Davis et al. (1937). The first major practical application was reported in 1948 with the publication of the U.S. Bureau of Reclamation’s data on the use of fly ash in the construction of the Hungry Horse Dam. Worldwide acceptance of fly ash as a component of concrete slowly followed these early efforts, but interest was particularly noticeable in the wake of the rapid increases in energy costs (and hence cement costs) that occurred during the 1970s.

In recent years, it has become evident that fly ashes differ in significant and definable ways that reflect their combustion and, to some extent, their origin. The ASTM recognizes two general classes of fly ash:

- Class C, normally produced from lignite or subbituminous coals
- Class F, normally produced from bituminous coals

Several publications are available that discuss in detail the properties and use of fly ash in concrete (ASTM, 1978; Berry and Malhotra, 1978; Malhotra and Mehta, 1996; Malhotra and Ramezani-pour, 1994), and Table 2.1 shows the estimated production and use of coal ash in major coal-using countries (Malhotra and Ramezani-pour, 1994).

TABLE 2.1 Coal Ash Production and Use in Major Coal-Using Countries

Country	Fly Ash (kt/yr)	Coarse Ash (kt/yr)	Total Ash (kt/yr)	Use (kt/yr)	Use (%)	Year

2.1.2 Physical, Chemical, and Mineralogical Properties of Fly Ash

2.1.2.1 Physical Properties

Fly ash is a fine-grained material consisting mostly of spherical, glassy particles. Some ashes also contain irregular or angular particles. The size of particles varies depending on the sources. Some ashes may be finer or coarser than Portland cement particles. Figure 2.2 and Figure 2.3 show scanning electron

FIGURE 2.2 SEM micrograph of a subbituminous ash: backscattered electron image of a polished section of the dispersed sample. (From Malhotra, V.M. and Ramezani-pour, A.A., *Fly Ash in Concrete*, MSL 94-45(IR), Canada Center for Mineral and Energy Technology (CANMET), Ottawa, 1994.)

FIGURE 2.3 SEM micrograph of a lignite fly ash: backscattered electron image of a polished section of the dispersed sample. (From Malhotra, V.M. and Ramezaniapour, A.A., *Fly Ash in Concrete*, MSL 94-45(IR), Canada Center for Mineral and Energy Technology (CANMET), Ottawa, 1994.)

microscope (SEM) micrographs of polished sections of subbituminous and lignite fly ashes, and Figure 2.4 shows a secondary electron SEM image of bituminous fly-ash particles. Some of these particles appear to be solid, whereas other larger particles appear to be portions of thin, hollow spheres containing many smaller particles.

TABLE 2.2 Fineness of Fly Ashes

Fly Ash Source	Type of Coal ^a	Physical Properties			Blaine Specific Surface (m ² /kg)
		Specific Gravity (Le Chatelier Method)	Fineness (% Retained on 45- μ m Sieve)		
			Wet Sieving ^b	Dry Sieving (Alpine Jet)

2.1.2.2 Fineness

Dry- and wet-sieving methods are commonly used to measure the fineness of fly ashes. ASTM C 311-77 recommends determining the amount of the sample retained after it is wet sieved on a 45- μ m sieve, in accordance with ASTM C 430, except that a representative sample of the fly ash or natural pozzolan is substituted for hydraulic cement in the determination. Dry sieving on a 45- μ m sieve can be performed according to a method established at the Canada Center for Mineral and Energy Technology (CANMET) (Malhotra and Wallace, 1993). Table 2.2 shows the fineness of 11 fly ashes as determined by wet and dry sieving. The particle-size distribution of fly ash can be determined by various means, such as x-ray sedimentation, laser particle-size analyzer, and Coulter counter. In some cases, agglomeration of a number of small particles may form a large particle. In most cases, fly ashes contain particles greater than 1 μ m in diameter. Mehta (1994), using an x-ray sedimentation technique, reported particle-size distribution data for several U.S. fly ashes. Mehta found that high-calcium fly ashes were finer than low-calcium fly ashes, and he related this difference to the presence of larger amounts of alkali sulfates in the high-calcium fly ashes.

2.1.2.3 Specific Surface

The specific surface of fly ash, which is the area of a unit of mass, can be measured by various techniques. The most common technique is the Blaine specific-surface method, which measures the resistance of compacted particles to air flow. ASTM C 204 describes this method for measurement of the surface area of Portland cement.

2.1.2.4 Specific Gravity

The specific gravity of hydraulic cements is determined according to ASTM C 188. This method can also be used to determine the specific gravity of fly ashes. If fly ashes contain water-soluble compounds, the use of a nonaqueous solvent, instead of water, is recommended. The specific gravity of different fly ashes varies over a wide range. In the CANMET investigation of 11 fly ashes (Carette and Malhotra, 1986), the specific gravity ranged from a low value of 1.90 for a subbituminous ash to a high value of 2.96 for an iron-rich bituminous ash. Three subbituminous ashes had a comparatively low specific gravity of \sim 2.0, and this suggested that hollow particles, such as cenospheres or plerospheres, were present in significant proportions in the three ashes.

In general, the physical characteristics of fly ashes vary over a significant range, corresponding to their source. Attempts have been made to correlate the physical properties of different fly ashes. In one CANMET investigation, no apparent relationship was found between type of fly ash and fineness, as determined by the percentage retained on a 45- μm sieve. Fineness is probably influenced more by factors such as coal combustion and ash collection and classification than by the nature of the coal itself (Carette and Malhotra, 1986). Similarly, the type of fly ash showed no apparent influence on the specific surface as measured by the Blaine technique. Moreover, except in one or two cases, there was very little relationship between the specific surface as measured by the Blaine technique and the fineness as determined by percentage retained on a 45- μm sieve.

2.1.3 Chemical and Mineralogical Composition

2.1.3.1 Chemical Composition

Several authors have reported the chemical composition of various fly ashes produced in North America. In their study of 11 Canadian fly ashes, Carette and Malhotra (1986) reported a wide range of chemical compositions (Table 2.3). Manz et al. (1989) examined 19 North American lignite fly ashes, and their data are given in Table 2.4. The results of the CANMET investigations (Carette and Malhotra, 1986) and the data reported by Manz et al. (1989) on bituminous, subbituminous, and lignite ashes obtained from various coal-powered plants in North America show significant differences in the chemical composition of fly ashes.

2.1.3.2 Mineralogical Composition

In general, both the type and source of fly ash influence its mineralogical composition. Due to the rapid cooling of burned coal in the power plant, fly ashes consist of noncrystalline particles ($\leq 90\%$), or glass and a small amount of crystalline material. Depending on the system of burning, some unburned coal may be collected with ash particles. In addition to a substantial amount of glassy material, each fly ash may contain one or more of the four major crystalline phases: quartz, mullite, magnetite, and hematite. In subbituminous fly ashes, the crystalline phases may include C_3A , $\text{C}_4\text{A}_3\bar{\text{S}}$, calcium sulfate, and alkali sulfates (Mehta, 1989). Table 2.5 shows the mineralogical composition of some selected fly ashes. The reactivity of fly ashes is related to the noncrystalline phase or glass. The reasons for the high reactivity of high-calcium fly ashes may lie partially in the chemical composition of the glass. Mehta (1989) pointed out that the composition of glass in low-calcium fly ashes is different from that in high-calcium fly ashes.

2.1.4 Proportioning Concretes Containing Fly Ash

In most applications, the objective of using fly ash in concrete is to achieve one or more of the following benefits:

- Reducing the cement content to reduce costs
- Obtaining reduced heat of hydration
- Improving workability
- Attaining required levels of strength in concrete at ages >90 days
- Improving durability

The properties of any particular fly ash will greatly affect the properties of the concrete in which it is used. The mixture-proportioning method can minimize the effects that the inclusion of different fly ashes has on concrete performance. In practice, fly ash can be introduced into concrete in one of two ways:

- A blended cement containing fly ash may be used in place of Portland cement.
- Fly ash may be introduced as an additional component at the concrete-mixing stage.

The use of blended cement is the simpler of the two, as it is free from the complication of batching additional materials and may ensure more uniform control. The relative proportions of fly ash and cement are predetermined, and this limits the range of mixture proportions.

The addition of fly ash at the concrete-mixing stage is flexible and allows for more complete exploitation of the qualities of fly ash as a component of concrete. It does, however, demand that the unique properties of fly ash be considered in determining the proportions of the mixture. In current trends, fly ash plays more than one role in concrete. In freshly mixed concrete, it generally acts as a fine aggregate and to some degree may reduce the demand for water. In hardened concrete, because of the pozzolanic nature of fly ash, it becomes a component of the cementitious matrix and influences strength and durability. Thus, the use of fly ash in a concrete introduces a number of complexities regarding proportioning, if the accepted relationships among workability, strength, and the water/cement ratio are taken into account. Two common assumptions are made when selecting an approach to mixture proportioning of fly-ash concrete:

- Fly ash usually reduces the strength of concrete at early ages.
- For equal workability, concrete incorporating fly ash usually requires less water than concrete containing only Portland cement.

Neither assumption is universally true, and both are influenced by the presence of other common concrete components; however, both assumptions have strongly influenced the approach to mixture proportioning of fly-ash concrete. As with any other type of concrete, the mixture proportions for a fly-ash concrete can be selected either by reference to some standard concrete (excluding fly ash) or on the basis of the ways in which all the concrete components (including fly ash) will behave in fresh and hardened states.

Throughout the more than 40 years that fly ash has been used in concrete, common practice has been to use some plain concrete as a standard of comparison for the mixture proportions of fly-ash concretes. Similarly, the properties of both fresh and hardened concrete usually have been compared with those of a reference concrete. Thus, fly ash has generally been considered to be a replacement for cement, rather than a component that complements the functions of the cement, sand, or water. The trend now is to consider the components of fly-ash concrete as a whole and to treat it as a unique material without reference to an equivalent plain-concrete mixture.

2.1.5 Influence of Fly Ash on the Setting Time of Portland Cement Concrete

The rate at which concrete sets during the first few hours after mixing is expressed as the initial and final setting time and is determined by some form of penetrometer test. Fly ash may be expected to influence the rate of hardening of cement for a number of reasons:

- The ash may be cementitious (high calcium).
- Fly ash may contain sulfates that react with cement in the same way as the gypsum added to Portland cement does.

- The fly-ash–cement mortar may contain less water as a consequence of the presence of fly ash, and this will influence the rate of stiffening.
- The ash may absorb surface-active agents added to modify the rheology (water reducers) of concrete, and, again, this influences the stiffness of the mortar.
- Fly-ash particles may act as nuclei for crystallization of cement hydration products.

There seems to be general agreement in the literature that low-calcium fly ashes retard the setting of cement. In experiments conducted at CANMET (Carette and Malhotra, 1986), the data show that all but 2 of the 11 ashes significantly increase both the initial and final setting times.

2.1.6 Effect of Fly Ash on Workability, Water Requirement, and Bleeding of Fresh Concrete

The small size and the essentially spherical form of low-calcium fly-ash particles influence the rheological properties of cement pastes, causing a reduction in the water required or an increase in workability compared with that of an equivalent paste without fly ash. As Davis et al. (1937) noted, fly ash differs from other pozzolans that usually increase the water requirement of concrete mixtures. The improved workability allows a reduction in the amount of water used in concrete. According to Owens (1979), the major factor influencing the effects of ash on the workability of concrete is the proportion of coarse material (>45 mm) in the ash. Owens has shown, for example, that substitution of 50% by mass of the cement with fine particulate fly ash can reduce the water requirement by 25%. A similar substitution using ash with 50% of the material larger than 45 mm has no effect on the water requirement.

2.1.7 Effects of Fly Ash on Air Entrainment in Fresh Concrete

Cycles of freezing and thawing are extremely destructive to water-saturated concretes that are not properly proportioned. Concrete will be frost-resistant if it is made with sound, coarse aggregate and is properly protected until some maturity is attained. To obtain the number of correctly spaced air voids in hardened concrete necessary for frost resistance, an air-entraining admixture (AEA) is added (at a prescribed dosage) to the concrete during mixing. Two attributes are important: (1) the AEA must produce the required volume of air bubbles of the desired size and spacing in the concrete, and (2) it must do so in a manner that allows the air content to remain stable while the concrete is mixed, transported, and placed. The use of some fly ashes causes an increase in the quantity of AEA required to produce a given level of air entrainment in fresh concrete. Larson (1994), writing on the use of fly ash in air-entrained concrete and reviewing the work of other investigators, concluded that the primary effect of fly ash was on the AEA requirement rather than on the air entrainment as such.

Gebler and Klieger (1983) examined 10 different fly ashes representing a range of chemical and physical properties. Carbon content was 0.14 to 4.19%, total organics were 0.09 to 1.04%, CaO was 1.2 to 9.0%, and fineness (as a percentage retained on a 45- μm sieve) was 11.24 to 38.45%. Concretes were proportioned by simple replacement of 25% of the cement by fly ash (by mass). All mixtures were proportioned to have 75 ± 25 -mm slump and $6 \pm 1\%$ air. Neutralized Vinsol™ resin was the only AEA used. The AEA requirement as a percentage of that for the control concrete (for 6% air content) showed the following results:

- For ashes containing >10% CaO, the range of AEA requirements was 126 to 173%.
- For ashes containing <10% CaO, the range of AEA requirements was 170 to 553%.

Gebler and Klieger (1983, p. 107) offered the following summary of the findings and conclusions relevant to air entrainment in fresh concrete:

- Generally, concretes containing Class C fly ash require less air-entraining admixture than those concretes with Class F fly ash. All concretes with fly ash required more air-entraining admixture than Portland cement concretes without fly ash.

- Plastic concretes containing Class C fly ash tended to lose less air than concretes with Class F ash.
- As the air-entraining admixture requirement increases for a concrete containing fly ash, the air loss increases.
- Air contents in plastic concrete containing Class F fly ash were reduced as much as 59%, 90 minutes after completion of mixing.
- As the organic matter content, carbon content, and loss-on-ignition of fly ash increase, the air-entraining admixture requirement increases, as does the loss of air in plastic concrete.
- Generally, as the total alkalis in fly ash increase, the air-entraining admixture requirement decreases.
- As the specific gravity of a fly ash increases, the retention of air in the concrete also increases. Concrete containing a fly ash that has a high lime content (Class C fly ash) and less organic matter tends to be less vulnerable to loss of air.
- Generally, as the SO_3 content of fly ash increases, the retained air in concrete increases.

2.1.8 Effects of Fly Ash on Properties of Hardened Concrete

2.1.8.1 Strength Development in Fly-Ash Concrete

As discussed earlier, the main factors determining strength in concrete are the amount of cement used and the water/cement ratio. In practice, these are established as a compromise between the need for workability in the freshly mixed state, strength and durability in the hardened state, and cost. The degree and manner in which fly ash affects workability are major factors in its influence on strength development. As was shown earlier, a fly ash that permits a reduction in the total water requirement in concrete will generally present no problems in selection of mixture proportions and permit any rate of strength development. Many variables influence the strength development of fly-ash concrete; the most important are the following:

- The properties of the fly ash
- Chemical composition
- Particle size
- Reactivity
- Temperature and other curing conditions

2.1.8.2 Effect of Fly-Ash Type on Concrete Strength

The first difference among fly ashes is that some are cementitious even in the absence of Portland cement; these are the so-called ASTM Class C, or high-calcium, fly ashes, usually produced at power plants that burn subbituminous or lignitic coals. In general, the rate of strength development in concretes tends to be only marginally affected by high-calcium fly ashes. Concrete incorporating high-calcium fly ashes can be made on an equal-weight or equal-volume replacement basis without any significant effect on strength at early ages. Yuan and Cook (1983) examined the strength development of concretes with and without high-calcium fly ash ($\text{CaO} = 30.3 \text{ wt}\%$). The data from their research are shown in Figure 2.5 and Figure 2.6. Using a simple replacement method of mixture proportioning (Table 2.6), they found the rate of strength development of fly-ash concrete to be comparable to that of the control concrete, with or without air entrainment. Low-calcium fly ashes, the so-called ASTM Class F fly ashes, were the first to be examined for use in concrete. Most of what has been written on the behavior of fly-ash concrete examines concretes that use Class F ashes. In addition, the ashes used in much of the early work came from older power plants and were coarse in particle size, contained unburned fuel, and were often relatively inactive pozzolans. Used in concrete and proportioned by simple replacement, these ashes showed exceptionally slow rates of strength development. This led to the erroneous view that fly ash reduces strength at all ages. Gebler and Klieger (1986) evaluated the effect of ASTM Class F and Class C fly ashes from 10 different sources on the compressive strength development of concretes under different curing conditions, including effects of low temperature and moisture availability. Their tests indicated that concrete containing fly ash had the potential to produce satisfactory compressive strength development. The influence of the class of fly ash on the long-term compressive strength of concrete was not significant. In general,

FIGURE 2.5 Compressive strength development of non-air-entrained concretes containing high-calcium fly ash. (From Yuan, R.L. and Cook, J.E., in *Fly Ash, Silica Fume, Slag, and Other Mineral Byproducts in Concrete*, Spec. Publ. SP-79, Malhotra, V.M., Ed., American Concrete Institute, Detroit, MI, 1983, pp. 307–319.)

FIGURE 2.6 Compressive strength development of air-entrained concrete containing high-calcium fly ash. (From Yuan, R.L. and Cook, J.E., in *Fly Ash, Silica Fume, Slag, and Other Mineral Byproducts in Concrete*, Spec. Publ. SP-79, Malhotra, V.M., Ed., American Concrete Institute, Detroit, MI, 1983, pp. 307–319.)

compressive strength development of concretes containing Class F fly ash was more susceptible to low curing temperature than concretes with Class C fly ash or the control concretes. Gebler and Klieger concluded that Class F fly-ash concretes required more initial moist curing for long-term, air-cured compressive strength development than did concretes containing Class C fly ashes or the control concretes.

2.1.8.3 Effects of Temperature and Curing Regime on Strength Development in Fly-Ash Concretes

When concrete made with Portland cement is cured at temperatures greater than 30°C, an increase in strength occurs at early ages but a marked decrease in strength in the mature concrete. Concretes containing fly ash and control concretes behave significantly differently. Figure 2.7 shows the general way in which the temperature maintained during the early ages of curing influences the 28-day strength of concrete (Williams and Owens, 1982).

2.1.8.4 Effect of Fly-Ash on Elastic Properties of Concrete

Published data indicate that fly ash has little influence on the elastic properties of concrete. Abdun-Nur (1961) made the following observation:

The modulus of elasticity of fly ash concrete is lower at early ages and higher at later ages. In general, fly ash increases the modulus of elasticity of concrete when concretes of the same strength with and without fly ash are compared.

2.1.8.5 Effect of Fly Ash on Creep Properties of Concrete

Data on creep of fly-ash concrete are limited. Ghosh and Timusk (1981) examined bituminous fly ashes of different carbon contents and fineness values in concretes at nominal strength levels of 20, 35, and 55 MPa (water/cement ratio of 1.0, 0.4, and 0.2, respectively). Each concrete was proportioned for equivalent strength at 28 days. Fly-ash concretes showed less creep in the majority of specimens than the reference concretes. This was attributed to a relatively higher rate of strength gain after the time of loading for the fly-ash concretes than for the reference concretes. Yuan and Cook (1983) investigated creep of high-strength concrete containing a high-calcium fly ash and showed that concrete containing 30 and 50% fly ash exhibited more creep than either the control concrete or a concrete with 20% fly ash.

2.1.8.6 Effect of Fly Ash on Volume Changes of Concrete

It has been generally reported that the use of fly ash in normal proportions does not significantly influence the drying shrinkage of concrete. Typical of the conclusions of most researchers in this area are those made by Davis et al. (1937), who commented as follows:

- For masses of ordinary thickness, such as are normally found in highway slabs and in the walls and frames of buildings, the drying shrinkage at the exposed surfaces of concrete up to the age of one year for fly-ash cements is about the same as, or somewhat less than, that for corresponding Portland cement. At a short distance from the exposed surface the drying shrinkage up to the age of one year is substantially less for concretes containing corresponding Portland cements.
- For very thin sections and for cements of normal fineness, the drying shrinkage of concretes containing finely ground high-early-strength cements may be somewhat reduced by the use of fly ash.

2.1.9 Effects of Fly Ash on the Durability of Concrete

Increasingly, concrete is being selected for use as a construction material in aggressive or potentially aggressive environments. Concrete structures have always been exposed to the action of seawater. In modern times, the demands placed on concrete in marine environments have increased greatly, as concrete structures are used in arctic, temperate, and tropical waters to contain and support the equipment, people, and products of oil and gas exploration and production. Concrete structures are used to contain nuclear reactors and must be capable of containing gases and vapors at elevated temperatures and pressures under emergency conditions. Concrete is increasingly being placed in contact with sulfate and acidic waters. In all of these instances, the use of fly ash as a concrete material plays a role, and an understanding of its effect on concrete durability is essential to its correct and economical application.

2.1.9.1 Effects of Fly Ash on Permeability of Concrete

A number of investigations have studied the influence of fly ash on the relative permeability of concrete pipes containing fly ash substituted for cement in amounts of 30 to 50%. In a study by Davis (1954), permeability tests were made on 150 × 150-mm cylinders at the ages of 28 days and 6 months. The results of these tests are shown in Table 2.7. It is clear from these data that the permeability of the concrete was directly related to the quantity of hydrated cementitious material at any given time. After 28 days of curing, at which time little pozzolanic activity would have occurred, the fly-ash concretes were more permeable than the control concretes. At 6 months, this was reversed. Considerable imperviousness had developed, presumably as a result of the pozzolanic reaction of fly ash. Short and Page (1982) reported on the diffusion of chloride ions in solution into Portland blended cement pastes and found the following values of diffusion coefficient (D_c) for different cement types:

Type of Cement	D_c Value ($\times 10^{-9}$ cm ² /s)
Normal Portland	44.7
Sulfate-resisting	100.0
Fly-ash/Portland	14.7
Slag/Portland	4.1

It was concluded from these data that slag and fly-ash cements were more effective in limiting chloride diffusion in pastes than were normal or sulfate-resisting cements.

2.1.9.2 Effects of Fly Ash on Carbonation of Concrete

In moist conditions, calcium hydroxide, and to a lesser degree, calcium silicates and aluminates in hydrated Portland cement react with carbon dioxide from the atmosphere to form calcium carbonate. The process, termed *carbonation*, occurs in all Portland cement concretes. The rate at which concrete carbonates is determined by its permeability, the degree of saturation, and the mass of calcium hydroxide available for reaction. Well-compacted and properly cured concrete, at a low water/cement ratio will be sufficiently impermeable to resist the advance of carbonation beyond the first few millimeters. If carbonation progresses into a mass of concrete, two deleterious consequences may follow: shrinkage may occur, and carbonation of concrete immediately adjacent to steel reinforcement may reduce the resistance of steel to corrosion.

Nagataki et al. (1986) reported the long-term results of experiments carried out since 1969 that investigated the depth of carbonation in concrete with and without fly ash. The authors concluded that the initial curing period affects the carbonation of concrete cured indoors; hence, it is necessary for fly-ash concrete to have a longer curing period in water at early ages. The carbonation of concrete cured outdoors is not affected by the initial curing period in water, provided it is cured in water for a period of 7 days.

2.1.9.3 Effects of Fly Ash on the Durability of Concrete Subjected to Repeated Cycles of Freezing and Thawing

It is generally accepted, other criteria also being met, that air entrainment renders concrete frost resistant. Fly ashes, in common with other finely divided mineral components in concrete, tend to cause an increase in the quantity of admixture required to obtain specified levels of entrained air in concrete. In some instances, the stability of the air or the rate of air loss from fresh concrete is also affected. In general, the observed effects of fly ash on freezing and thawing durability support the view expressed by Larson (1994):

Fly ash has no apparent ill effects on the air voids in hardened concrete. When a proper volume of air is entrained, characteristics of the void system meet generally accepted criteria.

Klieger and Gebler (1987) also evaluated the durability of concretes containing ASTM Class F and Class C fly ashes. Their test results indicated that air-entrained concretes, with or without fly ash, that were moist cured at 23°C generally showed good resistance to freezing and thawing. For specimens cured at a low temperature (4.4°C), air-entrained concretes with Class F fly ash showed slightly less resistance to freezing and thawing than similar concretes made with Class C fly ash.

Bilodeau et al. (1991), in an investigation carried out at CANMET, determined the scaling resistance of concrete incorporating fly ashes. Water/cement + fly ash ratios of 0.35, 0.45, and 0.55 were used. Concrete without fly ash and concretes containing 20 and 30% fly ash as replacement by mass for cement were made. The results of Bilodeau et al. showed that the concrete containing $\geq 30\%$ fly ash performed satisfactorily under the scaling test with minor exceptions (Table 2.8).

Carette and Langley (1990) studied the performance of fly ash concrete subjected to 50 freezing and thawing cycles in the presence of deicing salts. They concluded that the incorporation of fly ash in concrete mixtures with $\leq 30\%$ replacement of Portland cement did not show significant difference in salt-scaling resistance in the presence of a 4% calcium chloride solution when examined by visual rating of surface

TABLE 2.8 Mass of Scaling Residue after 50 Freezing and Thawing Cycles—Series I

Time of Moist Curing (days)	Time of Air Drying (weeks)	Mass of Scaling Residue (kg/m ³)

deterioration. In the measurement of weight loss due to surface deterioration, which they believed was a meaningful way to assess surface deterioration, concretes containing fly ash showed greater weight loss than control concrete. Carette and Langley stated that the surface scaling appeared not to be sensitive to the length of time that specimens were moist cured or air dried subsequent to initial moist curing, at least within the periods investigated.

2.1.9.4 Abrasion and Erosion of Fly-Ash Concrete

Under many circumstances, concrete is subjected to wear by attrition, scraping, or the sliding action of vehicles, ice, and other objects. When water flows over concrete surfaces, erosion may occur. In general, regardless of the type of test performed, the abrasion resistance of concrete is usually found to be proportional to its compressive strength. Similarly, at constant slump, resistance to erosion improves with increased cement content and strength. It may be anticipated that fly-ash concrete that is incompletely or inadequately cured may show reduced resistance to abrasion.

Carrasquillo (1987) examined the abrasion resistance of concretes containing no fly ash, 35% ASTM Class C fly ash, or 35% ASTM Class F fly ash. Specimens tested were cast from concretes having similar strengths, air contents, and cementitious materials contents. The abrasion resistance of concrete containing Class C fly ash was greater than that of concrete containing Class F fly ash or no fly ash. The latter two exhibited approximately equal abrasion resistance; measurement was based on the depth of wear.

Naik et al. (1992) carried out an investigation of the compressive strength and abrasion resistance of concrete containing ASTM Class C fly ash. They proportioned concrete mixtures to have cement replacement in the range of 15 to 70 wt% fly ash. The water/cementitious materials ratio varied from 0.31 to 0.37. Their results showed that the abrasion resistance of concrete containing ≤30% fly ash was similar to that of the control concrete; however, the abrasion resistance of concretes containing >40% fly ash was lower than that of control concrete without fly ash.

2.1.9.5 Effects of Fly Ash on Sulfate Resistance of Concrete

In 1967, Dikeou (1970) reported the results of sulfate-resistance studies on 30 concrete mixtures made with Portland cement, Portland fly-ash cement, or fly ash. From this work, it was concluded that all of the 12 fly ashes tested greatly improved sulfate resistance. Kalousek et al. (1972) studied the requirements of concretes for long-term service in a sulfate environment. From their study, they drew the following conclusions:

- Eighty-four percent of ASTM Types V and II cement concretes without pozzolan showed a life expectancy of <50 years.
- Certain pozzolans very significantly increased the life expectancy of concrete exposed to 2.1% sodium sulfate solution. Fly ashes meeting current specifications were prominent among the group of pozzolans showing the greatest improvements.
- Concretes for long-term survival in a sulfate environment should be made with high-quality pozzolans and a sulfate-resisting cement. The pozzolan should not increase significantly but should preferably decrease the amount of water required.
- Cement to be used in making sulfate-resisting concrete with pozzolan of proven performance should have a maximum C_3A content of 6.5% and maximum C_4AF content of 12%. Restriction of cements to those meeting present-day specifications for Type V cement does not appear justified.

The fly-ash samples examined by Dikeou (1970) and those examined by Kalousek et al. (1972) originated from bituminous coals.

Dunstan (1976) reported the results of experiments on 13 concrete mixtures made with fly ashes from lignite or subbituminous coal sources. On the basis of this work, he concluded that lignite and subbituminous fly-ash concrete generally exhibited reduced resistance to sulfate attack. The *Concrete Manual* published by the U.S. Bureau of Reclamation gives options for cementitious materials for producing sulfate-resistant concretes (Bureau of Reclamation, 1981; Pierce, 1982).

2.1.9.6 Effects of Fly Ash on Alkali–Aggregate Reactions in Concrete

Shortly after Stanton (1940) discovered that alkali–aggregate reactions (AARs) caused expansion and damage in some concretes, he reported that the effects could be reduced by adding finely ground reactive materials to the concrete mixture. Subsequently, a variety of natural and artificial pozzolans and mineral admixtures, including fly ash, were found to be effective in reducing the damage caused by AARs. The effectiveness of fly ash (and other mineral admixtures) in reducing expansion due to AARs appears to be limited to reactions involving siliceous aggregates. A form of AAR known as the alkali–carbonate reaction (Poole, 1981) is relatively unresponsive to the addition of pozzolans (Swenson and Gillott, 1960). The role of fly ashes in reducing expansion by AAR can be summarized as follows:

- Substantial published data show that low-calcium fly ashes with alkali contents of less than about 4% are effective in reducing expansion caused by alkali–silica reactions when the fly ashes are used at a replacement level in the range of 25–30%. High-volume fly ash concrete is very effective in this regard.
- The use of high-calcium ashes has received less attention; hence, the background information relevant to their use is less well developed. If they are to be used, there is some indication that effective replacement levels may be higher than those for low-calcium ashes.
- The mechanism and details of the control of expansion caused by alkali–silica reactions are not fully understood. Much research remains before a satisfactory understanding can be developed.

2.1.9.7 Effects of Fly Ash on the Corrosion of Reinforcing Steel in Concrete

Recently, an issue of concern has been the corrosion of steel reinforcement in fly-ash concrete structures exposed to chloride ions from deicing salts or seawater. If the concrete cover over steel reinforcement is sufficiently thick and impermeable, it will normally provide adequate protection against corrosion. The protective effect of the concrete cover is of both a physical and a chemical nature and functions in three ways:

- It provides an alkaline medium in the immediate vicinity of the steel surface.
- It offers a physical and chemical barrier to the ingress of moisture, oxygen, carbon dioxide, chlorides, and other aggressive agents.
- It provides an electrically resistive medium around the steel members.

Under alkaline conditions (pH higher than ~11.5), a protective oxide film will form on a steel surface, rendering it immune to further corrosion.

When concrete carbonates and the depth of carbonation reach the steel–concrete boundary, passivation may be reduced and corrosion may occur if sufficient oxygen and moisture reach the metal surface. Chlorides or other ions may also undermine the protective effect of passivation and encourage corrosion.

The *Réunion internationale des laboratoires d'essais et de recherches sur les matériaux et les constructions* (RILEM) Technical Committee on Corrosion of Steel in Concrete (1974) made the following statement, which gives perspective to this issue:

The efficiency of the (concrete) cover in preventing corrosion is dependent on many factors which collectively are referred to as its “quality.” In this context, the “quality” implies impermeability and a high reserve of alkalinity which satisfies both the physical needs and chemical requirements of the concrete cover. If the concrete is permeable to atmospheric gases or lean in cement, corrosion of the reinforcement can be anticipated and good protection should be attempted by the use of dense aggregate and a well-compacted mix with a reasonably low water/cement ratio. . . . If chloride corrosion is expected, it is now usually agreed that carbonation of concrete cover is the essential condition for corrosion of reinforcement.

As discussed in the Effects of Fly Ash on Carbonation of Concrete section above, the issue of carbonation of fly-ash concrete has received some attention in recent years; however, it is our belief that the carbonation of fly-ash concrete is not a matter of concern, provided attention is paid to obtaining adequate impermeability in the concrete mass.

2.1.9.8 Effects of Fly Ash on Concrete Exposed to Seawater

Exposure of concrete to the marine environment subjects it to an array of severely aggressive factors, including most of those discussed in the preceding sections of this chapter. Concrete in tidal zones is the most severely attacked, subjected as it is to alternating wetting and drying, wave action, abrasion by sand and debris, frequent freezing and thawing cycles, and corrosion of reinforcement—all occurring in a chemically aggressive medium. Permanently immersed concrete is less severely affected.

Very little direct observation of fly-ash concrete in seawater has been reported in the literature, although some research in this area has been reported (Malhotra et al., 1980). In 1978, CANMET (Malhotra et al., 1988, 1992) initiated a long-term project on marine-environment performance of concretes incorporating supplementary cementing materials. Test specimens were exposed to repeated cycles of wetting and drying and up to approximately 100 freezing and thawing cycles per year. Even under exposure to severe marine conditions, concretes incorporating 25% fly ash from a bituminous source were in satisfactory condition after 15 years. The only exceptions were the specimens with a water/cement + fly ash ratio of 0.60. It was concluded that fly-ash concrete at a 25% cement replacement level (by mass) can be satisfactory under such conditions of exposure, provided the water/cementitious materials ratio is ≤ 50 .

Whereas permeability is considered to be the major factor affecting the durability of concrete in seawater, it is evident that fly ash has the potential to contribute to a number of aspects of concrete durability in the marine environment. It is clear also that this is an area of fly-ash concrete behavior that is greatly in need of research.

2.2 Blast-Furnace Slag

2.2.1 Ground, Granulated, or Pelletized Blast-Furnace Slag

Blast-furnace slag is a byproduct of iron manufacture. When it is rapidly quenched with water to a glassy state and finely ground, it develops the property of latent hydraulicity. Most of the slags so produced are, in themselves, cementitious materials to a certain degree, whereas others become so in the presence of activators such as Portland cement and calcium sulfate. Their performance in concrete,

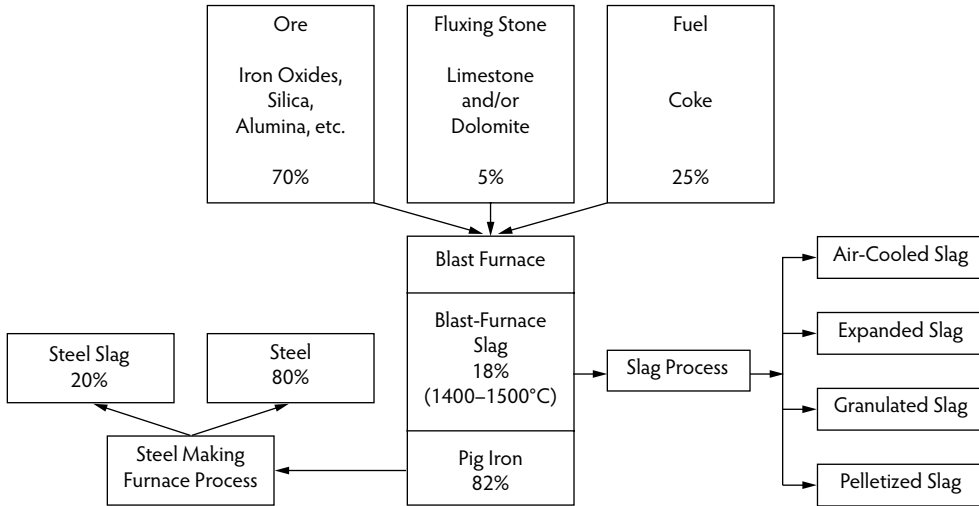

FIGURE 2.8 Flowchart showing production of pig iron and blast-furnace slag. (From Kim, C.S., Waste and Secondary Product Utilization in Highway Construction, M.S. thesis, McMaster University, Hamilton, Ontario, 1975.)

FIGURE 2.9 Diagram of a typical slag pelletizer. (From Hooton, R.D., in *Supplementary Cementing Materials*, Malhotra, V.M., Ed., Canada Center for Mineral and Energy Technology (CANMET), Ottawa, Ontario, 1987, pp. 247-330.)

however, is independent of whether they are inherently cementitious or not. Figure 2.8 shows a flow chart for the production of pig iron and blast-furnace slag (Kim, 1975). The technology for utilization of granulated blast-furnace slags in concrete is now well established worldwide. In the early 1970s, a pelletizing process to produce glassy slag was introduced in southern Ontario. This process uses considerably less water than granulation techniques. The molten slag is first expanded by treatment with water sprays, and the material is then passed over a rotating finned drum. The semimolten material is then thrown into the air for cooling and pelletization (Figure 2.9). Several pelletization plants are in operation worldwide (Hooton, 1987a).

2.2.2 Mixture Proportions and Properties of Fresh Concrete Incorporating Blast-Furnace Slag

2.2.2.1 Mixture Proportions

The proportions of ground, granulated, or ground, pelletized, blast-furnace slag* used in concrete depend on the job requirements. In normal ready-mixed concrete operations, in which the primary aim is to conserve cement, the usual proportions vary from 25 to 50% by weight of cement on a cement-replacement basis; however, if the purpose is to enhance some aspect of concrete durability (for example, sulfate resistance), then the slag content is at least 50% of the total cementitious material. As each slag has a unique chemical composition, glass content, and fineness, it is necessary to perform exploratory laboratory investigations with the cement, aggregates, and chemical admixtures to be used at a project to determine the correct percentage of slag to be incorporated into the concrete. This aspect cannot be overemphasized. The specific gravity of slags ranges from 2.85 to 2.95, compared with 3.15 for Portland cements; thus, a given replacement of cement by slag on a weight basis results in a higher volume of paste in a concrete mixture. This result is of little consequence at lower percentages of cement replacement. If, however, 50 to 75% cement replacements are being considered, this will affect the rheology of the concrete mixtures and may allow some increase in the volume of coarse aggregate to be used, especially in mixtures incorporating higher amounts of cement.

2.2.2.2 Time of Setting

The incorporation of slag as a replacement for Portland cement in concrete normally results in increased setting time. Final setting time can be delayed up to several hours depending on the ambient temperature, concrete temperature, and mixture proportions. At temperatures lower than 23°C, considerable retardation in setting time can be expected for slag concretes compared with control concrete, which has serious implications in winter concreting. At higher temperatures (>30°C), there is little or no change in the setting time of slag concrete as compared to control concrete. Data by Hogan and Meusel (1981) on initial and final setting for concrete incorporating granulated slag are shown in Table 2.9.

2.2.2.3 Bleeding

Few published data are available on the bleeding of slag concretes. Slags are generally ground to a higher fineness than normal Portland cement; therefore, a given mass of slag has a higher surface area than the corresponding mass of Portland cement. As the bleeding of concrete is governed by the ratio of the surface area of solids to the volume of water, in all likelihood the bleeding of slag concrete will be lower than that of the corresponding control concrete. The slags available in Canada and the United States have fineness, as measured by the Blaine method, greater than 4500 cm²/g, compared with that of about 3000 cm²/g for Portland cement. Thus, in concrete in which a given mass of Portland cement is replaced by an equivalent mass of slag, bleeding should not be a problem.

2.2.2.4 Dosage of Air-Entraining Admixtures

The dosage requirement of an air-entraining admixture to entrain a given volume of air in slag concrete increases with increasing amounts of slag. The increased demand for the admixture is, once again, probably due to the higher total surface area of the slag particles compared with that of the Portland cement particles. In an investigation reported by Malhotra (1979), the admixture dosage required to entrain about 5% air increased from 177 mL/m³ for the control concrete to 562 mL/m³ for a concrete mixture incorporating 65% pelletized slag. The water/cement + slag ratio was 0.30.

*Granulated slag implies that the slag is granulated by rapid-water quenching of the molten slag, whereas pelletized slag implies that the granulation is achieved by a pelletizing process. Hereafter, these are referred to either as *granulated* or *pelletized slag* or only as *slag* when reference is made to both types.

TABLE 2.9 Data on Time of Setting for Air-Entrained Concrete Incorporating Granulated Slag

Properties	Control, No Slag	Slag Content (%)			Control, No Slag	Slag Content (%)		
		40	50	65		40	50	65

2.2.2.5 Rates of Slump Loss

Meusel and Rose (1979) have shown that the rate of slump loss of concrete incorporating granulated slag at 50% cement replacement was comparable to that of the control concrete.

2.2.3 Properties of Hardened Concrete

2.2.3.1 Color

Concrete incorporating slags is generally lighter in color than normal Portland cement concrete, due to the lighter color of slags. When concrete is tested for compression or flexure, the interior of the broken specimens exhibit a deep blue–green color. After sufficient exposure to air, the color disappears. The degree of color, which results from the reaction of sulfides in the slag with other compounds in cement, depends on the percentage of slag used, curing conditions, and the rate of oxidation.

2.2.3.2 Curing

The rate and degree of hydration of cement paste, and consequently its strength, are affected significantly by lack of proper curing because of the slow formation of strength-producing hydrates. This effect becomes more pronounced when the paste incorporates high percentages of slag. To ensure proper strength and durability of concretes incorporating high percentages of slag (>30%), it is important that they be given more curing than concretes without slag. Such extended curing is especially important during winter concreting in Canada and the northern United States. The increase in curing time would depend on the ambient temperature, the concrete temperature, the type and amount of cement used, and the percentage of cement replacement.

2.2.3.3 Compressive Strength

The compressive strength development of slag concrete depends primarily on the type, fineness, activity index, and proportions of slag used in concrete mixtures. Other factors that affect the performance of slag in concrete are the water/cementitious materials ratio and the type of cement used. In general, the strength development of concrete incorporating slags is slow at 1 to 5 days, compared to that of the control concrete. Between 7 and 28 days, the strength approaches that of the control

FIGURE 2.10 Age vs. compressive strength relationship for air-entrained concrete: $W/(C + S) = 0.40$. (From Hogan, F.J. and Meusel, J.W., *ASTM Cement, Concrete, Aggregates*, 3(1), 40–52, 1981.)

FIGURE 2.11 Age vs. compressive strength relationship for concrete incorporating condensed silica fume and pelletized slag, water/cement + blast-furnace slag ($W/(C + BFS) = 0.50$). (From Malhotra, V.M. et al., in *Proceedings of the RILEM/ACI Symposium on the Technology of Concrete When Pozzolans, Slags and Chemical Admixtures Are Used*, Monterey, Mexico, 1985, pp. 395–414.)

concrete, and beyond this period the strength of slag concrete exceeds the strength of the control concrete. Figure 2.10 and Figure 2.11 show compressive strength development with age for granulated slag concrete for water/cement + slag ratios of 0.40 and 0.55. Note that the highest strength gain at 28 days was for concrete with a slag content of 40% cement replacement.

Malhotra et al. (1985) reported investigations in which small amounts of condensed silica fume were added to pelletized slag concrete to increase the early-age strength. Figure 2.11 illustrates the strength development of concrete from 1 to 180 days. The authors concluded that:

- The low early-age strength of Portland cement concrete incorporating blast-furnace slag can be increased by the incorporation of condensed silica fume. The gain in strength is generally directly proportional to the percentage of the fume used.
- At 3 days, the increase in strength is generally marginal, especially for concrete with high W/C + blast-furnace slag (BFS) ratios. However, at the age of 14 days and beyond, with minor exceptions, the loss in compressive strength of concrete due to the incorporation of BFS can be fully compensated for with a given percentage of condensed silica fume, regardless of the W/(C + BFS). This is also true for the flexural strength.
- The continuing increase in strength at 56, 91, and 180 days of the concrete incorporating BFS and condensed silica fume indicates that sufficient lime (liberated during the hydration of Portland cement) is present at these ages for the cementitious reaction to continue.

2.2.3.4 Flexural Strength

In general, at 7 days and beyond, the flexural strength of concrete incorporating slag is comparable to, or greater than, the corresponding strength of control concrete; however, in one instance, the reverse was reported for a water/cement + slag ratio of 0.38. The increased flexural strength of slag concrete is probably due to the stronger bonds in the cement–slag–aggregate system because of the shape and surface texture of the slag particles.

2.2.3.5 Young's Modulus of Elasticity

According to Stutterheim (1960), at the same strength level, there is little, if any, difference between the modulus of elasticity of the control concrete and a concrete containing a granulated slag of South African origin. No published data are available on Young's modulus of elasticity of slags currently available in North America. Investigations performed by Nakamura et al. (1986) on a Japanese slag showed no significant difference between the values of the Young's modulus of elasticity of concrete incorporating granulated slag and that of the control concrete.

2.2.3.6 Drying Shrinkage

Hogan and Meusel (1981) showed that drying shrinkage of concrete incorporating granulated slag is more than that of control concrete. The increase in shrinkage is attributed to increased paste volume in concrete when slag is used as replacement for Portland cement on an equal weight basis because of the lower specific gravity of the slag. This finding may or may not be true for other slags, and further research is needed to confirm this. Fulton (1974) suggested that the shrinkage of concrete incorporating granulated slag can be reduced by taking advantage of improved workability to increase the aggregate/cement ratio or by reducing the water/cement ratio of concrete.

2.2.3.7 Creep

Few published data are available on creep of concrete incorporating North American slags. The available data from South Africa and Japan are conflicting (Fulton, 1974). This conflict is due primarily to the fineness of slags used, methods of tests, age of testing, humidity conditions, and the stress/strength ratio employed; for example, it has been shown that the fineness of cement significantly affects the creep strains (Fulton, 1974). Bamforth (1980) has reported limited data on creep strains for concretes with and without fly ash and granulated slags, loaded to a constant stress/strength ratio of 0.25. He found that for concretes loaded at an age greater than 24 hours, the effects of fly ash and slag significantly reduced the magnitude of the creep. Neville and Brooks (1975) showed that, when creep tests are performed at ordinary room temperature and humidity conditions (i.e., 20°C and 60% relative humidity) on test specimens that have been loaded after moist curing for 28 days, the total creep of the concrete incorporating a slag from a British source was greater than that of the control concrete, although not significantly so. The rationale for this finding may be that under such test conditions, the rate of gain of strength of the slag concrete is lower than that of the control concrete.

2.2.3.8 Permeability

The permeability of concrete depends mainly on the permeability of the cement paste, which, in turn, depends on its pore-size distribution. Using mercury-intrusion techniques, several investigators (Manmohan and Mehta, 1981; Mehta, 1983) demonstrated that incorporating granulated slags in cement paste helps transform large pores into smaller pores, resulting in decreased permeability of the matrix and, hence, of the concrete. The exact mechanism by which the pore refinement occurs in a hydrated slag-cement matrix, however, is not fully understood. Detailed data comparing the permeability of concrete with and without slags are not available, although it has been observed that granulated slag concretes incorporating slags at up to 75% cement replacement have performed satisfactorily when exposed to seawater (Wiebenga, 1980).

2.2.4 Durability of Concrete Incorporating Blast-Furnace Slag

It is believed that the increased durability of Portland cement concrete incorporating blast-furnace slag results from a finer pore structure and a reduction in easily leached calcium hydroxide in the hardened cement paste. Subsequently, the volume previously occupied by calcium hydroxide is filled in with hydration products, resulting in a less-permeable material. Permeability controls the physical and chemical processes of degradation caused by the action of migrating water; therefore, permeability to water determines the rate of deterioration.

2.2.4.1 Resistance to Sulfate Attack

Sulfates attack concrete and affect its coherence and strength. The resistance of concrete to sulfate attack is improved by partially replacing Portland cement with ground granulated blast-furnace slag. In Germany, France, and the Netherlands, cements with a high blast-furnace slag content have been used for many years and are considered appropriate for use in a high-sulfate environment (DIN 1164, 1978; NEN 3550, 1979). Hogan and Meusel (1981) carried out a study that demonstrated high resistance to sulfate attack when the granulated slag proportion exceeded 50% of the total cementitious material; ASTM Type II cements were used. Results of studies carried out by Frearsen (1986) confirmed that ordinary Portland cements and blends of both ordinary and sulfate-resisting Portland cement containing lower levels of granulated slag replacement have inferior resistance to sulfate attack. Sulfate resistance increased with granulated slag content, and a mortar with 70% slag content was found to have a resistance superior to mortars containing sulfate-resisting Portland cements alone. Also, the influence of slag content on sulfate resistance was found to be more significant than the water/cement ratio in the mixtures investigated. According to Ludwig (1989), the cements exhibiting resistance to sulfate attack are:

- Portland cement with C_3A content ≤ 3 wt%
- Portland cement with $\leq 70\%$ slag content
- Nonstandard cements such as high-alumina and supersulfated cements

Bakker (1983) found that slag concretes with a high slag content display an increased resistance to sulfates because of the low permeability of the concrete to different ions and water, as shown by the various coefficient values in Table 2.10.

Where granulated slag is used in sufficient quantities, several changes occur that improve resistance to sulfate attack. These changes include the following:

- The C_3A content of the mixture is proportionally reduced depending on the percentage of slag used; however, Lea (1970) reported that increased sulfate resistance depends not only on the C_3A content of Portland cement alone but also on the Al_2O_3 content of the granulated slag. Lea further reported that sulfate resistance increased where the alumina content of the slag is less than 11%, regardless of the C_3A content of the Portland cement when blends with 20 to 50% granulated slags were used.

TABLE 2.10 Diffusion Coefficients of Na, K, and Cl Ions in Hardened Cement Paste and Mortars Made with Portland and Blast-Furnace Cement after Different Hardening Times

Diffused Ion	Hardening Time (days)	D_m (10^{-8} cm ² /sec)			Slag Content (%)

- Through the reduction of soluble Ca(OH)₂ in the formation of calcium silicate hydrates (CSHs), the environment for the formation of ettringite is reduced. Resistance to sulfate attack is greatly dependent on the permeability of the concrete or cement paste. The formation of CSH in pore spaces usually occupied by alkalis and Ca(OH)₂ reduces the permeability of the paste and prevents the intrusion of aggressive sulfates.

Mehta (1981) tested pastes incorporating natural pozzolans, rice-husk ash, and granulated slag. The 28-day-old paste of the blended cement containing 70% blast-furnace slag showed excellent resistance to sulfate attack. Few large pores were present in the hydrated paste, although the total porosity (pores >45 Å) was the highest among all the cements tested. The direct relationship between sulfate resistance of a cement and the slope of its pore-size distribution plot in the range of 500 to 45 Å probably shows that the presence of a large number of fine pores is associated with improved sulfate resistance of the material (Figure 2.12). Although the total porosity of the cement containing 30% slag was considerably less than the cement containing 70% slag, the former was not found to be sulfate resistant. On the basis of the test results, Mehta proposed that the chemical resistance of blended Portland cements results mainly from the process of pore refinement, which is associated with the pozzolanic reactions involving the removal of Ca(OH)₂.

2.2.4.2 Resistance to Seawater

The action of sulfate in seawater on concrete is rather similar to that of sulfate-bearing groundwater, but in the former case the attack is not accompanied by expansion of the concrete. The absence of expansion is partly due to the presence of a large quantity of chlorides in the seawater that inhibit the expansion; gypsum and calcium sulfoaluminate are more soluble in a chloride solution than in water, so they either do not form or are leached out by the seawater.

Regourd et al. (1977) studied mortar cubes that had been exposed to seawater since 1904 at the port of La Rochelle, France. They concluded that all Portland slag cements with a slag content >60% perform well in seawater. In the case of lower slag content, the MgSO₄ reacts with the Ca(OH)₂ from C₃S and C₂S hydration and produces gypsum. The gypsum reacts with the aluminates to form expansive ettringite. Mehta (1989), on the other hand, proposed that the deterioration of concrete by seawater is not characterized by expansion but rather is affected by erosion or loss of the solid constituents from the mass. Mehta suggested that ettringite expansion is suppressed in environments where (OH)⁻ ions have been replaced by Cl⁻ ions.

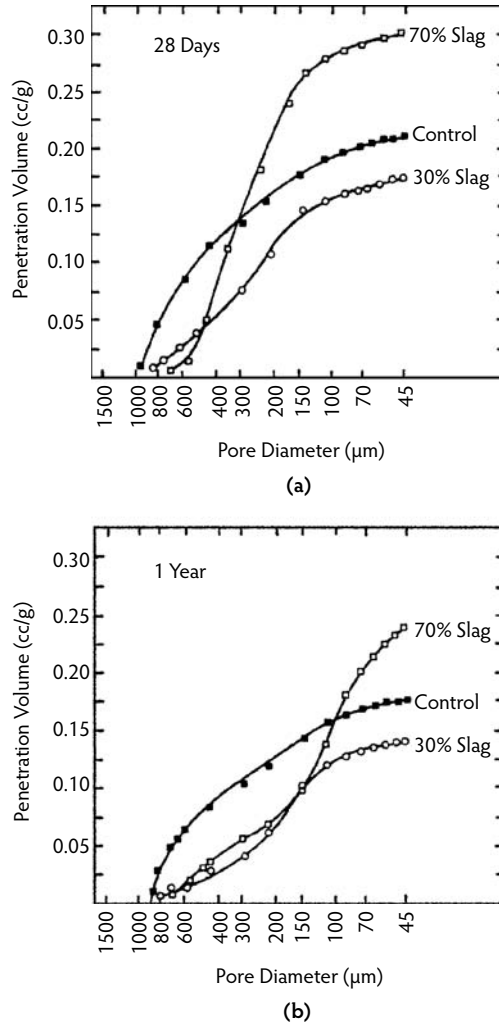

FIGURE 2.12 Pore-size distribution of hydrated cements containing 30% or 70% granulated blast-furnace slag. (From Mehta, P.K., in *Proceedings of the Fifth International Symposium on Concrete Technology*, Rivera, R., Ed., Monterey, Mexico, 1981, pp. 35–50.)

In seawater, well-cured concretes containing large amounts of granulated slag or pozzolan usually outperform reference concretes containing only Portland cement, partly because the former contain less uncombined $\text{Ca}(\text{OH})_2$ after curing. In permeable concretes, the normal amount of CO_2 present in seawater is sufficient to decompose the cementitious products. The presence of calcium silicocarbonate (thaumasite), calcium carboaluminate hydrate (hydrocalumite), and calcium carbonate (aragonite) have been reported in cement pastes derived from deteriorated concretes exposed to seawater for long periods.

2.2.4.3 Reduction of Expansion Due to Alkali-Silica Reactions

In concrete containing reactive siliceous aggregates, slag cements are preferable to Portland cements, which are rich in alkalis (Regourd, 1980). Research undertaken at the Concrete Research Institute of the Dutch Cement Industry and by other investigators (Smolczyk, 1974, 1975) confirmed that the reason for the high resistance of concretes incorporating slags to the alkali-silica reaction is the low permeability

of these concretes to various ions and to water. The low permeability is due not only to the amount of gel formed but also to the locality where the gel is precipitated; that is, the gel can block a pore when Portland cement and slag grains are close to each other. The potential alkali–aggregate reactivity for combinations of Portland cement and granulated slag was investigated by Hogan and Meusel (1981) using ASTM Test C 227; the aggregate used was Pyrex® glass, known to be highly reactive. The data indicate that the expansion of mortar bars made with slag–cement mixtures and Pyrex® glass is significantly less than for bars made with Portland cement alone. The cement used for these tests had an alkali content of 0.51% sodium oxide equivalent, which conforms to the ASTM C 150 specification for Portland cement requirement for low-alkali cement. Suppression of the alkali–aggregate reaction by the addition of slag was cited by Mather (1965), who suggested that an alkali limit for Portland slag cements, which have a performance equal to that of 0.60% Na₂O for Portland cements alone, could be as high as 1.20% Na₂O equivalent.

2.2.4.4 Resistance to Repeated Cycles of Freezing and Thawing

Many studies have been published in which granulated blast-furnace slag has been used as partial replacement for Portland cement in concrete subjected to repeated cycles of freezing and thawing (Fulton, 1974; Klieger and Isberner, 1967; Mather, 1957). Results of these studies indicated that, when mortar or concrete made with granulated slag and Portland cement were tested in comparison with Type I and Type II cements, their resistance to freezing and thawing (ASTM C 666, Procedure A) was essentially the same, provided the concrete was air entrained. Malhotra (1983b) reported results of tests performed in an automatic unit capable of performing eight freezing and thawing cycles per day (ASTM C 666, Procedure B). The percentage of slag used as replacement for normal Portland cement varied from 25 to 65 wt% of cement. Initial measurements were taken at 14 days. After about every 100 cycles, the specimens were measured, weighed, and tested by resonant frequency and by the ultrasonic-pulse velocity method. The test was terminated at 700 freezing and thawing cycles. Durability of the exposed concrete prisms was determined from weight, length, resonant frequency, and pulse velocity of the test prisms before and after the freezing and thawing cycling, and relative durability factors (ASTM C 666) were calculated. The test results (Table 2.11) indicated that, regardless of the water/cement + slag ratio and whether the concretes were air entrained or air entrained and superplasticized, these specimens performed excellently in freezing and thawing tests, with relative durability factors greater than 91%.

2.2.5 Carbonation

Concrete exposed to air will partially release its free water from the layers next to the surface. During evaporation, the pore water in the concrete is replaced by air, and reactions between the CO₂ of the atmosphere and the alkali compounds of the concrete take place. This process between the CO₂ of the atmosphere and the hydration products of the hardened cement paste is called *carbonation*. The properties of the concrete, as well its protective properties against corrosion of reinforcing steel, are affected by these reactions. In general, in well-compacted low water/cement ratio slag concrete, carbonation is not a problem; however, if the concrete incorporates a large percentage of slag, is not cured properly, and has a high water/cement + slag ratio, then the depth of carbonation will exceed that for normal Portland cement concrete. Steel in the presence of high concentrations of hydroxyl does not corrode. Bird (1969) suggested that this passivity is the result of the formation of a protective film of gamma ferric oxide on the surface of the steel. As long as this protective film is maintained by a high pH and is not disrupted by aggressive substances, complete protection of the steel against corrosion is assured. Carbonation can reduce the pH to an extent determined by the permeability of the concrete. Hamada (1968) and Meyer (1968) agreed that carbonation proceeds more rapidly in concretes incorporating slag than in those made with ordinary Portland cement; however, this finding was disputed by Schröder and Smolczyk (1968), who pointed out that comparative tests should be based on specimens of equal initial permeability rather than on specimens of equal age.

2.3 Silica Fume

2.3.1 Production of Silica Fume

Silica fume is a byproduct of the manufacture of silicon or of various silicon alloys produced in submerged electric-arc furnaces. The type of alloy produced and the composition of quartz and coal, the two major components used in the submerged-electric arc furnace, greatly influence the chemical composition of silica fume (Malhotra et al., 1987). Most of the published data on the use of silica fume in cement and concrete are related to silica fume collected during the production of a silicon alloy containing at least 75% silicon.

2.3.1.1 Forms of Silica Fume

Silica fume is available commercially in several forms in both North America and Europe:

- *As-produced silica fume* is silica fume collected in dedusting systems known as *bag houses*. In this form, the material is very fine and has a bulk density of about 200 to 300 kg/m³, compared with 1500 kg/m³ for Portland cement (Malhotra et al., 1987). As-produced silica fume is available in bags or in bulk. Because of its extreme fineness, this form poses handling problems; in spite of this, the material can be and has been transported and handled like Portland cement.
- *Compacted silica fume* has a bulk density ranging from 500 to 700 kg/m³ and is considerably easier to handle than as-produced silica fume. To produce the compacted form, the as-produced silica fume is placed in a silo, and compressed air is blown in from the bottom of the silo. This causes the particles to tumble, and in doing so they agglomerate. The heavier agglomerates fall to the bottom of the silo and are removed at intervals. The air compaction of the as-produced silica fume is designed so the agglomerates produced are rather weak and quickly break down during concrete mixing. Mechanical means have also been used to produce compacted silica fume.
- *Water-based silica fume slurry* overcomes the handling and transporting problems associated with as-produced silica fume; the slurry contains about 40 to 60% solid particles. Typically, these slurries have a density of about 1300 kg/m³. Some slurries may contain chemical admixtures such as superplasticizers, water reducers, and retarders. One such product (known as Force 10,000®) has been successfully marketed in North America.

2.3.2 Physical and Chemical Characteristics of Silica Fume

2.3.2.1 Physical Characteristics of Silica Fume

Silica fume varies in color from pale to dark gray. The carbon content and, to a lesser extent, the iron content seem to have significant influence on the color of silica fume. The bulk specific weight is of the order of 200 kg/m³ and is 500 kg/m³ when compacted. The specific gravity of silica fume is about 2.20. The particles have a wide range of sizes, but they are perfectly spherical (Figure 2.13). The mean particle diameter is 0.1 μm, compared with 10 μm for particles of cement. The specific surface of silica fume ranges from 13,000 to 30,000 m²/kg as measured by the nitrogen adsorption technique; the values for Portland cement are 300 to 400 m²/kg as measured by the Blaine method. Table 2.12 gives values for the fineness, specific surface, pozzolanic activity index, and specific gravity for silica fume from the production of silicon and ferrosilicon alloys (Malhotra et al., 1987). X-ray diffractograms of samples of different types of silica fume have shown them to be vitreous. All the diffractograms exhibit a very wide scattering peak centered at about 4.4 Å, the most important peak of cristobalite (Figure 2.14). When heated to 1100°C, silica fume crystallizes in the form of cristobalite, except the FeSi-50% type, which crystallizes as enstatite, most probably due to the presence of a high amount of iron and magnesium oxide.

2.3.2.2 Chemical Composition of Silica Fume

The chemical composition of silica fume from different furnaces is given in Table 2.13. A change in the type of alloy manufactured may cause changes in the characteristics of the silica fume produced; therefore, it is important that concrete plants using silica fume know of any changes in the source of raw materials used for the furnace or changes in the nature of the alloy being produced by a plant.

2.3.3 Physical and Chemical Mechanisms in the Cement-Silica Fume System

2.3.3.1 Physical Mechanisms

Silica fume enhances the properties of concrete by several physical mechanisms, including increasing the strength of the bond between the paste and aggregate by reducing the size of the CH crystals in the region by: (1) providing nucleation sites for the CH crystals so they are smaller and more randomly oriented, and (2) reducing the thickness of the weaker transition zone (Detwiler and Mehta, 1989; Monteiro and Mehta, 1986). Physical mechanisms also include increasing the density of the composite system due to

the filler packing effect and by providing a more refined pore structure (Bache, 1981; Hjorth, 1982; Sellevold and Nilsen, 1987). For the above mechanisms to take place, it is essential that silica-fume particles be well dispersed in a concrete mixture. To achieve this, the use of high-range water reducers (superplasticizers) becomes almost mandatory.

2.3.3.2 Chemical Mechanisms and Pozzolanic Reactions

Malhotra et al. (1987) have reported extensively on the chemical reactions involved in the cement–silica fume–water system. In the presence of Portland cement, the basic reaction, known as the *pozzolanic reaction*, involves combining finely divided amorphous silica with lime to form a calcium silicate hydrate.

2.3.4 Properties of Fresh Concrete

2.3.4.1 Color

In general, the color of silica-fume concrete is darker than that of conventional concrete. This color difference is more evident on the surface of wet-hardened concrete and in fresh concrete. Also, in concretes incorporating high levels of silica fume that has high carbon content, the dark color is more pronounced. In investigations of silica-fume concrete made with dark-colored fume, it was observed that the color difference disappeared when concrete specimens were stored in the laboratory environment for extended periods. Presumably, this difference in color was neutralized by drying and perhaps by carbonation.

2.3.4.2 Water Demand

Due to its spherical, small particles, silica fume fills the pores between larger grains of cement and gives a better particle-size distribution, leading to a decrease in water demand in silica-fume concrete; however, the high specific area of the silica-fume particles tends to increase water demand, giving a net effect of increased water demand compared to Portland cement concrete with the same level of workability. Figure 2.15 shows that the increase in water demand is almost directly proportional to the amount of silica fume used in concretes that have an initial water/cement ratio of 0.64 (Carette and Malhotra, 1983). Superplasticizers or high-range water reducers can be used in silica-fume concretes to reduce the water demand. In a study using high-resolution nuclear magnetic resonance (NMR) in combination with thermal analysis (DTA/TG), Justnes et al. (1992) investigated the pozzolanicity of condensed silica fume

FIGURE 2.15 Relation between water requirement and dosage of silica fume for concrete with a $W/(C + SF)$ of 0.64. (From Carette, G.G. and Malhotra, V.M., *ASTM J. Cement, Concrete, Aggregates*, 5(1), 3–13, 1983.)

in cement pastes. Their results confirmed that condensed silica fume is a very reactive pozzolan. The conversion rate of condensed silica fume to hydration products after 3 days of curing was higher than for cement at the same age. In a parallel study, Sellevold and Justnes (1992) studied the decrease in relative humidity and chemical shrinkage during hydration for sealed cement pastes. The Portland cement pastes incorporated 0, 8, and 16% condensed silica fume and had water/cement + silica fume ratios of 0.2, 0.3, and 0.40, respectively. They found that the relative humidity (RH) decreased rapidly during the first 2 weeks and reached about 78% after more than a year for the pastes with the lowest water/cement + silica fume ratios; the value for the paste with the highest water/cement + silica fume ratio was about 87% RH. According to the authors, the decrease in RH is the main cause of increased cracking tendency in high-strength concretes that incorporate silica fume.

2.3.4.3 Bleeding

Bleeding of silica fume concretes is generally lower than that of plain Portland cement concrete. The extremely fine silica-fume particles attach themselves to the cement particles, reducing the channels for bleeding and leaving very little free water available in the fresh concrete.

2.3.4.4 Workability

When compared to Portland cement concrete, silica-fume concrete is more cohesive and resistant to segregation due to the increase in the number of solid-to-solid contact points. Silica-fume concrete also tends to lose slump rapidly, and a higher initial slump than that of a conventional concrete is often required. In lean concretes incorporating less than 300 kg/m^3 cement, however, workability appears to improve when silica fume is added.

2.3.4.5 Air Entrainment

Because of the extremely high surface area of the silica fume, the dosage of air-entraining admixture required to produce a certain volume of air in silica fume concretes increases considerably with increasing silica-fume dosage. The presence of carbon in the silica fume adds to the increase in air-entraining admixture demand. It has been reported that entrainment of more than 5% air is difficult in concretes that incorporate high amounts of silica fume, even in the presence of a superplasticizer (Carette and Malhotra, 1983).

2.3.4.6 Shrinkage Cracking

Shrinkage cracking occurs in fresh concrete under curing conditions that cause a net removal of water from exposed concrete surfaces, thus creating tensile stresses beyond the low early-age tensile strength capacity of concretes. As concretes containing silica fume show little or no bleeding, thus allowing very little water to rise to the surface, the risk of cracking is high in fresh concrete. Shrinkage cracking can be a very serious problem under curing conditions of elevated temperatures, low humidity, and high winds, which allow rapid evaporation of water from freshly placed concrete. Johansen (1980) and Sellevold (1984) reported that fresh concrete is most vulnerable to shrinkage cracking as it approaches initial set. To overcome this problem, the surface of concrete should be protected from evaporation by covering it with plastic sheets or wet burlap or by using curing compounds and evaporation-retarding admixtures.

2.3.4.7 Setting Time

Ordinary mixtures (with 250 to 300 kg/m³ cement) that incorporate small amounts of silica fume, up to 10% by weight of cement, exhibit no significant difference in setting times compared with conventional concretes. As silica fume is invariably used in concretes in combination with water reducers and superplasticizers, the effect of silica fume on the setting of concrete is masked by the effects of the admixtures. Investigations by Bilodeau (1985) showed that the addition of 5 to 10% silica fume to superplasticized and nonsuperplasticized concretes had a negligible effect on the setting time of concrete; however, in concrete with a water/cementitious materials ratio of 0.40 and 15% silica fume, there was a noticeable delay in setting time. The high dosage of superplasticizer used because of the high silica-fume content in the concrete could have contributed to the setting delay (Bilodeau, 1985).

2.3.5 Properties of Hardened Concrete

2.3.5.1 Compressive Strength

It is well recognized that silica fume can contribute significantly to the compressive strength development of concrete. This is because of the filler effect and the excellent pozzolanic properties of the material, which translate into a stronger transition zone at the paste–aggregate interface. The extent to which silica fume contributes to the development of compressive strength depends on various factors, such as the percentage of silica fume, the water/cement + silica fume ratio, cementitious materials content, cement composition, type and dosage of superplasticizer, temperature, curing conditions, and age.

Superplasticizing admixtures play an important role in ensuring optimum strength development of silica-fume concrete. The water demand of silica-fume concrete is directly proportional to the amount of silica fume (used as a percentage replacement for Portland cement) if the slump of concrete is to be kept constant by increasing the water content rather than by using a superplasticizer. In such instances, the increase in the strength of silica-fume concrete over that of control concrete is largely offset by the higher water demand, especially for high silica-fume content at early ages. In general, the use of superplasticizer is a prerequisite to achieving proper dispersion of the silica fume in concrete and fully utilizing the strength potential of the fume. In fact, many important applications of silica fume in concrete depend strictly upon its utilization in conjunction with superplasticizing admixtures.

Silica-fume concretes have compressive strength development patterns that are generally different from those of Portland cement concretes. The strength development characteristics of these concretes are

somewhat similar to those of fly-ash concrete, except that the results of the pozzolanic reactions of the former are evident at earlier ages. This is due to the fact that silica fume is a very fine material with a very high amorphous silica content. The main contribution of silica fume to concrete strength development at normal temperatures takes place between the ages of about 3 and 28 days. The overall strength development patterns can vary according to concrete proportions and composition and are also affected by the curing conditions.

Carette and Malhotra (1992) reported investigations dealing with the short- and long-term strength development of silica-fume concrete under conditions of both continuous water curing and dry curing after an initial moist-curing period of 7 days. Their investigations covered superplasticized concretes incorporating 0 and 10% silica fume as a replacement by weight for Portland cement and water/cement + silica fume ratios ranging between 0.25 and 0.40. As expected, the major contributions of silica fume to the strength took place prior to 28 days; the largest gains in strength of the silica-fume concrete over the control concrete were recorded at the ages of 28 and 91 days, although this gain progressively diminished with age. For concretes with water/cement + silica fume ratios of 0.30 and 0.40, the gain largely disappeared at later ages. Under air-drying conditions, the strength development pattern was found to be significantly different from that of water-cured concretes up to the age of about 91 days; thereafter, however, air drying clearly had some adverse effect on the strength development of both types of concrete. The effect was generally more severe for silica-fume concrete, where some reduction in strength was recorded between the ages of 91 days and 3.5 years, especially for concretes with water/cement + silica fume ratios of 0.30 and 0.40. These trends of strength reduction have not yet been clearly explained, but they appear to stabilize at later ages and therefore are probably of little practical significance.

Curing temperatures have also been shown to affect significantly the strength development of silica-fume concrete. This aspect has been examined in some detail by several investigators in Scandinavia. In general, these investigations have indicated that the pozzolanic reaction of silica fume is very sensitive to temperature, and elevated-temperature curing has a greater strength-accelerating effect on silica-fume concrete than on comparable Portland cement concrete. The dosage of silica fume is obviously an important parameter influencing the compressive strength of silica-fume concrete. For general construction, the optimum dosage generally varies between 7 and 10%; however, in specialized situations, up to 15% silica fume has been incorporated successfully in concrete.

2.3.5.2 Young's Modulus of Elasticity

Based on the data published by various investigators, there appears to be no significant differences between the Young's modulus of elasticity (E) of concrete with and without silica fume. Malhotra et al. (1985) reported data on the Young's modulus of elasticity of Portland cement–blast-furnace slag–silica-fume concrete. They found no significant difference between the E values obtained at 28 days, regardless of the various percentages of silica fume and water/cementitious materials ratios.

2.3.5.3 Creep

The published data on the creep strain of silica-fume concrete are sparse; Bilodeau et al. (1989) reported an investigation on the mechanical properties, creep, and drying shrinkage of high-strength concretes incorporating fly ash, slag, and silica fume. The cementitious-material content of the concretes was about 530 kg/m^3 , and the water/cementitious material ratio was 0.22. In addition to the reference concrete, concretes with silica fume at 7 and 12% cement replacements, fly ash at 25% cement replacement, slag at 40% cement replacement, a combination of 7% silica fume and 25% fly ash, and 7% silica fume and 40% slag were investigated. Specimens of these concretes were subjected to creep loading after 35 days of moist curing and an applied stress equivalent to 35% of the compressive strength. After one year, the creep strains of the reference, 7% silica fume, and 12% silica fume concretes were 1505×10^{-6} , 713×10^{-6} , and 836×10^{-6} , respectively. For concrete with 7% silica fume and 40% slag, the creep strain measured was the lowest at 641×10^{-6} . The pore structure and minimal quantity of free water in concrete with the highest amount of supplementary materials could have resulted in these very low creep values, about 40% of the creep of the reference concrete.

2.3.5.4 Permeability

The incorporation of supplementary cementing materials such as fly ash, slag, silica fume, and natural pozzolans in concrete results in fine pore structure and changes to the paste–aggregate interface, leading to a decrease in permeability. This decrease is much higher in concretes incorporating silica fume, due to its high pozzolanicity. The filler and pozzolanic activity of the silica fume, as well as the virtual elimination of bleeding, improve the interfacial zone through pore refinement. Plante and Bilodeau (1989) reported that the addition of 8% silica fume significantly reduced the penetration of chloride ions into concrete. With increasing cementitious materials content and decreasing water/cementitious materials ratios, the chloride-ion penetration was reduced further. At a water/cement + silica fume ratio of 0.21 and 500 kg/m³ cement and 40 kg/m³ silica fume, the chloride-ion penetration was found to be 196 coulombs at 28 days, compared to 1246 C for the reference concrete. This reduction is primarily due to the refined pore structure and increased density of the matrix.

2.3.6 Durability Aspects

2.3.6.1 Carbonation

Silica fume, like other pozzolanic materials, reduces the Ca(OH)₂ content of the concrete, and this promotes a faster rate of carbonation. On the other hand, this effect may be offset by the more impermeable nature of silica-fume concrete, which tends to impede the ingress of CO₂ into concrete. The net effect can be somewhat variable, as it depends on various factors such as silica-fume content, water/cementitious materials ratio, and curing conditions, all of which can have a determinant influence on the ultimate Ca(OH)₂ content and permeability of the concrete. Vennesland and Gjorv (1983) reported that using up to 20% silica fume as an addition to cement in concrete, in combination with the use of a plasticizer, reduced the rate of carbonation. The concrete specimens were initially moist cured for a period of 7 days prior to air storage at 60% relative humidity. Carette and Malhotra (1992) compared the rate of carbonation of silica-fume concrete with that of reference Portland cement concrete up to the age of 3.5 years. The test specimens had been initially moist cured for 7 days before being stored under ambient room drying conditions. At a water/cementitious materials ratio of 0.25, they found that all concretes remained free of any noticeable carbonation during a 3.5-year period, whereas at a water/cement + silica fume ratio of 0.40, all specimens exhibited signs of carbonation, the effect being slightly more marked for the silica-fume concrete. In general, however, it is agreed that carbonation is not a problem in adequately cured, high-quality, low water/cement ratio concrete, and this also applies to silica-fume concrete.

2.3.6.2 Chemical Resistance

Chemical attack on concrete causes destructive expansion and decomposition of the cement paste, leading to severe deterioration. A permeating solvent as innocuous as water can result in the leaching of calcium hydroxide liberated from the hydration of cement. The ingress of chemicals and acids into concrete allows them to react with calcium hydroxide to form water-soluble salts that leach out of concrete, increasing the permeability of concrete and allowing further ingress of chemicals. Sulfates react with calcium hydroxide, forming ettringite, which causes expansion and cracking of the concrete. Silica-fume concretes have better resistance to chemicals than comparable Portland cement concretes due to the depletion of calcium hydroxide liberated during the hydration of Portland cement by means of pozzolanic reaction with silica fume, which thus reduces the amount of lime available for leaching, and also due to the decrease in permeability resulting from the refined pore structure of the mortar phase of the concrete.

Mehta (1985) compared the chemical resistance of low water/cement ratio (0.33 to 0.35) concretes exposed to solutions of 1% hydrochloric acid, 1% sulfuric acid, 1% lactic acid, 5% acetic acid, 5% ammonium sulfate, and 5% sodium sulfate. Specimens of a reference concrete, latex-modified concrete, and silica-fume concrete with 15% silica fume by weight of cement were used, and the criteria for failure

was 25% weight loss when fully submerged in the above solutions. The investigation showed that concrete incorporating silica fume better resisted chemical attacks than did the other two types of concrete. The only exception was the silica-fume concrete specimens immersed in ammonium sulfate solution which performed poorly. This was attributed to the ability of the ammonium salts to decompose the calcium silicate hydrate in the hydrated cement paste.

2.3.6.3 Freezing and Thawing Resistance

Extensive laboratory and field experience in Canada and the United States has shown that, for satisfactory performance of concrete under repeated cycles of freezing and thawing, the cement paste should be protected by incorporating air bubbles, 10 to 100 μm in size, using an air-entraining admixture. Briefly, the most important parameters concerning the entrainment of air in concrete are the air content, bubble-spacing factor, and specific surface. For satisfactory freezing and thawing resistance, it is recommended that air-entrained concrete should have bubble-spacing factor (\bar{L}) values of less than 200 μm and specific surface (α) greater than 24 mm^{-1} . Usually, fresh Portland cement concrete incorporating between 4 to 7% entrained air by volume will yield the above values of \bar{L} and α .

Several investigators have performed studies on the freezing and thawing resistance of silica-fume concrete. These include, among others, Sorensen (1983), Gjørsvik (1983), Carrette and Malhotra (1983), Malhotra (1984), Yamato et al. (1986), Hooton (1987b), Hammer and Sellevold (1990), Virtanen (1985), Pigeon et al. (1986), and Batrakov et al. (1992). In one CANMET investigation, the freezing and thawing resistance of non-air-entrained and air-entrained concrete incorporating various percentages of silica fume was compared (Malhotra, 1984). The study led to the following conclusions:

- *Non-air-entrained concrete:* Non-air-entrained concrete, regardless of the water/cement + silica fume ratio and irrespective of the amount of condensed silica fume, shows very low durability factors and excessive expansion when tested in accordance with ASTM C 666 (Procedure A or B). The concrete appears to show somewhat increasing distress with increasing amounts of fume; therefore, the use of non-air-entrained condensed silica-fume concrete is not recommended when it is to be subjected to repeated cycles of freezing and thawing.
- *Air-entrained concrete:* Air-entrained concrete, regardless of the water/cement + silica fume ratio and containing up to 15% condensed silica fume as partial replacement for cement, performs satisfactorily when tested in accordance with ASTM C 666 (Procedures A and B). However, concrete incorporating 30% of the fume and a water/cement + silica fume ratio of 0.42 performs very poorly (durability factors less than 10), regardless of the procedure used. This is probably due to the fact that the hardened concrete has high values of \bar{L} , or it might be due to the high amount of condensed silica fume in concrete, resulting in a very dense cement matrix system that, in turn, might adversely affect the movement of water. It is difficult to entrain more than 5% air in the above type of concrete, and this amount of air may or may not provide satisfactory \bar{L} values in hardened concrete for durability purposes. The users are therefore asked to exercise caution when using high percentages of condensed silica fume as replacement for Portland cement in concretes with water/cement + silica fume ratios of the order of 0.40 if these concretes are to be subjected to repeated cycles of freezing and thawing.

2.3.6.4 Frost Resistance in the Presence of Deicing Salts

Limited published data are available on the deicing salt scaling resistance of silica-fume concrete. Gagne et al. (1990) reported that the frost resistance of concrete incorporating 6% silica fume as an addition to cement is satisfactory in the procedure of deicing salt scaling tests (ASTM C 672). This was true for both air-entrained and non-air-entrained concrete. The water/cement + silica fume ratio of the concretes ranged from 0.23 to 0.30, and the concretes were air dried for 28 days before being subjected to the deicing salt scaling test. Using the ASTM C 672 tests, Bilodeau and Carrette (1989) investigated the deicing salt scaling resistance of Portland cement concrete and concretes incorporating 8% silica fume

as replacement for cement. In their investigation, superplasticized and nonsuperplasticized concretes were made, with water/cementitious materials ratios ranging from 0.40 to 0.65, all having adequate air-void parameters. They reported that, in general, all concretes performed satisfactorily under the action of deicing salts, although the silica-fume concrete exhibited a slightly inferior performance when compared to that of Portland cement concrete. In particular, silica-fume concrete with a water/cement + silica fume ratio of 0.60 showed appreciable weight loss after 50 cycles.

2.3.6.5 Role of Silica Fume in Reducing Expansion Due to Alkali-Silica Reaction

A number of laboratory investigations have indicated that silica fume, like other pozzolans, is effective in reducing the above-mentioned expansions due to alkali-silica reactions; however, the percentage of silica fume to be incorporated into concrete would depend on the type of reactive aggregate, the exposure conditions, the alkali and silica contents, the silica fume used, the type of cement used, and the water/cementitious materials ratio of the mixture. Published data indicate that the percentage replacement of cement by silica fume may range from about 10 to 15% (Durand, 1991). CANMET-funded studies have indicated that silica fume is not effective in controlling expansions due to alkali-carbonate reactions (Chen and Sunderman, 1990). At present, no significant well-documented data are available as to the long-term effectiveness of silica fume in controlling alkali-silica expansions in actual field structures. Based on current knowledge, it is recommended that those contemplating the use of silica fume to control expansion due to alkali-silica reactions perform accelerated tests in the laboratory, using the materials to be employed on a job site, to determine the percentage of silica fume to be used as replacement for cement.

2.4 Highly Reactive Metakaolin

Highly reactive metakaolin has recently become available as a very active pozzolanic material for use in concrete. Unlike fly ash, slag, or silica fume, this material is not a byproduct but is manufactured from a high-purity kaolin clay by calcination at temperatures in the region of 700 to 800°C (Caldarone et al., 1994). The material, ground to an average particle size of 1 to 2 μm , is white in color. In 1994, a plant was commissioned in Atlanta to produce the material on a commercial scale.

2.4.1 Chemical and Mineralogical Composition

Unlike silica fume, which contains more than 85% SiO_2 , highly reactive metakaolin contains equal proportions of SiO_2 and Al_2O_3 by mass. A typical oxide analysis is given below:

SiO_2	Al_2O_3	Fe_2O_3	CaO	MgO	Alkalis	Loss on Ignition
51	40	1	2	0.1	0.5	2

The highly reactive metakaolin derives its reactivity from the combination of two factors—namely, a totally noncrystalline structure and a high surface area. As far as mineralogical character is concerned, like silica fume, metakaolin is composed essentially of noncrystalline aluminosilicate (Si-Al-O) phase. Occasionally, a small amount of crystalline impurities may be present—that is, 1 to 2% of quartz, feldspar, or titania. The material has a specific surface of about 20 m^2/g and a specific gravity of 2.5.

2.4.2 Properties of Fresh Concrete

According to the limited published data, the initial and final setting time of concrete incorporating 10% of metakaolin by mass are comparable to those of control concrete and concrete incorporating

FIGURE 2.16 Autogenous temperature rise in control, silica fume, and metakaolin concretes.

10% silica fume. Also, the air-entraining admixture demand is similar to that of silica-fume concrete. Because of its very high specific surface, the bleeding of concrete incorporating metakaolin is negligible. According to the data published by Zhang and Malhotra (1995), the autogenous temperature rise of concrete made with metakaolin was higher than that of the control and silica-fume concrete at ages up to 6 days, indicating high reactivity of the material (Figure 2.16).

2.4.3 Mechanical Properties of Hardened Concrete

2.4.3.1 Strength Development

Table 2.14 gives some data on strength development and Young's modulus for concrete made with metakaolin; also, data on the control concrete and silica fume are included for comparison purposes. The faster strength development of the metakaolin concrete at early ages as compared with the silica-fume concrete is probably due to the faster rate of hydration, as discussed earlier.

2.4.3.2 Drying Shrinkage

Zhang and Malhotra (1995) investigated the drying shrinkage of concrete incorporating metakaolin; the data are shown in Figure 2.17, together with data for control and silica-fume concrete. The concretes were exposed to drying shrinkage after 7 days of initial curing in lime-saturated water. The metakaolin concrete had a lower drying shrinkage strain compared with that of the control and silica-fume concrete. After 112 days of drying at a relative humidity of 50%, the metakaolin concrete had a drying shrinkage strain of 427×10^{-6} compared with 596×10^{-6} for the control concrete.

2.4.4 Durability Aspects of Hardened Concrete

Air-entrained concrete incorporating 10% metakaolin by mass of cement has high resistance to the penetration of chloride ions and excellent durability in regard to repeated cycles of freezing and thawing. Table 2.15 and Table 2.16 show some test results on these above aspects of durability (Zhang and Malhotra, 1995). Limited data on the deicing salt scaling resistance of the metakaolin concrete indicates that its performance in the ASTM deicing salt scaling test (ASTM C 672) is comparable to that of silica-fume concrete but somewhat inferior to that of plain Portland cement concrete.

3.1 Introduction to Chemical Admixtures

In recent decades, tremendous success has been achieved in the advancement of chemical admixtures for Portland cement concrete. Materials scientists, chemists, engineers, and manufacturers' technical representatives have helped the concrete industry to improve our ability to control work times, workability, strength, and durability of Portland cement concrete. Most efforts have centered on improving the properties of concrete with minimal investments by ready-mix suppliers and contractors in the way of specialized equipment or special skills and education of their labor forces. This approach has resulted in construction cost reductions and universally accepted ready-made remedies for unexpected problems during construction.

The function of each admixture focuses on a specific need, and each has been developed independently of the others. Some admixtures already have chemistry that affects more than one property of concrete, and some have simply been combined for ease of addition during the batching process. Their definitions and specifications are discussed in the American Society for Testing and Materials (ASTM) C 494 and in the American Concrete Institute (ACI) *Manual of Concrete Practice* 212.3R and 212.4R. Retarders have been developed that allow for longer working times with minimal effect on the final cure strength. These retarders provide better finishing and higher quality concrete in the heat of the summer. Accelerators have been produced that initiate the cement hydration process much earlier in lower temperatures. Air-entraining agents were developed into commercial admixtures when it was observed that air entrainment

* Research Operations Manager, Research Engineer, Construction Materials Research Group, The University of Texas at Austin; expert in construction materials with emphasis on concrete durability, polymers, and other additives.

improved the resistance of concrete to freezing and thawing. This is accomplished by the production of many well-distributed tiny bubbles that act as pressure-relief mechanisms in the matrix whenever water in the pores expands and contracts under freezing and near-freezing conditions.

Water reducers, or plasticizers, have allowed finishers to place and work the concrete with much less water and thus produce higher strengths and more durable concrete. High-range water reducers (HRWRs), or superplasticizers, were developed to adjust the plasticity of low-water concrete to a consistency that can easily be pumped up to higher elevations without compromising strength or durability. Later, organic polymers such as latex and epoxies were developed to modify the concrete matrix in such a way as to improve the bond of the cured concrete to a given substrate or to reduce permeability and internally reinforce the cured matrix. Often, a stronger matrix is also a result. Monomer systems have also been used to impregnate cured Portland cement concrete, filling the small pores, capillaries, and voids with a liquid that quickly hardens, leaving a less porous, higher modulus, and more chemical-resistant concrete.

All of these admixtures have been refined to provide concrete designers and builders with increasing options and greater adaptability to an expanding variety of applications and ambient conditions. It is estimated that one or more chemical admixtures, not including air-entraining agents, are present in 80% of the concrete placed today, and the figure rises to almost 100% when air-entraining agents are included (Whiting et al., 1994).

The most commercially important chemical admixtures are described in the *ACI Manual of Concrete Practice* (ACI Committee 212 on Admixtures for Concrete) and ASTM C 494 (Specifications for Chemical Admixtures for Concrete); in the Canadian Standards Association's admixture standards A 266.1, A 266.2 M78 (chemical admixtures), A 266.4 M78 (guidelines for the use of admixtures), 266.5 M 1981 (guidelines for use of HRWRs), and 266.6 M85 (HRWR requirements); and in the Reunion Internationale des Laboratoires d'Essais et de Recherches sur les Matériaux et les Constructions (RILEM) *Guide for Use of Admixtures in Concrete*. To better understand recommended usage for various applications of these chemical admixtures in concrete, a review of each functional category is presented. This review would be simpler if each of the admixtures worked independently in the matrix, but the performance of each is often affected by the presence of another. For this reason, known reactions and interactions are discussed wherever appropriate for specific materials.

3.2 Retarding Admixtures

Retarding admixtures are used to slow down the initial set of the concrete whenever elevated ambient temperatures shorten working times beyond the practical limitations of normal placement and finishing operations. Retarders are specified in ASTM C 494 as Type B admixtures and are used in varying proportions, often in combination with other admixtures, so that, as working temperatures increase, higher doses of the admixture may be used to obtain a uniform setting time (ACI 305R). Simple retarders typically consist of one of four relatively inexpensive materials: lignin, borax, sugars, or tartaric acids or salts. Retarders serve best to compensate for unwanted accelerations of working times due to changes in temperature or cement or due to other admixture side effects. They also are used to extend the working time required for complicated or high-volume placements and for retarding the set of concrete at a surface where an exposed aggregate finish is desired.

Retarding admixtures interfere with the critical chemical reactions of the fastest hydrating cement reactant groups, C_3A and C_3S (Colleparidi, 1984). These reactants normally initiate the hydration process in the early stages. Eventually, the hydration process accelerates due to another initially slower reaction group, and the heat of reaction allows the hydration to continue at a normal rate until completion. Typical retardation effects are significant for the first 24 to 72 hours.

The intent is for concrete in its plastic state to be affected by retarders with little or no negative effect on the hardened properties. Improvements in fresh concrete properties include extended times for workability and set, better workability with less water, frequently an increase in air content, and minimal

FIGURE 3.1 Effect of delayed addition of retarding admixture on its retarding power. (From Mindess, S. and Young, J.F., *Concrete*, Prentice Hall, Englewood Cliffs, NJ, 1981.)

delay in final cure time. Retarders may reduce critical physical properties when used in excess. Changes in hardened concrete properties due to retarders usually relate to delayed early strength development, which may affect early (especially plastic) shrinkage and creep (Daugherty and Kowalewski, 1976).

Dosage rates vary considerably depending on the needs of the concrete application, ambient and material temperatures, retarder type and concentration, cement type and content, and presence of other admixtures in the concrete, but it generally is best to use the least amount necessary to produce the required properties. This is typically between 2 and 7 fluid ounces per 100 pounds cement (ACI 211.1-4) added with a portion of the mixing water a few minutes after the first addition of water. This is recommended to ensure the most efficient and uniform dispersion throughout the batch (Figure 3.1). Manufacturers' recommendations are a good place to start, but trial batches under the expected field conditions followed by a complete evaluation of effects on all critical properties should be conducted.

It should be noted that retardation may be a side effect of other chemical admixtures that are specified for the adjustment of other properties in the matrix. If the retardation effect is desirable and predictable, as in many water-reducing admixtures, the material is marketed as such (e.g., water-reducing and -retarding admixtures). Because users noticed that earlier water reducers tended to retard set times, today many retarders are meant to serve double duty as water reducers. This added functionality is discussed in the next section. If the retardation side effect is predictable but not desired, the simple addition of a compatible accelerator may be all that is necessary. If, however, the retardation side effect is not desired or predictable, an incompatibility may exist between the cement or other admixtures and the corrupting admixture (Dodson and Hayden, 1989; Johnston, 1987). Every effort must be made to determine the faulty ingredient and substitute it with a more compatible choice.

3.3 Water-Reducing Admixtures

Water-reducing agents, or plasticizers, are added to provide workability in the freshly mixed concrete matrix while using significantly lower amounts of mix water, thus achieving better strength and durability. These agents provide the lubricity in coarse mixes that would normally require additional paste or more water in the paste. According to ASTM C 494, these admixtures are classified as Type A and must allow at least a 5% reduction in water without changing the consistency or reducing the strength of the control batch having the higher water content without this admixture. They often are able to reduce the water demand by 10% and as much as 15% for even greater strength and durability benefits derived from lowering the water/cement ratio (Figure 3.2). This class of admixtures is typically made from relatively inexpensive lignosulfonates, hydroxylated carboxylic acids, or carbohydrates.

FIGURE 3.2 Typical relationship between 28-day compressive strength and water/cement ratio for a wide variety of air-entrained concretes using Type I cement. (From Kosmatka, S.H. and Panarese, W.C., *Design and Control of Concrete Mixtures*, 13th ed., Portland Cement Association, Skokie, IL, 1988.)

Several theories exist as to what mechanisms are responsible for the reduction in water demand in the plastic concrete matrix, but all agree that the improvement is mainly due to the chemical and physical effects of the water-reducing admixtures (WRAs) on the surface of the hydrating cement particles. Deflocculating and dispersion of the cement particles are the net result and allow better use of the available water for more uniform lubrication and hydration. Also, because many WRAs entrain as much as 2% air, increased lubricity is partly due to the distribution of tiny added air bubbles.

Many WRAs retard set times and are sometimes used with an accelerator for compensation. WRAs that are combined with an accelerator into one admixture are classified as Type E under ASTM C 494. Of course, retardation may be desired for higher temperature concreting conditions. Whenever the natural tendency of WRAs to retard hydration is not adequate for the desired application, additional retarders are added. Commercially available single admixtures that combine a retarder with the WRA are classified as Type D under ASTM C 494.

Many WRAs are associated with higher shrinkage rates and faster slump loss even though the water/cement ratio is reduced. Bleeding properties, too, are sometimes affected by the choice of WRA. To overcome these tendencies WRAs are often added at the batch plant along with much less of the more expensive, but more efficient, high-range (or mid-range) water reducers described in the next section.

Considerations for usage of WRAs are economically based, and strategies fall into the following three main categories (Collepari, 1984):

1. Reduce the water/cement ratio for higher strengths and improved durability while maintaining the same workability and cement content.
2. Reduce the paste portion of the matrix, water, and cement, for the purpose of reducing shrinkage and heat development in massive placements; workability, strength, and durability are maintained at a comparative level.
3. Keep water and cement the same and maintain the same strength and durability but improve flow and workability.

Efficient dosage rates vary with chemical composition of the WRA, individual batch designs, cement types, other admixtures, environmental conditions (Kosmatka and Panarese, 1988), flow and workability constraints in the job, and end-product needs. Manufacturers' guidelines typically recommend 2 to 7 fluid ounces per 100 pounds cement added into the mix water. These recommendations should be used as a starting place for several trial batches closely monitored for critical properties under field conditions in both the fresh and hardened states.

FIGURE 3.3 Effect of superplasticizers on slump loss. (From Mindess, S. and Young, J.F., *Concrete*, Prentice Hall, Englewood Cliffs, NJ, 1981.)

3.4 High-Range, Water-Reducing Admixtures

High-range water reducers (HRWRs) are also known as superplasticizers, super fluidizers, and super water reducers due to their higher efficiency than conventional WRAs in improving workability and flow of concrete mixes. They were developed for use where the amount of WRAs required to reach a desired slump or flow resulted in unacceptable reductions of other critical properties. Different chemistry enabled developers to produce an admixture that allowed contractors to place highly workable, pumpable, or even flowing concrete with higher strengths and greater durability and less shrinkage when the concrete mix was properly designed. The specifications for superplasticizers are detailed in ASTM C 494 as Type F for high-range water reduction with normal set times or Type G for high-range water reduction with retarded setting times. ASTM C 1017 specifies chemical admixtures for use in flowing concrete. HRWRs are typically one of four chemical groups: sulfonated melamine–formaldehyde condensate (SMF), sulfonated naphthalene–formaldehyde condensate (SNF), modified lignosulfonate (MLS), and others that may include sulfonic acid esters or carbohydrate esters (carboxylates). HRWRs deflocculate and disperse the cement particles in a similar manner but much more efficiently than WRAs. Superplasticizers can reduce water demand in the matrix by as much as 30%, and, because HRWRs can be added into the transit mixer at the plant and again at the jobsite, workability can continue to be customized at the site for specific application needs regardless of transit-time slump loss (Fisher, 1994) (Figure 3.3). HRWRs are often referred to as first-, second-, and third-generation superplasticizers:

1. First-generation superplasticizers are primarily anionic materials that create negative charges on the cement particles, resulting in reduced friction due to the same-charge particles repelling each other. These HRWRs have no effect on the hydration process, but using them to reduce water/cement ratios without the addition of retarders makes for quicker set times. Because of the shorter workability times, first-generation HRWRs are normally added at the jobsite. Their chemistry allows a reduction in water of 20 to 30%.
2. Second-generation superplasticizers, which are normally added at the batch plant, coat the cement particles with a thixotropic material; they lubricate the mix, allow lower water/cement ratios, and add a measure of control in the hydration process. Second-generation HRWRs can be used at higher concrete temperatures, thus reducing or eliminating the need for ice. Water demand is typically reduced 20 to 30%, and the higher workability time is extended.

3. Third-generation superplasticizers coat the cement particles and are added at the batch plant, just like the second-generation HRWRs. Third-generation superplasticizers offer the same advantages as second-generation HRWRs, plus they offer the added bonus of maintaining initial setting characteristics similar to normal concrete while producing a highly plastic mix at an extremely low water/cement ratio. Second-generation and third-generation superplasticizers are relatively expensive (typically \$5 to \$6 additional per yard of concrete), but they have proven themselves to be cost effective in such applications as hot weather concreting, wall placements, bucket and crane placements, slabs on grade, and pumped concrete (Guennewig, 1993). Modern trends are clearly moving toward the use of polycarboxylates over the older sulfonated lignins or melamine-based products, as they are so much more effective at deflocculating cement grains due to steric hindrance.

Strategies for the use of HRWRs include those listed in the WRA section above, but application-related considerations may dictate that HRWRs must be used and require decisions of which type and quantity are required to achieve the proper concrete placement. Determining optimal superplasticizer dosage can be a relatively complex task involving consideration of costs, rheology of the fresh concrete, mechanical properties at early ages, and long-term durability under expected service conditions. Optimal dosage is highly dependent on determination of the saturation concentration—the highest ratio of the mass of HRWR solids to the mass of cementitious materials over which any higher dosage will not significantly improve the workability of the paste (Gagné et al., 1996). This ratio is usually 0.8 to 1.2% and is affected by type and quality of superplasticizer, fineness of the cement, C_3A content, type and content of sulfates, and the speed and shearing action of the mixer employed (Baalbaki, 1990).

The ability of superplasticized concrete to flow through congested reinforcement and into otherwise inaccessible areas and a requirement for minimal vibration make it a natural choice in any applications presenting such problems. The ease with which it can be pumped and placed makes it a good choice for floors, structural and foundation slabs, pavements, bridges, and roof decks. Contractors and precasters prefer superplasticized concrete for its faster strength gain, improved surface details, and pigment dispersion in architectural applications. HRWRs are used in sprayed concrete applications, self-consolidating concrete, and tremie pipe placements because of the increased fluidity and higher strengths. High-performance concrete has been implemented primarily through the engineered concrete mix designs made possible by using HRWRs to reduce water/cement ratios and by adding high-surface fine materials such as silica fume and fly ash while maintaining good workability and minimal segregation. Consequently, higher and earlier strengths and increased durability are commonly expected and achieved.

Regular reporting of successful concrete applications relying on HRWRs has led to a tendency to think of HRWRs as a panacea for all concrete problems; however, good batch designs that consider the level of HRWRs to be added are critically important to avoid serious segregation, excessive bleeding, and needless extra expense. Normal mixes made flowable through the addition of HRWRs typically require an increase of approximately 5% more sand. Surface finishes can become mottled and irregular when too much HRWR is used. Water/cement ratios are critical to strength and durability, but, for even minimal workability and accounting for evaporation and substrate absorption, the practical lower water/cement ratio limits of concrete mixtures without HRWRs are well above the theoretical minimum required for complete hydration. Because HRWRs allow concrete to be made with the lowest water/cement ratios, care must be exercised to ensure that enough water is present in the matrix throughout the entire hydration process to fully hydrate all of the cement in the matrix.

As for WRAs, HRWRs tend to retard concrete setting times, but this effect may be compensated for or overridden by the addition of accelerating admixtures or the further addition of retarding admixtures. When a retarder is combined with a superplasticizer, the resulting admixture is classified by ASTM C 494 as Type G.

Slump loss is a problem of particular importance in high-slump or flowable concretes utilizing HRWRs. The rate of slump loss may be affected by the type and dosage of HRWR, other admixtures, order of addition, type and brand of cement, concrete temperature, and concrete batch design. Concrete that has

HRWRs added at the batch plant will tend to experience moderate to rapid slump loss, unless special slump-loss-control admixtures are also added. Normally, the higher dosage rates tend to slow down the rate of slump loss, and cement with higher levels of C_3A , as found in Type I and Type III cements, exhibit a more rapid rate of slump loss. Higher concrete temperatures also tend to accelerate the rate of slump loss (ACI Committee 212), but adherence to ACI Committee 305 hot-weather concreting procedures can minimize slump loss.

Entrained air content is initially increased by the addition of HRWRs, but redoing flowing concrete causes loss of entrainment with each dose. Also, air bubbles may have a tendency to be larger and coalesce in flowing concrete. Shrinkage and creep are generally as good as or better than control mixes, but flowing concrete may exhibit more shrinkage depending on water and cement content and the choice of HRWRs. Durability is generally better for concrete modified with HRWRs because strength is higher, cement particles are more uniformly dispersed and hydrated, and permeability of the hardened concrete is lower. Resistance to sulfate attack and abrasion should be better, and resistance to salt scaling and resistance to corrosion of reinforcing steel are comparable with control batches containing no superplasticizer (ACI Committee 212). As always, evaluation of trial batches cured under field conditions is highly recommended.

3.5 Accelerating Admixtures

Accelerators are commonly used to offset retardation effects from other admixtures, although overcoming weather-induced retardation due to colder temperatures at the job site is probably their primary application. Through the use of accelerators contractors can place concrete at much lower temperatures than would be practical without their use (ACI 306R). Accelerating admixtures are also commonly used to speed up normal set and cure times for purposes of earlier service than would be possible with an unaccelerated mix design. Such an application is most often the case for concrete repair mix designs and in prestressed or precast applications, where time delays cost customers or precasters significant amounts of money and inconvenience.

Accelerating admixtures should conform to ASTM C 494 Type C. These materials are predominantly calcium chloride or closely related salts because of their availability, relatively low costs, and more than a century of documented usage. Caution should be exercised, however, as the use of chloride accelerators will corrode reinforcement in concrete exposed to water. Other materials such as silicates, fluorosilicates, thiocyanates, alkali hydroxides, calcium formate, calcium nitrate, calcium thiosulfate, potassium carbonate, sodium chloride, aluminum chloride, and various organic compounds, including triethanolamine, are also used as accelerating admixtures (ACI 517.2R). Calcium nitrite is frequently recommended and commercially available as an accelerator that also inhibits corrosion of reinforcing steel wherever exposure to precipitation and salt from deicing materials or seawater is likely to initiate corrosion problems. Lignosulfonate, benzoates, phosphates, hypophosphates, chromates, fluorides, Calgon®, and alkali nitrates have also been promoted as corrosion inhibitors, too, but their effectiveness is not widely accepted.

Because of the long-term usage of calcium-chloride-based accelerating admixtures, many of their effects on concrete are well known and highly touted in manufacturers' literature. They should conform to ASTM D 98 requirements and be sampled and tested according to the procedures in ASTM D 345. Calcium chlorides are known to reduce initial and final setting times. The workability of the mix is usually improved by accelerators, and the air content of the matrix may be increased slightly with average-sized voids (Figure 3.4). Accelerators also tend to reduce the bleeding rate and bleeding capacity of concrete.

The effects of accelerators on hardened concrete are as important as they are for the fresh mix. Benefits of their use include accelerated strength development in both compression and in flexural modes, although less so in the latter. Modulus of elasticity, too, increases at a faster rate. Abrasion resistance and erosion resistance are improved with the use of accelerating admixtures, as is pore structure, due to reduced porosity. Frost resistance in concrete is better at early ages when calcium chloride accelerators are used, but performance declines with time, and resistance is actually worse at later ages. Other

FIGURE 3.4 Effect of set-modifying admixtures on strength development of concrete. (From Mindess, S. and Young, J.F., *Concrete*, Prentice Hall, Englewood Cliffs, NJ, 1981.)

disadvantages of using common calcium chloride accelerating admixtures in concrete include slight increases in drying shrinkage and creep increases from 20 to 35%, all of which may occur because rapid strength gain is usually obtained at the expense of reduced ultimate strength (Figure 3.4). Accelerators also often increase alkali-silica reactions and decrease resistance to external sulfate attack. Additionally, they are known to increase the rate of freeze-thaw scaling and of corrosion of steel reinforcement, except for those previously mentioned accelerating admixtures known as corrosion inhibitors (i.e., calcium nitrite and sodium thiocyanate) (Nmai et al., 1994). Accelerated concrete is also usually darker in color than unaccelerated concrete.

With these effects on properties in mind, the Portland Cement Association (PCA) recommends that calcium chloride and other admixtures containing soluble chlorides should not be used under the following conditions:

- Prestressed concrete, due to potential corrosion hazards
- Concrete containing embedded aluminum, due to serious corrosion problems in humid environments
- Concrete subjected to alkali-silica reactions or exposed to soil or water containing sulfates
- Floor slabs intended to receive dry-shake metallic finishes
- Hot ambient conditions or hot constituent materials such as aggregates or water
- Massive concrete placements

The PCA also recommends caution when using calcium chloride in the following applications (Kosmatka and Panarese, 1988):

- Concrete subjected to steam curing because of possible expansion problems with delayed ettringite formation
- Concrete containing embedded dissimilar metals, especially when electrically connected to reinforcing steel
- Concrete slabs supported on galvanized steel forms

The ACI 318 Committee on Building Code Requirements for Reinforced Concrete has recommended maximum allowable levels of chloride ions for corrosion protection in steel reinforced concrete under various service exposures. These levels are shown in Table 3.1. In spite of the cautions, calcium chlorides are used on a regular basis for interior concrete with predictable performance. Recommended usage rates vary with mixture designs, temperatures, and exposure conditions. As with any admixture,

TABLE 3.1 ACI 318 Maximum Chloride-Ion Content for Corrosion Protection (ACI 318/318R Building Code and Commentary)

Type of Application	Maximum Water-Soluble Chloride Ion (Cl ⁻) in Concrete (Percent by Weight of Cement)
Prestressed concrete	0.06
Reinforced concrete exposed to chloride in service	0.15
Reinforced concrete that will be dry or protected from moisture in service	1.00
Other reinforced concrete construction	0.30

though, no more should be used in the batching than is necessary to accomplish its intended purpose. Even then it is not generally used at rates higher than 2% of the weight of cement (Kosmatka and Panarese, 1988), and care must be taken to ascertain complete dissolution of all of the salt into the mixing water before adding it to the rest of the matrix to avoid popouts and serious local staining problems. Laboratory evaluations of field-cured trial batches are recommended before full-scale placements are made.

3.5.1 Accelerating Corrosion-Inhibiting Admixtures

When designers have concerns about corrosion of reinforcing steel under shallow concrete cover, corrosion-inhibiting admixtures are often prescribed as a mitigation strategy. This class of materials electrochemically interferes with the galvanic corrosion process by scavenging either electrons or protons near the steel reinforcement. The three general categories of corrosion inhibitors are:

1. *Anodic* or *active* corrosion inhibitors actively interfere with the corrosion process by occupying overactive electrons oxidizing rapidly dissolving ferrous oxide ions into an insoluble protective coating of ferric oxide on their way to the surface of the anodic steel reinforcement. Calcium nitrite is the primary material in this category, although sodium nitrite, sodium benzoate, and sodium chromate are also used outside the United States.
2. *Cathodic* or *passive* corrosion inhibitors indirectly interfere with the corrosion process by slowing down the cathodic reactions by serving as proton acceptors and thus impeding the corrosion current. They are normally highly alkaline materials that render the ferrous ions at the surface of the reinforcing steel insoluble in water and unable to participate in the corrosion current. The most commonly used materials in this category are sodium hydroxide, sodium bicarbonate, and ammonium hydroxide, although the use of organic materials such as substituted forms of aniline and mercaptobenzothiazole has been reported.
3. *Mixed* or *passive-active* corrosion inhibitors might be preferable over either of the previous two types by themselves, as this type attacks the problem at both ends of the reaction, interfering more completely with the corrosion process before it can begin. These materials can be in the form of more complicated organic molecules that are attracted to and tie up both cathodic and anodic sites, forming salts as they accept either the available electrons or protons. This category may also be a physical mixture of two simpler compounds where one component reacts at the cathodic reaction site while the other reacts at the anodic site.

Corrosion inhibitors are typically used at dosage rates of 1 to 4%, based on the weight of the cement. Properties of concrete are affected by the use of corrosion-inhibiting admixtures. Inorganic salts such as calcium nitrite are known accelerators, but organic corrosion inhibitors may retard set times. Workability may be improved at levels up to 2% but begins to degenerate above that. Hardened concrete strengths are often slightly diminished, and alkali-silica reaction may be aggravated by corrosion inhibitors if reactive aggregates are present in the matrix.

FIGURE 3.5 Relationship between air content and expansion of concrete test specimens during 300 cycles of freezing and thawing for various maximum aggregate sizes. (From Kosmatka, S.H. and Panarese, W.C., *Design and Control of Concrete Mixtures*, 13th ed., Portland Cement Association, Skokie, IL, 1988.)

3.6 Air-Entraining Admixtures

Air-entrained concrete was developed in the 1930s, and it is still recommended today for nearly every commercial application. Air-entraining agents are provided already ground into the cement (air-entrained cement) or as an admixture whose addition can be adjusted for individual batch design needs. Because air-entraining agents provide extremely small and well-dispersed air bubbles in the paste, they act as localized stress reducers in the cured matrix. This is advantageous in concrete exposed to moisture and especially to wet deicing chemicals during freezing and thawing conditions (Figure 3.5). Because the bubble voids provide room for microscopically localized expansions, resistance to damage from alkali-silica reactions and sulfate attack is enhanced as well. The trade-off is that air is compressible and not strength enhancing; therefore, some loss in strength of the concrete will result. A good rule of thumb is that every 1% increase in air content reduces the strength of a well-designed concrete 2 to 4% (Kosmatka and Panarese, 1988) (Figure 3.6). Generally, manufacturers recommend between 0.3 and 2.0 mL/kg cement depending on the specific air-entraining admixture, mineral admixtures also included in the batch, batch conditions, and the amount of air required. Manufacturers' recommendations for a specific air-entraining agent should be used as a guideline, but property evaluations should be made on several small batches before deciding on the optimum quantity required to produce the air content necessary for the batch design (Table 3.2).

Air-entraining admixtures are members of a class of chemicals known as surface-active substances or *surfactants*. These surfactants are made of molecules having a polar (water-attracted) head and a nonpolar (water-repulsed) tail. If the head is negatively charged, the surfactant is anionic, as represented by carboxylates, sulfonates, and sulfate esters. When the head is positively charged, the surfactant is cationic, as represented by substituted ammonium ion products. Nonionic surfactants are made of molecules with uncharged polar heads, and they are generally polyoxyethylenated compounds. Commercial air-entraining agents for concrete are inexpensive and have served the concrete industry well over time. They come from surfactants that can be categorized into the following seven groups (Dolch, 1984):

1. **Vinsol™** is the most widely used type of air-entraining admixture. It is the byproduct of the distillation and extraction of pine stumps for other materials. The leftover insoluble residue is neutralized in sodium hydroxide, resulting in the soluble solution used to produce entrained air in concrete.

FIGURE 3.6 Relationship between air content and 28-day compressive strength for concrete at three constant cement contents. Water content was reduced with increased air content to maintain a constant slump. (From Kosmatka, S.H. and Panarese, W.C., *Design and Control of Concrete Mixtures*, 13th ed., Portland Cement Association, Skokie, IL, 1988.)

TABLE 3.2 Properties of Typical Air-Entraining Admixtures

Product	Manufacturer	Active Ingredient	Dosage	Specific Gravity
Protex® Regular	Protex Industries	Neutralized Vinsol™ resin	0.3–1.0	1.044
Darex® AEA	W.R. Grace & Co.	Organic acid salts	0.65–1.95	1.00–1.05
Airex® “D”	Mulco, Inc.	Sulfonated HC salt	1.5–1.85	1.01–1.03
Oxy-Plastair	Sider-Oxydro, Inc.	Vinsol™ resin	1.4	—
Plastade	Sternson, Ltd.	Coconut acid amide	0.6–1.9	1.0

Source: Dolch, W.L., in *Concrete Admixtures Handbook: Properties, Science, and Technology*, Ramachandran, V.S., Ed., Noyes Publications, Park Ridge, NJ, 1984, pp. 269–302. With permission.

2. **Synthetic detergents**, normally alkyl aryl sulfonates, come from petroleum-based (typically C_{12}) residues that are condensed with benzene then sulfonated and neutralized to obtain the soluble salt.
3. **Salts of sulfonated lignin** are byproducts of the paper industry. These tend to be relatively poor air-entraining agents but have been used extensively in concrete as water reducers and retarders.
4. **Salts of petroleum acids** are the leftovers from petroleum refineries. Sludge left after the extraction of white oils with sulfuric acid contains water-soluble sulfonates that are then neutralized with sodium hydroxide.
5. **Salts of proteinaceous materials** are products of animal- and hide-processing industries. They consist of salts from a complex mixture of carboxylic and amino acids. This group does not produce many commercial air-entraining admixtures.
6. **Fatty and resinous acids and their salts** are produced from various sources such as vegetable oil, coconut oil, and tall oil, another byproduct of the paper industry.
7. **Organic salts of sulfonated hydrocarbons** are the same water-soluble sulfonates described in group 4, except they are neutralized with triethanolamine instead of sodium hydroxide.

When determining air contents, an observant technician would note that even concrete without air-entraining admixtures contains some air. This air, however, is air that has become entrapped during the mixing process. Entrapped air is evident as much larger, irregularly spaced voids that do nothing to resist freeze–thaw stresses.

TABLE 3.3 Effect of Entrained Air on Concrete

Properties	Effect
<i>Plastic</i>	
Bleeding	Significant reduction of bleeding
Plastic shrinkage	Reduction
Slump	Increases (25 mm more slump/0.5–1% more air)
Unit weight	Decreases as air content increases
Water demand (for equal slump)	Decreases 3–6 kg/m ³ /1% increase in air
Workability	Increases as air increases
<i>Hardened</i>	
Abrasion	Insignificant (only as it relates to strength and modulus)
Absorption	Insignificant
Alkali–silica reactivity	Concrete expansion decreases as air increases
Bond to steel	Decreases as air increases
Compressive strength	Typically decreases strength 2–6%/1% air increase; unusually harsh or lean mixes may gain strength
Creep	Insignificant (only as it relates to strength and modulus)
Deicer scaling	Significantly more resistant as air increases
Fatigue	Insignificant (only as it relates to strength and modulus)
Flexural strength	Decreases strength 2–4%/1% increase in air
Freeze–thaw resistance	Water-saturated F-T resistance improves with added air
Heat of hydration	Insignificant
Modulus of elasticity	Decreases 724–1380 MPa (1.05×10^5 – 2.00×10^5 psi) per 1% air increase
Permeability	Minimal; if higher air means lower w/c then lower permeability results

Source: Kosmatka, S.H. and Panarese, W.C., *Design and Control of Concrete Mixtures*, 13th ed., Portland Cement Association, Skokie, IL, 1988.

Entrained air has a significant influence on many of the properties of both fresh and cured concrete. In fresh concrete, it is known to reduce water demand and the tendency toward bleeding, as well as plastic shrinkage. It increases slump and workability. In hardened concrete, entrained air improves deicer scaling resistance and resistance to freezing and thawing degradation, although small and predictable reductions in compressive, flexural, and bond strengths are to be expected (Table 3.3).

If air is determined to be excessive, very small quantities of defoaming or air-detraining agents may be used as recommended by the manufacturer. Defoaming agents are typically composed of silicones, esters of carbonic acid (water-insoluble), octyl alcohol, dibutylphthalate, or tributylphosphate. These materials are very effective, but too much may hurt concrete properties; thus, care must be taken to use only enough defoamer or detrainer to bring concrete air into the specified range. All air-entraining admixtures that are to be added at the time of mixing should conform to ASTM C 260 specifications. Air-entraining cements should conform to ASTM C 150 and ASTM C 595 with ASTM C 226 specifications for the air-entraining additives in air-entraining cements.

Typically total air content needs are dependent on anticipated exposure conditions vs. the strength and quality of the matrix mortar and coarse aggregates. Table 3.4 illustrates target air content considerations for various coarse aggregates. It should be noted that sometimes other chemical or mineral admixtures in the matrix may detrimentally reduce the anticipated volume of entrained air. Of course, trial batching to verify the effects of air-entraining admixtures on critical properties for any proposed batch design is recommended.

3.7 Antifreezing Admixtures

As the name implies, this category of admixtures is employed to allow most types of concrete construction work and precasting to take place at freezing and well below freezing temperatures. These admixtures are sometimes used in conjunction with external energy and heat sources, but they are often used without

TABLE 3.4 Total Target Air Content for Concrete

Nominal Maximum Aggregate Size (in.)	Air Content (%) ^a		
	Severe Exposure ^b	Moderate Exposure ^b	Mild Exposure ^b
3/8	7-1/2	6	4-1/2
1/2	7	5-1/2	4
3/4	6	5	3-1/2
1	6	4-1/2	3
1-1/2	5-1/2	4-1/2	2-1/2
2 ^c	5	4	2
3 ^c	4-1/2	3-1/2	1-1/2

^a Project specifications often allow the air content of the delivered concrete to be within -1 to $+2$ percentage points of the table target values.

^b Severe exposure is an environment in which concrete is exposed to wet freeze-thaw conditions, deicers, or other aggressive agents. Moderate exposure is an environment in which concrete is exposed to freezing but will not be continually moist, will not be exposed to water for long periods before freezing, and will not be in contact with deicers or aggressive chemicals. Mild exposure is an environment in which concrete is not exposed to freezing conditions, deicers, or aggressive agents.

^c These air contents apply to total mix, as for the preceding aggregate sizes. When testing these concretes, however, aggregate larger than 1-1/2 in. is removed by hand picking or sieving, and air content is determined on the $-1-1/2$ in. fraction of mix. (Tolerance on air content as delivered applies to this value.) Air content of total mix is computed from value determined on the $-1-1/2$ in. fraction.

them, even under bitterly cold environmental conditions. Antifreezing admixtures work by lowering the freezing point of the water in fresh concrete (Brook et al., 1993; Ratinov and Rosenberg, 1984). This is accomplished by dissolving salts and mixing in higher-molecular-weight alcohols, ammonia, or carbamide into the mix water. For this reason, the admixture dosage rates are based on the amount of mixing water in the given batch design. These antifreeze admixtures tend to seriously retard the set and cure properties of the matrix, as do freezing temperatures. It is obvious, then, that at the same time the water is being kept unfrozen and thus available for hydration acceleration of the hydration process is also important and must be designed to work with the antifreezing component. Thus, these two admixtures—antifreeze and accelerator—are often combined into one complex multicomponent additive. This compensating type of antifreeze typically consists of inexpensive combinations of potash and calcium-chloride-type additives. A third group of antifreeze admixture used occasionally promotes a highly accelerated hydration process and utilizes the much higher earlier exothermic temperatures in the concrete mass to push the curing process in spite of ambient temperatures that are too low to allow normal curing. Chemicals in this group include ferric sulfate and aluminum sulfate. Dosage rates for the various materials may differ significantly even for the same antifreeze admixture, because their effect is influenced by many things, including the temperature of the forms, air, aggregates, and mix water, as well as the concrete mass and geometry, mitigating construction technology, and type and brand of cement used.

3.8 Antiwashout Admixtures

This class of chemical admixture was developed as a viscosity-modifying admixture that could improve the rheological properties of the cement paste. It has proved itself in the field by significantly improving the cohesiveness of concrete being placed underwater, where the exposed matrix is in jeopardy of being diluted and segregated or washed away by the surrounding water. It is most commonly used underwater in large placements and in repairs. These admixtures are also known as viscosity-enhancing admixtures

and are sometimes used to produce self-leveling concrete or self-consolidating concrete (SCC), which is used wherever extreme congestion due to reinforcement configurations or unusual geometry of the forms requires a very fluid, cohesive concrete that resists bleeding and segregation (Khayat, 1996).

Disadvantages of antiwashout or viscosity-enhancing admixtures include the typical reductions in strength and modulus of elasticity. Depending on the base concrete batch design, water/cement ratio, and the type and dosage rate of antiwash admixture (AWA), compressive strength has been determined to be 75 to 100% of the same control mix without this admixture. Flexural strengths have been reported at 84 to 100%, and modulus of elasticity measurements are 80 to 100% of the control batch.

The two most commonly used AWAs are based on either welan gum or hydroxypropylmethylcellulose. Some AWAs are made from variations of related microbial saccharides similar to welan gum or various cellulose-based polymers such as hydroxyethylcellulose and hydroxyethylmethylcellulose. The thixotropic mechanisms that enable this admixture to work include attachment of its long molecules to water molecules. This inhibits the free displacement of the water by heavier mix constituents. The long chains can slip past each other under conditions of high shear, such as mixing and pumping and rapid flow, but when the moving concrete slows down the chains intermesh and the matrix behaves in a much more viscous state. This self-adjusting behavior minimizes segregation and bleeding. Workability is usually better, too, because the constituents of the mix are better dispersed, even with the higher additions of HRWRs.

Set time, cure time, shrinkage, and creep are not significantly affected by the presence of AWAs themselves but may be influenced by the addition of higher levels of HRWR associated with the use of AWAs. Electric current passed through cured permeability specimens is lower in concrete containing AWAs, indicating reduced chloride ion permeability. Addition levels for AWAs are totally dependent on the application needs and constraints, but the mechanism suggests that its function is based on the availability of free water. It is essential that trial batches be made and evaluated for all important properties before concrete containing AWA is placed. Known interactions include higher air-entraining admixture demand when higher levels of HRWRs are needed. Acceptable entrainment levels are easily attainable but require trial batch evaluations. Hydroxypropylmethylcellulose tends to entrap air unless a deaerating agent is added into the mixer with it; therefore, careful adherence to a specific mixing procedure may be more important than with other batch designs.

3.9 Shrinkage-Reducing Admixtures

Shrinkage-reducing or shrinkage-compensating admixtures promote expansion of the concrete at about the same volume that normal drying shrinkage is contracting it. The net change in length of the hardened concrete should be small enough to prevent shrinkage cracks. The typical materials used for shrinkage compensation in concrete are based on calcium sulfoaluminate or calcium aluminate and calcium oxide. Some losses in properties are typical with the introduction of these antishrinkage agents. Any ill effects on strength are minimized by the use of HRWRs, which provide good workability while allowing reduction of the water content. These admixtures can be used to great advantage in slabs, bridge decks, structures, and repair work where cracking can lead to steel reinforcement corrosion problems, but maintaining effective air entrainment for resistance to freezing and thawing damage can be difficult with shrinkage-reducing admixtures. Usage rates vary with batch designs and water content but typically range from 8 to 25%. ACI 223 (Standard Practice for the Use of Shrinkage-Compensating Concrete) specifies the best methods for utilization of this admixture.

3.10 Polymer Modifier Admixtures

Different types of polymers can be used in concrete as polymerizing admixtures for comatrix formation or where the hydraulic cement paste and the polymer simultaneously form into separate, but interdependent, phases in the matrix. This polymer-modified concrete (PMC) is the result of adding higher-

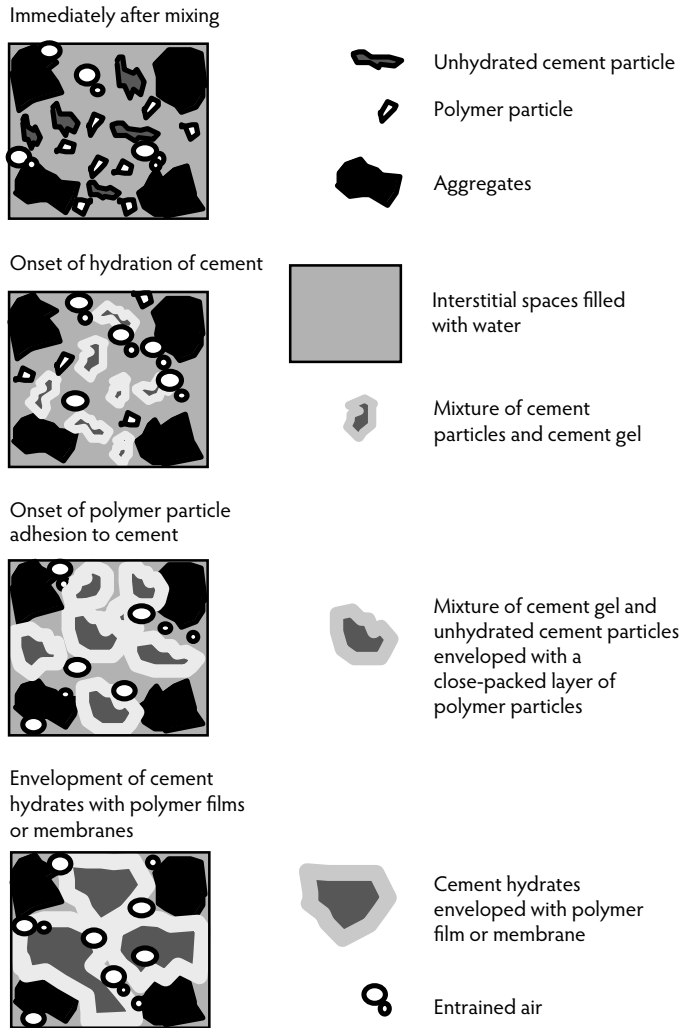

FIGURE 3.7 Simplified formation model for latex-cement co-matrix. (From Ohama, Y., in *Report of the Building Research Institute No. 65*, Building Research Institute, Tokyo, Japan, 1973.)

molecular-weight polymers to concrete batch designs for the purposes of improved adhesion, greater chemical resistance, lower permeability, lower drying shrinkage, improved tensile strength, or accelerated cure. Different chemical families and physical forms of polymers have been tried with varying degrees of success, but latex, acrylic, and epoxy additives are the most commonly used. They are available as powdered or liquid forms of resins, monomers, or emulsions, and their uses include concretes and mortars for flooring, ship decks, bridge decks overlays, repair, anticorrosive coatings, and adhesives. Improvements over the properties of normal concrete or mortar depend on the polymer phase formation and the cement hydration forming an interpenetrating network structure of polymer and hydrated cement phases. The resulting monolithic matrix exhibits properties beyond either isolated phase material.

Initially, the mixing process disperses the admixture into the fresh concrete matrix. As hydration begins and free water is lost, membrane strands of polymer begin forming either through water loss or independent polymerization. These membranes adhere to major portions of the hydrating cement particle surfaces. As the process continues, membranes interconnect and hydration progresses somewhat independently until both constituents of the matrix have cured (Figure 3.7). This modified matrix tends to arrest propagating microcracking due to local tensile or impact insults to the concrete. The mechanics

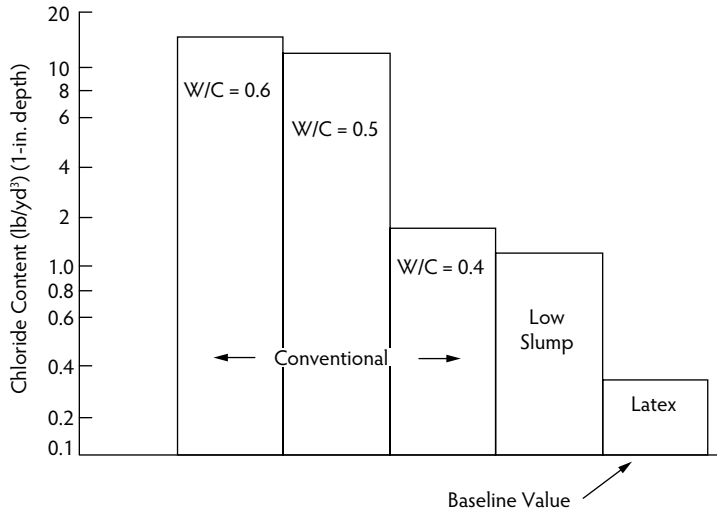

FIGURE 3.8 FHWA test results of 90-day ponding test. (Figure courtesy of Dow Chemical Company, Midland, MI.)

of this phenomenon seem to rely upon higher tensile strengths of the polymer network and the better bond to aggregates and hydration product. Additionally, higher curing shrinkage strains and resulting stresses in the polymer may post-tension the polymer phase, internally compressing the Portland cement concrete phase. Because of their significantly higher costs, these polymer modifiers are considered premium admixtures for concrete with special needs. The gains in tensile and flexural strength over normal concrete are primarily a function of the polymer/cement ratio rather than water/cement ratio.

Although mixing and placement of PMC are similar to normal concrete, there are some important differences, and finishing and curing may be very different. Normally, set times are delayed in PMC, and initial set times for PMC may be much more sensitive to ambient, substrate, and concrete constituent temperatures. Because of this sensitivity to temperature and unwanted additional air content from overmixing, latex-modified concrete is generally batched and mixed in mobile batching-plant trucks or trailers at the jobsite. With latex in particular, too much entrained air requires the addition of an antifoaming agent if it is not already included in the admixture. Initially, workability may be better than unmodified concrete, but as the polymer phase progresses and the surface begins to dry, finishing operations may tear the sticky or crusty surface due to polymer adhesion, so workers need to quickly place and finish PMC. Styrene-butadiene resin (SBR) concretes should be wet cured for 24 to 48 hours to permit concrete to gain adequate strength before the latex is allowed to cure and shrink.

Bleeding and segregation are also less in most PMCs because of the hydrophilic nature of the polymer modifiers used. Placement and finishing tools must be cleaned thoroughly and immediately after each use, and reusable formwork must be carefully coated with a special form release that releases from latex or epoxy as well as the cement paste. All joints should be formed, including construction joints and control joints. Sawed joints for control of cracking are not recommended (ACI 548 Committee, 1992).

Changes in hardened concrete properties are important to anticipate. Shrinkage is dependent on the batch design and the choice and amount of polymer modifier. Some PMCs exhibit the same or less shrinkage, and some exhibit more than expected from normal concrete. Creep properties from SBR latex-modified concrete are typically lower than for normal concrete, but epoxy-modified concrete may be higher, depending on the polymer loading in the matrix. The coefficient of thermal expansion for PMCs is minimally affected by the polymer, as it such a small constituent in the matrix compared to the aggregates. Although significant increases in tensile strength, flexural strength, and bond strength may be expected, compressive strengths do not necessarily increase. Cured PMC typically exhibits lower water absorption and water or water vapor permeability due to larger pores being filled with polymer (Figure 3.8, Figure 3.9, and Figure 3.10); however, some polymers can re-emulsify, which may reduce the strength

FIGURE 3.9 Permeability vs. water/cement ratio. (Figure courtesy of Dow Chemical Company, Midland, MI.)

FIGURE 3.10 Effect of latex level on permeability. (Figure courtesy of Dow Chemical Company, Midland, MI.)

of the matrix at least near the surface when it is saturated with water over time. Epoxy-modified concretes are more suitable for constantly wet conditions (Popovic, 1985).

Polymer-modified concrete strengths are normally better than for conventional concrete with similar water/cement ratios at ambient temperatures below 100°F. Due to marked decreases in the polymer’s modulus at polymer-specific glass transition temperatures (T_g s), usually somewhere between 100 and 120°F, the strength differences may decrease in service temperatures at or above this range. Abrasion resistance, frost resistance, chemical resistance, and bond to concrete or steel substrates are normally better in PMC than unmodified concrete.

Epoxy-modified concrete typically has a polymer/cement ratio of 20% for water-reducible resins and more than 30% for others (even more than 50% for some resins) (Ohama, 1984). This makes epoxy-modified concretes more expensive than latex-modified concretes, but all strengths are typically higher, including compressive strength, and these systems can be cured in water, whereas latex-modified concrete usually must be allowed to dry after 48 hours of moist curing.

Other commercially available polymers such as polyvinyl acetates, water-soluble unsaturated polyester resins, methylcellulose, and polyurethanes are used to modify concrete for specific applications, but latexes (particularly SBR and acrylic) and epoxies are the two that claim most of the market. PMC is used most often in protective coatings such as shotcrete (Shorn, 1985), overlays (Irvin, 1989), and large-

surface-area repairs (Smoak, 1985), because these applications can take cost-effective advantage of the better adhesion, better abrasion resistance, and lower permeability afforded the matrix through the use of polymer modifiers. Also, crews associated with these applications generally tend to be better trained for the special batching, placing, finishing, and curing requirements of PMC. Job-specific materials, usage, and batch design recommendations from polymer modifier manufacturers should be solicited and closely followed to make trial batches under field conditions which must be tested for critical properties before large-scale use of PMC is implemented.

3.11 Alkali–Silica Reaction Prevention Admixtures

In recent years, alkali–silica reaction (ASR) has been found to be responsible for much of the premature deterioration of many concrete structures in the United States and other countries throughout the world; consequently, there has been renewed interest in using lithium compounds (lithium hydroxide, lithium carbonate, and lithium nitrate) to combat this deleterious chemical reaction. The most promising of these lithium compounds is a solution of lithium nitrate. Research efforts are increasingly focused on understanding the mechanism by which lithium materials inhibit alkali–silica reaction. Furthermore, work continues toward improving the cost effectiveness of this mitigation strategy (Folliard et al., 2006).

3.12 Conclusion

It should be noted that all of the many admixtures are intended to enhance the properties of concrete, but they are not intended to substitute for proper concrete design, batching, transport, and finishing practices. It is often more cost effective to change the mixture proportions or the aggregate than to use higher quantities of admixtures; therefore, it is recommended that a cost analysis be done on both proposed and alternative batch designs. Any change in admixtures or their quantities should be verified in trial batch evaluations for strength and any other critical properties before delivered to any jobsite. Trial batches should be mixed with all intended admixtures and cured under expected field conditions before evaluation.

4.1 Creep and Shrinkage Deformations in Concrete

Creep, or lateral material flow, is the increase in strain with time due to sustained load. Initial deformation due to load is the **elastic strain**, while the additional strain or time-dependent deformation due to the same sustained load is the **creep strain**. Drying shrinkage, on the other hand, is the decrease in volume

FIGURE 4.1 Three-dimensional model of time-dependent structural behavior. (From Nawy, E.G., *Reinforced Concrete: A Fundamental Approach*, 6th ed., Prentice Hall, Upper Saddle River, NJ, 2008.)

of the concrete element when it loses moisture due to evaporation. Because every infrastructure element under load will suffer this long-term deformation that has to be accounted for in a durable system, this aspect has been chosen as one of the major topics for consideration in this chapter.

If we look at the three-dimensional representation in Figure 4.1 and its two-dimensional counterpart in Figure 4.2, we can see that the nonlinear relationship in the creep and shrinkage behavior makes it difficult to come up with an exact model of prediction. This has been a challenge for researchers from the 1920s onwards and is why there are so many models of prediction (ACI 209, 1992; Bazant and Boweja, 1995a,b, 2000a,b; Bazant and Murphy, 1995; Branson, 1971, 1977; CEB-FIP, 1990; Gardner, 2000; Gardner and Lockman, 2001; Ross, 1937). Because of the incomplete reversibility of both creep and shrinkage strains, we can observe cracking, sagging of elements, and progressive deterioration as the strain continues to increase with time. Figure 4.2a shows a section of the three-dimensional model presented in Figure 4.1 parallel to the plane that contains the stress and deformation axes at time t_1 . The figure indicates that both elastic and creep strains are linearly proportional to applied stress. In a similar manner, Figure 4.2b illustrates a section parallel to the plane that contains the time and strain axes at a stress f_1 ; hence, it shows the familiar creep time and shrinkage time relationships.

The current ACI 318 code expressions due to Branson are still the acceptable general-purpose expressions for the prediction of creep and shrinkage as embodied in the ACI 209 model, and the designer can use other methods such as the CEB-FIP (1990), Bazant's B3 model (Bazant and Boweja, 1995a,b, 2000a,b), or Gardner's GL 2000 model (Gardner, 2000; Gardner and Lockman, 2001) for refined predictions (Nawy, 2006a,b, 2008). Recent work by Nassif at Rutgers (Saksawang et al., 2005), shown in Figure 4.3, indicates that the ACI 209 model seems to be a close best fit for creep prediction in high-strength, high-performance concrete; Figure 4.4 shows essentially similar characteristics for shrinkage but with lesser correlation.

4.2 Creep Deformations in Concrete

Creep or lateral material flow is the increase in strain with time due to sustained load. Initial deformation due to load is the *elastic strain*, while the additional strain due to the same sustained load is the *creep strain*. This practical assumption is quite acceptable, as the initial recorded deformation includes few time-dependent effects. Figure 4.5 illustrates the increase in creep strain with time; in the case of

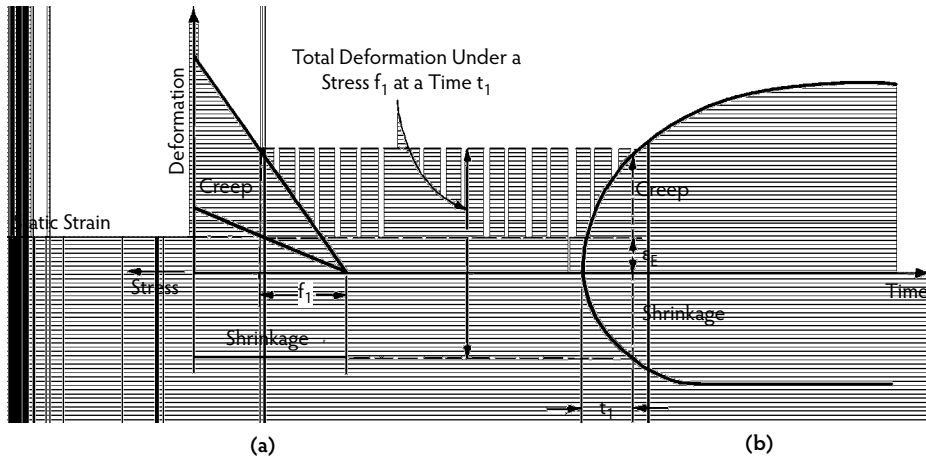

FIGURE 4.2 Two-dimensional section of deformations in Figure 4.1: (a) Section parallel to stress-deformation plane; (b) section parallel to deformation-time plane. (From Nawy, E.G., *Reinforced Concrete: A Fundamental Approach*, 6th ed., Prentice Hall, Upper Saddle River, NJ, 2008.)

FIGURE 4.3 Comparison of measured and calculated specific creep for ACI 209 model.

shrinkage, it can be seen that the rate of creep decreases with time. Creep cannot be measured directly but is determined only by deducting elastic strain and shrinkage strain from the total deformation. Although shrinkage and creep are not independent phenomena, it can be assumed that superposition of strains is valid; hence,

$$\text{total strain } (\epsilon_t) = \text{elastic strain } (\epsilon_e) + \text{creep } (\epsilon_c) + \text{shrinkage } (\epsilon_{sh})$$

An example of the relative numerical values of strain due to elastic strain creep and to shrinkage is presented in the figure for a normal concrete specimen subjected to 900 psi in compression (Nawy, 2001; Ross, 1937). These relative values illustrate that stress-strain relationships for short-term loading in

FIGURE 4.4 Comparison of measured and calculated shrinkage strain for ACI 209 model.

FIGURE 4.5 Long-term creep stress–time curve. (From Nawy, E.G., *Reinforced Concrete: A Fundamental Approach*, 6th ed., Prentice Hall, Upper Saddle River, NJ, 2008.)

normally reinforced or plain concrete elements lose their significance and the effects of long-term loadings become dominant on the behavior of a structure. In cases of large heavily reinforced columns in buildings, elastic strain can be a more significant component of the total strain.

Numerous tests have indicated that creep deformation is proportional to the applied stress, but the proportionality is valid only for low stress levels. The upper limit of the relationship cannot be determined accurately but can vary between 0.2 and 0.5 of the ultimate strength f'_c . This range in the limit of the proportionality is expected due to the large number of microcracks that exist at about 40% of the ultimate load.

As in the case of shrinkage, creep is not completely reversible. If a specimen is unloaded after a period of being under a sustained load, an immediate elastic recovery is obtained that is less than the strain precipitated on loading. The instantaneous recovery is followed by a gradual decrease in strain, called **creep recovery**. The extent of the recovery depends on the age of the concrete when loaded; older concretes present higher creep recoveries, while residual strains or deformations become frozen in the structural element, as shown in Figure 4.6.

FIGURE 4.6 Creep recovery vs. time. (From Nawy, E.G., *Reinforced Concrete: A Fundamental Approach*, 6th ed., Prentice Hall, Upper Saddle River, NJ, 2008.)

4.2.1 Creep Effects

As in shrinkage, creep increases the deflection of beams and slabs and causes loss of prestress in prestressed concrete elements. In addition, the initial eccentricity of a reinforced concrete column increases with time due to creep, resulting in the transfer of the compressive load from the concrete to the steel in the concrete section. When the steel yields, additional load has to be carried by the concrete; consequently, the resisting capacity of the column is reduced, and the curvature of the column increases further, resulting in overstress in the concrete and leading to failure. Similar behavior occurs in axially loaded columns.

4.2.2 Rheological Models

Rheological models are mechanical devices that portray the general deformation behavior and flow of materials under stress. A model is basically composed of elastic springs and ideal dashpots denoting stress, elastic strain, delayed elastic strain, irrecoverable strain, and time. The springs represent the proportionality between stress and strain, and the dashpots represent the proportionality of stress to the rate of strain. A spring and a dashpot in parallel form a Kelvin unit, and in series they form a Maxwell unit.

Two rheological models are discussed here: the Burgers model and the Ross model. The Burgers model (Figure 4.7) is shown because it can approximately simulate the stress–strain–time behavior of concrete at the limit of proportionality, with some limitations. This model simulates the instantaneous recoverable strain (a), the delayed recoverable elastic strain in the spring (b), and the irrecoverable time-dependent strain in dashpots (c and d). The weakness in this model is that it continues to deform at a uniform rate as long as the load is sustained by the Maxwell dashpot—a behavior not similar to concrete, where creep reaches a limiting value with time, as shown in Figure 4.7. A modification in the form of the Ross rheological model (Ross, 1958) (Figure 4.8) can eliminate this deficiency. In this model, A represents the Hookian direct proportionality of the stress-to-strain element, D represents the Newtonian element, and B and C are the elastic springs that can transmit the applied load $P(t)$ to the enclosing cylinder walls by direct friction. Because each coil has a defined frictional resistance, only those coils whose resistance equals the applied load $P(t)$ are displaced; the others remain unstressed, symbolizing irrecoverable deformation in concrete. As the load continues to increase, it overcomes the spring resistance of unit B,

FIGURE 4.7 The Burgers rheological model. (From Nawy, E.G., *Reinforced Concrete: A Fundamental Approach*, 6th ed., Prentice Hall, Upper Saddle River, NJ, 2008.)

FIGURE 4.8 Ross rheological model. (From Nawy, E.G., *Reinforced Concrete: A Fundamental Approach*, 6th ed., Prentice Hall, Upper Saddle River, NJ, 2008.)

pulling the spring from the dashpot and signifying failure in a concrete element. More rigorous models have been used, such as Roll's model, to assist in predicting the creep strains. Mathematical expressions for such predictions can be very rigorous. One convenient expression from Ross defines creep (C) under load after time interval t as follows:

$$C = \frac{t}{a + bt} \quad (4.1)$$

where a and b are constants that can be determined from tests. As will be discussed in the next section, this model seems to represent the creep deformation of concrete and is the background for the ACI code equations for creep.

4.3 Creep Prediction

4.3.1 Creep Prediction for Standard Conditions

Creep and shrinkage are interrelated phenomena because of the similarity of the variables affecting both, including the forms of their strain–time curves, as seen in Figure 4.2. The ACI (ACI Committee 209, 1992) proposed a similar model for expressing both creep and shrinkage behavior. The expression for creep is as follows:

$$C_t = \frac{t^\alpha}{a + t^\alpha} C_u \quad (4.2)$$

where a and α are experimental constants and t , in days, is the duration of loading.

Work by Branson (1971, 1977) formed the basis for Equation 4.2 and Equation 4.3 in a simplified creep evaluation. The additional strain (ϵ_{cu}) due to creep can be defined as:

$$\epsilon_{cu} = \rho_u f_{ci} \quad (4.3)$$

where:

ρ_u = unit creep coefficient, generally referred to as **specific creep**.

f_{ci} = stress intensity in the structural member corresponding to initial unit strain ϵ_{cu} .

FIGURE 4.9 Water/cement ratio effect on the relative specific creep. (From Mindess, S. et al., *Concrete*, Prentice Hall, Upper Saddle River, NJ, 1999. With permission.)

- *Sustained load.* Creep as a result of sustained load is proportional to the sustained stress and is recoverable up to 30 to 50% of the ultimate strain.
- *Water/cementitious materials ratio ($w/(c + p)$ or w/cm).* The higher this ratio, the larger the creep, as seen in Figure 4.9, which relates specific creep to the $w/(c + p)$ ratio (Mindess et al., 1999).
- *Aggregate modulus and aggregate/paste ratio.* For a constant paste-volume content, an increase in aggregate volume decreases creep. As an example, an increase from 65 to 75% lowered creep by 10%. This behavior is the same whether the coarse aggregate is natural stone or lightweight artificial aggregate.
- *Age at time of loading.* The older the concrete at the time of loading, the smaller the induced creep strain for the same load level.
- *Relative humidity.* Reconditioning the concrete at a lower relative humidity before applying the sustained external load reduces the resulting creep strain. If creep is considered in two categories—drying creep and wetting creep—the creep strain develops irrespective of the direction of change (Mindess et al., 1999), provided the exposure is above 40%.
- *Temperature.* Creep increases with increase in temperature if the concrete is maintained at elevated temperatures while under sustained load. It increases in a linear manner up to a temperature of 175°F (80°C). Its value at this temperature level is almost three times the creep value at ambient temperatures.
- *Concrete member size.* Creep strain decreases with increasing thickness of the concrete member.
- *Reinforcement.* Creep effects are reduced by use of reinforcement in the compressive zones of concrete members.

4.3.3 Creep Prediction for Nonstandard Conditions

As the standard conditions for creep described in Table 4.1 change, corrective modifying multipliers have to be applied to the ultimate creep coefficient (C_u) in Equation 4.5. If the average ultimate creep C_u is 2.35 for standard conditions, it has to be adjusted by a multiplier (γ_{CR}) so:

$$C_u = 2.35\gamma_{CR} \quad (4.7a)$$

Here, γ_{CR} has component coefficients that account for the change in conditions enumerated in the preceding section. ACI Committee 209 recommends, in detailed tabular form, the various component

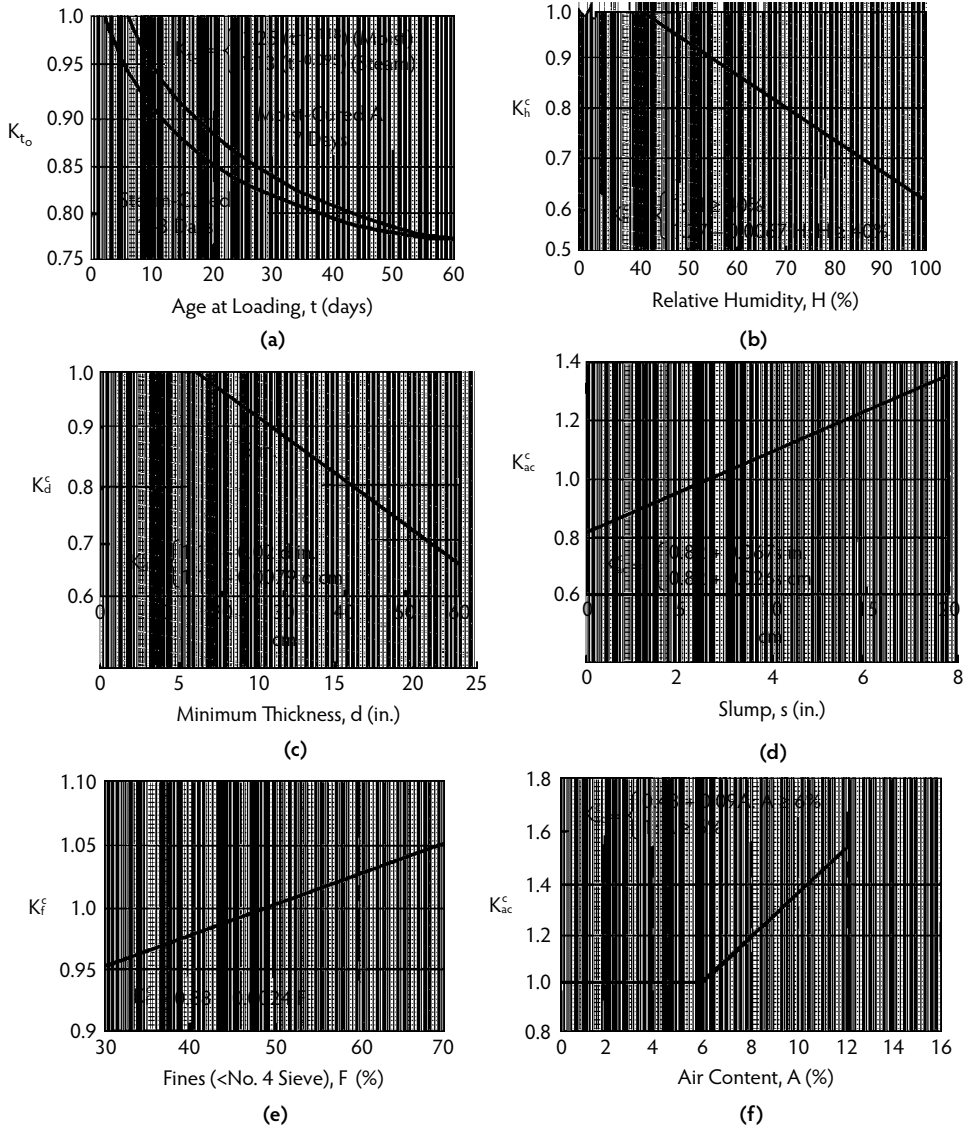

FIGURE 4.10 Creep correction factors for nonstandard conditions, ACI 209 method. (From Meyers, B.L. and Thomas, E.W., in *Handbook of Structural Concrete*, Kong, F.K. et al., Eds., McGraw-Hill, New York, 1983, pp. 11.1–11.33. With permission.)

coefficients for the γ_{CR} multiplier (ACI Committee 209, 1992). These are generally based on Branson’s (1977) studies. Tabulated values are given in graphical form (ACI Committee 435, 1995; Branson, 1977; Meyers and Thomas, 1983) in Figure 4.10 for the multiplier as follows:

$$\gamma_{CR} = K_h^c K_d^c K_s^c K_f^c K_{ac}^c K_{t_0}^c \tag{4.7b}$$

where:

- $\gamma_{CR} = 1$ for standard conditions.
- K_h^c = relative humidity factor.
- K_d^c = minimum member thickness factor.
- K_s^c = concrete consistency factor.

- K_f^c = fine aggregate content factor.
 K_{ac}^c = air-content factor.
 $K_{t_0}^c$ = age of concrete at load application factor.

4.3.4 CEB-FIP Model Code for Creep

The total stress-dependent strain per unit stress in the CEB-FIP 90-99 model is given by the following expression:

$$\varepsilon_{CR(t,t_s)} = \frac{1}{E_{t_0}} + \frac{\Phi_{(t,t_0)}}{E_{28}} \quad (4.8)$$

where:

- E_{t_0} = modulus of elasticity at age of loading (MPa).
 E_{28} = modulus of elasticity at 28 days (MPa).
 $\Phi_{(t,t_0)}$ = creep coefficient dependent on several factors, each defined by a separate equation relating to cement type, relative humidity, concrete strength, and age of concrete.

4.4 Shrinkage in Concrete

4.4.1 General Shrinkage Behavior

In general, the two types of shrinkage are **plastic shrinkage** and **drying shrinkage**; carbonation shrinkage is another form of shrinkage. Plastic shrinkage occurs during the first few hours after placing fresh concrete in forms. Exposed surfaces such as floor slabs are more easily affected by exposure to dry air because of their large contact surface. In such cases, moisture evaporates from the concrete surface faster than it is replaced by bleed water from the lower layers. Drying shrinkage, on the other hand, occurs after the concrete has already attained its final set and a good portion of the chemical hydration process in the cement gel has been accomplished. Drying shrinkage is the decrease in the volume of a concrete element when it loses moisture by evaporation. The opposite phenomenon—volume increase through water absorption—is termed *swelling*. In other words, shrinkage and swelling represent water movement out of or into the gel structure of a concrete specimen that is caused by the difference in humidity or saturation levels between the specimen and the surroundings, regardless of the external load.

Shrinkage is not a completely reversible process. If a concrete unit is saturated with water after having fully shrunk, it will not expand to its original volume. Figure 4.11 relates the increase in shrinkage strain

FIGURE 4.11 Concrete shrinkage vs. time curve. (From Nawy, E.G., *Reinforced Concrete: A Fundamental Approach*, 6th ed., Prentice Hall, Upper Saddle River, NJ, 2008.)

FIGURE 4.12 Aggregate modulus effect on shrinkage strain. (From Mindess, S. et al., *Concrete*, Prentice Hall, Upper Saddle River, NJ, 1999. With permission.)

(ϵ_{sh}) with time. The rate decreases with time, as older concretes are more resistant to environmental effects and consequently undergo less shrinkage, so the shrinkage strain becomes almost asymptotic with time. Several factors affect the magnitude of drying shrinkage:

- *Aggregate.* Aggregate acts to restrain the shrinkage of cement paste; hence, concretes with a high aggregate content are less vulnerable to shrinkage. In addition, the degree of restraint of a given concrete is determined by the properties of the aggregates; those with a high modulus of elasticity or with rough surfaces are more resistant to the shrinkage process (see Figure 4.12 and Figure 4.13) (Mindess et al., 1999).
- *Water/cementitious materials ratio.* Traditionally, it is accepted that the higher the water/cementitious materials ratio, the higher the shrinkage effects. Figure 4.14 is a typical plot relating shrinkage to aggregate content and, significantly, to the water/cement ratio. More recent work (Suprenant and Malisch, 2000), shown in Figure 4.15, indicates only a slight increase in average drying shrinkage with increase in water content.
- *Size of the concrete element.* Both the rate and total magnitude of shrinkage decrease with an increase in the volume of the concrete element; however, the duration of shrinkage is longer for larger members as more time is needed for drying to reach the internal regions. It is possible that 1 year may be required for the drying process to begin at a depth of 10 inches from the exposed surface and 10 years for drying to begin at 24 inches below the external surface; large members may never dry out completely.
- *Ambient conditions of the medium.* The relative humidity of the medium greatly affects the magnitude of shrinkage; the rate of shrinkage is lower at high relative humidity. Temperature is another important factor, in that shrinkage becomes stabilized at low temperatures.
- *Amount of reinforcement.* Reinforced concrete shrinks less than plain concrete; the relative difference is a function of the reinforcement percentage.
- *Admixtures.* This effect varies depending on the type of admixture. An accelerator such as calcium chloride, used to accelerate the hardening and setting of the concrete, increases the shrinkage. Pozzolans can also increase the drying shrinkage, whereas air-entraining agents have little effect.
- *Type of cement.* Rapid-hardening cement shrinks somewhat more than other types, whereas shrinkage-compensating cements minimize or eliminate shrinkage cracking when used with restraining reinforcement.

FIGURE 4.13 Aggregate content effect on drying shrinkage. (From Mindess, S. et al., *Concrete*, Prentice Hall, Upper Saddle River, NJ, 1999. With permission.)

FIGURE 4.14 Water/cement ratio and aggregate content effect on shrinkage. (From Nawy, E.G., *Reinforced Concrete: A Fundamental Approach*, 6th ed., Prentice Hall, Upper Saddle River, NJ, 2008.)

- **Carbonation.** Carbonation shrinkage is caused by the reaction between carbon dioxide (CO_2) present in the atmosphere and that present in the cement paste. The amount of combined shrinkage from carbonation and drying varies according to the sequence of carbonation and drying processes. If both phenomena take place simultaneously, less shrinkage occurs. The process of carbonation, however, is dramatically reduced at relative humidity below 50%.

4.4.2 Shrinkage Prediction for Standard Conditions

The mathematical model for shrinkage prediction in Equation 4.3 as an ACI 209 model is:

$$(\epsilon_{SH})_t = \frac{t^\beta}{b + t^\beta} (\epsilon_{SH})_u \quad (4.9)$$

FIGURE 4.15 Effect of water content on 1-year drying shrinkage for concretes with and without water reducers. (From Suprenant, B.A. and Malisch, W. R., *A New Look at Water, Slump, and Shrinkage*, Technical Note, Paper No. C00D048, Hanley-Wood, Washington, D.C., 2000, pp. 1–6. With permission.)

where β is a constant and t , in days, is the amount of time after curing that the concrete hardened. The value of the ultimate shrinkage strain at the standard conditions defined in Table 4.1 has the following range:

$$(\epsilon_{SH})_u = 415 \times 10^{-6} \text{ to } 1070 \times 10^{-6} \text{ in./in. (mm/mm)}$$

stipulated by ACI Committee 209 (1992) is as follows:

Moist-cured for 7 days:

$$(\epsilon_{SH})_u = 800 \times 10^{-6} \text{ in./in. (mm/mm)}$$

Steam-cured for 1 to 3 days:

$$(\epsilon_{SH})_u = 730 \times 10^{-6} \text{ in./in. (mm/mm)}$$

A common sufficiently accurate average shrinkage strain in standard conditions for both moist-cured and steam-cured concretes (ACI Committee 209, 1992) is:

$$(\epsilon_{SH})_u = 780 \times 10^{-6} \text{ in./in. (mm/mm)}$$

The values of constant b in the mathematical model of Equation 4.8 are $b = 35$ for 7-day moist-cured specimens and $b = 55$ for 1- to 3-day steam-cured specimens; hence, the shrinkage-strain prediction expressions for standard conditions become:

Shrinkage after 7 days of moist curing:

$$(\epsilon_{SH})_t = \frac{t}{35+t} (\epsilon_{SH})_u \tag{4.10a}$$

where t is the age of concrete in days after curing.

Shrinkage after 1 to 3 days of steam curing:

$$(\epsilon_{SH})_t = \frac{t}{55+t} (\epsilon_{SH})_u \tag{4.10b}$$

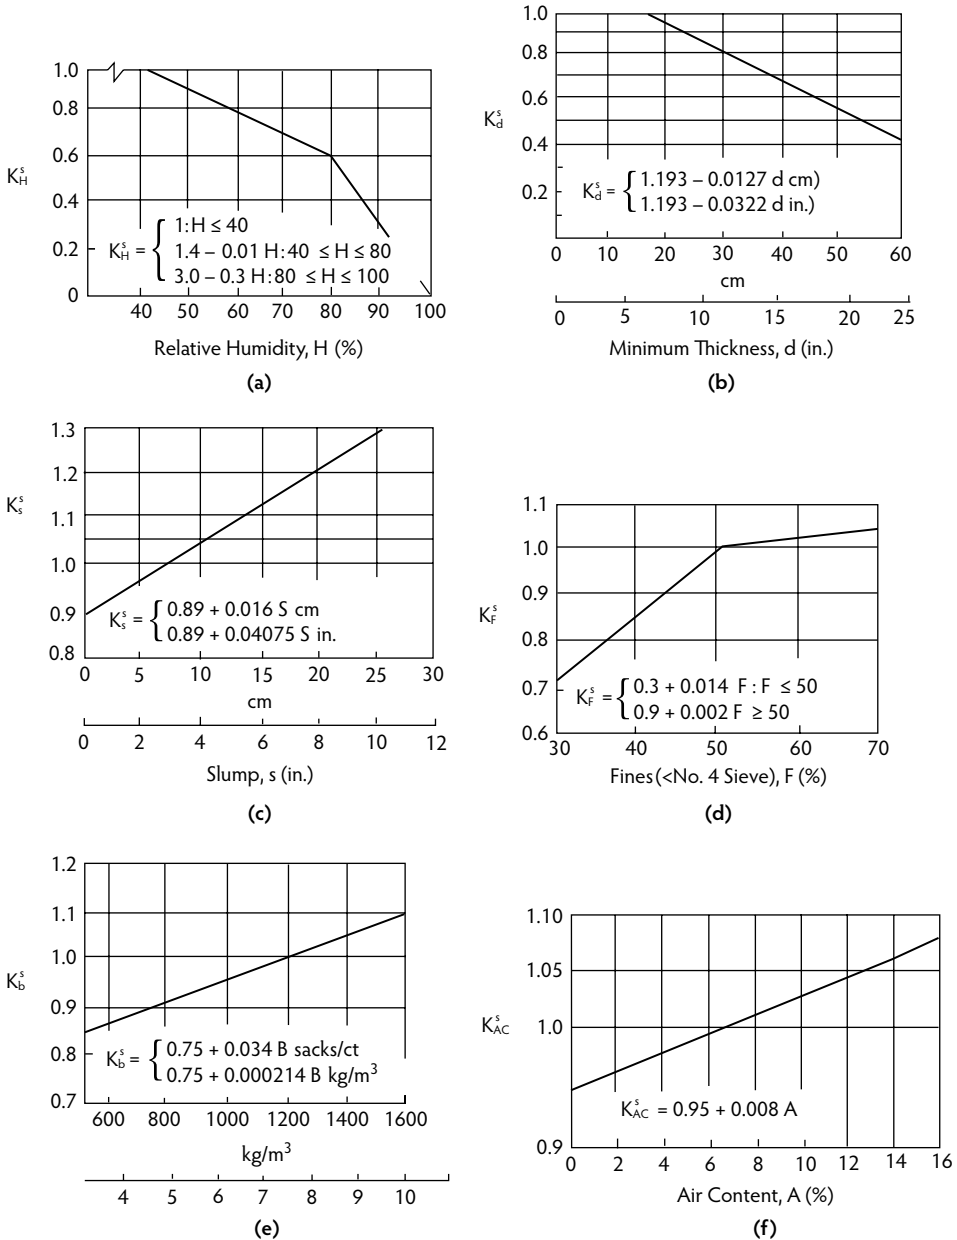

FIGURE 4.16 Shrinkage correction factors for nonstandard conditions, ACI method. (From Meyers, B.L. and Thomas, E.W., in *Handbook of Structural Concrete*, Kong, F.K. et al., Eds., McGraw-Hill, New York, 1983, pp. 11.1–11.33. With permission.)

4.4.3 Shrinkage Prediction for Nonstandard Conditions

As the standard conditions for shrinkage described in Table 4.1 change, corrective modifying multipliers have to be applied to the ultimate value of the shrinkage strain (ϵ_{SH})_u in Equations 4.10a and 4.10b. If γ_{SH} is the shrinkage-adjusting multiplier, then the average ultimate shrinkage strain for nonstandard conditions becomes:

$$(\epsilon_{SH})_u = 780 \times 10^{-6} \gamma_{SH} \tag{4.11a}$$

TABLE 4.2 Values of K_{SH} for Post-Tensioned Members

	Time from End of Moist Curing to Application of Prestress (Days)							
	1	3	5	7	10	20	30	60
K_{SH}	0.92	0.85	0.80	0.70	0.73	0.64	0.58	0.45

Source: Precast/Prestressed Concrete Institute (PCI), Chicago, IL.

or

$$(\epsilon_{SH})_{u,n} = \gamma_{SH}(\epsilon)_u \tag{4.11b}$$

where $(\epsilon_{SH})_{u,n}$ is the average ultimate strain for nonstandard conditions; hence, for nonstandard conditions, Equations 4.10a and 4.10b, respectively, become:

$$(\epsilon_{SH})_t = \frac{1}{35+t} \gamma_{SH}(\epsilon_{SH})_u \tag{4.12a}$$

and

$$(\epsilon_{SH})_t = \frac{1}{55+t} \gamma_{SH}(\epsilon_{SH})_u \tag{4.12b}$$

The multiplier γ_{SH} has component coefficients that account for the change in conditions enumerated in Section 4.4.1 (General Shrinkage Behavior). ACI Committee 435 (1995) recommends, in detailed tabular form, the various component coefficients for the γ_{SH} multiplier. These are generally based on Branson’s (1977) studies. The tabulated values (ACI Committee 435, 1995; Branson, 1977; Meyers and Thomas, 1983) are given in graphical form in Figure 4.16 for:

$$\gamma_{SH} = K_H^s K_d^s K_s^s K_F^s K_B^s K_{AC}^s \tag{4.12c}$$

where values of these factors are given in Figure 4.13:

- $\gamma_{SH} = 1$ for standard conditions.
- $K_H^s =$ relative humidity-factor.
- $K_d^s =$ minimum member thickness factor.
- $K_s^s =$ slump factor.
- $K_F^s =$ fine aggregate content factor.
- $K_B^s =$ cement-content factor.
- $K_{AC}^s =$ air-content factor.

4.4.4 Alternate Method for Shrinkage Prediction in Prestressed Concrete Elements

For standard conditions, the Precast/Prestressed Concrete Institute (PCI) stipulates an average value for nominal ultimate shrinkage strain $(\epsilon_{SH})_u = 820 \times 10^{-6}$ in./in. (mm/mm). If ϵ_{SH} is the shrinkage strain after adjusting for relative humidity (RH, in percent) at a volume-to-surface ratio (V/S, in inches), the shrinkage strain is:

$$\epsilon_{SH} = 8.2 \times 10^{-6} K_{SH} \left(1 - 0.06 \frac{V}{S} \right) (100 - RH) \tag{4.13}$$

where $K_{SH} = 1.0$ for pretensioned members. Table 4.2 gives the values of K_{SH} for post-tensioned members. Adjustment of shrinkage losses for standard conditions as a function of time t , in days, is made using Equations 4.10a and 4.10b for standard conditions and Equations 4.12a and 4.12b for nonstandard conditions.

4.4.5 CEB-FIP Model Code for Shrinkage

The CEB-FIP 90 model proposed by the Euro-International Concrete Committee and the International Federation for Prestressing is based on Muller and Hillsdorf (1990) and is only applicable for concrete with 28-day compressive strength in the range of 20 to 90 MPa. The input parameters of this model differ from the ACI model in terms of compressive strength and type of curing method. The strain due to shrinkage at normal temperature may be calculated from:

$$\epsilon_{SH(t,t_s)} = \epsilon_{cs0} \beta_s (t - t_s) \quad (4.14)$$

where:

- ϵ_{cs0} = shrinkage coefficient.
- β_s = coefficient to describe shrinkage with time.
- t = age of concrete (days).
- t_s = age of concrete (days) at the beginning of shrinkage.

4.4.6 Effects of Water and Slump on Drying Shrinkage

Traditionally, it has been accepted that the higher the water/cement ratio (w/c) and, correspondingly, the higher the water/cementitious materials ratio (w/cm), the higher the shrinkage effects. This concept dates back to the early days of the 1930s and is exemplified by the relationship shown in Figure 4.16, which relates shrinkage to aggregate content and, significantly, to the water/cement ratio. More recent work (Suprenant and Malisch, 2000) has produced results that bring into question the degree of influence on the drying shrinkage value by the increase in slump resulting from an increase in water content in the mix. The indicated work, monitoring the increase in drying shrinkage over a 1-year period, demonstrated that only a 5% increase in shrinkage resulted for each 2-inch increase in slump: "As a general rule of thumb, each added gallon of water per cubic yard increases slump by 1 inch" (Suprenant and Malisch, 2000). Figure 4.15 graphically illustrates that only a slight increase in average drying shrinkage results from appreciable increase in water content. The authors proposed in their investigation that, with proper inspection, jobsite water additions seldom exceed 2 gallons of water per cubic yard of concrete, or enough to increase the slump 2 inches. On this basis, the 2 gallons of water, or the extra 2 inches of slump, "might increase drying shrinkage by 4% to 5%," which is not significant over a 1-year period after placement of the concrete.

4.5 Strength and Elastic Properties of Concrete vs. Time

4.5.1 Cylinder Compressive Strength (f'_c)

Cylinder compressive strength increases with time as the cement hydration reaction progresses in the presence of water. As a function of time, the developing compressive strength is:

$$(f'_c)_t = \frac{1}{\alpha/\beta + t} (f'_c)_u \quad (4.15)$$

where:

- α/β = age of concrete, in days, at which one half of the ultimate (in time) compressive strength of concrete (f'_c)_u is reached.
- t = age of concrete in days.

The range of α and β for normal weight, sand lightweight, and all lightweight concrete is $\alpha = 0.05$ to 9.25, and $\beta = 0.67$ to 0.98. These constants are a function of the type of cement and the type of curing applied. Typical values for α/β and the time strength ratios are given in Table 4.3.

TABLE 4.3 Values of Constant α/β and Time Strength Ratio $(f'_c)_t/(f'_c)_u$ at a Given Age

Type of Curing	Cement Type	Constant α/β	Concrete Age								Ultimate (in time)	
			Days						Years			
			3	7	14	21	28	56	91	1		10
Moist	I	4.71	0.39	0.60	0.75	0.82	0.86	0.92	0.95	0.99	1.0	1.0
	III	2.5	0.54	0.74	0.85	0.89	0.92	0.96	0.97	0.99	1.0	1.0
Steam	I	1.50	0.74	0.87	0.93	0.95	0.96	0.98	0.99	1.0	1.0	1.0
	III	0.71	0.81	0.91	0.95	0.97	0.97	0.99	0.99	1.0	1.0	1.0

Source: ACI Committee 209, *Prediction of Creep, Shrinkage, and Temperature Effects in Concrete Structures*, ACI 209R-92, American Concrete Institute, Farmington Hills, MI, 1992, pp. 1-47.

4.5.2 Modulus of Rupture (f_r) and Tensile Strength (f'_t)

The modulus of rupture (f_r) can be expressed as:

$$f_r = g_r \sqrt{w(f'_c)_t} \tag{4.16}$$

where g_r has a range of 0.6 to 1.00, with an average value of 0.65 (in SI units, this range is 0.012 to 0.021, with an average of 0.0135 MPa for f_r); w is the unit weight of the concrete in pounds per cubic foot for f_r in psi or kg/m³ for f_r in megapascals. Hence, Equation 4.16 becomes:

$$f_r \text{ (psi)} = 0.65 \sqrt{wf'_c} \tag{4.17a}$$

and

$$f_r \text{ (MPa)} = 0.013 \sqrt{wf'_c} \tag{4.17b}$$

Equation 4.17 is applicable for concrete strengths up to 12,000 psi (83 MPa). For normal weight concrete, $w = 145 \text{ lb/ft}^3$ (2320 kg/m³), and Equation 4.17 becomes:

$$f_r \text{ (psi)} = 7.5 \sqrt{f'_c} \tag{4.18a}$$

and

$$f_r \text{ (MPa)} = 0.60 \sqrt{f'_c} \tag{4.18b}$$

ACI Committee 363 (1992) on high-strength concrete (Nawy, 1996, 2001) recommends higher values for the modulus of rupture for normal weight concrete:

$$f_r \text{ (psi)} = 11.7 \sqrt{f'_c} \tag{4.19a}$$

and

$$f_r \text{ (MPa)} = 0.94 \sqrt{f'_c} \tag{4.19b}$$

The tensile splitting strength f'_t as recommended in ACI Committee 363 (1992) and ACI Committee 435 (1995) for normal weight concrete of a compressive-strength range up to 12,000 psi (83 MPa) is:

$$f'_t \text{ (psi)} = 7.4 \sqrt{f'_c} \tag{4.20a}$$

and

$$f'_t \text{ (MPa)} = 0.59 \sqrt{f'_c} \tag{4.20b}$$

4.5.3 Modulus of Elasticity (E_c)

The modulus of elasticity of concrete is strongly influenced by the concrete materials and mix proportions used. An increase in compressive strength is accompanied by an increase in the modulus, as the slope of the ascending branch of the stress–strain diagram becomes steeper. For concretes with densities in the range of 90 to 155 lb/ft³ (1440 to 2320 kg/m³), based on the secant modulus at 0.45 f'_c intercept and compressive strength up to 6000 psi (42 MPa):

$$E_c \text{ (psi)} = 33w^{1.5} \sqrt{f'_c} \quad (4.21a)$$

and

$$E_c \text{ (MPa)} = 0.0143w_c^{1.5} \sqrt{f'_c} \quad (4.21b)$$

As the strength of the concrete increases beyond 6000 psi, the measured value of E_c increases at a slower rate such that the value expressed in Equation 4.21 underestimates the actual value of the modulus. The value of the modulus for a compressive strength range of 6000 to 12,000 psi (42 to 83 MPa) (Nilson, 1985) can be predicted by:

$$E_c \text{ (psi)} = \left(40,000 \sqrt{f'_c} + 1.0 \times 10^6 \right) \left(\frac{w_c}{145} \right)^{1.5} \quad (4.22a)$$

and

$$E_c \text{ (MPa)} = \left(3.32 \sqrt{f'_c} + 6895 \right) \left(\frac{w_c}{2320} \right)^{1.5} \quad (4.22b)$$

Figure 4.17 gives the best fit for E_c vs. f'_c for high-strength concretes. Deviations from the predicted values are highly sensitive to properties of the coarse aggregate such as size, porosity, and hardness. When very high-strength concretes (20,000 psi or 140 MPa, or higher) are used in major structures or when deformation is critical, E_c should be determined from actual field cylinder test values and the 0.45 f'_c intercept in the resulting stress–strain diagram. Long-term effects on the modulus of elasticity can be viewed in terms of the gain in the compressive strength (f'_c)_t such that:

$$E_{ct} = E_c \sqrt{[(f'_c)_t / f'_c]} \quad (4.23)$$

where (f'_c)_t is equal to compressive strength at later ages and (f'_c) is equal to the 28-day compressive strength.

4.6 Serviceability Long-Term Considerations

In concrete structural members, serviceability is evaluated by cracking and deflection behavior. Creep and shrinkage effects on cracking and deflection are well established. Both deflections and crack widths increase with time. As a section cracks, its gross moment of inertia is reduced, resulting in reduced stiffness and larger deformations and deflections. The crack width (w) and the cracking moment (M_{cr}), are the principal parameters, together with the contribution of the reinforcement (compressive reinforcement in the case of deflection), that determine the long-term behavior of structural elements and systems.

4.6.1 Cracking Moment (M_{cr}) and Effective Moment of Inertia (I_e)

4.6.1.1 Reinforced Concrete Beams

Tension cracks develop when externally imposed loads cause bending moments in excess of the cracking moment, M_{cr} . As a result, tensile stresses in the concrete at the tensile extreme fibers exceed the modulus

FIGURE 4.17 Modulus of elasticity vs. concrete strength. (From Nilson, A.H., *Design Implications of Current Research on High Strength Concrete*, ACI SP-87-7, American Concrete Institute, Farmington Hills, MI, 1985.)

of rupture (f_r) of the concrete. The cracking moment for an uncracked section can be computed from the basic flexural formula:

$$M_{cr} = \frac{f_y I_g}{y_t} \tag{4.24a}$$

or

$$M_{cr} = \frac{f_r}{S_t} \tag{4.24b}$$

where:

- I_g = gross moment of inertia.
- y_t = distance from the neutral axis to the extreme tension fibers.
- f_r = modulus of rupture.
- S_t = section modulus to the extreme tension fibers.

Cracks develop at several sections along a member length. At those sections where the modulus of rupture (f_r) is exceeded, cracks develop and the moment of inertia is reduced to a cracked moment (I_{cr}). At other sections where cracks do not develop, I_g is used for evaluating the stiffness of the sections.

Branson's work (1977), the basis of the ACI 318 Code, proposed using the effective moment of inertia (I_e) for cracked sections:

$$I_e = \left(\frac{M_{cr}}{M_g} \right)^3 I_g + \left[1 - \left(\frac{M_{cr}}{M_a} \right)^3 \right] I_{cr} \leq I_g \tag{4.25}$$

FIGURE 4.18 Bilinear moment of inertia diagram. (From ACI Committee 435, *Control of Deflection in Concrete Structures*, American Concrete Institute, Farmington Hills, MI, 1995.)

where:

- M_{cr} = cracking moment.
- M_a = maximum moment at the stage at which deflections are being considered.
- I_g = gross moment of inertia of the section.
- I_{cr} = moment of inertia of the cracked transformed section.

The two moments, I_g and I_{cr} , are based on the assumption of bilinear load-deflection behavior, as seen in Figure 4.18 (Nawy, 2008). The cracked moment of inertia (I_{cr}) is:

$$I_{cr} = nA_s d \left(1 - 1.6\sqrt{n\rho} \right) \tag{4.26}$$

where:

- n = modular ratio = E_s/E_c .
- ρ = A_s/bd .
- d = effective depth.

Equation 4.25 can be rewritten as follows:

$$I_e = I_{cr} + \left(\frac{M_{cr}}{M_a} \right)^3 (I_g - I_{cr}) \leq I_g \tag{4.27}$$

For continuous beams, ACI 318 allows I_e to be taken as the average value obtained from Equation 4.25 or Equation 4.26 for the critical positive and negative moment sections. For prismatic sections, I_e may be taken as the value obtained at midspan for continuous spans. If the designer chooses to average the effective moments of inertia (I_e), the following expression can be used:

$$I_e = 0.5I_{e(m)} + 0.25(I_{e1} - I_{e2}) \tag{4.28}$$

where m , 1, and 2 refer to midspan and the two beam ends, respectively. Improved results for continuous prismatic members can be obtained by using a weighted average (ACI Committee 435, 1995) for beams that are continuous on both ends:

$$I_e = 0.70I_{e(m)} + 0.15(I_{e1} + I_{e2}) \tag{4.29a}$$

Or, for beams continuous on one end:

$$I_e = 0.85I_{e(m)} + 0.15(I_{e1}) \quad (4.29b)$$

4.6.1.2 Prestressed Concrete Beams

The effective moment of inertia (I_e) in Equation 4.25 and Equation 4.27 is based on different moment levels for M_{cr} and M_a in the case of prestressed concrete beams because of the initial compressive stress imposed by the prestressing force. The M_{cr}/M_a value is defined by:

$$\left(\frac{M_{cr}}{M_a}\right) = \left(1 - \frac{f_{TL} - f_r}{f_L}\right) \quad (4.30)$$

where:

$$f_r = 7.5\lambda\sqrt{f'_c}$$

Here, $\lambda = 1.0$ for normal weight concrete; $\lambda = 0.85$ for sand lightweight concrete; $\lambda = 0.75$ for all lightweight concrete, and

M_{cr} = moment due to that portion of the *unfactored live-load* moment that causes cracking.

M_a = maximum *unfactored* live-load moment.

f_{TL} = *total* calculated stress in the member.

f_L = calculated stress owing to *live load*.

In prestressed beams that are partially prestressed by the addition of mild steel reinforcement:

$$I_{cr} = \left(n_p A_{ps} d_p^2 + n_s A_s d^2\right) \left[1 - 1.6\sqrt{n_p \rho_p + n_s \rho}\right] \quad (4.31)$$

4.6.1.3 Effect of Compression Reinforcement

Compression reinforcement in reinforced flexural members and nontensioned reinforcement such as mild steel in prestressed flexural members tend to offset the movement of the neutral axis caused by creep (ACI Committee 209, 1992). A reverse movement toward the tensile fibers can thus result. A multiplier (γ) has to be used to account for increase in deflection, as required in the ACI 318 Building Code:

$$\gamma = \frac{\xi}{1 + 50\rho'} \quad (4.32)$$

where:

ξ = time-dependent factor for the long-term increase in deflection obtained from Figure 4.19 (ACI Committee 435, 1995).

ρ' = A'_s/bd .

A'_s = area of compression reinforcement (in square inches).

Nilson (1985) suggested that two modifying factors should be applied to Equation 4.32: the material modifier (μ_m) to be applied to ξ and the section modifier (μ_s) to be applied to ρ' . Both μ_m and μ_s have a value of 1 or less. Combining the two multipliers, without significant loss in accuracy, Equation 4.32 becomes:

$$\gamma = \frac{\mu\xi}{1 + 50\mu\rho'} \quad (4.33)$$

FIGURE 4.19 Multipliers for long-term deflection. (From Nawy, E.G., *Reinforced Concrete: A Fundamental Approach*, 6th ed., Prentice Hall, Upper Saddle River, NJ, 2008.)

with the range of μ values as follows within the 6000- to 9500-psi (42- to 66-MPa) compressive strength tests conducted:

$$\mu \geq 0.7 \quad (4.34a)$$

$$\mu \leq (1.3 - 0.00005f'_c) \leq 1.0$$

or, megapascals for f'_c :

$$\mu \leq (1.3 - 0.0072f'_c) \leq 1.0 \quad (4.34b)$$

Further evaluations are needed for cases where the concrete strength is higher than 12,000 psi (83 MPa).

4.6.2 Flexural Crack Width Development

External load results in direct and bending stresses, which cause flexural, bond, and diagonal tension cracks. Immediately after the tensile stress in the concrete exceeds its tensile strength at a particular location, any internal microcracks that might have formed begin to propagate into macrocracks. These cracks develop into macrocracks that propagate to the external fiber zones of the element. Immediately after full development of the first crack in a reinforced concrete element, the stress in the concrete at the cracking zone is reduced to zero and is assumed by the reinforcement (Nawy, 2001, 2008). The distribution of ultimate bond stress (μ), longitudinal stress in the concrete (f_t), and longitudinal tensile stress (f_s) in the reinforcement can be schematically represented as shown in Figure 4.20. Crack width is primarily a function of the deformation of reinforcement between the two adjacent cracks, 1 and 2 (Figure 4.20), if the small concrete tensile strain along the crack interval a_c is neglected. The crack width is thus a function of crack spacing up to the load level at which no more cracks develop, which leads to stabilization of the crack spacing, as shown in Figure 4.21. The major parameters affecting the development and characteristics of cracks are percentage of reinforcement, bond characteristics and size of bar, concrete cover, and the concrete area in tension. On this basis, one can propose the following mathematical model:

$$w = \alpha a_c^\beta \epsilon_s^\gamma \quad (4.35)$$

where w is maximum crack width and α , β , and γ are nonlinearity constants. Crack spacing (a_c) is a function of factors to be subsequently discussed and is inversely proportional to bond strength and active steel ratio (steel percentage in terms of the concrete area in tension). Here, ϵ_s is the strain in the reinforcement induced by the external load.

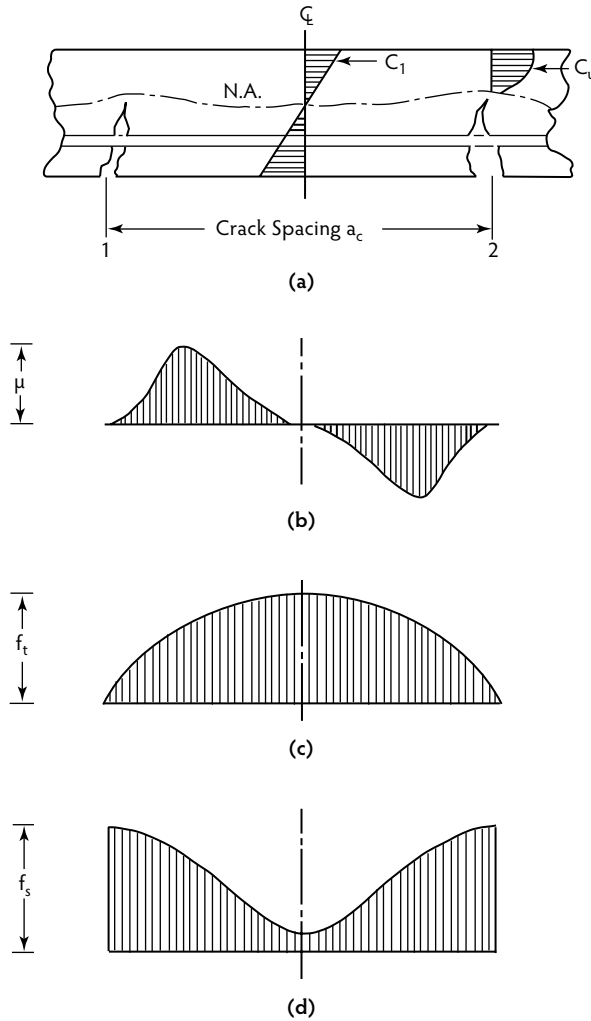

FIGURE 4.20 Schematic stress distribution between two flexural cracks. (From Nawy, E.G. and Blair, K.W., in *Cracking, Deflection, and Ultimate Load of Concrete Slab Systems*, ACI SP-30, Nawy, E.G., Ed., American Concrete Institute, Farmington Hills, MI, 1971, pp. 1–41.)

FIGURE 4.21 Schematic variation of crack width with crack spacing. (From Nawy, E.G. and Blair, K.W., in *Cracking, Deflection, and Ultimate Load of Concrete Slab Systems*, ACI SP-30, Nawy, E.G., Ed., American Concrete Institute, Farmington Hills, MI, 1971, pp. 1–41.)

The basic mathematical model (Equation 4.35), with the appropriate experimental values of the constants α , β , and γ , can be derived for a particular type of structural member. Such a member can be a one-dimensional element such as a beam, a two-dimensional structure such as a two-way slab, or a three-dimensional member such as a shell or circular tank wall. Hence, it is expected that different forms or expressions apply for evaluation of macrocracking behavior of different structural elements consistent with their fundamental structural behavior (ACI Committee 224, 2001; ACI Committee 318, 2008; CEB-FIP, 1990; Gergely and Lutz, 1968; Nawy, 1972a,b, 1994; Nawy and Blair, 1971).

4.6.2.1 Reinforced Concrete Beams and One-Way Slabs

The requirements for crack control in beams and thick one-way slabs—10 in. (250 mm) or thicker—in the ACI Building Code (ACI Committee 318, 2008) are based on the statistical analysis of maximum crack width data from a number of sources. On the basis of the analysis, the following general conclusions were reached (Gergely and Lutz, 1968; Nawy, 1972a,b, 1994; Nawy and Blair, 1971):

1. The steel stress is the most important variable.
2. The thickness of the concrete cover is an important variable.
3. The area of concrete surrounding each reinforcing bar is an important geometric variable.
4. Bar diameter is not a major variable.
5. The bottom crack width is influenced by the amount of strain gradient from the level of the steel to the tension face of the beam.

The simplified expression relating crack width to steel stress is (Gergely and Lutz, 1968):

$$w_{\max} (\text{in.}) = 0.076\beta f_s \sqrt[3]{d_c A} \times 10^{-3} \quad (4.36a)$$

where:

f_s = reinforcing steel stress (ksi).

A = area of concrete symmetrical with reinforcing steel divided by number of bars (in.^2).

d_c = thickness of concrete cover measured from extreme tension fiber to center of bar or wire closest thereto (in.).

β = h_2/h_1 , where h_1 is the distance from the neutral axis to the reinforcing steel (in.), and h_2 is the distance from the neutral axis to the extreme concrete tensile surface.

When the strain (ϵ_s) in the steel reinforcement is used instead of stress (f_s), Equation 4.36a becomes:

$$w = 2.2\beta \epsilon_s \sqrt[3]{d_c A} \quad (4.36b)$$

Equation 4.36b is valid in any system of measurement.

The cracking behavior in thick one-way slabs is similar to that in shallow beams. For one-way slabs that have a clear concrete cover in the range of 1 in. (25.4 mm), Equation 4.38 can be adequately applied if $\beta = 1.25$ to 1.35 is used.

The ACI 318 Building Code currently uses reinforcement spacing as the criteria for control of the crack width. It recommends for beams and one-way slabs the following expression:

$$s (\text{in.}) = 15 \left(\frac{40,000}{f_s} \right) - 2.5c \quad (4.37)$$

but not greater than $12(40,000/f_s)$, where:

s = spacing (in.).

f_s = calculated reinforcement stress at service level or alternatively taken as 2/3 the yield strength f_y (psi).

c = clear cover to the reinforcement (in.).

TABLE 4.4 Maximum Tolerable Flexural Crack Widths

Exposure Condition	Crack Width	
	Inch	Min.
Dry air or protective membrane	0.016	0.40
Humidity, moist air, soil	0.012	0.30
Deicing chemicals	0.007	0.18
Seawater and seawater spray; wetting and drying	0.006	0.15
Water-retaining structures (excluding nonpressure pipes)	0.004	0.10

Sources: ACI Committee 224, *Proc. ACI J.*, 20(10), 35–76, 2001; Nawy, E.G., *Reinforced Concrete: A Fundamental Approach*, 6th ed., Prentice Hall, Upper Saddle River, NJ, 2008, p. 864.

The SI expression in Equation 4.37 is:

$$s \text{ (mm)} = 380 \left(\frac{280}{f_s} \right) - 2.5c_c \tag{4.38}$$

but not to exceed $300(280/f_s)$, where f_s in usual cases is taken as 252 MPa.

It should be noted that the ACI expression is applicable to reinforced concrete beams and one-way slabs in normal environmental conditions. In aggressive environments, such as liquid-retaining sanitary structures, Equations 4.36a and 4.36b, with the appropriate limitation of tolerable crack widths listed in Table 4.4, are more appropriate in such cases.

4.6.2.2 Prestressed Concrete Beams

4.6.2.2.1 Crack Spacing

Primary cracks form in the region of maximum bending moment when the external load reaches the cracking load. Sometimes, in post-tensioned parking garage elements, cracks form in the draped region before forming at the maximum moment region. They can also form at debonded tendon locations. As loading is increased, additional cracks will form, and the number of cracks will be stabilized when the stress in the concrete no longer exceeds its tensile strength at further locations, regardless of load increase. This condition is important, as it essentially produces the absolute minimum crack spacing that can occur at high steel stresses, and is termed the **stabilized minimum crack spacing**. The maximum possible crack spacing under this stabilized condition is twice the minimum and is termed the *stabilized maximum crack spacing*. Hence, the **stabilized mean crack spacing** (a_{cs}) is deduced as the mean value of the two extremes. The total tensile force (T) transferred from the steel to the concrete over the stabilized mean crack spacing (Nawy, 1990, 1994, 1996) can be defined as:

$$T = \gamma a_{cs} \mu \sum o \tag{4.39a}$$

where:

- γ = a factor reflecting the distribution of bond stress.
- μ = maximum bond stress that is a function of $\sqrt{f'_c}$.
- $\sum o$ = sum of reinforcing elements' circumferences.

Figure 4.22 illustrates the forces that cause the formation of the stabilized crack.

The resistance (R) of the concrete area in tension (A_c) can be defined as:

$$R = A_c f'_t \tag{4.39b}$$

where f'_t is the tensile splitting strength of the concrete.

FIGURE 4.22 Force and stress distribution in stabilized crack in a prestressed beam. (From Nawy, E.G., in *Cracking in Prestressed Concrete Structures*, ACI SP-113, American Concrete Institute, Farmington Hills, MI, 1990, pp. 1-42.)

By equating Equations 4.39a and 4.39b, the following expression for a_{cs} is obtained, where c is a constant to be developed from the tests:

$$a_{cs} = c \frac{A_t f_t'}{\sum o \sqrt{f_c'}} \tag{4.40a}$$

The concrete stretched area (namely, the concrete area A_t that is under tension for both the evenly distributed and unevenly distributed reinforcing elements) is illustrated in Figure 4.23. With a mean value of:

$$f_t' / \sqrt{f_c'} = 7.95$$

the mean stabilized crack spacing becomes:

$$a_{cs} = 1.20 \frac{A_t}{\sum o} \tag{4.40b}$$

4.6.2.2.2 Crack Width

If Δf_s is the net stress in the prestressed tendon or the magnitude of the tensile stress in normal steel at any crack-width load level in which the decompression load (decompression here means $f_c' = 0$ at the

FIGURE 4.23 Effective concrete area in tension: (a) even reinforcement distribution; (b) non-even reinforcement distribution. (From Nawy, E.G., in *Cracking in Prestressed Concrete Structures*, ACI SP-113, American Concrete Institute, Farmington Hills, MI, 1990, pp. 1-42.)

level of the reinforcing steel) is taken as the reference point (Nawy, 1990, 1996), then for the prestressed tendon:

$$\Delta f_s = f_{nt} - f_d \tag{4.41}$$

where:

f_{nt} = stress in the prestressing steel at any load beyond the decompression load.

f_d = stress in the prestressing steel corresponding to the decompression load.

Unit strain $\epsilon_s = \Delta f_s / E_s$. It is logical to disregard as insignificant unit strains in the concrete caused by temperature, shrinkage, and elastic shortening effects. The maximum crack width as defined in Equation 4.35 can therefore be taken as:

$$w_{\max} = k a_{cs} \epsilon_s^\alpha \tag{4.42a}$$

or

$$w_{\max} = k' a_{cs} (\Delta f_s)^\alpha \tag{4.42b}$$

where k' is a constant in terms of constant k .

4.6.2.2.3 Expression for Pretensioned Beams

Equation 4.42b is rewritten in terms of Δf_s to give the maximum crack width at the reinforcement level as follows:

$$w_{\max} \text{ (in.)} = 5.85 \times 10^{-5} \frac{A_t}{\Sigma o} (\Delta f_s) \tag{4.43a}$$

where A_t = square inches, Σo = inches, and Δf_s = kips/in.², and

$$w_{\max} \text{ (mm)} = 8.48 \times 10^{-5} \frac{A_t}{\Sigma o} (\Delta f_s) \tag{4.43b}$$

where A_t = cm², Σo = cm, and Δf_s = MPa.

FIGURE 4.24 Linearized maximum crack width vs. $(A_t/\Sigma_o)\Delta f_s$ for pretensioned beams (Nawy, 1990, 1994, 1996, 2005).

The maximum crack width (inches) at the tensile face of the concrete is:

$$w'_{max} = 5.85 \times 10^{-5} R_i \sum_o \frac{A_t}{\Sigma_o} (\Delta f_s) \tag{4.43c}$$

where R_i is the distance ratio equal to h_2/h_1 , where h_2 is the distance from the neutral axis to the extreme tension fibers and h_1 is the distance from the neutral axis to the reinforcement centroid. A plot of the pretensioned beams test data and the best fit expression for Equation 4.43a is given in Figure 4.24 with a 40% spread, which is reasonable in view of the randomness of crack development.

4.6.2.2.4 Expressions for Post-Tensioned Beams

The expression developed for the crack width in post-tensioned bonded beams that contain mild steel reinforcement is:

$$w_{max} \text{ (in.)} = 6.51 \times 10^{-5} \sum_o \frac{A_t}{\Sigma_o} (\Delta f_s) \tag{4.44a}$$

and

$$w_{max} \text{ (mm)} = 9.44 \times 10^{-5} \sum_o \frac{A_t}{\Sigma_o} (\Delta f_s) \tag{4.44b}$$

for the crack width at the reinforcement level closest to the tensile face.

At the tensile face, the crack width for the post-tensioned beams becomes:

$$w_{max} \text{ (in.)} = 6.51 \times 10^{-5} R_i \sum_o \frac{A_t}{\Sigma_o} (\Delta f_s) \tag{4.44c}$$

For nonbonded beams, the factor 6.51 in Equations 4.44a and 4.44c becomes 6.83. A plot of the data and the best-fit expression for Equation 4.44a is given in Figure 4.25. A typical plot of the effect of the various steel percentages on the crack spacing at various stress levels (Δf_s) is given in Figure 4.26. It can be seen from this plot that crack spacing stabilizes at a net stress level range of 30 to 36 kips/in.² (207 to 248 MPa).

FIGURE 4.25 Linearized maximum crack width vs. $(A_t/\Sigma_o)\Delta f_s$ for post-tensioned beams (Nawy, 1990, 1994, 1996, 2005).

FIGURE 4.26 Effect of steel percentage on mean crack spacing in prestressed beams (Nawy, 1990, 1994, 1996, 2005).

4.6.2.2.5 Cracking of High-Strength Prestressed Beams

Analysis of continuing subsequent work by the first author on the cracking behavior of pretensioned and nonbonded post-tensioned beams having cylinder compressive strengths in the range of 10,200 to 14,200 psi (70.3 to 97.9 MPa) have resulted in the following expression for crack width at the reinforcement level of pretensioned members:

$$w_{\max} \text{ (in.)} = 2.75 \times 10^{-5} \frac{A_t}{\Sigma_o} (\Delta f_s) \tag{4.45a}$$

and

$$w_{\max} \text{ (mm)} = 4.0 \times 10^{-5} \frac{A_t}{\Sigma_o} (\Delta f_s) \tag{4.45b}$$

FIGURE 4.27 Reinforcement stress vs. crack width (best-fit data of several investigators). (From Nawy, E.G., in *Proceedings of CANMET International Symposium on Advances in Concrete Technology*, 2nd ed., Malhotra, V.M., Ed., Canada Center for Mineral and Energy Technology (CANMET), Ottawa, 1994, pp. 203–242.)

The factor 2.75 is an average of values from the following statistical expression (Nawy, 1994) for a reduction multiplier λ_r of w_{\max} in Equation 4.43 such that:

$$\lambda_r = \frac{2}{(0.75 + 0.06\sqrt{f'_c})\sqrt{f'_c}} \quad (4.45c)$$

This reduced crack width due to use of high-strength concrete is expected in view of the increased bond interaction between the concrete and the reinforcement.

4.6.2.2.6 Other Work on Cracking in Prestressed Concrete

After analyzing results from various investigators (Harajli and Naaman, 1989; Naaman and Siriakson, 1979), Naaman produced the following modified expression for partially prestressed pretensioned members:

$$w_{\max} (\text{in.}) = \left(42 + 5.58 \frac{A_t}{\Sigma o} (\Delta f_s) \right) \times 10^{-5} \quad (4.46)$$

This expression is very close to that in Equation 4.43 by Nawy. If plotted against results of the various researchers' work, it gives a best fit as shown in Figure 4.27.

4.6.2.3 Two-Way Supported Slabs and Plates

Flexural crack control is essential in structural floors, most of which are under two-way action. Cracks at service-load and overload conditions can be serious in floors such as those in office buildings, schools, parking garages, and industrial buildings and in other floors where the design service load and overload levels exceed loads in normal-size apartment building panels. Such cracks can only lead to detrimental effects on the integrity of the total structure, particularly in adverse environmental conditions.

4.6.2.3.1 Flexural Cracking Mechanism and Fracture Hypothesis

Flexural cracking behavior in concrete structural floors under two-way action is significantly different from that in one-way members. Crack control equations for beams underestimate crack widths developed in two-way slabs and plates and do not tell the designer how to space reinforcement. Cracking in two-way slabs and plates is primarily controlled by the steel stress level and the **spacing** of reinforcement in two perpendicular directions. In addition, the clear concrete cover in two-way slabs and plates is nearly

constant (3/4 in., or 20 mm, for interior exposure), whereas it is a major variable in the crack control equations for beams. Results from extensive tests on slabs and plates (Nawy, 1972a, 1994; Nawy and Blair, 1971) demonstrate this difference in behavior in a fracture hypothesis on crack development and propagation in two-way plate action. Nawy's work also conclusively demonstrated that surface deformations of individual reinforcing elements have little effect on arresting the generation of cracks or controlling crack type or width in a two-way-action slab or plate. One may also conclude that the scale effect on two-way-action cracking behavior is insignificant, as the cracking grid is a reflection of the reinforcement grid if the preferred orthogonal narrow cracking widths develop. To control cracking in two-way-action floors, then, the major parameter to be considered is the reinforcement spacing in the two perpendicular directions. Concrete cover has only a minor effect, as the cover is usually small, with a constant value of 0.75 in. (20 mm). Maximum spacing of the reinforcement in both orthogonal directions should not exceed 12 in. (30 cm) in any structural floor.

4.6.2.3.2 Crack Control Equation

The basic Equation 4.35 for relating crack width to strain in the reinforcement is:

$$w = \alpha a_c^\beta \epsilon_s^\gamma$$

The effect of the tensile strain in the concrete between the cracks is neglected as insignificant. The parameter a_c is the crack spacing, ϵ_s is the unit strain in the reinforcement, and α , β , and γ are constants evaluated by tests. The mathematical model in Equation 4.35 and statistical analysis of the data of 90 slabs tested to failure give the following equation (ACI Committee 224, 2001; Nawy and Blair, 1971) for serviceability requirements for crack control:

$$w \text{ (in.)} = K \beta f_s \sqrt{G_I} \tag{4.47}$$

Using SI units, the expression becomes:

$$w_{\max} \text{ (mm)} = 0.145k \beta f_s \sqrt{G_I} \tag{4.48}$$

where f_s is in megapascals, and all the terms for the grid index (G_I) in Equation 4.49 are in millimeters. $G_I = d_{b1}s_2/\rho_{t1}$ is the grid index that defines the reinforcement distribution in two-way action slabs and plates. It can be transformed in Equation 4.47 to:

$$G_I = \frac{s_1 s_2 d_c}{d_{b1}} \frac{8}{\pi} \tag{4.49}$$

where:

K = fracture coefficient, having a value of $K = 2.8 \times 10^{-5}$ for uniformly loaded restrained two-way action square slabs and plates. For concentrated loads or reactions, or when the ratio of short to long span is less than 0.75 but larger than 0.5, a value of $K = 2.1 \times 10^{-5}$ is applicable. For a span-aspect ratio of 0.5, $K = 1.6 \times 10^{-5}$. Units of coefficient K are in square inch per pound. (See also Table 4.5.)

β = ratio of the distance from the neutral axis to the tensile face of the slab to the distance from the neutral axis to the centroid of the reinforcement grid (to simplify the calculations use, $\beta = 1.25$, although it varies between 1.20 and 1.35).

f_s = actual average service load reinforcement stress level, or 40% of the design yield strength (ksi).

d_{b1} = diameter of the reinforcement in direction 1 closest to the concrete outer fibers (in.).

s_1 = spacing of the reinforcement in perpendicular direction 1 (in.), closest to the tensile face.

s_2 = spacing of the reinforcement in perpendicular direction 2 (in.).

1 = direction of the reinforcement closest to the outer concrete fibers; this is the direction for which the crack control check is to be made.

ρ_{t1} = active steel ratio in direction 1:

TABLE 4.5 Fracture Coefficients for Slabs and Plates

$$\rho_{t1} = \frac{\text{Area of steel } A_s \text{ per foot width}}{12(d_{b1} + 2c_1)}$$

where c_1 is the clear concrete cover measured from the tensile face of the concrete to the nearest edge of the reinforcing bar in direction 1, and w is the crack width (in.) at the face of the concrete caused by flexural load. Subscripts 1 and 2 pertain to the directions of reinforcement. Detailed values of the fracture coefficients for various boundary conditions are given in Table 4.5. A graphical solution for Equation 4.47 is given in Figure 4.28 for $f_y = 60$ ksi (414 MPa), $f_s = 40\%$, and $f_y = 40$ ksi (165.5 MPa) for rapid determination of the reinforcement size and spacing needed for crack control.

Because cracking in two-way slabs and plates is primarily controlled by the grid intersections of the reinforcement, concrete strength is not of major consequence; hence, the value of crack width in two-way action predicted by Equation 4.47 should not be significantly affected if higher strength concretes are used in excess of 6000 psi (41.4 MPa). It has to be pointed out that in two-way normal-slab floors, the use of much higher strengths is not justified in economical terms.

4.6.2.3.3 Tolerable Crack Widths in Concrete Structures

The maximum crack width that a structural element should be permitted to develop depends on the particular function of the element and the reasonable guide to the tolerable average crack widths in concrete structures under various normally encountered environmental conditions. Its values are in close agreement with the Comité Eurointernational du Béton recommendations (CEB-FIP, 1990) foremost exposure conditions. The crack-control equation and guidelines presented are important not only for the control of corrosion in reinforcement but also for deflection control. The reduction of the stiffness (EI) of the two-way slabs or plates due to orthogonal cracking when the tolerable crack widths in Table 4.6 are exceeded can lead to both short- and long-term excessive deflection. Deflection values that are several times greater than those anticipated in the design, including deflection due to construction loading, can be reasonably controlled through camber and control of the flexural crack width in the slab or plate. Proper selection of reinforcement spacing s_1 and s_2 in the perpendicular directions, as discussed in this section, that does not exceed 12 in. (30 cm) center-to-center can maintain the good serviceability performance of a slab system under normal and reasonable overload conditions.

4.6.2.3.4 Long-Term Effects on Cracking

In most cases, the magnitude of crack widths increases in long-term exposure and long-term loading. Increase in crack width can vary considerably in cases of cyclic loading, such as in bridges; however, the crack width increases at decreasing rate with time. In most cases, a doubling of crack width after several years under sustained loading is not unusual.

4.6.2.4 Cracking in Circular Prestressed Concrete Tanks

Circular prestressed tanks are cylindrical shell elements of very large diameter in relation to their height; hence, with respect to flexural cracking, it is possible to treat the wall of a tank in a manner similar to the treatment of two-way action plates. Vessey and Preston (1978) modified Nawy and Blair’s (1971) expressions for two-way action slabs and plates so the maximum crack width can be defined as:

$$w_{\max} (\text{in.}) = 4.1 \times 10^{-6} \epsilon_{ct} E_{ps} \sqrt{G_I} \quad (4.50)$$

Using SI units, the expression becomes:

$$w_{\max} (\text{mm}) = 0.6 \times 10^{-6} \epsilon_{ct} E_{ps} \sqrt{G_I} \quad (4.51)$$

where, in the SI expression, E_{ps} is in MPa, the dimensions of all the parameters of the grid index G_I are in millimeters, and

ϵ_{ct} = tensile surface strain in the concrete = $(\lambda_t F_p)/(E_{ps})$.

f_p = actual stress in the steel.

f_{pi} = initial prestress before losses.

$\lambda_t = f_p/f_{pi}$.

$G_I = \text{grid index} = (s_1 s_2 d_c/d_{b1})(8/\pi)$.

d_{b1} = diameter of steel in direction 1.

s_1 = spacing of the reinforcement in direction 1 closest to the tensile face.

s_2 = spacing of the reinforcement in direction 2.

d_c = concrete cover to center of steel, inches.

Note that $w_{\max} = 0.004$ in. (0.1 mm) should be the limit of crack width for liquid-retaining tanks.

4.7 Long-Term Shrinkage and Temperature Reinforcement Controlling Cracking Between Joints in Walls and Slabs of Liquid-Retaining Structures

Cracking resulting from these unavoidable short-term and long-term strain gradients has always been a problem for the designer to consider as a significant factor in any structural design; hence, the use of joints is inevitable. It would be rare to find a structural system with total stress relievers, where if enough reinforcement is provided in the direction of the induced forces to prevent the cracks from opening then no joint would be needed. It would be economically prohibitive, as the volume of reinforcement required to perform this task would be significant. Because the induced forces are highly indeterminate, engineering judgment has to be exercised in interpreting the imprecise guidelines in codes and the literature on the type and spacing of joints to control cracking, which often render conflicting solutions.

Table 4.6 and Figure 4.29 (ACI Committee 350, 2001) stipulate the reinforcement percentages of shrinkage and temperature reinforcement for effective control of cracks that is essential to maintain between joints in liquid-retaining structures. Whereas the maximum percentage in Table 4.6 is given as 0.5% for movement joints of 40 feet, the high rigidity of the foundation slab at the wall joint to the slab renders this percentage inadequate. The relative lower flexibility of the wall as compared to the stiff foundation slab at the lower wall segment makes the connection totally rigid with a low magnitude of rotation at the joint, as the wall is almost fixed at the base and free at the top. To prevent long-term vertical cracking concentration at the lower quarter of the wall height, it might even be prudent to use almost 1.0 to 1.25% horizontal reinforcement for the lowermost segment of the wall if the wall thickness is in the range of 30 in. Details regarding the design, spacing, and construction of joints in most types of structural systems for the control of long-term cracking are covered in Chapter 17 of this *Handbook*.

4.8 Autogenous Shrinkage in Early-Age Concrete

Shrinkage in early-age concrete is an important aspect in determining the long-term cracking performance of concrete. The methods of curing have a significant effect on the level of shrinkage strains that develop, so it is useful to observe the different performances expected from different methods of curing and also the effect of the constituent cementitious materials on the autogenous shrinkage performance of the system. Tests by Suksawang et al. (2005) have provided a measure of differences in strains (hence, stresses) at 0 to 7 days and up to 100 days of curing. Figure 4.30a (early-age performance) and Figure 4.30b (100-day performance) indicate that, after 28 days of curing, the dry-cured specimen exhibited steeper shrinkage levels than the others due to the fact that less internally adsorbed water was available to prevent a higher increase in shrinkage strains. Figure 4.31 shows the effect of the pozzolanic content in the mixture on the autogenous shrinkage, where concrete with fly ash outperformed the others. Figure 4.32 demonstrates the significant difference between the shrinkage performance of lightweight and normal weight aggregate concrete under identical dry curing conditions and having the same water/cementitious ratio (w/cm) of 0.29. Shrinkage in the lightweight aggregate concrete was almost stabilized with minimal increase in shrinkage strain after 36 hours at a shrinkage strain of $200 \mu\epsilon$, whereas in the case of normal weight concrete it was close to $700 \mu\epsilon$ at the same time interval and continuing to increase at a fast rate. This behavior has been observed by many investigators and can be attributed to the fact that lightweight aggregate concrete has a higher inert moisture content; hence, as the cement hydrates, it is constantly supplied with adsorbed moisture, making the specimen, through internal curing, less susceptible to shrinkage.

5.1 Introduction

Portland cement concrete is a simple material in appearance but has a very complex internal nature. Despite its internal complexity, the versatility, durability, and economy of concrete have made it the world's most used construction material. This can be seen in the variety of structures for which it is used, from highways and bridges to buildings and dams (Figure 5.1). Concrete is a mixture of Portland cement, water, and aggregates, with or without admixtures. Portland cement and water form a paste that hardens due to chemical reactions between the cement and water. The paste acts as a glue, binding the aggregates, composed of sand and gravel or crushed stone, into a solid rock-like mass. The quality of the paste and aggregates dictates the engineering properties of concrete construction. Paste qualities are directly related to the amount of water used in relation to the amount of cement. The less water used, the better the quality of the concrete. Reduced water content results in improved strength and durability and reduced permeability and shrinkage. Fine and coarse aggregates make up 60 to 75% of the total volume of the concrete (Figure 5.2); therefore, selection of aggregate is important. Aggregates must be of adequate strength, resistant to exposure conditions, and durable.

Concrete is often discussed as being of “normal strength” or “high strength.” Normal-strength concrete typically has a compressive strength of between 3000 and 6000 psi (20 to 40 MPa). In this chapter, high-strength concrete refers to concrete with a compressive strength of between 6000 and 20,000 psi (40 to 140 MPa). The distinction between normal- and high-strength concrete has changed through history as concrete technology has advanced. One hundred years ago, 4000-psi (28-MPa) concrete would have been considered a high-strength concrete. Today, concretes for special applications can achieve compressive strengths over 120,000 psi (800 MPa)—these are called *reactive powder concretes*. These very exotic materials will not be addressed due to their limited use in general construction; however, for efficiency, normal- and high-strength concretes (up to 20,000 psi) are discussed in tandem, as they use the same materials and have similar properties (Kosmatka et al., 2006; Nawy, 1996, 2008).

Normal-strength concrete is used in most construction applications. Only a small percentage of concrete structures use high-strength concrete. High-strength concrete is used for reduced weight, creep, or permeability; for improved durability; or where architectural considerations require smaller load-carrying elements. The Two Union Square building in Seattle has the highest strength concrete used in a major building—almost 20,000 psi (140 MPa) in the columns (Figure 5.3). In this case, high strength was needed to minimize creep. In other high-rise buildings, high-strength concrete helps achieve more efficient floor plans through smaller vertical members.

5.2 Workability, Bleeding, and Consolidation

Freshly mixed concrete should be plastic or in a semifluid state that can be molded by hand or by mechanical means. In a plastic concrete mixture, all the particles of sand and coarse aggregate are encased and held in suspension. The ingredients should not segregate or separate during transport or handling. A uniform distribution of aggregate particles helps control segregation. After the concrete hardens, it becomes a homogeneous mixture of all the components. Concrete of plastic consistency should not crumble but should flow sluggishly without segregation (Figure 5.4). Concrete consistency is measured by the slump test, ASTM C 143 (Figure 5.5). Slumps of 1 to 3 in. (25 to 75 mm) are used for pavements and slabs. Slumps of 3 to 5 in. (75 to 125 mm) are used for columns and walls. Higher slump concretes, made with plasticizers, are used in thin applications, in locations with large amounts of reinforcing steel, or where concrete needs to be essentially self-consolidating.

Workability reflects the ease of placing, consolidating, and finishing freshly mixed concrete. Concrete should be workable but should not segregate or bleed excessively. Normal-strength concrete usually has good workability as long as concrete ingredients are used in proper proportions and an adequate aggregate gradation is used; however, high-strength concrete is often sticky and difficult to handle and place, even with the aid of plasticizers, due to its high cement content. Concrete temperature also affects workability. Figure 5.6 illustrates that increases in temperature for an established mix reduce slump and workability,

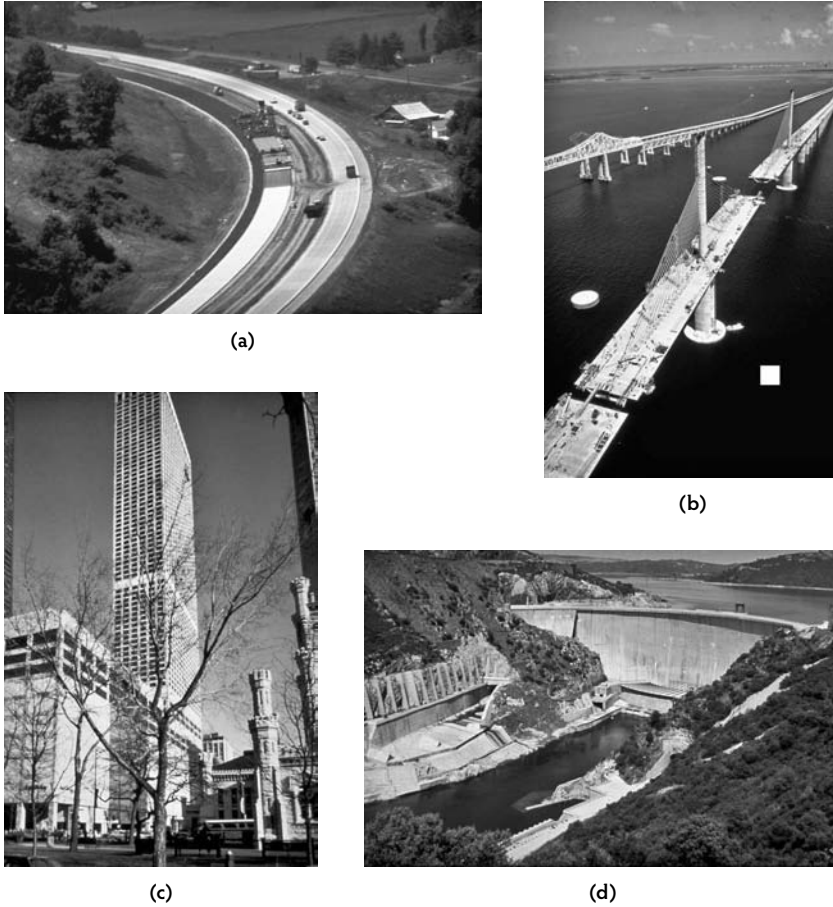

FIGURE 5.1 Concrete used in a variety of applications: (a) highways, (b) bridges, (c) buildings, and (d) dams. (Figure courtesy of the Portland Cement Association, Skokie, IL.)

FIGURE 5.2 Range of proportions of materials used in concrete. (From Kosmatka, S.H. et al., *Design and Control of Concrete Mixtures*, EB001, Portland Cement Association, Skokie, IL, 2006.)

resulting in the need to adjust the mix for environmental conditions. As concrete mixture temperature is increased from 73°F (23°C), slump will decrease approximately 0.8 in. for each 20°F temperature increase (20 mm for each 10°C increase).

FIGURE 5.3 High-strength concrete in buildings in the 1980s and 1990s. (From Farny, J.A. and Panarese, W.C., *High-Strength Concrete*, EB114, Portland Cement Association, Skokie, IL, 1994.)

FIGURE 5.7 Bleed water on freshly placed concrete surface. (Figure courtesy of the Portland Cement Association, Skokie, IL.)

Bleeding is the development of a layer of water at the top of freshly placed concrete that is caused by settlement of solid particles of cement and aggregate and the simultaneous upward migration of water (Figure 5.7). A small amount of bleeding is normal and will not affect the durability or strength of the concrete; however, excessive bleeding can result in high water/cement ratios that can cause durability and surface-strength problems. Finishing should be performed after the presence of bleed water is gone. Use of a properly graded aggregate and a proper dosage of cementitious materials will reduce bleeding to an acceptable level. High-strength concrete essentially does not bleed due to its low water content and large amount of cementitious materials. Air-entrained concrete also has little to no bleed water. To achieve desired strength and durability, concrete must be consolidated to form a homogeneous mass without the presence of large voids. Internal and external vibration of concrete, using vibrators, allows stiff, low-slump mixtures to be properly densified. The use of mechanical vibration provides an economical, practical method to quickly consolidate concrete without detrimentally affecting its properties (Figure 5.8).

5.3 Mixing, Transporting, and Placing Concrete

All concrete should be mixed thoroughly until it is uniform in appearance and all ingredients are evenly distributed. If concrete has been adequately mixed, samples taken from different portions of a batch will have essentially the same unit weight, air content, slump, and strength. Concrete is sometimes mixed at a jobsite in a stationary mixer or paving mixer; at other times, it is mixed in central mixers at ready-mix plants. Ready-mixed concrete can be manufactured by any of the following methods:

- Centrally mixed concrete is completely mixed in a stationary mixer and then delivered in a truck agitator or in a truck mixer at agitating speed to the job site.
- Shrink-mixed concrete is partially mixed in a stationary mixer and completed in a truck mixer.
- Truck-mixed concrete is mixed completely in a truck mixer.

When concrete has been transported to a job site, it is conveyed by a variety of methods, including belt conveyors, buckets, shoots, cranes, pumps, wheelbarrows, and other equipment (Figure 5.9). Concrete should be conveyed in such a manner that it is not allowed to dry out; it should not be delayed, and it should not be allowed to segregate before it is placed. Table 5.1 describes the advantages of various methods and types of equipment for transporting and handling concrete.

FIGURE 5.8 Proper vibration facilitates concrete placement even in heavily reinforced members. (Figure courtesy of the Portland Cement Association, Skokie, IL.)

(a)

(b)

FIGURE 5.9 (a) Truck-mounted pump and boom, and (b) a conveyer belt, which can conveniently move concrete to the desired location. (Figure courtesy of the Portland Cement Association, Skokie, IL.)

Concrete should be deposited continuously as near as possible to its final position. Concrete should be placed in horizontal layers of uniform thickness, each layer being thoroughly consolidated before the next is placed. The rate of placement should be rapid enough that a layer of concrete is not yet set when a new layer is placed upon it. Drop shoots should be used to prevent segregation and spattering of mortar on reinforcement and forms in wall placements.

When the concrete has been placed in a form or layer, it should be consolidated or compacted into the mold so it forms in and around embedded items and reinforcement and removes entrapped air. Consolidation is usually accomplished by mechanical methods. Use of internal vibrators is the most common method of consolidating concrete. When concrete is vibrated, it behaves like a liquid; it settles in the forms by the action of gravity, and large entrapped air voids rise to the surface. Workers must be careful to make sure that the vibrator is inserted into the concrete at a uniform distribution within the radius of action of the vibrator to properly consolidate all of the concrete. Even highly fluid, plasticized mixes with slumps over 7-1/2 in. (190 mm) require some vibration for proper consolidation.

TABLE 5.1 Methods and Equipment for Transporting and Handling Concrete

Equipment	Type and Range of Work for Which Equipment Is Best Suited	Advantages	Points to Watch for
Mobile batcher mixers	Used for intermittent production of concrete at jobsite	Combined materials transporter and mobile batching and mixing system provides quick, precise proportioning of specified concrete; one-man operation.	Trouble-free operation requires a preventive maintenance program equipment. Materials must be identical to those in original mix design.
Nonagitating trucks	Used to transport concrete on short hauls over smooth roadways	Capital cost of nonagitating equipment is lower than that of truck agitators or mixers.	Concrete slump should be limited. Segregation is possible. Height is necessary for high lift of truck body discharge.
Pneumatic guns (shotcrete)	Used where concrete is to be placed in difficult locations and where thin sections and large areas are needed	Shotcrete is ideal for placing concrete in free-form shapes, for repairing and strengthening buildings, for protective coatings, and thin linings.	Quality of work depends on skill of those using equipment; only experienced nozzle-men should be employed.
Pumps	Used to convey concrete directly from central discharge point at jobsite to formwork or to secondary discharge point	Pipelines take up little space and can be readily extended. Pump delivers concrete in continuous stream and can move concrete both vertically and horizontally. Mobile pumps can be delivered when necessary to small or large projects. Stationary pump booms provide continuous concrete for tall building construction.	Constant supply of freshly mixed concrete with average consistency and without any tendency to segregate is necessary. Care must be taken in operating pipeline to ensure an even flow and to clean out pump at the conclusion of each operation. Pumping vertically, around bends, and through flexible hose will considerably reduce the maximum pumping distance.
Screw spreaders	Used for spreading concrete over flat areas, as in pavements	With a screw spreader, a batch concrete discharged from bucket or truck can be quickly spread over a wide area to a uniform depth. The spread concrete has good uniformity of compaction before vibration is used for final compaction.	Screw spreaders are usually used as part of a paving train. They should be used for spreading before vibration is applied.
Tremies	For placing concrete underwater	Tremies can be used to funnel concrete down through the water into the foundation or other part of the structure being cast.	Precautions are necessary to ensure that the tremie discharge end is always buried in fresh concrete so a seal is preserved between the water and concrete mass. Diameter should be 10 to 12 in. unless press is available. Concrete mixture requires more cement (700 lb/yd ³) and greater slump (6 to 9 in.) because concrete must flow and consolidate without any vibration.
Truck agitators	Used to transport concrete for all uses in pavements, structures, and buildings	Truck agitators usually operate from central mixing plants where quality concrete is produced under controlled conditions. Discharge from agitators is well controlled. Concrete is uniform and homogeneous on discharge.	Timing of deliveries must suit job organization. Haul distances must allow discharge of concrete within 1-1/2 hours, but limit may be waived under certain circumstances. Concrete crew and equipment must be ready onsite to handle concrete.

Truck mixers	Used to transport concrete for all uses in pavements, structures, and buildings	No central mixing plant is needed, only a batching plant, as concrete is completely mixed in truck mixer. Discharge is the same as for truck agitators.	Timing of deliveries must suit job organization. Haul distances must allow discharge of concrete within 1 to 1/2 hours, but limit may be waived under certain circumstances. Concrete crew and equipment must be ready onsite to handle concrete. Control of concrete quality is not as good as with central mixing. Method is slow and labor intensive.
Wheelbarrows and buggies	For short flat hauls on all types of onsite concrete construction, especially where accessibility to work area is restricted	Wheelbarrows and buggies are very versatile and therefore ideal for inside work and on jobsites where placing conditions are constantly changing.	
Belt conveyors	For conveying concrete horizontally or to a higher or lower level; usually used between main discharge point and secondary discharge point	Belt conveyors have an adjustable reach, a traveling diverter, and variable speed, both forward and reverse. They can place large volumes of concrete quickly when access is limited.	End-discharge arrangements are necessary to prevent segregation and leave no mortar on return belt. In adverse weather (hot, windy), long reaches of belt require cover.
Belt conveyors mounted on truck mixers; buckets	For conveying concrete to a lower, horizontal, or higher level; used with cranes, cableways, and helicopters for construction of buildings and dams convey concrete directly from central discharge point to formwork or to secondary discharge point	Conveying equipment arrives with the concrete. Equipment has an adjustable reach and variable speed; allows the full versatility of cranes, cableways, and helicopters to be exploited; and has a clean discharge. Buckets offer a wide range of capacities.	End-discharge arrangements are necessary to prevent segregation and leave no mortar on return belt. Select bucket capacity to conform to the size of the concrete batch and capacity of placing equipment. Discharge should be controllable.
Chutes	For conveying concrete to lower levels, usually below ground level, on all types of concrete construction	Chutes offer low cost and are easy to maneuver. No power is required, as gravity does most of the work.	Slopes range between 1 to 2 and 1 to 3, and chutes must be adequately supported in all positions. Arrange for discharge at the end (downpipe) to prevent segregation.
Cranes	The right tool for work above ground level	Cranes can handle concrete, reinforcing steel, formwork, and sundry items in high-rise, concrete-framed buildings.	A crane has only one hook. Careful scheduling between trades and operations is necessary to keep it busy.
Dropchutes	Used for placing concrete in vertical forms of all kinds; some chutes are one piece, but others are assembled from loosely connected segments	Dropchutes direct concrete into formwork and carry it to bottom of forms without segregation. Their use avoids spillage of grout and concrete on the form sides, which is harmful when off-the-form surfaces are specified. They also will prevent segregation of coarse particles.	Dropchutes should have sufficiently large, splayed-top openings into which concrete can be discharged without spillage. The cross-section of the dropchute should be chosen to permit inserting it into the formwork without interfering with reinforcing steel.

FIGURE 5.10 Water permeability of concrete as influenced by water/cement ratio and curing. (From Whiting, D., in *Permeability of Concrete*, SP108-11, American Concrete Institute, Farmington Hills, MI, 1988, pp. 195–225.)

5.4 Permeability

Concrete's durability, corrosion resistance, and resistance to chemical attack are directly related to permeability. If a substance cannot enter concrete, it cannot damage it. Concrete permeability is a function of the permeability of the paste and aggregate. Decreased permeability improves concrete's resistance to saturation, sulfate attack, chemical attack and chloride penetration. Paste permeability has the greatest influence on concrete permeability. Paste permeability is directly related to the water/cement ratio and the degree of hydration or length of moist-curing. A low water/cement ratio and an adequate moist curing period result in concrete with low permeability. The permeability of mature, good-quality, normal-strength concrete is approximately 1×10^{-10} cm/sec. Figure 5.10 illustrates the relationship between the water/cement ratio and permeability. Supplementary cementing materials such as fly ash and, especially, silica fume reduce permeability. High-strength concrete usually has very low permeability as a result of its low water/cement ratio and the common use of silica fume. High-strength concretes often have water permeability coefficients from 1×10^{-11} to 1×10^{-13} cm/sec. Low permeability and inherent resistance to chlorides make high-strength concrete ideal for structures such as bridges and parking decks that are exposed to deicers or seawater. A variety of methods are used to determine the permeability of concrete. Some of the common methods are the chloride ponding test (AASHTO T259), electrical conductance-rapid chloride permeability test (ASTM C 1202), water permeability (Army Corps CRD-C 163), air permeability (SHRP 2031), and volume of permeable voids (ASTM C 642). Table 5.2 illustrates the relationship between various permeability methods and normal- and high-strength concretes of different water/cement ratios. Table 5.3 provides conversions for various permeability units. The first step in achieving a low permeability is to specify a water/cement ratio of 0.4 or less and then consider using a supplementary cementing material or blended hydraulic cement.

5.5 Carbonation

Carbonation is related to permeability. Carbonation of Portland cement concrete paste occurs on all exposed concrete surfaces. Carbonation is a chemical reaction in which carbon dioxide in air or water reacts with compounds in the hardened cement paste to form carbonates, primarily calcium carbonate.

Note: To convert from units in first column to units at the top, multiply by the indicated factor. Conversions given are appropriate for cases of saturated, steady-state flow. For units associated with diffusion processes or with relative, empirical test procedures, no direct conversions are available.

Source: Whiting, D., in *Permeability of Concrete*, SP108-11, American Concrete Institute, Farmington Hills, MI, 1988, pp. 195–225.

The reaction begins immediately upon exposure of the concrete to air. The rate of carbonation is largely a function of paste permeability, temperature, relative humidity, and the concentration of carbon dioxide in the air. Paste permeability is controlled by the water/cement ratio, amount of moist curing, and the degree of densification of the exposed surface. Carbonation increases drying shrinkage and lowers the alkalinity (pH) of concrete. The inherent high alkalinity of concrete (pH greater than 12.5) protects embedded reinforcing steel from corrosion by causing a passive and noncorroding protective oxide film to form on the steel surface. By reducing the pH, carbonation destroys the protective film and, in the presence of moisture and oxygen, allows steel to corrode. Engineers specify a certain amount of protective concrete cover over reinforcing steel, assuming that the small depth of carbonated concrete will fall far short of the steel. In effect, the designer assumes that the concrete will not carbonate down to the depth of the steel during the expected life of the structure. The depth of carbonation is usually of little importance, less than 0.5 in. (13 mm) after 10 years for good-quality Portland cement concrete, and the depth of cover required by building codes provides an adequate factor of safety against corrosion (Campbell et al., 1991; Kosmatka and Farny, 2007).

FIGURE 5.11 Temperature effect on set time. (From Burg, R.G., *The Influence of Casting and Curing Temperatures on the Properties of Fresh and Hardened Concrete*, RD113, Portland Cement Association, Skokie, IL, 1996.)

5.6 Early-Age Characteristics and Strength

Concrete is primarily known for its massive compressive strength. Concrete gains strength through the reaction between cement and water called *hydration*. Portland cement is primarily a calcium silicate cement. The calcium silicate combines with water and forms calcium silicate hydrate, which is responsible for the primary engineering properties of concrete, such as strength and dimensional stability. During the first few hours, the cement in the concrete slowly reacts with water, giving the concrete some early strength. This period of early hardening is the *setting time*. Initial set is defined as the time at which concrete has attained 500 psi (3.5 MPa); final set is defined as the time at which it reaches 4000 psi (27.6 MPa), based on penetration resistance. The contractor should be aware of the setting properties of a concrete to properly control finishing operations on slabs and pavements. Temperature has one of the greatest effects on setting time. Figure 5.11 illustrates how an increase in temperature decreases set time and a decrease in temperature increases set time. Setting time can be expected to change approximately 30% for each 10°F change (50% for each 10°C change) in temperature from a base temperature of 73°F (23°C).

The compressive strength of concrete is directly related to the water/cement ratio. A decrease in water/cement ratio results in higher strength. Table 5.4 illustrates a conservative relationship between strength and water/cement ratio, and Table 5.5 and Table 5.6 illustrate typical mix designs for concretes with

TABLE 5.4 Typical Relationship between Water/Cement Ratio and Compressive Strength of Concrete

Compressive Strength at 28 Days, psi (MPa) ^a	Water/Cement Ratio by Weight	
	Non-Air-Entrained Concrete	Air-Entrained Concrete
6000 (41)	0.41	—
5000 (34)	0.48	0.40
4000 (28)	0.57	0.48
3000 (21)	0.68	0.59
2000 (14)	0.82	0.74

^a Values are estimated average strengths for concrete.

Note: Strength is based on 6 × 12-in. cylinders moist-cured 28 days at 73.4°F ± 3°F in accordance with Section 9b of ASTM C31. Relationship assumes maximum size of aggregate of about 3/4 in. to 1 in.

FIGURE 5.12 Increase in concrete strength with age as affected by curing moisture levels. (Figure courtesy of the Portland Cement Association, Skokie, IL.)

various water/cement ratios. The compressive strength of concrete increases with age as long as an appropriate moisture content and temperature are available (Figure 5.12 and Figure 5.13). The compressive strength of concrete at 7 days is approximately 75% of the 28-day strength for concrete cast and cured at 73°F (23°C). Later-age strength of concrete cast and cured at 50°F (10°C) often equals or exceeds that of the same concrete cast and cured at 73°F (23°C). For most concretes cast and cured at 90°F (32°C), 3-day compressive strength will be approximately 70% of 28-day compressive strength of concrete cast and cured at 90°F (32°C). The effect of casting and curing at 90°F (32°C) roughly results in a 3-day compressive strength similar to 7-day strength for concrete cast and cured at 73°F (23°C).

Outdoor concrete continues to gain strength as moisture is maintained by natural humidity or rainfall. Strength gains for various concretes under different environmental conditions are illustrated in Figure 5.14, Figure 5.15, and Figure 5.16. Figure 5.14 also illustrates the effect of water/cement ratios. Compressive strength is usually specified at the age of 28 days; however, depending on the project, ages of 3 and 7 days can also be specified. For high-strength concrete, ages of 56 or 90 days may be specified. For general-use concrete, a compressive-strength between 20 and 35 MPa (3000 psi and 6000 psi) is used. Compressive strength development of high-strength concrete is illustrated in Figure 5.17 and corresponds to the mixes in Table 5.7. The rate of strength gain for high-strength concrete vs. that of normal-strength concrete is illustrated in Figure 5.18. Compressive strength is usually determined by casting and testing 6 × 12-in. (150 × 300-mm) cylinders; however, 4 × 8-in. (100 × 200-mm) cylinders are commonly used for high-strength concrete and sometimes for normal-strength concrete. For high-strength concrete, 4 × 8-in. (100 × 200-mm) cylinders generally have strengths within about 1% of 6 × 12-in. (150 × 300-mm) cylinders.

Increase in strength with age continues as long as any unhydrated cement is still present, the relative humidity in the concrete is approximately 80% or higher, and the concrete temperature is favorable. To maintain this increase in strength, concrete must be properly cured. Curing means that not only must a favorable temperature be present but also moisture loss will not be permitted or extra water will be provided at the surface. Use of a wet burlap or plastic covering for 7 days or use of a curing compound usually provides adequate curing for normal- and high-strength concrete.

Although concrete is very strong in compression, it is weak in tensile strength. Tensile strength is about 8 to 12% of the compressive strength. Flexural strength (modulus of rupture) is 5 to 7.5 times (0.7 to 0.8 times for metric units) the square root of the compressive strength. Shear strength is about 20% of the

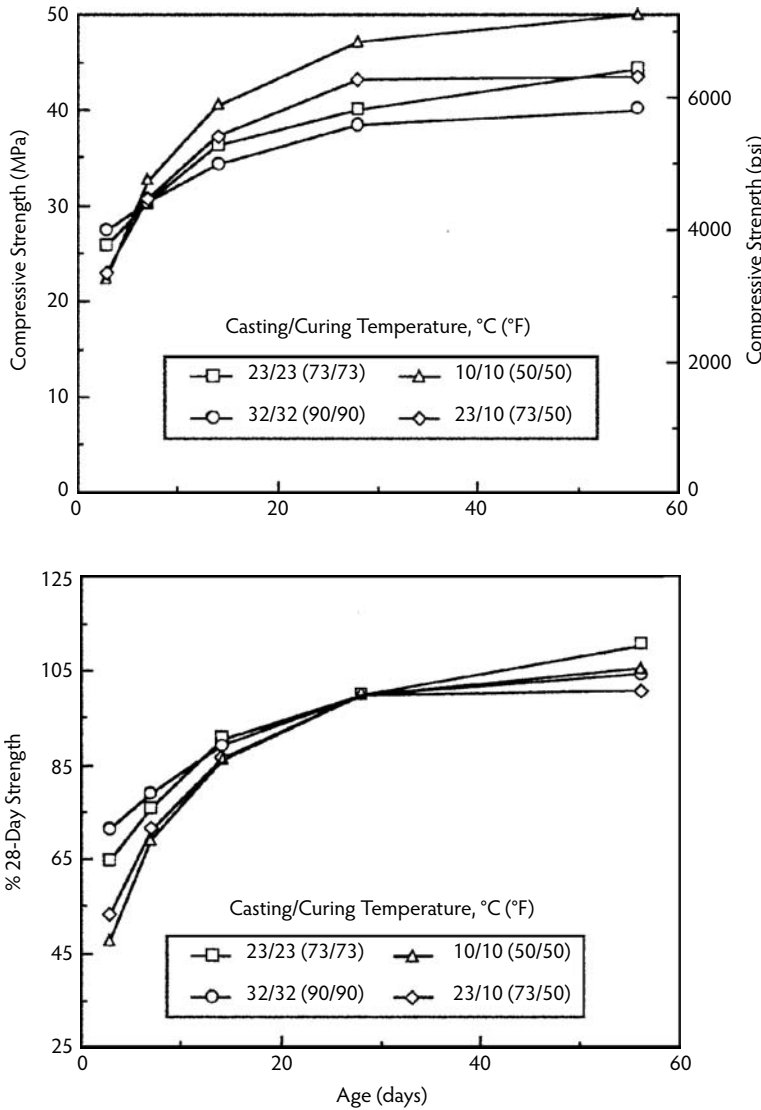

FIGURE 5.13 Strength gain vs. age for different casting and curing temperatures. (From Burg, R.G., *The Influence of Casting and Curing Temperatures on the Properties of Fresh and Hardened Concrete*, RD113, Portland Cement Association, Skokie, IL, 1996.)

compressive strength. Modulus of elasticity ranges from 2 to 6 million psi or 57,000 times the square root of the compressive strength (in English units, 14,000 to 41,000 MPa) and can be estimated as 5000 times the square root of the compressive strength in metric units. Figure 5.19, Figure 5.20, and Figure 5.21 illustrate these properties. Table 5.8 lists the flexural and tensile strengths for high-strength concretes cited in Table 5.7.

5.7 Density

Normal weight concrete, as is used in pavements and bridges, has a density of 140 to 150 lb/ft³ (2240 to 2400 kg/m³). The density of concrete varies with the relative density of the aggregate, the amount of air present in the paste, and the amount of water and cement in the mixture. The density of non-air-entrained, high-strength concrete is often over 150 lb/ft³ (2400 kg/m³). The high-strength concretes in

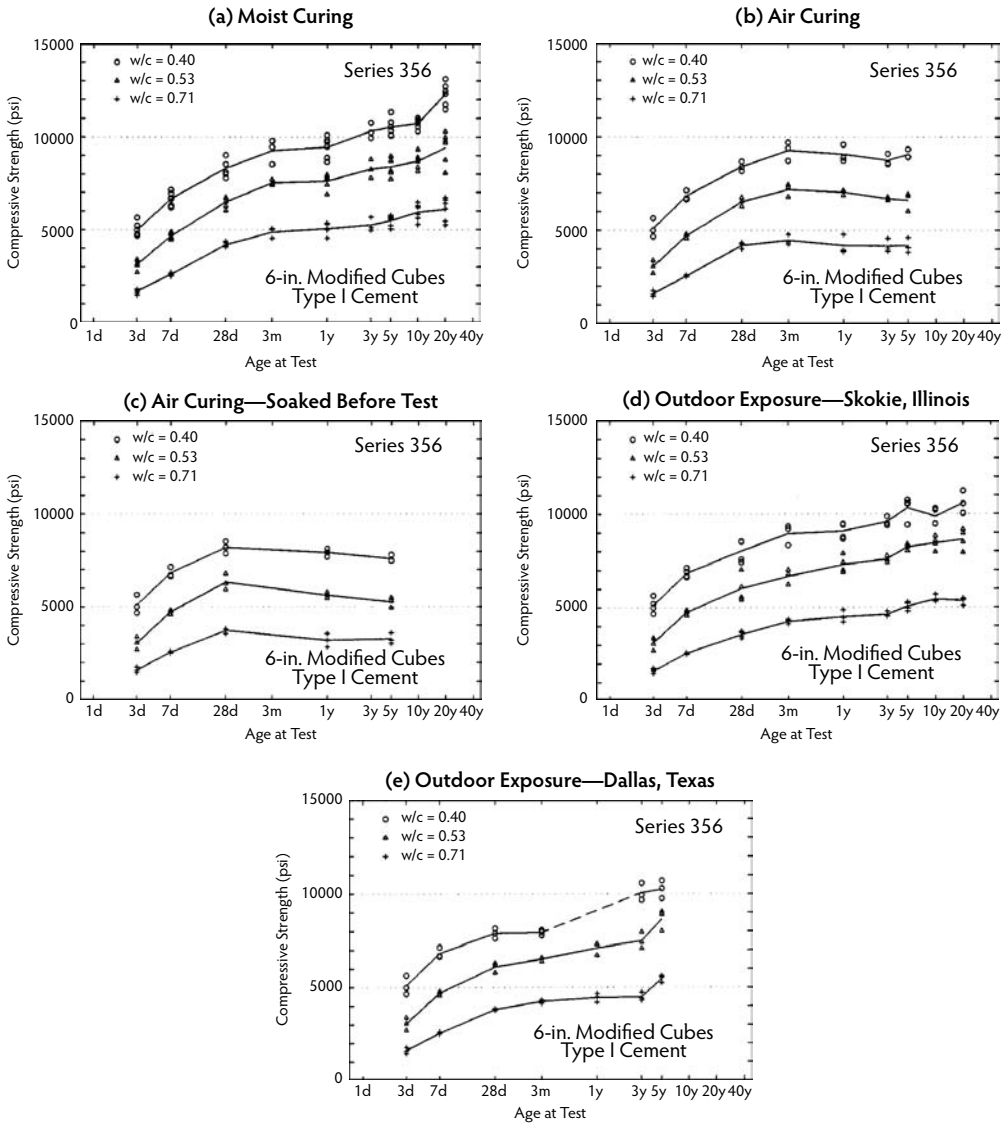

FIGURE 5.14 Variation of compressive strength with log age for different exposure conditions (all specimens received a 7-day moist curing prior to ultimate exposure). (From Wood, S.L., *Evaluation of the Long-Term Properties of Concrete*, RD102, Portland Cement Association, Skokie, IL, 1992.)

Table 5.7 use a crushed dolomite coarse aggregate and have densities ranging from 152 to 155 lb/ft³ (2430 to 2490 kg/m³) and air contents ranging from 0.7 to 1.6%. Heavyweight concretes, used for radiation shielding, can have densities approaching 400 lb/ft³ (6400 kg/m³).

5.8 Abrasion Resistance

Structures such as pavements and bridge decks are subjected to constant abrasion; therefore, concrete in these applications must have a high degree of abrasion resistance. Abrasion resistance is directly related to the compressive strength of the concrete. The type of aggregate and surface finish also have a strong influence on abrasion resistance. A hard aggregate, such as a granite, provides more abrasion resistance than a soft limestone aggregate.

FIGURE 5.15 Distribution of compressive strength normalized to 28 days for Type I cement concrete (all specimens received a 7-day moist curing prior to ultimate exposure). (From Wood, S.L., *Evaluation of the Long-Term Properties of Concrete*, RD102, Portland Cement Association, Skokie, IL, 1992.)

5.9 Volume Change and Crack Control

Concrete changes slightly in volume for various reasons. Understanding the nature of these changes is useful in planning concrete work and preventing cracks from forming. If concrete is free to move, normal volume changes have very little consequence, but, because concrete in service is usually restrained by foundations, subgrades, reinforcement, or connecting elements, significant stresses can develop. As the concrete shrinks, tensile stresses develop that can exceed the tensile strength of the concrete, resulting in crack formation. The primary factors affecting volume change are temperature and moisture changes. Concrete expands slightly as temperature rises and contracts as temperature falls. The average value for

FIGURE 5.18 Compressive strength vs. time for normal and high-strength concretes cast in the 1980s and 1990s, normalized to 28-day strength. (From Lange, D.A., *Long-Term Strength Development of Concrete*, RP326, Portland Cement Association, Skokie, IL, 1994.)

the coefficient of thermal expansion of concrete is about 5.5 millionths per degree Fahrenheit (10 millionths per degree Celsius). This amounts to a length change of 0.66 in. for 100 ft (5 mm for a 10-m length) of concrete subjected to a rise or fall of 100°F (50°C). The thermal coefficient of expansion for steel is about 6.5 millionths per degree Fahrenheit (12 millionths per degree Celsius), comparable to that of concrete. The coefficient for reinforced concrete can be assumed to be 6 millionths per degree Fahrenheit (11 millionths per degree Celsius). Concrete expands slightly with a gain in moisture and contracts with a loss in moisture. The drying shrinkage of normal- and high-strength concrete specimens ranges from 400 to 800 millionths when exposed to air at 50% relative humidity. Figure 5.22 illustrates the drying-shrinkage characteristics of high-strength concretes in Table 5.7. Concrete with a unit shrinkage of 550 millionths shortens by about the same amount as a thermal contraction caused by a decrease in temperature of 100°F (55°C). The shrinkage of reinforced concrete is less than that for plain concrete due to the restraint offered by the reinforcement. Reinforced concrete structures with normal amounts of reinforcement have a drying shrinkage in the range of 200 to 300 millionths. The amount of shrinkage is directly related to the amount of water in the concrete. Higher water content results in higher shrinkage. Specimen size also has an effect. Larger specimens shrink less than small specimens. Cement type and content have little effect on drying shrinkage. Drying shrinkage can also be reduced by using aggregates that do not have high drying-shrinkage properties such as quartz, granite, or limestone. Some chemical admixtures may increase drying shrinkage. Drying shrinkage is an inherent and unavoidable property of concrete; therefore, properly positioned reinforcing steel is used to reduce crack widths, or joints are used to predetermine or control the location of cracks. Thermal stress due to fluctuations in temperature can also cause cracking, particularly at early ages.

5.10 Deformation and Creep

Concrete deforms a small amount at initial loading. When concrete is loaded, the deformation caused by the load can be divided into two parts: a deformation that occurs immediately, such as elastic strain, and a time-dependent deformation that begins immediately but continues at a decreasing rate for as long

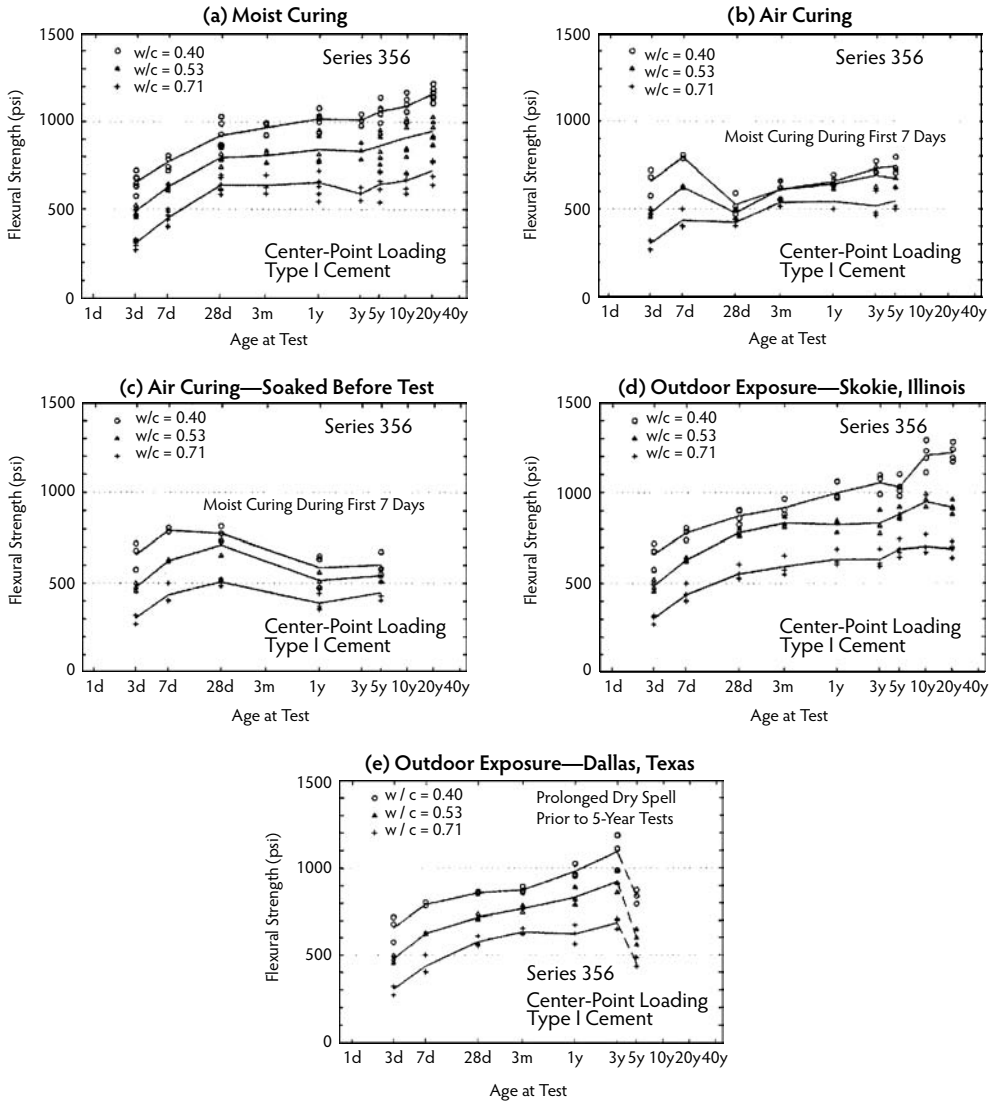

FIGURE 5.19 Variation of concrete flexural strength with log of age. (From Wood, S.L., *Evaluation of the Long-Term Properties of Concrete*, RD102, Portland Cement Association, Skokie, IL, 1992.)

as the concrete is loaded. This latter is called *creep*. The amount of creep is dependent on the magnitude of the stress, the age and strength of the concrete when the stress is applied, and the length of time the concrete is stressed. Figure 5.23 illustrates the combined effects of elastic and creep strains. Creep is of little concern for normal concrete buildings, pavements, and bridges; however, creep should be considered when designing for very tall buildings or very long bridges. High-strength concrete is sometimes used to control creep by keeping load values low. The specific creep of high-strength concretes in Table 5.7 is illustrated in Figure 5.24.

5.11 Concrete Ingredients

Normal- and high-strength concretes use a variety of cements, aggregates, mineral admixtures, and chemical admixtures. These materials are reviewed briefly in this section.

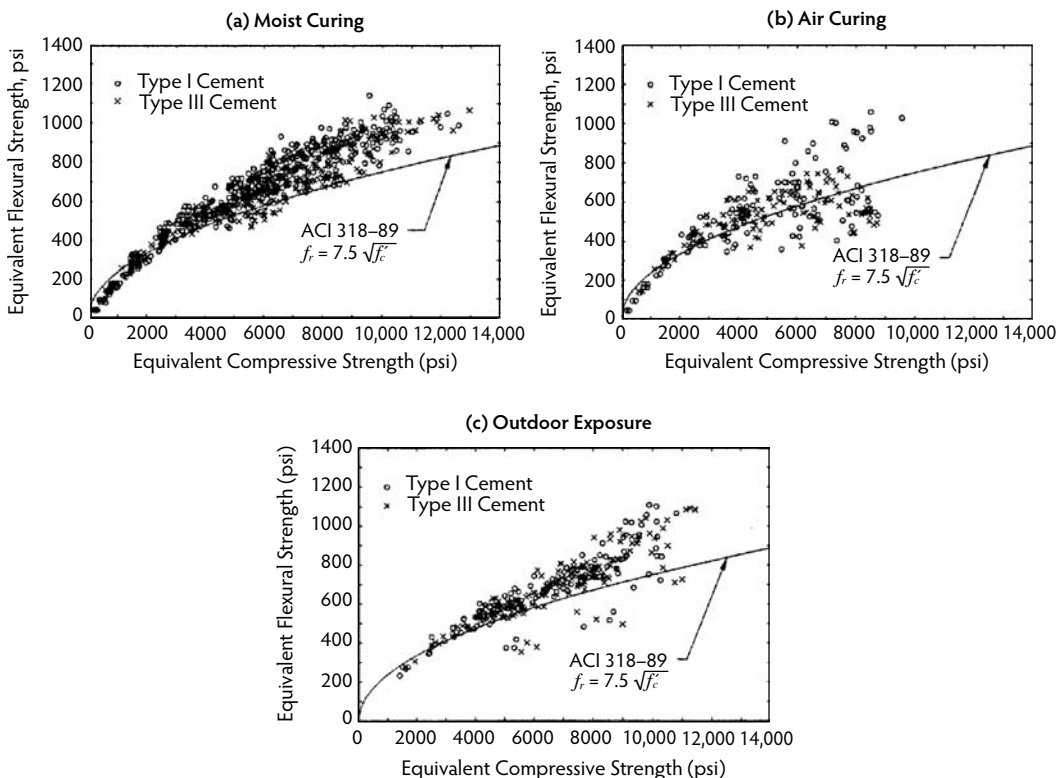

FIGURE 5.20 Flexural strength vs. compressive strength (such a relationship is often used in paving projects where cylinders are used in place of flexural beams). (From Wood, S.L., *Evaluation of the Long-Term Properties of Concrete*, RD102, Portland Cement Association, Skokie, IL, 1992.)

5.11.1 Portland Cements

Portland cements are hydraulic cements; that is, they set and harden by reacting with water. This reaction, called *hydration*, causes water and cement to combine to form a stone-like mass. Portland cement was invented in 1824 by an English mason, Joseph Aspdin, who named his product Portland cement because it produced a concrete that was of the same color as natural stone from the Isle of Portland in the English Channel. Portland cement is produced by combining appropriate proportions of lime, iron, silica, and alumina and heating them. These raw ingredients are fed into a kiln that heats the ingredients to temperatures from 2600 to 3000°F (1450 to 1650°C) and chemically changes the raw materials into cement clinker. The clinker is cooled and then pulverized. During this operation, a small amount of gypsum is added to control the setting of the cement. The finished pulverized product is Portland cement. Portland cement is essentially a calcium silicate cement. Powdered coal, oil, natural gas, or other materials are used as fuel for the kiln. A detailed discussion of cements and their chemistry is given in Chapter 1 of this *Handbook*. The American Society for Testing and Materials (ASTM) Standard C 150, Specification for Portland cement, defines the following types of Portland cement:

- Type I—general Portland cement
- Type II—moderate sulfate-resistant cement
- Type III—high-early-strength cement
- Type IV—low heat of hydration cement
- Type V—high sulfate-resistant cement

Types I, II, and III may also be designated as being air entraining.

5	Moist	1390	9.6	950	6.6
5	Air	940	6.5	670	4.6

^a Values are averages of three 6 × 6 × 30-in. (152 × 152 × 762-mm) specimens.

^b Values are averages of three 6 × 12-in. (152 × 305-mm) specimens.

Note: See compressive strengths in Figure 5.17 and mixes in Table 5.7.

Source: Burg, R.G. and Ost, B.W., *Engineering Properties of Commercially Available High-Strength Concretes (Including Three-Year Data)*, RD104, Portland Cement Association, Skokie, IL, 1994.

Type I Portland cement is a general cement suitable for all uses where the special properties of other cements are not required. It is commonly used in pavements, buildings, bridges, and precast concrete products. Type II Portland cement is used where precaution against moderate sulfate attack is important, as in bridge or pavement structures, or where sulfate concentrations in groundwater or soil are higher than normal but not too severe. Type II cement can also be specified to generate less heat than Type I

FIGURE 5.22 Drying shrinkage of $3 \times 3 \times 11.25$ -in. ($76 \times 76 \times 286$ -mm) prisms of high-strength concrete after 28-day moist curing. FIGURE 5.23 Combined elastic-creep strain vs. time (cylinders loaded at 8 days immediately after removal from fog room, then stored at 70°F and 5% relative humidity; applied stress = 25% compressive strength at 8 days). (From Kosmatka, S.H. et al., *Design and Control of Concrete Mixtures*, EB001, Portland Cement Association, Skokie, IL, 2006.)

cement. This moderate heat of hydration is helpful when placing massive structures such as piers, heavy abutments, and retaining walls. Type II cement may be specified when water-soluble sulfate in soil is between 0.1 and 0.2% or when the sulfate content in water is between 150 and 1500 ppm.

Type III Portland cement provides strength at an early age. Figure 5.25 illustrates the earlier strength gain of Type III cement over that of other cement types. It is chemically similar to Type I cement except that the particles are ground finer to increase the rate of hydration. It is commonly used in fast-track paving or when a concrete structure must be put into service as soon as possible, as in bridge deck repair.

Type IV Portland cement is used where the rate and amount of heat generated from hydration must be minimized. This low heat of hydration cement is intended for massive structures such as gravity dams. Type IV cement is rarely available. Type V Portland cement is used in concrete subject to very severe sulfate exposures. Type V cement is used when concrete is exposed to soil with a water-soluble sulfate content of 0.2% and higher or to water with over 1500 ppm of sulfate. The high sulfate resistance of Type V cement is attributed to its low tricalcium aluminate content.

FIGURE 5.24 Specific creep of high-strength concrete in 6 × 12-in. (150 × 300-mm) cylinders. (From Burg, R.G. and Ost, B.W., *Engineering Properties of Commercially Available High-Strength Concretes (Including Three-Year Data)*, RD104, Portland Cement Association, Skokie, IL, 1994.)

FIGURE 5.25 Strength gain curves for ASTM C 109 mortar cubes for various 1990s cement types. (From Detwiler, R.J., *Concrete Technol. Today*, 17(2), 1–4, 1996 (PL962).)

Cement Types I and II are commonly available and represent about 90% of the cement shipped in the United States, while Type III and white cement (discussed in the following section) represent only 4% of the cement produced. Type IV cement is manufactured only when specified for massive structures and is therefore not readily available. Type V is only available in specific severe sulfate environments.

5.11.2 White Portland Cement

White Portland cement has essentially the same chemistry as regular gray Portland cement except that it is white in color. White Portland cement is made of select raw materials that contain a negligible amount of iron and other dark metal oxides. White Portland cement is usually used for architectural purposes such as noise barrier walls and decorative concrete.

5.11.3 Blended Hydraulic Cements

Blended hydraulic cements are produced by blending two or more types of cementitious material. Primary blending materials are Portland cement, ground granulated blast-furnace slag, fly ash, natural pozzolans, and silica fume. These cements are commonly used in the same manner as Portland cements. Blended hydraulic cements conform to the requirements of ASTM C 595 or C 1157. ASTM C 595 cements are as follows: Type IS, Portland blast-furnace slag cement, and Type IP, Portland–pozzolan cement. The naming practice for blended cements allows adding the suffix (X) to the type designation, where (X) equals the targeted percentage of slag or pozzolan in the product expressed as a whole number by mass of the final blended product. These blended cements may also be designated as air-entraining (A), as moderate sulfate-resistant (MS), or as moderate (MH) or low (LH) heat of hydration. The United States uses a relatively small amount of blended cement compared with countries in Europe or Asia; however, this may change as consumer demands for products with specific properties and as environmental and energy concerns change.

5.11.4 Hydraulic Cements

ASTM C 1157 (Performance Specification for Hydraulic Cements) uses performance criteria, instead of constituent and prescription criteria, for blended and Portland cements. ASTM C 1157 hydraulic cements include the following: Type GU, for general construction use; Type HE, high early-strength cement; Type MS, moderate sulfate-resistant cement; Type HS, high sulfate-resistant cement; Type MH, moderate heat of hydration cement; and Type LH, low heat of hydration cement. These cements can also be designated for low reactivity (option R) with alkali-reactive aggregates. These cements may be specified as Portland cements, blended cements, or hydraulic cements. Except for the Portland designation, no restrictions are placed on the composition of the ASTM C 1157 cements. The manufacturer can optimize ingredients, such as pozzolans and slags, to optimize particular concrete properties.

5.11.5 Supplementary Cementing Materials

Supplementary cementing materials, previously called *mineral admixtures*, contribute to the properties of hardened concrete through hydraulic or pozzolanic activity. Typical examples are natural pozzolans, fly ash, ground granulated blast-furnace slag, and silica fume, which can be used individually with Portland or blended cement or in different combinations. These materials react chemically with calcium hydroxide released from the hydration of Portland cement to form cement compounds. Fly ash is a finely divided residue that results from the combustion of pulverized coal and is carried from the combustion chamber of the furnace by exhaust gases. Commercially available fly ash is a byproduct of thermal power-generating stations. Blast-furnace slag, or iron blast-furnace slag, is a nonmetallic product consisting essentially of silicates, aluminosilicates of calcium, and other compounds that form in a molten condition simultaneously with iron in the blast furnace. Silica fume, also called *condensed silica fume* and *microsilica*, is a finely divided residue resulting from the production of elemental silicon or ferrosilicon alloys that is carried from the furnace by the exhaust gases. Silica fume, with or without fly ash or slag, is usually used to make high-strength concrete. The following is a summary of the specifications and classes of supplementary cementing materials.

- Ground granulated iron blast-furnace slag (ASTM C 989)
 - Grade 80—Slags with a low activity index
 - Grade 100—Slags with a moderate activity index
 - Grade 120—Slags with a high activity index
- Fly ash and natural pozzolan (ASTM C 618)
 - Class N—Raw or calcined natural pozzolans including diatomaceous earth, opaline cherts, shales, tuffs, volcanic ashes, and some calcined clays and shales
 - Class F—Fly ash with pozzolanic properties
 - Class C—Fly ash with pozzolanic and cementitious properties
- Silica fume (ASTM C 1240)

A detailed discussion of supplementary cementitious materials is given in Chapter 2 of this *Handbook*.

5.11.5.1 Effects of Supplementary Cementing Materials on Properties of Freshly Mixed Concrete

Concrete mixes containing fly ash or slag will generally require less water, about 1 to 10%, for a given slump than concrete containing only Portland cement. Silica fume requires more water unless a water reducer is used. The amount of air-entraining admixture required to obtain a specified air content is normally greater when fly ash or silica fume is used. Class C fly ash generally requires less air-entraining admixture than Class F fly ash and tends to lose less air with mixing time. Ground slag has about the same effect as Portland cement on air-entrainment dosage. Fly ashes with high carbon contents require higher air-entraining dosages and also tend to lose more air with mixing or agitation. Fly ash and ground slag will generally improve the workability of concrete of equal slump and strength. Silica fume may reduce workability. Fly ash and ground slag can reduce the amount of heat of hydration in concrete for structures where lower heat development is required. The use of fly ash, natural pozzolans, and ground slag will generally retard the setting time of concrete. In one study, for example, fly ash caused the initial set to be retarded by 10 to 55 minutes and the final set to be retarded by 5 to 130 minutes for concrete incorporating 10 different fly ashes (Gebler and Klieger, 1986). The degree of retardation depends on the amount of Portland cement, the water requirement, the type of supplementary cementing material, and the concrete temperature. Finishability and pumping are generally improved with these materials.

Fly ash is commonly used in the United States at a dosage of 15 to 25% by mass of cementitious material. High-calcium Class C ashes have been used at higher dosages for particular situations. Ground slag commonly averages about 40% of the cementing material in the mix. Silica fume is typically used at a 5 to 10% dosage rate by weight of cementitious material. The dosage of a supplementary material depends on the particular concrete property the user is trying to improve or affect; therefore, it is very important to determine the optimal amount of the fly ash, slag, or silica fume to use. An overdose or underdose can be harmful or not have the desired effect. Also, these materials react differently with different cements.

The effects of temperature and moisture on the setting properties and strength development of concretes containing supplementary cementing materials are similar to the effects on concrete made with only Portland cement; however, the curing time may have to be longer for some materials. Relatively high dosages of silica fume can make a very cohesive concrete with very little bleeding. With little to no bleed water available at the surface for evaporation, plastic cracking can readily develop on hot days; therefore, special precautions to minimize evaporation during early curing are essential when using silica fume in concrete.

5.11.5.2 Effects on Hardened Concrete

Supplementary cementing materials contribute to the strength gain of concrete by providing additional cementitious compounds; however, the rate of strength gain of concrete containing these materials often differs from the strength gain of concrete that uses Portland cement as the only cementitious material. Due to the lower rate of hydration when using some of these materials, the early strength gain can be

lower than that of comparable concrete without such materials; yet, other materials perform in a manner very similar to Portland cement. Drying shrinkage and creep are little affected by the presence of normal dosages of supplementary cementing materials. The permeability of concrete containing supplementary cementing materials is usually reduced with adequate curing. Silica fume is frequently used in bridges to minimize chloride penetration into concrete.

5.11.5.3 Effects on Durability

The effect on durability of normal dosages of supplementary cementing materials is usually insignificant with regard to freeze–thaw resistance and deicer scaling. Depending on the dosage and the specific mineral admixture, alkali–silica reactivity and sulfate resistance may be improved, not affected, or even aggravated. These materials will usually improve the corrosion resistance of embedded steel because they reduce permeability and help keep chloride ions out of the concrete; however, some materials may slightly increase the depth of carbonation of concrete. Carbonation reduces the alkalinity of the concrete that is required to protect the embedded steel. Normal dosages of supplementary materials have an insignificant effect on carbonation.

5.11.6 Mixing Water for Concrete

Almost any natural water that is drinkable can be used as mixing water for concrete; however, some waters that are not fit for consumption may be suitable for concrete. Of particular concern are the levels of chloride, sulfate, and alkalis, as these can affect the durability of the concrete. Kosmatka et al. (2006) provide guidance concerning the use of waters containing alkali carbonates, chlorides, sulfates, acids, oils, and other materials, as well as guidance regarding allowable levels of contamination. Seawater containing salt can be suitable for nonreinforced concrete, but it should not be used for steel-reinforced concrete due to corrosion concerns. Mixing water should meet ASTM C 1602 (Specification for Mixing Water Used in the Production of Hydraulic Cement Concrete).

5.11.7 Aggregates for Concrete

The importance of using the right type and quality of aggregates cannot be overemphasized as the fine and coarse aggregates occupy between 60 and 75% of the concrete volume and strongly influence the freshly mixed and hardened properties, mix proportions, and economy of the concrete. Fine aggregates consist of natural sand or fresh stone with particles smaller than 0.2 in. (5 mm). Coarse aggregates consist of a combination of gravel or crushed aggregate with particles predominately larger than 0.2 in. (5 mm) and generally between 3/8 and 1-1/2 in. (10 and 38 mm). The most common coarse-aggregate sizes are 3/4 and 1 in. (19 and 25 mm). High-strength concrete often uses 1/2 in. (12 mm) maximum coarse aggregate. Natural gravel and sand are usually dug from pits. Crushed aggregate is produced by crushing quarry rock, boulders, or large-size gravel. Crushed air-cooled blast-furnace slag is also used as a fine or coarse aggregate. About half of the coarse aggregates used in Portland cement concrete in the United States are gravels and the remainder are crushed stone. Recycled concrete or crushed waste concrete is also a common source of aggregates and an economic necessity where good aggregates are scarce.

The most commonly used aggregates, such as gravel or crushed stone, produce a concrete with a freshly mixed unit weight of about 140 to 150 lb/ft³ (2240 to 2400 kg/m³). Special heavyweight or lightweight aggregates are also available for making concretes with a range of densities. Normal-weight aggregates should meet the requirements of ASTM C 33. This specification limits the amounts of harmful substances and states the requirements for aggregate characteristics such as grading.

Grading is the particle-size distribution of an aggregate and is determined by a sieve analysis. The 7 standard ASTM C 33 sieves for fine aggregate have openings ranging from 150 μ m to 3/8 in. (10 mm). The 13 standard sieves for coarse aggregate have openings ranging from 0.046 to 4 in. (1.18 to 100 mm). For highway construction, ASTM D 448 lists the 13 sizes in ASTM C 33 plus additional coarse aggregate sizes.

The grading and maximum size of the aggregate affect the relative aggregate proportions as well as cement and water requirements, workability, pumpability, economy, shrinkage, and durability of the concrete. Variations in grading can seriously affect the uniformity of the concrete from batch to batch. In general, aggregates that do not have a large deficiency or excess of any size and have a uniform distribution of particle sizes will produce the most satisfactory results.

The particle shape and surface texture of an aggregate influence the properties of freshly mixed concrete more than the properties of hardened concrete. Rough-textured, angular, elongated particles require more water to produce a workable concrete mixture than do smooth, rounded, compact aggregates; hence, aggregate particles that are angular require more cement to maintain the same water/cement ratio. With satisfactory gradation, both crushed and noncrushed aggregates of the same rock type generally give essentially the same strength for the same cement content and water/cement ratio.

The unit weight, also called the *unit mass* or *bulk density*, of an aggregate is the weight of aggregate required to fill a container of a specified unit volume. The volume referred to here is occupied by both the aggregate and the voids between aggregate particles. The approximate bulk density of aggregates commonly used in concrete ranges from about 70 to 110 lb/ft³ (1120 to 1760 kg/m³). Most natural aggregates have specific gravities or mass densities of between 2.4 and 2.9, with corresponding solid densities of 150 to 180 lb/ft³ (2400 to 2880 kg/m³). The density of an aggregate used in mixture-proportioning computations (not including voids between particles) is determined by multiplying the relative density (specific gravity) of the aggregate times the density of water. A value of 62.4 lb/ft³ (1000 kg/m³) is used for the density of water.

The absorption and surface moisture of aggregate should be determined according to ASTM test methods so the net water content of the concrete can be controlled and correct batch weights determined. The internal structure of an aggregate particle is made up of solid matter and voids that may or may not contain water. Following are the moisture conditions of aggregate:

- Oven dry—fully absorbent
- Air dry—dry at the particle surface but containing some interior moisture and thus still somewhat absorbent
- Saturated surface dry (SSD)—neither absorbing water nor contributing water to the concrete mixture
- Damp or wet—containing excessive moisture on the surface (free water)

The amount of water used in the concrete mixture must be adjusted for the moisture conditions of the aggregates to meet the designated water requirement. If the water content of the concrete mixture is not kept constant, the compressive strength, workability, and other properties will vary from batch to batch. Coarse and fine aggregate will generally have absorption levels in the range of 0.2 to 0.4% and 0.2 to 2%, respectively. Free-water contents will usually range from 0.5 to 2% for coarse aggregate and 2 to 6% for fine aggregate.

Harmful substances that may be present in aggregates include organic impurities, silt, clay, shale, iron oxide, coal, and certain lightweight or soft particles. In addition, certain substances and minerals such as chert may also be reactive to alkalis in the concrete. Certain aggregates such as shales will cause pop-outs at the concrete surface. Most specifications limit the permissible amounts of these substances in aggregates. Aggregates are potentially harmful if they contain compounds known to react chemically with Portland cement concrete and produce significant volume changes in the paste, aggregates, or both; interfere with the normal hydration of the cement; or otherwise have harmful byproducts. Alkali-aggregate reactivity is discussed in Section 5.18.

5.11.8 Chemical Admixtures for Concrete

Admixtures are ingredients in concrete other than Portland cement, water, and aggregates that are added to the mixture immediately before or during mixing. Common chemical admixtures include air-entraining, water-reducing, retarding, accelerating, and superplasticizing admixtures. The major reasons for

using admixtures are to reduce the cost of concrete construction, achieve certain properties in concrete more effectively than by other means, and to ensure the quality of concrete during the stages of mixing, transporting, placing, or curing in adverse weather conditions.

The most common admixtures are air-entraining admixtures. Air-entraining admixtures are used to purposely entrain microscopic air bubbles in concrete. Air entrainment will dramatically improve the durability of concrete exposed to moisture during freezing and thawing. Entrained air greatly improves the resistance of concrete to surface scaling caused by chemical deicers. The workability of fresh concrete is also improved significantly, and segregation and bleeding are reduced or eliminated. Air-entraining admixtures are commonly used to provide between 5 and 8% air content in concrete. The second most common admixture is the water-reducing admixture. Water-reducing admixtures are used to reduce the quantity of mixing water required to produce concrete of a certain slump, reduce the water/cement ratio, reduce cement content, or increase slump. Typical water reducers reduce the water content by approximately 5 to 10%. High-range water reducers reduce the water content by approximately 12 to 30%.

Retarding admixtures are used to retard the rate of setting of concrete. High temperatures of fresh concrete, around 90°F (32°C) or higher, often cause an increased rate of hardening that makes placing and finishing difficult. One of the most practical methods of counteracting this effect is to reduce the temperature of the concrete by cooling the mix water or aggregates. Retarders are sometimes used to offset the accelerating effect of hot weather on the setting of concrete, delay the initial set of concrete when difficult or unusual conditions of placement occur, or delay the set for special finishing processes, such as exposed aggregate finishes.

An accelerating admixture is used to accelerate the strength development of concrete at an early age. Calcium chloride is the most common accelerating admixture used for nonreinforced concrete. Care must be taken to make sure that the chloride content induced by the calcium chloride does not exceed the maximum chloride content allowed by local building codes. An excess of calcium chloride can cause corrosion in reinforced concrete. Besides accelerating strength gain, calcium chloride causes an increase in drying shrinkage and may slightly darken the concrete. Calcium chloride is not an antifreeze and will not reduce the freezing point of water by more than a few degrees. The amount of calcium chloride added should be no more than necessary to produce the desired results and should in no case exceed 2% by weight of cement in nonreinforced concrete. Nonchloride, noncorrosive admixtures are also available where corrosion is a concern.

Superplasticizers are high-range water reducers that are added to concrete with a low to normal slump and water/cement ratio to make high-slump flowing concrete. Flowing concrete is a highly fluid, workable concrete that can be placed with little or no vibration or compaction and yet is free of excessive bleeding or segregation. Superplasticized flowing concrete is used in thin section placements, areas of closely spaced reinforcing steel, underwater placements, and other applications where a more fluid mixture is more economically handled or placed.

All of the admixtures discussed in this section must meet the appropriate ASTM standards. When used at appropriate dosages, these materials should not adversely affect concrete properties; however, an overdose has significant effects on strength, shrinkage, and durability. In-depth details of chemical admixtures are given in Chapter 3 of this *Handbook*.

5.12 Proportioning of Concrete Mixtures

The objective in proportioning concrete mixtures is to determine the most economical and practical combination of readily available materials to produce a concrete that will satisfy the performance requirements (design) for the particular conditions of use. To fulfill these objectives, a properly proportioned concrete mix should possess these following qualities: (1) acceptable workability of freshly mixed concrete; (2) durability, strength, and uniform appearance of hardened concrete; and (3) economy. Only with proper selection of materials and mixture characteristics can the above qualities be obtained in concrete production. Concrete mixtures should be kept as simple as possible, as an excess number of ingredients can make a concrete mixture difficult to control.

The key to designing a concrete mixture is to be fully aware of the relationship between water/cement ratio and strength and durability. The specified compressive strength at 28-day and durability concerns dictate the water/cement ratio established for a concrete mixture. The water/cement ratio is simply the weight of water divided by the weight of cement. If pozzolans or slag are used, the ratio would include their weights and be referred to as the water/cementitious material ratio. The water/cement ratio can be established by a known relationship to strength or by durability requirements. For example, a concrete structure may require only 3000 psi (20 MPa) compressive strength, which would relate to a water/cement ratio of about 0.6; however, if the concrete is exposed to deicers, the maximum water/cement ratio should be 0.45. For corrosion protection or for reinforced concrete exposed to deicers, the maximum water/cement ratio should be 0.40. When designing concrete mixtures, it is important to remember that, where durability is concerned, the water/cement ratio should be as low as practical.

Aggregate grading and the nature of the particles such as shape, size, and surface texture all affect the mix design. The maximum size that can be used depends on the size and shape of the concrete member to be cast as well as on the amount of reinforcing steel present. The maximum size of coarse aggregate should not exceed one fifth of the narrowest dimension between sides of the forms or three fourths of the clear space between individual reinforcing bars.

The designer has to decide whether air entrainment is required. Entrained air must be used in all concrete that will be exposed to freezing and thawing and deicing chemicals. The typical range for the amount of entrained air depends on the size of the coarse aggregate and the degree of exposure. A typical air content for concrete would range from 5 to 8%. Concrete must also be workable and have an adequate consistency for the job placement conditions. The slump test is a measure of concrete consistency. The slump range for pavements and slabs is between 1 and 3 in. (25 and 75 mm). Slumps for wall and other applications can range from 3 to 6 in. (75 to 150 mm).

The water content of concrete is influenced by a number of factors: aggregate size and shape, slump, water/cement ratio, air content, cement content and admixtures, and environmental conditions. Increased air content and aggregate size, reduction in water/cement ratio and slump, rounded aggregates, and the use of water-reducing admixtures or fly ash all reduce water demand. On the other hand, increased temperatures, cement contents, water/cement ratio, and aggregate angularity all increase water demand. The cement content is determined from the selected water/cement ratio and water content.

Kosmatka et al. (2006) provide the Portland Concrete Association's step-by-step procedures for proportioning concrete by absolute volume methods from field or laboratory data. Farny and Panarese (1994) provide guidance for high-strength concrete. Chapter 6 of this *Handbook* presents a detailed treatment including numerical examples of the design of concrete mixtures for both normal- and high-strength concretes using the methods of the American Concrete Institute (see ACI 211 and related proportioning documents at www.concrete.org).

5.13 Hot and Cold Weather Concreting

All concrete must be properly cured. Curing is maintaining a satisfactory moisture content and temperature in concrete for some definite time period immediately following placing and finishing so the desired properties of strength and durability may develop. Concrete should be moist cured for 7 days at a temperature of between 50 and 80°F (10 to 27°C). Common methods of curing include the use of ponding, spraying, or fogging; wet covers; impervious paper; plastic sheets; or membrane-forming curing compounds, or some combination of these. These techniques will properly maintain adequate moisture in the concrete. When hot or cold weather conditions are present, temperature protection must be provided. In hot weather concreting, the concrete temperature should be less than 90°F (32°C). This can be achieved by cooling the concrete with ice, cold water, or nitrogen injection when the concrete is batched. High-strength concrete especially requires extra care to minimize plastic cracking during hot weather.

When the temperature approaches freezing, cold-weather concreting practices should be instituted. This may include methods for accelerating the early strength of the concrete such as using extra cement, a lower water/cement ratio, or an accelerator. Cold temperatures can dramatically reduce the setting rate

FIGURE 5.26 Temperature rise vs. time for high-strength concrete in a 4-ft (1.2-m) cube (TC1 through TC5 represent temperatures from the outside to the inside of the cube). (From Burg, R.G. and Ost, B.W., *Engineering Properties of Commercially Available High-Strength Concretes (Including Three-Year Data)*, RD104, Portland Cement Association, Skokie, IL, 1994.)

of concrete. The use of insulating blankets or temporary heated enclosures is an effective means of providing an adequate temperature for concrete. The natural temperature rise of concrete helps maintain the desired temperature. The temperature rise of high-strength concrete is illustrated in Figure 5.26. The temperature rise of high-strength concrete, being greater than that of normal-strength concrete, also leads to concern about controlling the cracking caused by extreme temperature differences. Figure 5.11 and Figure 5.13 illustrate the effects of temperature on set time and strength gain for normal-strength concrete. Concrete temperatures below freezing essentially halt hydration and strength gain. With appropriate precautions, concrete can be successfully placed in the winter (Figure 5.27).

5.14 Control Tests

Satisfactory concrete construction and performance require concrete possessing specific properties. To ensure that these properties are obtained, quality control and acceptance testing are indispensable parts of the construction process. Past experience and sound judgment must be relied on in evaluating tests and assessing their significance in the ultimate performance of concrete. The most common tests performed on concrete include the slump, strength, temperature, and air-content tests. The number of tests done depends on project conditions and specifications. Strength tests should be done every day at least and should be done no less than once for each 150 yd³ (115 m³) of concrete. A 7-day strength cylinder, along with two 28-day cylinders, is often made to provide early indications of strength development. The slump test should be performed in accordance with ASTM C 143; the temperature of concrete should be measured in accordance with ASTM C 1064; the air content should be determined in accordance with ASTM C 231, C 173, or C 138; and strength specimens should be made and cured in accordance with ASTM C 31. Traditionally, concrete cylinders 6 in. (150 mm) in diameter by 12 in. (300 mm) high were used for concretes with aggregates no larger than 2 in.; however, because most aggregates are less than 1 in. (25 mm) in size, most testing laboratories use 4 × 8-in. (100 × 200-mm) cylinders.

FIGURE 5.28 Frost-damaged concrete with surface scaling. (Figure courtesy of the Portland Cement Association, Skokie, IL.)

5.15 Freeze–Thaw and Deicer Scaling Resistance

As water freezes in wet concrete, it expands 9%, producing hydraulic pressures in the capillaries and pores of cement paste and aggregate. If the pressure exceeds the tensile strength of the paste or aggregate, the cavity will rupture. Accumulated effects of successive freeze–thaw cycles and disruption of the paste and aggregate eventually cause significant expansion and extensive deterioration of the concrete. The deterioration is visible in the form of cracking, scaling, and crumbling, as seen in Figure 5.28. The resistance of hardened concrete to freezing and thawing in moist conditions, with or without the presence

FIGURE 5.29 Air content vs. expansion of normal-strength concrete (air content above 5 to 6%, depending on aggregate size, essentially eliminates frost damage). (From Klieger, P., *Studies of the Effect of Entrained Air on the Strength and Durability of Concretes Made with Various Maximum Sizes of Aggregates*, RX040. Portland Cement Association, Skokie, IL, 1952.)

of deicers, is significantly improved by the use of entrained air. Air entrainment prevents frost damage and scaling and is required for all concretes exposed to freezing and thawing or deicer chemicals. An air content of between 5 and 8% should be specified for normal- and high-strength concrete exposed to wet freezing conditions (Figure 5.29). In the past, it was thought that high-strength concrete did not have to be air entrained because of its low permeability; however, research has shown that in most cases high-strength concrete also requires air entrainment (Figure 5.30). A good air-void system should have a spacing factor of less 0.008 in. (0.203 mm). Air-entrained concrete should be composed of durable materials and have a low water/Portland cement ratio (maximum 0.45), a minimum cement content of 564 lb/yd³ (335 kg/m³), proper finishing after bleed water has evaporated from the surface, adequate drainage, a minimum of 7-day moist curing at or above 50°F (10°C), a minimum compressive strength upon frost exposure of 4000 psi (28 MPa), and a minimum 30-day drying period after moist curing. Sealers may also be applied to provide additional protection against the effects of freezing and thawing and deicers; however, a sealer should not be necessary for properly proportioned and placed concrete.

5.16 Sulfate-Resistant Concrete

Excessive amounts of sulfates in soil or water can, over 5 to 30 years, attack and destroy concrete that is not properly designed. Sulfates attack concrete by reacting with hydrated compounds in the hardened cement paste, especially calcium aluminate hydrate. Due to crystallization, these expansive reactions can induce sufficient pressure to disrupt the cement paste, resulting in cracking and disintegration of the concrete. Furthermore, magnesium sulfate solutions can attack concrete by reacting with calcium silicate hydrate, the primary binding material in Portland cement paste. Advanced sulfate attack can turn concrete into a noncohesive mass of rubble, similar to crushed stone or gravel in appearance.

FIGURE 5.30 Length change vs. wet freeze-thaw cycles in non-air-entrained, high-strength concrete prisms (see Table 5.7). Expansions over 0.10% are considered failure; hence, most non-air-entrained, high-strength concretes are not durable under frost exposure. (From Burg, R.G. and Ost, B.W., *Engineering Properties of Commercially Available High-Strength Concretes (Including Three-Year Data)*, RD104, Portland Cement Association, Skokie, IL, 1994.)

TABLE 5.9 Requirements for Concrete Exposed to Sulfate

Sulfate Exposure	Water-Soluble Sulfate (SO ₄) in Soil (% by Mass)	Sulfate (SO ₄) in Water (ppm)	Cement Type ^a	Maximum Water/Cementing Material Ratio (by Mass)
Negligible	0.00–0.10	0–150	Use any cement	—
Moderate ^b	0.10–0.20	150–1500	II, IP (MS), IS (<70) (MS), MS	0.50
Severe	0.20–2.00	1500–10,000	V, HS	0.45
Very severe	Over 2.00	Over 10,000	V, HS	0.40

^a Cement Type II and Type V are specified in ASTM C 150, and the remaining types are specified in ASTM C 595 or ASTM C 1157. Pozzolans or slags determined by test to improve sulfate resistance may also be used.

^b Seawater.

Note: HS, high sulfate-resistant; IP, Portland-pozzolan cement; IS, Portland blast-furnace slag; MS, moderate sulfate-resistant.

The water/cement ratio (or water/cementitious materials ratio) is the most critical part of a mix design for preventing sulfate attack. The ratio should be no more than the value recommended in Table 5.9 for a particular sulfate exposure and should preferably be less than 0.4 where practical to maximize sulfate resistance. Figure 5.31 and Figure 5.32 clearly illustrate the great importance of using a low water/cementitious materials ratio to protect concrete against the ravages of sulfate attack. Air entrainment is also helpful for improving sulfate resistance when it reduces the water/cement ratio. The cement content for normal weight and lightweight concrete should be at least 564 lb/yd³ (335 kg/m³). When possible, concrete should be allowed to achieve its design strength before it is exposed to sulfate solutions.

Selection of the cement type is the second step (after selecting the water/cement ratio) in designing a sulfate-resistant concrete. Table 5.9 provides recommendations for cement types for different sulfate conditions (adapted from requirements originally established by the U.S. Bureau of Reclamation). Cement standards such as ASTM C 150 (Specification for Portland Cement), ASTM C 595 (Specification for Blended Hydraulic Cements), and ASTM C 1157 (Performance Specification for Blended Hydraulic

FIGURE 5.31 Sulfate attack of concrete beams placed in high-sulfate soil; 5-year performance with water/cementitious ratios of (a) 0.50 and (b) 0.39. (From Stark, D., *Durability of Concrete in Sulfate-Rich Soils*, RD097, Portland Cement Association, Skokie, IL, 1989.)

FIGURE 5.32 Sulfate resistance of concrete with various cement types and water/cement ratios; a rating of 1 is no deterioration, and a rating of 5 is severe deterioration (namely, mortar loss). (From Stark, D., *Durability of Concrete in Sulfate-Rich Soils*, RD097, Portland Cement Association, Skokie, IL, 1989.)

Cement) provide specifications for cements that are to be used in concrete exposed to sulfate conditions. Portland cements for sulfate exposures must have low amounts of tricalcium aluminate (C_3A). Type II and V ASTM C 150 cements are intended for use in moderate and severe sulfate exposures, respectively. Type II cement is usually available where needed; however, Type V and the blended cements are available only in certain areas. Supplementary cementing materials can also be used in sulfate environments, especially in low water/cement ratio concrete; however, their effects on sulfate resistance should be demonstrated by field record or test. Some supplementary cementing materials are helpful and others are detrimental. For concrete exposed to seawater, cement with a C_3A content up to 10% can be used due to the ability of chloride in seawater to inhibit expansive sulfate reactions. Usually a Type II cement is specified for use in seawater (see Table 5.9), but some Type I cements will meet this criteria. An analysis of the sulfate conditions to which concrete will be exposed and proper selection of materials, proportioning, and testing of concrete mixtures will minimize the effects of sulfate attack and ensure the long-term durability of concrete structures.

5.17 Corrosion Protection

Concrete protects embedded steel from corrosion through its highly alkaline nature. The high-pH environment (usually greater than 12.5) causes a passive and noncorroding protective oxide film to form on steel; however, carbonation or the presence of chloride ions from deicers or seawater can destroy or penetrate the film. When this happens, an electric cell is formed along the steel or between steel bars and the electrochemical process of corrosion begins. Some steel areas along the bar become anodes,

discharging current in the electric cell, and in those areas the iron goes into solution. Steel areas that receive current are cathodes, where hydroxide ions are formed. The iron and hydroxide ions form iron hydroxide (FeOH), which further oxidizes to form rust, or iron oxide. Rusting is an expansive process—rust expands to up to four times its original volume—that induces internal stress and eventual spalling in concrete over reinforcing steel. The cross-sectional area of the steel can also be significantly reduced. Once it starts, the rate of steel corrosion is influenced by the electrical resistivity of the concrete, its moisture content, and the rate at which oxygen migrates through the concrete to the steel. Chloride ions alone can also penetrate the passive film on the reinforcement and combine with iron ions to form a soluble iron chloride complex that carries the iron into the concrete, where it is later oxidized and forms rust. As little as 0.15% water-soluble chloride (about 0.2% acid-soluble) by weight of cement is sufficient to initiate corrosion of embedded steel under some conditions.

Premature deterioration of concrete bridges and parking structures can be a major concrete problem. These structures are often exposed to very severe conditions. Deicer and ocean salts, temperature and moisture changes, freezing and thawing, and abrasion all challenge the life of bridges and other structures. Of these exposure conditions, chloride salts from deicers and ocean spray in marine environments provide the greatest challenge to durability. They can corrode embedded steel, usually causing cracks, spalls, rust stains, and sometimes structural failure.

Deficient corrosion protection has resulted in millions of dollars in repairs over the last two decades. The severity of chloride-induced corrosion and the need for extra protection were not fully realized in the design, construction, and maintenance of early structures; however, field experience and extensive research in recent years have provided new insights into the mechanism of chloride-induced corrosion and methods to cope with the problem. The use of certain protective strategies to prevent or retard steel corrosion can result in bridges with long-term durability, extended structural life, and significantly reduced maintenance and repair costs. To reduce the risk of corrosion, the following protective strategies can be used individually or in combination:

- Cover thickness of 3.5 in. (90 mm) or more of concrete over the top of reinforcing steel in compression zones in bridge decks (note that excessive cover in tension zones exacerbates surface-crack width)
- Low-slump dense concrete overlay
- Latex-modified concrete overlay
- Interlayer membrane/asphaltic concrete systems
- Epoxy-coated reinforcing steel
- Corrosion-inhibiting admixtures in concrete
- Sealers with or without overlay
- Silica fume or other pozzolans that significantly reduce concrete permeability
- Low water/cement ratio superplasticized concrete, monolithic or in overlay
- Cathodic protection
- Polymer concrete overlay
- Galvanized reinforcing steel
- Polymer impregnation
- Lateral and longitudinal prestressing for crack control
- Blended cements containing silica fume or other pozzolans to reduce permeability

The purpose of most of these strategies is to delay or stop chloride ions from coming in contact with reinforcing steel. Most of the strategies can also be used alone or in combination for repair and maintenance of older structures showing signs of deterioration.

Studies of the corrosion activity of concretes made with varying water/cement ratios, calcium nitrite corrosion-inhibiting admixtures, silane and methacrylate surface treatments, epoxy-coated rebars and prestressing strands, galvanized reinforcement, and silica-fume admixtures were reported in *Protective Systems for New Prestressed and Substructure Concrete* FHWA/RD-86/193 (FHA, 1987). The 3-year

corrosion research project involved 11 protection systems. A summary of some design considerations and research conclusions from this study are as follows:

- The lowest possible water/cement ratio should be used, preferably in the range of 0.32 to 0.44. Concrete permeability and corrosion severity both decrease dramatically as the water/cement ratio is decreased. Long-term chloride permeability to the 1-in. (25-mm)-deep level in concrete was reduced in this study by about 80% and 95% when the water/cement ratio was reduced from 0.51 to 0.4 and 0.28, respectively.
- The clear concrete cover over reinforcement should be maximized—it should be as large as possible to minimize long-term penetration of water and chloride ions.
- Silica-fume admixtures and surface sealers (such as silane) both drastically reduce chloride penetration.
- Corrosion-inhibiting admixtures can significantly reduce corrosion severity.
- Epoxy-coated reinforcing bars and coated prestressing strands were found to be free of corrosion in chloride-laden concrete.

A belt-and-suspenders approach to bridge construction (using more than one protection method simultaneously) can result in significant savings in maintenance costs and produce a structure with a long trouble-free life. Examples of some double-protection systems would include the use of silica fume and a corrosion inhibitor, silica fume and cathodic protection, or latex-modified concrete and extra concrete cover over steel, assuming a low water/cement ratio in each case.

In addition, concrete surfaces must be sloped for adequate drainage, and concrete must be properly proportioned, placed, finished, and cured. Admixtures containing chlorides should be avoided, or, at least, the acid-soluble chloride content should be limited to a maximum of 0.08% and 0.20% (preferably less) by weight of cement for prestressed and reinforced concrete, respectively (ACI Committee 222, 2003; Stark, 1989b). Today, engineers can feel confident that, with the use of good design and construction practices and one or more available corrosion protection systems, a concrete structure can be built to endure even the most severe environment for many years with little maintenance.

5.18 Alkali–Silica Reaction

Most aggregates are chemically stable in hydraulic cement concrete; that is, they are without deleterious interaction with other concrete ingredients. This is not the case, however, for aggregates containing certain siliceous substances that react with alkali hydroxides in concrete. Alkali–silica reactivity (ASR) has been reported in structures throughout the world. ASR is usually first identified by surface map-pattern cracks. Very reactive aggregates can induce cracks within a year, whereas slowly reactive aggregates can take over 20 years to induce noticeable cracks (Figure 5.33). Because ASR deterioration is slow, the risk of catastrophic failure is low; however, cracking due to ASR can cause serviceability problems and can exacerbate other deterioration mechanisms such as occur in frost, deicer, or sulfate exposures. Normal-strength and high-strength concretes are both susceptible to ASR. The basic options for avoiding reactivity problems are relatively simple in concept:

- Do not use potentially reactive aggregates.
- Use fly ash, slag, silica fume, natural pozzolans, or blended hydraulic cement to control reactions.
- Reduce the level of soluble alkalis in the concrete.

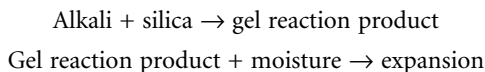

Avoiding potentially reactive aggregates is the most effective approach to solving reactivity problems; unfortunately, with a diminishing supply of proven nonreactive aggregate sources, concrete producers have no alternative but to use potentially reactive aggregate. As this is often the case, other options must be considered. Use of pozzolans, slag, or blended cement is an effective option in areas where appropriate materials are available. Reducing alkalis is commonly equated with using low-alkali cement; however, for

FIGURE 5.33 Cracking of concrete as a result of alkali-silica reactivity.

a number of reasons, low-alkali cements are not always readily available nor is reliance on a simple low-alkali cement specification always effective with highly reactive aggregates. The following provides guidance for detecting which aggregates are potentially reactive and methods of controlling ASR based on the current state of the art.

Alkali-silica reactivity is an expansive reaction between reactive forms of silica in aggregate and alkali hydroxides. The alkalis potassium and sodium come mostly from cement, although some come from aggregates, pozzolans, admixtures, and mixing water. External sources of alkali from soils, deicers, and industrial processes can also contribute to reactivity. The reaction forms an alkali-silica gel that swells as it draws water from the surrounding paste, inducing pressure, expansion, and cracking of the aggregate and surrounding paste. The reaction can be visualized as a two-step process:

The outward manifestation of the expansion often results in map-pattern cracks or longitudinal cracks. Crack patterns are affected by restraint conditions and other volume change movements.

Aggregate sources are prone to ASR if the following silica constituents are present: opal (more than 0.5%); chert and chalcedony (more than 3.0%); tridymite and cristobalite (more than 1.0%); strained or microcrystalline quartz (more than 5.0%), as found in granites, granite gneiss, graywackes, argillites, phyllites, siltstones, and natural sand and gravel; and natural volcanic glasses. The aggregate should then be evaluated for ASR in accordance with ASTM C 1260 (rapid mortar bar test) or ASTM C 1293 (concrete prism test). As with other methods, the ASTM C 1260 test is an accelerated procedure that is intended to force the potential reactions. The high alkali content and temperature are not representative of field conditions. ASTM C 1567 (a variation of ASTM C 1260) or ASTM C 1293 can be used to determine the effectiveness of pozzolans or slags to control ASR. The use of ASTM C 1293 comes from demonstrated Canadian practice. Criteria to determine if the aggregate is potentially reactive based on these physical tests follow:

- ASTM C1260—Mean expansion at 14 days, >0.10%, potentially reactive
- ASTM C1293—Expansion at 1 year, >0.04%, potentially reactive

FIGURE 5.34 ASR expansion vs. dosage for silica fume (CSF), fly ash (FA), and slag (GBFS). (From Berube, M.A. and Duchesne, J., in *Fly Ash, Silica Fume, Slag, and Natural Pozzolans in Concrete*, American Concrete Institute, Farmington Hills, MI, 1992, pp. 549–575.)

After an aggregate is determined to be potentially reactive by the above tests, special precautions in mix proportioning and mix ingredient selection must be taken. ASR is avoidable by using the following approaches individually or in combination (Farny and Kerkhoff, 2007; Portland Cement Association, 2007).

5.18.1 Blended Cement

Blended hydraulic cement meeting ASTM C 595 or ASTM C 1157 can be used to control alkali–silica reactivity as long as it has been demonstrated to be effective in controlling it using ASTM C 1293 or ASTM C 1567.

5.18.2 Supplementary Cementing Materials

Supplementary cementing materials such as fly ash, slag, silica fume, and natural pozzolans can be added to concrete to control alkali–silica reactivity (Figure 5.34). The benefits of these materials come from their pozzolanic properties. Fly ash and natural pozzolans should meet ASTM C 618 requirements. Ground granulated blast-furnace slag should meet ASTM C 989. Silica fume should meet ASTM C 1240. As an incorrect dosage of supplementary cementing materials may not control ASR or can increase the potential for ASR, the optimum amount should be determined using ASTM C 1293 or ASTM C 1567. Low-alkali Class F ash is generally more effective than many Class C ashes in reducing ASR.

5.18.3 Controlling Concrete Alkali Content

The concrete alkali content can be limited to a level that has been demonstrated to be effective by the field performance of concretes with the potentially reactive aggregate. This approach assumes that concrete ingredients for future construction are the same as those materials used in the past where detrimental alkali–silica reactivity did not occur. Specifications in the United States have traditionally limited the alkali content in concrete through the use of low-alkali Portland cement. ASTM C 150 defines low-alkali

cement as having a maximum alkali content of 0.60% equivalent sodium oxide; however, higher alkali limits have been safely used with certain moderately reactive aggregates. Low-alkali cements are not available in many areas, and deleterious reactivity has been observed with certain glassy volcanic aggregates, especially andesite and rhyolite rocks, even when low-alkali cements (alkali contents of 0.35 to 0.6%) were used (Farny and Kerkhoff, 2007). Thus, the use of local cements in combination with one or more of the above alternatives is the preferable approach to controlling ASR.

The methods outlined to evaluate the potential for aggregate reaction provide estimates based on accelerated laboratory tests. Although these methods are often the only approach available, the best indicator of potential aggregate performance is field history under conditions similar to the intended application. If a proven service record can be documented, the comfort level regarding potential performance is increased dramatically. Complete documentation of service history should include condition evaluations of several structures, preferably at least 15 years old, exposed to moisture in service, and made with concrete containing the aggregates in question and cement having an alkali content at least as high (equivalent sodium oxide) as the cement intended for the new construction. Condition evaluations should include petrographic examination of the concrete by ASTM C 856. Requirements for reactivity are:

- A potentially reactive aggregate
- Sufficiently available alkali
- Sufficiently available moisture

If any of the three requirements is missing, deleterious reactivity will not occur. The approaches listed above for avoiding reactivity focus on the first two requirements; however, the moisture requirement, while difficult to control, should not be ignored. Of particular importance are wetting and drying exposures, as they can concentrate alkalis near the drying surface, inducing reactivity. Design considerations should include steps to minimize available moisture and wet-dry cycles. Alkali-silica reactivity requires at least 80% relative humidity (RH) at 73°F (23°C) in the concrete to develop. In some applications, it may be possible to dry out the concrete to less than 80% RH. For example, sealed laboratory concrete with a water/cement ratio of 0.35 or less can self-desiccate to below 80% RH, which provides little opportunity for expansion due to ASR. Another environmental factor that affects reactivity is temperature. As with any chemical reaction, the rate of reactivity increases with temperature; thus, structures in warmer exposures are more susceptible to ASR than those in colder climates.

5.19 Heat-Induced Delayed Expansion

Heat-induced delayed expansion (HIDE), also called *delayed ettringite formation* (DEF), refers to a rare condition of internal sulfate attack in which mature concretes undergo expansion and cracking. Only concretes of particular chemical makeup are affected when they have achieved high temperatures—158 to 212°F (70 to 100°C)—usually after the first few hours of placement, depending on the concrete ingredients and the time the temperature is achieved after casting. This can occur because the high temperature decomposes any initial ettringite formed and holds the sulfate and alumina tightly in the calcium silicate hydrate (C-S-H) gel of the cement paste. The normal formation of ettringite is thus impeded. In the presence of moisture, sulfate desorbs from the confines of the C-S-H and reacts with calcium monosulfaluminate to form ettringite in cooled and hardened concrete. After months or years of desorption, ettringite forms in confined locations within the paste. Such ettringite can exert crystallization pressures because it forms in a limited space under supersaturation. This paste expansion usually results in a visible separation of the paste from the aggregate. Only concretes in massive elements that retain the heat of hydration or elements exposed to very high temperatures at an early age are at risk of HIDE; of these, only a few have the chemical makeup or temperature profile to cause detrimental expansion. Normal-sized concrete elements cast and maintained near ambient temperatures cannot experience HIDE when sound materials are used. The best way to avoid HIDE is to not let concrete exceed 158°F (70°C) at an early age. Delayed ettringite formation must not be confused with the beneficial

primary ettringite formation required to help control early strength gain and harmless secondary ettringite formation, an opportunistic and nonexpansive reformation of ettringite in cracks and voids, often found in connection with frost damage, ASR, or aging in a moist environment.

5.20 Self-Consolidating Concrete

Self-consolidating concrete (SCC) is normal- or high-strength concrete that is able to flow and consolidate under its own weight. At the same time, it is cohesive enough to fill spaces of almost any size and shape without segregation or bleeding. This makes SCC particularly useful wherever placing is difficult, such as in heavily reinforced concrete members or in complicated formwork. This technology, developed in Japan in the 1980s, is based on increasing the amount of fine material (e.g., fly ash or limestone filler) without changing the water content compared to common concrete. This changes the rheological behavior of the concrete. SCC has to have a low yield value to ensure high flowability; a low water content ensures high viscosity, so the coarse aggregate can float in the mortar without segregating. To achieve a balance between deformability and stability, the total content of particles finer than the 150- μm (No. 100) sieve has to be high, usually about 520 to 560 kg/m^3 (880 to 950 lb/yd^3). High-range water reducers based on polycarboxylate ethers are typically used to plasticize the mixture. SCC is very sensitive to fluctuation in water content; therefore, stabilizers such as polysaccharides are used. Because SCC is characterized by special fresh concrete properties, many new tests have been developed to measure flowability, viscosity, blocking tendency, self-leveling, and stability of the mixture (Lange, 2007). The ASTM C 1611 slump flow test is the most common testing method for flowability. The final slump flow diameter and time to reach a spread diameter of 20 in. (50 cm) are recorded. The ASTM C 1621 J-ring test, along with the U-box and L-box test, is used to evaluate passing ability. The strength and durability of well-designed SCC are similar to conventional concrete. Without proper curing, SCC tends to have higher plastic shrinkage. It is difficult to keep SCC in the desired consistency over a long period of time; however, construction time is shorter, and the production of SCC is environmentally friendly (no noise, no vibration). Furthermore, SCC produces a good surface finish. These advantages make SCC especially valuable for use in precasting plants, but SCC is also used in cast-in-place construction.

Part A. Design of Concrete Mixtures (E.G. Nawy)

6.1 General

The design of concrete mixtures involves choosing appropriate proportions of ingredients for particular strengths, long-term qualities, and performance of the concrete produced. Several factors determine these properties. They include the following parameters, which are summarized in Figure 6.1:

- Quality of cement
- Proportion of cement in relation to water in the mix (water/cementitious material ratio)
- Strength and cleanliness of aggregate
- Interaction or adhesion between cement paste and aggregate
- Adequate mixing of the ingredients
- Proper placing, finishing, and compaction of the fresh concrete
- Curing at a temperature not below 50°F while the placed concrete gains strength
- Chloride content not to exceed 0.15% in reinforced concrete exposed to chlorides in service and 1% in dry protected concrete

A study of these requirements shows that most control actions have to be taken prior to placing the fresh concrete. Because such control is governed by the proportions of ingredients and the mechanical ease or difficulty in handling and placing the concrete, the development of criteria based on the theory of proportioning for each mix should be studied. Most mixture design methods have become essentially only of historical and academic value. The two universally accepted methods of mixture proportioning for normal weight and lightweight concrete are the American Concrete Institute's methods of proportioning, described in their recommended practices for selecting proportions for normal weight, heavy-weight, and mass concrete, and in the recommended practice for selecting proportions for structural lightweight concrete (ACI Committee 211, 1991a,b; ASTM, 1993; Nawy, 1996).

6.2 Selection of Constituent Materials

6.2.1 Cement and Other Cementitious Materials

As discussed in Chapter 1, several types of cement are available. The most commonly used is Portland cement. Table 6.1 lists the general composition of the various types of Portland cement. Types I and III fundamentally differ in that Type III (high early cement) is considerably finer than Type I, and in 7 days achieves the strength that normal cement concrete achieves in 28 days. Other hydraulic cements include blended cements, rapid-setting cements, expansive cements (type K), very high early cements, and exotic cements such as macrodefect-free cement (MDF), densified cement (DSP), perlite cement, and alkali-activated cement.

6.2.2 Normal Weight and Lightweight Aggregate

Aggregates are those parts of the concrete that constitute the bulk of the finished product. They comprise 60 to 80% of the volume of the concrete and have to be graded so the whole mass of concrete acts as a relatively solid, homogeneous, dense combination, with the smaller particles acting as inert filler for the voids that exist between the larger particles. Aggregates are of two types:

FIGURE 6.1 Principal properties of good concrete. (From Nawy, E.G., *Reinforced Concrete: A Fundamental Approach*, 6th ed., Prentice Hall, Upper Saddle River, NJ, 2008.)

- *Coarse aggregate*—gravel, crushed stone, or blast-furnace slag
- *Fine aggregate*—natural or manufactured sand

Because the aggregate constitutes the major part of the mix, the more aggregate in the mix the less expensive the concrete, provided the mix is of reasonable workability for the specific job for which it is used. Coarse aggregate is classified as such if the smallest particle is greater than 1/4 in. (6 mm). Properties of coarse aggregate affect the final strength of hardened concrete and its resistance to disintegration, weathering, and other destructive effects. Mineral coarse aggregates must be clean of organic impurities and bond well with the cement gel. Common types of coarse aggregate include:

- *Natural crushed stone* is produced by crushing natural stone or rock from quarries. The rock may be igneous, sedimentary, or metamorphic. Crushed rock gives higher concrete strength but is less workable for mixing and placing than the other types of aggregate.

TABLE 6.1 Percentage Composition of Portland Cements

Type of Cement	Component (%)							General Characteristics
	C ₃ S	C ₂ S	C ₃ A	C ₄ AF	CaSO ₄	CaO	MgO	
Normal (I)	49	25	12	8	2.9	0.8	2.4	All-purpose cement
Modified (II)	45	29	6	12	2.8	0.6	3.0	Comparatively low heat liberation; used in large structures
High early strength (III)	56	15	12	8	3.9	1.4	2.6	High strength in 3 days
Low heat (IV)	30	46	5	13	2.9	0.3	2.7	Used in mass concrete dams
Sulfate-resisting (V)	43	36	4	12	2.7	0.4	1.6	Used in sewers and structures exposed to sulfates

Source: Data from Nawy, E.G., *Reinforced Concrete: A Fundamental Approach*, 6th ed., Prentice Hall, Upper Saddle River, NJ, 2008; Nawy, E.G., *Fundamentals of High-Strength, High-Performance Concrete*, Addison Wesley Longman, London, 1996; Nawy, E.G., *Fundamentals of High-Performance Concrete*, John Wiley & Sons, New York, 2001.

- *Natural gravel* is produced by the weathering action of running water on the beds and banks of streams. It gives less strength than crushed rock but is more workable.
- *Artificial coarse aggregates* are mainly slag and expanded shale and are frequently used to produce lightweight concrete. They are byproducts of other manufacturing processes such as blast-furnace slag or expanded shale, or pumice for lightweight concrete.
- *Heavyweight and nuclear-shielding aggregates* have been produced to meet the specific demands of our atomic age and the hazards of nuclear radiation; due to the increasing number of atomic reactors and nuclear power stations, special concretes have had to be produced to shield against x-rays, gamma rays, and neutrons. In such concretes, economic and workability considerations are not of prime importance. The main heavy coarse aggregate types are steel punchings, barites, magnetites, and limonites. Whereas concrete with ordinary aggregate weighs about 144 lb/ft³, concrete made with these heavy aggregates weighs from 225 to 330 lb/ft³. The property of heavy-weight radiation shielding in concrete depends on the density of the compact product rather than on the water/cement ratio criterion. In certain cases, high density is the only consideration, whereas in others both density and strength govern.
- *Fine aggregate* is a smaller filler made of sand. It ranges in size from No. 4 to No. 100 in U.S. standard sieve sizes. A good fine aggregate should always be free of organic impurities, clay, or any deleterious material or excessive filler of size smaller than No. 100 sieve. Preferably, it should have a well-graded combination conforming to the American Society for Testing and Materials (ASTM) sieve analysis standards. For radiation-shielding concrete, fine steel shot and crushed iron ore are used as fine aggregate.

The recommended grading of coarse and fine aggregates for normal weight concrete is presented in Table 6.2 (ASTM C 33), grading requirements for lightweight aggregate (ASTM C 330) are given in Table 6.3, and Table 6.4 provides grading requirements for coarse aggregate for aggregate concrete (ASTM C 637). The unit weights of the commonly used aggregates in structural concrete are given in Table 6.5.

6.2.3 Workability-Enhancing and Strength-Enhancing Admixtures

Admixtures are materials other than water, aggregate, or hydraulic cement that are used as ingredients of concrete and that are added to the batch immediately before or during mixing. Their function is to modify the properties of concrete for strength, workability, and long-term performance. The major types of admixtures can be summarized as follows:

TABLE 6.2 Grading Requirements for Aggregates in Normal Weight Concrete (ASTM C-33)

U.S. Standard Sieve Size	Percent Passing				
	Coarse Aggregate				Fine Aggregate
	No. 4 to 2 in.	No. 4 to 1-1/2 in.	No. 4 to 1 in.	No. 4 to 3/4 in.

6.2.3.1 Accelerating Admixtures

Accelerating admixtures are added to the concrete mixture to reduce the time of setting and accelerate early strength development. The best known are calcium chlorides. Other accelerating chemicals include a wide range of soluble salts such as chlorides, bromides, carbonates, and silicates, as well as other organic compounds such as triethanolamine. It must be stressed that calcium chlorides should not be used where progressive corrosion of steel reinforcement can occur. The maximum dosage recommended is 0.5% by weight of Portland cement.

6.2.3.2 Air-Entraining Admixtures

Air-entraining admixtures form minute bubbles that are 1 mm in diameter or smaller in concrete or mortar during mixing; they are used to increase both the workability of the mix during placing and the frost resistance of the finished product. Most air-entraining admixtures are in liquid form, although a few are powders, flakes, or semisolids. The amount of admixture required to obtain a given air content depends on the shape and grading of the aggregate used. The finer the aggregate, the larger the percentage of admixture needed. The amount required is also governed by several other factors, such as type and condition of the mixer, use of fly ash or other pozzolans, and degree of agitation of the mix. It can be expected that air entrainment reduces the strength of the concrete. Maintaining cement content and workability, however, offsets the partial reduction of strength because of the resulting reduction in the water/cement ratio.

(a)

(b)

PHOTO 6.3 Slump test of fresh concrete. (Photograph courtesy of E.G. Nawy et al.)

6.2.3.3 Water-Reducing and Set-Controlling Admixtures

Water-reducing and set-controlling admixtures increase the strength of the concrete. They also enable reduction of cement content in proportion to the reduction of water content. Most admixtures of the water-reducing type are water soluble. The water they contain becomes part of the mixing water in the concrete and is added to the total weight of water in the design of the mix. It has to be emphasized that the proportion of mortar to coarse aggregate should always remain the same. Changes in the water content, air content, or cement content are compensated for by changes in the fine-aggregate content so the volume of the mortar remains the same.

6.2.3.4 Finely Divided Admixtures

Finely divided admixtures are mineral admixtures used to rectify deficiencies in concrete mixes by providing missing fines from the fine aggregate, improving one or more qualities of the concrete (such as reducing permeability or expansion), and reducing the cost of concrete-making materials. Such admixtures include hydraulic lime, slag cement, fly ash, and raw or calcined natural pozzolans.

6.2.3.5 Admixtures for No-Slump Concrete

No-s slump concrete is defined as a concrete with a slump of 1 in. (25 mm) or less immediately after mixing. The choice of admixture depends on the desired properties of the finished product such as plasticity, setting time and strength development, freeze–thaw effects, strength, and cost.

6.2.3.6 Polymers

Polymer admixtures allow production of concretes of very high strength up to a compressive strength of 15,000 psi or higher and a splitting tensile strength of 1500 psi or higher. Such concretes are generally produced using a polymerizing material through: (1) modification of the concrete property by water reduction in the field, or (2) impregnation and irradiation under elevated temperature in a laboratory environment. Polymer concrete (PC) is concrete made through the addition of resin and hardener as admixtures. The principle is to replace part of the mixing water with the polymer to attain a high compressive strength and other desired qualities. The optimum polymer/concrete ratio by weight to achieve such high compressive strengths seems to lie within the range of 0.3 to 0.45.

6.2.3.7 Superplasticizers

Superplasticizers can be termed *high-range water-reducing chemical admixtures*. The types of plasticizers include:

- *Sulfonated melamine formaldehyde* (SMF) condensates, with a chloride content of 0.005%
- *Sulfonated naphthalene formaldehyde* (SNF) condensates, with negligible chloride content
- *Modified lignosulfonates*, which contain no chlorides

These plasticizers are made from organic sulfonates and are considered superplasticizers in view of their considerable ability to facilitate reduction of water content in a concrete mix while simultaneously increasing the slump up to 8 in. (206 mm) or more. A dosage of 1 to 2% by weight of cement is advisable; higher dosages can result in a reduction in compressive strength. Other superplasticizers include *sulfonic acid esters* or other *carbohydrate esters*. A dosage of 1 to 2-1/2% by weight of cement is advisable; higher dosages can result in a reduction in compressive strength unless the cement content is increased to balance the reduction. It should be noted that superplasticizers exert their action by decreasing the surface tension of water and by equidirectional charging of cement particles. These properties, coupled with the addition of silica fume, help achieve high strength and water reduction in concrete without loss of workability.

6.2.3.8 Silica Fume Admixture Use in High-Strength Concrete

Silica fume is generally accepted as an efficient mineral admixture for high-strength concrete mixes. It is a pozzolanic material that has received considerable attention in both research and application. Silica

fume is a byproduct resulting from the use of high-purity quartz with coal in electric-arc furnaces during production of silicon and ferrosilicon alloys. Its main constituent, fine spherical particles of silicon dioxide, makes it an ideal cement replacement and simultaneously raises concrete strength. As it is a waste product that is relatively easy to collect compared to fly ash or slag, silica fume is used extensively worldwide. Proportions of silica fume in concrete mixes vary from 5 to 30% by weight of the cement, depending on strength and workability requirements. Water demand is greatly increased as the proportion of silica fume is increased, and high-range water reducers are essential to keep the water/cementitious material ratio low to produce higher strength yet workable concrete. Silica fume seems to reach a high early strength in about 3 to 7 days with relatively less increase in strength at 28 days. The strength-development pattern of flexural and splitting tensile strengths is similar to that of compressive-strength gain for silica-fume-added concrete. The addition of silica fume to the mixture can produce significant increases in strength in excess of 20,000 psi, increased modulus of elasticity, and increased flexural strength.

6.3 Mixture Proportioning for High-Performance, Normal-Strength Concrete (Cylinder Compressive Strength Limit 6000 psi)

The ACI method of designing mixtures for normal weight concrete is summarized in Figure 6.2, based on water slump values selected from Table 6.6, Table 6.7, and Table 6.8. One aim of the mixture design is to produce workable concrete that is easy to place in forms. A measure of the degree of consistency and extent of workability is the **slump**. In the slump test, a plastic concrete specimen is formed into a conical metal mold, as described in ASTM C 143. The mold is lifted, leaving the concrete to slump—that is, to spread or drop in height. This drop in height is the slump measure of the degree of workability of the mixture.

6.3.1 Example 6.1: Mixture Proportions Design for Normal-Strength Concrete

Design a concrete mixture using the following details:

- Required strength—4000 psi (27.6 MPa)
- Type of structure—beam
- Maximum size of aggregate—3/4 in. (18 mm)
- Fineness modulus of sand—2.6
- Dry-rodded weight of coarse aggregate—100 lb/ft³
- Moisture absorption—3% for coarse aggregate and 2% for fine aggregate

Solution

- Required slump for beams (Table 6.6) is 3 in.
- Maximum aggregate size (given) is 3/4 in.
- For a slump between 3 and 4 in. and a maximum aggregate size of 3/4 in., the weight of water required per cubic yard of concrete (Table 6.7) is 340 lb/yd³.

For the specified compression strength (4000 psi), the water/cement ratio (Table 6.8) is 0.57. Table 6.9 is also required if volumes instead of weights are used in the mix design calculations. Therefore, the amount of cement required per cubic yard of concrete is $340/0.57 = 596.5$ lb/yd³.

Using a sand fineness value of 2.6 and Table 6.9, the volume of coarse aggregate is 0.64 yd³. Using the dry-rodded weight of 100 lb/ft³ for coarse aggregate, the weight of coarse aggregate is $(0.64) \times (27 \text{ ft/yd}^3) \times 100 = 1728$ lb/yd³. The estimated weight of fresh concrete for aggregate of 3/4 in. is as follows:

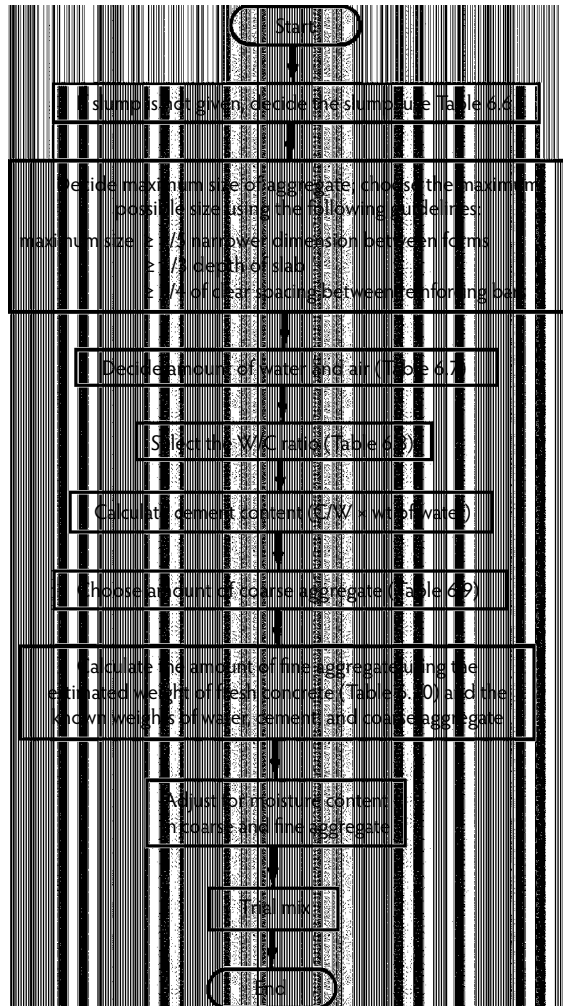

FIGURE 6.2 Flow chart for normal weight concrete mixture design. (From Nawy, E.G., *Reinforced Concrete: A Fundamental Approach*, 6th ed., Prentice Hall, Upper Saddle River, NJ, 2008.)

TABLE 6.6 Recommended Slumps for Various Types of Construction

Types of Construction	Slump (in.) ^a	
	Maximum ^b	Minimum
Reinforced foundation walls and footings	3	1
Plain footings, caissons, and substructure walls	3	1
Beams and reinforced walls	4	1
Building columns	4	1
Pavements and slabs	3	1
Mass concrete	2	1

^a 1 in. = 25.4 mm.

^b May be increased 1 in. for methods of consolidation other than vibration.

<i>Recommended average total air content^d (percent for level of exposure)</i>								
Mild exposure	4.5	4.0	3.5	3.0	2.5	2.0	1.5 ^{e,f}	1.0 ^{e,f}
Moderate exposure	6.0	5.5	5.0	4.5	4.5	4.0	3.5 ^{e,f}	3.0 ^{e,f}
Extreme exposure ^g	7.5	7.0	6.0	6.0	5.5	5.0	4.5 ^{e,f}	4.0 ^{e,f}

^a These quantities of mixing water are for use in computing cement factors for trial batches. They are maximal for reasonably well-shaped angular coarse aggregates graded within limits of accepted specifications.

^b The slump values for concrete containing aggregate larger than 1-1/2 in. are based on slump tests made after removal of particles larger than 1-1/2 in. by wet screening.

^c These quantities of mixing water are for use in computing cement factors for trial batches when 3-in. or 6-in. nominal maximum-size aggregate is used. They are average for reasonably well-shaped coarse aggregates, well graded from coarse to fine.

^d Additional recommendations for air content and necessary tolerances on air content for control in the field are given in a number of ACI documents, including ACI 201, 345, 318, 301, and 302. ASTM C 94 for ready-mixed concrete also gives air-content limits. The requirements in other documents may not always agree exactly, so in proportioning concrete consideration must be given to selecting an air content that will meet the needs of the job and also meet the applicable specifications.

^e For concrete containing large aggregates that will be wet screened over the 1-1/2-in. sieve prior to testing for air content, the percentage of air expected in the 1-1/2-in. material should be tabulated in the 1-1/2-in. column; however, initial proportioning calculations should include the air content as a percent of the whole.

^f When using large aggregate in low-cement-factor concrete, air entrainment need not be detrimental to strength. In most cases, the mixing water requirement is reduced sufficiently to improve the water/cement ratio and thus to compensate for the strength-reducing effect of entrained-air concrete. Generally, therefore, for these large maximum sizes of aggregate, air contents recommended for extreme exposure should be considered even though there may be little or no exposure to moisture and freezing.

^g These values are based on the criteria that 9% air is needed in the mortar phase of the concrete. If the mortar volume will be substantially different from that determined in this recommended practice, it may be desirable to calculate the needed air content by taking 9% of the actual mortar volume.

Source: Data from ACI Committee 211, *Standard Practice for Selecting Proportions for Normal, Heavyweight, and Mass Concrete*, ACI 211.1-91, American Concrete Institute, Farmington Hills, MI, 1991; Nawy, E.G., *Reinforced Concrete: A Fundamental Approach*, 6th ed., Prentice Hall, Upper Saddle River, NJ, 2008.

- Maximum size (Table 6.10) = 3960 lb/yd³.
- Weight of sand = weight of fresh concrete – weight of water – weight of cement – weight of coarse aggregate:

$$3960 - 340 - 596.5 - 1728 = 1295.5 \text{ lb}$$

- Net weight of sand to be taken (moisture absorption 2%) = $1.02 \times 1295.5 = 1321.41 \text{ lb}$.

TABLE 6.8 Relationship between Water/Cement Ratio and Compressive Strength of Concrete

Compressive Strength at 28 Days (psi)	Water/Cement Ratio (by weight)	
	Non-Air-Entrained Concrete	Air-Entrained Concrete
6000	0.41	—
5000	0.48	0.40
4000	0.57	0.48
3000	0.68	0.59
2000	0.82	0.74

Note: 1000 psi = 6.9 MPa. Values are estimated average strengths for concrete containing not more than the percentage of air shown in Table 6.7. For a constant water/cement ratio, the strength of concrete is reduced as the air content is increased. Strength is based on 6 × 12-in. cylinders moist-cured 28 days at 73.4 ± 3°F (23 ± 1.7°C) in accordance with Section 9(b) of ASTM C 31 (Making and Curing Concrete Compression and Flexure Test Specimens in the Field). Relationship assumes maximum size of aggregate about j to 1 in.; for a given source, strength produced for a given water/cement ratio will increase as maximum size of aggregate decreases.

Source: Data from ACI Committee 211, *Standard Practice for Selecting Proportions for Normal, Heavyweight, and Mass Concrete*, ACI 211.1-91, American Concrete Institute, Farmington Hills, MI, 1991; Nawy, E.G., *Reinforced Concrete: A Fundamental Approach*, 6th ed., Prentice Hall, Upper Saddle River, NJ, 2008.

TABLE 6.9 Volume of Coarse Aggregate per Unit of Volume of Concrete

Maximum Size of Aggregate (in.) ^a	Volume of Dry-Rodded Coarse Aggregate ^b per Unit Volume of Concrete for Different Fineness Moduli of Sand			
	2.40	2.60	2.80	3.00
3/8	0.50	0.48	0.46	0.44
1/2	0.59	0.57	0.55	0.53
3/4	0.66	0.64	0.62	0.60
1	0.71	0.69	0.67	0.65
1 1/2	0.75	0.73	0.71	0.69
2	0.78	0.76	0.74	0.72
3	0.82	0.80	0.78	0.76
6	0.87	0.85	0.83	0.81

^a 1 in. = 25.4 mm.

^b Volumes are based on aggregates in dry-rodded condition, as described in ASTM C 29 (Unit Weight of Aggregate). These volumes are selected from empirical relationships to produce concrete with a degree of workability suitable for usual reinforced construction. For less workable concrete, such as that required for concrete pavement construction, they may be increased about 10%. For more workable concrete, the coarse aggregate content may be decreased up to 10%, provided that the slump and water/cement ratio requirements are satisfied.

Source: Data from ASTM, *Annual Book of ASTM Standards*. Part 14. *Concrete and Mineral Aggregates*, American Society for Testing and Materials, Philadelphia, PA, 1993; ACI Committee 211, *Standard Practice for Selecting Proportions for Normal, Heavyweight, and Mass Concrete*, ACI 211.1-91, American Concrete Institute, Farmington Hills, MI, 1991; Nawy, E.G., *Reinforced Concrete: A Fundamental Approach*, 6th ed., Prentice Hall, Upper Saddle River, NJ, 2008.

- Net weight of gravel (moisture absorption 3%) = $1.03 \times 1728 = 1779.84$ lb.
- Net weight of water = $340 - (0.02 \times 1295.5) - (0.03 \times 1728) = 262.25$ lb.

For 1 yd³ of concrete:

- Cement = 596.5 lb = 600 lb (273 kg).
- Sand = 1321.41 lb = 1320 lb (600 kg).
- Gravel = 1779.84 lb = 1780 lb (810 kg).
- Water = 262.25 lb = 260 lb (120 kg).

TABLE 6.10 First Estimate of Weight of Fresh Concrete

Maximum Size of Aggregate (in.) ^a	First Estimate of Concrete Weight (lb/yd ³) ^b	
	Non-Air-Entrained Concrete	Air-Entrained Concrete
3/8	3840	3690
1/2	3890	3760
3/4	3960	3840
1	4010	3900
1-1/2	4070	3960
2	4120	4000
3	4160	4040
6	4230	4120

^a 1 in. = 25.4 mm.

^b Values calculated and presented in this table are for concrete of medium richness (550 lb of cement per cubic yard) and medium slump with aggregate specific gravity of 2.7. Water requirements are based on values for 3- to 4-in. slump in Table 5.3.2 of ASTM C 143. If desired, the estimated weight may be refined as follows if necessary information is available: For each 10-lb difference in mixing water from Table 5.3.2 values for 3- to 4-in. slump, correct the weight per cubic yard 15 lb in the opposite direction; for each 100-lb difference in cement content from 550 lb, correct the weight per cubic yard 10 lb in the same direction; for each 0.1 by which aggregate specific gravity deviates from 2.7, correct the concrete weight 100 lb in the same direction.

Source: Data from ACI Committee 211, *Standard Practice for Selecting Proportions for Normal, Heavyweight, and Mass Concrete*, ACI 211.1-91, American Concrete Institute, Farmington Hills, MI, 1991; Nawy, E.G., *Reinforced Concrete: A Fundamental Approach*, 6th ed., Prentice Hall, Upper Saddle River, NJ, 2008.

6.3.1.1 PCA Method of Design of Concrete Mixtures

The mixture design method of the Portland Cement Association (PCA) is essentially similar to the ACI method. Generally, results would be very close once trial batches are prepared in the laboratory. The PCA publication *Design and Control of Concrete Mixtures* (Kosmatka and Panarese, 1994) provides details regarding the method as well as other information on properties of the ingredients.

6.3.2 Estimating Compressive Strength of a Trial Mixture Using the Specified Compressive Strength

The compressive strength for which the trial mixture is designed is not the strength specified by the designer. The mixture should be overdesigned to ensure that the actual structure uses concrete with the specified minimum compressive strength. The extent of mixture overdesign depends on the degree of quality control available in the mixing plant. ACI Committee 318 (2008a,b) specifies a systematic way of determining the compressive strength for mixture designs using the specified compressive strength (f'_c). The procedure is presented in a self-explanatory flow-chart form in Figure 6.3. The cylinder compressive strength (f'_c) is the test result 28 days after casting normal weight concrete. Mixture design has to be based on an adjusted higher value, the adjusted cylinder compressive strength (f'_{cr}). The f'_{cr} value for which a trial mixture design is calculated depends on the extent of field data available, as shown below:

- *No cylinder test records available.* If field-strength test records for the specified class (or within 1000 psi of the specified class) of concrete are not available, the trial mixture strength can be calculated by increasing the cylinder compressive strength (f'_c) by a reasonable value, depending on the spread in values expected in the supplied concrete. Such a spread can be quantified by the standard deviation values represented by values in excess of f'_c in Table 6.11. Table 6.12 can then be used to obtain the water/cement ratio necessary for the required cylinder compressive strength value f'_c .

FIGURE 6.3 Flow chart of selection and documentation of concrete properties. (From Nawy, E.G., *Reinforced Concrete: A Fundamental Approach*, 6th ed., Prentice Hall, Upper Saddle River, NJ, 2008.)

PHOTO 6.4 Cylinder compressive-strength testing set-up.

TABLE 6.11 Required Average Compressive Strength When Data Are Not Available to Establish a Standard Deviation

Specified Compressive Strength (f'_c) (psi)	Required Average Compressive Strength (f'_{cr}) (psi)
Less than 3000	$f'_c + 1000$
3000–5000	$f'_c + 1200$
More than 5000	$f'_c + 1400$

Note: 1000 psi = 6.9 MPa.

Source: Data from ACI Committee 211, *Standard Practice for Selecting Proportions for Normal, Heavyweight, and Mass Concrete*, ACI 211.1-91, American Concrete Institute, Farmington Hills, MI, 1991; Nawy, E.G., *Reinforced Concrete: A Fundamental Approach*, 6th ed., Prentice Hall, Upper Saddle River, NJ, 2008.

- *Data are available on more than 30 consecutive cylinder tests.* If more than 30 consecutive test results are available, Equation 6.1, Equation 6.2, and Equation 6.3a can be used to establish the required mixture strength (f'_{cr}) from f'_c . If two groups of consecutive test results with a total of more than 30 are available, f'_{cr} can be obtained using Equation 6.1, Equation 6.2, and Equation 6.3b.
- *Data are available on fewer than 30 consecutive cylinder tests.* If the number of consecutive tests results available is fewer than 30 and more than 15, Equation 6.1, Equation 6.2, and Equation 6.3a should be used in conjunction with Table 6.13. Essentially, the designer should calculate the standard deviation (s) using Equation 6.3a, multiply the s value by the magnification factor provided in Table 6.13, and use the magnified s in Equation 6.1 and Equation 6.2. In this manner, the expected degree of spread of cylinder test values as measured by the standard deviation (s) is well accounted for.

6.3.3 Recommended Proportions for Concrete Strength (f'_{cr})

When the required average strength (f'_{cr}) for the mixture design has been determined, the actual mixture required to obtain this strength can be established using either existing field data or a basic trial mixture design:

TABLE 6.12 Maximum Permissible Water/Cement Ratios for Concrete When Strength Data from Field Experience or Trial Mixtures Are Not Available

Specified Compressive Strength (f'_c) (psi) ^a	Absolute Water/Cement Ratio by Weight	
	Non-Air-Entrained Concrete	Air-Entrained Concrete
2500	0.67	0.54
3000	0.58	0.46
3500	0.51	0.40
4000	0.44	0.35
4500	0.38	— ^b
5000	— ^b	— ^b

^a 28-day strength; with most materials, the water/cement ratios shown will provide average strengths greater than those calculated using Equation 6.1 and Equation 6.2.

^b For strengths above 4500 psi for non-air-entrained concrete and 4000 psi for air-entrained concrete, mix proportions should be established using trial mixes.

Note: 1000 psi = 6.9 MPa.

Source: Data from ACI Committee 211, *Standard Practice for Selecting Proportions for Normal, Heavyweight, and Mass Concrete*, ACI 211.1-91, American Concrete Institute, Farmington Hills, MI, 1991; Nawy, E.G., *Reinforced Concrete: A Fundamental Approach*, 6th ed., Prentice Hall, Upper Saddle River, NJ, 2008.

TABLE 6.13 Modification Factor for Standard Deviation When Fewer Than 30 Tests Are Available

Number of Tests ^a	Modification Factor for Standard Deviation ^b
Less than 15	Use Table 6.11
15	1.16
20	1.08
25	1.03
30 or more	1.00

^a Interpolate for intermediate number of tests.

^b Modified standard deviation to be used to determine required average strength f'_{cr} in Equation 6.1 and Equation 6.2.

Source: Data from ACI Committee 211, *Standard Practice for Selecting Proportions for Normal, Heavyweight, and Mass Concrete*, ACI 211.1-91, American Concrete Institute, Farmington Hills, MI, 1991; Nawy, E.G., *Reinforced Concrete: A Fundamental Approach*, 6th ed., Prentice Hall, Upper Saddle River, NJ, 2008.

- *Use of field data*—Field records of existing f'_{cr} values can be used if at least 10 consecutive test results are available. The test records should cover a period of at least 45 days. The material and conditions of the existing field mix data should be the same as those to be used in the proposed work.
- *Trial mixture design*—If field data are not available, trial mixtures should be used to establish the maximum water/cement ratio or minimum cement content necessary for designing a mix that produces a 28-day f'_{cr} value. In this procedure, the following requirements have to be met:
 1. The materials used and age at testing should be the same for the trial mixture and the concrete used in the structure.
 2. At least three water/cement ratios or three cement contents should be tried in the design of the mixture. The trial mixtures should result in the required f'_{cr} value. Three cylinders should be tested for each water/cement ratio and each cement content tried.

3. The slump and air content should be within ± 0.75 in. and 0.5% of permissible limits.
4. A plot should be constructed of the compressive strength at the designated age vs. the cement content or water/cement ratio, from which one can then choose the water/cement ratio or the cement content that will give the average f'_{cr} value required.

If field test data are available for more than 30 consecutive tests, the trial mixture should be designed for a compressive strength (f'_{cr}) calculated from:

$$f'_{cr} = f'_c + 1.34s \quad (6.1)$$

or from:

$$f'_{cr} = f'_c + 2.33s - 500 \quad (6.2)$$

where f'_c is the individual strength, and f'_{cr} is the average of the n specimens. The larger value of f'_{cr} from Equation 6.1 and Equation 6.2 should be used in designing the mixture, with the expectation that the minimum specified compressive strength will be attained. The standard deviation (s) is defined by the expression:

$$s = \left[\frac{\sum (f_i - f'_c)^2}{(n-1)} \right]^{1/2} \quad (6.3a)$$

If two test records are used to determine the average strength, the standard deviation becomes:

$$s = \left[\frac{(n_1 - 1)(s_1)^2 + (n_2 - 1)(s_2)^2}{(n_1 + n_2 - 2)} \right]^{1/2} \quad (6.3b)$$

where s_1 , s_2 are the standard deviations calculated from two test records, 1 and 2, respectively, and n_1 and n_2 are the number of tests in each test record, respectively. If the number of test results available is fewer than 30 and more than 15, the value of s used in Equation 6.1 and Equation 6.2 should be multiplied by the appropriate modification factor given in Table 6.13.

6.3.4 Example 6.2: Calculation of Design Strength for a Trial Mixture

Calculate the average compressive strengths for the design of a concrete mixture where the specified compressive strength is 5000 psi (334.5 MPa) and:

1. The standard deviation obtained using more than 30 consecutive tests is 500 psi (3.45 MPa).
2. The standard deviation obtained using 15 consecutive tests is 450 psi (3.11 MPa).
3. Records of prior cylinder test results are not available.

Solution

1. Using Equation 6.1:

$$f'_{cr} = 5000 + 1.34 \times 500 = 5670 \text{ psi}$$

Using Equation 6.2:

$$f'_{cr} = 5000 + 2.33 \times 500 = 5665 \text{ psi}$$

Hence, the required trial mix strength is 5670 psi (39.12 MPa).

2. The standard deviation is equal to 450 psi in 15 tests. From Table 6.13, the modification factor for s is 1.16; hence, the value of the standard deviation to be used in Equation 6.1 and Equation 6.2 is $1.16 \times 450 = 522$ psi (3.6 MPa). Using Equation 6.1:

$$f'_{cr} = 5000 + 1.34 \times 522 = 5700 \text{ psi}$$

Using Equation 6.2:

$$f'_{cr} = 5000 + 2.33 \times 522 = 5716 \text{ psi}$$

Hence, the required trial mixture strength is 5716 psi (39.44 MPa).

3. Records of prior test results are not available. Using Table 6.11:

$$f'_{cr} = f'_c + 1200$$

for 5000-psi concrete, so the trial mixture strength is $5000 + 1200 = 6200$ psi (42.78 MPa).

If a mixing plant keeps good records of its cylinder test results over a long period, the required trial mixture strength can be reduced as a result of quality control, thus reducing costs for the owner.

6.4 Mixture Proportioning for High-Performance, High-Strength Concrete (Cylinder Compressive Strength Exceeding 6000 psi)

6.4.1 General

By current ACI definitions, high-strength concrete covers concretes whose cylinder compressive strength exceeds 6000 psi (41.4 MPa). Proportioning concrete mixtures is more critical for high-strength concrete than for normal-strength concrete. The procedure is similar to the proportioning process for normal-strength concrete, except that adjustments have to be made for admixtures that replace part of the cement content in the mixture and it is often necessary to use smaller size aggregates in very high-strength concretes.

As discussed in Chapter 2 and Chapter 3 and in Section 6.5, there are several types of strength-modifying admixtures: high-range water reducers (superplasticizers), fly ash, polymers, silica fume, and blast-furnace slag. When mix proportioning for very high-strength concrete, however, isolating the water/cementitious materials ratio, $W/(C + P)$, from the paste/aggregate ratio because of the very low water content can be more effective for arriving at the optimum mixture with fewer trial mixtures and field trial batches. Few other methods are available today. The very low $W/(C + P)$ ratios necessary for strengths in the range of 20,000 psi (138 MPa) or higher require major modifications to the standard approach used for mixture proportioning that seems to work well for strengths up to 12,000 psi (83 MPa). The optimum mixture, chosen with minimum trials, has to produce a satisfactory concrete product in both its plastic and its hardened states.

An approach presented by ACI Committee 211 (1993) is based on the mortar volume/stone volume ratio and proportions the solids in the mortar on the basis of the ratio:

$$\frac{\text{Solid sand volume} \pm \text{cementitious solid volume}}{\text{Mortar volume}}$$

The ACI standard is well established for fly ash concrete (FAC). Ample mixture-proportioning results are available for polymers, and the same is true for silica-fume concrete (SFC) and slag concrete (SC or GGBFSC); however, they are not established in the form of a standard such as the committee reports of the *ACI Manual of Concrete Practice* (ACI, 1997). Additionally, several sections in the ACI manual list mixture proportions for the types of strength-generating admixtures that have been discussed in this chapter. The computational example in this chapter on fly ash concrete design for strengths up to 12,000 psi (83 MPa) should serve as a systematic step-by-step guide for proportioning mixtures using polymers, silica fume, and granulated blast-furnace slag within the compressive strength range of the example.

PHOTO 6.5 Splitting tensile strength test to failure.

6.4.2 Strength Requirements

The age at test is a governing criteria for selecting mixture proportions. The standard 28-day strength for normal-strength concrete penalizes high-strength concrete because the latter continues gaining strength after that age. One also has to consider that a structure is subjected to its service load at 60 to 90 days age at the earliest; consequently, in this case mixture proportioning has to be based on the latter age levels and also on either *field experience* or *laboratory batch trials*. The average compressive field-strength results should exceed the specified design compressive strength by a sufficiently high margin so as to reduce the probability of lower test results.

6.4.2.1 Mixture Proportions on the Basis of Field Experiences

If the concrete producer chooses the mixture on the basis of field experience, the required average strength f'_{cr} should be the larger of:

$$f'_{cr} = f'_c + 1.34s$$

or

$$f'_{cr} = 0.90f'_c + 2.33s$$

where f'_c is the specified design compressive strength, and s is the sample standard deviation (lb/in.²) from Equation 6.3.

6.4.2.2 Mixture Proportions on the Basis of Laboratory Trial Batches

In this case, the laboratory trial batches should give:

$$f'_{cr} = \frac{(f'_c + 1400)}{0.90} \text{ psi} \quad (6.4a)$$

or, in SI units:

$$f'_{cr} = \frac{(f'_c + 27.6)}{0.90} \text{ MPa} \quad (6.4b)$$

It is important to note that high-strength, high-performance concrete requires special attention in the selection and control of ingredients in the mixture to obtain optimum proportioning and maximum strength. To achieve this aim, care in the choice of the particular cement, admixture brand, dosage rate, mixing procedure, and quality and size of aggregate becomes paramount. Because not all of the cement hydrates, it is advisable that the cement content be kept at a minimum for optimum mixture proportioning.

PHOTO 6.7 Failure patterns of higher strength concrete compressive test. (Photograph courtesy of E.G. Nawy et al.)

6.4.3 Selection of Ingredients

6.4.3.1 Cement and Other Cementitious Ingredients

A proper selection of types and source of cement is extremely important. ASTM cement requirements are only minimum requirements, and certain brands are better than others due to variations in the physical and chemical makeup of various cements. High-strength concrete requires high cementitious materials content (namely, a low water/cementitious materials ratio), and the fineness of the cementitious materials has a major effect on the workability of the fresh mixture and the strength of the hardened concrete. They contribute to the reduction in water demand and lower the temperature of hydration; hence, a determination has to be made whether to choose Class F fly ash or Class G silica fume or granulated slag. The discussion in Chapter 2 of these cementitious materials gives guidelines for choosing ingredients.

6.4.3.2 Coarse Aggregate

Aggregates greatly influence the strength of the hardened concrete, as they comprise the largest segment of all the constituents; consequently, only hard aggregate should be used for normal weight high-strength concrete so the aggregate has at least the strength of the cement gel. As higher strength is sought, aggregate size should be decreased. It is advisable to limit aggregate size to a 3/4-in. (19-mm) maximum size for strengths up to 9000 psi (62 MPa). For higher strengths, a 1/2-in. or preferably 3/8-in. aggregate should

be used (12.7 to 9.5 mm). To achieve very high strengths in the range of 15,000 to 20,000 psi (103 to 138 MPa), higher-strength trap rock from selected quarries should be used. Beyond 20,000 to 30,000 psi, aggregate size should not exceed 3/8 in. for structural components.

6.4.3.3 Fine Aggregate

A fineness modulus (FM) in the range of 2.5 to 3.2 is recommended for high-strength concrete to facilitate workability. Lower values result in decreased workability and a higher water demand. The mixing-water demand is dependent on the void ratio in the sand. The basic void ratio is 0.35 and should be adjusted for other void ratios such that the void content (V , in percent) can be evaluated from:

$$V = \left(1 - \frac{\text{Oven-dry-rodded unit weight (lb/ft}^3\text{)}}{\text{Bulk dry specific gravity} \times 62.4} \right) 100 \quad (6.5a)$$

or, in SI units:

$$V = \left(1 - \frac{\text{Oven-dry-rodded unit weight (kg/m}^3\text{)}}{\text{Bulk dry specific gravity} \times 10^3} \right) 100 \quad (6.5b)$$

The mixing water has to be adjusted accordingly to account for the change in the basic void ratio such that the mixing-water adjustment (A) would be as follows:

$$A = 8(V - 35) \quad (6.6a)$$

where A is pounds per cubic yard. In SI units,

$$A = 4.7(V - 35) \quad (6.6b)$$

where A is kilograms per cubic meter.

6.4.3.4 Workability-Enhancing Chemical Admixtures

High-strength mixtures have a rich cementitious content that requires a high water content. Because excessive water reduces the compressive strength of the concrete and affects its long-term performance, water-reducing admixtures become mandatory. For these applications, high-range water reducers (HRWRs) are used (see Chapter 2 and Chapter 3). These are sometimes called *superplasticizers*. The dosage rate is usually based on fluid ounces per 100 pounds (45 kg) of total cementitious materials if the HRWRs are in liquid form. If the water-reducing agent is in powdered form, the dosage rate would be on a weight-ratio basis. The optimum admixture percentage should be determined on a trial-and-adjustment basis, as admixtures can reduce the water demand by almost 30 to 35% with a corresponding increase in compressive strength. A slump of 1 to 2 in. (25 to 50 mm) is considered adequate; however, if no HRWR admixtures are used, then the slump should be increased to 2 to 4 in. (50 to 100 mm). In addition, air-entraining admixtures are used if the concrete is exposed to freezing and thawing cycles in severe environmental conditions. For structural components in building systems, air entraining is unnecessary as these usually are not subjected to the type of frost action that exposed bridge decks or marine platforms endure.

6.4.4 Recommended Proportions

Table 6.14 to Table 6.22, adapted from ACI Committee 211 (1993), ACI Committee 212 (1983), ACI Committee 221 (1961), Nawy (2001), Neville (2001), and Russell (1993), recommend the necessary ingredients for proportioning mixes for high-strength concrete. Where the void content (V , in percent) is:

$$V = \left(1 - \frac{\text{Oven-dry-rodded unit weight}}{\text{Bulk dry specific gravity (dry)} \times 62.4} \right) 100$$

TABLE 6.14 Recommended Slump

With HRWR, in. (mm) ^a	Without HRWR, in. (mm)
1–2 (25–50) before adding HRWR	2–4 (50–100)

^a Adjust slump to that desired in the field by adding HRWR.

Note: HRWR, high-range water reducer.

TABLE 6.15 Required Average Compressive Strength When Data Are Not Available to Establish a Standard Deviation

Specified Strength (f'_{cr}), psi (MPa)	Required Strength (f'_{cr}), psi (MPa)
>5000 (34.5)	$f'_c + 1400$ ($f'_c + 9.7$)

TABLE 6.16 Maximum-Size Coarse Aggregate

Required Concrete Strength (f'_c), psi (MPa)	Maximum Aggregate Size, in. (mm)
<9000 (62)	3/4–1 (19–25)
≥9000 (62)	3/8–1/2 (9.5–12.7)

TABLE 6.17 Ratio of Coarse Aggregate to Concrete Fractional Volume (Sand Fineness Modulus 2.5 to 3.2)

	Nominal Maximum Size, in. (mm)			
	0.03352	0.004701	3/4 (19)	1 (25)
Fractional volume of oven-dry rodded coarse aggregate	0.65	0.68	0.72	0.75

the mixing-water adjustment, in pounds per cubic yard, is:

$$(V - 35) \times 8$$

and in kilograms per cubic meter is:

$$(V - 35) \times 4.7$$

6.4.5 Step-by-Step Procedure for Selecting Proportions

The following are the steps necessary in the proportioning selection process:

1. Select the slump and required strength (f'_{cr}) (Table 6.14 and Table 6.15).
 - Based on field experience, select the f'_{cr} that is the larger of $f'_c + 1.34s$ or $0.9f'_{cr} + 2.33s$.
 - Based on laboratory batching, use $(f'_c + 1400)/0.9$.
2. Select the maximum size of aggregate (Table 6.16).
3. Select the optimum coarse-aggregate content (Table 6.17).
4. Estimate the mixing water and air content (Table 6.18).
5. Select the $W/(C + P)$, where C is the cement content and P is the pozzolanic content by weight (Table 6.19 and Table 6.20).
6. Compute the necessary content of the cementitious material P . This can be obtained by dividing the amount of mixing water per cubic yard or cubic meter of concrete (step 4) by the $W/(C + P)$ ratio.

TABLE 6.18 Mixing-Water Requirement and Air Content of Fresh Concrete Using Sand with 35% Void Ratio—First Trial Water Content

Slump, in. (mm)	Mixing Water, lb/yd ³ (kg/m ³)			
	Maximum-Size Coarse Aggregate, in. (mm)			
	3/8 (9.5)	1/2 (12.7)	3/4 (19)	1 (25)

^a Here, $f'_{cr} = f'_c + 1400$ ($f'_{cr} = f'_c + 9.7$).

^b These are average field values; enter into the table 0.9 (required f'_{cr}).

7. Proportion a basic mixture without the cementitious pozzolanic material P.
8. Proportion a companion mixture using the cementitious pozzolanic material P such as fly ash.
9. Produce a trial mix for each of the trial mix proportions designed in steps 1 to 8.
10. Adjust the mixture proportions to achieve the required slump by changing the contents and adjusting the HRWR agent rate for several trial mixes.
11. Select the optimum mixture.

6.4.6 Example 6.3: Mixture Proportions Design for High-Strength Concrete

Design a high-strength concrete mixture for columns in a multistory structure for a 28-day compressive strength of 10,000 psi (69 MPa). A slump of 9 in. (229 mm) is necessary for the workability required for congested reinforcement in the columns. Do not use an aggregate size exceeding 1/2 in. (12.7 mm). Use a high-range water reducer (HRWR) to obtain the 9-in. slump and a set-retarding admixture. Assume that the ready-mix producer has no prior history with high-strength concrete. Also assume the following sand properties:

TABLE 6.20 W/(C + P) Ratio for Concrete with High-Range Water Reducer

Field Strength f'_{cr} , psi (MPa) ^{a,b}		W/(C + P) Ratio			
		Maximum-Size Coarse Aggregate, in. (mm)			
		3/8 (9.5)	1/2 (12.7)	3/4 (19)	1 (25)
7000 (48)	28 days	0.50	0.48	0.45	0.43
	56 days	0.55	0.52	0.48	0.46

	56 days	0.37	0.35	0.33	0.32
11,000 (76)	28 days	0.30	0.29	0.27	0.27
	56 days	0.37	0.31	0.29	0.29
12,000 (83)	28 days	0.27	0.26	0.25	0.25
	56 days	0.30	0.28	0.27	0.26

^a Here, $f'_{cr} = f'_c + 1400$ ($f'_{cr} = f'_c + 9.7$).

^b These are average field values; enter into the table 0.9 (required f'_{cr}).

Note: A comparison of the values contained in Table 6.19 and Table 6.20 permits, in particular, the following conclusions: (1) For a given water/cementitious material ratio, the field strength of concrete is greater with the use of HRWR than without it, and this greater strength is reached within a shorter period of time. (2) With the use of HRWR, a given concrete field strength can be achieved in a given period of time using less cementitious material than would be required when not using HRWR.

- Fineness modulus (FM) = 2.90.
- Bulk specific gravity (over dry) (BSG)_{dry} = 2.59.
- Absorption based on dry weight (Abs) = 1.1%.
- Dry-rodded unit weight (DRUW) = 103 lb/ft³ (1620 kg/m³).
- Moisture content in sand = 6.4%.

Solution

1. Select the slump and required concrete strength.

Because a HRWR agent is used, choose strength on the basis of a 1- to 2-in. slump prior to the addition of HRWR. Also, because the ready-mix producer has no prior history with high-strength concrete, laboratory trial mixtures have to be designed for selection of the optimum proportions. From Equation 6.4a:

$$f'_{cr} = (f'_c + 1400)/0.90 = (10,000 + 1400)/0.90 = 12,670 \text{ psi (87 MPa)}$$

2. Select the maximum aggregate size.

A crushed limestone graded 1/2 in. (12.7 mm) maximum size is selected with BSG_{dry} = 2.76, Abs = 0.70, DRUW = 101 lb/ft³, and stone moisture content = 0.5%.

3. Select the optimum coarse aggregate content.

From Table 6.16, the fractional ratio is equal to 0.68. The dry weight (W_{dry}) of coarse aggregate per cubic yard of concrete is:

$$W_{dry} = (\%DRUW) \times (DRUW \times 27) = 0.68 \times 101 \times 27 = 1854 \text{ lb (841 kg)}$$

4. Estimate the mixing water and air content.

From Table 6.18, the first estimate of the required mixing water is 295 lb/yd³ (174 kg/m³) of concrete, and the entrapped air content when HRWR is used is 2.0%. From Equation 6.5a, the void content of the sand to be used is:

$$V = \left[1 - \frac{103}{2.59 \times 62.4} \right] \times 100 = 36\%$$

From Equation 6.6a, the mixing water adjustment (A) is:

$$A = 8(V - 35) = 8(36 - 35) = +8 \text{ lb/yd}^3 \text{ (4.7 kg/m}^3\text{) of concrete}$$

Hence, the total mixing water (W) is $295 + 8 = 303 \text{ lb (138 kg)}$.

5. Select the water/cementitious materials ratio, W/(C + P).

The values in Table 6.19 and Table 6.20 are average field-strength values; hence, the strength f'_{cr} for which the W/(C + P) ratio is to be found is:

$$f'_{cr} = 0.90 \times 12,670 = 11,400 \text{ psi (77 MPa)}$$

From Table 6.20, for a 1/2-in. aggregate, the desirable W/(C + P) ratio is 0.272, by interpolation.

6. Compute the content of cementitious material. From step 6, the mixing water (W) is 303 lb; hence,

$$C + P = 303/0.272 = 111 \text{ lb (505 kg)}$$

7. Proportion the basic mixture with cement only.

Volumes of all materials per cubic yard, except sand, are as follows:

- Cement = $1114/(3.15 \times 62.4) = 5.67 \text{ ft}^3$.
- Stone = $1854/(2.76 \times 62.4) = 10.77 \text{ ft}^3$.
- Water = $303/62.4 = 4.86 \text{ ft}^3$.
- Air = $0.02 \times 27 = 0.54 \text{ ft}^3$.
- Total = $21.77 \text{ ft}^3 \text{ (0.62 m}^3\text{)}$.

(Note: $1 \text{ m}^3 = 35.31 \text{ ft}^3$.) Hence, the required volume of sand per cubic yard of concrete is:

$$27 - 21.77 = 5.23 \text{ ft}^3$$

Converting the sand volume to weight:

$$\text{Sand} = 5.23 \times 62.4 \times 2.59 = 845 \text{ lb (384 kg)}$$

The mixture proportions by weight for the no-fly-ash concrete would be:

	lb/yd ³	kg/m ³
Cement	1114	661
Sand, dry	845	501
Stone, dry	1854	1100
Water (including 3 oz./cwt retarding admixture) ^a	303	180
Total	4116	2442

^a Here, cwt = 100 weight of cement.

8. Proportion companion mixtures using cement and fly ash.

In this case, use ASTM Class C fly ash (FA), which has a bulk specific gravity of 2.64. From Table 6.21, the fly ash replacement is 20 to 35%. Use four trial mixture levels: 20%, 25%, 30%, and 35%. For trial mixture 1, the silica fume is $0.20 (1114) = 223 \text{ lb}$; hence, the cement is $1114 - 223 = 891 \text{ lb}$. In a similar manner, the weights of the cementitious materials would be as shown in the following table:

Mixture	Cement, lb (kg)	Fly Ash, lb (kg)
1	891 (404)	223 (101)
2	835 (379)	279 (126)
3	780 (354)	334 (151)
4	724 (328)	390 (177)

TABLE 6.21 Fly Ash Values to Replace Part of the Cement

Type	Replacement % by Weight
ASTM Class F	15–25
ASTM Class C	20–35

TABLE 6.22 Modification Factor for Standard Deviation When Fewer Than 30 Tests Are Available

Number of Tests ^a	Modification Factor for Standard Deviation ^b
Less than 15	Use Table 6.15
15	1.16
20	1.08
25	1.03
30 or more	1.00

^a Interpolate for intermediate number of tests.

^b Modified standard deviation to be used to determine required average strength f'_{cr} in Equation 6.1 and Equation 6.2.

TABLE 6.23 Mixture Proportion in Example 6.3 without Moisture Trial Batch Adjustment

Ingredient	Basic Mix Cement Only (lb)	Cement + CFA Mixes (lb)			
		#1	#2	#3	#4
Cement	1114	891	835	780	724
Fly ash	0	223	279	334	390
Sand (dry)	845	800	790	781	773
Stone (dry)	1854	1854	1854	1854	1854
Water (plus retarder)	303	303	303	303	303
Total (lb/yd ³ concrete)	4116	4071	4061	4052	4044
Total (kg/m ³ concrete)	2428	2402	2396	2391	2386

Note: 1 lb/yd³ = 1 kg/m³. CFA, fly ash Class C.

In mixture 1, the volumes of components, except sand, per cubic yard of concrete are:

- Cement = $891 / (3.15 \times 62.4) = 4.53 \text{ ft}^3$.
- Fly ash = $223 / (2.64 \times 62.4) = 1.35$.
- Stone = 10.77 (from earlier table).
- Water (including 2.5 oz./cwt retarder) = 4.86 (from earlier table).
- Air = 0.54 (from earlier table).
- Total = 22.05 ft³.

The sand volume is $27 - 22.05 = 4.95 \text{ ft}^3 = 4.95 \times 62.4 \times 2.59 = 800 \text{ lb}$. The mixture proportions by weight for the fly-ash concrete mixture 1 would be:

	lb/yd ³	kg/m ³
Cement	891	526
Fly ash	223	132
Sand (dry)	800	472
Stone (dry)	1854	1094
Water plus retarder	303	179
Total	4071	2402

Note: 1 lb/yd³ = 0.59 kg/m³.

TABLE 6.24 Moisture-Adjusted Mixture Proportion in Example 6.3

Ingredient	Basic Mix Cement Only (lb)	Cement + CFA Mixes (lb)			
		#1	#2	#3	#4
Cement	1114	891	835	780	724
Fly ash	0	223	279	334	390
Sand (wet)	899	851	841	831	823
Stone (wet)	1863	1863	1863	1863	1863
Water (plus retarder)	262	262	262	262	262
Total (lb/yd ³ concrete)	4138	4090	4080	4070	4062
Total (kg/m ³ concrete)	2441	2413	2407	2401	2397

Note: 1 lb/yd³ = 0.89 kg/m³. CFA, fly ash Class C.

In a similar manner, the mixture proportions for 25%, 30%, and 35% fly ash content are computed to give the companion mixtures shown in Table 6.23.

9. Adjust the trial mixtures for absorbed water content in aggregate.

From before, the moisture content in sand is 6.4%, and the moisture content in stone is 0.5%. From Table 6.23, corrections in the basic mixture for the wetness of the aggregates are as follows:

$$\text{wet sand} = 845 (1 + 0.064) = 899 \text{ lb}$$

$$\text{wet stone} = 1854 (1 + 0.005) = 1863 \text{ lb}$$

From input data, the sand absorption based on dry weight is 1.1% and the stone absorption is 0.7%. Hence, the water correction is:

$$303 - 845(0.064 - 0.011) - 1854(0.005 - 0.007) = 303 - 45 + 4 = 262 \text{ lb (119 kg)}$$

Accordingly, the batch weight of water has to be corrected to account for the excess moisture contributed by:

$$\text{Aggregates} = \text{Total moisture} - \text{aggregate absorbed moisture}$$

Hence, Table 6.23 is modified to give Table 6.24.

10. Select the size of the laboratory trial mixture.

The usual size of the trial mixture is 3.0 ft³ (0.085 m³). The reduced batch weights to yield 3.0 ft³ of concrete would be 1/9 of the values tabulated in Table 6.24 to yield the values in the following table:

Ingredient	Basic Mix Cement Only (lb)	Cement + CFA Mixes (lb)			
		#1	#2	#3	#4
Cement	123.78	99.00	92.78	86.67	80.44
Fly ash	0	24.78	31.00	37.11	43.33
Sand (dry)	99.89	94.56	93.44	92.33	91.44
Stone (dry)	207.00	207.00	207.00	207.00	207.00
Water plus retarder	29.11	29.11	29.11	29.11	29.11
Total (lb/3 yd ³ concrete)	460	455	453	452	451
Total (kg/1/10 m ³ concrete)	245.3	242.7	241.6	241.1	240.5

11. Adjust the trial mixture on the basis of slump observation.

(a) *Basic mixture.* Assume that the water calculated to produce 1- to 2-in. slump (29.11 lb) was found not to be adequate and has to be increased to 30 lb per 3 ft³, including the 2.5 oz./cwt retarding admixture. The actual batch weights have to be adjusted so the actual batch weight for the basic mixture (no fly ash) becomes:

- Cement = 123.78 lb.
- Sand = 99.89 lb.
- Stone = 207.00 lb.
- Water = 30.00 lb.

These values have to be adjusted for moisture correction to the dry weight. The basic total added water is $30 \times 9 = 270 \text{ lb/yd}^3$. From before, the absorbed water in the aggregates is $45 - 4 = 41 \text{ lb}$. The actual total water content is $270 + 41 = 311 \text{ lb/yd}^3 = 34.56 \text{ lb/ft}^3$; thus,

- Cement = 123.78 lb.
- Sand = $99.89/1.064 = 93.88 \text{ lb}$.
- Stone = $207/1.005 = 205.97 \text{ lb}$.
- Batch water = $30.00 + 45/9 - 4/9 = 34.56 \text{ lb}$.

(b) *Yield of trial batch.* The actual yield of the trial mixture becomes:

- Cement = $123.78/(3.15 \times 62.4) = 0.63 \text{ lb}$.
- Sand = $93.88/(2.59 \times 62.4) = 0.58 \text{ lb}$.
- Stone = $205.97/(2.76 \times 62.4) = 1.20 \text{ lb}$.
- Water = $34.56/62.4 = 0.55 \text{ lb}$.
- Air = $0.02 \times 3 \text{ ft}^3 = 0.06 \text{ lb}$.
- Total yield volume of trial batch = 3.02 ft^3 .

The yield in pounds per cubic yard of concrete is obtained by multiplying all of the previous values by 9 and converting the volumes to weights, giving:

- Cement = $1114 \times (3.0/3.02) = 1107 \text{ lb}$.
- Sand (dry) = $845 \times (3.0/3.02) = 839 \text{ lb}$.
- Stone = $1854 \times (3.0/3.02) = 1841 \text{ lb}$.
- Water (plus retarder) = $311 \times (3.0/3.02) = 309 \text{ lb}$.

The new mixture proportions result in a water/cementitious materials ratio of:

$$W/(C + P) = 309/1107 = 0.28$$

vs. the desirable ratio of 0.272 previously obtained from Table 6.20. To maintain the 0.272 ratio, the weight of the cement should be increased to $309/0.272 = 1136 \text{ lb/yd}^3$ of concrete. The increase in volume due to the adjustment of the weight of cement is:

$$(1136 - 1107)/(3.15 \times 62.4) = 0.148 \text{ ft}^3$$

This increase in volume should be adjusted for by the removal of an equal volume of sand; hence, the weight of sand to be removed is $0.148 \times 2.59 \times 62.4 = 23.98 \text{ lb/yd}^3$, say, 18 lb/yd^3 . The resulting adjusted mixture proportions become:

- Cement = 1131 lb.
- Sand (dry) = $839 - 24 = 815$.
- Stone (dry) = 1841.
- Water + 2.5 oz./cwt retarder = 309.

(c) *Increase slump to 9 in. (229 mm).* The required slump in this example is 9 in. (229 mm). To achieve this value without the addition of water, which will reduce the strength, a high-range water reducer (namely, a plasticizer) is used. The dosage recommended by the manufacturer of the HRWR varies from

TABLE 6.25 Laboratory Final Trial Mixtures

Ingredient	Basic Mix Cement Only (lb)	Cement + CFA Mixes (lb)			
		#1 (20% CFA)	#2 (25% CFA)	#3 (30% CFA)	#4 (35% CFA)

8 to 16 oz. per 100 lb of cementitious material. Tests performed in a laboratory with an ambient temperature of 74°F indicated the following:

- An 8-oz. dosage produced a 5-in. slump.
- An 11-oz. dosage produced 10-in. slump.
- A 16-oz. dosage produced segregation of the fresh concrete.

In all of these cases, a constant dosage rate of a retarding admixture of 2.5 oz./cwt was also added to the mixture along with the mixing water. When the HRWR was added to the mixture about 15 minutes after the initial mixing, it was determined that:

- The mixture with 10-in. (255 mm) slump had adequate workability; hence, no correction to the coarse aggregate content was necessary.
- The air content of the HRWR concrete mixture was found to be 1.9%; hence, no correction was necessary.
- The 28-day compressive strength of the No. 3 mixture was found to be 12,750 psi, satisfying the required f'_{cr} value of 12,670 psi. (Note: It is important to recognize that if additional water at this stage was required to produce the necessary slump and workability, then an additional cycle of corrections to actual batches of aggregate would have to be executed in the same manner as in the previous steps.)

12. Summary of the trial mixtures laboratory performance.

Table 6.25 provides a summary of the performance of the five mixtures: the basic no-fly-ash concrete and the four concretes with fly-ash contents of 20%, 25%, 30%, and 35% of the total cementitious material. Slump values for no-HRWR mixtures and those with HRWR were measured in the laboratory slump tests.

In addition, field trials must be done to verify the choice of laboratory trial mix. In this case, Mix 3 from Table 6.25, which gave the highest 28-day compressive strength of 12,750 psi (88 MPa), is closest to the required f'_{cr} of 12,670 psi that gives the compressive strength (f'_c) of 10,000 required in this example.

Part B. Applications and Constructability (J. Moreno and J. Albinger)

6.5 Applications and Constructability with an Emphasis on High-Strength, High-Performance Concrete

6.5.1 General

High-strength concrete (HSC) has a relative meaning according to the availability and utilization of materials and resources in each geographical area. In several parts of the country, concrete strengths of more than 112 MPa (16,000 psi) have been produced, while in other parts of the country 42 MPa (6,000 psi) is considered high. The type of market, availability of materials, and know-how are the reasons for such divergence. It should be understood that these factors are relative to the type of construction, initiative of the design engineer, commitment of the concrete producer, and quality of local materials. The permissible margin of error for high-strength concrete is smaller than for normal-strength concrete. Small variations in mixture proportions and deviations from good testing practices can have a greater effect on the strength or perceived strength of HSC than on normal-strength concrete. Preconstruction meetings are advisable to define responsibilities and avoid problems during construction.

6.5.2 Constructability Preparation Process

6.5.2.1 Preconstruction Meetings

Prior to construction, all of the project participants should meet to clarify contract requirements, discuss planned placement conditions, and review the planned inspection and testing programs of the various parties. The effects of time, temperature, placing, curing, and acceptance criteria and how those criteria will be established should be reviewed. The capabilities of the contractor's work force, the inspection staff, the testing laboratory, and the batching facilities should also be evaluated or inspected. The meeting should establish lines of communication and identify responsibilities. It is especially important to review the procedures the inspector will follow when noncompliance with contract requirements is found or suspected. This advance understanding will minimize future disputes and will give all members of the construction team an opportunity to participate in the quality process. Timely and accurate reporting are paramount. In addition to the required structural characteristics, trial production batches should take workability and placeability into consideration. It may, however, be necessary to make adjustments due to placement conditions or weather conditions when the job has started. The ready-mix concrete producer is essential to this discussion, as the producer is most familiar with and responsible for the product. Only designated individuals should have the authority to add admixtures or water or make any other mix changes on the site. No water in excess of the approved mixture proportions should be added to high-strength concrete.

6.5.2.2 Material Selection and Proportioning

Unlike more conventional, lower strength concrete, established procedures cannot always be used to determine the proportioning of high-strength concrete. As will be seen later, modifications to published procedures for mixture design of HSC must be made, although the basic principles remain. Maintaining the lowest possible water/cementitious materials ratio, for example, is not merely important but also critical (Table 6.26). The basic consideration is still the selection of a combination of materials that will produce a quality concrete with the desired workability, ease of placement, strength, and durability. Because of the innumerable types and grades of aggregate, varying chemical contents, and physical characteristic of cements, pozzolans, and chemical admixtures, and the interaction of these materials, arriving at the optimum combination often becomes a matter of producing several trial mixes. Caution must be exercised when examining the data of others, inasmuch as conclusions reached may reflect a particular set of materials unlike those in the researcher's area. For this reason, it is suggested that the following data be evaluated in a conceptual rather than quantitative manner. The slump required for pumping, placement, and consolidation normally varies with individual job conditions. If a high-range water reducer (superplasticizer) is not part of the original design, it should be considered to facilitate placement.

TABLE 6.26 Suggested Water/Cementitious Material (W/C) Ratio

Specified Strength, psi (MPa)	Maximum W/C
6000 (41.4)	0.40
8000 (55.2)	0.36
9000 (62.1)	0.34
10,000 (69.0)	0.32
12,000 (82.8)	0.30
14,000 (96.6)	0.28

Note: For purposes of calculating the W/C of the mixture, the weight of all pozzolan should be added to the weight of the cement.

6.5.3 Mixture Components

6.5.3.1 Cement

In a study conducted by Blick et al. (1973), five cements of various types were ground and evaluated (Table 6.27). It was found that mortar cubes of Brand C, Type III, performed best at all ages (Figure 6.4). When it was used in concrete, the results were quite different (Figure 6.5). This phenomenon was further substantiated by tests conducted in the laboratory. In this study, mortar cubes were made with five different types of cement. When 20% of the cement, by mass, was replaced with fly ash, the results were quite different, as seen in Figure 6.6. The mortar containing the highest strength cement showed a loss of strength, while the mortar with the lowest strength cement showed the highest strength gain. Mortar cubes alone might not tell the whole story at the design level, but they are an important means of control after a selection has been made. Stress performance at ages up to 90 days should be evaluated. Limits of the physical properties of the cement should be established and submitted to the cement producer for compliance. The optimum cement quantity must be obtained through a series of laboratory trial mixtures. At least three cement quantities ranging from 136 to 409 kg/m³ (600 to 900 lb/yd³) should be tested. The tests should be conducted at a constant slump if a superplasticizer is not used or at a constant water/cementitious materials (W/C) ratio if a superplasticizer is used. The strength efficiency per pound of cement is influenced by all the variables that affect the strength of concrete. If the cement quantity of a mix is below optimum, higher strength may be obtained by using a larger size aggregate. If the cement quantity is above the optimum, higher strength may be achieved by using a smaller aggregate. After an optimum cement content for a given set of materials is selected, the maximum strength will not be increased by adding additional cement (Figure 6.7). Excessive cement content will also cause the concrete to become sticky and unworkable.

6.5.3.2 Fly Ash

The benefits derived from the use of fly ash vary with its class (ASTM C 618), chemical and physical properties, and quantity and compatibility with the cement. Cook (1982) and others have shown that higher strengths can be achieved using a Class C fly ash with a high calcium oxide content, as shown in Figure 6.8. Amounts of 10 to 15% of fly ash by mass of cement are common, but amounts of 25% and higher should be evaluated if Class C fly ash is being considered. The calcium hydroxide liberated during the hydration of the cement combines with the silica in the fly ash to form additional calcium silicate hydrate gel. This strength gain generally occurs after 14 days. Class F will have more of an effect on later strength, 28 to 90 days. The gains achieved with the use of fly ash cannot be attained through the use of additional cement. Additional benefit is derived mechanically from the fly ash as it acts as a filler that optimizes the particle distribution of the cementitious materials.

^a This cement does not meet Type II specifications for moderate heat of hydration. Maximum percent of C₃S + C₃A = 58%, and maximum percent of C₃A = 8% (according to ASTM C 150).

6.5.3.3 Microsilica

Microsilica, or silica fume as it is sometimes called, has been used to create high-strength concretes. Its chemistry is similar to both cement and fly ash (Table 6.28). Its super fineness of over 100,000 cm³/g, in combination with its pozzolanic reactivity, offers strengths in excess of 15,000 psi (103.4 MPa). Quantities of 5 to 15% of cement weight should be evaluated. A superplasticizer must be used in conjunction with microsilica because of the negative affect on the slump caused by the fineness of the silica. Microsilica has been used with and without fly ash. The benefit of the fly ash may be lessened when it is used with microsilica, but when attempting to produce an ultra-high-strength concrete, every benefit must be exploited (Figure 6.9).

FIGURE 6.4 Effect of various cements on mortar cube compressive strength.

FIGURE 6.5 Effect of various cements on concrete compressive strength.

6.5.3.4 Granulated Blast-Furnace Slag

Granulated blast-furnace slag (GBFS) is a byproduct of the steel production process. It is a glassy granular material primarily consisting of aluminates, silicates, and calcium-alumina-silicates. Grinding reduces the particle size to a cement fineness typically less than 3500 cm³/g. It reacts with liberated calcium hydroxide, the same as fly ash. Its benefits are most realized when used in conjunction with fly ash and microsilica; ternary mixes further optimize particle distribution of the cementitious materials.

6.5.3.5 Chemical Admixtures

The use of a normal-set water reducer, retarding water reducer, or a combination of these becomes necessary to efficiently utilize all cementitious materials and to maintain the lowest practical water/cement ratio. Dosages higher than those recommended by the admixture manufacturer have been found to increase strength without detrimental affects (Figure 6.10). The use of an ASTM Type D retarding water reducer was found to offer strength benefits beyond 56-day strengths. Varying dosages of this material

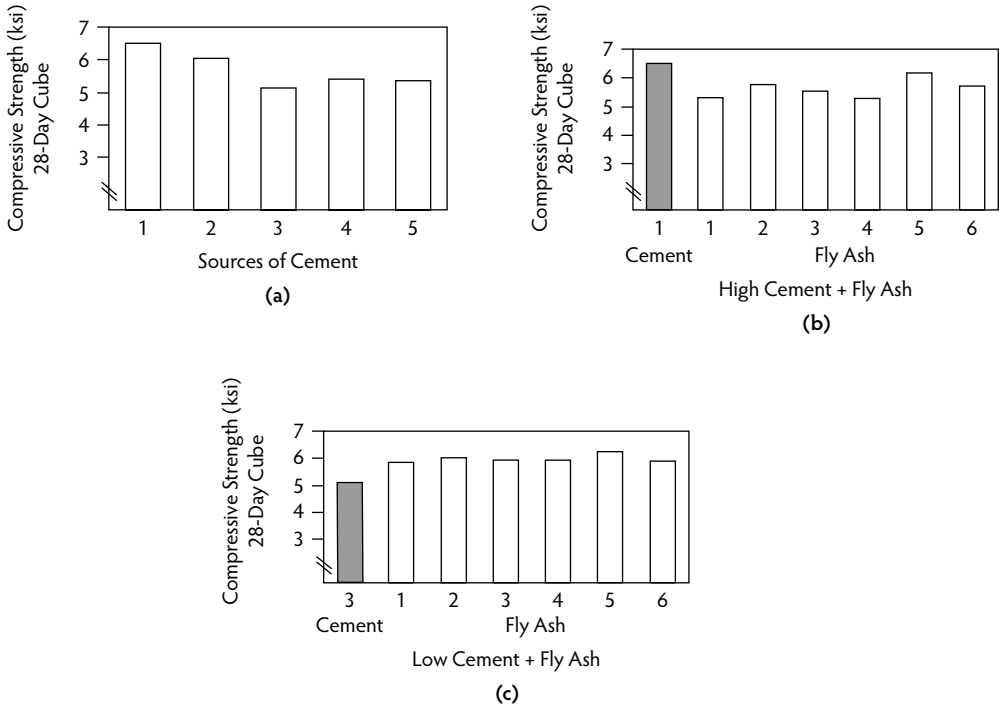

FIGURE 6.6 Effect of compressive strength on various cements and fly ash: (a) source of cement, (b) high cement content plus fly ash, and (c) low cement content plus fly ash.

FIGURE 6.7 Cement efficiency vs. compressive strength.

help offset the rapid setting time that might be expected from a mix containing a high amount of cement. During hot weather, this type of control is imperative. The heat of hydration of this type of concrete generates quickly and if left uncontrolled will cause high early strength, lower ultimate strength, and excessive cracking. Factors to be considered when evaluating an admixture are cement and fly-ash compatibility, water reduction, setting times, workability, time of addition, and dosages.

FIGURE 6.8 Effect of CaO on compressive strength (ASTM C 618, Class C fly ash).

TABLE 6.28 Chemical Analysis

Superplasticizers (high-range water reducers) offer the ability to achieve higher strengths than were previously attainable. Water reductions of up to 30% are possible while still maintaining a placeable consistency (Figure 6.11). This additional water reduction was instrumental in increasing our 9000-psi mix to 11,000 psi. Superplasticizers may be used in conjunction with an ASTM Type D retarder and can successfully be added at the ready-mix plant and again at the jobsite if necessary.

Recently, superplasticizers have been developed using polycarboxylate polymers in the development of self-consolidating concrete (SCC). SCC is characterized in terms of a measured slump flow of 18 to 26 in. (ASTM C 1611-05). SCC can be described as a very flowable cohesive concrete that does not segregate. These properties make the SCC capable of being placed with little or no vibration even in the presence of dense reinforcement. Mix designs may have to be modified to produce SCC, and care should be taken not to use polycarboxylate polymers in combination with naphthalate-based HRWRs. Air-entraining agents are not generally used because of the accompanying strength loss and because the type of application normally precludes their use (i.e., caissons, interior columns, and shear walls).

FIGURE 6.9 Benefit of fly ash when used with microsilica.

FIGURE 6.10 Effect of chemical admixtures on concrete compressive strength.

6.5.3.6 Aggregates

Careful consideration should be given to the shape, surface texture, and mineralogy of aggregates. Cubically shaped crushed stone with a rough surface texture appears to produce the highest strength. Smoother faced, uncrushed gravel may be used to produce strengths of up to about 10,000 psi, but it does not have the bond strength necessary to produce higher strengths. Tests we have conducted showed that gravels produce lower compressive strengths and moduli of elasticity when compared to the same size crushed stone with equal cement content (Figure 6.12). Each strength level will have an optimum size aggregate that will yield the greatest compressive strength. Because of the high volume of cementitious materials in high-strength concrete, the optimum aggregate surface area is necessary to provide maximum bonding. In addition to optimizing the gradation of the coarse aggregate, further benefit can

FIGURE 6.11 Compressive strength of high-strength concrete containing a high-range water reducer.

FIGURE 6.12 Compressive strength and modulus of elasticity vs. age for various sizes and types of coarse aggregate.

TABLE 6.29 Volume of Dry-Rodded Coarse Aggregate per Unit Volume of Concrete for 2.80 Fineness Modulus of Sand

Maximum Size of Aggregate (in.)	Modified for High Strength	From ACI 211.1-82
3/8	0.61	0.46
1/2	0.64	0.55
3/4	0.66	0.62
1	0.70	0.67

be derived from altering the proportions of coarse to fine aggregate. It was found that the proportions recommended by ACI 211.1-82 do not apply, as seen from the comparative values in Table 6.29. Well-graded fine aggregates that provide good finishing characteristics in regular-strength concrete are not only unnecessary but may also require more water than can be tolerated (Table 6.30). Fine aggregates, with a fineness modulus of 2.5 and under will produce concrete with a sticky consistency, less workability, and lower compressive strength. A fineness modulus of 2.75 to 3.20 appears to produce the highest strengths. As with coarse aggregates, cubically shaped particles in fine aggregate have been found to increase bonding (NCSA, 1975, 1976). Very angular manufactured sands should not be used because they increase water demand.

Slag	1/week	Hold for 120 days
Admixtures	Each delivery	Specific gravity
Water	As needed	—
Aggregates	1/week	Gradation 200 wash specific gravity

6.5.3.7 Water

Various sources of water have been evaluated, and it appears that the limitations listed in ASTM C 94 are adequate. Water need not be potable. ASTM C 94 states, "If it contains quantities of substances which discolor it or make it smell or taste unusual or objectionable or cause suspicion, it shall not be used unless service records of concrete made with it or other information indicates that it is not injurious to the quality of the concrete."

6.5.4 Materials Control

After the materials are chosen, the consistency of the materials becomes imperative. If variations become excessive, the required average strength may become unattainable. As an example, if the specified strength was 9000 psi and the standard deviation was 697 psi (7% coefficient of variation), the overdesign required would be 8.4 MPa (1200 psi). On the other hand, if the standard deviation is 1414 psi (13% coefficient of variation), the overdesign would have to be nearly 21 MPa (3000 psi) (Table 6.31). A materials-sampling program should be established so the appropriate test may be run in the event of low breaks (Table 6.32). All suppliers of constituent materials should be made aware of the importance of providing consistent

materials. As the job progresses, they should also be involved in the periodic testing of the material they supply. The handling and storage of materials need not be substantially different from the procedures used for conventional concrete. Proper stockpiling of aggregates, control of moisture, and adequate segregation of cementitious materials are essential. Table 6.33 gives selected data on some HSC mixes used; however, the information tabulated is intended to serve as only an example and should not replace locally generated data.

6.5.5 Mixing, Transporting, Placing, and Curing

6.5.5.1 Mixing

High-strength concrete may be produced in manual, semiautomatic, or automatic plants. It should be noted, however, that total automation almost always improves consistency. Normal batching procedures need not be altered, but a modification in timing may help. Admixtures have been found to be most effective if they are introduced after the cement has been wetted. Caution should be exercised if the concrete is to be truck mixed. Truck mixers that are not maintained or that have worn fins and blades will not thoroughly mix the concrete and will cause unacceptable variations in all the physical characteristics of the concrete. Once in the stationary or truck mixer, the materials should be mixed as follows: 1 minute for 1 yd³ plus 0.25 minute for each additional cubic yard; for example, 3.75 m³ (5 yd³) = 2 minutes. The speed at which the concrete is mixed should be in accordance with the mixer manufacturer's recommendations. Care should be taken so the temperature of the concrete as delivered does not exceed 42°C (90°F). As with all concrete, higher temperatures mean more water. If the water demand becomes excessive or slump loss becomes rapid, increased dosages of chemical retarders or superplasticizers should be considered. If problems persist, ice or chilled aggregates may be required to lower the temperature. Maintaining a minimum temperature is normally not a problem, in that the concrete is typically used in more massive structural members where lower temperatures are beneficial. Additionally, lower concrete temperature means less total water, higher later strengths, and less cracking.

6.5.5.2 Transporting

High-strength concrete can be successfully mixed and transported in a number of ways. Quality assurance/quality control (QA/QC) personnel must be aware that prolonged mixing will cause slump loss and result in lower workability. Adequate job control must be established to prevent delays. When practical, withholding some of the high-range water-reducing admixture until the truck arrives at the jobsite or on-site addition of high-range water-reducing admixtures may be desirable. When materials are added at the site, proper mixing is required. Because of the consequences of segregation, QA/QC personnel should pay close attention to on-site mixing and verify that the mixture is uniform. The ACI 304.R Committee Report contains information on proper mixing. Truck mixers should be equipped with drum revolution counters, and their fins should be in good condition. All mixer trucks used to transport high-strength concrete should be regularly inspected and certified to comply with the National Ready Mixed Concrete Association (NRMCA) inspection requirements prior to and during their use in this capacity.

6.5.5.3 Placing

High-strength concrete is typically produced with slumps in excess of 200 mm (8 in.). Despite their fluid appearance, these mixes require thorough consolidation. All concrete should be consolidated quickly and thoroughly. Standby vibratory equipment is recommended, with at least one standby vibrator for every three vibrators required. The provisions in the ACI 309 Committee Report (1987) should be followed for proper consolidation. In construction, different strength concretes are often used within or between different members. QA/QC personnel should be aware of the exact location for each approved mixture. Often, *mushrooming* is performed over column and shear-wall locations when placing floor slabs; that is, high-strength concrete is mushroomed around those locations to form a cap prior to placing lower-strength concrete around it in the floor. QA/QC personnel should be aware of how far the cap should extend. Because cold joints between the two concretes are not allowed, the inspector should determine that the high-strength mushroom is still plastic enough to blend with the lower-strength slab concrete. When two (or more) concrete mixes are being used in the same pour, it is mandatory that sufficient control be exercised at the point of discharge from each truck to ensure that the intended concrete is placed as specified. Planning is necessary to determine the best procedures. Consideration might be given to the use of retarding admixtures.

6.5.5.4 Curing

The full potential strength and durability of high-strength concrete will be fully developed only if it is properly cured for an adequate period prior to being placed in service or subjected to construction loading. Many acceptable methods for curing are available, as presented in the ACI 308 Committee Report (1992). High-strength concretes are extremely dense and impermeable; therefore, appropriate curing methods for various structural elements should be selected in advance. For interior columns, curing is often impractical, and durability is not a problem. The period during which the forms are in place may be adequate in such instances. QA/QC personnel should verify that the accepted methods are properly employed in the work.

High-strength concretes usually do not exhibit much bleeding, and, without protection from loss of surface moisture, plastic shrinkage cracks may form on exposed surfaces. Protection methods include fog misting, use of evaporation retarders, covering concrete with polyethylene sheeting, or application of a curing compound. Water curing of high-strength concrete is recommended because of the low water/cementitious material ratios employed. Water curing of vertical members is usually impractical, and other curing methods should be employed. When forms are released or removed at very early ages, typically less than 1 day, prevention of thermal cracking by providing insulation should be considered, particularly in cold weather. Each high-strength mixture has heat evolution and dissipation characteristics in the context of its curing environment. Maximum temperature and thermal gradients and their effects on constructability and long-term design properties should be determined by preconstruction trials. Consideration might be given to computer simulation of the expected thermal history in a structure so appropriate curing and protection can be performed.

The higher cement contents of high-strength concrete generate a higher heat of hydration and, possibly, thermal gradients in excess of 20°C/m (11°F/ft), especially in uninsulated mass placements; however, studies have shown that thermal gradients are similar to those for conventional-strength concretes. Data have shown that for deep foundations, when the ultimate internal temperature developed during hydration rose to 78°C (172°F), the *in situ* strength and stiffness were not adversely affected. The architect or engineer should understand the effects of heat generation in the various structural elements and address them in-project specifications. Specifications for mass concrete often require that the temperature difference between the concrete interior and surface not exceed 20°C (36°F). The inspector should monitor and record ambient temperatures and curing temperatures at the surface and center of large concrete components so the design/construction team can effectively make any adjustments such as mixture design changes or use of insulating forms during the course of the project. Concrete delivered at temperatures exceeding specification limits should be rejected, unless alternative procedures are agreed to at the preconstruction meeting.

6.6 Jobsite Control

Coordination of delivery time between the concrete supplier and contractor is critical. Concrete should be delivered so minimal waiting is experienced. Delays on the job may result in slump loss and, subsequently, the concrete may require retempering. Water added at the jobsite can be extremely detrimental to the structural integrity of the concrete and should not be permitted. Any adjustments made in the slump should be made with a high-range water reducer. As always, the amount of water in the admixture must also be considered in the water/cementitious material ratio. The time allowed from loading to discharge should be limited to 90 minutes. If the concrete is older but still has a placeable consistency, it may be used. Again the concern is that retempering may be required as the concrete ages. If a high-range water reducer is being used, slumps should not be used as a basis of acceptance or rejection. The concrete should be used, regardless of the slump, as long as it is placeable or not segregated. The specified water/cement ratio should be the governing factor. The method of placement (pump, bucket, or conveyor), quantity, and spacing of reinforcement will also dictate what slump is necessary.

6.7 Testing

6.7.1 General

Measurement of mechanical properties during construction provides the basic information required to evaluate whether design considerations are met and the concrete is acceptable. Because high-strength concrete is more sensitive to testing variables than normal-strength concrete, the quality of these measurements is very important. Factors having little or no effect on 21-MPa (3000 psi) concrete can have significant effects on high-strength concrete, especially on compressive strength. Standard, established procedures such as the latest editions of ASTM C 31, ASTM C 39, and ASTM C 94 must be followed. Deviation from these procedures cannot be tolerated. Such deviations not only result in nonrepresentative tests but also introduce variations that cannot be compensated for.

6.7.2 Sampling

Statistical methods are an excellent means to evaluate high-strength concrete. For statistical procedures to be valid, the data (slump, unit weight, temperature, air content, and strength) should be derived from samples obtained by means of a random sampling plan designed to reduce the possibility that choice will be exercised by the testing technician. Random sampling means that any portion of the material being presented has an equal chance of being selected. The samples should represent the quality of concrete supplied; therefore, composite samples are taken in accordance with ASTM C 172. They should be combined and remixed to ensure uniformity prior to testing the freshly mixed concrete or casting test

specimens. These samples are representative of the quality of concrete delivered to the jobsite and may not truly represent the quality of the concrete in the structure, which may be affected by site transportation and placing methods. If additional test samples are required to check the quality of the concrete at the point of placement, as in pumped concrete, this should be established at the preconstruction meeting.

6.7.3 Extent of Testing

Tests for air content, unit weight, slump, and temperature should be made on the first truckload each day to establish that batching is adequate; thereafter, these tests should be performed on a random basis in accordance with project specifications. When visual inspection reveals inconsistent concrete, it should be rejected unless additional tests show it to be acceptable. Such test results should not be counted in the statistical evaluation of the mixture unless they are made on samples that are taken at random. The architect or engineer will generally take advantage of the fact that high-strength concrete containing fly ash or ground granulated blast-furnace slag develops considerable strength at later ages (that is, at 56 and 90 days). It is not uncommon, therefore, that more test specimens than normally required are specified. The technician should be prepared to take a large enough sample to properly accommodate the volume required to cast all test specimens. Under no circumstances should the technician use other samples to top-off test specimens. If the sample is too small, another sample should be taken; however, only a reasonable number of specimens can be made in a high-quality manner and within the correct time frame from collection of each sample. Where later ages are specified to enable the use of more economical mixes, it may be desirable to make an early assessment of potential strength by testing early-age specimens or specimens with accelerated curing.

6.7.4 Compressive Strength Specimens

Because one of the main interests in high-strength structural concrete is its strength in compression, compressive-strength measurements are of primary concern. The primary function of standard laboratory-cured specimens is to provide assurance that the concrete mix as delivered to the jobsite has the potential to meet contract-specification requirements. The potential strength and variability of the concrete can be established only by specimens made, cured, and tested under standard conditions. Cylindrical specimens used can be 150 mm (6-in.) by 300-mm long or 100 mm (4-in.) by 200 mm long. The use of the smaller cylinder is recommended, provided the test result is determined in accordance with ASTM C 39. Regardless of specimen size, the size used to determine mix proportions should be consistent with the size specified for acceptance testing and approved by the engineer of record.

6.7.4.1 Mold Type

The choice of mold material can have a significant effect on measured compressive strength. A given consolidation effort is more effective with rigidly constructed molds. Rigid single-use plastic molds with 6-mm (1/4-in.) wall thickness or greater have been used successfully for 112-MPa (16,000-psi) concrete. The mold type used for field specimens should be the same as the mold type used to develop the design mix. Molds should comply with ASTM C 470.

6.7.4.2 Testing Apparatus

The higher compressive loads carried by high-strength concrete put more demands on compression machines. Machine characteristics that may affect the measured strength include calibration accuracy, longitudinal and lateral stiffness, alignment of the machine components, type of platens, and the behavior of the platen spherical seating. Testing machines should meet the requirements of ASTM C 39. On the basis of practical experience, it is recommended that the machine have a load capacity at least 20% in excess of the expected cylinder breaking load, as premature damage and loss of calibration have been known to occur as a result of large numbers of explosive failures at high loads.

6.7.5 Prequalification of Testing Laboratories and Ready-Mix Suppliers

To prequalify a laboratory as well as a ready-mix supplier, both should be examined from two perspectives: how they have performed in the past and how well they are equipped to perform properly in the future. A review of past test data for high-strength concrete analyzed in accordance with ACI 214 will show that in-test variability is a measure of the testing consistency of the laboratory. The qualifications and experience of technicians and inspectors should be reviewed. The laboratory should be accredited or inspected for conformance to the requirement of ASTM C 1077 by a recognized agency such as the American Association for Laboratory Accreditation (AALA), AASHTO Materials Reference Laboratory (AMRL), National Voluntary Laboratory Accreditation Program (NV-LAP), Cement and Concrete Reference Laboratory (CCRL), or their equivalent. The architect or engineer should approve the testing laboratory. A comprehensive internal quality control protocol that covers test procedures; the use, care, and calibration of testing equipment; and the checking and reporting procedures to be followed provides evidence of a well-run laboratory. Depending on the results of the review of past and potential performance of the laboratory, some tests of personnel and equipment may or may not be made to conclude the prequalification examinations.

FIGURE 7.1 Formwork serves as a mold to define concrete structure shape.

FIGURE 7.2 Formwork elements must support many heavy loads.

7.1 Introduction

Forms are extremely important in concrete construction. They mold the concrete to the required size and shape while controlling its position and alignment (Figure 7.1). Forms are self-supporting structures that are also sufficient to hold the dead load of the reinforcement and fresh concrete and the live load of equipment, workers, and miscellaneous materials (Figure 7.2). In building and designing formwork, three major objectives must be considered:

1. *Quality*—Forms must be designed and built with sufficient stiffness and accuracy so the size, shape, position, and finish of the cast concrete are attained within the required tolerances.
2. *Safety*—Forms must be built with sufficient strength and factors of safety so they are capable of supporting all dead and live loads without collapse or danger to workers and to the concrete structure.
3. *Economy*—Forms must be built efficiently, minimizing time and cost in the construction process and schedule for the benefit of both the contractor and the owner.

FIGURE 7.3 Large and complex placements require substantial formwork.

Economy is important because the costs of formwork often range from 35 to 60% or more of the total cost of the concrete structure. Considering the impact of formwork on total cost, it is critical that the structural engineer of the facility also design the facility structure for economy of forming, not just for economy of the materials in the finished structure.

Ideally, the builder will achieve maximum economy with no cost to either safety or specified quality. In designing formwork, the construction engineer can reduce costs by carefully considering the materials and equipment to be used; the fabrication, erection, and stripping procedures; and the reuse of forms. However, economy measures that result in either formwork failure or poor-quality products that require (often expensive) modification are self-defeating.

Correctly designed formwork will ensure that the concrete maintains the desired size and shape by having the proper dimensions and being rigid enough to hold its shape under the stresses of the concrete. It must be stable and strong to keep large sections of concrete in alignment (Figure 7.3). Finally, formwork must be substantially constructed so it can be reused and frequently handled while maintaining its shape. Formwork must remain in place until the concrete is strong enough to carry its own weight. In addition, the surface finish of the concrete is dependent on the contact material of the form.

The quality of the formwork itself has a direct impact on safety, accidents, and failures. A floor formwork system filled with wet concrete has its weight at the top and is not inherently stable. As a result, one of the most frequent causes of failure is from effects that induce lateral forces or displacement of supporting elements; therefore, inadequate cross-bracing or horizontal bracing is one of the most frequently involved factors in formwork failure. Poor bracing can make a minor failure turn into a major disaster, in what might be thought of as a domino effect or a **progressive failure**: A failure at one point in the formwork that can become an extensive collapse through chain reaction. Vibration is one factor that can trigger failure through inadequate bracing. Two other formwork problems are unstable soil under mudsills and shoring that is not plumb. Formwork is stable if adequately braced and built so all loads are carried to solid ground through vertical and bracing members.

FIGURE 7.4 Planning is required to achieve maximum overall construction efficiency.

Regardless of the quality of the formwork, premature removal of the forms or shores, often out of a wish for economy, can result in collapse or sagging. Sagging, while not an immediate problem, can lead to hairline cracks and extensive maintenance problems. Careless reshoring, often involving inadequate size, spacing, or attachment, can also cause damage or collapse. Specific related standards (e.g., OSHA, ACI, ASCE) for formwork are discussed in Section 7.3.

In addition to optimizing material in the form design process, there are three major factors to be considered when planning forms that are cost effective:

- Designing and planning for maximum reuse
- Economical form assembly
- Efficient setting and stripping

Each factor must be balanced with the other two to determine the most efficient form design.

In planning for maximum reuse, the specifications, rate of concrete strength gain, and local code requirements regarding stripping must be taken into account. The sooner a form can be stripped safely, the more practical it is to reschedule many reuses. In addition, for a minimum of cost, the least number of forms required for a smooth work schedule should be built. For example, the formwork on the outside of a spandrel beam can be stripped sooner than the formwork on the bottom; hence, fewer side forms than bottom forms must be built because they can be reused more frequently. It is also important to consider the labor involved in reuse; for example, does the form need to be disassembled and rebuilt? To create a plan for reuse, the construction engineer needs to make a detailed study of the work flow and construction sequence to determine the practical number of reuses that will result in smooth and efficient construction with the lowest total cost (Figure 7.4). When comparing designs, the construction engineer should calculate the ratio of total contact area of the formed concrete structure to the first-use form contact area for various alternatives, which is a general indication of overall reuse efficiency.

Several considerations are involved in determining an economical form construction, such as:

- Cost and feasibility of adapting materials on hand vs. cost of buying or renting new materials
- Cost of a higher grade of material vs. cost of lower grade of material plus labor to improve for required quality and use
- Selection of more expensive materials that provide greater durability and capability for reuse vs. less expensive materials that have a shorter use-life
- Building on-site vs. building in a central shop and shipping to site (this depends on the site itself and space available, the size of project, the distance of shipping, etc.)

An estimate of the cost of constructing a particular job-built form can be obtained by determining the quantity of wood materials required to make 1 square foot of contact area, while allowing for waste and rejection of some wood, and multiplying by the unit prices of lumber involved. This provides the contractor with an estimate of lumber costs for 1 square foot of contact area. In addition to lumber, the costs for labor, hardware, miscellaneous materials, handling, and clean-up must also be evaluated. The construction engineer should also consider the possibility of using prefabricated forms, either rented or purchased. The advantages of using rented prefabricated forms are reduced risk, no investment cost, and transfer of some management responsibility to the formwork supplier or subcontractor.

The last major factor, efficient setting and stripping practices, has a direct impact on the two already discussed. Reuse of a form is only fully efficient if the form can be stripped and rebuilt without too much labor time or damage to the form. The estimate for constructing a form must take into account the worker hours required to erect and dismantle the form during each reuse. When calculating time and cost for setting and stripping forms, the contractor should allow for delays from weather, equipment problems, etc., as well as cleaning and other miscellaneous expenses.

In addition to the above elements of cost, planning of formwork operations should consider the overall flow of operations, including the following:

- *Crew efficiency*—Providing a reasonable schedule creates a smooth daily repetition of the same operation so the workers can be familiar with their tasks and thus perform efficiently.
- *Concreting*—The ease and speed of pouring the concrete are directly related to the choice of design and the construction schedule.
- *Bar setting and other trades (mechanical, electrical, piping)*—Schedules of these activities must be coordinated with the concreting schedule so that all groups can work efficiently.
- *Cranes and hoists*—Plan to use appropriate cranes at times when they are not needed for other functions and reduce idle time.

7.2 Types of Formwork

Formwork components can be assembled in a wide variety of systems for casting many structural shapes. The terms **formwork** and **falsework** are often used in combination. Formwork is the total system of support for freshly placed concrete and includes the sheathing that is in contact with the concrete as well as all supporting members, hardware, and necessary bracing. Falsework is a temporary structure erected to support work in the process of construction. Falsework may be the temporary support for steel bridge girders, for precast concrete elements to be post-tensioned together, or for many other applications. When this term is used in relation to formwork, the forms are often considered to be the horizontal system of elements directly under heavier concrete placements, such as cast-in-place bridges (Figure 7.2), and the falsework includes the temporary girders, shores or vertical posts, and lateral bracing. Forms can either be job built or prefabricated. Job-built forms, frequently of wood (Figure 7.5), are most frequently selected where the shape does not conform to the constraints of commercial systems or where the economics are viable. Prefabricated forms can be purchased, rented, or rented with an option to buy. They are usually constructed substantially for the purpose of frequent reuse. These forms can either be ready made or custom made (Figure 7.6). The latter is designed for specialized use, usually on a single job, but is often reused multiple times on that project.

FIGURE 7.5 Wood column form.

FIGURE 7.6 Custom-made steel form with integrated access platforms.

7.2.1 Contact Surface Materials

The material serving as the contact face of forms is known as **sheathing** and sometimes is referred to as *lagging* or *sheeting* in specialty applications. Plywood is frequently used for sheathing, but some forms use steel sheet metal, steel plate, fiber-reinforced plastic, paperboard, wood boards, or other materials.

FIGURE 7.7 Plastic form liner used to create rough ribbed pattern.

FIGURE 7.8 Stay-in-place corrugated galvanized metal deck for bridge-slab form.

A primary characteristic in selection of the sheathing type and grade is the quality of surface required by the specification. For some applications, steel or high-density overlay plywood may be needed. In other cases where a decorative surface is required, the sheathing may be specially treated (wire brushing to expose wood grain, addition of rustication strips, etc.) or fitted with a commercial plastic liner imprinted or shaped to provide a specified design (Figure 7.7). **Permanent forms** are any form that remains in place after the concrete has developed its design strength. The form may or may not become an integral part of the structure. Metal deck forms, the most prevalent permanent form, are made of a ribbed or corrugated steel sheet, usually galvanized to reduce the potential for future rust staining, and are secured to the structure with clips or by welding. The diaphragm created by the attached deck may also contribute to the lateral stability of the supporting members during concrete placement. Metal deck forms are used in floor and roof slabs cast over steel joists or beams, in bridge decks (Figure 7.8), and over pipe trenches and other inaccessible locations where removing wood forms is impractical. Precast concrete deck forms are often used in combination with prestressed concrete bridge girders. Sometimes

FIGURE 7.9 Typical elevated flat-slab formwork elements. (From Hurd, M.K., *Formwork for Concrete*, 7th ed., SP-4, American Concrete Institute, Farmington Hills, MI, 2005.)

the deck forms must be temporarily shored at intermediate points to support the loads applied during construction; however, deck forms of adequate section profile can often be selected to span between the permanent structural members and safely support the weights of reinforcement, fresh concrete, and construction live loads. In the latter case, the added cost of the stronger section is often offset by savings in shoring materials and labor.

7.2.2 Floor-Forming Systems

Floor-forming systems vary somewhat with the configuration of the concrete floor system being cast. Figure 7.9 illustrates the basic wood member arrangements for flat-plate floors, most areas of flat slabs, and the slab areas of slab and beam floors. The terms used to describe the members are the same in systems assembled from steel or aluminum members. The **joist** is a horizontal structural member supporting the deck-form sheathing and usually rests on stringers or ledgers. **Stringers** are horizontal structural members usually (in slab-forming) supporting joists and resting on vertical supports such as shores.

FIGURE 7.10 Fiber-reinforced plastic pan and dome molds for floor formwork.

In one-way (pan joist) and two-way (waffle) joist construction, a similar layout is usually adopted. **Pans and domes** (Figure 7.10) are used in concrete joist construction, which is a cast-in-place floor system with a thin slab integral with regularly spaced joists that span to beams and columns. In some cases, the pans or domes are placed on the plywood sheathing; in other cases, the pan or dome edges are supported on wide joists, and the sheathing is omitted. Pans are prefabricated form units, usually steel or fiberglass, used to form single-direction joists. Domes, also usually made of steel or fiberglass, are square pan forms used in two-way, or waffle, concrete joist construction.

Steel and aluminum joists and stringers are usually flanged shapes. Some aluminum extrusions have special configurations allowing easy connection and incorporating a top channel for a wood nailer. Commercial steel sections fabricated specifically for formwork systems also incorporate connection features. **Horizontal shoring** is formed by adjustable beams, trusses, or combinations of the two that support formwork over clear spans and eliminate numerous vertical supports. Metal or timber support beams are used for small spans. Telescoping shores, steel lattice, plate, or box members are used to support forms in spans of 6 to 30 feet. Heavy-duty horizontal shores (for example, trusses supporting flying-form panels) can span up to 80 feet. The disadvantage of using horizontal shoring is the potential need for special bearing plates to support the high end load on each individual shore.

Flying forms, or table forms, are large crane-handled sections of floor formwork (frequently including supporting truss, beam, or scaffolding frames) that are completely unitized. Such forms can be lowered for clearance under joists or beams, rolled out the face of the building bay, picked by a crane, and reset at the next floor level. By having a large movable unit, the costs of stripping and reassembly are reduced, particularly when a crane is available on site.

7.2.3 Column Forms

Column-form materials tend to vary with the column shape. Wood or steel is often used with square or rectangular columns (Figure 7.11). Round column forms (Figure 7.12), more typically premanufactured in a range of standard diameters, are available in steel, paperboard, and fiber-reinforced plastic. Square and rectangular forms are composed of short-span bending elements contained by external ties or clamps. Round column forms are more structurally efficient because the internal concrete pressures can be resisted by a hoop membrane tension in the form skin with little or no bending induced. Round, single-piece glass-fiber-reinforced plastic tubes with a single joint can be removed from the column without cutting. They are held together with either bolts or clamps. Round paperboard tubes are single-use forms that are stripped by unwrapping and then discarded. They can be cut to the exact length needed, and sections of the tube can be adapted to making partial column sections (e.g., half-round, quarter-round). Steel column forms have built-in bracing for short heights so the only external bracing required serves to keep the column plumb and for taller columns. Both half-round and rectangular panel units are available in various section heights that can be connected vertically to form tall columns. Round steel forms are generally used for larger columns and bridge piers and come in diameters ranging from about 14 inches to 10 feet.

FIGURE 7.11 Modular steel form for rectangular columns.

FIGURE 7.12 Steel round-column form with access scaffolding in preparation.

7.2.4 Wall Forms

Wall forms principally resist the lateral pressures generated by fresh concrete as a liquid or semi-liquid material. The pressures can be quite large, certainly many times the magnitude of live loads on permanent floors. Thus, wall form design often involves closely spaced and well-supported members, as shown in Figure 7.13. As mentioned, the contact surface of the wall form is referred to as *sheathing*. **Studs** are

FIGURE 7.13 Typical wall form components with alternate sheathing materials illustrated. (From Hurd, M.K., *Formwork for Concrete*, 7th ed., SP-4, American Concrete Institute, Farmington Hills, MI, 2005.)

vertical supporting members to which sheathing is attached. **Wales** are long horizontal members (usually double) used to support the studs. The studs and wales are often wood, steel, or aluminum beam-like elements. Commercial form suppliers are innovative in devising elements as well as hardware for connections. The wall form members are sometimes oriented with the stud members placed horizontal rather than vertical, and the wales are run vertical.

The wales are in turn supported on washer plates or other bearing devices attached to form ties. A concrete **form tie** is a tensile unit connecting opposite sides of the form and providing a link for equilibrium. Form ties are usually steel, although some fiber-reinforced plastic ties are also available. The ties come in a wide range of types (Figure 7.14) and tension working capacities rated by the manufacturer. Snap ties, loop ties, and flat ties are single-use ties, usually of relatively low capacity (1500 to 3200 lb) that are twisted and snapped off a specified distance back from the concrete surface. Coil ties, she bolts, and he bolts are examples of ties where some parts are left embedded within the cast wall and some parts can be reused. The taper tie, a tapered rod threaded on each end, is completely removed and reused. The tension capacity of heavy ties can range upward to over 60,000 lb. Some of the ties have built-in provisions for spacing the forms a definite distance apart; this is particularly true of single-use ties if this feature is ordered. An alternative means of maintaining the correct inside distance is by means of a **spreader**, a strut (usually of wood) inserted inside the forms that can be retrieved with an attached rope or wire when the concrete placement reaches that level.

Strong-backs, frames attached to the back of a form or additional vertical wales placed outside horizontal wales, are sometimes added for strength, to improve alignment, or to assemble a ganged form. **Gang forms** (Figure 7.15) are prefabricated panels joined to make a much larger unit for convenience in erection, stripping, and reuse; they are usually braced with wales, strong-backs, or special lifting hardware. Such units require the use of a crane for stripping and resetting.

Panel forms, sections of form sheathing constructed from boards, plywood, metal, etc. that can be erected and stripped as units, are primarily used in wall construction. They may be adapted for use as slab or column forms. The four basic types of panel forms are unframed plywood, plywood in a metal frame (Figure 7.16), all-metal, and heavier steel frame. The first two are most frequently used for general light

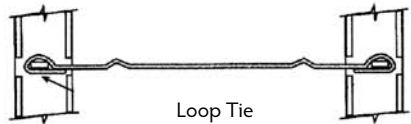

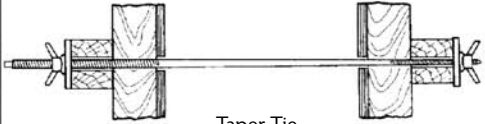

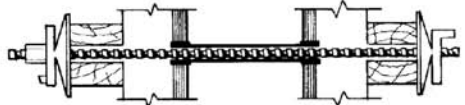

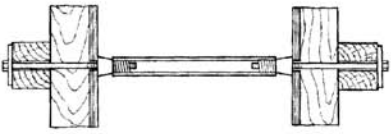

One-Piece Ties		Used to secure and space modular panel forms Available in several configurations Notched for breakback Safe Loads 1500, 2250, and 3000 lb
		Secures and spaces prefabricated modular forms Notched for a 1-in. breakback Crimp is anti-turn feature Safe Loads: 2250 and 3000 lb
		Used for job-built forms, lighter construction May have cone spreader and waterseal washer Notched for 1-in. breakback Safe Loads: 2250 and 3350 lb
		Long lengths supplied for cutting as desired on the job Custom colors available Cut off flush with surface of hardened concrete Safe Loads: 3000, 7500, and 25,000 lb
		Used where specs require or permit complete removal of tie from concrete Tie is reusable Safe Loads: 7500 to 50,000 lb
		Standard 20-ft lengths cut to meet project requirements Double nuts may be needed for higher load capacities Bar is reusable Safe Loads: 10,000 to 32,500 lb
Internally Disconnecting Ties		Heavy duty, with reusable end bolts No internal spreader, but external spreader bracket available Safe Loads: 4900 to 64,000 lb Up to 155,000 in High-Strength Steel
		Designed for medium to heavy construction With or without cone spreaders Bolts reusable Safe Loads: Two-strut, 3000 to 13,500 lb; Four-strut, 9000 to 27,000 lb

FIGURE 7.14 Examples of form ties. (From Hurd, M.K., *Formwork for Concrete*, 7th ed., SP-4, American Concrete Institute, Farmington Hills, MI, 2005.)

construction and erecting walls with heights ranging from 2 to 24 feet. Both are sometimes backed by steel braces. All-metal panel forms can be made of either steel or aluminum. The heavier steel frame panel forms are faced with either wood or plywood and are used for projects involving large pressures or loads.

Slip forms are forms that move, usually continuously, during placing of the concrete. Movement may be either horizontal or vertical. Slip-forming is like an extrusion process, with the forms acting as moving dies to shape the concrete. In wall forming, the slip form is usually moved vertically at a rate of 6 to 12 inches per hour. This method can be economical when constructing concrete cores of tall buildings, tall concrete stacks, and concrete towers.

FIGURE 7.15 Ganged forms allow movement by crane and reduce re-erection costs.

FIGURE 7.16 Steel-framed plywood panel system with integrated loop-tie anchors.

Climbing forms, or jump forms, are forms that are raised vertically for succeeding lifts of concrete in a given structure, usually supported by anchors embedded in the previous lift. The form is moved only after an entire lift is placed and (partially) hardened; this should not be confused with a slip form that moves during placement of the concrete. Support of the climbing form is usually provided by anchors cast in the previous placements. It is critical that the concrete strength gain at the anchors be sufficient at each stage of the operation to resist the imposed loads.

Although the use of proper support chairs for reinforcement is routinely required in horizontal construction, similar elements are sometimes neglected in wall and column forms. **Side form spacers** are devices similar to chairs that can be used to advantage in wall and column forms to attain correct cover for the reinforcement.

7.2.5 Shoring

Shores are vertical or inclined column-like compression supports for forms. Shoring systems may be made of wood or metal posts, scaffold-type frames, or various patented members. **Scaffolding** is an elevated platform to support workmen, tools, and materials. In concrete work, heavy-duty scaffolding is often adapted to double as shoring. The simplest type of vertical shore is a 4×4 or 6×6 piece of lumber with special hardware attached to the top to facilitate joining to the stringers with a minimum of nailing. Metal shore-jack fittings may be placed at the lower end of the shore to allow some adjustment for exact height. Various manufacturers sell all-metal adjustable shores, also known as **jack shores** or simply as *jacks*, in a number of designs. They are usually available in adjustable heights from 6 to 16 ft and can carry working loads ranging from 2500 to 9000 lb with a safety factor of 2.5, depending on the type and the length of the shore. A third type of vertical support is a device that attaches to a column or bearing wall of the structure. Components of this kind of shore include friction collars and shore brackets that are attached to the support with through bolts or heavy embedded anchors. These attached supports are particularly useful in supporting slab-forming systems.

Basic scaffold-type shoring is made from tubular steel frames. End frames are assembled with diagonal bracing, locking connections, and adjustable bases to create a shoring tower. These may have flat top plates, U-heads, or other upper members for attaching to supported forms. Most scaffold-type shoring has a safe working load between 4000 and 25,000 lb per leg, depending on the height, bracing, and construction of the tower (Figure 7.17). Ultra-high-load shoring frames can support up to 100,000 lb of load per leg. Scaffold-type shoring can also be made of tubular aluminum, which has the advantage of being more lightweight than a similar steel frame.

In multistory concrete building construction (Figure 7.4), a process called **shoring and reshoring** is used (ACI Committee 347, 2005). The weight of the fresh concrete, reinforcing, forms, and construction live load for an individual floor usually exceeds the design live-load capacity of the floor below. Furthermore, that floor has not gained full 28-day strength, as floors are often cast at intervals of 4 to 14 days. By interconnecting several floors with shores and reshores, the loads at the top can be distributed over several floors. When this construction process is engineered and controlled properly, the time-varying loads on all elements (floors, forms, shores, and reshores) are safely within their time-varying strengths. One or more sets of floor forms with shores may be used. After the forms and shores are stripped completely from the lowest form-supported floor, that floor and the cast floors above deflect and must share the equivalent of the support that has been removed. Reshores are then placed under the stripped floor. **Reshores** are shores placed snugly under a concrete floor so future loads imposed from construction at the highest level can be shared over sufficient floors to carry the dead and live loads safely.

In some multistory construction, this process is varied slightly. **Backshores** are shores placed snugly under a concrete slab or structural member after the original forms and shores have been removed from a small area without allowing the slab or member to deflect or support its own weight or existing construction loads from above. **Preshores** are added shores placed snugly under selected panels of a deck-forming system before any primary (original) shores are removed. Preshores and the panels they support remain in place until the remainder of the bay has been stripped and backshored, a small area at a time.

Shoring systems produced by some manufacturers include a **drophead** mechanism (Figure 7.18). The systems include panels, beams, and a shore with a top plate that is in direct contact with the concrete slab underside. When the drophead mechanism is released, the beams and panels can be lowered and removed while the shore stays in place. This allows rapid reuse of the panels and beams while the shore continues to support the early-age, low-strength slab. Overall, this approach allows rapid reuse of components, increasing speed of construction and reducing forming materials needed. Keeping the shores

FIGURE 7.17 Shoring towers used for bridge falsework.

FIGURE 7.18 Drop-head shore allowing removal of panels and beams. (Figure courtesy of MEVA Formwork Systems, Haiterbach, Germany.)

in place longer under the most recently placed slab also increases safety. After appropriate slab strength gain to support the slab self-weight and construction loads, the slab is activated by releasing the shores and then resnugging them to act as reshores.

FIGURE 7.19 Precast concrete mudsills distribute bridge falsework load to soil.

Centering is a specialized temporary vertical support used in construction of arches, shells, and space structures where the entire temporary support is lowered (**struck** or **decentered**) as a unit to avoid introduction of injurious stresses in any part of the structure. Shores that are supported on the ground must have a temporary footing (termed, in formwork, a **mudsill**) that is of adequate strength and size (Figure 7.19). The mudsill may be a plank, wood grillage, or precast pad, depending on the loads and ground conditions.

7.2.6 Bracing and Lacing

A brace is any structural member used to support another, always designed for compression loads and sometimes for tension under special load conditions. In formwork, **diagonal bracing** is a supplementary (not horizontal or vertical) member designed to resist lateral load. Form braces are frequently made of wood or steel. Commercial steel pipe braces in various diameters and wall thicknesses and load-rated for adjustable lengths are popular. Buckling strength of braces is always a primary design consideration. **Horizontal lacing**, horizontal members attached to shores or braces to reduce their unsupported length, can thus increase the available load capacity. Both bracing and lacing must be adequately connected at each end. This can be accomplished with bolts, nails, and a variety of commercial devices, depending on the materials involved. When attaching braces to the ground, a buried or above-ground concrete mass known as a *deadman* is sometimes used (Figure 7.20).

7.2.7 Other Forms and Components

The above represents only a brief summary of some of the most typical form elements. Many other configurations must be considered in many jobs. Beam forms are somewhat like short wall forms in that lateral pressures must be resisted; however, they also involve concentrations of vertical load, requiring strong bottom forms and more shoring. The casting of footings sometimes requires forming where the concrete cannot be cast against vertical earth sides. This forming often must be braced from the outside to hold the lateral pressure of the earth if the width of the foundation is large. Supplementary forming elements such as **templates** are often incorporated in foundation forms to precisely locate anchor bolts and dowels (Figure 7.21). Where concrete elements must be subdivided into two or more placement sections, a form **bulkhead** is usually placed, either as a construction joint or as an end closure. The bulkhead, although involving short spans, must be carefully designed and connected as it must resist the same pressure magnitudes as the faces of the form.

FIGURE 7.20 Formwork brace anchored to buried concrete mass.

FIGURE 7.21 Plywood templates secure dowels or anchor bolts at correct position.

Forms may also incorporate a host of other features. **Chamfer strips** are triangular or curved inserts placed in the inside corner of a form to produce a rounded or beveled corner. These are often specified in rectangular columns and at outside corners of walls. **Cleanouts** are openings sometimes provided at the bottom of wall or column forms for removal of refuse before the concrete is placed to ensure a good construction joint. There must be a means of closing and supporting the cleanout door to resist concrete pressure. **Wrecking strips** are small pieces or panels fitted into a formwork assembly in such a way that they can be easily removed ahead of the main panels or sections, making it easier to strip the major form components. Various references, such as Hurd (2005) and form-supplier catalogs, provide numerous illustrations of formwork details.

7.3 Formwork Standards and Recommended Practices

Ultimately, formwork safety is dependent on the system in place on individual projects to ensure proper and safe design, fabrication, handling, erection, inspection, monitoring, and stripping of the forms and supports (Figure 7.22). As noted earlier, formwork materials and labor are roughly equal in cost to the concrete and reinforcing materials and placing labor. The loads supported by formwork

FIGURE 7.22 Guardrails and rated, well-maintained access ladders are components of a safety system.

(say, for an individual floor) are usually similar in magnitude to the loads supported by the finished structure and are sometimes much greater. Thus, it is justifiable for the design and planning of formwork to require the significant time of a professional, just as is required for design of the structure of the facility being built. Savings can accrue from a well planned and designed system. This section summarizes some of the resources available to the construction engineer to guide the planning and design of formwork. Most of the resources are in the form of guides or recommended practices. Except for some provisions of OSHA, there has previously been no uniformly mandated standard in the United States for design of temporary structures such as formwork; however, this is in the process of change, as is noted in the following sections. As in all engineering work, the construction engineer should seek the most recent edition of the following resources. Most standards are updated or reconfirmed on a cycle of 6 years or less.

7.3.1 American Concrete Institute Recommendations

Prior to about 1958, formwork was designed based on only limited data and guidance for loads. At that time, recommendations for loads and pressures for the design of formwork became available from the American Concrete Institute (ACI). These recommendations have evolved over the years and are available in three often-consulted and periodically updated ACI publications:

- *Guide to Formwork for Concrete*, ACI 347-04 (ACI Committee 347, 2004)
- *Formwork for Concrete*, 7th ed., ACI SP-4 (Hurd, 2005)
- *Guide for Shoring and Reshoring of Multistory Concrete Buildings*, ACI 347.2R (ACI Committee 347, 2005)

The first provides the recommended practice for design and construction of formwork, including recommendations for loads and pressures. The second is a manual that extensively describes systems and provides design procedures, design aids, and examples. The third provides methods for determining shore, reshore, and early-age slab loads during multistory building construction. ACI also publishes, through its journals and other monographs, numerous articles on concrete formwork as well as guides for craftspersons involved in formwork fabrication and erection. ACI Committee 347 recommendations for loads and pressures to be applied in the design of formwork are discussed more thoroughly in Section 7.4 of this chapter.

FIGURE 7.23 Fall-protection nets.

FIGURE 7.24 Work platform being installed on tall wall form.

7.3.2 OSHA Standards

By the early 1970s, legislation to establish the Occupational Health and Safety Administration (OSHA) began to have an impact on formwork. OSHA expectations not only include an adequate temporary structure but also emphasize components for worker fall protection (Figure 7.23 and Figure 7.24) and procedures for safe handling and erection of formwork. Some states have their own requirements that are different from, but cannot be less restrictive than, the federal requirements. Sections of the federal OSHA *Occupational Safety and Health Standards for the Construction Industry* (29 CFR, Part 1926) particularly affecting formwork planning, design, and execution includes the following requirements:

- Subpart L—Scaffolding
- Subpart M—Fall Protection
- Subpart Q—Concrete and Masonry Construction

Subpart Q contains sections on scope, application, and definitions; general requirements; equipment and tools; cast-in-place concrete; precast concrete; lift-slab operations; and masonry construction. Of primary interest here is the following section on cast-in-place concrete:

§ 1926.703 Requirements for cast-in-place concrete.

(a) General requirements for formwork.

(1) Formwork shall be designed, fabricated, erected, supported, braced, and maintained so that it will be capable of supporting without failure all vertical loads that may reasonably be anticipated to be applied to the formwork. Formwork which is designed, fabricated, erected, supported, braced, and maintained in conformance with the Appendix to this section will be deemed to meet the requirements of this paragraph.

(2) Drawings or plans, including all revisions, for the jack layout, formwork (including shoring equipment), working decks, and scaffolds, shall be available at the jobsite.

(b) Shoring and reshoring.

(1) All shoring equipment (including equipment used in reshoring operations) shall be inspected prior to erection to determine that the equipment meets the requirements specified in the formwork drawings.

(2) Shoring equipment found to be damaged such that its strength is reduced to less than that required by § 1926.703(a)(1) shall not be used for shoring.

(3) Erected shoring equipment shall be inspected immediately prior to, during, and immediately after concrete placement.

(4) Shoring equipment that is found to be damaged or weakened after erection, such that its strength is reduced to less than that required by § 1926.703(a)(1), shall be immediately reinforced.

(5) The sills for shoring shall be sound, rigid, and capable of carrying the maximum intended load.

(6) All base plates, shore heads, extension devices, and adjustment screws shall be in firm contact, and secured when necessary, with the foundation and the form.

(7) Eccentric loads on shore heads and similar members shall be prohibited unless these members have been designed for such loading.

(8) Whenever single post shores are used one on top of another (tiered), the employer shall comply with the following specific requirements in addition to the general requirements for formwork:

(i) The design of the shoring shall be prepared by a qualified designer and the erected shoring shall be inspected by an engineer qualified in structural design.

(ii) The single post shores shall be vertically aligned.

(iii) The single post shores shall be spliced to prevent misalignment.

(iv) The single post shores shall be adequately braced in two mutually perpendicular directions at the splice level. Each tier shall also be diagonally braced in the same two directions.

(9) Adjustment of single post shores to raise formwork shall not be made after the placement of concrete.

(10) Reshoring shall be erected, as the original forms and shores are removed, whenever the concrete is required to support loads in excess of its capacity.

(c) Vertical slip forms.

(1) The steel rods or pipes on which jacks climb or by which the forms are lifted shall be

(i) Specifically designed for that purpose; and

(ii) Adequately braced where not encased in concrete.

- (2) Forms shall be designed to prevent excessive distortion of the structure during the jacking operation.
 - (3) All vertical slip forms shall be provided with scaffolds or work platforms where employees are required to work or pass.
 - (4) Jacks and vertical supports shall be positioned in such a manner that the loads do not exceed the rated capacity of the jacks.
 - (5) The jacks or other lifting devices shall be provided with mechanical dogs or other automatic holding devices to support the slip forms whenever failure of the power supply or lifting mechanism occurs.
 - (6) The form structure shall be maintained within all design tolerances specified for plumbness during the jacking operation.
 - (7) The predetermined safe rate of lift shall not be exceeded.
- (d) Reinforcing steel.
- (1) Reinforcing steel for walls, piers, columns, and similar vertical structures shall be adequately supported to prevent overturning and to prevent collapse.
 - (2) Employers shall take measures to prevent unrolled wire mesh from recoiling. Such measures may include, but are not limited to, securing each end of the roll or turning over the roll.
- (e) Removal of formwork.
- (1) Forms and shores (except those used for slabs on grade and slip forms) shall not be removed until the employer determines that the concrete has gained sufficient strength to support its weight and superimposed loads. Such determination shall be based on compliance with one of the following:
 - (i) The plans and specifications stipulate conditions for removal of forms and shores, and such conditions have been followed, or
 - (ii) The concrete has been properly tested with an appropriate ASTM standard test method designed to indicate the concrete compressive strength, and the test results indicate that the concrete has gained sufficient strength to support its weight and superimposed loads.
 - (2) Reshoring shall not be removed until the concrete being supported has attained adequate strength to support its weight and all loads in place upon it.

APPENDIX TO § 1926.703(a)(1) General requirements for formwork. (This Appendix is non-mandatory.)

This appendix serves as a non-mandatory guideline to assist employers in complying with the formwork requirements in §1926.703(a)(1). Formwork which has been designed, fabricated, erected, braced, supported, and maintained in accordance with Sections 6 and 7 of the American National Standard for Construction and Demolition Operations—Concrete and Masonry Work, ANSI A10.9-1983, shall be deemed to be in compliance with the provision of § 1926.703(a)(1).

7.3.3 American National Standards Institute

The standard suggested in the above OSHA provisions as a means for achieving compliance is the American National Standard for Construction and Demolition Operations—Concrete and Masonry Work—Safety Requirements, ANSI A10.9-1997(R2004). Section 6, on vertical shoring, has provisions for loads and design, field practices, removal, tubular welded frame shoring, tube and coupler tower shoring, and single-post shores. Section 7, on formwork, has provisions for loads, formwork design, placing and removal of forms, vertical slip forms, flying-deck forms, and horizontal shoring beams. Most of the load and design provisions refer to the ACI Committee 347 *Guide to Formwork for Concrete* as the procedure to follow.

7.3.4 Scaffolding, Shoring, and Forming Institute Guides and Rules

This industry-supported institute publishes many relevant guides, rules, and training aids related to formwork and its support systems. Examples include the following:

- Scaffold Code of Safe Practice
- Safety Procedures for Vertical Formwork
- Flying and Handling Concrete Formwork
- The Difference Between Scaffolding and Shoring
- Wind Loads and Shoring
- Safe Practices for Erecting and Dismantling Frame Shoring
- Horizontal Shoring Beam Safety Rules
- Single Post Shore Safety Rules
- Rolling Shore Bracket Safety Rules
- Recommended Frame Shoring Erection Procedures
- Flying Deck Form Safety Rules

7.3.5 American Society of Civil Engineers Standards

A committee of the American Society of Civil Engineers has developed ASCE 37-02 *Design Loads on Structures during Construction*, a standard for loads imposed on structures during construction, including temporary structures. The standard covers many topics, including loads for formwork, falsework, and shoring. The loads and pressures imposed by concrete, construction interval winds, and other sources are defined. For wind loadings, reference for analysis method is made to ASCE 7, but ASCE 37 defines wind velocity reductions reflecting the short period of exposure during construction. As with any voluntary consensus standard, it is available for groups to specify in individual contracts, or it could be cited as the standard for use by government agencies in rule making. Although various guides and industry practices have been available for many years for the design of formwork, this standard makes available for the first time in the United States a document that defines loads in mandatory language that can be incorporated in contracts, codes, and safety laws.

7.3.6 Information from Formwork Suppliers

Formwork suppliers, of course, publish literature defining their products and limitations for their use. Data sheets indicate the load ratings of products such as form ties, shores, braces, wales, etc. for reference by form designers of job-built systems. In addition, many form manufacturers supply preengineered formwork systems (Figure 7.25) under rental or purchase arrangements for individual projects or general use. Such systems will come with rules and limitations whose implementation is required by the contractor as part of the rental or sales agreement. It is critical that these requirements be implemented as the normal procedures for use and for training workers involved with the formwork.

7.3.7 General Material Design Standards

Although they do not specifically address formwork, the same criteria used for the design of permanent structures in any particular material should also be applied to the design of formwork once the loads and safety factors appropriate for formwork have been determined. Most forms are made of wood, steel, or aluminum or some combination of these materials. The usual reference design standards for these materials are as follows:

- *National Design Specification for Wood Construction*, ASD/LRFD, ANSI/AF&PA NDS-2005, American Forest & Paper Association, Washington, D.C., 2005
- *Steel Construction Manual: Allowable Stress Design*, 13th ed., American Institute of Steel Construction, Chicago, 2005

FIGURE 7.25 Preengineered wall form system.

- *Aluminum Design Manual*, The Aluminum Association, Arlington, VA, 2005
- *Plywood Design Specification*, APA—The Engineered Wood Association, Tacoma, WA, 1997

The use of *allowable stress design* (ASD) currently dominates in the design of formwork, but use of the *load and resistance factor design* (LRFD) method is expected to gradually increase. Addresses for many of the above sources of standards and specifications are given following the references at the end of this chapter.

7.4 Loads and Pressures on Formwork

The possible loads acting on formwork are many. Vertical loads are usually associated with the dead load of the placed concrete and formwork and the live load of workers and their equipment. Internal pressures on vertical formwork result from the liquid or semi-liquid behavior of the fresh concrete. External forces such as wind exert horizontal loads on the forms, requiring bracing systems for lateral form stability.

7.4.1 Vertical Loads

Vertical loads acting on formwork (Figure 7.26) include the self-weight of the forms, the placed reinforcement, the weight of fresh concrete, the weight of the workers, and the weight of placing equipment and tools. The dead load of the concrete is usually estimated at 145 to 150 lb/ft³, including an allowance for normal amounts of reinforcement. In cases where the reinforcement appears to be heavy, the materials should be calculated separately to determine the actual unit weight. Adjustments are also made for lightweight concrete densities. An 8-in. normal weight slab thus imposes a dead load of 150 lb/ft³ × (8 in./12 in./ft), or 100 psf, on horizontal formwork. ACI Committee 347 (2004) recommends that horizontal formwork be designed for a minimum vertical live load of 50 psf to allow for workers and their incidental

FIGURE 7.26 Weights of concrete, reinforcing, and formwork contribute to dead load.

placing tools such as screeds, vibrators, and hoses. When motorized carts or buggies are used, a minimum live load of 75 psf is recommended. Furthermore, it is recommended that the minimum combined total design dead and live load should be no less than 100 psf, or 125 psf if motorized buggies are used. Formwork self-weight can be calculated from the unit weights and sizes of the components. The weight of the formwork is often much less than the dead load of the concrete and the construction live loads; thus, during design, an allowance is frequently made for the form components as a superimposed load per square foot. Because forms often weigh 5 to 15 psf, an initial estimate is made in this range based on experience and then is verified after the members are sized.

7.4.2 Lateral Pressures of Concrete

Vertical formwork, such as that for walls and columns, is subjected to internal lateral pressure from the accumulated depth of concrete placed. In a placement, fresh concrete, at least near the top and sometimes at greater depths, behaves as a liquid during vibration and generates lateral pressures equal to the vertical liquid head. Although concrete is a granular material with internal friction, the fluidization of the concrete resulting from internal vibration at least temporarily creates a liquid state; however, many factors appear to contribute to the lateral pressures being less than a liquid head at depths below the controlled depth of vibration. If the vertical placement rate is slow, the concrete mass below may have time to begin stiffening. If the concrete is warm, this stiffening may begin earlier. Internal concrete granular friction, form friction, migration of pore water, and other factors may also reduce the resulting lateral pressures. Admixtures, different types of cements, cement substitutes, and construction practices also affect the level of lateral pressure.

Tests have indicated that the pressures often have a distribution, as indicated in Figure 7.27, starting as a liquid pressure near the top and reaching a maximum at some lower level. For simplicity, design practice usually assumes that the maximum pressure is uniform at a conservative value. ACI Committee 347 (2004) recommends that, unless certain conditions are met, calculation of the pressure magnitude vs. depth should be as a full liquid head:

$$p = wh \quad (7.1)$$

where p is the lateral pressure of concrete (lb/ft^2), w is the unit weight of fresh concrete (lb/ft^3), and h is the depth of fluid or plastic concrete from the top of the placement to the point of consideration in the form (ft).

FIGURE 7.27 Typical and assumed distributions of concrete lateral pressure.

TABLE 7.1 Unit Weight Coefficient (C_W)

Unit Weight of Concrete	C_W
Less than 140 lb/ft ³	$C_W = 0.5[1 + (w/145 \text{ lb/ft}^3)]$
140 to 150 lb/ft ³	1.0
More than 150 lb/ft ³	$C_W = w/145 \text{ lb/ft}^3$

TABLE 7.2 Chemistry Coefficient (C_C)

Cement Type or Blend	C_C
Types I, II, and III without retarders ^a	1.0
Types I, II, and III with a retarder ^a	1.2
Other types or blends containing less than 70% slag or 40% fly ash without retarders ^a	1.2
Other types or blends containing less than 70% slag or 40% fly ash with a retarder ^a	1.4
Blends containing more than 70% slag or 40% fly ash	1.4

^a Retarders include any admixture, such as a retarder, retarding water reducer, retarding midrange water-reducing admixture, or high-range water-reducing admixture (superplasticizer), that delays setting of concrete.

ACI 347-04 further states, however, that for concrete having a slump no greater than 7 in. and placed with normal internal vibration to a depth of 4 ft or less, the formwork may be designed for a lateral pressure as follows, where p_{max} is the maximum lateral pressure (psf), R is the rate of vertical placement (ft/hr), T is the temperature of concrete (°F), C_W is the unit weight coefficient per Table 7.1, and C_C is the unit weight coefficient per Table 7.2:

1. For columns:

$$p_{max} = C_W C_C [150 + 9000R / T] \tag{7.2}$$

with a minimum of $600C_W$ psf, but in no case greater than wh .

2. For walls with rate of placement (R) less than 7 ft/hr and a placement height not exceeding 14 ft:

$$p_{max} = C_W C_C [150 + 9000R / T] \tag{7.3}$$

with a minimum of $600C_W$ psf, but in no case greater than wh .

FIGURE 7.28 Tall wall form with internal pressures resisted by ties and wind resisted by external braces.

3. For walls with rate of placement (R) less than 7 ft/hr where placement height exceeds 14 ft and for walls with a placement rate of 7 to 15 ft/hr:

$$p_{\max} = C_w C_c [150 + 43,400/T + 2800R/T] \quad (7.4)$$

with a minimum of $600C_w$ psf but in no case greater than wh .

For the purpose of the pressure formulas, columns are defined as vertical elements with no plan dimension exceeding 6.5 ft, and walls are vertical elements with at least one plan dimension exceeding 6.5 ft.

When working with concrete mixtures using newly introduced admixtures that increase set time or increase slump characteristics, such as self-consolidating concrete, Equation 7.1 should be used until the effect on formwork pressure is understood by measurement. Caution should be used if a concrete form is filled by pumping upward from the base of the form. Not only can a liquid head be developed, but also a portion of the pump surcharge pressure is likely to be developed due to friction and drag resistance of the concrete moving upward through the form and reinforcing.

Internal concrete lateral pressures are usually resisted in wall forms by transferring the pressures through beamlike members (plywood, studs, and wales) to tension ties linking the two wall form sides (Figure 7.28). Because tension elements are the most efficient structural members, this is also the most cost-effective solution. The internal pressures in most column forms are transferred to external tie elements on adjacent faces of the form that serve as links between the opposite sides of a square or rectangular column form. Circular columns have a great forming advantage in that the column-form skin can act as a hoop, resisting the pressures in tension. Although these are effective methods of resisting internal pressures of the concrete, separate resisting elements, such as external braces, must be provided to resist external horizontal loads that tend to overturn wall, column, and slab forms.

FIGURE 7.29 Schematic bracing of slab formwork.

FIGURE 7.30 Schematic bracing of wall formwork.

7.4.3 Horizontal Loads

Horizontal loads from such forces as wind, seismic activity, cables, inclined supports, inclined dumping of concrete, and starting or stopping of equipment must be resisted by braces and shores. ACI Committee 347 (2004) recommends the following minimum loads for design to prevent lateral collapse of the formwork. For elevated floor formwork in building construction, the horizontal load (w) for design in any direction at each floor line should not be less than 100 lb per linear foot of floor edge or 2% of the total dead load on the form distributed as a uniform load per foot of slab edge, whichever is greater (see Figure 7.29). For wall forms, bracing should be designed to meet the minimum wind load requirements of ASCE 7-05 with wind velocity adjustment for shorter recurrence interval as provided in ASCE 37-02. If exposed to elements, the minimum wind design pressure (q) should not be less than 15 psf, and bracing should be designed for at least $w = 100$ lb per linear foot of wall, applied at the top. In Figure 7.30, the minimum lateral load (w) for design of the bracing system would be the greater of $q \times h/2$ or 100 lb/ft. The formwork designer must also be alert for other conditions such as post-tensioning operations, unusual geometry, or sequence of construction of operations that may create special loads on the forming system.

7.5 Formwork Design Criteria

Formwork components can be designed and constructed in many materials, such as plywood, wood, steel, aluminum, and fiber composites. Frequently, a mixture of materials is used (Figure 7.31). Steel, aluminum, and fiber composites are more likely to be parts of manufactured components or systems that are rated or designed by the producer and may be supplied predesigned on a rental basis for the project needs. Forms intended to be job built are often made of wood and require design by the construction engineer associated with the project or by a consultant to the contractor. The examples in this chapter illustrate the latter case for wood components designed by allowable stress methods. To understand the examples, it is necessary to provide some of the essentials of wood design. Readers undertaking the design of formwork in wood are advised to obtain and follow the more comprehensive specifications in the *National Design Specification for Wood Construction* (AFPA, 2005) and the *Plywood Design Specification* (APA, 1997).

Most of the lumber used in formwork is surfaced on four sides (S4S) to achieve its final dimensions as shown in Table 7.3. The S4S dimensions are smaller than the nominal sizes referred to in the table. Except for classification purposes, it is the actual dimensions and actual section properties that are used

FIGURE 7.31 Wood joists supported on steel beams and steel scaffolding towers.

in design. A second set of sizes known as *rough lumber* (not shown in Table 7.3) has slightly larger dimensions but is still not the full nominal size. Rough lumber sizes are sometimes used in heavy falsework-supporting forms.

Plywood is frequently used as the surface layer of the formwork in contact with the fresh concrete. Plywood has different strengths and stiffness depending on the direction of its span relative to the direction of the grain in the outer layers. The equivalent section, considering the varying elastic modulus and strength between parallel-to-grain loading and side-grain loading, is illustrated by equivalent sections in Figure 7.32. When the grain of the outer layers is parallel to the span direction, the strength and stiffness are greatest (Figure 7.33). Many types of plywood are available. Section properties for B-B Plyform, Class I, plywood, one of the most frequently selected types for moderate reuse in formwork, are given in Table 7.4. Note that, due to the alternating grain directions in the plywood veneer layers, conventional methods for calculating section properties of homogeneous, isotropic sections do not apply. The section properties given in Table 7.4 have been determined by considering the varying properties in the different layers as well as the complications of weakness induced by the tendency of fibers to roll over each other in shear lateral to the grain, or **rolling shear** (Figure 7.34). For these reasons, use the listed value of S only in bending calculations, use I only for deflection calculations, and use Ib/Q , the rolling-shear constant, for shear calculations.

The basic design values for wood and for plywood of the species, grades, sizes, and types frequently used in formwork are listed in Table 7.5. The species and grades readily available in the area of the project should always be verified. Contractors also often have stocks of form lumber for reuse from previous projects. Such lumber should always be inspected for defects as the material is assembled, and unsuitable pieces must be rejected.

7.5.1 ASD Adjustment Factors for Lumber Stresses

The AFPA-NDS (AFPA, 2005) provides for adjustment of the lumber **reference design values** (F), such as those given in Table 7.5, by a series of multipliers yielding the **allowable design values** (F') for stress as follows:

Bending:

$$F'_b = F_b \times C_D \times C_M \times C_L \times C_F \times C_{fu} \times C_r \times [C_t \times C_i] \quad (7.5)$$

TABLE 7.3 Example Section Properties of Standard Dressed (S4S) Sawn Lumber

Nominal Size	Standard Dressed Size (S4S) $b \times d$ ($x-x$) $d \times b$ ($y-y$) (in. \times in.)	Area of Section (A) (in. ²)	$x-x$ Axis			$y-y$ Axis			Approximate Weight (lb/ft) When Wood Density Equals the Following Weights		
			Section Modulus (S_{xx}) (in. ³)	Moment of Inertia (I_{xx}) (in. ⁴)	Section Modulus (S_{yy}) (in. ³)	Moment of Inertia (I_{yy}) (in. ⁴)	25 (lb/ft ³)	30 (lb/ft ³)	35 (lb/ft ³)		
2 \times 4	1-1/2 \times 3-1/2	5.250	3.063	5.359	1.313	0.984	0.911	1.094	1.276		
2 \times 6	1-1/2 \times 5-1/2	8.250	7.563	20.80	2.063	1.547	1.432	1.719	2.005		
2 \times 8	1-1/2 \times 7-1/4	10.88	13.14	47.63	2.719	2.039	1.888	2.266	2.643		
2 \times 10	1-1/2 \times 9-1/4	13.88	21.39	98.93	3.469	2.602	2.409	2.891	3.372		
4 \times 4	3-1/2 \times 3-1/2	12.25	7.146	12.51	7.146	12.51	2.127	2.522	2.977		
4 \times 6	3-1/2 \times 5-1/2	19.25	17.65	48.53	11.23	19.65	3.342	4.010	4.679		
4 \times 8	3-1/2 \times 7-1/4	25.38	30.66	111.1	14.80	25.90	4.405	5.286	6.168		

Note: Table is an abbreviated list of properties of selected sizes; see AFPA-NDS (2005) for additional data.

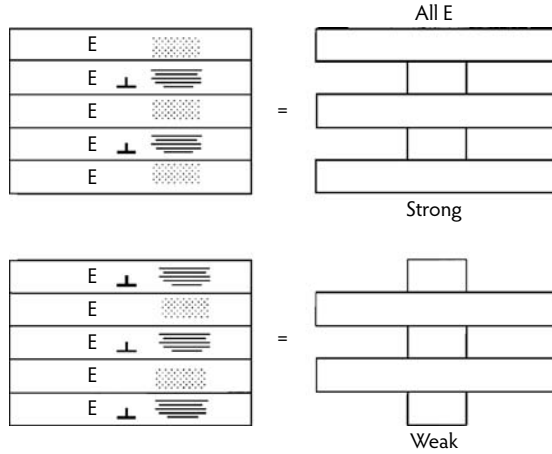

FIGURE 7.32 Plywood equivalent sections recognizing the weakness of lateral modulus.

FIGURE 7.33 Plywood load capacity and stiffness varies with direction of face grain span.

Shear:

$$F'_v = F_v \times C_D \times C_M \times [C_t \times C_i] \tag{7.6}$$

Bearing:

$$F'_{c\perp} = F_{c\perp} \times C_M \times C_b \times [C_t \times C_i] \tag{7.7}$$

Compression:

$$F'_c = F_c \times C_D \times C_M \times C_F \times C_P \times [C_t \times C_i] \tag{7.8}$$

Elastic modulus:

$$E' = E \times C_M \times [C_t \times C_i] \tag{7.9a}$$

$$E'_{\min} = E_{\min} \times C_M \times [C_t \times C_i \times C_T] \tag{7.9b}$$

TABLE 7.4 Example Effective Section Properties for Plywood: 12-in. Unit Width of B-B Plyform, Class I

Plywood Net Thickness (in.)	12-in Width, Used with Face Grain Parallel to Span			12-in. Width, Used with Face Grain Perpendicular to Span			Weight (psf)
	Moment of Inertia (I) (in. ⁴)	Effective Section Modulus (S) (in. ³)	Rolling Shear Constant (Ib/Q) (in. ²)	Moment of Inertia (I) (in. ⁴)	Effective Section Modulus (S) (in. ³)	Rolling Shear Constant (Ib/Q) (in. ²)	
1/2	0.077	0.268	5.153	0.024	0.130	2.739	1.5
5/8	0.130	0.358	5.717	0.038	0.175	3.094	1.8
3/4	0.199	0.455	7.187	0.092	0.306	4.063	2.2
7/8	0.296	0.584	8.555	0.151	0.422	6.028	2.6
1	0.427	0.737	9.374	0.270	0.634	7.014	3.0

Note: Use listed S value in bending calculations and use I only in deflection calculations. Properties of B-B Plyform, Class I, are taken from APA (2004). Consult reference or manufacturer for other plywood types.

FIGURE 7.34 Grains of wood tend to roll when subjected to lateral shear.

Some of the adjustment factors (in brackets) only apply to truss members (buckling stiffness factor, C_T), when the member is incised (incising factor, C_i) or when the temperature is $>100^\circ\text{F}$ (temperature factor, C_t), and thus have only rare uses in formwork. The remaining factors are discussed below.

7.5.2 Load Duration Factor (C_D)

The adjustment for load duration (C_D) reflects the ability of wood to exhibit increased strength under shorter periods of loading. The following values may be applied for the indicated cumulative maximum load durations:

- $C_D = 0.9$ Load duration > 10 year
- $C_D = 1.0$ 2 months $<$ load duration ≤ 10 year
- $C_D = 1.15$ 7 days $<$ load duration ≤ 2 months
- $C_D = 1.25$ Load duration ≤ 7 days
- $C_D = 1.6$ Wind/earthquake
- $C_D = 2.0$ Impact

For most formwork, an adjustment of $C_D = 1.25$ is applied; however, when the components are reused for longer cumulative durations at maximum level, C_D should be appropriately reduced.

TABLE 7.5 Example Reference Design Values for Visually Graded Dimension Lumber at 19% Maximum Moisture and Plywood Used Wet

Species, Specific Gravity, Grade, and Size Category	Extreme Fiber Bending (F_b) (psi)	Compression \perp to Grain (F_{\perp}) (psi)	Compression \parallel to Grain, F_c (psi)	Shear \parallel to Grain (F_v) (psi)	Modulus of Elasticity

Construction	2 and 3	1.0	1.0	1.0	1.0	—
	4	1.0	1.0	1.0	1.1	1.0

7.5.3 Moisture Factor (C_M)

Wood gains in strength as it loses moisture in a range below the fiber saturation point (about 30% moisture content). The basic design values are established for lumber that has a moisture content of 19% or less, typical of air-dried lumber. When the exposure is such that the wood moisture content will exceed 19% for an extended period of time, the design values should be multiplied by the C_M values indicated in Table 7.5.

7.5.4 Size Factor (C_F)

Tests indicate that member overall size affects the failure stress. To account for these variations, the size factor (C_F) as shown in Table 7.6 is applied to the bending and compression basic design values. Note that the size factor does not apply to the basic design values of Southern Pine, whose basic design values in Table 7.5 are preadjusted to reflect most of the size effect.

7.5.5 Flat-Use Factor (C_{fu})

Lumber loaded on its wide face and bending about its weak axis (y - y) exhibits a slightly higher failure stress. To reflect these variations, the flat-use factor (C_{fu}) adjustments in Table 7.6 may be applied to the basic design values for bending stress.

7.5.6 Beam-Stability Factor (C_L)

The AFPA-NDS (AFPA, 2005) provides equations for determining the beam-stability factor (C_L), an adjustment less than 1.0, when the compression edge of a beam may become unstable. For sawn lumber, however, the AFPA-NDS also provides prescriptive d/b ratios, based on nominal dimensions and lateral support conditions where the member may be assumed to be stable and no reduction for C_L is needed, as follows:

- $d/b = 2$ to 1 or less, no lateral support is necessary.
- $d/b = 3$ to 1 or 4 to 1, ends shall be held in position against lateral rotation or displacement by blocking or connection to other members.
- $d/b = 5$ to 1, one edge shall be held in line for the entire length.
- $d/b = 6$ to 1, bridging, blocking, or cross-bracing shall be installed at intervals not exceeding 8 ft unless both edges are held in line.
- $d/b = 7$ to 1, both edges shall be held in line for the entire length.

7.5.7 Column-Stability Factor (C_p)

The column-stability factor (C_p) is an adjustment less than 1.0 to reduce the allowable compression stress parallel to the grain when longer column-like members such as shores or braces may fail in a buckling mode rather than by crushing. The factor is given by:

$$C_p = \frac{1 + (F_{cE} / F_c^*)}{2c} - \sqrt{\left[\frac{1 + (F_{cE} / F_c^*)}{2c} \right]^2 - \frac{F_{cE} / F_c^*}{c}} \quad (7.10)$$

where:

F_c^* = tabulated compression design value multiplied by all applicable adjustment factor except C_p

c = 0.8 (for sawn lumber).

$F_{cE} = 0.822E'_{\min} / (l_e/d)^2$, where l_e is the effective length, and l_e/d is the larger of the slenderness ratios about the possible buckling axes; the value of l_e/d shall not normally exceed 50, except for short-duration loadings during construction when it shall not exceed 75.

7.5.8 Bearing-Area Factor (C_b)

The bearing-area factor (C_b) is for the case of bearing perpendicular to the grain of the wood—that is, bearing on the side grain. The bearing factor is normally taken as 1.0; however, if the bearing area is more than 3 in. from the end of the member and less than 6 in. in length as measured along the grain, then the following increase factor may be applied:

$$C_b = \frac{l_b + 0.375}{l_b} \quad (7.11)$$

where l_b is the length of bearing (in inches) measured parallel to the grain. Note that in formwork design, unless there is certainty that the bearing area will not be within 3 in. of the end of the member, it is usually best to assume $C_b = 1.0$.

7.5.9 Repetitive-Use Factor (C_r)

The AFPA-NDS (AFPA, 2005) includes a repetitive-use factor (C_r) that may be used to increase the bending design value when there are at least three members spaced not more than 24 in. on-center, such as joists and studs, and they are joined by a load-distributing member, such as sheathing. The increase is allowed because it is unlikely that normal defects would occur in the repetitive members at the same critical location and the load could be shared if one had a defect. In formwork design, however, ACI SP-4 (Hurd, 2005) suggests that this factor should only be applied to carefully constructed panels whose components are securely nailed or bolted together. The factor values > 1.0 are listed in the AFPA-NDS.

7.5.10 Adjustment Factors for Plywood Stresses

Relative to formwork, the allowable stresses given by the APA—The Engineered Wood Association (APA, 2004) are subject to three primary adjustments: load duration, wet use, and experience factors. A load duration factor similar to the value of C_D for wood is normally applied as listed in Table 7.5. The wet use and experience factors appropriate to formwork applications have been incorporated in the allowable stresses listed for B-B Plyform, Class I, plywood in Table 7.3. The calculation of plywood deflection can be refined to include both the bending deflection and the shear deflection. In this presentation, for simplicity, only the bending deflection is considered, but the lower value of the plywood elastic modulus will be used to partially compensate for this. Consult APA (2004) for procedures for calculating the shear deflection component.

TABLE 7.7 Minimum Safety Factors of Formwork Accessories

Accessory	Safety Factor	Type of Construction
Form tie	2.0	All applications
Form anchor	2.0	Formwork supporting form weight and concrete pressures only
	3.0	Formwork supporting form weight of forms, concrete, construction live loads, and impact
Form hanger	2.0	All applications
Anchoring inserts used as form ties	2.0	Precast concrete panels when used as formwork

7.5.11 Manufactured Wood Products

Various manufactured wood products are sometimes used in formwork applications. These include not only sheathing but also structural composite lumber. **Laminated veneer lumber (LVL)** is made of wood-veneer sheet elements 1/4-in. thick or less, bonded with an exterior adhesive, with wood fibers oriented along the length of the member. **Parallel strand lumber (PSL)** is made of wood strands having a least dimension of 1/4 in. or less and an average length of at least 150 times the least dimension, bonded with exterior adhesive, and with strands oriented along the length of the member. **Laminated strand lumber (LSL)** is made of wood strands with a least dimension of about 1/32 in., approximately 12 in. long, parallel to the length of the member, and bonded with an exterior adhesive. The suitability of these materials for exposed formwork should be evaluated for each application. Design information can be obtained from the manufacturers or the APA.

7.5.12 Safety Factors for Formwork Accessories

Various accessories are used in formwork such as form ties, anchors, and hangers. Most of these devices are made of steel and are rated by the manufacturers. The ratings may be listed as either the allowable or ultimate strengths of the devices under certain types of loading. The type of rating (allowable or ultimate) should be carefully determined from the information provided. If ultimate strengths are listed, the allowable strength should be calculated by dividing by an appropriate factor of safety. ACI Committee 347 (2004) has recommended the safety factors listed in Table 7.7 for such accessories.

7.6 Formwork Design

Most components of a form system can be subdivided into members that are primarily bending elements (sheathing, joists, studs, stringers, and wales) and members that are primarily tension or compression elements (shores, braces, etc.). In addition, there are numerous details to design, such as connections (Figure 7.35), hangers, and footings or mudsills (Figure 7.36). The following sections provide example designs, in wood, of the main members of an elevated floor slab form and a vertical wall form to convey a sense of the procedures involved. After the design is complete, the formwork material specifications, member layout, member sizes, connection details, erection procedures, and use limitations should be conveyed by means of drawings with appropriate notes to the field workers who will fabricate and erect the form.

7.6.1 Determination of Resultants from Loads

The bending members of a wood form system are either single-span or continuous multiple-span elements, usually with bearing supports as illustrated in Figure 7.37. Although the members may sometimes have more than three spans, the benefits from considering more than three span conditions are very limited. Many of the member loads are uniform. In other cases, the loadings may be a series of closely spaced concentrated loads that can often be approximated as a uniform load if there is a sufficient number in a span. Figure 7.37 also provides the formulas for the maximum moments, shears, and

FIGURE 7.35 Connections at corners, braces, and bulkheads require specific design.

FIGURE 7.36 Wood timber grillage mudsill.

deflections for the uniformly loaded one-, two-, and three-span cases. It should be noted that the formulas for calculating the maximum shear force are modified to calculate the shear at a distance d from the face of the supporting member, where d is the depth of the member being designed and l_b is the length of bearing at the supporting member. In wood design, the AFPA-NDS provides that loads within a distance d of the face of the support can be neglected when designing for shear if the member is loaded on one face and supported on the opposite face or edge. However, in cases where the member is notched or connection is made in the web, as by bolting, other AFPA-NDS special provisions should be consulted which, in effect, magnify the shear force used for design.

7.6.2 Fundamental Relations between Resultants and Stresses

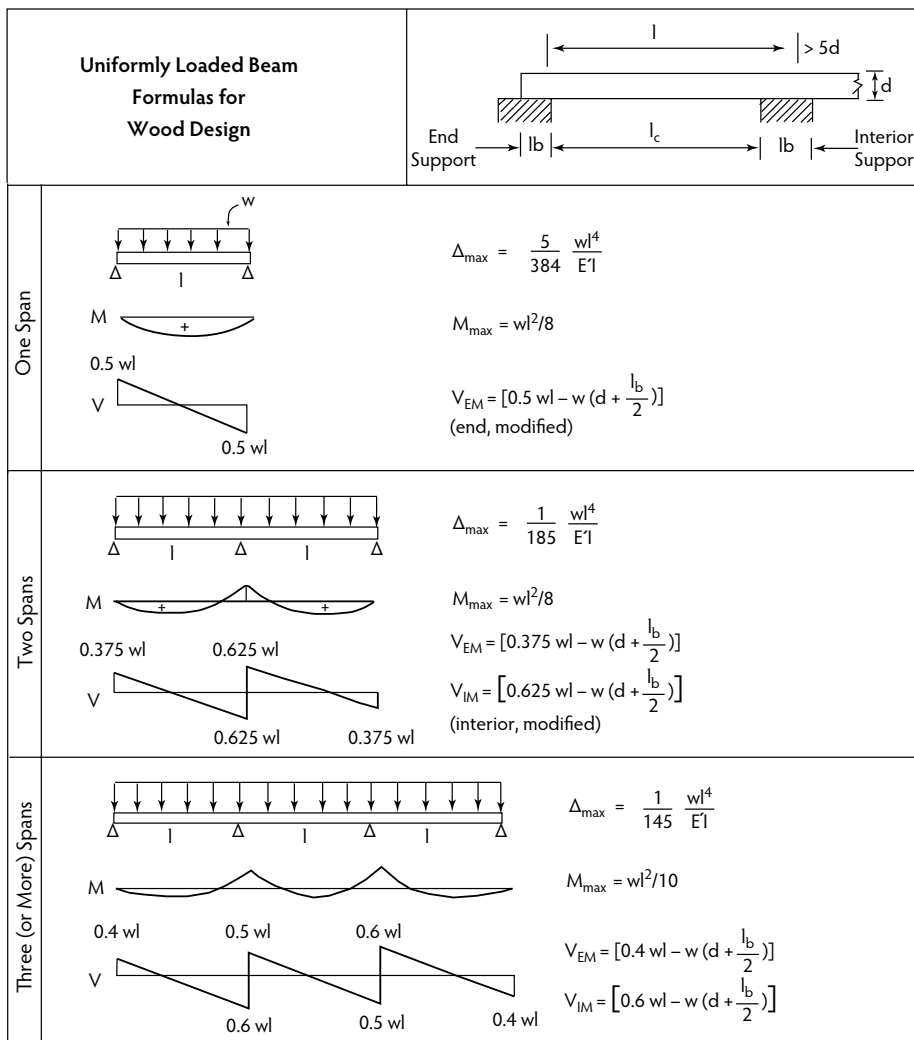

From mechanics of solids, the following relationships apply to the elastic design of wood elements:

Bending of beams or plywood:

$$f_b = \frac{M}{S} \quad (7.12)$$

Shear of solid rectangular beams:

$$f_v = \frac{3}{2} \frac{V}{bd} \quad (7.13)$$

Design Notes: 1. If l_b is unknown, use $l_b = 0$ for shear calculations.
 2. If d is unknown when calculating shear force, either:
 a) Assume $d = 0$ in calc. and reevaluate with d determined if shear controls.
 b) Assume a likely value of d and check with an additional iteration when d is determined.

FIGURE 7.37 Beam formulas for one-, two-, and three-span conditions.

Shear of plywood:

$$f_v = \frac{VQ}{Ib} = \frac{V}{Ib/Q} \tag{7.14}$$

where Ib/Q is the rolling shear constant.

Bearing and axial compression:

$$f_{c\perp} \text{ or } f_c = \frac{P}{A} \tag{7.15}$$

When f is used in the above equations, the actual stress is sought in the calculation from the actual resultant. When F is used, the maximum allowable stress is implied and the maximum resultants are sought. Load-deflection relationships are given in Figure 7.37 as a function of the number of spans.

7.6.3 Basis of Examples

When undertaking a form design, some parameters are frequently known, and others must be calculated to meet the required strength needs and deflection limitations. For example, the spacings of members may be dictated by the geometry of the area to be formed or the modular needs of the system or plywood facing. For this case, the unknowns become the required member sizes. In another case, the contractor may have material of a given size that is desired to be used. For the latter case, the unknowns are the maximum spacings of the members required to limit the loads on each to its allowable value. In the following elevated slab form example, the spacings are assumed to be set by job conditions and the members are the unknowns. In the wall form design example, the member sizes are assumed to be predetermined by available material and the spacings are the unknowns. For both examples, the ASD procedures of the AF&PA NDS-2005 will be used.

7.7 Slab-Form Design Example

Assume that an elevated flat-plate floor slab of 8-in. thickness is to be formed with a top elevation 10 ft above the supporting surface below. The general layout of the plywood sheathing, joists, stringers, and shores is shown in Figure 7.9 and Figure 7.38. Because of the floor layout, the contractor desires to space the joists at 16 in. on-center, the stringers at 5 ft on-center under the joists, and the shores at 5 ft on-center under the stringers. The materials are B-B Plyform, Class I, plywood and No. 2 Spruce–Pine–Fir (SPF) joists, stringers, and shores. It has been determined that the strength gain of the concrete will allow the forms to be stripped in 4 days, followed by installation of reshores. The project specification requires that the formwork element deflections shall be no greater than $l/360$. The plywood will be assumed to be used wet, as it is frequently exposed for a lengthy period during rebar placement and in contact with the fresh concrete; however, the lumber elements will be assumed to be relatively sheltered and not exposed to significant moisture for lengthy periods. The plywood will be oriented with its face grain parallel to the span direction—that is, the strong way. From the earlier section on vertical loads, the distributed pressure (q) for design on a working basis is:

Dead load of 8-in. concrete slab	100 psf
Construction live load	50 psf
Formwork estimated dead load	<u>5 psf</u>
Total	155 psf

7.7.1 Sheathing Design

The plywood span is the spacing of the joists, and 8-ft-long plywood panels can typically have three or more spans. The plywood allowable stresses adjusted for load duration (see Table 7.5) are:

$$F'_b = F_b \times C_D = 1545 \text{ psi} \times 1.25 = 1931 \text{ psi}$$

$$F'_v = F_v \times C_D = 57 \text{ psi} \times 1.25 = 71 \text{ psi}$$

$$E' = E = 1,500,000 \text{ psi}$$

Considering the loading to be a uniform load (w) of 1-ft width, corresponding to the section properties of the plywood based on 12-in. width:

$$w = q \times \text{unit width} = 155 \text{ psf} \times 1.0 \text{ ft} = 155 \text{ lb/ft}$$

For the limitation of flexural bending, the maximum moment (M) is:

$$M = \frac{wl^2}{10} = \frac{155 \text{ lb/ft} \times (1.33 \text{ ft})^2}{10} = 27.5 \text{ ft}\cdot\text{lb} = 330 \text{ in}\cdot\text{lb}$$

FIGURE 7.38 Slab formwork layout.

and the required section modulus (S) is given by:

$$S = \frac{M}{F'_b} = \frac{330 \text{ in.-lb}}{1931 \text{ psi}} = 0.171 \text{ in.}^2$$

For the shear limitation, the maximum shear force for design is determined at the center of the support as the support width is not yet known:

$$V = 0.62wl = 0.62(155 \text{ lb/ft})(16 \text{ in./12 in./ft}) = 124 \text{ lb}$$

$$\frac{Ib}{Q} = \frac{V}{F'_v} = \frac{124 \text{ lb}}{71 \text{ psi}} = 1.74 \text{ in.}^2$$

The deflection limit is determined from:

$$\frac{l}{360} = \frac{1}{145} \frac{wl^4}{EI}$$

$$I = \frac{360}{145} \frac{155 \text{ lb/ft}}{12 \text{ in./ft}} \frac{(16 \text{ in.})^3}{1,500,000 \text{ psi}} = 0.0876 \text{ in.}^4$$

From these requirements, 1/2-in. plywood would be adequate for bending and shear, but 5/8-in. is required for deflection. Select the plywood thickness to be 5/8 in. Because deflection controls, there is no benefit to further refining the shear calculation after the joist width is known.

7.7.2 Joist Design

The joist span is the 5-ft spacing of the stringers, and the joists can be constructed with a three-span continuous arrangement (Figure 7.9 and Figure 7.38). Lateral buckling of the joists will be restrained by nailing the sheathing to the joists. For selection of the joist reference design values (Table 7.5) and adjustment factors, assume initially that a 2 × 6 joist might work. Allowable stresses for the No. 2 SPF joist are as follows:

$$F'_b = F_b \times C_D \times C_M \times C_L \times C_M \times C_F \times C_r = 875 \text{ psi} \times 1.25 \times 1.0 \times 1.0 \times 1.3 \times 1.0 = 1421 \text{ psi}$$

$$F'_v = F_v \times C_D \times C_M = 135 \text{ psi} \times 1.25 \times 1.0 = 169 \text{ psi}$$

$$E' = E \times C_M = 1,400,000 \text{ psi} \times 1.0 = 1,400,000 \text{ psi}$$

Considering the loading to be a uniform load (w) of 16-in. tributary width corresponding to the spacing of the joists:

$$w = q \times \text{tributary width} = 155 \text{ psf} \times 1.33 \text{ ft} = 207 \text{ lb/ft}$$

For the limitation of flexural bending, the maximum moment (M) is:

$$M = \frac{wl^2}{10} = \frac{207 \text{ lb/ft} \times (5 \text{ ft})^2}{10} = 517 \text{ ft}\cdot\text{lb} = 6210 \text{ in}\cdot\text{lb}$$

and the required section modulus (S) is given by:

$$S = \frac{M}{F'_b} = \frac{6210 \text{ in}\cdot\text{lb}}{1421 \text{ psi}} = 4.37 \text{ in}^3$$

For the shear limitation, the maximum shear force for design is determined at d from the center of the support, as the supporting stringer width is not yet known. At the interior support,

$$V = 0.6wl - wd = 0.6(207 \text{ lb/ft}) - 207 \text{ lb/ft} \left(\frac{5.5}{12} \text{ ft} \right) = 526 \text{ lb}$$

$$bd = (3/2)(V/F'_v) = 3 \times 526 \text{ lb} / (2 \times 169 \text{ psi}) = 4.67 \text{ in}^2$$

The deflection limit is determined from:

$$\frac{l}{360} = \frac{1}{145} \frac{wl^4}{E'I}$$

$$I = \frac{360}{145} \frac{207 \text{ lb/ft}}{12 \text{ in./ft}} \frac{(60 \text{ in.})^3}{1,400,000 \text{ psi}} = 6.61 \text{ in}^4$$

From these combined requirements, a 2×6 joist is the optimum size having the least area. The result also agrees with the size assumption for selecting the reference design values and size factor. If the size did not agree, the calculations would be repeated with an improved size assumption. In this case, there is no benefit to further refining the shear calculation after the joist width is known because shear alone is not controlling the size.

7.7.3 Stringer Design

The stringer span is the 5-ft spacing of the shores, and the stringers can be constructed with a three-span continuous arrangement. For selection of the stringer basic design values (Table 7.5), assume initially that a 4×6 stringer might work. Lateral buckling of a stringer of this size would not be a problem because $d/b \leq 2$ to 1. Allowable stresses for the No. 2 SPF stringers are as follows:

$$F'_b = F_b \times C_D \times C_M \times C_L \times C_F \times C_r = 875 \text{ psi} \times 1.25 \times 1.0 \times 1.0 \times 1.3 \times 1.0 = 1421 \text{ psi}$$

$$F'_v = F_v \times C_D \times C_M = 135 \text{ psi} \times 1.25 \times 1.0 = 169 \text{ psi}$$

$$E' = E \times C_M = 1,400,000 \text{ psi} \times 1.0 = 1,400,000 \text{ psi}$$

The stringer loading is actually a series of concentrated loads from the joists at 16 in. on-center; however, the starting position of the loads can vary in each span. Due to the complications involved in considering many possible starting positions and recognizing that loads within distance d of the support can be neglected for shear calculations, it is often the practice in formwork to assume a uniform load as being adequately similar (Hurd, 2005). This assumption works reasonably well when three or more equally

spaced concentrated loads of equal magnitude are in the span. Considering the loading to be a uniform load (w) of 5-ft tributary width corresponding to the spacing of the stringers:

$$w = q \times \text{tributary width} = 155 \text{ psf} \times 5 \text{ ft} = 775 \text{ lb/ft}$$

For the limitation of flexural bending, the maximum moment (M) is:

$$M = \frac{wl^2}{10} = \frac{775 \text{ lb/ft} \times (5 \text{ ft})^2}{10} = 1938 \text{ ft}\cdot\text{lb} = 23,250 \text{ in}\cdot\text{lb}$$

and the required section modulus (S) is given by:

$$S = \frac{M}{F'_b} = \frac{23,250 \text{ in}\cdot\text{lb}}{1421 \text{ psi}} = 16.36 \text{ in}^3$$

For the shear limitation, the maximum shear force for design is determined at distance d from the face of the support, assuming the shore will be at least 4×4 or have a head of equal or larger size if it is a metal shore. At the interior support where shear is greatest:

$$V = 0.6wl - w(d + l_b/2) = 0.6(775 \text{ lb/ft})(5 \text{ ft}) - 775 \text{ lb/ft} \left\{ \left[5.5/12 \right] + (3.5/2)/12 \right\} \text{ ft} = 1857 \text{ lb}$$

$$bd = (3/2)(V/F'_v) = (3/2) \times (1857 \text{ lb}/169 \text{ psi}) = 16.5 \text{ in}^2$$

The deflection limit is determined from:

$$\frac{l}{360} = \frac{1}{145} \frac{wl^4}{EI}$$

$$I = \frac{360}{145} \frac{775 \text{ lb/ft}}{12 \text{ in./ft}} \frac{(60 \text{ in.})^3}{1,400,000 \text{ psi}} = 24.73 \text{ in}^4$$

From these requirements, a 4×6 stringer is the optimum size meeting all the requirements and having the least area. The result also agrees with the size assumption for selecting the reference design values and size factor. If the size did not agree, the calculations would be repeated with an improved size assumption. A check is also necessary to make sure that there is adequate bearing area for the joist on the stringer.

The tributary load is:

$$P = 155 \text{ psf} \times 1.33 \text{ ft} \times 5 \text{ ft} = 1031 \text{ lb}$$

The allowable bearing stress is given by:

$$F'_{c\perp} = F_{c\perp} \times C_M \times C_b = 425 \text{ psi} \times 1.0 \times 1.0 = 425 \text{ psi}$$

and the actual stress is:

$$f_{c\perp} = \frac{P}{A} = \frac{1031 \text{ lb}}{1.5 \text{ in.} \times 3.5 \text{ in.}} = 196 \text{ psi} < 425 \text{ psi}$$

7.7.4 Shore Design

To determine the shore unbraced height, the slab thickness and depth of forming elements are subtracted from the floor-to-floor height:

$$l_e = 120 - 8 - 0.625 - 5.5 - 5.5 \text{ in.} = 100.4 \text{ in.}$$

For design purposes, the shore is assumed to be concentrically loaded, pinned at the top and the bottom and prevented from translation by an adequate overall form diagonal bracing system. The load to be supported based on the tributary area is:

$$P = 155 \text{ psf} \times 5 \text{ ft} \times 5 \text{ ft} = 3875 \text{ lb}$$

Two stress checks are necessary to size the shore: (1) the bearing perpendicular to the grain of the stringer at the upper end of the shore, and (2) the compression parallel to the grain of the shore (including the possibility of buckling). Evaluation of bearing first will establish a first trial size of the shore area. The allowable bearing stress is:

$$F'_{c\perp} = F_{c\perp} \times C_M \times C_b = 425 \text{ psi} \times 1.0 \times 1.0 = 425 \text{ psi}$$

C_b is assumed to be 1.0, because the bearing length is not yet known and the shore may sometimes be located at the end of the stringer. The required bearing area is given by:

$$A = \frac{P}{F'_{c\perp}} = \frac{3875 \text{ lb}}{425 \text{ psi}} = 9.12 \text{ in.}^2$$

A 4 × 4 shore is adequate for bearing perpendicular to the grain of the stringer and matches the width of the 4 × 6 stringer. For this 4 × 4 shore size, the allowable compression stress parallel to grain is:

$$F'_c = F_c \times C_D \times C_M \times C_F \times C_P = 1150 \text{ psi} \times 1.25 \times 1.0 \times 1.15 \times C_P = 1653 \text{ psi} \times C_P = F_c^* \times C_P$$

$$E'_{\min} = E_{\min} \times C_M = 510,000 \text{ psi} \times 1.0 = 510,000 \text{ psi}$$

Because the trial shore is square and braced only at the ends to resist translation, the l_e/d ratios for each buckling axis are equal; thus,

$$\frac{l_e}{d} = \frac{100.4 \text{ in.}}{3.5 \text{ in.}} = 28.68 < 50$$

and

$$F_{cE} = 0.822 E'_{\min} / (l_e/d)^2 = 0.822 \times 510,000 \text{ psi} / (28.68)^2 = 510 \text{ psi}$$

so

$$F_{cE} / F_c^* = 510 \text{ psi} / 1653 \text{ psi} = 0.308$$

and C_P from Equation 7.10 is:

$$C_P = \left[(1 + 0.308) / (2 \times 0.8) \right] - \left\{ \left[(1 + 0.308) / (2 \times 0.8) \right]^2 - (0.308 / 0.8) \right\}^{0.5} = 0.285$$

Thus, the allowable stress in compression parallel to the grain for the unbraced length is:

$$F'_c = F_c = 1653 \text{ psi} \times C_P = 1653 \text{ psi} \times 0.285 = 471 \text{ psi}$$

Because $F'_c > F'_{c\perp}$, compression perpendicular to the grain in the bearing controls the design, and the 4 × 4 shore is adequate.

In summary, the design requires 5/8-in. Plyform spanning the strong way, 2 × 6 joists at 16 in. on-center, 4 × 6 stringers at 5 ft on-center, and 4 × 4 shores at 5 ft on-center each way.

FIGURE 7.39 Wall-form components.

7.7.5 Bracing Design Considerations

The slab form must be braced, as a minimum, to resist the horizontal loads recommended by ACI 347-04. When the concrete columns have been placed prior to erection of the floor forms, the column can contribute to lateral stability if the form has an adequate horizontal diaphragm and is tied to the columns. Horizontal cross-bracing can be added to improve the diaphragm. Vertical cross-bracing in two directions at right angles, in combination with an adequate diaphragm, can also provide a workable system. The braces need not be located in the opening between every pair of shores (Figure 7.29). Often, they are located between alternate pairs of shores (and sometimes farther apart) in a well-dispersed, symmetrical pattern in each direction. The brace size is usually controlled by the buckling resistance in the compression direction of force, and the analysis and design proceed in a manner similar to that for the shore or wall form brace design. It is critical to provide a connection at the top and bottom ends of the brace that is adequate to resist the forces imposed.

7.8 Wall-Form Design Example

Assume that a form is needed for the placement of a 12-ft high wall. The general layout of the plywood sheathing, studs, and wales is shown in Figure 7.39. Because of the availability of the material from previous projects, the contractor wishes to use 3/4-in. B-B Plyform, Class I, plywood for the sheathing and No. 2 Southern Pine 2 × 4 studs and double 2 × 4 wales. Ties can be ordered to meet project needs. The project specification requires that the formwork element deflections be no greater than $l/240$. The plywood will be assumed to be used wet, as it is in contact with the fresh concrete, and the lumber elements will be assumed to be exposed to sufficient rain moisture on the job such that the wood moisture content might rise to above 19%. The normal weight 145 pcf concrete, made with Type II cement, has a slump of <7 in. and contains a set-retarding admixture. Internal vibration during placement will be controlled and limited to an immersion depth <4 ft. The rate of vertical placement (R) will be limited to 4 ft per hour, and the concrete temperature (T) is expected to be above a minimum of 80°F.

From the earlier section on lateral pressures, the maximum distributed pressure (p) for design on a working basis is given by Equation 7.2:

$$p_{\max} = C_w C_c [150 + 9000R/T] = 1.0 \times 1.2 [150 + (9000 \times 4/80)] = 720 \text{ psf}$$

The pressure is assumed to gradually increase with depth at a rate of 150 lb/ft³/ft until reaching the maximum uniform pressure at a depth of 720 psf/150 lb/ft³ or 4.8 ft. For purposes of illustrating the form design procedure, first consider the spacing of members in the uniform pressure region. Because the sizes of the members are predetermined, the unknowns are the maximum allowable spacings of their supports.

7.8.1 Sheathing Design

The plywood span is the spacing of the studs, and the 8-ft-long plywood panels can typically have three or more spans. The plywood allowable stresses adjusted for load duration (see Table 7.5) are:

$$F'_b = F_b \times C_D = 1545 \text{ psi} \times 1.25 = 1931 \text{ psi}$$

$$F'_v = F_v \times C_D = 57 \text{ psi} \times 1.25 = 71 \text{ psi}$$

$$E' = E = 1,500,000 \text{ psi}$$

Considering the loading to be a uniform load (w) of 1-ft unit width corresponding to the section properties of the plywood based on 12-in. width,

$$w = p_{\max} \times \text{unit width} = 720 \text{ psf} \times 1.0 \text{ ft} = 720 \text{ lb/ft}$$

For the limitation of flexural bending, the maximum allowable moment (M) is:

$$M = f'_b S = 1931 \text{ psi} \times 0.455 \text{ in.}^3 = 878 \text{ in.-lb} = 73.2 \text{ ft.-lb}$$

and the maximum span (l) is given by:

$$M = wl^2/10$$

$$73.2 \text{ ft.-lb} = 720 \text{ lb/ft} \times l^2/10$$

$$l = 1.01 \text{ ft} = 12.1 \text{ in.}$$

For the shear limitation, the support width is known to be 1.5 in., so the maximum shear force for design can be determined at the face of the support:

$$V = F'_v (lb/Q) = 71 \text{ psi} \times 7.187 \text{ in.}^2 = 510 \text{ lb}$$

$$V = 0.6wl - w(l_b/2)$$

$$510 \text{ lb} = 0.6(720 \text{ lb/ft})(l) - 720 [(1.5 \text{ in.}/2)/12 \text{ in./ft}]$$

$$l = 1.26 \text{ ft} = 15.4 \text{ in.}$$

For the deflection limit, the maximum span is determined from:

$$l/240 = (1/145)(wl^4/E'I)$$

$$l/240 = (1/145) \left[720 \text{ lb/ft} \times l^4 / \left(12 \text{ in./ft} \times 1,500,000 \text{ psi} \times 0.199 \text{ in.}^4 \right) \right]$$

$$l = 14.4 \text{ in.}$$

From these requirements, 12.1 in. (based on bending) is the maximum span of the plywood. Considering the 8-ft modular length of the plywood panel, provide 8 equal spans with the studs spaced at 12 in. on-center.

7.8.2 Stud Design

The stud span is the spacing of the double wales, and the studs can be constructed with a three-span continuous arrangement. Lateral buckling of the studs will be restrained by nailing the sheathing to the studs. Allowable stresses for the No. 2 Southern Pine 2 × 4 stud from Table 7.5 are as follows:

$$F'_b = F_b \times C_D \times C_M \times C_L \times C_F \times C_r = 1500 \text{ psi} \times 1.25 \times 0.85 \times 1.0 \times 1.0 \times 1.0 = 1593 \text{ psi}$$

$$F'_v = F_v \times C_D \times C_M = 175 \text{ psi} \times 1.25 \times 0.97 = 212 \text{ psi}$$

$$E' = E \times C_M = 1,600,000 \text{ psi} \times 0.9 = 1,440,000 \text{ psi}$$

Considering the loading as a uniform load (w) of 12-in. tributary width corresponding to the spacing of the studs,

$$w = q \times \text{tributary width} = 720 \text{ psf} \times 1.0 \text{ ft} = 720 \text{ lb/ft}$$

For the limitation of flexural bending, the maximum allowable moment (M) is:

$$M = F'_b S = 1593 \text{ psi} \times 3.063 \text{ in.}^3 = 4879 \text{ in.-lb} = 406.6 \text{ ft-lb}$$

and the maximum allowable span is given by:

$$M = w l^2 / 10$$

$$406.6 \text{ ft-lb} = 720 \text{ lb/ft} \times l^2 / 10$$

$$l = 2.37 \text{ ft} = 28.5 \text{ in.}$$

For the shear limitation, the maximum shear force for design is determined at distance d from the face of the support because the supporting wale width ($2 \times 1.5 \text{ in.} = 3 \text{ in.}$) is known. At the interior support where shear is greatest:

$$V = (2/3) F'_v b d = (2/3) \times 212 \text{ psi} \times 1.5 \text{ in.} \times 3.5 \text{ in} = 742 \text{ lb}$$

$$V = 0.6 w l - w(d + l_b / 2)$$

$$742 \text{ lb} = 0.6(720 \text{ lb/ft})(l) - 720 \text{ lb/ft} \left\{ \left[(3.5/12) + (3.0/2)/12 \right] \text{ ft} \right\} = 1857 \text{ lb}$$

$$l = 2.41 \text{ ft} = 28.9 \text{ in.}$$

The deflection limit is determined from:

$$l / 240 = (1/145)(w l^4 / E'I)$$

$$l / 240 = (1/145) \left[720 \text{ lb/ft} \times l^4 / \left(12 \text{ in./ft} \times 1,440,000 \text{ psi} \times 5.359 \text{ in.}^4 \right) \right]$$

$$l = 42.6 \text{ in.}$$

From these requirements, the spans for bending and shear control the maximum span, which is 28.5 in. Use 28 in. for layout convenience.

7.8.3 Wale Design

The wale span is the spacing of the form ties, and the wales can be constructed with a three-span continuous arrangement. Lateral buckling of the wale is not a problem because $d/b \leq 2$ to 1. Allowable stresses for the No. 2 Southern Pine double 2×4 wales are the same as determined above for the studs. The wale loading is actually a series of concentrated loads from the studs at 12 in. on-center; however, the starting position of the loads can vary in each span. Due to the complications involved in considering the many possible starting positions and recognizing that loads within distance d of the support can be neglected for shear calculations, it is often the practice in formwork to assume a uniform load to be adequately similar to many closely spaced equally concentrated loads (Hurd, 2005). This assumption works reasonably well when three or more equally spaced concentrated loads of equal magnitude are in the span. Considering the loading to be a uniform load (w) of 2.33-ft tributary width corresponding to the spacing of the wales,

$$w = q \times \text{tributary width} = 720 \text{ psf} \times 2.33 \text{ ft} = 1680 \text{ lb/ft}$$

For the limitation of flexural bending, the maximum allowable moment (M) is:

$$M = F_b' S = 1593 \text{ psi} \times 2 \times 3.063 \text{ in.}^3 = 9758 \text{ in.-lb} = 813 \text{ ft.-lb}$$

and the maximum allowable span is given by:

$$\begin{aligned} M &= w l^2 / 10 \\ 813 \text{ ft.-lb} &= 1680 \text{ lb/ft} \times l^2 / 10 \\ l &= 2.2 \text{ ft} = 26.4 \text{ in.} \end{aligned}$$

For the shear limitation, the maximum shear force for design is determined at distance d from the face of the support assuming that the tie-washer plate will have at least a 3-in. length of bearing. The wale interior support is examined where shear is greatest. At the interior support:

$$\begin{aligned} V &= (2/3) F_v' b d = (2/3) \times 212 \text{ psi} \times 2 \times 1.5 \text{ in.} \times 3.5 \text{ in.} = 1484 \text{ lb} \\ V &= 0.6 w l - w (d + l_b / 2) \\ 1484 \text{ lb} &= 0.6 (1680 \text{ lb/ft}) (l) - 1680 \text{ lb/ft} \left\{ \left[(3.5/12) + (3.0/2) \right] 12 \right\} \text{ ft} \\ l &= 2.17 \text{ ft} = 26.0 \text{ in.} \end{aligned}$$

The deflection limit is determined from:

$$\begin{aligned} l / 240 &= (1/145) (w l^4 / E T) \\ l / 240 &= (1/145) \left[1680 \text{ lb/ft} \times l^4 / \left(12 \text{ in./ft} \times 1,440,000 \text{ psi} \times 5.359 \text{ in.}^4 \right) \right] \\ l &= 40.5 \text{ in.} \end{aligned}$$

From these requirements, the maximum span is 26.0 in. and is controlled by shear. Select a wale span of 24 in. so the tie spacing can be coordinated easily with the stud spacing.

A check is also needed to make sure that there is adequate bearing area for the stud on the double wale. The tributary load is:

$$P = 720 \text{ psf} \times 1.0 \text{ ft} \times 2.33 \text{ ft} = 1678 \text{ lb}$$

The allowable bearing stress is given by:

$$F_{cL} = F_{cL} \times C_M \times C_b = 565 \text{ psi} \times 0.67 \times 1.0 = 378 \text{ psi}$$

and the actual stress is:

$$f_{cL} = P/A = 1678 \text{ lb} / (1.5 \text{ in.} \times 3.0 \text{ in.}) = 373 \text{ psi} < 378 \text{ psi}$$

7.8.4 Tie Design

Select the tie capacity to exceed the tie force (T) based on the tributary area supported:

$$T = p_{\max} \times \text{wale spacing} \times \text{tie spacing} = 720 \text{ psf} \times 2.33 \text{ ft} \times 2.0 \text{ ft} = 3350 \text{ lb}$$

Select a heavy snap tie with a 3350-lb working capacity, and check the bearing of the 3-in. square tie washer on the double wale (Figure 7.40):

$$f_{cL} = P/A = 3350 \text{ lb} / (2 \times 1.5 \text{ in.} \times 3.0 \text{ in.}) = 372 \text{ psi} < 378 \text{ psi}$$

7.8.5 Bracing Design

Braces are required to keep the form from overturning due to wind or incidental construction loads such as ladders leaning on the form or workers climbing on the form. The effects of an elevated work platform may also have to be considered in some designs. If designing for the minimum recommendations of ACI

FIGURE 7.40 Bearing of form tie bracket on double wood wale.

FIGURE 7.41 Layout of wall-form members.

347-04, the loadings would include a wind pressure of 15 psf or a line load of 100 lb/linear foot at the top, whichever is greater. The contractor desires to lay out the braces as shown in Figure 7.41, with the braces at 4 ft on-center, the brace attached at an elevation of 10 ft on the 12-ft form, and the brace anchored to the ground 7.5 ft from the form. This results in a brace length of 12.5 ft, including the adjustable connectors at each end. For design purposes, the brace is assumed to be concentrically loaded, pinned at the top and the bottom, and prevented from translation by the longitudinal rigidity of the form. The horizontal brace load (H) from the wind is:

$$H = 15 \text{ psf} \times 4 \text{ ft} \times 12 \text{ ft} \times 6 \text{ ft}/10 \text{ ft} = 432 \text{ lb}$$

Alternatively, the horizontal brace load from the 100 lb/ft line load is:

$$H = 100 \text{ lb/ft} \times 4 \text{ ft} \times 12 \text{ ft}/10 \text{ ft} = 480 \text{ lb}$$

The brace should be designed to resist a horizontal component of 480 lb, which results in an axial compression force (P) of:

$$P = 480 \text{ lb} \times 12.5 \text{ ft} / 7.5 \text{ ft} = 800 \text{ lb}$$

Try a No. 2 Southern Pine 2×4 brace with a bracing strut at mid-length in the weak buckling direction. For this 2×4 size, the allowable compression stress is:

$$F'_c = F_c \times C_D \times C_M \times C_F \times C_p = 1650 \text{ psi} \times 1.25 \times 0.8 \times 1.0 \times C_p = 1650 \text{ psi} \times C_p = F_c^* \times C_p$$

$$E'_{\min} = E_{\min} \times C_M = 580,000 \text{ psi} \times 0.8 = 464,000 \text{ psi}$$

Because the trial brace is rectangular, check the l_e/d ratios for each buckling axis:

$$\frac{l_1}{d_1} = \frac{150 \text{ in.}}{3.5 \text{ in.}} = 42.8 \leq 50$$

$$\frac{l_2}{d_2} = \frac{75 \text{ in.}}{1.5 \text{ in.}} = 50.0 \leq 50$$

For this short-term construction period loading, a l_e/d limit of 75 might also be considered if necessary. Thus, the weak axis controls, and $l_e/d = 50$. Substituting to determine C_p :

$$F_{cE} = 0.822E'_{\min} / (l_e/d)^2 = 0.822 \times 464,000 \text{ psi} / (50.0)^2 = 152 \text{ psi}$$

so

$$F_{cE} / F_c^* = 152 \text{ psi} / 1650 \text{ psi} = 0.092$$

and C_p from Equation 7.10 is:

$$C_p = \left[(1 + 0.092) / (2 \times 0.8) \right] - \left\{ \left[(1 + 0.092) / (2 \times 0.8) \right]^2 - (0.092 / 0.8) \right\}^{0.5} = 0.090$$

Thus, the allowable stress in compression parallel to the grain for the unbraced length is:

$$F'_c = F_c^* \times C_p = 1650 \text{ psi} \times C_p = 1650 \text{ psi} \times 0.090 = 149 \text{ psi}$$

$$f_c = P/A = 800 \text{ lb} / 5.25 \text{ in.}^2 = 153 \text{ psi} > 149 \text{ psi (not adequate)}$$

The 2×4 brace with the mid-length strut is slightly less than the needed section. Increase to a 2×6 brace with a mid-length strut, which will be adequate based on the increased area. Alternatively, a steel-pipe brace rated for the load at the extended length of 12.5 ft could be used. Appropriate connection, adequate for a tension or compression of 800 lb, must be made at the top and bottom ends of the brace by bolting, nailing, or use of a rated commercial hardware device, without inducing significant eccentricities.

A possible layout for the wall form is shown in Figure 7.41. The top and bottom extensions of the studs beyond the wales are usually about 1/3 of the adjacent span up to perhaps 12 in. At the top of the form, where the pressures are lower, the span of the studs can be investigated with ramp loading, and the wale spacing can often be increased, sometimes eliminating a level of wales and ties in comparison to the number required for a constant spacing. Careful consideration of all design details, communicating these requirements to the form craftspersons, and providing knowledgeable verification of execution can lead to safe and economical support of concrete during construction.

8.1 Introduction

Structural formwork and its support system must be given careful consideration in two different respects: (1) loads that are applied to the formwork and its supports, and (2) loads that the formwork and its supports apply to the structure. The first is the subject of Chapter 7 on formwork and falsework; the second is the subject of this chapter.

8.2 Construction Loads

8.2.1 Design Considerations

In the construction of multistory buildings with reinforced concrete floor slabs, a step-by-step sequence of operations is employed. The sequence is comprised of the steps of setting up shoring on the most recently poured floor, forming the next floor, setting up reinforcement, and concreting the slab. Because the floor below the one being concreted is usually only a few days old, it is common practice to leave

FIGURE 8.1 Construction sequence using three levels of shores.

formwork supports in place between that floor and a small number of floors below it. A typical construction cycle using three levels of shores is illustrated in Figure 8.1.

In discussing construction loads, it is convenient to express them as a factor times the sum of the self-weight of the floor and the dead load of the formwork. The term **floor loading ratio** is used for this factor. Progressive slab deflections that had been causing problems in Sweden in the early 1950s led to the first study by Nielsen (1952) of a rational approach to stripping formwork for floors. Nielsen gave a detailed analysis of the distribution of load between a system of connected shores and floor slabs. The method considered the deformation characteristics of both the slabs and the shores. The maximum load ratio obtained by Nielsen on a slab assuming three levels of shores was 2.56. Grundy and Kabaila (1963) developed a simplified method of analysis for floor loads based on the following assumptions:

1. The slabs behave elastically.
2. Initially, the slabs are supported from a completely rigid foundation.
3. The shores supporting the slabs and formwork may be regarded as a continuous uniform elastic support, the elastic properties of which may be expressed by a coefficient K , where K is the load intensity that produces unit deformation of the support.
4. Any added load is distributed among the supporting slabs in proportion to their relative flexural stiffnesses.

Grundy and Kabaila assumed that K was infinite and carried out their analyses assuming a constant flexural stiffness for all connected slabs, as well as a flexural stiffness increasing with age. It was found that the error introduced by assuming equal relative stiffnesses for the floors is not appreciable.

Figure 8.2 represents the construction of a multifloor building using three levels of shores (and forms) for a 7-day casting cycle, with stripping in 5 days. The loads carried by the slabs and the shores, in terms of the loading ratio, are indicated on the figure adjacent to the element concerned. Floors 1, 2, and 3, supported from the ground by stiff shores, cannot deflect and therefore carry no load; all the load is carried by the shores directly to the foundation. At the age of 26 days, the lowest level of shores is removed, allowing all three slabs to deflect and carry their self-weight. The removed shores are placed on the third floor slab and the fourth floor is poured. As all three supporting slabs have equal stiffness, the weight of the newly poured slab is carried equally by the three lower slabs. The absolute maximum load ratio occurs when the shores connecting the supporting assembly with the ground level are removed; however, the load ratio converges for upper floor levels. For the same structure considered by Nielsen, Grundy

FIGURE 8.3 Load-ratio history for three levels of shores.

and Kabaila obtained an absolute maximum load ratio of 2.36, while the converged value for upper floor levels was 2.00 (Figure 8.2). The most heavily loaded slab is always the last slab that is supported directly from the foundation. The load time histories of the third floor slab and a typical slab are shown in Figure 8.3. Altering the number of shored levels has little effect on the maximum load ratio value; however, by

TABLE 8.1 Floor-Loading Ratio

Author	Maximum Value (Converged Values in Brackets)				Comment
	$m = 2$	$m = 3$	$m = 4$	$m = 5$

decreasing the number of shored levels, the age of the slab at which the maximum ratio occurs also decreases. Beresford (1964) used infinite as well as various finite values of K (see assumption 3 above) and found that the results of floor-load analysis were not appreciably affected.

In addition to variations in moduli of elasticity due to concrete age, cracking of slabs occurring during construction affects the distribution of loads among slabs in the supporting assembly. Sbarounis (1984) reported that incorporating the effects of cracking into the load distribution factors for the supporting slabs reduced the previously calculated maximum load ratios by approximately 10%. Blakey and Beresford (1965) recommended a stepped sequence of construction in a system of floors and shores as a means of controlling the construction loads imposed on both the slabs and the shores. The advantage of this method lies in the fact that a young slab is given more time to develop adequate strength before the application of construction load from the casting of a new slab directly above. Table 8.1, adapted from Wheen (1982), shows clearly that all writers on the subject agree that floor loading ratios during construction usually exceed values of 2.

The sequence of construction illustrated in Figure 8.1 uses three sets of forms. Economic considerations usually necessitate the removal of formwork as soon as possible for reuse. This necessity has given rise to the widespread practice of *reshoring*. The reshoring technique typically involves using only one level of forms or shores and several levels of reshores. Basically, the forms or shores are removed from beneath a slab, allowing it to deflect and carry its own weight; reshores are then installed, allowing the load during subsequent concrete placement to be shared between the various slabs in the supporting assembly. At the time of installation, reshores carry no significant load. Figure 8.4 illustrates a construction scheme with two levels of shoring and one level of reshoring.

Agarwal and Gardner (1974) in Canada and Marosszeczy (1972) in Australia analyzed the loads imposed on slabs using the shoring/reshoring method of construction and utilizing the same simplifying assumptions as used earlier by Grundy and Kabaila (1963). The slab loads when using two levels of shores and one level of reshores are calculated as shown in Figure 8.5. The time history of slab loads using two levels of shores and one level of reshores is shown in Figure 8.6.

Taylor (1967) suggested a technique of stripping formwork to reduce the loads imposed on a slab during construction. By slackening and tightening adjustable shores before each new slab is cast, the loads distributed to the shores and slabs are reduced considerably. With this method, all shores at one level must be slackened simultaneously; thus, it requires greater supervision and inspection. Taylor reported that the maximum load ratio was reduced from the 2.36 obtained by Grundy and Kabaila to a

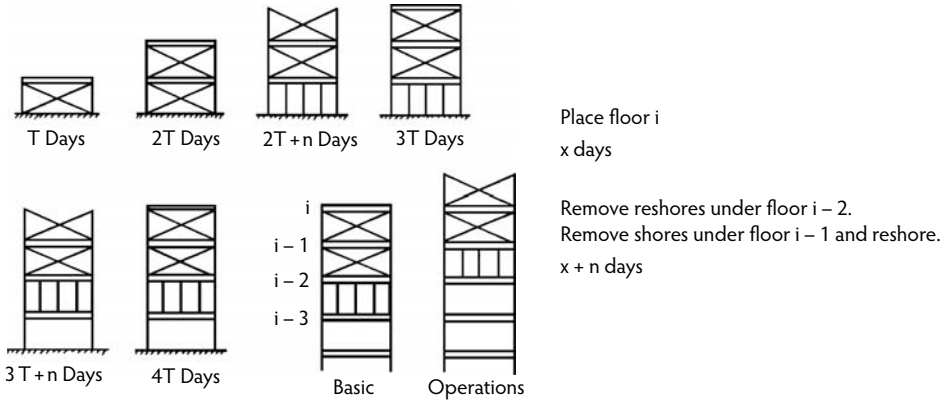

FIGURE 8.4 Construction sequence using two levels of shores and one level of reshores.

value of 1.44. Taylor's method is the same in principle as stripping and immediate reshoring of a slab. Marosszky (1972) described complete release and reshoring of a floor slab such that the floor carried its own dead weight at a time $(T - 1)$ days, where T is the construction cycle of floors. This reshoring technique produces less construction load on the supporting slabs and props when compared with using undisturbed shores.

Although the load ratios previously defined reflect the slab-plus-formwork dead weights, a construction live load is also present. Whereas the dead load can be estimated with reasonable certainty, the live loads can vary significantly depending on the construction method used to place concrete. ACI Committee 347 (2004) recommends that the design live load should be at least 50 psf (2.4 kPa) of the horizontal projection. A comprehensive study (Fattal, 1983) on construction loads in concrete buildings indicated that, when concrete is placed by a bucket, the live load may be as high as 40 to 50 psf (1.9 to 2.4 kPa). On the other hand, the American National Standards Institute (ANSI) Standard A10.9 (1997) does not provide a numerical value and leaves the determination of live load to the formwork designer; however, the standard does list factors to be considered in estimating the design load, such as the weight of workers, equipment, runways, and impact of concrete.

Hurd (2005) has suggested a minimum construction live load of 50 psf (2.4 kPa) for designing forms. Lasisi and Ng (1979) presented a method to include the live-load effect. For a typical flat-plate structure, assuming a supporting assembly of two shore levels plus one reshore level, a construction live load of 50 psf (2.4 kPa) removed after the casting day, and a constant modulus of elasticity for the connected slabs, the absolute maximum load ratio would increase 9% over that predicted by Grundy and Kabaila (1963). Both Agarwal and Gardner (1974) and Sbarounis (1984) accounted for the construction live-load effect by increasing the maximum load carried by the lowest slab in the supporting assembly. Sbarounis recommended additional loads, due to a 50-psf (2.4-kPa) live load, of $55/N$ and $35/N$ psf ($2.6/N$ and $1.7/N$ kPa) for uncracked and cracked slabs, respectively, with N representing the total number of levels in the supporting assembly.

Table 8.2 shows absolute maximum and converged maximum load ratios on slabs and supporting props for various combinations of levels of shores and reshores. Table 8.2 and Figure 8.6 indicate that the use of two levels of shoring and one level of reshoring, rather than three levels of shores, reduces the

TABLE 8.3 Comparison of Construction Loads with Service Loads

Construction Loads (psf)		Service Loads (psf)	
8-in. slab	100	8-in. slab	100
Formwork	10	Ceiling and mechanical	15
Subtotal	110	Partitions	20
		Live load	50
		Total (after 28 days)	185

1.00 at 26 days	110		

^a Deflection not restrained beyond 19 days.

^b Allowed to deflect under these construction loads at 12 days. Further deflections partly restrained for the next 7 days.

absolute maximum load ratio from 2.00 to 1.78. This is advantageous in most situations, although with reshoring the maximum load ratios come into play at an earlier age than with shoring, as should be apparent from Figure 8.2 and Figure 8.5. Table 8.3 presents construction loads for floor 3, which experiences the absolute maximum load ratio. The construction loads are compared with the design service loads in the table. It is clear that the construction loads are more critical than the design loads. Also important, construction loads act on concrete that has not attained the age at which it is supposed to experience design service loads.

8.2.2 Field Verification

Agarwal and Gardner (1974) used field measurements to check the accuracy of various analysis methods for estimating the shore and slab load distribution. Their investigation consisted of directly measuring the load ratios applied to shores and reshores during construction and determining the loads carried by the floor slabs at different stages of construction. The shore and reshore loads for two buildings were measured: Alta Vista Towers in Ottawa, Ontario, Canada, and Place du Portage in Hull, Quebec, Canada. Steel shores were used for both structures. Three levels of shores and four levels of reshores were used to temporarily support the flat-slab floors in the construction of the 22-story Alta Vista Towers. Measurement of the shore and reshore loads, for the shore and reshore arrangements shown in Figure 8.7, was limited to the 7th through the 13th stories. Three levels of shores and no reshores were used in the construction of the 27-story Place du Portage structure, which is a flat-slab office building. The shoring arrangement is shown in Figure 8.8. Measurements were taken from the 19th through the 22nd stories.

According to Liu et al. (1985a), three factors concerning the field measurement data should be noted:

1. Field measurements were not taken from the ground level, so the actual slab and shore loads of the entire system during construction were not available.
2. Typical shores and reshores chosen for instrumentation were located in the central portions of the slabs (Figure 8.7 and Figure 8.8); thus, the influence of the surrounding boundary beams and columns was less pronounced. From the measured data reported in Agarwal and Gardner (1974),

the coefficient of variation of the shore axial force varied from 0.04 to 0.23, depending on the distance of the shore from the boundary line.

3. The values of the modulus of elasticity of concrete (E_c) and the shore height were not reported in Agarwal and Gardner (1974). Without these, it is not possible to use the measured shore-load data to check other methods further.

Comparisons between field measurements for both buildings and the slab and shore loads given by the simplified analysis of Grundy and Kabaila (1963) are reported in Agarwal and Gardner (1974). To check the assumptions of equal slab stiffness originally used by Grundy and Kabaila, the slab shore loads were calculated by both using equal slab stiffnesses and varying the slab stiffness for each floor to account for an increase in E_c with age. Table 8.4 shows the comparison of field measurements for each story in both buildings to the calculated maximum slab and shore loads.

Good agreement between the predictions of simplified analysis and the field measurements was generally observed. Uses of variable slab stiffnesses in the simplified analysis produced closer agreement: The maximum discrepancy for variable slab stiffness was less than 10%, but for constant slab stiffness it was as high as 16%. Further, it was shown in Agarwal and Gardner (1974) that the calculated results based on either constant or variable slab stiffnesses consistently predicted the correct construction step and the location of the maximum shore and slab loads.

Lasisi and Ng (1979) carried out measurements on 5 regular floors to investigate peak construction loads on slabs, shores, and reshores in a 15-story flat-slab office building in Ottawa, Canada. One level of shores and two levels of reshores were utilized in construction. The period between the casting of a slab section and the next slab directly above was 10 days on average. The forms were supported on tubular steel shores. Reshores were made of telescopic steel jacks. The average stripping time for a slab in the instrumented section of the building was 5 days. Measurement on this building was commenced during concreting of the 7th-floor slab and continued until after the stripping of the 11th floor. An interior bay of a section of the building was instrumented. Load cells were installed beneath a shore or a reshore at the chosen location; the instrumented reshore on each level was vertically below the load cell placed underneath the scaffold shore.

Shore and reshore loads were calculated by Lasisi and Ng (1979) using Grundy and Kabaila's simplified analysis, taking into consideration the presence of 50 psf (2.4 kPa) of construction live load during concrete placement. As can be seen from Table 8.5, there was reasonably close agreement between measured and theoretical maximum shore loads; however, the loads measured on the reshores were found to be on average considerably less than the corresponding theoretical values.

8.2.3 Refined Analysis

Liu et al. (1985a) carried out refined analysis to determine shore and slab load distribution, considering the actual rigidity of shores and the time-dependent variation in slab stiffness due to concrete maturity. Their refined analysis technique treated the shore-slab interaction as a two-dimensional problem and was based on the following assumptions:

1. The slabs behave elastically and their stiffnesses are time-dependent.
2. The shores and reshores behave as continuous uniform elastic supports, and their axial stiffnesses are finite and time-independent.
3. The foundation is rigid.
4. The joints between the shores and slabs are pinned connections.
5. The slab edges are either fixed or simply supported.

Comparison of maximum loads computed by the simplified Grundy-Kabaila method (1963) with those predicted by the refined method indicated that the maximum relative differences in the two methods varied between -5 and +9%. Because the effect of shore stiffness was not considered, the calculated results using the simplified method showed larger errors (deviations from field measurements) than the results

predicted using the refined method. The simplified Grundy–Kabaila method reliably predicted the construction step and location where the maximum slab and shore loads would occur but generally underestimated the actual load ratios; consequently, the maximum slab and shore loads predicted by the simplified method could be corrected using a modification coefficient. Liu et al. (1985a) recommended that the value of the modification coefficient for the simplified method vary from 1.05 to 1.10 for design purposes.

Liu et al. (1985b) also used a more realistic three-dimensional (3-D) model to check the approximation of the Grundy–Kabaila simplified method and the two-dimensional (2-D) refined method (Liu et al., 1985a). A number of simplifying assumptions were made when they conducted the refined 3-day analysis. First, the reinforced concrete slabs were assumed to behave elastically; their stiffnesses were taken as time dependent; slab edges were either free or rotationally fixed (but free to deflect). Second, the vertical deflections of the slabs at the slab–column joints were neglected. Third, the weight and structural details of each floor were assumed to be similar. Fourth, the shores and reshores were presumed to be continuous ideal elastic supports with equal axial stiffnesses; the joints between the shores and the slabs were assumed to be pin-ended connections. Finally, the foundation was assumed to be rigid and unyielding. The influences of foundation rigidity, column deformation, and slab aspect ratio were examined using the 3-day model.

On the basis of the various factors examined for the 3-day model, the following conclusions and observations were made:

1. The maximum slab loads given by the 2-day refined analysis and the 3-day refined analysis were nearly identical. The maximum shore load increased slightly for the 3-day refined analysis.
2. Variations of the foundation rigidity affected slab displacements more than the maximum shore loads and slab moments. When the rigidity of the foundation decreased, the maximum slab moments and the maximum shore loads decreased.
3. The vertical deformation of columns could be neglected when computing the maximum shore loads and slab moments.
4. A change in the slab aspect ratio produced very little increment in the maximum shore load for slabs with free edges. For a slab with fixed edges, the total increment of the maximum shore load was 3% for the aspect ratios examined (between 0.6 and 1.0).

In all cases examined, a modification coefficient that varied from 1.05 to 1.10 could be used to conservatively correct the results of the Grundy–Kabaila simplified method. It was found that nonuniform distribution of shore stiffnesses did not change the prediction of the construction step and location where the maximum slab moments and shore loads occurred.

Stivaros and Halvorsen (1990) questioned the good agreement mentioned earlier between the simplified Grundy–Kabaila method and existing field measurements. They pointed out that, in actual building cases investigated (Agarwal and Gardner, 1974; Lasisi and Ng, 1979), steel shoring systems had been used, justifying the Grundy–Kabaila assumption of infinite shoring system stiffness. The fact that the field measurements were observations around the center of the slab and thus ignored the influence of structural continuity contributed to the good agreement between field data and the theoretical values. Another important fact was that field measurements were not taken from the ground level, so the complete loading–unloading construction cycle was not recorded.

Stivaros and Halvorsen (1991) also pointed out that most practical methods for analyzing construction loads have employed single-bay idealizations of frames. This is a definite limitation to the proper evaluation of the punching shear forces that are the critical load effect in most flat-slab systems. A single-bay structural idealization cannot fully assess the maximum shear force effects at the columns from both direct shear forces and unbalanced moments; therefore, a practical and simple method that took into account the continuity of concrete structures over several bays, as well as the interaction of the floor slabs and the shoring system over several stories, was thought to be needed.

The *equivalent frame method* (EFM) of analysis was found by Stivaros and Halvorsen (1990) to be a reasonable procedure for accomplishing the preceding goal. The EFM was first developed as a viable procedure for analyzing reinforced concrete slab systems, particularly for the effects of gravity loads. It has been applied to lateral load analysis of slab systems, as well. A computer program was developed for the study to determine the construction load distribution among the slabs and the shoring system during the construction of multistory buildings. A multistory building under construction is modeled according to the assumptions of the equivalent frame method as described in ACI Committee 318 (2005). A schematic representation of an idealized structure is shown in Figure 8.9. The shores and reshores are replaced by an equal number of elastic supports, each having a stiffness equal to the total stiffness of the corresponding shores. It is assumed that the reshores carry no load at the time of installation. The load of the freshly cast concrete is applied to the top-floor shores as concentrated loads. The load is shared among the shores according to their tributary areas. The connection between the shores or reshores and the floor slabs can be reasonably assumed to be pin-jointed. At ground level, shores and reshores are assumed to be supported on a rigid foundation. The EFM concepts are applied to determine the frame member stiffness coefficients. The idealized two-dimensional frame is then analyzed elastically using conventional stiffness analysis procedures to determine the member forces, including the axial load on the shoring system.

A typical floor plan of the equivalent frame used by Stivaros and Halvorsen (1990) for parametric studies is shown in Figure 8.10. The shores and reshores are idealized as series of vertical truss-type elements, each with a stiffness equivalent to the total stiffness of the shores or reshores on the row it

FIGURE 8.10 Typical plan of equivalent frame studied by Stivaros and Halvorsen. (From Stivaros, P.C. and Halvorsen, G.T., *ACI Struct. J.*, 87(5), 589–596, 1990.)

represents. Two levels of shores and one level of reshores were assumed, with a construction rate of one floor per week. Only the slab dead load was considered in analysis. The loads in slabs were normalized to the self-weight of each slab, and the loads on shores were normalized to the weight of the slab supported by the shores. The construction operations were denoted with a set of two numbers. The first number represented the number of the floor level under construction, and the second indicated the phase of construction (Figure 8.11). The numeral 1 indicated casting of the top floor, 2 denoted the removal of lower level of reshores, and 3 indicated the removal of the lower level shores; for example, “Operation 3-2” referred to the maximum slab or shore loads during removal of the lower level of reshores after casting the third floor. The maximum slab loads evaluated using the EFM, both multi-bay and single-bay models, along with the corresponding results of the simplified Grundy–Kabaila method and results by Liu et al., are plotted in Figure 8.12 with respect to the sequential construction operations. The results reported for the EFM multi-bay model are those for an interior bay.

Figure 8.13 and Figure 8.14 show the variation of the maximum slab load with respect to the number of reshored levels for both the equivalent frame model and the simplified method for one level and two levels of shoring, respectively. As the figures show, the EFM and the simplified method diverge as the number of reshored levels increases. As the number of shored levels increases (comparing both figures), the diversion of the EFM from the simplified method slows. Figure 8.14 shows that the combination of

FIGURE 8.11 Construction phases. (From Stivaros, P.C. and Halvorsen, G.T., *Concrete Int.*, 14(8), 27–32, 1992.)

FIGURE 8.12 Comparison of methods of construction load analysis. (From Stivaros, P.C. and Halvorsen, G.T., *ACI Struct. J.*, 87(5), 589–596, 1990.)

two shored levels and one reshored level (the combination used by Liu et al.) is a case where the EFM and the simplified method converge with a difference of about 5%. The difference increases as the number of reshored levels increases, approaching 15% when three reshored levels are used. Considering the case of the one-shore scheme with four reshored levels from Figure 8.13, the difference between the two methods is about 30%.

Figure 8.15 shows the variation of the maximum slab load with respect to the number of reshored levels for one level of shoring and for both the single-bay and multi-bay models. As can be seen, the two methods diverge as the number of reshored levels increases. The multi-bay model always predicts higher maximum slab loads than the single-bay model, with differences as great as 14% in the case of three reshored levels.

FIGURE 8.13 Comparison of EFM and simplified method: one shored level. (From Stivaros, P.C. and Halvorsen, G.T., *ACI Struct. J.*, 87(5), 589–596, 1990.)

FIGURE 8.14 Comparison of EFM and simplified method: two shored levels. (From Stivaros, P.C. and Halvorsen, G.T., *ACI Struct. J.*, 87(5), 589–596, 1990.)

FIGURE 8.15 Comparison of single-bay and multi-bay models: one shored level. (From Stivaros, P.C. and Halvorsen, G.T., *ACI Struct. J.*, 87(5), 589–596, 1990.)

The stiffness of the shoring system affects the behavior of both the single-bay and multi-bay models. Figure 8.16 shows the variation of the maximum slab load of the first floor during the casting of the third floor with respect to the shoring system stiffness for both models. The stiffness of the shoring system varies

FIGURE 8.16 Comparison of analytical models based on shoring system stiffness. (From Stivaros, P.C. and Halvorsen, G.T., *ACI Struct. J.*, 87(5), 589–596, 1990.)

in five increments from the actual value to 20 times the actual value. As the figure shows, the multi-bay model predicts higher values than the single-bay model. As the stiffness of the shoring system increases, both methods tend to converge. When the stiffness reaches a relatively infinite value, both methods produce almost identical results approaching the simplified method. The multi-bay model is more advantageous than the single-bay model because it represents the concrete structure as a more realistic monolithic continuous frame. Furthermore, it can provide information about the total shear force (due to the gravity load and the unbalanced moments) applied to slab–column joints. Considering the advantages that multi-bay analysis offers, it is preferable to apply the more realistic continuous multi-bay model when possible.

To investigate the influence of slab stiffness, the construction example was analyzed for two construction cycles of 3 and 7 days. The percentages of the 28-day concrete strength for the 3- and 7-day cycles were determined using the maturity concept. The age of the slab at which the maximum load occurred differed for the two construction schedules. Figure 8.17 shows the maximum slab loads with respect to the slab age in days for the 3- and 7-day construction rates. Despite the fact that both schedules predict almost identical maximum slab loads, the ages of the slabs under these loads are different. The maximum load of 2.08 times the slab self-weight for the 3-day schedule occurred on a 7-day-old slab, whereas the maximum load of 2.06 times the slab self-weight for the 7-day schedule occurred on a 19-day-old slab.

The presence of drop panels around the columns or beams between columns can significantly increase the stiffness of slabs and columns. To determine the influence of drop panels and beams, the construction example was analyzed for two additional conditions. The first condition assumes beams spanning between columns in both directions, with an overall depth of 20 in. (510 mm) and width of 12 in. (300 mm). The second condition assumes a type of flat-slab construction with square drop panels around columns with depth equal to half the slab thickness of 7.1 in. (180 mm) and length equal to one third the 236-in. (6000-mm) span. Figure 8.18 compares the results of the cases with and without beams or drop panels. The slabs with beams or drop panels share higher loads than the flat-plate slab because the beams and the drop panels increase the stiffness of the slab. A similar construction load distribution occurs when the slab thickness and, consequently, the slab stiffness are increased. The degree of influence of beams, drop panels, or the slab thickness on the construction load distribution is totally dependent on the size of these structural members relative to the global size of the equivalent frame as well as on the stiffness of the shoring system. If the stiffness of the shoring system is infinite relative to the stiffness of the supported slabs, the effect of the slab stiffness variation on the load distribution will be minimal.

To determine the influence of the axial shore stiffness on the load distribution, the construction example was investigated by increasing the shoring system stiffness by 5 increments up to 20 times the actual value. The slab stiffness and the number of shores or reshores per bay were kept constant for this analysis, the results of which are shown in Figure 8.19. As can be seen, the shoring stiffness has a

FIGURE 8.17 Comparison of construction rates. (From Stivaros, P.C. and Halvorsen, G.T., *ACI Struct. J.*, 87(5), 589–596, 1990.)

FIGURE 8.21 Influence of the number of reshored levels on the maximum slab load. (From Stivaros, P.C. and Halvorsen, G.T., *ACI Struct. J.*, 87(5), 589–596, 1990.)

considerable influence on the construction load distribution. The difference in the slab load, for example, is up to 40% during Operation 3-1. Figure 8.19 also incorporates the values predicted by the simplified method and illustrates how the shoring system stiffness affects the slab load during construction. An important observation from Figure 8.19 is that, as the stiffness of the shoring system approaches infinity, the predicted maximum slab loads using the EFM draw near the loads predicted by the simplified method. This clearly shows that the differences of the equivalent frame method and the simplified method are very much due to the shoring system stiffness.

It has been common practice to consider the shores to be spaced closely enough that shore reactions can be treated as uniformly distributed. This may not be true when a flying-truss forming system is used. To determine the effects of various shoring systems, the construction example was investigated using two, three, four, and five shores in each bay. The total stiffness of shores and reshores in each bay was kept constant for all cases and was evenly distributed among the shores and reshores. The slab stiffness was also kept constant. As can be seen from Figure 8.20, the two-shore-per-bay configuration predicts lower values than the five-shore configuration throughout the construction, despite the fact that the total stiffness of the shoring system is the same for both cases. The fewer the number of shores per bay, the

FIGURE 8.22 Influence of the number of shored levels on the maximum slab load. (From Stivaros, P.C. and Halvorsen, G.T., *ACI Struct. J.*, 87(5), 589–596, 1990.)

lower the construction load the floor slabs share. A comparison between the two-shore and five-shore configurations and the simplified method shows that the two-shore configuration is closer to the simplified method. Thus, the simplified method is more suitable for cases with fewer concentrated reaction-type shores per bay. The simplified method underestimates the construction slab loads during the early stages of construction, when a more dense shoring system is used. Figure 8.21 shows how the maximum slab load changes with respect to the number of reshored levels for combinations with one and two levels of shoring. The maximum slab load decreases at a decreasing rate as the number of reshored levels increases.

According to the simplified method, any applied construction load is distributed equally among the interconnected slabs or in proportion to their relative stiffnesses. As the number of slabs in the shoring system increases, the amount of load that each slab shares decreases; however, when compressible shores or reshores are used, the uppermost floor slabs carry most of the applied construction load, leaving the lower slabs without much load to share. This makes the additional reshored levels redundant and ineffective. Figure 8.22 shows the relationship between the number of shored levels, along with various combinations of reshores, and the maximum slab load. The figure shows that as the number of the shored levels increases, the maximum slab load also increases. Although this is true, the maximum slab load occurs on an older slab, which has more strength, when more shored levels are used. During the design of the shoring system, it is important to determine the minimum number of shored levels required so the maximum applied load will occur on a slab that is old enough to have developed the necessary strength to withstand this load. Either the number of shored levels or the construction rate can be controlled. It is also interesting to observe from Figure 8.22 that all reshore combinations, from zero to three reshored levels, tend to converge as the number of shored levels increases; therefore, it is important to determine the maximum number of reshored levels that can cause an appreciable change in the maximum applied construction loads.

8.3 Properties of Concrete at Early Ages

As discussed in detail in Section 8.2, when the usual shore/reshore method of construction is used for multistory buildings, high early-age, short-duration loads are imposed on the slabs. These loads can be comparable in magnitude to, or even exceed, the design service loads. Also, they are applied to concrete slabs that have not achieved their specified concrete strength. The consequences may very well be structural failure, unless adequate precautions are taken during construction, based on proper evaluation of the construction loads and sound knowledge of the early-age properties of concrete. Structural failures

FIGURE 8.23 Compressive strength of concrete dried in laboratory air after preliminary moist curing. (From Price, W.H., *ACI J.*, 22(6), 417–432, 1951.)

may be associated with collapse of a structure or part of a structure or structural member, or they may be associated with structural distress that causes a significant reduction in the capability of a structure to function in the way originally intended. The former may be classed as *strength* failures, while the latter may be referred to as *serviceability* failures. Strength failures occur relatively infrequently but can be catastrophic, sometimes leading to loss of life. Serviceability failures occur more frequently and, although not usually catastrophic or life threatening, may result in significant financial losses. Objectionable cracking or excessive floor-slab deflections are examples of serviceability failure.

Heavy construction loads applied to slabs at early ages may be a major contributing factor to strength failures as well as serviceability failures. To understand the strength-related consequences, which may be due to deficiencies of flexural-axial loading strength, shear strength, or bond strength, a knowledge of the compressive strength, tensile strength, shear strength, and bond strength of concrete is necessary. For an understanding of the serviceability related consequences, a knowledge of the modulus of elasticity, shrinkage, and creep of concrete at early ages is essential.

8.3.1 Compressive Strength

Price (1951) and Klieger (1958) generated considerable information on the development of the compressive strength of concrete under varying temperature and moisture conditions. Temperature and moisture have pronounced effects on the strength development of concrete. Figure 8.23 (Price, 1951) shows that the development of strength stops at an early age when a concrete specimen is exposed to dry air with no previous moist curing. Concrete exposed to dry air from the time it is placed is about 42% as strong at 6 months as concrete that was continuously moist cured. Specimens cured in water at 70°F were found to be stronger at 28 days than those cured in a fog room at 100% relative humidity. The richer mixes showed up to better advantage than the leaner ones under water curing. The strength of the water-cured specimens was about 10% higher than that of the fog-cured specimens for concrete having water/cement ratios of 0.55 by weight.

Curing temperatures have a marked effect on the strength development of concrete. Test results were obtained by casting and curing concrete specimens at different temperatures, and under such treatment the highest temperatures developed the highest 28-day strength. Other concrete specimens were cured at 70°F after holding the specimens at different casting temperatures for 2 hours. Such treatment produced

opposite results, as the specimens made at the lower temperatures produced the highest 28-day strength. It was speculated that concrete cast at high temperatures is weakened by rapid setting, which is not overcome by subsequent curing at 70°F. Continued curing at higher temperatures for the full 28-day period, as was done for some of the first sets of specimens, accelerated the strength development sufficiently to produce the highest strength for the highest temperature. At later ages, however, the specimens made and cured at higher temperatures had lower strengths than those made and cured at lower temperatures.

In Klieger's (1958) investigation, concretes were mixed and placed at temperatures of 40, 55, 73, 90, 105, and 120°F. Specimens were tested at ages 1, 3, 7, and 28 days; 3 months; and 1 year. ASTM Type I, II, and III cements were used. Concretes were made both with and without calcium chloride as an accelerator. An air-entraining agent was added at the mixer to entrain a prescribed amount of air in all of the concretes. In Part I (73°F and lower), all specimens were continuously moist cured (100% relative humidity) at the mixing and placing temperature for 28 days or less, depending on the test age. After the initial 28-day period, half of the remaining specimens for tests at 3 months and 1 year, were stored at 73°F and 100% relative humidity and the other half at 73°F and 50% relative humidity. Additional concretes were mixed and placed at 40°F, and, immediately after placing, the specimens in their molds were stored at 25°F. All surfaces were kept continuously moist (prior to and following removal from the molds at 1 day of age) for 28 days or less, depending on test age. After 28 days, specimens kept for tests at 3 months and 1 year were treated like those stored at other temperatures.

In Part II (73°F and higher), half of the specimens were moist cured for 7 days at the fabrication temperature, and the remainder of the specimens were moist cured for 28 days at the fabrication temperature. At the end of the 7- and 28-day preliminary curing periods, each half was divided into two groups, one cured at 73°F and 100% relative humidity and the other at 73°F and 50% relative humidity. For concretes mixed at 40 and 73°F, the net water/cement ratio was held at the value determined to produce the target slump at 55°F. In Part II, the net water/cement ratio for each concrete was such as to produce a certain target slump at a concrete temperature of 90°F. Continuity between Parts I and II was provided by a repetition of the tests for all the concretes at 73°F; a small difference in net water/cement ratio between the concretes in Parts I and II was found.

Two 6 × 6 × 30-in. beam specimens were cast for each test age and curing condition. Beams were tested in flexure with load applied at the third points of an 18-in. span. Two flexural breaks were obtained for each beam. The two beam ends were tested for compression as 6-in. modified cubes. (For the particular aggregate, the ratio of 6 × 12-in. cylinder strength to 6-in. modified cube strength was taken as 0.93.) For each test age, concrete mix, and curing procedure, two beams were tested, yielding four flexural and four compressive test results for averaging. All strength tests were made at a concrete temperature of 73°F. Specimens stored at temperatures other than 73°F were placed in the 73°F moist room for temperature conditioning 1/2 hour before testing.

Figure 8.24 shows all the compressive strength data for three types of cement with and without accelerator, expressed as percentages of the strengths developed at 73°F for each test age. This figure shows the accelerating effect of temperatures above 73°F on the early-age strengths, with a sacrifice, however, in strength at later ages. On the other hand, concretes placed and cured at temperatures below 73°F, while showing lower strengths at the early ages, show strengths at the later ages in excess of those developed at 73°F. This was true even for concretes mixed and cast at 40°F and stored immediately after casting at 25°F for the first 28 days. For concretes cured initially at low temperatures followed by curing at 73°F, 1-year strengths close to or exceeding those for the concretes cured continuously moist at 73°F were attained only when moist curing was employed. Air drying during this subsequent 73°F period generally resulted in lower strengths, particularly for concretes made with Type I and Type II cements.

The data in Figure 8.24 are for concretes moist cured the first 28 days. In Part II, a 7-day moist-curing period at the fabrication temperature was included for comparison with the 28-day moist-curing period at the fabrication temperature. The qualitative interpretation of results for this 7-day group was similar to that for the 28-day group. The following conclusions were drawn by Klieger (1958):

FIGURE 8.24 Effect of temperature on compressive strength of concretes made with different types of cement with and without an accelerator. (From Klieger, P., *ACI J.*, 29(12), 1063–1081, 1958.)

1. At 1, 3, and 7 days, concrete compressive strengths increase with an increase in the initial and curing temperatures of the concrete.
2. Increasing the initial and curing temperatures results in considerably lower compressive strengths at 3 months and 1 year.
3. Compressive strengths of concretes made with the three cement types used were influenced in a like manner by temperature; differences were in degree only.
4. These tests indicated that there is a temperature during the early life of concrete that may be considered optimum with regard to strength at later ages or, more strictly, at comparable degrees of hydration. This temperature is influenced somewhat by cement type. For Types I and II, this temperature appears to be 55°F; for Type III, 40°F.
5. For concretes with calcium chloride added, compressive strength increases due to the accelerator were proportionately greater at early ages and lower temperatures.

ACI Committee 209 (1971) has recommended the following expression for the time-dependent strength of moist-cured (as distinct from steam-cured) concrete using Type I cement:

$$f'_a = \frac{t}{4.00 + 0.85t} f'_c \quad (8.1)$$

where t is the time in days from casting up to loading and f'_c is the 28-day compressive strength of concrete.

The validity of Equation 8.1 at very early ages needs to be examined in view of the data reported above and a significant volume of European data that is also available (Byfors, 1980; RILEM Commission 42-CEA, 1981).

8.3.2 Tensile Strength and Bond Strength

Price (1951) reported data (Table 8.6) from tests at the Portland Cement Association showing relationships among the compressive strength, the tensile strength, and the flexural strength (modulus of rupture) of concrete. It was not stated, but may probably be assumed, that the tensile strength reported was the splitting tensile strength: “The ratio of tensile to compressive strength decreases as the compressive strength increases and approaches a constant of about 7% for higher compressive strength. Other published data

TABLE 8.6 Comparison of Compressive, Flexural and Tensile Strength of Plain Concrete

Strength of Plain Concrete (psi)			Ratio (%)		
Compressive	Modulus of Rupture	Tensile	Modulus of Rupture to Compressive Strength	Tensile Strength to Compressive Strength	Tensile Strength to Modulus of Rupture
1000	230	110	23.0	11.0	48
2000	375	200	18.8	10.0	53
3000	485	275	16.2	9.2	57
4000	580	340	14.5	8.5	59
5000	675	400	13.5	8.0	59

FIGURE 8.25 Variation of bond with strength of concrete. (From Price, W.H., *ACI J.*, 22(6), 417-432, 1951.)

indicate that the ratio of tensile to compressive strength decreases as the age of concrete increases to the same constant value of 7%” (Price, 1951). Figure 8.25 shows in a qualitative way the relationship between bond strength and compressive strength of concrete for plain and deformed bars. The ratio of bond strength to compressive strength decreases as compressive strength increases. The bond strength of the deformed bars is 24% of the compressive strength for 2000-psi concrete and 18% of the compressive strength for 5000-psi concrete. “The relationship of bond to compressive strength apparently is not changed materially by air entrained in the proportions recommended” (Price, 1951).

Klieger’s (1958) flexural strength data for the same concretes as were tested for Figure 8.24 showed that the discussion about compressive strength data in the previous section applies equally to the flexural strength data. Flexural strengths at early ages increased with increase in temperature. At later ages, the effect of temperature was reversed. Concretes made and cured at lower temperatures showed the highest flexural strengths at 1 year. The optimum temperatures for flexural strength development appeared to be the same as those for compressive strength. The use of calcium chloride frequently resulted in flexural

strengths at later ages that were somewhat lower than for comparable concretes without calcium chlorides. Maximum reductions noted were on the order of 10%.

In a significant investigation by Gardner and Poon (1976), six series of specimens were cast: three using Type I and three using Type III cement concretes. The specimens for each series were cast from a single batch of ready-mixed concrete. Two series of tests, one made with Type I cement concrete and one with Type III cement concrete, were carried out with the concrete continuously moist cured at 72°F (22°C). Two series of specimens, one made using Type I cement concrete and one with Type III cement concrete, were subjected to extended curing under wet burlap at a steady temperature of 55°F (13°C). The remaining two series were subjected to extended curing under wet burlap at a steady temperature of 35°F (2°C). All specimens were cast at 72°F (22°C). To examine the effect of time on the concrete, specimens were cured at 72°F (22°C) for different periods before exposing them to low temperatures. One third of the specimens of each series were cured for 1 day, one third were cured for 3 days, and the remainder were cured for 7 days at 72°F (22°C) before being transferred to the cooler environment.

Each series involved the casting of 160 standard 6 × 12-in. (150 × 300-mm) cylinders and 80 bond specimens. Five specimens were tested for compressive strength, 5 for tensile strength, and 5 for bond strength at 1, 3, 7, 14, and 28 days and at 3 months for each of the 14 curing schedules. All concretes had a specified cylinder strength of 4000 psi (28 MPa) and a water/cement ratio of approximately 0.5. Compressive and tensile strengths were determined by the standard compressive strength test and the split-cylinder test, respectively, on 6 × 12-in. (150 × 300-mm) cylinders. Bond specimens were made by casting a #6 reinforcing bar into a 6 × 6-in. (150 × 150-mm) cylindrical block of concrete to closely approximate the ASTM standard specimen, which is a 6-in. (150-mm) concrete cube or a 6 × 6 × 12-in. (150 × 150 × 300-mm) block of concrete. Concrete strengths are plotted against the log of time in Figure 8.26 for concretes made with Type I cement and subjected to extended curing at 35°F (2°C). Figure 8.26 was typical of all six batches of concrete. The following conclusions were drawn:

1. Temperature influences the tensile and bond strength development of concrete in much the same manner as it does compressive strength development. Compressive strength, tensile strength, and bond strength are all related, and an increase in one is reflected in the others.
2. The compressive strength, tensile strength, and bond strength of concrete at early ages increases with increased curing temperature. The lower the initial curing temperature the greater the eventual ultimate strength of the concrete, provided curing is continuous.
3. Bond strength and tensile strength are proportional to the 0.8 power of the cylinder strength at the appropriate age. Neither extended curing at temperatures of 35°F (2°C) and 55°F (13°C) nor type of cement appears to have any significant effect on the interrelationship of bond strength or tensile strength and cylinder strength.
4. With respect to construction schedules, there is a 5 to 9% gain in the 7-day and in the 14-day strengths due to casting and curing Type I cement concretes for 3 days and 7 days, respectively, at 72°F (22°C), compared to casting and curing for 1 day at 72°F (22°C).
5. Type III cement concretes exhibited a small strength gain due to prolonged initial curing at 72°F (22°C) when subjected to extended curing at 35°F (2°C) but no strength gain for prolonged initial curing at 72°F (22°C) when subjected to extended curing at 55°F (13°C).

Lew and Reichard (1978) performed three types of tests:

1. Compressive strength tests of cylindrical specimens
2. Splitting tensile tests of cylindrical specimens
3. Bond-strength tests using cylindrical pullout specimens

All three types of tests were made on specimens cured at different temperatures—35°F (2°C), 55°F (13°C), and 73°F (22°C)—and tested at nine ages (1, 2, 3, 5, 7, 14, 21, 28, and 42 days).

FIGURE 8.26 Variation of concrete strength with temperature for Type I cement concrete cured at 35°F (2°C). (From Gardner, N.J. and Poon, S.M., *ACI J.*, 73(7), 405–409, 1976.)

The combined effect of temperature and time, or *maturity*, usually expressed in degree-days (or hours), may be defined as the sum of the product of the increment of age of cure and the difference between curing and some temperature below which no strength gain takes place. The definition can be written as:

$$M = \sum (T - T_0) \Delta t \tag{8.2}$$

where T is temperature of the concrete at any time, T_0 is a datum temperature below which no strength gain of concrete takes place, and Δt is the increment of time. Taking $T_0 = 10^\circ\text{F}$ (-12°C) on the basis of prior tests, Equation 8.2 can be rewritten as:

$$M = \sum (T - 10) \Delta t \tag{8.3}$$

FIGURE 8.27 Mechanical properties normalized with respect to 28-day values vs. maturity. (From Lew, H.S. and Reichard, T.W., *ACI J.*, 75(10), 533–542, 1978.)

where T is in degrees Fahrenheit. Analysis of Lew and Reichard's test data showed that the compressive strength of concrete can be related to maturity expressed in terms of concrete temperature and age of cure. When related to maturity, the elastic modulus data and the splitting tensile strength data of specimens cured at various temperatures could be treated as being from a single group. The pullout strength, when not governed by the yielding of the bar, could be expressed in terms of maturity, thus allowing the specimens cured at various ages to be treated as a single group as well. Figure 8.27 (Lew and Reichard, 1978) shows that, at early ages, the rate of increase in the splitting tensile strength is about the same as that of the compression strength, whereas the rate of increase in the pullout bond strength and the modulus are slightly greater than that of the compressive strength.

Carino and Lew (1982) performed a series of statistical analyses on published data of Gardner and Poon (1976), on published data from the National Bureau of Standards (NBS) (Lew and Reichard, 1978), and on previously unpublished data from the NBS. These data were used to determine the best relationship between the splitting tensile strength and the compressive strength of normal weight concrete, which was then compared with a larger group of published data. The unpublished data were from tests of specimens made with concretes similar to those reported in Lew and Reichard (1978) but which were allowed to cure under ambient, outdoor conditions. Three replicate specimens were tested at ages ranging from 1 to 37 days.

This study clearly indicated that the assumed proportionality of splitting tensile strength to the square root of compressive strength is not the most precise relationship when dealing with a wide range of compressive strengths. The square-root relationship was originally formulated on the basis of tests on mature concrete with strengths generally greater than 2500 psi (17.2 MPa). For low compressive strength, the current ACI formula overestimates splitting tensile strength and underestimates it for high compressive strength. A simple power law of the form $f'_{sp} = (f'_c)^b$ was found to be a more precise representation of data over the full range of concrete strengths. For the Gardner–Poon data and data from the two series of NBS tests mentioned above, the best-fit estimate of b was found to be 0.73. When additional data from four different published references and from other unpublished work at NBS were added to the mix, $f'_{sp} = (f'_c)^{(0.71)}$ seemed to be appropriate for estimating the average expected splitting tensile strength. The function $f'_{sp} = (f'_c)^{(0.71)}$ appeared to give a reasonable lower bound estimate, overestimating about 10% of the data.

8.3.3 Punching Shear Strength

According to Nilson (1991) (who was discussing mature concretes), a reasonable estimate for the split-cylinder strength (f'_{sp}) is 6 to 7 times the square root of f'_c for normal weight concretes. The true tensile strength (f'_t) is on the order of 0.5 to 0.7 times f'_{sp} (3 to $5\sqrt{f'_c}$), and the flexural tension strength (f'_r) (modulus of rupture) varies from 1.25 to 1.75 times f'_{sp} (7.5 to $12\sqrt{f'_c}$). The smaller of the foregoing factors apply to higher strength concretes and the larger to lower strength concretes. The modulus of rupture controls the behavior of flexural members subject to large bending moments and small shear forces; for large shear forces, the concern becomes safety against premature failure due to diagonal tension in the concrete, resulting from combined shear and longitudinal flexural stresses. In flexural members subject to large shear forces and small bending moments, *web-shear* cracks can be expected to form when the diagonal tension stress in the vicinity of the neutral axis becomes equal to the tension strength of the concrete (3 to $5\sqrt{f'_c}$). In members subject to large shear forces as well as large bending moments, *flexure-shear* cracks form when the diagonal tension stress at the tip of one or more flexural cracks exceeds the tensile strength of the concrete.

The information presented on the early-age modulus of rupture and split-cylinder strength of concrete in the previous section is directly relevant to the flexural and diagonal tension failure of beams and one-way slabs; however, as noted, one of the common causes of failure of flat-plate structures during construction is insufficient early-age punching shear strength under relatively high construction loads. Direct knowledge of early-age punching shear strength was thus thought to be desirable and was investigated by Gardner (1960). A relatively large number of circular flat plates were made and subjected to a centrally applied load through a circular steel plate. All steel was located on the tension side of the slabs, and steel ratios ranged from .5 to 5%. Concrete strengths ranged from 2000 to nearly 8000 psi (14 to 56 MPa). Slab thicknesses were 2, 4, and 6 in. (50, 100, and 150 mm). An initial set of experiments was undertaken to determine how punch diameter relates to slab thickness, slab outer diameter, and slab support diameter.

For punching shear failure to occur, at least three slab thicknesses are necessary between the punch and the slab support. Further, the slab outer diameter must be sufficient to enable the slab steel to develop any necessary stress; otherwise, the slab will fail in bond, separating at the reinforcement level. All specimens with zero steel or steel ratios less than .5% failed in flexure. A few conclusions, given below, were drawn.

1. The steel ratio in the region 3 dia from the column should be of the order of 0.5% in each direction, and the spacing should be similar to the effective depth.
2. In all cases, slabs should be detailed so some of the top (negative-moment tension) steel passes through the column.
3. The cube-root relationship between shear strength and concrete strength is preferable to the square-root relationship currently used by ACI Committee 318 (1995).
4. If the punching shear strength is in doubt, the shear perimeter should be increased by using larger columns or column capitals.

8.3.4 Modulus of Elasticity

Figure 8.28 (Byfors, 1980) provides an idea of how the stress–strain relationship of concrete in compression changes with age. The stress and the strain are related to the compressive strength and the corresponding strain, respectively. The arrows in the figure indicate possible unloading. The relationship is practically a straight-line curve at a very early age (5.0 hours). It can be seen that the strain is mainly inelastic. At this early stage, concrete shows properties that are similar to those of a claylike material. A few hours later (7.9 hours), the stress–strain relationship has a completely different character. One can see a clear transition from the elastic to the inelastic part. After 15.8 hours, the curve begins to get the appearance that normally characterizes concrete. The continued changes in the appearance of the stress–strain relationship are not, however, as radical any longer. Expressed in absolute values, the changes are nevertheless large.

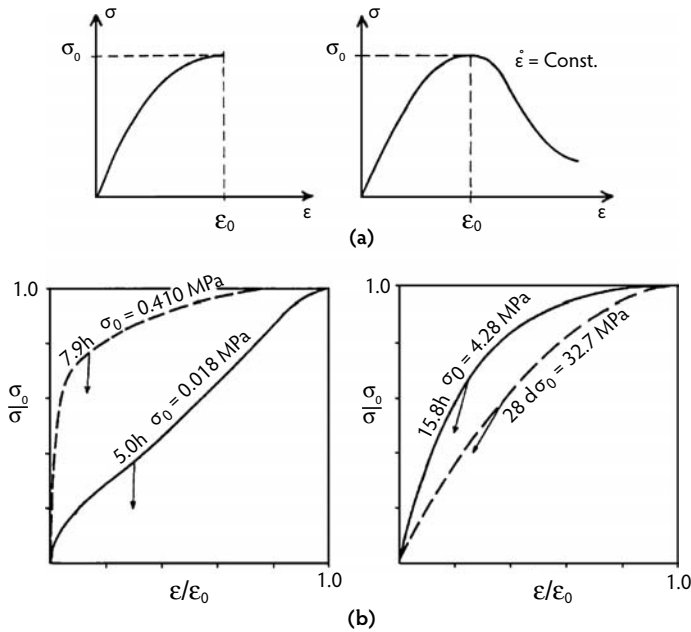

FIGURE 8.28 (a) Basic appearance of the compressive stress–strain relationship under constant stress rate (left) and constant deformation rate (right). (b) Change of shape of compressive stress–strain relationship at early ages. (From Byfors, J., *Plain Concrete at Early Ages*, Fo. 3, No. 80, Swedish Cement and Concrete Research Institute, Stockholm, Sweden, 1980.)

The modulus of elasticity, also referred to as elastic modulus, Young's modulus, and Young's modulus of elasticity, may be defined in general terms as the ratio of normal stress to corresponding strain for tensile or compressive stress below the proportional limit of the material. Few materials, however, conform to Hooke's law throughout the entire range of stress–strain relations; deviations there from are caused by inelastic behavior. If the deviations are significant, the slope of the tangent to the stress–strain curve at the origin, the slope of the tangent to the stress–strain curve at any given stress, the slope of the secant drawn from the origin to any specified point on the stress–strain curve, or the slope of the chord connecting any two specified points on the stress–strain curve may be considered to be the modulus. In such cases, the modulus is designated as the initial tangent modulus, the tangent modulus, the secant modulus, or the chord modulus, respectively, and the stress is stated. Normally, the static modulus of elasticity of concrete is determined as the secant modulus based on short-term experiments but with a certain number of repeated loadings at a low stress level. The stress level for the secant's intersection is normally 30 to 50% of strength. Studies leading to the expression for modulus of elasticity of concrete in ACI Committee 318 are summarized in Pauw (1960), where E_c was defined as the slope of the line drawn from a stress of zero to a compressive stress of $0.45f'_c$.

According to ACI Committee 209 (1971), the effect of age of concrete at the time of loading on the modulus of elasticity of concrete is accounted for when strength of concrete at the time of loading, rather than at 28 days, is inserted into the modulus of elasticity expression given in ACI Committee 318 (1995):

$$E_{ct} = 33w^{1.5}\sqrt{f'_{ct}} \quad (8.4)$$

where E_{ct} is the time-dependent modulus of elasticity of concrete in pounds per square inch, w is the unit weight of concrete in pounds per cubic feet, and f'_{ct} is the time-dependent concrete strength in pounds per square inch.

FIGURE 8.29 Modulus of elasticity of concrete at early ages. (From Fintel, M. et al., *Column Shortening in Tall Structures: Prediction and Compensation*, EB108-01D, Portland Cement Association, Skokie, IL, 1987.)

Equation 8.4 for normal weight concrete, when converted to SI units and rounded off, becomes:

$$E_{ct} = 5000\sqrt{f'_{ct}} \tag{8.5}$$

where E_{ct} and f'_{ct} are in megapascals. Figure 8.29 shows a comparison of Equation 8.5 with the experimental information currently available on the modulus of elasticity of concrete at early ages (RILEM Commission 42-CEA, 1981). Concrete strengths of 1 MPa (145 psi) and less are encountered only during the first few hours after concrete is poured and are not of interest here. In the range of practical interest, the ACI equation relating modulus of elasticity and strength agrees quite favorably with the trend of experimental results.

8.3.5 Shrinkage of Unreinforced (Plain) Concrete

Shrinkage of concrete is caused by the evaporation of moisture from the surface. The rate of shrinkage is high at early ages and decreases with an increase in age until the curve becomes asymptotic to the final value of shrinkage. The rate and amount of evaporation and consequently of shrinkage depend greatly upon the relative humidity of the environment, size of the member, and mix proportions of the concrete. In a dry atmosphere, moderate-size members (24-in. or 600-mm diameter) may undergo up to half of their ultimate shrinkage within 2 to 4 months, whereas identical members kept in water may exhibit growth instead of shrinkage. In moderate-size members, the inside relative humidity has been measured at 80% after 4 years of storage in a laboratory at 50% relative humidity.

8.3.5.1 Basic Value of Shrinkage

Let e_s denote the ultimate shrinkage of 6-in. (150-mm)-diameter standard cylinders (volume-to-surface or $v:s$ ratio = 1.5 in. or 38 mm) moist-cured for 7 days and then exposed to 40% ambient relative humidity. If concrete has been cured for less than 7 days, multiply e_s by a factor linearly varying from

1.2 for 1 days of curing to 1.0 for 7 days of curing (ACI Committee 209, 1971). Attempts have been made in the past to correlate e_s with parameters such as concrete strength. In view of available experimental data (Russell and Corley, 1977), it appears that no such correlation may in fact exist. The only possible correlation is probably that between e_s and the water content of a concrete mix (Troxell et al., 1968). In the absence of specific shrinkage data for concretes to be used in a particular structure, the value of e_s may be taken as between 500×10^{-6} in./in. (mm/mm) (low value) and 800×10^{-6} in./in. (mm/mm) (high value) (Fintel et al., 1987). The latter value has been recommended by the ACI Committee 209 (1971).

8.3.5.2 Effect of Member Size

Because evaporation occurs from the surface of members, the volume-to-surface ratio of a member has a pronounced effect on the amount of its shrinkage. The amount of shrinkage decreases as the size of the specimen increases. For shrinkage of members having volume-to-surface ratios different from 1.5, e_s must be multiplied by the following factor:

$$SH_{v:s} = \frac{0.037(v:s) + 0.944}{0.177(v:s) + 0.734} \quad (8.6a)$$

where $v:s$ is the volume-to-surface ratio in inches. The metric equivalent of Equation 8.6a is:

$$SH_{v:s} = \frac{0.015(v:s) + 0.944}{0.070(v:s) + 0.734} \quad (8.6b)$$

where $v:s$ is the volume-to-surface ratio in millimeters. As indicated in Fintel et al. (1987), Equation 8.6 is based on laboratory data (Hansen and Mattock, 1966) and European recommendations (CEB, 1964, 1972). Much of the shrinkage data available in the literature were obtained from tests on prisms of a 3×3 -in. (75×75 -mm) section ($v:s = 0.75$ in. or 19 mm). According to Equation 8.6, the size coefficient for prisms of that size is 1.12. Thus, shrinkage measured on a prism of a 3×3 -in. (75×75 -mm) section must be divided by 1.12 before the size coefficient given by Equation 8.6 is applied. It should be cautioned, however, that as the specimen size becomes smaller, the extrapolation to full-size members becomes less accurate.

8.3.5.3 Effect of Relative Humidity

The rate and amount of shrinkage greatly depend upon the relative humidity of the environment. If ambient relative humidity is substantially greater than 40%, then e_s must be multiplied by:

$$SH_H = \begin{cases} 1.40 - 0.010H & \text{for } 40 \leq H \leq 80 \\ 3.00 - 0.030H & \text{for } 80 \leq H \leq 100 \end{cases} \quad (8.7)$$

where H is the relative humidity in percent. Average annual values of H should probably be used. Maps giving average annual relative humidities for locations around the United States are available (Fintel et al., 1987). If locally measured humidity data are available, however, they are likely to be more accurate than information such as that included in Fintel et al. (1987) and should be used in conjunction with Equation 8.7, which is based on ACI Committee 209 (1971) recommendations. A comparison with European recommendations is shown in Fintel et al. (1987). If shrinkage specimens are stored under job-site conditions rather than under standard laboratory conditions, the correction for humidity, as given by Equation 8.7, should be eliminated.

8.3.5.4 Progress of Shrinkage with Time

Hansen and Mattock (1966) established that the size of a member influences not only the final value of shrinkage but also the rate of shrinkage, which appears to be only logical. Their expression giving the progress of shrinkage with time is:

FIGURE 8.30 Progress of shrinkage with time. (From Fintel, M. et al., *Column Shortening in Tall Structures: Prediction and Compensation*, EB108-01D, Portland Cement Association, Skokie, IL, 1987.)

$$SH_t = \frac{\epsilon_{st}}{\epsilon_s} = \frac{t}{26.0e^{0.36(v:s)} + t} \tag{8.8}$$

where ϵ_{st} and ϵ_s are shrinkage strains up to time t and time infinity, respectively, and t is measured from the end of moist curing. Equation 8.8 is compared in Figure 8.30 with the progress of shrinkage curve from the *Recommendations for an International Code of Practice for Reinforced Concrete* (CBE, 1964). Also shown in Figure 8.30 is a comparison of Equation 8.8 with the progress of shrinkage relationship recommended by ACI Committee 209 (1971). It should be noted that both the ACI and Cement and Concrete Association (C&CA) (CBE, 1964) and the ACI Committee 209 (1971) relationships are independent of the volume-to-surface ratio.

8.3.6 Creep of Unreinforced (Plain) Concrete

Creep is a time-dependent increment of the strain of a stressed element that continues for many years. The basic phenomenon of creep is not yet conclusively explained. During the initial period following the loading of a structural member, the rate of creep is significant. The rate diminishes as time progresses until it eventually approaches zero. Creep consists of two components:

1. Basic (or true) creep occurs under conditions of hygral equilibrium, which means that no moisture movement occurs to or from the ambient medium. In the laboratory, basic creep can be reproduced by sealing a specimen in copper foil or by keeping it in a fog room.
2. Drying creep results from an exchange of moisture between the stressed member and its environment. Drying creep has its effect only during the initial period under load.

Creep of concrete is very nearly a linear function of stress up to stresses that are about 40% of the ultimate strength. This includes all practical ranges of stresses in columns and walls. Beyond this level, creep becomes a nonlinear function of stress. For structural engineering practice, it is convenient to consider specific creep, which is defined as the ultimate creep strain per unit of sustained stress.

8.3.6.1 Value of Specific Creep

Specific creep values can be obtained by extrapolating results from a number of laboratory tests performed on samples prepared from the actual mix to be used in a structure. It is obvious that sufficient time for such tests must be allowed prior to the start of construction, as reliability of the prediction improves

FIGURE 8.31 Creep vs. age of concrete at time of loading. (From Fintel, M. et al., *Column Shortening in Tall Structures: Prediction and Compensation*, EB108-01D, Portland Cement Association, Skokie, IL, 1987.)

with the length of time over which creep is actually measured. A way of predicting basic specific creep (excluding drying creep), without testing, from the modulus of elasticity of concrete at the time of loading was proposed by Hickey (1968) on the basis of long-term creep studies at the Bureau of Reclamation in Denver. A simpler suggestion was made in Fintel et al. (1987), as described below:

Let ϵ_c denote the specific creep (basic plus drying) of 6-in. (150-mm)-diameter standard cylinders ($v:s = 1.5$ in. or 38 mm) exposed to 40% relative humidity following about 7 days of moist curing and loaded at the age of 28 days. In the absence of specific creep data for concretes to be used in a particular structure, the following likely values of ϵ_c may be used:

$$\epsilon_c = 0.003/f'_c \text{ (low value) to } 0.005/f'_c \text{ (high value)} \tag{8.9a}$$

where ϵ_c is in inch per inch per kips per square inch if f'_c is in kips per square inch, or in inch per inch per pounds per square inch if f'_c is in pounds per square inch. The metric equivalent of Equation 8.9a is:

$$\epsilon_c = 0.000435/f'_c \text{ (low value) to } 0.000725/f'_c \text{ (high value)} \tag{8.9b}$$

where ϵ_c is in millimeter per millimeter per megapascal if f'_c is in megapascal, or in millimeter per millimeter per kilopascal if f'_c is in kilopascal. The lower end of the proposed range is in accord with specific creep values suggested by Neville (1981). The upper end agrees with laboratory data obtained by testing the concretes used in Water Tower Place in Chicago (Russell and Corley, 1977).

8.3.6.2 Effect of Age of Concrete at Loading

For a given mix of concrete, the amount of creep depends not only on the stress level but also to a great extent on the age of the concrete at the time of loading. Figure 8.31 shows the relationship between creep and age at loading as developed by Comité Européen du Béton (CEB, 1972), using available information from many tests. The coefficient CR_{LA} relates the creep for any age at loading to the creep of a specimen loaded at the age of 28 days. The 28-day creep is used as a basis of comparison, the corresponding CR_{LA} being equal to 1.0. Figure 8.31 also depicts the following suggested relationship (Fintel et al., 1987) between creep and age at loading:

$$CR_{LA} = 2.3t_{LA}^{-0.25} \tag{8.10}$$

where t_{LA} is the age of concrete at the time of loading, in days. The form of Equation 8.10 is as suggested by the ACI Committee 209 (1971). Equation 8.10 gives better correlation with the CEB mean curve than the corresponding equation suggested by the ACI Committee 209. Figure 8.31 also provides comparison with a few experimental results (Lew and Reichard, 1978; Pfeifer et al., 1971). According to Equation 8.10, the creep of concrete loaded at 7 days of age is 41% higher than that of concrete loaded at 28 days.

8.3.6.3 Effect of Member Size

Creep is less sensitive to member size than shrinkage, as only the drying-creep component of the total creep is affected by the size and shape of members, whereas basic creep is independent of size and shape. For members with volume-to-surface ratios different from 1.5 in. or 38 mm, ϵ_c should be multiplied by:

$$CR_{v:s} = \frac{0.044(v:s) + 0.934}{0.1(v:s) + 0.85} \quad (8.11a)$$

where $v:s$ is the volume-to-surface ratio in inches. The metric equivalent of Equation 8.11a is:

$$CR_{v:s} = \frac{0.017(v:s) + 0.934}{0.039(v:s) + 0.85} \quad (8.11b)$$

where $v:s$ is the volume-to-surface ratio in millimeters. As indicated in Fintel et al. (1987), Equation 8.11 is based on laboratory data (Hansen and Mattock, 1966) and European recommendations (CEB, 1964, 1972). Much of the creep data available in the literature were obtained by testing 6-in. (150-mm)-diameter standard cylinders wrapped in foil. The wrapped specimens simulated very large columns. Equation 8.11 yields a value of $CR_{v:s}$ equal to 0.49 for $v:s = 100$. Thus, it is suggested that creep data obtained from sealed specimen tests should be multiplied by $2(1/0.49 \cong 2)$ before the modification factor given by Equation 8.11 is applied to such data.

8.3.6.4 Effect of Relative Humidity

For an ambient relative humidity greater than 40%, ϵ_c should be multiplied by the following factor, as suggested by ACI Committee 209 (1971):

$$CR_H = 1.40 - 0.01H \quad (8.12)$$

where H is the relative humidity in percent. Again, it is suggested that the average annual value of H be used.

8.3.6.5 Progress of Creep with Time

The progress of creep relationship recommended by ACI Committee 209 (1971) is given by the following expression:

$$CR_t = \frac{\epsilon_{ct}}{\epsilon_c} = \frac{t^{0.6}}{10 + t^{0.6}} \quad (8.13)$$

where ϵ_{ct} is the creep strain per unit stress up to time t , and t is measured from the time of loading. This relationship is plotted in Figure 8.32, where it compares well with the creep-vs.-time curve suggested in European recommendations (CEB, 1964).

8.3.6.6 Irreversible Nature of Creep

Another important aspect of creep of concrete must be addressed. Figure 8.33 shows the strain history of a concrete specimen that was stored in air at near 100% relative humidity to eliminate shrinkage and subjected to a sustained axial stress that was removed at 120 days from the time of loading. The instantaneous recovery is followed by a gradual decrease in strain, called *creep recovery*. The shape of the creep-

FIGURE 8.32 Progress of creep with time. (From Fintel, M. et al., *Column Shortening in Tall Structures: Prediction and Compensation*, EB108-01D, Portland Cement Association, Skokie, IL, 1987.)

FIGURE 8.33 Creep strain vs. time when part of sustained load is removed at a certain time after application. (From Fintel, M. et al., *Column Shortening in Tall Structures: Prediction and Compensation*, EB108-01D, Portland Cement Association, Skokie, IL, 1987.)

recovery curve is similar to that of the creep curve, but the recovery approaches its maximum value much more rapidly. The reversal of creep is not complete, so any sustained application of load, even over only a day, results in a residual deformation (Neville, 1981).

8.3.7 Effects of Drying on Flexural Cracking

Hover (1988) pointed out that the resistance to flexural cracking in beams and slabs decreases sharply during periods in which the surface of the concrete is drying, such as the period that immediately follows the removal of forms. Hover considered a 6-in. (150-mm)-thick reinforced concrete slab with a concrete compression strength of 4000 psi (28 MPa). The solid lines in Figure 8.34a show the increase in the allowable superimposed live load as a function of the amount of reinforcing steel for continuous spans of 14 to 18 ft (4.2 to 5.4 m). The allowable load was determined by subtracting the factored dead load from the ultimate load and dividing the result by an appropriate load factor. The dotted lines in Figure 8.34a indicate the superimposed live load that caused cracking of the same slabs. Note that, for lightly reinforced slabs, the cracking load is actually greater than the safe allowable load. This means that cracking will be avoided by complying with the load limitations imposed on the basis of strength calculations. Whereas the allowable

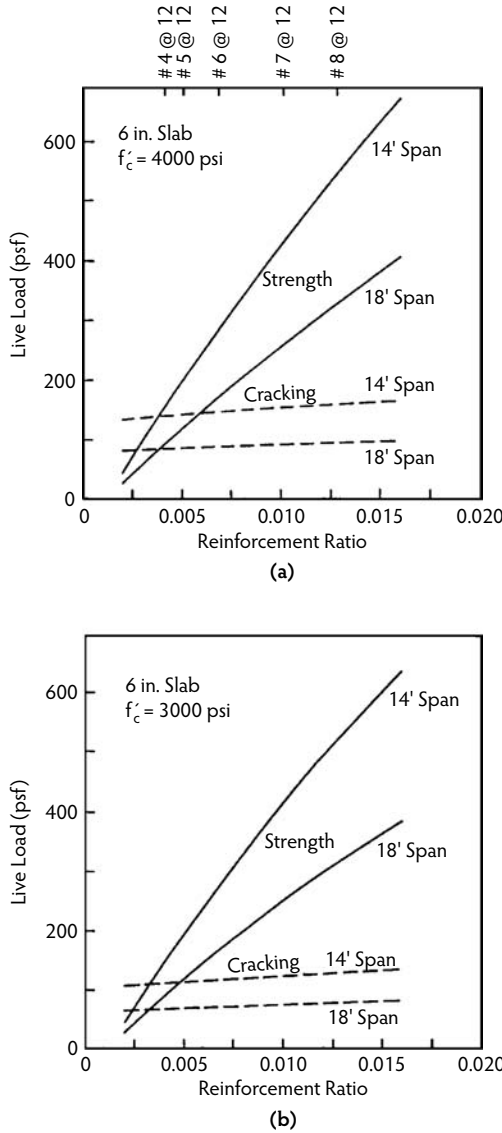

FIGURE 8.34 Allowable live load calculated on the basis of strength vs. cracking live load: (a) $f'_c = 4000$ psi (28 MPa); (b) $f'_c = 3000$ psi (21 MPa). (From Hover, K.C., in *Forming Economical Concrete Buildings: Proceedings of the Third International Conference*, SP107, American Concrete Institute, Farmington Hills, MI, 1988, pp. 169–184.)

load on the basis of strength considerations increases dramatically with an increasing amount of reinforcing steel, the cracking load increases by only 25% or so for an 8-fold increase in the amount of reinforcing steel. For members with the maximum allowable amount of reinforcing steel, the safe load on the basis of strength exceeds the cracking load by a factor of four. One would therefore expect heavily reinforced slabs and beams to crack at loads well below the safe or allowable load calculated on the basis of strength.

In Figure 8.34b, it is assumed that the same slabs have a compressive strength of only 3000 psi (21 MPa) at the time of load application. Note that this case corresponds to the above 4000-psi (28-MPa) concrete about 7 days after casting, when the concrete has attained approximately 75% of its expected 28-day strength. Comparison of Figure 8.34a with Figure 8.34b shows an approximate 6% decrease in the allowable load on the basis of strength and an approximate 20% decrease in the cracking load for a compression strength decrease from 4000 psi to 3000 psi (28 MPa to 21 MPa). Thus, low concrete

FIGURE 8.35 Data presented by Walker and Bloem (1957b) concerning the influence of drying on the flexural strength of concrete. (From Hover, K.C., in *Forming Economical Concrete Buildings: Proceedings of the Third International Conference*, SP107, American Concrete Institute, Farmington Hills, MI, 1988, pp. 169–184.)

compressive strength has a more significant effect on resistance to cracking than on the strength of the slabs considered in these examples.

Calculation of the cracking load in the above example was done using $f_r = 7.5 \sqrt{f'_c}$ as in ACI Committee 318 (2005). Walker and Bloem (1957a,b) and Hover (1984) studied the influence of surface drying on flexural tension strength. The essential results are shown in Figure 8.35, in which the modulus of rupture (MOR) is shown as a function of the time during which the concrete test specimen is exposed to air drying. The modulus of rupture of wet concrete is seen to decrease immediately upon exposure to air. This decrease continues for several days of air drying until a minimum is reached after 3 to 6 days, followed by a slow restoration of the original wet MOR. Continued slow drying eventually leads to a modulus of rupture that is greater than the original wet-tested value. It was found that the MOR could vary from a high of $16 \sqrt{f'_c}$ to an apparent lower limit of approximately $4 \sqrt{f'_c}$, depending entirely on moisture conditions at the time of testing. Critically, during the first few days and hours of surface drying, the actual modulus of rupture (and therefore the actual cracking resistance) could be as little as 55% of the commonly expected value ($4 \sqrt{f'_c}$ rather than $7.5 \sqrt{f'_c}$).

The surface of concrete beams and slabs begins to dry immediately upon the removal of the formwork and the subsequent exposure to dry, moving air. While this surface drying is taking place, the removal of shoring and further construction operations load the members. The removal of forms and shores from flexural members is therefore a delicate issue, not only because of the strength development of early-age concrete but also because the surface drying, which is an almost unavoidable consequence of form removal, can decrease the cracking resistance by almost 50%.

To further investigate the phenomenon, beam specimens were cast in forms with steel sides and oiled plywood bottoms. Four days after casting, the forms were removed from three beams, which were then permitted to dry for 4 hours in laboratory air. Three other beams were removed from their forms one at a time and immediately tested so as to avoid appreciable air drying. The average MOR of the beams that were tested immediately upon form removal was 573 psi (4.0 MPa), and the average MOR of the beams that had dried for 4 hours was 450 psi (3.1 MPa), representing a 25% decrease in cracking resistance due to short-term drying.

It is not unreasonable to envision a situation in which the conditions of this experiment are realized on the jobsite, where the removal of beam sides may precede the removal of the beam bottom and supporting shoring by several hours. In that case, the self-weight of the slab or beam would be applied during this critical drying period. Similarly, in the case of rapid construction where the weight of falsework, materials, flying forms, etc. is applied to the top of a recently stripped beam or slab, it is likely that superimposed load would be applied during the critical drying period during which the cracking resistance is substantially reduced.

As part of a related experiment, flexural specimens were cast against steel forms with oiled plywood bottoms, with companion specimens cast in similar forms that had been lined with polyethylene. From tests conducted at 4 hours, 2 hours, and immediately after removal of forms, the modulus of rupture of the beams with the plastic-lined forms was on an average 25% greater than for the beams cast in steel and wood forms. When companion specimens were tested after 28 days of drying in laboratory air, the results for the two types of forms were statistically indistinguishable. It was concluded that the influence of the form surface on the cracking resistance was primarily due to the effects of moisture conditions at early ages. It was pointed out that timing the removal of forms and shores so as not to load a member while the concrete surface is drying can reduce the incidence of flexural cracking or can increase the applied load necessary to initiate such cracking. The use of smooth form surfaces or nonabsorptive form liners may be beneficial in reducing flexural cracking.

8.4 Strength Consequences of Construction Loads

It would be instructive to begin this section with the following four paragraph reproduced, with only minor paraphrasing, from Kaminetzky and Stivaros (1994):

Throughout the history of concrete construction, numerous construction failures have occurred. Many statistical surveys point out that failures and total collapses occur more frequently during construction than during the service life of a structure. Also, it has been well documented that failure of concrete structures during construction most often occur as a result of formwork failure, concrete member failure due to overloading, or lack of concrete strength.

The most common and often devastating failures are punching shear failures. These are triggered by a localized failure around a single column at an upper-level floor, resulting in progressive collapse going all the way down to the lowest level. Such a domino-effect failure can be stopped by localizing it to a single level. Because punching shear is the weakest link in the chain, the use of large-size columns coupled with continuous reinforcing bars running through the column periphery at both the top and the bottom of the slab will minimize the possibility of progressive collapse.

The most devastating and well-known collapses, during construction, resulting from punching shear, are those that occurred at Bailey's Crossroads, Virginia (Skyline Plaza) (Leyendecker and Fattal, 1977), Commonwealth Avenue, Boston, Massachusetts (1971); and Cocoa Beach, Florida (Harbour Cay Condominiums) (Lew et al., 1982a,b). All of these multistory flat-plate buildings in late stages of construction collapsed vertically in a progressive manner to the ground. The triggering cause was typical: localized punching shear failure at the slab-column connection. Premature removal of formwork coupled with insufficient concrete strength at the time of the collapse were partially blamed for these disasters. The maturity of concrete was affected by the low temperatures that prevailed during the construction of these projects.

Although the Cocoa Beach collapse was mainly attributed to design and construction errors and not directly to concrete strength, procedures for concrete strength determination prior to the removal of forms were flawed. Construction records showed that laboratory-cured cylinders were used in order to determine the actual field strength of the slabs prior to stripping, where proper procedures and common sense dictated testing of field-cured cylinders.

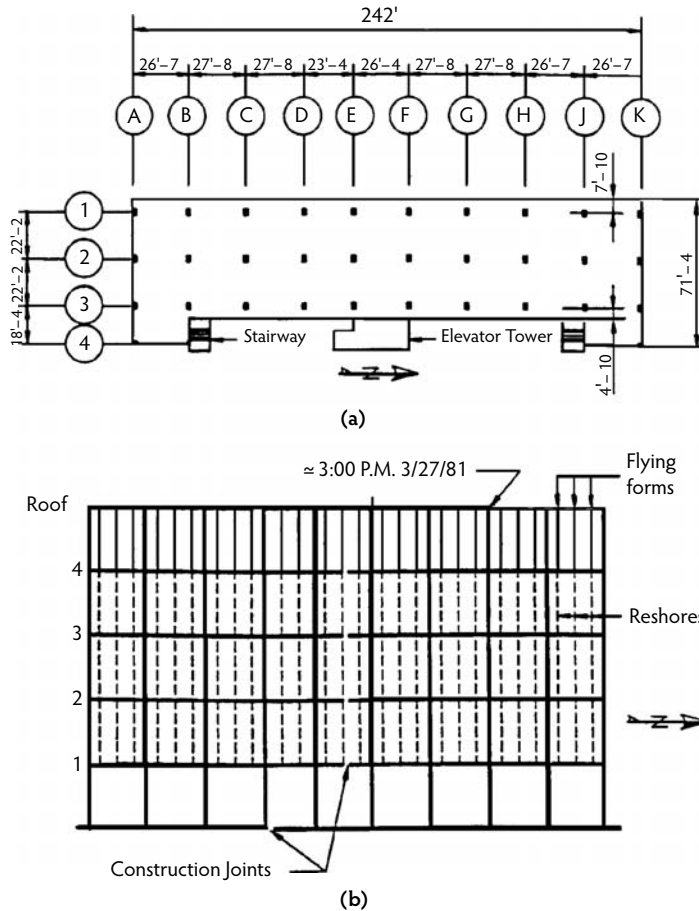

FIGURE 8.36 (a) Typical floor plan of the Harbour Cay Condominium, and (b) assumed state of construction at the time of collapse. (From Stivaros, P.C. and Halvorsen, G.T., *Concrete Int.*, 13(8), 57–62, 1991.)

A reexamination of the Harbour Cay Condominium failure later attributed it more directly to deficiency of punching shear strength (Stivaros and Halvorsen, 1992). The Harbour Cay was a five-story flat-plate concrete building. A typical floor framing plan is shown in Figure 8.36. At the time of collapse, flying forms on the fifth floor supported the fresh concrete roof slab. Three levels of wood reshores rested below. Figure 8.36 shows the flying form and reshore layout and indicates the portion of the roof believed to have been in place at the time of collapse.

National Institute of Standards and Technology (NIST) investigators (Lew et al., 1982a) used the ICES-STRUDL II finite-element program to analyze the Harbour Cay structure. The finite-element model consisted of rectangular plate bending elements for the columns and three-dimensional truss elements for the shoring system. The distribution of loads from the shoring and reshoring procedure was examined by means of the Grundy–Kabaila simplified method. The analysis indicated that, when all the floors were reshored to the ground, the removal of the flying forms at the topmost level completely relieved the forces in the reshores. The existing slabs always supported their own dead load and did not share in supporting a portion of the load of the newly cast floor. Only after the first-story reshores were removed, thus removing a direct load path to the ground, did the existing floor slabs share the load of a newly cast slab. These observations stem from Grundy–Kabaila's basic assumption of an infinitely stiff shoring system.

As a result of the above observations, to determine the state of load distribution at the time of collapse, NIST investigators studied two separate load cases (Figure 8.37). In the first, the structure without reshores

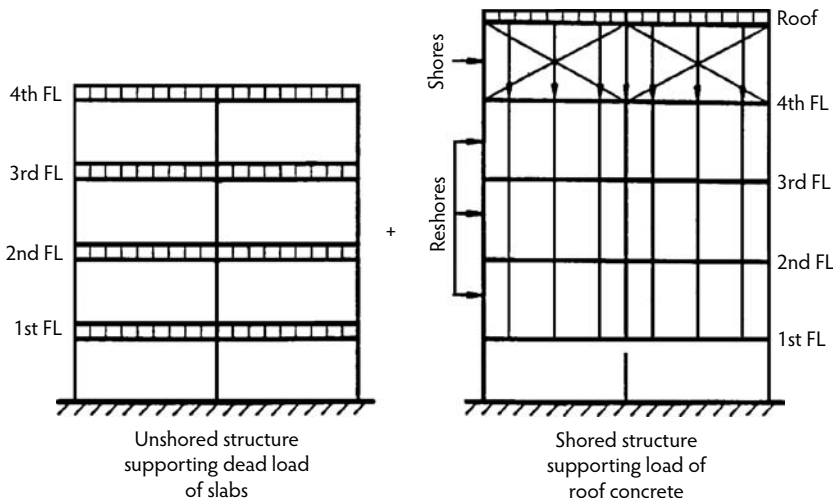

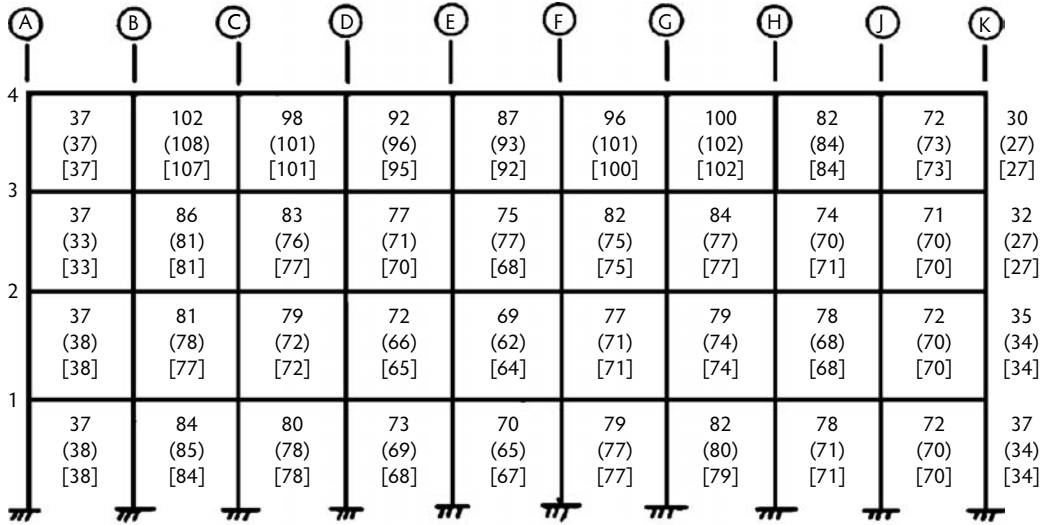

FIGURE 8.37 Two load cases considered in NIST analysis of Harbour Cay Condominium. (From Stivaros, P.C. and Halvorsen, G.T., *Concrete Int.*, 13(8), 57–62, 1991.)

was analyzed under the dead load of the slabs. In the second, the reshored structure was analyzed under the load of the fresh concrete and the formwork. The final result was obtained by superimposing the results of the two analyses. Given in Figure 8.38a are the combined punching shear forces, in kips, for the slab-column connections along column line 2 of the building.

Stivaros and Halvorsen (1992) carried out a preliminary equivalent frame analysis of the Harbour Cay failure, using the same structural data and loading conditions as those used by NIST investigators. The preliminary analysis used the plane frame capabilities of ICES-STRUDL II. The results of this analysis are shown in Figure 8.38a in square brackets. After the preliminary analysis indicated reasonable results, Stivaros and Halvorsen developed their special-purpose computer program [Stivaros and Halvorsen, 1990] that recognized time-dependent material properties and time in the construction process. This program was applied to the construction-load distribution of the Harbour Cay Condominium failure in two different ways. First, the structure was analyzed according to the two loading cases and structural details identified by Lew et al. (1982a). The results of this first analysis are shown in parentheses in Figure 8.38a.

An alternative approach assumed more realistic construction-loading conditions. Grundy–Kabaila’s simplified method, as mentioned, assumes an infinitely stiff shoring system; however, the Harbour Cay Condominium used compressible wooden reshores. In the course of the alternative analysis, the program built the structure from the first floor to the roof and considered the effects of all the cycles of loading and unloading as the construction progressed upward. Thus, the effect of compressible reshores could be assessed. Variations in concrete maturity, strength, and stiffness are also incorporated. The punching shear forces at slab-column joints along the height of column stack C-2 are shown in Figure 8.38b. The results of the alternative analysis, which considered the two separate loading cases, are shown in parentheses.

The accuracy of the Grundy–Kabaila simplified method was tested against observations of the Harbour Cay Condominium collapse. Figure 8.38c shows the punching shear forces at every slab–column joint along the height of column stack C-2. The first number indicates the force obtained by the alternative equivalent multi-bay frame, the second number (in parentheses) represents the force obtained by the alternative method using a single-bay model, and the third number (in square brackets) represents the force obtained from the simplified method that invariably uses a single-bay model. A comparison shows that the alternative equivalent single-bay model and the simplified method underestimate the punching shear forces along column stack C-2 on the top floor by 13 and 21%, respectively, as compared to the results of the equivalent multi-bay frame model. On the floors below, both the simplified method and the equivalent single-bay frame model differ by smaller percentages from the equivalent multi-bay frame model.

Legend:
 No. : NIST Analysis

(a)

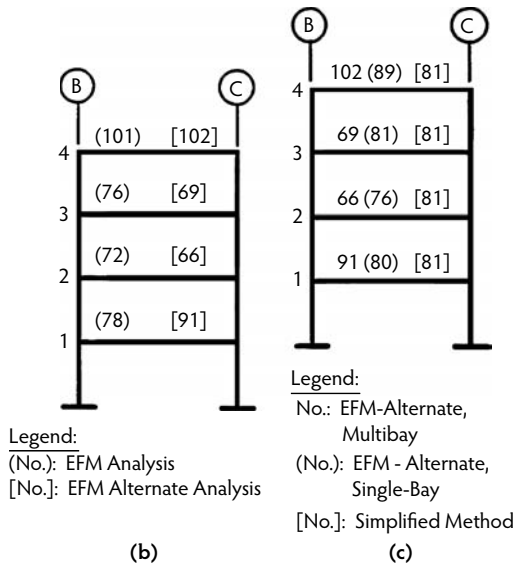

FIGURE 8.38 (a) Punching shear forces along column line 2 (kips); (b) slab loads on bay B-C from multi-bay EFM analysis (kips); (c) slab loads on bay B-C from EFM and simplified method (kips), Harbour Cay Condominium analysis. (From Stivaros, P.C. and Halvorsen, G.T., *Concrete Int.*, 13(8), 57–62, 1991.)

Based on the simplified method and the equivalent single-bay frame analysis, punching shear force at the top slab–column joint along column stack C-2 was within the punching shear strength of that joint; however, analysis based on the equivalent multi-bay frame model indicated that the available punching shear strength was exceeded at the same joint. According to Stivaros and Halvorsen (1992), “Here is exactly where the significance of the EFM multi-bay model lies....”

8.4.1 Safety Analysis

Gardner (1985) was the first to attempt a systematic safety analysis of construction (shoring/reshoring) schemes for multistory buildings, as described in this section. The strength of a reinforced concrete slab is a function of the design (factored) load, age of the slab, and the critical mode of behavior of the slab: flexure, bond, or shear. The required strength for various live-load/dead-load ratios, in terms of dead load, can be calculated from ACI 318-05 (ACI Committee 318, 2005) Appendix C as follows:

$$U = 1.4D + 1.7L = D \left[1.4 + 1.7 \frac{L}{D} \right] \tag{8.14}$$

Design strength (nominal strength reduced by the appropriate strength-reduction factor) must equal or exceed the required strength and was assumed by Gardner to equal the required strength. It should be noted that, in U.S. design practice, the design strength is assumed to be available at 28 days of age. The strength available at the early age at which a slab experiences construction loads is, of course, lower than the 28-day design strength. Gardner and Poon (1976) had concluded earlier that the tensile and bond strengths of concrete were proportional to the compressive cylinder strength raised to the power 0.8. As shear is governed by tensile strength, it was assumed that shear strength was also related to compressive strength the same way. Data in Table 8.7 were prepared by Gardner (1985) from Klieger’s (1958) data, using the 0.8-power criterion to estimate early-age strength as a fraction of the 28-day, 73°F cylinder strength for both Type I normal Portland cement and Type III high-early-strength cement concretes. Gardner (1985) noted that no existing design code specifies a construction load factor. ANSI A10.9-1997 (ANSI, 1997) recommends a load factor of 1.3 for both dead and live construction loads. Kaminetzky and Stivaros (1994) indicated preference for the more conservative load factors required by ACI 318 Appendix C for service conditions—that is, 1.4 and 1.7 for construction dead and live loads, respectively. Gardner used a construction load factor of 1.4 and assumed that the forms have self-weights equal to 10% of the slab self-weight and that the simplified Grundy–Kabaila method is approximately 10% in error. This yielded a factored construction load combination (required strength) of:

TABLE 8.8 Factored Construction Loads on Slabs with Two Shores and Two Reshores

Slab	Age of Slab (Cycles after Casting)							
	1		2		3		4	
	a	b	a	b	a	b	a	b
1	0 ^a	0 ^a	1.54 ^a	1.54 ^a	1.54 ^a	1.54 ^a	1.94	2.37
2	1.54 ^a	1.69 ^a	2.31 ^a	2.31 ^a	1.94	2.37	1.94	2.37

5	1.10	1.52	2.60	3.01	1.94	2.37	1.94	2.37

^a Slab supported on grade so construction live load transmission is directly to the ground.

Note: Operation a is removal of lowest level of shores and reshores; operation b is casting of next slab.

Source: Gardner, N.J., *Concrete Int.*, 7(4), 28–34, 1985.

$$U = \left[\underset{\text{(a)}}{1.1} \times \underset{\text{(b)}}{1.1} \times \underset{\text{(c)}}{1.4} \times \text{load ratio} + \frac{1}{\underset{\text{(e)}}{N}} \right] \text{dead load} \quad (8.15)$$

where (a) is error in simplified method, (b) is the weight of the formwork, (c) is the load factor, (d) is the calculated load ratio (Table 8.2), and (e) is an allowance for the construction live load where N is the total number of shore and reshore levels. Using Equation 8.15, the factored construction loads at various stages of construction are shown in Table 8.8 for two levels of shoring and two levels of reshoring. A complete version of Table 8.8 for other combinations of shore and reshore levels is shown in Table 8.9. Gardner (1985) provided the following three examples of safety analysis.

8.4.1.1 Example 8.1

Determine if a flat-slab structure designed for a live-load/dead-load ratio of 1.00 by ACI 318 can be constructed using a two-shore/two-reshore system with a seven-day casting cycle and form stripping one day before casting. Assume an ambient temperature of 73°F and Type I Portland cement concrete:

$$U = D \left[1.4 + 1.7 \frac{L}{D} \right] = 3.1D$$

Assuming that the 28-day design strength is equal to the required strength U , the strengths available at various ages of interest are as follows:

Age (days)	Strength Available
6	$0.76 \times 3.1D = 2.36D$
7	$0.79 \times 3.1D = 2.45D$
13	$0.89 \times 3.1D = 2.76D$
14	$0.90 \times 3.1D = 2.79D$
20	$0.96 \times 3.1D = 2.98D$
27	$1.00 \times 3.1D = 3.1D$
28	$1.00 \times 3.1D = 3.1D$

Using the load data from Table 8.8, the adequacy can be checked for every slab at every stage of construction. The results of the check are shown in Table 8.10. It can be seen that the proposed construction scheme overloads slab 4 at ages 13 and 14 days and slab 5 at 14 days. Thus, it cannot be used without modification.

8.4.1.2 Example 8.2

Determine the construction cycle for a slab designed for a live-load/dead-load ratio of 0.5, using one shore plus five reshore levels at a temperature of 55°F. Assume Type I Portland cement concrete and a specified concrete strength of 4000 psi. From Table 8.8, for one level of shores and five levels of reshores, the factored construction loads are $1.86D$ at stripping and $2.15D$ at casting of the next slab. The required strength is:

$$U = D \left[1.4 + 1.7 \frac{L}{D} \right] = 2.25D$$

Assuming that the 28-day, 73°F design strength is equal to the required strength U , the concrete strength at casting at 55°F needs to be $2.15/2.25 = 96\%$ of the 28-day strength, which occurs at approximately 23 days. The concrete strength at stripping has to be $1.86D/2.25D = 83\%$, which occurs at 13 days. In most cases, a 23-day cycle would not be economically acceptable.

8.4.1.3 Example 8.3

Redo the above example to achieve a 7-day placing cycle. The strength of the slab required at casting (7 days) is $0.96 \times 4000 \text{ psi} = 3840 \text{ psi}$; the strength of the slab required at stripping (6 days) is $0.83 \times 4000 \text{ psi} = 3320 \text{ psi}$. To obtain a concrete strength of 3840 psi at 7 days, either the concrete mix must be redesigned or heat must be supplied to accelerate the hydration process. It should be noted that this safety analysis is probably flawed if punching shear governs safety, as it usually does for slab systems without column-line beams. This is for two important reasons. First, as mentioned earlier, simplified Grundy–Kabaila-type analysis cannot lead to accurate estimates of punching shear forces at slab–column joints. Second, the assumption that punching shear strength varies with the 28-day compressive cylinder strength of concrete raised to the power 0.8 was not verified in later tests by Gardner (1960), who found punching shear strength to vary with the cube root of the 28-day compressive cylinder strength.

8.4.2 Refined Safety Analysis

A more refined safety analysis was carried out by Kaminetzky and Stivaros (1994) on a test multistory flat-plate office building (Figure 8.39), assumed to have been designed according to ACI 318 with a 50-psf (2.4 kPa) live load and an additional superimposed partition load of 30 psf (1.5 kPa). This example assumed one level of shores and three levels of reshores with a construction rate of two floors per week. It is also assumed that the shores and reshores were removed and relocated a day before casting the top slab. A 50-psf (2.4 kPa) construction live load was assumed to be present only during the placement of concrete in the top slabs. The *in situ* concrete strength can be estimated by testing field-cured cylinders in combination with other available nondestructive methods. Figure 8.40 shows the assumed compressive strength–time relationship for two different construction temperatures: 55 and 73°F.

Stivaros' computer program (Stivaros and Halvorsen, 1990), based on the equivalent frame method of analysis, was employed to evaluate the construction load distribution between the shoring system and the concrete frame. The program, as mentioned earlier, builds the structure from the first floor to the roof and evaluates the loads on each floor slab and the support system for every construction stage. The punching shear stresses due to applied loads are also computed at each column location for every construction step. The program provides the available load-carrying capacities of the slabs and the available punching shear strengths of slab–column connections at the time of application of the construction loads; thus, a safety comparison can be made. The load-carrying capacities are based on flexural considerations, accounting for partially developed concrete compressive strength. A key assumption is that the load factors and strength-reduction factors used for the design of the slabs for service conditions are the same for the construction stage as well. The available punching shear strength is evaluated according to ACI 318 (ACI Committee 318, 2005) and is equal to $\sqrt{F_{ct}}$, where $\phi = 0.85$, and F_{ct} is the available concrete strength at the time the load is applied. The results of the construction load analysis are shown in Figure 8.41 and Figure 8.42. The figures show the maximum factored slab loads (normalized

to the self-weight of the slab) and punching shear stresses that occurred on the floor slabs during construction. Also shown in the figures are the load-carrying capacities (allowable loads) and allowable punching shear stresses of the concrete slabs at two temperature conditions: 55 and 73°F. Figure 8.41 shows that the maximum applied factored load, which occurred on 4-day-old slabs, exceeded the allowable loads

for both temperature conditions. This means that the proposed construction scheme cannot be safely executed. Similar unsafe construction conditions are shown in Figure 8.42, where the punching shear stresses due to the applied loads exceeded the allowable stresses. For this particular example, the available strengths in both flexure and shear have been exceeded; however, because of the possibility of inelastic redistribution of bending moments and because of the improbabilities of any redistribution of punching shear stresses, a sudden shear failure is likely to occur prior to flexural failure. Kaminetzky and Stivaros (1994) pointed out that had some floors of the above building been designed for an additional live load of 20 psf (1.0 kPa), the slabs would have been flexurally adequate to carry the construction loads for the 73°F temperature condition at a rate of two floors per week (Figure 8.43). Also, a construction rate of one floor per week would have been safe even for the 55°F temperature condition; however, the construction operation still could not proceed safely because of the punching shear deficiency of the slabs.

8.5 Serviceability Consequences of Construction Loads

Floors in residential as well as office buildings are often made of thin, solid concrete slabs with two-way reinforcement. The trend in recent years has been toward a progressive decrease in the ratio of the thickness of slab to length of span. This obviously causes a corresponding reduction in the flexural rigidity

FIGURE 8.41 Allowable and applied slab loads from Kaminetzky’s (1994) analysis (live load = 50 psf).

FIGURE 8.42 Allowable and applied punching shear stress from Kaminetzky’s (1994) analysis.

FIGURE 8.43 Allowable and applied slab loads from Kaminetzky's (1994) analysis (live load = 70 psf).

of slabs. The consequent deformations have not always received as much attention as preventing collapse. Large permanent deformations of floor slabs have sometimes resulted. Whereas such deformations are often aesthetically unacceptable, their effects may also be seriously disturbing from a practical point of view. Cracking of brick partitions, jamming of doors, and cracking of windows have not been uncommon. At least in one reported case, long-term deflection of an interior span of a floor caused an adjacent balcony to slope inward. Rain falling on the balcony ran inward under the doorway and formed a pool in the middle of the floor, damaging carpets. Excessive long-term deflections of slabs are clearly to be avoided.

8.5.1 Causes of Excessive Deflections

Excessive deflections can sometimes be attributed to a single cause. More commonly, however, the problem may be traced to a combination of several contributing factors. Potential problem areas include design, construction, materials, environmental conditions, and change in occupancy (Scanlon, 1987).

8.5.1.1 Design

The single most common cause of large deflections associated with design is the selection of a slab thickness that is too small for the spans used. Another common problem is inadequate flexural reinforcement; as a result, premature yielding may occur, causing a substantial loss of flexural stiffness and leading to excessive deflection.

8.5.1.2 Materials

Higher than normal creep and shrinkage characteristics have been identified as contributing factors in cases of large deflections reported in Australia. While achieving high concrete strengths, high-shrinkage characteristics have sometimes been produced; the increase in slab warping has more than offset the benefits obtained from the increase in the modulus of elasticity of the concrete. In post-tensioned slabs, higher than normal prestress losses may lead to unanticipated deflections. Alkali-aggregate reactions produced by certain types of aggregate and cement may cause cracking that can adversely affect flexural stiffness.

8.5.1.3 Environmental Conditions

For slab surfaces exposed to daily or seasonal temperature fluctuations, temperature gradients set up through the member thickness may lead to unanticipated deflections.

8.5.1.4 Change in Occupancy

Slabs adequately designed and constructed for the original design loading may suffer deflection problems if the occupancy changes and if the change involves an increase in the sustained load applied to the slab.

8.5.1.5 Construction

The following is a list of factors, as compiled by Taylor and Heiman (1977), that contribute to excessive long-term slab deflections:

1. Formwork has not been cambered in cantilevers and large interior panels, so even early deflections are obvious.
2. Slabs have been supported by props bearing on sole plates that were of inadequate size to prevent appreciable settlement into the ground surface and hence induced slab deformation before stripping.
3. Construction loading from propping or the storage of materials during the early life of the slabs has been severe enough to cause extensive slab cracking and hence loss of stiffness.
4. Top reinforcement at supporting elements has been pushed down during slab construction, substantially reducing its effective depth and hence reducing the contribution made to slab stiffness by continuity at supports.
5. Curing has in many instances been inadequate and has sometimes led to insufficient strength development and excessive shrinkage cracking.

Item 4 above is a surprisingly common occurrence. Quite often, the top steel over supports is not securely held in place and is displaced toward the neutral axis, greatly reducing the stiffness over the support. If the effective depth is 7 in. instead of 8 in., as has been observed, the stiffness is reduced by 23%, and the member tends to behave as if it were simply reinforced.

Discussion here obviously needs to focus on the very important item 3 above. As noted earlier, when the shore/reshore method of multistory building construction is used, high-early-age, short-duration loads are imposed on the floor slabs. These loads can be comparable in magnitude to, or even exceed, the design service loads and are applied to concrete slabs that have not achieved their specified concrete strength. Because the slab concrete is immature with a reduced modulus of elasticity (see preceding section), the immediate deflections due to the construction loads are relatively large. Creep effects may be looked upon as being dependent upon the magnitude of the applied stress relative to the developed concrete strength; hence, creep deflections due to construction loads are also large. Deflection due to concrete shrinkage must also be considered.

8.5.2 Components of Long-Term Deflection

Shrinkage and creep are the two primary contributors to long-term deflections of reinforced concrete members. Shrinkage produces a shortening of the concrete in a member that is resisted by the reinforcing steel. The magnitude of shrinkage curvature (Figure 8.44b) depends on the amount of nonsymmetry of reinforcement and on the relative areas of concrete and steel in a reinforced concrete member. These shrinkage curvatures, which are the greatest for beams with tension reinforcement only, generally have the same sign as those due to moments produced by transverse loads, and thus they magnify the deflection due to load.

Considering creep alone, the increase in strain with time will be as shown by line B in Figure 8.45b, while line A indicates the strain distribution immediately on application of the load. Strain at the extreme fiber in compression increases considerably, while the strain at the level of the steel changes very little. As this occurs, the compressive stresses in the concrete are reduced (Figure 8.45c) because the neutral axis moves toward the reinforcement, and the steel stresses increase because the internal lever arm shortens. It can be seen from Figure 8.45b that the relative increase in curvature caused by creep is less than the relative increase in strain due to creep. Thus, the relative increase in deflection is also less than the increase in strain due to creep.

FIGURE 8.44 Shrinkage curvature of a section of a reinforced concrete flexural member.

FIGURE 8.45 Strain and stress distribution and curvature due to initial and creep deformation in a section of a reinforced concrete flexural member.

In addition to the difficulty of determining the creep-time history of a particular concrete under constant, uniformly distributed sustained stress, a reinforced concrete flexural member is subjected to a nonuniform stress distribution and often a variable load history. A detailed analysis of the effects of a variable stress history, even for uniformly loaded members, is usually not feasible, and shorter, more appropriate methods are used. One such method uses a reduced or effective modulus called the *sustained modulus of elasticity*, which refers to concrete under a constant sustained stress:

$$E_{ci} = \frac{\sigma_{\text{constant}}}{\epsilon_{\text{initial}} + \epsilon_{\text{creep},t}} = \frac{\sigma_{\text{constant}}}{(1 + C_t)\epsilon_{\text{initial}}} = \frac{E}{1 + C_t} \tag{8.16}$$

where $C_t = \epsilon_{\text{creep}}/\epsilon_{\text{initial}}$ is the creep coefficient at time t , the ultimate value of which may be denoted by C_u . It may be parenthetically noted that in considering creep deformations, use of the specific creep strain δ_t (creep per unit stress) or creep coefficient C_t (ratio of creep strain to initial strain) yields the same results (ACI Committee 209, 1971), as:

$$C_t = \delta_t E_{ci} \tag{8.17}$$

This can be seen from the following relations: creep strain at time $t = (\sigma_{\text{constant}})\delta_t = (\epsilon_{\text{initial}})C_t$, and $E_{ci} = \sigma_{\text{constant}}/\epsilon_{\text{initial}}$. The choice of δ_t or C_t is a matter of convenience, depending on whether applying the creep factor to stress or strain is desired.

With reference to Figure 8.45 and the earlier discussion on that figure,

$$\frac{\Delta_{\text{creep},t}}{\Delta_{\text{initial}}} = \frac{\phi_{\text{creep},t}}{\phi_{\text{initial}}} = k_{rc} \frac{\epsilon_{\text{creep},t}}{\epsilon_{\text{initial}}} = k_{rc} C_t \quad (8.18)$$

provided that the same moment of inertia is used in the computation of short- and long-term deflections. The factor k_{rc} accounts for the effect of compression steel and the offsetting effects of a downward movement of the neutral axis due to creep strain distribution and upward movement of the neutral axis due to progressive cracking under creep loading (plus the small effect, if any, of repeated live-load cycles). These offsetting effects normally appear to result in a downward movement of the neutral axis, such that k_{rc} is less than unity.

Because shrinkage and creep deflections are additive, their combined value is often estimated in approximate calculations with a single time-dependent factor applied to the initial deflection:

$$\Delta_t = k_r T_t \Delta_{\text{initial}} \quad (8.19)$$

where T_t is a multiplier for additional long-term deflections due to creep and shrinkage, the ultimate value of which may be denoted by T_u . The factor k_r in Equation 8.19 and the factor k_{rc} in Equation 8.18 serve largely the same purpose. The following values have been suggested for the two factors (ACI Committee 209, 1971):

$$k_{rc} = 0.85 - 0.45(A'_s / A_s) \geq 0.40 \quad (8.20)$$

$$k_r = 1.00 - 0.60(A'_s / A_s) \geq 0.40 \quad (8.21)$$

ACI 318 (ACI Committee 318, 2005) basically takes the Equation 8.19 approach to estimating long-term deflections.

The opportunity usually does not arise for temperature to influence deflections of floor systems, as these are usually protected from large temperature changes soon after casting. In slabs that are not so protected, temperature changes can be important. Because the thermal coefficients of steel and concrete are roughly the same, little if any curvature results from temperature changes that are uniform across a section of a member. With regard to differential temperatures (such as inside vs. outside temperatures of heated or cooled buildings), the deformation of reinforced concrete members is similar to or opposite that due to shrinkage; for example, the deflection would be downward in the case of roofs of heated buildings and upward in the case of roofs of air-conditioned buildings (Branson, 1977).

Because shrinkage is independent of load, it appears illogical for deflection directly caused by shrinkage to be related to load via the initial deflection; there is, however, an indirect way in which shrinkage can influence deflection. The stiffness of a cracked reinforced concrete section is usually less—sometimes much less—than the stiffness of the surrounding gross concrete section. It would appear that this change from an uncracked to a cracked section, which may be brought about and extended over a considerable period by shrinkage (plus creep and thermal) effects, offers the potential for a corresponding continuing increase in deflection. Branson (1987) cited laboratory tests by others to indicate that the formation of new cracks during sustained loading depends on the development of earlier cracks during the initial loading stage. For example, in beams with a low 0.60% steel and a steel stress $f_s = 20$ ksi at initial loading, about half the cracks occurred upon initial loading and the remainder during the sustained loading. In beams with the same low steel percentage but $f_s = 30$ ksi, almost all cracks occurred upon initial loading. In beams with a higher 2.0% steel, cracks appeared rather early, with little additional cracking occurring during the sustained loading. According to Branson, this effect, which would seem to require the use of a $k_r > 1$ in Equation 8.19, is for most practical purposes taken into account through the use of a suitable effective moment of inertia in initial deflection calculations and through the use of the k_r factor as given by Equation 8.21.

FIGURE 8.46 Details of one-way slab models tested by Fu and Gardner. (From Fu, H.C. and Gardner, N.J., in *Properties of Concrete at Early Ages*, SP-95, American Concrete Institute, Farmington Hills, MI, 1986, pp. 173–200.)

8.5.3 Experimental Investigation

Fu and Gardner (1986) fabricated five nominally identical single-span one-way slabs. All of the slabs (Figure 8.46) were 8 in. (203 mm) wide and 2.5 in. (64 mm) deep, spanned 77 in. (1960 mm), were reinforced with 5-mm diameter wires in one direction, and were cast from the same mix. Ready-mixed concrete with a target 28-day strength of 4000 psi (28 MPa) was used. Only the midspan deflections of the five one-way slabs were measured under load. After the formwork was stripped, measurements were made every day for the first month and then weekly afterward. In addition, shrinkage of four concrete prisms, compressive strength, and modulus of elasticity of the concrete were also measured. The five slabs were subjected to different load histories during the first 28 days after casting. Slabs 1 and 2 were subjected to simplified load histories, while slabs 3, 4, and 5 were subjected to load histories typical of one shore plus two reshores, one shore plus two levels of preshores (this term is discussed later), and three levels of shores. The load histories are given in Figure 8.47. The measured deflections are given in Figure 8.48a for the first 28 days and Figure 8.48b for the first 489 days. An examination of the deflection curves in Figure 8.48a reveals that the slopes of all these curves were virtually the same after day 28; subsequent deflections after removal of the construction loads seemed to be independent of prior loading. In other words, the additional deflections due to creep and shrinkage of concrete during the first 28 days of loading could not be recovered despite removal of the construction loads and even though identical loads were sustained on the slabs afterward. The net deflections after 28 days, taken as the sum of deflections due to loading (plus) and unloading (minus) alone and excluding deflections due to creep and shrinkage, were measured to be 0.60, 0.63, 0.62, 0.60, and 0.58 mm for slabs 1 to 5, respectively. It is equally interesting to note that the increases in deflections from day 28 to the end of the observation period (say, 489 days) for all five slabs were very close indeed: 1.60, 1.41, 1.49, 1.50, and 1.57 mm for slabs 1 to 5, respectively. However, due to the distinct loading histories in the initial stages, the corresponding final deflections after 489 days were 3.26, 4.13, 3.32, 3.51, and 4.31 mm, giving ratios of final deflection to net deflection at 28 days of 5.43, 6.56, 5.35, 5.85, and 7.43.

8.5.4 Control of Slab Deflections

The state of the art for control of two-way slab deflections was reviewed in ACI Committee 435 (1995). The methods of calculating slab deflections were presented, and the effects of two-way action, cracking, creep, shrinkage, and construction loads were considered. Probably the surest way to control deflections is to carefully sequence the operations of shore removal and reshoring. With a column layout like the one shown in Figure 8.49, stringers would normally be run in the short direction at about 4 ft on-center,

FIGURE 8.47 Loading histories on slab models tested by Fu and Gardner. (From Fu, H.C. and Gardner, N.J., in *Properties of Concrete at Early Ages*, SP-95, American Concrete Institute, Farmington Hills, MI, 1986, pp. 173–200.)

supported on shores. Ribs or purlins would then be run in the orthogonal direction, also at about 4 ft on-center, supported on the stringers. Finally, the 4 ft × 8-ft plywood sheets would be supported on the ribs. It has been suggested (Cantor and Rizzi, 1982), on the basis of successful experience with flat-plate buildings in the New York area, that alternate plywood sheets in both the long and the short direction (shown shaded in Figure 8.49) should be supported directly by extra shores (indicated by x in Figure 8.49). These latter shores (attached to the plywood rather than to the stringers as the other shores are), also called *preshores* or permanent shores, may be installed at the time the other shores are installed or just before shore removal. When the time comes for removal of formwork, a day or two after casting or when concrete strength reaches a certain minimum value, the regular shores, the stringers, the purlins, and the plywood sheets that are not directly held by the extra shores can all be removed. Before the extra shores and the plywood sheets held by them are removed, however, reshores should be installed at about 8 ft on-center directly to the concrete slab. The extra shores or preshores should be removed only after the reshores have been installed.

The above scheme of removing the shores and installing the reshores does not permit more than 8 ft of slab span to be left unsupported at any time until the slab is sufficiently mature. With such short unsupported slab spans, slab deflections under usual circumstances cannot assume disturbing proportions, however high the loading may be during construction and however immature the slab may be when it is called upon to support those loads.

FIGURE 8.48 Deflections due to construction loads measured in slab models tested by Fu and Gardner. (From Fu, H.C. and Gardner, N.J., in *Properties of Concrete at Early Ages*, SP-95, American Concrete Institute, Farmington Hills, MI, 1986, pp. 173–200.)

The above consideration applies for the use of flying forms also. Figure 8.50 shows a reinforced concrete slab supported on reinforced concrete columns spaced at 20 ft on-center in both directions. With such a column layout, an 18-ft-wide form table would normally be used; however, in that case, as soon as the

FIGURE 8.49 Sequence of shore removal and reshoring that restricts the slab span left unsupported at an early age. (From Cantor, I.G. and Rizzi, A.V., in *Proceedings of the First International Conference on Forming Economical Concrete Buildings*, Lincolnshire, IL, November 8–10, Portland Cement Association, Skokie, IL, 1982, pp. 18.1–18.12.)

flying form is removed 18 ft of slab span would be left unsupported. If deflections are of concern, two 8-ft-wide form tables, with a filler strip of formwork in between, may be used instead. With the narrower form tables, even when they are removed no more than 8 ft of slab span would be left unsupported. Admittedly, two 8-ft-wide form tables with a filler strip of formwork are significantly more expensive than a single 18-ft-wide form table. The added expense has to be weighed carefully against any advantage that is to be gained in terms of reduced deflections.

8.6 Codes and Standards

The following documents have been mentioned in this chapter:

1. *Guide to Formwork for Concrete*, ACI 347-04 (American Concrete Institute, Farmington Hills, MI)
2. *American National Standard for Construction and Demolition Operation—Concrete and Masonry Work—Safety Requirements*, ANSI A10.9-1997 (American National Standards Institute, New York)

The first of the items is an ACI committee report, and the second is an ANSI standard. Neither of the two is adopted into the International Building Code (IBC), the model code that increasingly forms the basis of the legal codes of various local jurisdictions (cities, counties, and states) within the United States. The latest edition of the IBC, dated 2006, adopts the 2005 edition of ACI Committee 318 *Building Code Requirements for Structural Concrete* for regulations concerning concrete design and construction. This edition of the standard contains interesting and important provisions related to the loading imposed on a concrete structure during construction. These provisions are discussed below. It should also be mentioned that the ASCE Standards Committee on Design Loads during Construction has issued a relatively new standard, ASCE/SEI 37-02 (*Design Loads on Structures during Construction*).

For the first time, the 1995 edition of the ACI 318 standard contained the following requirements, which have remained unchanged through the 2005 edition and are directly quoted from the standard:

FIGURE 8.50 Restriction on slab span left unsupported at an early age with the use of flying forms. (From Cantor, I.G. and Rizzi, A.V., in *Proceedings of the First International Conference on Forming Economical Concrete Buildings*, Lincolnshire, IL, November 8–10, Portland Cement Association, Skokie, IL, 1982, pp. 18.1–18.12.)

ACI 318 §6.2. Removal of forms, shores, and reshoring

ACI 318 §6.2.1. Removal of forms

Forms shall be removed in such a manner as not to impair safety and serviceability of the structure. Concrete to be exposed by form removal shall have sufficient strength not to be damaged by removal operation.

ACI 318 §6.2.2. Removal of shores and reshoring

The provisions of ACI 6.2.2.1 through ACI 6.2.2.3 shall apply to slabs and beams except where cast on the ground.

ACI 318 §6.2.2.1. Before starting construction, the contractor shall develop a procedure and schedule for removal of shores and installation of reshores and for calculating the loads transferred to the structure during the process.

- (a) The structural analysis and concrete strength data used in planning and implementing form removal and shoring shall be furnished by the contractor to the building official when so requested;
- (b) No construction loads shall be supported on, nor any shoring removed from, any part of the structure under construction except when that portion of the structure in combination with remaining forming and shoring system has sufficient strength to support safely its weight and loads placed thereupon;
- (c) Sufficient strength shall be demonstrated by structural analysis considering proposed loads, strength of forming and shoring system, and concrete strength data. Concrete strength data shall be based on tests of field-cured cylinders or, when approved by the building official, on other procedures to evaluate concrete strengths.

ACI 318 §6.2.2.2. No construction loads exceeding the combination of superimposed dead load plus specified live load shall be supported on any unshored portion of the structure under construction, unless analysis indicates adequate strength to support such additional loads.

ACI 318 §6.2.2.3. Form supports for prestressed concrete members shall not be removed until sufficient prestressing has been applied to enable prestressed members to carry their dead load and anticipated construction loads.

The ACI 318 Commentary explains that in determining the time for removal of forms, consideration should be given to the construction loads and to the possibility of deflections. The construction loads are frequently at least as great as the specified live loads. At early ages, a structure may be adequate to support the applied loads but may deflect sufficiently to cause permanent damage. It is further stated in the commentary that:

The removal of formwork for multistory construction should be a part of a planned procedure considering the temporary support of the whole structure as well as that of each individual member. Such a procedure should be worked out prior to construction and should be based on a structural analysis taking into account the following items, as a minimum:

- (a) the structural system that exists at the various stages of construction and the construction loads corresponding to those stages;
- (b) the strength of the concrete at the various ages during construction;
- (c) the influence of deformations of the structure and shoring system on the distribution of dead loads and construction loads during the various stages of construction;
- (d) the strength and spacing of shores or shoring systems used, as well as the method of shoring, bracing, shore removal, and reshoring including the minimum time intervals between the various operations; and
- (e) Any other loading or condition that affects the safety or serviceability of the structure during construction.

For multistory construction, the strength of the concrete during the various stages of construction should be substantiated by field-cured test specimens or other approved methods.

It should be noted that the above requirements of ACI 318 and the accompanying suggestions in the commentary, while fairly comprehensive and meaningful, do not necessarily reflect current practice. It is also of interest to note here that prescriptive detailing requirements for structural integrity were added for the first time to the 1989 edition of the ACI 318 standard for cast-in-place concrete structures. Similar requirements were added to ACI 318-95 for precast concrete structures. The requirements were prompted by experience showing that the overall integrity of a structure can be substantially enhanced by minor changes in the detailing of reinforcement. It is the intent of Section 7.13 of ACI 318-95 (requirements for structural integrity) to improve the redundancy and ductility in structures so that, in the event of damage to a major supporting element or an abnormal loading event, the resulting damage may be confined to a relatively small area and the structure may have a better chance to maintain overall stability. Specifically for flat-plate and flat-slab construction, ACI 318-89 required that at least two of the column

strip bottom bars or wires in each direction should be made continuous, pass within the column core, and be anchored at exterior supports. Since its 1995 edition, ACI 318 has contained the following expanded requirements for flat plates or flat slabs:

ACI 318 §13.3.8.5. All bottom bars or wires within the column strip, in each direction, shall be continuous or spliced with Class A splices...At least two of the column strip bottom bars or wires in each direction shall pass within the column core and shall be anchored at exterior supports. The continuous column strip bottom reinforcement provides the slab with some residual ability to span to the adjacent supports, should a single support be damaged. A structural integrity provision has now also been added for other two-way slabs without beams:

ACI 318 §13.3.8.6. In slabs with shearheads and in lift-slab construction..., at least two bonded bottom bars or wires in each direction shall pass through the shearhead or lifting collar as close to the column as practicable and be continuous or spliced with a Class A splice. At exterior columns, the reinforcement shall be anchored at the shearhead or lifting collar.

9.1 Introduction

When applying strength design procedures, engineers can obtain building structures that have adequate strength but unsatisfactory serviceability; that is, they exhibit excessive deflection. Thus, the size of many flexural members is determined by deflection response rather than by strength. The purpose of this chapter is to outline efficient procedures for estimating deflection, discuss factors affecting the variability of deflections, suggest procedures for use in the design process to reduce the expected deflection, and enable design engineers to proportion building structures closer to both strength and

* Practicing consulting structural engineer who has served on many technical committees of the American Concrete Institute and as President of the Institute in 1976.

** Professor of Civil Engineering, Penn State University, who has served on several technical committees of the American Concrete Institute, including serving as Chair of ACI Committee 435 (Deflections).

FIGURE 9.1 Recommended calculation procedures.

serviceability requirements. The result could be more economical structures compared to those designed too conservatively because of concerns about deflection or those designed without adequate deflection control resulting in expensive repair costs. Throughout this chapter, the discussion assumes that a competent design is prepared according to ACI 318 Building Code (ACI Committee 318, 2005) and that construction follows good practices. It should be noted that the ACI Code provides minimum requirements for design. The engineer should determine (in consultation with the owner) whether these minimum requirements are adequate for the project in question; for example, certain types of brittle partitions such as unreinforced masonry may require smaller deflection limits, and certain types of sensitive equipment may require more stringent limits than those given in the code.

9.2 Elastic Calculation Methods

9.2.1 Selection of Methods

Perhaps the most important step in computing deflection is to sketch the deflected shape of the structure, especially if its geometry or loading is somewhat complicated. Computations of deflection magnitude will be meaningless if the engineer has the wrong concept of deflection response. Horizontal members can deflect upward as well as downward, and vertical members can deflect in either direction. Sometimes a member is in double curvature and deflects in both directions. One load may cause a member to deflect in one direction, and another load may cause the same member to deflect in the opposite direction. If an engineer has difficulty visualizing the direction of deflection, experimentation with a simple model of heavy paper, balsa wood, plastic, or other flexible material should clarify the deflection response. The labor in preparing deflection calculations can be considerably reduced by the judicious selection of a few critical members in a structure for which deflection calculations will be made and disregarding all other members. The success of this approach depends on the skill of the engineer in selecting critical members. Labor in preparing deflection calculations can also be reduced by first deciding the reason for limiting the deflection (see Section 9.6) and directing the calculations to that end. Finally, deflection calculations can be minimized by determining the deflection limit and span and then selecting an appropriate calculation method by referring to Figure 9.1. There are no precise lines of demarcation between methods. Experienced engineers will consider computation time available, the importance of the member and its deflection response, and the importance that owners and users of the structure will assign to proper deflection behavior before selecting a calculation method. Some details of the normal or extended calculation methods can be used in a simpler method as the situation warrants. For these reasons, an engineer may want to start with the simplest calculation method and extend it if results of the first calculation indicate a potential deflection problem.

FIGURE 9.2 Moment of inertia (I_g) of uncracked T-beams (in.⁴).

9.2.2 Indirect Method (Minimum-Thickness Tables)

Deflection can be limited indirectly by limiting the span-to-depth ratio of a member or by limiting the stress level. For beams and one-way slabs, deflection need not be further calculated if the minimum thickness given in the ACI Code is met and if members do not support and are not attached to partitions or other construction likely to be damaged by large deflections. This is an important qualification as many members do support or are attached to fragile building elements. Likewise, deflection of flat slabs and flat plates need not be calculated if the thickness is limited to values given in the ACI Code. A satisfactory deflection response can normally be expected if the superimposed load is small in relation to the self-weight of the concrete, as is usually the case with buildings intended for human residence. Alternatively, experience indicates that flexural members remaining essentially uncracked at service loads will generally not have excessive deflection. This condition can be easily checked using structural mechanics; that is, $f_r \leq M_{cr}/S$. The section modulus (S) of T-beams can be approximated by increasing the section modulus by half as much as the moment of inertia is increased by the flanges for tensile stress at the bottom of the stem $[1 + (\beta_g - 1)/2]$ and increasing the section modulus twice as much as the moment of inertia for tensile stress at the top of the flange $[1 + 2(\beta_g - 1)]$. The factor β_g can be taken from Figure 9.2. The error introduced by this approximation is normally less than 10%. Use of indirect methods should be limited to members with a span no more than about 25 or 30 ft, usual loading conditions, and normal allowable deflections. Reasons for these limitations are further discussed in Sections 9.4 and 9.6.

9.2.3 Simplified Method (Use of Graphs to Estimate Stiffnesses)

For a quick estimate of deflection, use the midspan moment at service loads as calculated for strength design (or maximum moment in cantilevers). If only factored moment is available, divide it by the estimated average load factor to obtain the service moment. Alternatively, service moments may be

FIGURE 9.3 Flexural stiffness $E_c I_{cr}$ of cracked beams (lb/in.²).

computed directly. If concentrated loads or variable uniform loads are present, use an average uniform load, taking care to make due allowance for loads concentrated near the center of the span. If end moments are not equal to zero or to fixed end moments, use an appropriate moment coefficient from standard references. Estimate whether or not the beam is cracked at midspan by using Equation 9.1 and calculate either $E_c I_g$ or $E_c I_{cr}$. Use Figure 9.2 to assist in calculating I_g and Figure 9.3 to assist in calculating $E_c I_{cr}$. Do not include the effects of compression reinforcement. Use the appropriate flexural stiffness in the usual equations for deflection of indeterminate structures to determine the immediate deflection:

$$M_{cr} = f_r I_g / y_t \tag{9.1}$$

where M_{cr} , f_r , I_g , E_c , I_{cr} , and y_t are defined in the ACI Code. Estimate the additional long-term deflection due to creep and shrinkage by multiplying the immediate deflection by a factor λ taken from Figure 9.4. Do not calculate incremental deflection. Incremental deflection is that portion of the total deflection that occurs after the installation of deflection-sensitive elements of construction and continues until these elements are removed.

9.2.4 Normal Method

For a more careful estimate of deflection, use actual service loads and moments and calculate deflection using normal methods of structural mechanics. Calculate I_g using the normal procedures of structural mechanics, then calculate the cracking moment for the midspan section. If service moment M_a is less than the cracking moment, use I_g in the deflection calculations. If the service moment is more than the cracking moment, calculate I_{cr} and I_e , and use the latter in the calculations. Computation of I_g , I_{cr} , and I_e is developed in Chapter 4 and Chapter 27 of this *Handbook*, and the resulting equations are given below.

FIGURE 9.4 Values of multiplier λ for sustained load.

Neglecting compression reinforcement (and tension reinforcement in the gross section) will meet ACI Code requirements. For the cracked moment of inertia I_{cr} use Equation 9.2a:

$$I_{cr} = nA_s(1-k)jd^2 \quad (9.2a)$$

Alternatively, for the cracked flexural stiffness $E_c I_{cr}$ use Equation 9.2b:

$$E_c I_{cr} = E_s A_s (1-k)jd^2 \quad (9.2b)$$

where the depth of compression block kd by elastic theory is computed using:

$$k = \left[(\rho n)^2 + 2\rho n \right]^{0.5} - \rho n \quad (9.3)$$

and the internal lever arm by elastic theory jd is computed using:

$$j = (1 - k/3) \quad (9.4)$$

For the effective moment of inertia I_e use Equation 9.5:

$$I_e = I_{cr} + \left(M_{cr} / M_a \right)^3 (I_g - I_{cr}) \quad (9.5)$$

The labor in making these calculations can be considerably eased, and the chance for error reduced, by using a spreadsheet program prepared by the user. Deflection of concrete increases with time; see Section 9.3.1, Chapter 8 of Fling (1987) and Fling (1996). Incremental deflection that is less than the total long-term deflection may have to be compared to the allowable deflection; see Section 9.6 for a discussion of incremental deflection.

9.2.5 Extended Method

Extended methods involve consideration of all relevant factors affecting deflection as listed in Section 9.4. By carefully allowing for each relevant factor, an engineer can significantly improve the accuracy of deflection calculations. Extended calculations may result in better estimates of deflection, but they do not necessarily meet ACI Code requirements.

TABLE 9.1 Variations in Creep Coefficient from Standard Conditions

Parameter	Standard Conditions	Variations (%) ^a
Age at loading	7 days	-23
Relative humidity	40%	-40

9.3 Other Calculation Considerations

9.3.1 Long-Term Deflection

The ACI Code procedures using a single multiplier for additional long-term deflection may be used for simplified-method and normal-method calculation procedures. The initial deflection is multiplied by a single factor that depends only on the duration of the load and the quantity of compressive reinforcement. No other factor, such as ambient conditions, materials, or construction conditions, need be considered, yet these and many other factors do affect long-term deflection. This observation alone should raise a warning flag about the accuracy of the procedure under all possible conditions. When more accurate deflection estimates are needed, using extended method procedures, consider the six parameters that affect the magnitude of the creep coefficient and shrinkage strain, listed by Branson and Christiason (1971), ACI Committee 209 (1992), and ACI Committee 435 (1995). The numerical values they assigned to each factor for potential variations from standard conditions for the creep coefficient are summarized in Table 9.1. In addition, it is known that temperature, coarse aggregate, and the stress/strength ratio affect creep (ACI Committee 209, 1992; Smadi et al., 1987).

The volume/surface (v/s) ratio has an important effect on the modulus of rupture (f_r). In thin members (small v/s ratio), excess mixing water has a shorter average distance to the surface, where it can evaporate, leaving the concrete more prone to shrinkage and a lower flexural strength. Conversely, thicker members (large v/s ratio) take longer to dry out, maintaining the flexural strength as the concrete gains strength with time. Experience indicates that thin members with a v/s ratio of 2 may have a flexural strength of only $5(f'_c)^{0.5}$, whereas thick members with a v/s ratio of 6 or more may have a flexural strength of $10(f'_c)^{0.5}$. Whereas this is only a one third variation from the ACI Code value for flexural strength, the effect on deflection can be more dramatic because it may determine whether a member is cracked in flexure or not and to what extent it is cracked. When flanges are a significant part of a member, they should be included in the v/s calculation.

Current computation procedures do not consider the amount and location of tensile reinforcement or the location of compressive reinforcement with respect to the centroid of the gross concrete section, even though it is likely that location of reinforcement has some affect on shrinkage warping and long-term creep. Indeed, experience indicates that ribbed slabs do deflect more than thicker beams that are loaded to the same stress level and have the same span as the slabs. This can be attributed to thin flanges with potentially higher creep and shrinkage due to their lower volume/surface ratio and to flange location as far as possible from tensile reinforcement. The distance from tension steel to the centroid of the compression zone in ribbed slabs is often 0.8 to 0.9 times the total depth, whereas in rectangular beams it is usually about 0.6 to 0.7 times the depth. The factors for additional long-term deflection contained in the ACI Code make no distinction between members that are fully cracked and those that are

uncracked. If a beam is **uncracked**, the creep deflection should be proportional to the creep coefficient. If, however, a beam is **cracked**, it is more likely that creep deflection is proportional to some fraction of the creep coefficient.

The long-term creep factors given in the ACI Code and illustrated graphically in Figure 9.4 normally give satisfactory results. This may be because most concrete flexural members are partially cracked and the ultimate creep coefficient is normally about 2.0, rather than because the procedure is valid over a wide range of conditions. For conditions other than “normal,” the procedure may be flawed and contribute to erratic fluctuation in the ratio of calculated to measured deflection.

9.3.2 Continuous Members

For continuous members, it is essential that an accurate assessment of the distribution of moments be used in calculating deflection. Use of inaccurate moment values is the largest single source of error (Fling, 1996). Deflection calculations may proceed in the normal manner for structural mechanics; however, most continuous members are not prismatic if flexural cracking occurs somewhere in the span. Thus, the most important decision is what flexural stiffness value EI to use. For simplified or normal calculation methods (see Section 9.2), it is satisfactory to use the midspan flexural stiffness because it has the greatest effect on deflection. For greater accuracy, an average of midspan and end-region flexural stiffness can be used, taking care to give greater weight to the midspan stiffness than to the end-region stiffnesses. Guidance on averaging the stiffnesses is given in ACI Committee 435 (1995). For cantilevers, flexural stiffness at the end support should be used for calculations.

9.3.3 Two-Way Construction

When two-way construction consists of beams and slabs of normal proportions, deflection is considered for each direction (beams or slabs) independently of the other. When two-way slab systems, with or without beams in one or both directions, fall into the limitations of Chapter 13 of the ACI Code (ACI Committee 318, 2005), deflection can still be considered for each direction independently of the other, but deflection of that portion of the slab on the column line (column strip) will be greater than that portion spanning in midbay (middle strip). Appropriate allowance for this phenomenon can be made by adjusting the moments used in the deflection calculations in proportion to the positive moments used for design of the slab system. The procedure is known as the *crossing-beam method* and is discussed in ACI Committee 435 (1995). For all types of two-way construction, the maximum deflection at midbay will be the sum of the deflections in the two directions.

9.3.4 Prestressed Members

Normally, prestressing tends to balance the dead load. With perfect balance, there would be no immediate deflection under dead loads and no long-term deflection. Only live-load deflections would occur. Such balance can rarely be achieved because of construction tolerances and the difficulty of placing tendons in the theoretically correct location. Also, prestressing cannot simultaneously balance concrete self-weight, superimposed dead loads, and semipermanent live loads. The engineer must make a choice of which loads to balance. Nevertheless, prestressed members can generally be made thinner with lower deflection than nonprestressed members under similar conditions. Chapter 3 of the latest ACI Committee 435 report (1995) gives extensive guidance on calculation of deflection of prestressed members.

9.3.5 Torsional Deflection

Sometimes it is necessary to calculate the rotation of a member with torsional moment or the deflection of an element supported by the member but eccentric to its center of gravity. In such cases, the twist ϕ over a length l_t of a member can be calculated as:

$$\theta = \Sigma T / GK \tag{9.6}$$

where:

Σt = summation of the service torsional moment along length l_i of the member (see Figure 9.5).
 GK = torsional stiffness similar to the flexural stiffness EL .

For an uncracked member, it is sufficiently accurate to take:

$$\begin{aligned} G &= 0.3E_c \\ K_g &= \Sigma x^3 y / 3 \\ GK_g &= 0.1E_c \Sigma x^3 y \end{aligned} \tag{9.7}$$

where:

x = shorter overall dimension of the rectangular part of the cross-section.
 y = longer overall dimension of the rectangular part of the cross-section.

Component rectangles of flanged sections should be selected to yield the largest value of $\Sigma x^3 y$ as in strength design for torsion.

For a torsionally cracked member, it is sufficiently accurate to use an equation developed by Lampert (1973):

$$GK_{cr} = \frac{E_s (x_0 y_0)^2 A_n (1+m)}{2(x_0 + y_0)s} \tag{9.8}$$

where:

- E_s = modulus of elasticity of steel.
- x_0 and y_0 = shorter and longer dimension, respectively, between longitudinal corner bars.
- s = stirrup spacing.
- A_n = area of one stirrup leg:

$$m = \frac{(A_s + A'_s)s}{2A_n(x_0 + y_0)}$$

FIGURE 9.5 Twist on an isolated beam due to eccentric loads.

FIGURE 9.6 Deflection due to beam rotation.

FIGURE 9.7 Beam subject to rotation.

where:

- A_s = area of longitudinal tension steel.
- A'_s = area of longitudinal compression steel.

Deflection of an element supported by a twisting member can be calculated by multiplying the angle of twist in the member at the element by the distance from the center of gravity of the member to the point in question (see Figure 9.6).

For most cases in which twist or deflection due to twisting members is significant, the member will be at least partially torsionally cracked, and torsional stiffness given by Equation 9.8 should be used, as it will give an upper bound to the deflection. Torsional stiffness of an uncracked member is usually much larger than that of the same member torsionally cracked, but little research is available to indicate the proper transition from uncracked to cracked stiffnesses. Procedures for calculating torsional rotation are not intended for application to moment-distribution procedures.

9.3.5.1 Example 9.1

What is the twist in an 11-ft length of a rectangular beam 16 in. wide by 24 in. deep with a uniform service torsional moment of 50 ft-kips? The beam is reinforced with four No. 9 bottom and two No. 9 top bars, as shown in Figure 9.7. Shear reinforcement is No. 4 bars at 5 in. center-to-center. Assume that $f'_c = 3$ ksi.

Solution. Using Equation 9.8, $2(x_o + y_o) = 2(10.5 + 18.5) = 58$, and cracked torsional stiffness is:

$$GK_{cr} = \frac{29 \times 10^6 (10.5 \times 18.5)^2 \times 0.20}{58 \times 5} \times \left(1 + \frac{6.00 \times 5}{0.2 \times 58} \right) = 2.7 \times 10^9 \text{ psi}$$

Using Equation 9.6, torsional rotation or twist is:

$$\theta = \frac{50 \times 10^3 \times 12 \times (11 \times 12)}{2.7 \times 10^9} = 2.9 \times 10^{-2} \text{ rad} \approx 1.7^\circ$$

Actual twist may be less than that calculated if the beam remains partially uncracked.

9.3.6 Temperature Deflection

When there is a temperature gradient across a flexural member from one side to the other, temperature warping will result. In most structures, the temperature gradient is small, so the movement is small. In some structures, such as the top level of a parking garage, the gradient may be large, but the resulting movement is inconsequential because it does not affect either the serviceability of the structure or nonstructural elements. Occasionally, a structure will have large thermal gradients, and serviceability or nonstructural elements will be affected; for example, tall buildings with exposed exterior columns may

TABLE 9.2 Parameters Affecting Deflection: Known before Construction

2	<i>Flexural Stiffness</i>
2.1	Member sizes (including flange width) and bar placement
2.2	Presence of compression and tension bars in uncracked concrete
2.3	Tolerances on concrete outlines and bar locations
2.4	Relation of steel reinforcement to centroid of concrete section
2.5	Location of compression reinforcement at end sections, midspan, and in columns
2.6	Specified concrete compressive strength f'_c , flexural strength f_r , and modulus of elasticity E_c
2.7	Modulus of rupture f_r based on specified minimum compressive strength f'_c vs. the actual average f'_c
3	<i>Moment Distribution</i>
3.1	Frame completion before loads are applied
3.2	Homogeneous, isotropic, monolithic material
3.3	Rigid joints
3.4	Pattern loading
4	<i>Time-Dependent Factors</i>
4.1	Multiplier based on Yu and Winter's (1960) work that ignores relevant parameters such as cracked vs. uncracked sections, volume/surface ratio (V/S), absolute size of member, and shape of member (e.g., T-beam vs. rectangular beam)
4.2	Creep coefficient and shrinkage coefficient
4.3	Properties of concrete proportional to its compressive strength (or its square root); relationships assumed constant for all ages and not interrelated (e.g., shrinkage is assumed not to affect effective modulus of rupture f_r)
4.4	Constant normal ambient conditions of humidity and temperature
4.5	Calculations not separated for creep deflection using reduced E_c and shrinkage warping
5	<i>Criteria for Deflection Limits</i> (considering only span/deflection ratios and ignoring other relevant parameters such as the following)
5.1	Spans over 30 ft or under 10 ft
5.2	Absolute values of deflection limits
5.3	Dynamic (vibration) characteristics

experience thermal lengthening and shortening relative to internal columns that are at a nearly constant temperature. Thin precast wall-cladding panels may also be susceptible to temperature deflection, particularly if they span more than one story. An exposed roof may deflect up and down with seasonal or daily changes in temperature and affect partitions and ceilings below. In such cases, ACI Committee 435 (1995) offers guidance on temperature deflection.

9.4 Factors Affecting Deflection

To properly assess the variability of deflections, it is important to understand and consider all parameters that have an effect on the variability. Table 9.2 lists most of the parameters that are known or that might be determined before construction starts. Table 9.3 lists parameters that, by their very nature, cannot be known before construction starts. Parameters are separated between Table 9.2 and Table 9.3 to illustrate the difficulties facing a design engineer attempting to make a precise estimate of deflection. The values of the parameters that have the largest effect on the actual deflection of a structure are unknown at the time of design (those in Table 9.3); indeed, they *cannot* be known. Although it is theoretically possible to determine the value of parameters in Table 9.2 before construction starts, it is frequently impractical to obtain all necessary information; thus, an even higher proportion of variables cannot be determined

TABLE 9.3 Parameters Affecting Deflection: Not Known before Construction

1	<i>Loading</i>
1.1	Actual live load
1.2	Actual superimposed dead loads
1.3	Concrete dead load due to actual dimensions and weight of concrete
1.4	Construction loads due to shoring and reshoring procedures
1.5	Loading history: magnitude, duration, and frequency of application
1.6	Arching of masonry and fabricated walls, thus reducing load on supporting beams
2	<i>Flexural Stiffness</i>
2.1	Bar sizes and quantities actually installed
2.2	In-tolerance and out-of-tolerance construction of member sizes and bar placement
2.3	Actual concrete properties f'_c, f_r, E_c
3	<i>Moment Distribution</i>
3.1	Moment redistribution due to incomplete frame (e.g., upper columns or adjacent beams not yet constructed)
3.2	Moment redistribution due to creep and shrinkage
3.3	Moment distribution due to nonprismatic members (prismatic outlines may become nonprismatic members because of cracking and location of reinforcement)
3.4	Moment redistribution due to construction overloads
3.5	Cracking of supporting columns, especially those with light reinforcement and low axial load levels
3.6	Transverse (deflection) and torsional (rotation) movements of supporting girders
3.7	Joint stiffness less than infinite
4	<i>Time-Dependent Factors</i>
4.1	Actual shrinkage coefficient and its time variation
4.2	Actual creep coefficient and its time variation
4.3	Stress/strength ratio f_c/f'_c ratio at time of loading
4.4	History of actual ambient conditions of humidity and temperature
4.5	Location of compression reinforcement with respect to centroid of section

5.1	Changed or refined criteria

by the design engineer before construction. When the parameters that can be anticipated before construction are separated from the parameters that cannot be anticipated, the effect of unanticipated variations can be more than four times the effect of anticipated variations.

Design engineers attempting to accurately assess probable deflection should consider all parameters affecting deflection and assign realistic values to each parameter, not conservative values as is done for strength design; that is, in computing deflections, loads should not be higher and concrete strength lower than expected. The potential variability of deflection can be estimated by computing deflections using realistic maximum and minimum values for parameters. Although the length of the lists in the tables may seem daunting, design engineers can increase the accuracy of their computations by carefully selecting the values of parameters used in the calculations.

It is unlikely that the actual deflection would reach either the extreme minimum or extreme maximum computed deflection, assuming the maximum variation is in the same direction for all parameters. For example, if the probability of reaching one of the extreme values in each of nine steps is 20%, the probability of the actual deflection reaching either extreme of the computed deflections is less than one chance in a million. Note, however, that the probability of variation in some parameters could be higher than 20% in actual practice. Furthermore, the probability that actual deflection will be less than computed is about the same as the probability that it will be more than computed, even though the latter event gets more attention in actual construction. Factors considered in more precise calculations can be categorized under computational errors, loading, flexural stiffness, fixity, creep and shrinkage, and construction variations.

9.4.1 Computational Errors

Because computations are usually made by humans, computational errors become a significant source of discrepancy between the calculated and actual values of deflection. Some of these computational errors are outlined below:

- There are many steps in the calculation of deflection. If the probability of error in each step is 1%, then the probability of error in the final calculation could be almost 10%. If the probability of error in each step increases to 5%, then the probability of error in the final calculation could be as much as 40%. The magnitude and type of individual errors are such that even an experienced engineer might not notice errors of 1 to 5% on casual inspection. Calculation errors of 25 to 50% are not uncommon.
- The length and intricacy of deflection computations can be alleviated and the chances of error minimized if a computer program is used. The program should be capable of taking into account most of the known parameters affecting deflection. The program, no matter how sophisticated, should credibly predict the deflection of actual structures (not just laboratory specimens) with reasonable accuracy over a wide range of conditions. These are high standards, and whether such a program exists is open to question. Practicing design engineers should make a habit of comparing deflection performance with calculated deflection and thereby sharpen their judgment skills.
- Factored moments or loads determined in the design for strength might be inadvertently used in deflection computations instead of the actual service moments or loads.
- Maximum moments from pattern loading or from moment coefficients might be used rather than actual moments for the loading condition under consideration. Unrealistically large moments result in unrealistically large computed deflections.

9.4.2 Loading

- Consider the loading history, including the age at loading and unloading for each increment, as it will affect the immediate deflection because concrete strength and modulus of elasticity may be different at different ages. The degree of cracking could affect the flexural stiffness under first, partial loading but this is usually not a factor in multistoried buildings because construction loading frequently equals or even exceeds design loading and should therefore be used to determine the effective moment of inertia under subsequent loading.
- Use actual loads rather than those assumed in strength design. It is not unusual to find that live loads specified by the building code having jurisdiction are never reached in the actual structure. On the other hand, numerous studies indicate that reshoring loads on lower floors in multistoried buildings can be as much as twice the self-weight of the floor construction. Concrete dead load is frequently more than the specified live load plus superimposed dead load.
- Consider the proportion of long-term vs. transient loading. Permanent live load will cause more creep deflection than will transient live load because creep occurs only under loads lasting for some time. Some live loads may remain in place for significant periods of time and contribute to creep deflection, while others are in place such a short time that they have no measurable effect on long-term deflection.
- Correctly assess the live load. If actual service live load is smaller than the design live load, the ratio of the applied service moment (M_a) to the cracking moment (M_{cr}) is lower, probably resulting in a higher effective moment of inertia (I_e). Thus both dead-load as well as live-load deflection would be lower.
- Consider redundancy; for example, walls may arch from end to end of beams and carry their own weight. Also, concrete members transverse to the main span might carry some load, thus reducing the moment and hence the deflection of the member under consideration.
- Calculate the service load moments separately for live and dead loads rather than proportion the moments at critical sections for every loading stage to the moments at the final loading stage. For

many beams, dead load moments will be nearly equal to moments in a fixed-end beam, but with live load on just one of the spans (pattern loading) live-load moments compared to fixed-end moments are proportionally larger at midspan and smaller at the ends. If deflections are calculated using separate moments for dead and live loads, the computed total long-term deflection and the computed incremental deflection may differ 5 to 10% from those calculated using the same moment pattern. A separate distribution of moments for dead and live loads may not be justified for simplified and normal calculation methods but should be considered for extended-method calculations.

- Consider the support that members transverse to the span may provide. Such support has the effect of reducing the load; for example, slabs nominally designed as spanning one way may actually receive some support from parallel side members.

9.4.3 Flexural Stiffness

- Use the actual, measured modulus of elasticity of concrete (E_c), if available.
- Even if preconstruction tests are required, use the measured modulus of rupture of concrete (f_r) because it is one of the more important parameters affecting deflection. The ACI Code specifies a ratio of $f_r/(f'_c)^{0.5} = 7.5$, whereas research indicates the ratio usually varies from a low value of 7.5 to a high of about 10. A one third increase in f_r (and, hence, M_{cr}) will increase the effective moment of inertia (I_e) by as much as 75%.^{*} The ACI Code value is conservative, which means the actual deflection will frequently be less than the computed deflection. On the other hand, if there is significant restraint to shortening of flexural members by shrinkage, the resulting tensile stresses may reduce the effective or apparent modulus of rupture (f_r). Shrinkage restraint can result from a number of factors, including embedded reinforcing bars, stiff supporting elements such as walls, adjacent portions of slabs placed at different times, and nonuniform shrinkage through the thickness of the member. The effect is more significant in lightly loaded slabs with low reinforcement ratios than more heavily reinforced beams. For members with reinforcement ratios greater than about 1%, the effective moment of inertia rapidly approaches the cracked moment of inertia and is not sensitive to the actual cracking moment. When interpreting the results of tests for modulus of rupture, make allowance for the relative humidity of ambient conditions around the test specimen and for its size. See the discussion in Section 9.3.1.
- If construction loads are not allowed to crack the concrete prematurely, consider the effective moment of inertia at every loading stage based on the amount of cracking at that stage. If the maximum load on a structure occurs during construction, only one cracking condition need be considered and one flexural stiffness calculation need be made—that is, for the amount of cracking that occurs at full load. This assumption results in simpler calculations and is usually justified by the field observation that the most severe loading condition frequently occurs during construction when material stockpiles, shoring loads from the floor above, and other construction loads are on the structure. Many papers have been published on this subject (e.g., see Grundy and Kabaila, 1963; Sbarounis, 1984).
- For investigation of completed structures, use the actual location of reinforcement as built, especially if there is significant deviation from the specified location.
- Use the amount and location of compression reinforcement in computing I_g and I_{cr} . The transformed area of the steel can contribute significantly to the flexural stiffness of the cross section, even though it is not part of the ACI Code requirements.
- Use the amount and location of tension reinforcement in computing I_g . As with compression reinforcement, it can contribute significantly to the gross flexural stiffness. For cracked-section flexural stiffness, tension reinforcement is specifically considered in the calculation.

^{*} For example, assume that $I_{cr}/I_g = 0.25$. When $M_{cr}/M_a = 7.5/10 = 0.75$, $I_e = (0.75)^3 I_g + [1 - (0.75)^3] 0.25 I_g = 0.57 I_g$ and $1/0.57 = 1.76$.

- For deflection calculations based on curvature along the span, use variation in flexural stiffness EI along the span due to change in cross-section, change in amount of reinforcement, and degree of cracking.
- Include the effect of flanges, even though they may be small. If a rectangular beam instead of a T-beam (flanges are usually present) is used in computations, both the cracked and uncracked (or gross) moments of inertia will be unrealistically low and the computed deflection unrealistically high. For more than 50 years, the ACI Code (currently Section 8.10) has specified essentially the same criteria for determining the width of the flange. Although the rationale for these criteria may be lost, the criteria have served well for strength design because few, if any, failures due to inadequate flange width have been reported. For deflection computations, the situation is not so good. The design engineer is concerned with an accurate estimate of deflection, neither high nor low, as contrasted with an effort to estimate minimum strength, not necessarily the actual strength. ACI Code T-beam procedures are inconsistent and probably conservative.
- Make a realistic assessment of the contribution of end-region stiffness to the overall stiffness rather than a simple averaging of end and midspan region stiffnesses. A simple average gives far more weight to the end-region stiffnesses than is justified. Using midspan stiffness is satisfactory for simple and normal calculation procedures, but accuracy can be increased somewhat for extended procedures by including the effect of stiffness in the end regions. For beams continuous on two ends, ACI 435 recommends the following:

$$I_e = 0.70I_{e(m)} + 0.15(I_{e(1)} + I_{e(2)}) \quad (9.9a)$$

For beams continuous on one end only:

$$I_e = 0.85I_{e(m)} + 0.15(I_{e(1)}) \quad (9.9b)$$

where subscript (m) indicates a midspan location, and subscripts (1) and (2) indicate locations at ends one and two.

9.4.4 Factors Affecting Fixity

- Consider the support rotation for cantilevers because movement due to support rotation at the end of the cantilever could be greater than the flexural deflection of the member itself. Furthermore, rotation could result in the end rising or lowering, depending on the back-span dimensions and loading.
- Consider the restraint that nearby, unloaded, parallel members provide through the torsional stiffness of supporting beams. In a load test of a large beam and slab roof, it was found that parallel members as far as 200 ft away helped restrain end rotation of a loaded member (Fling, 1996). Of course, this is a consideration primarily when individual members are loaded; if the entire structure is loaded simultaneously, restraint from parallel members will be minimized.
- Base the moment distribution on actual conditions of loading and stiffness of members rather than on assumed prismatic members. Until the advent of computers, such a consideration was beyond the capacity of manual computations. Depending on the physical conditions, a moment analysis based on nonprismatic members may give small to significant results for deflection considerations.
- Make allowance for the stiffness of joints if they are weak or have inadequately anchored reinforcement. The effect will be similar to rotation of the support for cantilevers. At present, no satisfactory analytical tools are available to deal with this consideration.
- Analyze end spans carefully, because they are especially sensitive to assumptions of moment at critical sections. The less stiffness the end support is assumed to have, the higher the positive moment in the end span and the higher the computed deflection, even though more positive-

moment steel is provided to resist the higher moment. For this reason, an engineer might use wider beams and more reinforcement in end spans simply to control deflection rather than as a necessary requirement for strength. Edge columns in the upper stories of multistoried buildings are frequently cracked from the high moment induced by the beams framing into them. Thus, their stiffnesses will be less than that for the gross uncracked section assumed in the moment analysis.

- Carefully control shoring and reshoring procedures, because moment distribution has the largest effect on deflection variability. Unsuitable procedures, especially near construction joints, may impose moments during construction that are more adverse than those assumed in design.

9.4.5 Construction Variations

In design, an engineer can do little about construction variations beyond taking care to specify reasonable tolerances and procedures. One might also make a study of the effect certain tolerable variations have on the deflection of a critical member. Of course, in an investigation of an existing member, some construction variations can be measured and allowance made in the deflection calculations. ACI Committee 117 (1990) recommended tolerances on concrete outlines, steel placement, and material properties that are considered reasonable and achievable. If deflection is computed using the maximum variation in one direction, the effect on deflection can be dramatic (Fling, 1992). Fortunately, variations tend to cancel each other, but if a number of variables each affected deflection in the same direction, the effect could be significant. Following is a list of the most serious variations:

- Tolerances on concrete outlines may result in a larger or smaller member than specified.
- Concrete cover on bottom bars may be smaller than specified due to gravity. The increase in effective depth will increase the cracked moment of inertia. Likewise, the cover on the top bars may be greater than specified with a reduction in effective depth and moment of inertia, but end-region stiffness has a much smaller effect on deflection than does the midspan stiffness.
- Concrete modulus of rupture is more variable than compressive strength; however, variability could be along the length of a member and thus tend to reach an average in its effect on deflection. There are few studies on this variation.
- Concrete compressive strength may average 15% higher than the specified strength, with a consequent increase in the modulus of elasticity (E_c) of 7%. Depending on job conditions, the average could diverge from the specified strength even more than 15%. When a structure is loaded before it has reached its design strength, the adverse effects on deflection may be even more severe than indicated by a lower compressive strength because the creep coefficient can be up to 50% higher for stress/strength ratios f_c/f_c' greater than 0.50 than for f_c/f_c' less than 0.5. For this reason, engineers should specify procedures that avoid loading deflection-sensitive structures before concrete reaches its design strength.
- Concrete modulus of elasticity (E_c) depends on many parameters other than compressive strength, such as, for example, the aggregates. Lightweight aggregates in the concrete will generally result in a lower modulus. The ACI Code gives an average value, but specific aggregates could vary significantly. In addition, certain very hard aggregates could result in a much higher modulus than assumed for the strength of the concrete.
- If the number of bottom tension bars is more than or less than specified, the effect on deflection will be proportional, if the section is cracked.

9.4.6 Creep and Shrinkage

Factors affecting creep and shrinkage have been discussed by ACI Committee 209 (1992) and some are noted in Section 9.3.1. These factors include age at loading, relative humidity, minimum thickness, volume/surface ratio, slump, cement content, air content, aggregates, admixtures, and ambient temperature.

9.5 Reducing Deflection of Concrete Members

The size of flexural members is in many cases determined by deflection response rather than by strength. This section gives design procedures for reducing the expected deflection that will enable design engineers to proportion building structures to meet both strength and serviceability requirements. The result could be more economical structures compared to those designed with unnecessarily conservative deflection response or those exhibiting deflection problems requiring costly repairs. The discussion assumes that a competent design is prepared in accordance with the ACI Code and construction follows good practices. To properly evaluate options for reducing deflection, a design engineer must know the level of stress in the member under consideration. That is, is the member uncracked, partially cracked, or fully cracked, and does light or heavy reinforcement indicate low or high stresses? Heavily reinforced members tend to be fully cracked because they are highly stressed. This chapter considers only two limiting conditions: uncracked members and fully cracked members. For the purposes of this chapter, if the applied moment in the positive region is more than twice the cracking moment, considering the effect of flanges, the member may be considered to be fully cracked. Frequently, a member is only partially cracked ($M_{cr} < M_a < 2M_{cr}$), and the statements about both limiting conditions are not strictly applicable. Instead, engineers must use their judgment or make appropriate calculations to interpolate between the limiting conditions. See Section 9.2.4 for methods to compute the degree of cracking in a member. In addition to the stress conditions, there may be physical or nonstructural constraints on the use of some options, such as limits on increasing concrete outlines. For all options, the financial implications must be evaluated for each situation. Some options may increase the cost, some may have offsetting considerations that reduce the cost, and still others may have little effect on cost. Except as noted, only non-prestressed, reinforced concrete members are discussed below. For each option presented, the discussion includes the effect of implementation on deflection, the approximate range of potential reduction of deflection, and appropriate situations in which the option should be considered. Options are arranged in three groups: design techniques, construction techniques, and materials selection.

9.5.1 Design Techniques

9.5.1.1 Option 1: Make the Member Deeper

While increasing the depth may not be possible after schematic design of the building has been established because it affects the architectural and mechanical work, there are many instances where beam depth can be increased. The reduction in deflection is approximately equal to the square of the ratio of effective depths d for cracked sections* and approximately equal to the cube of the ratio of total concrete depths for uncracked sections.** For example, if an 18-in.-deep, rectangular beam with an effective depth of 15.5 in. is increased to 20 in. deep, and all other parameters are kept the same, the cracked stiffness will increase by $(17.5/15.5)^2 = 1.27$, and the uncracked stiffness will increase by $(20/18)^3 = 1.37$. For heavily reinforced members, if the amount of steel is reduced when the depth is increased, the cracked stiffness is increased only in proportion to the increase in depth, or by 13% for this example.*** The increase in stiffness of an uncracked T-beam when it is made deeper will be less than that for a rectangular beam because the flanges do not change. Flanges tend to have a fixed influence rather than a proportional influence on uncracked stiffness. If, by increasing the depth, the concrete tensile stress in a member is reduced sufficiently so it changes from a cracked, or partially cracked, to an uncracked member, the stiffness could increase dramatically. The uncracked stiffness can be as much as three times the partially cracked stiffness (Grossman, 1981).

* $I = nA_s(1 - k)jd^2$, $I \approx d^3$.

** $I = bh^3/12$, $I \approx h^3$.

*** $A_s = M/f_jd$, $I \approx d$.

9.5.1.2 Option 2: Make the Member Wider

This option is not applicable to slabs or other members with physical constraints on their width; however, where beams cannot be made deeper because of floor-to-floor height limitations but can be made wider, the increase in stiffness is proportional to the increase in width if the member is uncracked. If the member is cracked and remains cracked after increasing the width, the increase in stiffness is very small; however, if a cracked member will be uncracked after the width is increased, the stiffness will increase dramatically, possibly by as much as a factor of three (Grossman, 1981).

9.5.1.3 Option 3: Add Compression Reinforcement

Using ACI Code procedures, compression reinforcement has no effect on immediate deflection but can reduce additional long-term or incremental deflection by a factor of up to about 50% (Branson, 1971). The effect on total deflection is somewhat less; for example, if immediate deflection is 0.50 in. and additional long-term deflection is 1.00 in., then the total deflection is 1.50 in. The addition of 2% compression reinforcement reduces the additional long-term deflection to 0.50 in., or by 50%, and the total deflection to 1.00 in., or by 33%. Long-term deflection has two components: creep deflection and shrinkage warping. Compression reinforcement reduces deflection because concrete creep tends to transfer the compression force to the compression steel, which does not itself creep. The closer the steel is to the compression face of the member, the more effective the steel is in reducing long-term creep deflection; thus, compression steel will be more effective in deeper beams than in shallower beams or slabs if concrete cover to the compression face is a constant value. Indeed, in some very shallow members, due to the requirements of minimum bar cover, compression steel could be at or near the neutral axis and almost totally ineffective in reducing long-term creep deflection. Shrinkage warping occurs where the centroids of steel and concrete do not coincide and the shrinkage of concrete, combined with the dimensional stability of steel, warps the member, similar to a piece of bimetal subject to temperature variations. Compression steel reduces shrinkage warping because it brings the centroid of all reinforcement (tension plus compression) closer to the concrete neutral axis. Although this is true of all flexural members, compression steel is especially effective for T-beams where the neutral axis is close to the compression face and far from the tension steel. If the T-beam has a thin slab subject to higher than normal shrinkage because of its high surface/volume ratio, then compression reinforcement will be more effective than for a rectangular beam. This will be true for ribbed slabs or joist systems as well.

9.5.1.4 Option 4: Add Tension Reinforcement

For uncracked members, the addition of tension steel has hardly any effect on deflection. For fully cracked members, the addition of tension steel will reduce both immediate and long-term deflection almost in proportion to the increase in steel.* For example, if the total deflection of a cracked member is 1.50 in., as in the example above, increasing the tension steel by 50% will reduce the deflection to about 1.10 in. Of course, the increased steel area should still be less than the maximum permitted by the ACI Code or $0.75\rho_b$ (rho balanced). This option is most useful for lightly reinforced solid and ribbed slabs. The option of adding more tension reinforcement is not available or is limited for heavily reinforced beams unless compression reinforcement is also added to balance the increase in tension-bar area in excess of $0.75\rho_b$. If this option is selected, excessive bar congestion may result.

9.5.1.5 Option 5: Add or Increase Prestressing

Many prestressed members are designed for load balancing; that is, the upward reaction of the prestressing tendons approximately equals the downward force of dead and other sustained loads. Deflection due to live-load and other transient loads will be the same as for an ordinary reinforced concrete member, subject to two qualifications. If prestressing keeps the member in an uncracked state, whereas otherwise it would

* The moment of inertia of cracked sections $I = nA_s(1 - k)jd^2$ and $I \approx 0.9A_s$, because $(1 - k)j$ does not vary much with changes in A_s .

be cracked, the live-load deflection will be smaller. On the other hand, if the member size is reduced to take advantage of the prestressing, the live-load deflection could be larger. For this reason, the span/depth ratio is usually limited to 48 for floor slabs with light live loads and 52 for roof slabs. See the ACI Code Commentary, Section R18.12.3 (ACI Committee 318, 1995). If the member has a high ratio of live load to dead load, the span/depth ratio must be proportionally smaller to give satisfactory deflection performance. If the sole purpose of prestressing a member is to achieve satisfactory deflection response, then prestressing to achieve full dead-load balancing is not necessary. Only a prestressing force sufficient to produce satisfactory deflection response is required. In this situation, the member may be partially cracked.

9.5.1.6 Option 6: Revise Structure Geometry

Common solutions include increasing the number of columns to reduce the length of the spans, adding cross members to create two-way systems, and increasing the size of columns to provide more end restraint to flexural members (this is especially effective for end spans).

9.5.1.7 Option 7: Revise Deflection Limit Criteria

If deflection of a member is excessive, the deflection limits may be reexamined to determine if they are unnecessarily tight. If experience or analysis indicates that the limits (see Section 9.6) can be loosened, then other action might not be required. Many building codes do not set absolute restrictions on deflection. An engineer might decide that the building occupancy or construction conditions such as a sloping roof do not require the normal deflection limits.

9.5.2 Construction Techniques

9.5.2.1 Option 8: Cure the Concrete to Allow It to Gain Strength

Deflection response is determined by concrete strength at first loading, not by its final strength. If the construction schedule makes early loading of the concrete likely or desirable, then measures to ensure high strength at first loading can be effective. For example, if design compressive strength f'_c is 4 ksi, if the member would be uncracked as designed, and if it is loaded when concrete strength is 2.5 ksi, it could be highly cracked due to a lower modulus of rupture even though its load-carrying ability is satisfactory. A cracked member will deflect several times as much as the same member in an uncracked state. Furthermore, the modulus of elasticity of 4-ksi concrete is higher than that of 2.5-ksi concrete. See the discussion in Option 19 and Option 20 for the effect of these parameters on deflection.

9.5.2.2 Option 9: Cure the Concrete to Reduce Shrinkage and Creep

Good curing will not affect the immediate deflection, but additional long-term deflection will be reduced. Assuming that the long-term component of deflection is evenly split between shrinkage and creep, if shrinkage is reduced 20% by good curing, the additional long-term deflection due to shrinkage will be reduced by 10%. The effect will be most pronounced on members subject to high shrinkage such as those with a low volume/surface ratio (small members), those with thin flanges, structures in arid atmospheres, or members that are restrained. The effect of good curing on creep is similar to the effect on shrinkage.

9.5.2.3 Option 10: Control Shoring and Reshoring Procedures

Many studies indicate that the shoring load on floors of multistoried buildings can be up to two times the dead weight of the concrete slab itself (Sbarounis, 1984). Because the design superimposed load is frequently less than the concrete dead load, the slab may be seriously overstressed and cracked due to shoring loads instead of remaining uncracked as assumed by calculations based on design loads. Thus, the flexural stiffness could be reduced to as little as one third of the value calculated by assuming design loads only. Furthermore, the shoring loads may be imposed on the floor slabs before the concrete has reached its design strength. See the discussion in Option 8. Construction of formwork and shoring should ensure that a sag or negative camber is not built into the slab. Experience indicates that frequently the

apparent deflection varies widely between slabs of identical design and construction. Some reasons for this may be that such slabs were not all built level or at specified grade or that the method and timing of form stripping were not uniformly applied. Also, construction loads may not have been applied uniformly. Soil conditions for shoring supported at ground level should be checked to ensure that the formwork does not sag under the weight of freshly placed concrete due to soil settlement.

9.5.2.4 Option 11: Delay the First Loading

This allows the concrete to gain more strength than specified or helps ensure that it reaches its design strength. Both the modulus of elasticity (E_c) and the modulus of rupture (f_r) will be increased. An increase in E_c will increase the flexural stiffness as noted in Option 19. An increase in f_r will reduce the amount of cracking or even allow the member to remain uncracked with an increase in flexural stiffness EI as noted in Option 20. Creep deflection will also be reduced by delaying first loading.

9.5.2.5 Option 12: Delay Installation of Deflection-Sensitive Elements or Equipment

Such delay will have no effect on immediate or total deflection, except as noted in Option 11, but incremental deflection (that occurring from the time a deflection-sensitive component is installed until it is removed or deflection reaches its final value) will be reduced. For example, if the additional long-term deflection is 1.00 in. and installation of partitions is delayed for 3 months, then the incremental deflection will be approximately 0.50 in. or one half as much as the total (see Section 9.5.2.5 of the ACI Code).

9.5.2.6 Option 13: Locate Deflection-Sensitive Equipment to Avoid Deflection Problems

Printing presses, scientific equipment, and other equipment that must remain level should be located at midspan where the change in slope is very small with an increase in deflection. On the other hand, because the amplitude of vibration is highest at midspan, vibration-sensitive equipment may be best located near the supports.

9.5.2.7 Option 14: Provide Architectural Details to Accommodate the Expected Deflection

Partitions that abut columns may show the effect of deflection by separating horizontally from the column near the top, even though the partition is not cracked or otherwise damaged. Architectural details should accommodate such movements. Likewise, windows, walls, partitions, and other nonstructural elements supported by or located under deflecting concrete members can be provided with slip joints to accommodate the expected deflections or differential deflections between concrete members above and below the nonstructural elements.

9.5.2.8 Option 15: Build Camber into the Floor Slab

Camber will have no effect on computed deflection of the slab, after deflection takes place, for installation of partitions and equipment. For best results, deflection must be carefully calculated (not overestimated), the pattern of cambering specified (not just a single value), results monitored during construction, and procedures revised as necessary for slabs constructed later.

9.5.2.9 Option 16: Ensure That Top Bars Are Not Displaced Downward

Downward displacement will always reduce strength. The effect on deflection in uncracked members will be minimal. The effect on cracked members (those that are heavily loaded) is in proportion to the square of the ratio of change in effective depths for cantilevers but much less for continuous spans because the flexural stiffness (and resulting deflection) of the member is determined primarily by member stiffness at the midspan section. Thus, the deflection of cantilevers is especially sensitive to misplacement of the top bars. In continuous members, if the reduction in strength at negative moment regions results in redistribution of moments, then deflection could be increased.

9.5.3 Materials Selection

9.5.3.1 Option 17: Select Materials That Reduce Shrinkage and Creep or Increase the Moduli of Elasticity and Rupture

Materials having an effect on these properties include aggregates, cement, silica fume, and admixtures. See Options 19 and 20.

9.5.3.2 Option 18: Use a Mix Design That Will Reduce Shrinkage and Creep or Increase the Moduli of Elasticity and Rupture

For example, use a lower water/cement ratio or a lower slump or change the proportions of materials. See Options 9, 19, and 20 for a discussion of the effects of these properties on deflection.

9.5.3.3 Option 19: Use a Concrete with a Higher Modulus of Elasticity

Using ACI Code procedures, the stiffness of an uncracked member will increase in proportion to the elastic modulus or in proportion to the square root of the cylinder strength (see ACI Code Sections 9.5.2.2 and 8.5). The stiffness of a cracked section is affected very little by a change in modulus of elasticity. Highly cracked members will not be affected.

9.5.3.4 Option 20: Use Concrete with a Higher Modulus of Rupture

Stiffness of partially cracked members will increase because the degree of cracking will be reduced. The increase in stiffness (decrease in deflection) will depend on steel percentage, the increase in the modulus of rupture, and magnitude of applied moment.

9.5.3.5 Option 21: Add Short Discrete Fibers to the Concrete Mix

The effect is to reduce shrinkage (see Option 9) and increase the cracking strength (see Option 20), both of which will reduce deflection, but the increase in cost may be substantial.

Table 9.4 summarizes some of the preventive measures required to reduce or control deflection. This table can serve as a general guide for the design engineer but is not all inclusive, and engineering judgment has to be exercised in the choice of the most effective parameters to control deflection behavior.

9.6 Allowable Deflections

Allowable deflection is the other side of the equation to which computed deflection should be compared. If there are no deflection limits, then the computed deflection is irrelevant. When the computed deflection is more than the presumed allowable deflection, it is appropriate to carefully consider the reason for limiting deflection. In some cases, the deflection limit might be increased while in other cases, it might be tightened. Incremental deflection is that portion of the total deflection that occurs after the construction or installation of a part of the facility until it is removed. In many cases, incremental deflection controls the design, not the live-load deflection or the total deflection. As spans exceed 25 to 30 ft, the absolute deflection becomes more critical than the span/deflection ratio; for example, a span/deflection ratio of 360 for a 30-ft span is 1 in. Deflections of this amount and greater can be seen with the naked eye, and many owners and users will object. Also, standard tolerances for many construction components have stated or assumed values that do not exceed about 1 in. Deflection limitations can be categorized into four groups: sensory acceptability, serviceability of the structure, effect on nonstructural elements, and effect on structural elements. Each group is discussed below. For a more complete discussion, see ACI Committee 435 (1984a,b).

9.6.1 Sensory Acceptability

Droopy cantilevers and excessive sag in long-span beams may be unacceptable to the public. The total deflection is relevant. Cambering can alleviate this concern almost regardless of the amount of deflection. Floors that vibrate can distress occupants. The rate of change in the acceleration is the relevant parameter,

TABLE 9.4 Deflection-Reducing Options

Description	Effect on Stiffness of Section	
	Uncracked	Cracked
<i>Design Techniques</i>		
1 Deeper members	$(h^*/h)^3$ for rectangular beams less for T-beams	$(d^*/d)^2$ or (d^*/d) if change to uncracked section, up to 300%
2 Wider members	(b^*/b)	Small, or change to uncracked section
3 Add A'_s	Up to 50% for D_{LT} No effect for D_i	Up to 50% for D_{LT} No effect for D_i
4 Add A_s	No effect	A'_s/A_s
5 Add prestress	Reduces dead load deflection to nearly zero	Reduces dead load deflection to nearly zero and changes member to uncracked
6 Structure geometry	Large effect	Large effect
7 Revise criteria	See text	See text
<i>Construction Techniques</i>		
8 Cure: f'_c	Same as higher E_c and f_r	Same as higher E_c and f_r and could change to uncracked section
9 Cure: ϵ_{sh} and ϵ_{cr}	For long-term deflection, $(\epsilon_{sh}^*/\epsilon_{sh})$ and $(\epsilon_{cr}^*/\epsilon_{cr})$	For long-term deflection, $(\epsilon_{sh}^*/\epsilon_{sh})$ and $(\epsilon_{cr}^*/\epsilon_{cr})$
10 Shoring	Large effect, see text	Large effect, see text
11 Delay first loading	Similar to Options 19 and 20	Similar to Options 19 and 20
12 Delay installation	Up to 50%+, depending on time delay	Up to 50%+, depending on time delay
13 Locate equipment	See text	See text
14 Architectural details	See text	See text
15 Camber	See text	See text
16 Top bars	No effect	Up to $(d^*/d)^2$ for cantilevers
<i>Materials</i>		
17 Materials	See Options 19 and 20	See Options 19 and 20
18 Mix design	See Options 9, 19, and 20	See Options 9, 19, and 20
19 Higher E_c	(E_c^*/E_c) or $(f_c^*/f_c)^{0.5}$	Small
20 Higher f_r	None	Significant
21 Use fiber reinforcement	See Options 9 and 20	See Options 9 and 20

but live-load deflection is commonly used to judge the acceptability of floors. More sophisticated analyses consider amplitude, frequency, and damping of vibration. Although vibration is not a problem for most structures, it should be considered if the structure supports, for example, vibration-sensitive laboratory equipment or for a long-span open floor in an important public building.

9.6.2 Serviceability of the Structure

Roofs and outdoor decks that should drain water must do so. The total deflection is relevant. Cambering and other construction such as topping fills or tapering insulation must also be considered. Tolerances on the levelness of floor-finishing generally require a slope of 1% or greater to ensure complete water drainage. Floors for gymnasias and bowling alleys must remain plane and level. Both total deflection and incremental deflection are relevant. Cambering may compensate for some of the total deflection, but it is difficult to build in most structures. Incremental deflection occurring after the floor has been installed should be limited to an acceptable amount for the anticipated use. Members supporting sensitive equipment such as printing presses and certain building mechanical equipment must not deflect more than the amount permitted for the equipment. The incremental deflection occurring after the equipment has been installed is relevant. In some cases, deflection between two points on the span, not the ends, is relevant and limits can be measured in thousandths of an inch.

9.6.3 Effect on Nonstructural Elements

Partition walls built of brittle materials such as masonry and plaster cannot tolerate large deflections. Even an incremental deflection of span/360 after installation of the partition may not be tolerable. More forgiving materials such as gypsum wallboard partitions (drywall) can tolerate larger incremental deflections. Prefabricated metal partitions may not be damaged by incremental deflections, but the total deflection may cause problems if the partitions are set to a laser-leveled ceiling and must meet a floor that is not level. Most ceilings installed today are not damaged by deflections that are acceptable by other criteria. Curtain walls, windows, doors, and certain other nonstructural building elements can be damaged by incremental deflection that exceeds the tolerance built into the element in question. In some cases, such as windows or cabinetwork that must fit between concrete floors above and below, the total deflection must be limited. In such cases, tolerances and perhaps other construction details must also be considered.

9.6.4 Effect on Structural Elements

Occasionally, deflections can cause instability of the primary structure, such as arches, shells, and long columns, for example. Deflection can cause higher stresses in another element, such as, for example, in masonry supporting a beam that rotates at the support. Mutually perpendicular cantilevers meeting at their tips must have the same deflection but may have different deflection properties. Thus deflection becomes a problem in moment analysis. In other cases, a slab supported on a deflecting beam may rest at the other end on an unyielding support, thus causing a moment pattern in the slab that is different from that computed using two unyielding supports. Engineers should be alert to special situations of this type that may distress the structure as well as cause damage to nonstructural elements.

10.1 Overview

10.1.1 Introduction

Concrete structural systems must be durable, constructable, economical, and functional. The system selected must be strong and in many cases aesthetically pleasing. The system must have deflections that are within acceptable limits and, in seismic areas, must have the ability to absorb the large amounts of energy generated by seismic events. Selection of a structural system can sometimes be a difficult process. In many cases, structural steel is the more economical system to use. In general, when the system is to be hidden by architectural finishes, concrete systems are not the systems of choice. When the structure itself becomes an architectural expression, concrete is often the material of choice. In most cases, the formwork for the concrete system selected represents almost half of the total expense of the structure. Obviously, repetitive systems that reduce the cost of formwork relative to the cost of the concrete and reinforcing are candidates for concrete systems. In fact, under certain conditions concrete systems may be the structural systems of choice, even when the concrete is not exposed or architectural. The plastic nature of the material provides an effective structural solution to any unusual requirements. In such cases, structural steel systems cannot provide the freedom of design that concrete provides.

10.1.2 Durability

Properly proportioned concrete, when placed, finished, and cured in accordance with established standards, provides a durability that is virtually maintenance free and seldom matched by structural steel systems. The weathering steels, often used in bridge design, are the closest rivals to a good dense concrete with proper air entrainment. The problems associated with rust staining have largely limited the use of steel structural systems to bridge structures. The durability of concrete is directly related to the quality of the concrete. Dense, well-consolidated concrete with a low water/cement ratio and proper amounts of entrained air will be durable in all but the most hostile environments. Varying cement types, additives, and surface treatments are effective in extending the durability of concrete subjected to less than desirable conditions.

10.1.3 Constructability

The choice of the structural system must be based on the availability of skilled labor to accomplish the design requirements. Concrete construction, unlike steel, is somewhat regional with respect to accepted and common practices. For example, the use of high-strength concrete (f'_c in excess of 5000 psi) is more prevalent in metropolitan areas of the United States. Experience with the construction of ductile moment frames is more widespread in geographic areas traditionally considered to be seismically active. Bridges, highways, water treatment facilities, and buildings each have their own special sets of design requirements, specialized techniques, and selection of materials developed to address these needs. Localized labor practices and costs have a major influence on the degree to which concrete structural systems are utilized. Cast-in-place concrete is considerably more labor intensive than the fabrication of precast concrete. Conversely, transportation and erection of precast systems are obviously more expensive than those of cast-in-place systems. In theory, the optimum reinforcement for reinforced concrete would be an extremely large number of very small reinforcing bars to provide a uniform distribution of tensile reinforcing. The reality is that one is forced to use the least number of reinforcing bars and to use large bars to keep the labor costs within reason. Local union agreements, in many cases, place restrictions on which bars may be cut and fabricated in the field vs. which may be shop cut and fabricated. Obviously, shop fabrication is more desirable, because the equipment available and the controlled work environment generally result in a better product.

The cost of formwork constitutes a major portion of the cost of concrete structures. It is not uncommon for the cost of the formwork to represent 50% of the total cost of the in-place concrete. Systems that require simple, straightforward, reusable forms have a significant cost advantage over systems requiring

more complex forms. Many times the effort to reduce the complexity of formwork leads to simpler configurations that, unfortunately, require additional concrete along with additional loads, which must be carried by the foundation system. Whenever formwork can be reused, more complex configurations can be utilized. The ability to quickly strip and re-erect forms is a major cost savings in that overall construction time and general condition-related costs are reduced. For a structure under construction, the use of concrete or masonry usually results in the greatest time exposure to the elements. Given this significant length of exposure, the geographic location and the time of year that construction takes place can have a major impact on the costs of concrete construction. Obviously, some steps can be taken to allow concreting operations to continue during weather extremes, but this invariably results in additional job costs. An added concern during periods of weather extremes is quality control.

10.1.4 Appearance

In many cases, concrete is called upon to perform several functions. In addition to providing strength for a structure, it also acts as cladding, it must be durable and weather resistant, and it must have a pleasing appearance. The design of the exposed finish may require a simple rubbed surface to remove minor surface blemishes and form marks or a considerably more expensive architectural surface finish. Great care must be taken to successfully achieve consistent architectural finishes. Elements that must be considered include:

- A workable concrete mix to facilitate placing and finishing activities
- Consistent, controlled water content in the mix
- Use of cement from a single batch, as ASTM C 150 allows for a wide variation in the coarseness and thus color of the cement powder
- Accurate batching of the components of the cement
- Leak-free formwork to eliminate bleed marks due to loss of paste
- Proper placing techniques to avoid segregation of the mix and cold joints
- Consideration of varying weather conditions
- Proper curing
- Careful formwork removal
- Protection of the concrete from damage and staining during subsequent construction operations

Failure to successfully accomplish all of the above will almost certainly lead to less than satisfactory finishes, placing the designer and owner in the unenviable position of deciding to accept blemished concrete or delaying the project while the defective concrete is removed and replaced. Repaired honeycombing of exposed surfaces invariably deteriorates with time (at least with respect to appearance) and is a major contributor to unsightly concrete. In some instances, surface coatings are the only way to obtain an acceptable surface finish. Structural concrete not required to meet the visual requirements of architectural concrete must nevertheless be durable and weather resistant. The placing and curing requirements above should still be required. The color variations resulting from use of cement from varying batches and manufacturers and some relaxation of moisture control may be acceptable for the application.

10.2 Building Loads

10.2.1 Introduction

Design loads dictated by model building codes reflect the statistically probable maximum loads that can be expected to act upon a structural system. These loads are typically quoted as service loads, meaning that they have not been factored upward. Load factors are employed to account for inconsistencies in material properties, construction and fabrication practices, and the predictability of the load itself. They are, in essence, safety factors. In addition, load factors are employed to conduct analysis of the structural system in the ultimate stress range, as opposed to the service stress range.

Typically, the yield point of commonly used construction materials, such as steel and concrete, is well established; therefore, it is possible to design to the ultimate performance range of these materials. It is not desirable, however, to design structures so they perform in the ultimate range under typical loading conditions. This would not leave a sufficient factor of safety in the event of anomalies in the design assumptions. For this reason, the service loads quoted by the model building codes are intended to be applied to materials within their elastic stress ranges. If the designer wishes to analyze a structure by considering the ultimate performance of the materials, then load factors must be applied to the service loads.

As noted above, load factors are the product of both materials analysis and probabilistic theory concerning the construction and fabrication processes. Concrete design per ACI 318-05 employs load factors of 1.2 for dead loads and 1.6 for live loads acting simultaneously. Other combinations of load factors are employed depending on the code being used and the effect of one or more loads being applied at the same time. The distinction between these values is primarily based on the lack of predictability of how live loads will be applied to a structure. How to classify a dead load and a live load is a question to be addressed by the designer; however, certain truisms should be considered.

Material weights are generally predictable and can be specifically calculated as they apply to a given structural member. The weights of large, immovable objects, such as mechanical equipment, permanent shelving or storage racks, or planters are also fairly predictable. These elements can be classified as dead loads with little risk of inaccuracy.

Human occupancy, furniture, and transient storage that fluctuate in volume and intensity are among the items that are less predictable and thus subject to a higher load factor. In addition, external loads that act on structures are equally unpredictable. Wind, seismic, hydrostatic, and earth loads must be factored as live loads to consider their inherent unpredictable nature.

Maximum load combinations, such as live plus dead plus wind, have the statistical tendency to occur so infrequently that the various model building codes and material-design manuals permit reductions in the overall load applied to the structural system. The reduction factors differ according to the codes and manuals, so the designer should check the applicable references for the particular project.

Model building codes determine the load factor combinations that must be used. Individual jurisdictions must adopt the provisions of a model building code for it to be the governing code. Jurisdictions might consist of municipalities, counties, or whole states. Jurisdictions may adopt only certain provisions of a model code and not others. They might supplement the model code with additional design information that is specifically applicable to a given region.

The designer is cautioned to fully understand the applicable building code where his or her project is to be built. It is the location of the structure that dictates the governing code, not the location of the designer, client, or reviewing agency. The designer must also be aware of local provisions that supersede the model code; for example, municipalities located close to hurricane zones may adopt more stringent wind loads than are dictated by the adopted model code.

Finally, third-party sources assemble construction data pertaining to loads and material performance. These resources, such as Factory Mutual and Underwriters Laboratories, often develop their data to assist insurance companies in establishing rate structures for coverage. As such, they tend to be slightly more conservative in their statement of loads than the model building codes. The designer is obligated to follow these design guidelines only if the jurisdiction has adopted them into the local building code or if the building owner, for whom the designer is producing the design, dictates that the more stringent design standard be used. If these resources are used, specific attention should be paid to the treatment of snow and wind loading and to the fire rating of structural assemblies.

The most frequently referenced model building code in the United States is the International Building Code (IBC), which is used by 47 states and Washington, D.C. Adopted code editions and supplements might vary with each jurisdiction. It is incumbent on the designer to make certain which model code and what code amendments and provisions have been adopted for the location of the project. For the purposes of the following discussion, the IBC 2006 edition is referenced.

10.2.2 Gravity Live Loads

Analytically, design loads can be divided into two primary groups: gravity loads, which predominantly act vertically on the structure, and lateral loads, which predominantly act horizontally on the structure. Gravity loads account for all dead loads and those live loads associated with occupancy of the structure. The designer can refer to several sources for information to provide weight data regarding various building materials. Manufacturers provide tabulated load data for proprietary building materials. Nonproprietary material weights, such as concrete, asphalt, and roofing and flooring materials, can be found in the American Society of Civil Engineers' publication ASCE 7 (*Minimum Design Loads for Buildings and Other Structures*, Tables C3-1 and C3-2). Live-load data are developed with respect to the use and occupancy of a given structure. IBC Chapter 16, Section 1607, is devoted to establishing the intensity of various live loads as they relate to various uses and types of structures. IBC Tables 1607.1 and 1607.6 provide a breakdown of the maximum anticipated design live loads for a wide variety of use conditions. The designer should refer to these tables and the subsections of Section 1607 to establish the design live load for the use that most closely matches the anticipated use of the given structure. Local building codes do not generally permit interpolation between specified live loads; therefore, larger, multiuse facilities may require subdivision into several analytical pieces for design purposes. It is both permissible and recommended that different live loads be applied to the structural model, as required to satisfy the variety of intended uses. An example of this is the application of a 100-psf load near public means of exit, although the remainder of the building requires only a 50-psf live load to satisfy an office-use criteria. The designer is reminded that the IBC live load data for use and occupancy are quoted as service loads. Appropriate load factors must be applied to permit analysis of the ultimate material stress range.

10.2.3 Lateral Live Loads

The second group of live loads that must be considered by the designer are lateral loads, which are frequently the least predictable live loads. Such loads include wind, seismic, hydrostatic, and earth loads. Per IBC 2006, wind loads are determined in accordance with Chapter 6 of ASCE 7. The designer must first establish the applicable basic wind speed for the locale of the given structure. The basic wind speed is defined as the fastest 3-second gust speed in miles per hour for a given locale associated with an annual probability of 0.02 (50-year mean recurrence interval) and measured at a point 33 feet above the ground in Exposure C. The next design task is to determine the applicable exposure for the given structure. The exposure classifications differentiate between sites that are subjected to high, direct wind forces due to terrain characteristics and those that do not experience such wind forces due to shielding effects, building or forest density, or other terrain irregularities. Because subsequent adjustment factors are determined based on the exposure classification, it is crucial that the designer make a thoughtful selection. The designer is cautioned that wind forces are notoriously unpredictable. Large, concentrated forces can accumulate due to irregular building geometry or aerodynamic effects around canopies, roofs, balconies, or multiple-story structures. Consequently, it is not recommended that liberties be taken with the exposure classification in an attempt to refine the load analysis. The most prominent physical features of the terrain, surrounding buildings, the given structure, and potential changes over the life span of the structure should be considered when selecting the exposure group. The design wind pressure is determined by applying several modification factors to the basic wind pressure. These factors consider gust effects, the windward or leeward face of the building, the type of structure involved, and the slope of the roof. Special factors are provided for chimney, tower, sign, and flagpole structures. When determining the wind force on an entire structure, the designer is reminded that the combination of both windward and leeward forces must be considered. ASCE 7 distinguishes between *main wind force-resisting systems* and *components and cladding*. This distinction is based on the acknowledgment that, although the combination of windward and leeward forces acts only upon a primary system, components often experience intense concentrated forces due to surface irregularities of the building. Consequently, determining forces and gusts acting on components requires that the designer consider both the size and the position of the component in question relative to the entire building.

In practical application, buildings with multiple roof heights and articulated facades often require the development of a wind-pressure chart superimposed over each elevation of the building. This exercise permits the designer to account for major component features on the building exterior. In addition, because the design industry has moved progressively further away from requiring individual structural engineering consultants to shoulder the entire design responsibility for all building components, the development of a wind-force chart by the primary structural engineer provides appropriate information for subconsultants to design cladding systems and canopies.

Application of wind loads to a structural model is generally considered to occur at the slab-column joints for each floor level. This mode of application addresses the usual facade configuration in which the cladding is connected to the structure at each floor diaphragm. Where the facade treatment attaches to the structure in a different fashion, the designer must follow the load path from the cladding to the framing to determine the most accurate mode of application of wind loads. The designer is reminded that the wind-load data provided in the IBC and ASCE 7 are service loads and must be factored upward by the appropriate load factor in order to work in the ultimate material stress range.

The second form of lateral load to be considered is seismic load. Seismic load is generated from the movement of the ground and thus acts on the structure in a very different manner than wind loads. Seismic forces are transferred to the structure through the foundation elements. The influence on the supported floors occurs as a function of the weight of each floor. The acceleration of the ground thus causes the mass of each floor to accelerate, resulting in a seismic force in each diaphragm.

A delay occurs between the initial seismic force impact at the foundation level and the influence on the supported floors. Depending on the configuration of the structural components and the distribution of stiffness, the frequency and period of motion of the structure will vary. These variables—frequency and period—play an important role in establishing the design loads to be applied to the structural system. The stiffer the lateral load resisting system, the shorter the period of motion and the greater the frequency. Ductile systems tend to absorb load rather than transfer it through to the other structural members. Thus ductile systems result in longer periods of motion and lower frequencies of vibration. The detailing of reinforcement and the degree of confinement to increase ductility is of major importance. Sufficient reinforcement at the locations of large stress concentrations have to be provided. Beam-or slab-column connections are particularly susceptible to stress concentrations due to the large differences in stiffness between the members. In addition, re-entrant corners, edges near shear walls, and openings for stairs and elevators must be carefully detailed to avoid cracking problems. Chapter 21 of the ACI 318 Building Code (ACI Committee 318, 2005) covers the provisions for seismic proportioning of members and their detailing. The reader is referred to Chapter 26 of this *Handbook* for details of design and proportioning of seismic-resistant concrete structures, their shear-wall components, and the latest provisions on this subject.

It is important to highlight some of the major factors in the context of this general discussion. Typically, shear-wall systems provide satisfactory resistance to seismic loads due to their unique performance characteristics. Shear walls tend to be very stiff at the base but gradually become more flexible as they increase in height. At extensions above approximately 120 feet, shear walls tend to deflect more than $h/300$, where h represents the height of the structure. It is advisable that the deflection level does not exceed $h/400$.

For high-rise construction, a dual system is recommended that employs a combination of both shear-wall elements and moment-resisting frame elements. Frames are flexible throughout but tend to deflect in a regular and predictable manner throughout their height. Thus, at lower elevations on the structure, the shear walls act to restrain the frames, while at higher elevations in the structure the frames act to restrain the deflection of the shear walls. The designer should note that a dual system employing ordinary moment-resisting frames and concrete shear walls provides better resistance than either an independent shear-wall system or an independent ordinary moment-resisting frame system.

Finally, when considering deflections of structures subjected to seismic loads, the designer must acknowledge that the building codes are developed to prevent catastrophic collapses. This should be understood to mean that conformance with the provisions of the model codes will not ensure that a

FIGURE 10.1 Composite beam systems: (a) composite steel beam, and (b) composite precast prestressed concrete beam.

structure will survive seismic activity unharmed. It can be expected that cracking and possibly spalling of concrete near high-stress-concentration zones may occur. In addition, peak deflections due to maximum anticipated seismic ground accelerations can be more than 10 times greater than those that will be generated using the design seismic base shear; however, adherence to code provisions will dramatically improve the potential for a structure to survive seismic activity. Localized repairs are preferable to the complete demolition of a structure.

10.3 Composite Steel–Concrete Construction

10.3.1 Introduction

Composite construction is the use of two or more building materials or systems that are bonded or interlocked to act as a single unit. In most common building systems, composite construction involves the use of concrete and steel. These materials work extremely well together for beam construction due to the high compression resistance and stability provided by concrete combined with the good tension-resisting attributes of steel. In the early part of the twentieth century, composite beam construction existed primarily as a result of fire protection needs, the end result of complete concrete encasement of steel I-shaped beams. In most cases, the composite action of the two building materials was not realized and was completely neglected in design. The composite action existed due to chemical bonding and friction at the material interface and by the shear strength of the concrete along the shortest failure plane. Although this type of construction and design is still permitted, it is very rarely used. With the development of welding techniques, a more solid mechanical interlock could be developed to resist the horizontal shear that develops during bending. The use of a mechanical interlock to develop this composite action was first utilized in bridge construction beginning in the 1930s. Economics prevented the widespread use of composite construction of this nature in buildings until the 1960s. Today, composite construction has been used worldwide in both bridge and building construction. Figure 10.1 illustrates two composite beam–slab systems.

10.3.2 Advantages and Disadvantages

Several advantages can be realized with the use of composite construction. As a rule of thumb, composite action becomes most efficient when loads are heavy, the beams are spaced as far apart as practical, and spans are relatively long. Typically, a 20 to 30% reduction in steel weight can be gained, providing better economy and, in many instances, shallower beam depths. Shallower beam depths may result in substantial savings in high rises, where floor-to-floor depths can be reduced. Lower floor-to-floor depths result in smaller overall building heights, generating savings from reduced wall materials and reduced lengths of mechanical, electrical, and plumbing risers. Compared with a noncomposite floor system, the stiffness and overload strength of a composite floor system are considerably greater. This is because the concrete slab acts as a large cover plate, shifting the neutral axis upward and allowing more efficient use of the two materials. This often allows a section that works as a noncomposite member to be used like a

composite member for longer spans without creating deflection concerns. Although composite construction does have some disadvantages, the advantages and overall economy favor its use. The cost of providing and placing mechanical shear connectors has significantly decreased over the years but should be considered, particularly on small jobs where mobilization of additional trades may completely offset the savings provided by reduced steel weight. In some cases, although smaller beam sizes may theoretically work as composite members, their use is not practical. Beams with flange thickness less than 1/4 inch require careful shear-stud placement to guard against burn-through failure during welding. The use of projecting shear connectors also increases safety hazards by keeping workmen from walking on the beams; for that reason, the installation of the shear connectors is often delayed until the deck forms or metal decking is installed.

10.3.3 Other Considerations

The advantages of composite action are largely unrealized in continuous-beam or frame construction due to the limited continuity in areas of negative bending. Because concrete is unable to effectively resist tension, continuity in these areas is limited to that which is provided by bar reinforcement and is usually neglected. Because the negative moment at a support often exceeds the positive midspan moment, composite action will have little effect other than to reduce midspan deflections. End reactions for composite beams are almost always larger than those for noncomposite beams of the same size. Engineers and fabricators often design connections based on uniformly loaded, noncomposite beam capacity. Such a practice potentially understates the shear loads and should not be used for composite construction. Long-term creep deflections are usually small enough to be neglected in composite beams but may warrant special consideration where heavy, sustained loading situations are encountered and when deflection criteria are more stringent.

10.3.4 Composite Action

Composite steel beam and concrete-slab systems behave in a similar manner to reinforced concrete T-beams. The analysis procedure is based on a standard transformed-section methodology. For detailed information on the design of composite members, the designer is referred to AISC Specification Chapter I. For buildings, AISC limits the portion of the slab that can be considered to participate as a flange for beam action. The AISC limits are very similar in nature to the T-beam construction requirements of the ACI 318 Code. The effective flange width on each side of the beam centerline for an interior beam is taken as the smaller value of 1/8 the beam span, 1/2 the distance to the nearest adjacent beam, and the distance to the edge of the slab. The slab thickness criteria of ACI 318 Section 8.10 are not considered in the AISC specification. Although composite construction using steel and concrete has only been discussed thus far, it should be noted that conventional slabs are sometimes designed to act compositely with precast, prestressed concrete beams. In such cases, the T-beam requirements of the ACI 318 Building Code should be followed.

The computation of section properties is based on the principle of transforming all components into a single, homogenous member. This is done on the basis of the ratio of the moduli of elasticity of the two materials. If a steel beam is used, the concrete slab is converted into an equivalent width of steel by dividing the effective flange width by the modular ratio $n = E_s/E_c$. The calculations necessary for composite design are similar to those for a built-up beam. The composite section must be proportioned to resist the loads, and the shear connectors must be adequate to ensure that the section acts as a solid, single member. The design of the shear connectors between the slab and the beam is based on the total horizontal shear that exists at the interface. The shear flow is the force per unit length that must be resisted at the interface to achieve composite action. Shear flow is given as:

$$f = \frac{VQ}{I}$$

FIGURE 10.2 Shear–stress distribution across a composite section.

FIGURE 10.3 Types of shear connectors: (a) headed stud, (b) spirals, and (c) channels.

where V is the shear force, Q is the first moment of the effective area above the interface with respect to the neutral axis, and I is the moment of inertia of the composite section. If a given connector has a shear capacity of q , the maximum spacing can then be determined as:

$$s \leq \frac{q}{f}$$

In Figure 10.2, the shear flow at the steel–concrete interface is $v_i b_{\text{eff}}$. Numerous types of shear connectors have been utilized over the years. They include headed studs, spiral rods, channels, angles, and L-shaped connectors. Figure 10.3 illustrates some of these connectors. In building construction, composite sections usually involve using steel deck as a slab form. When composite metal decking is used, AISC only allows the use of welded studs. The minimum stud length is equal to the rib height of the deck plus 1-1/2 in. A minimum of 1/2 in. of concrete cover is required above the top of the installed studs. The shear studs are commonly fastened in the field with special stud-welding guns. This is done to prevent damage to the connectors during transportation and to allow easier steel erection and deck placement. It should be noted that shear connectors must be capable of resisting both horizontal and vertical forces. Because of the tendency of the slab to separate vertically from the beam, it is good practice to limit the connector spacing to around 2 ft. AISC limits the maximum stud connector spacing to eight times the total slab thickness. The reader is referred to the AISC Code for specifics regarding the use of form deck for composite construction.

10.3.5 Unshored vs. Shored Construction

For unshored construction, the beam member must be capable of supporting its own self-weight plus the weight of the wet slab concrete. Once the slab concrete attains about 75% of its 28-day compressive strength, the beam and slab are considered to act as composites. The composite section must then be capable of resisting the live loads and any additional superimposed dead loads. For unshored construction, the compressive stresses in the concrete slab will seldom be critical. For unshored construction, the service-load stresses can be computed as:

$$f = \frac{M_c}{S_d} + \frac{M_s}{S_c}$$

where M_c is the moment due to construction loads, M_s is the moment due to superimposed loads after slab curing, S_b is the section modulus of the beam, and S_c is the section modulus of the *composite member*. When shored construction is used, the working stresses are computed as follows:

$$f = \frac{M_c M_s}{S_c}$$

Although shored construction is usually more costly, dead-load deflections can be significantly reduced. Shored construction also results in higher concrete compressive stresses.

10.3.6 Composite Columns

Composite-column construction usually combines the use of concrete and steel. The two primary forms of composite column construction are (1) concrete-encased steel sections, and (2) steel-encased concrete members. It is important to realize that composite construction implies that there is a shear transfer between the concrete and steel. Simply filling a steel pipe or tube column with concrete will not create a composite member. Section 10.16.3 of the ACI 318-05 Code requires that any axial load assumed to be resisted by the concrete must be transferred to the concrete via lugs or brackets in direct bearing. Similarly, all axial load strength not taken by the concrete must be developed by a direct bearing or shear connection to the structural steel member. The capacity of a composite column is computed on the basis of the same requirements as a conventionally reinforced concrete column. For structural-steel-encased concrete sections, the thickness of the wall jacket must be sufficient to reach longitudinal yield stress before buckling outward. To ensure this, ACI 318 Section 10.16.6.1 stipulates minimum wall thicknesses for both rectangular and circular sections. For concrete-encased structural steel members, ACI 318 Section 10.16.7 sets limits on the compressive strength of the concrete and the design yield strength of the structural steel for members with a spirally reinforced steel core. The radial confining pressure provided by the spiral results in sufficient composite action between the concrete, reinforcing bars, and steel core such that the reinforcing bars assist in both stiffening and strengthening the member. ACI therefore permits the inclusion of the longitudinal bars when computing the area and moment of inertia of the steel core for evaluation of slenderness effects. For structural steel cores confined by tie reinforcement, it is likely that there will not be complete interaction between the concrete, steel, and reinforcing bars; therefore, use of the longitudinal reinforcing bars is permitted for computing the moment of inertia of the steel core because they assist in strengthening the section but do not effectively stiffen it. The tie-spacing requirements are similar to the spacing requirements of ACI 318 Section 7.10.5, with the exception that tie spacing for composite columns may not exceed one half the smallest side dimension of the member. This increased spacing requirement is intended to help maintain the concrete core, which may separate from the smooth surfaces of the structural steel. ACI 318 Section 10.16.8 defines the requirements for concrete-encased steel sections with transverse tie reinforcement.

10.4 Foundations

10.4.1 Shallow Foundations

Foundation systems are commonly referred to as *shallow* or *deep*, depending on the depths to which they extend to achieve adequate bearing capacity. Shallow foundations are those foundations that transfer column loads either directly or through relatively short piers, pilasters, or walls to the supporting soil below. The most common types of shallow foundations are strip or wall footings, spread footings, and combined footings. Strip footings are commonly used beneath walls and rely on one-way action as they

FIGURE 10.4 Footings with resultant vertical reaction of the middle third of the footing.

FIGURE 10.5 Footings with resultant vertical reaction outside the middle third of the footing.

cantilever a short distance on either side of the wall. Spread footings are usually square or rectangular pads that act to distribute individual column loads over a soil area large enough to support imposed loads. Combined footings act to distribute loads from two or more columns to the soil. Spread and combined footings rely on two-way distribution of the loads to the soil. In general, these footings are subjected to axial loads, shears, and moments from above that mobilize resisting soil pressures that can be determined by one of the following formulas. For those footings in which the resultant vertical reaction occurs in the middle third of the footing (Figure 10.4):

$$f_{p \max} = \frac{P}{A} \left(1 + \frac{6e}{L} \right) \tag{10.1}$$

For those footings in which the resultant vertical reaction occurs outside of the middle third of the footing (Figure 10.5), equilibrium requires that the total resisting force equal the imposed force. Assuming a triangular pressure distribution:

$$P = f_{p \max} \frac{Bx}{2} - 5pt \tag{10.2}$$

where:

$$x = 3 \left(\frac{L}{2} - e \right), \quad f_{p \max} = \frac{4P}{3A(L - 2e)}, \quad f_{p \min} = 0 \tag{10.3}$$

where:

- f_p = soil pressure (kips/ft²).
- P = vertical load (kips).
- e = eccentricity of the vertical load (ft).

- A = contact area of the footing in square feet.
 L = length of footing, perpendicular to axis of the moment (eP) in feet.
 B = width of footing, parallel to axis of the moment (eP) in feet.

The design of a shallow footing must consider resistance to flexural and shear forces. ACI 318, Chapter 15, outlines the code requirements for the design of isolated column footings. Section 10.5.4 states that the minimum reinforcement for structural footings must meet the shrinkage and temperature requirements for steel given in Section 7.12. For grade-60 reinforcement, the minimum area of the temperature flexural reinforcement becomes:

$$A_{s(\min)} = 0.0018(bh) \quad (10.4)$$

where b is the width, and h is the thickness of the footing. The maximum spacing of footing reinforcement must not exceed the smaller of $5h$ or 18 in.

The thickness of a footing is usually governed by shear. This is because it is generally less expensive and easier to increase the depth of a footing than to try to provide web reinforcement in the form of stirrups. The standard requirements of ACI 318, Chapter 11, are used for shear design. For spread footings, both one-way shear based on beam action and two-way punching shear must be checked. The critical section for one-way shear is located at a distance d from the face of the concrete column or halfway between the face of the column and edge of the base plate for steel columns.

Another form of shallow foundation is a mat foundation, which becomes viable in locations with relatively low bearing conditions and potential water conditions. If the sum of the footing areas exceeds one half of the total building areas, it is usually preferable to combine the footings into a mat (also referred to as a *raft*) foundation. Because mat foundations may be used at locations where the bearing capacity can be marginal, it is important to recognize that the excess loads (above those acting on the natural deposit prior to construction) imposed upon the soil are significant. Excess loads can be reduced by increasing the basement depth. This increases the factor of safety with respect to bearing and also reduces settlement.

It should be recognized that the seat of settlement of a mat foundation extends deeper than conventional isolated footings; thus, consideration should be given to compressible layers within the depths of concern. Because of the random distribution of compressible zones in subsoil, combined with the stiffening effect of the mat and the superstructure frame, it can safely be assumed that the differential settlement of a mat foundation (per total inches of maximum settlement) will not be more than 0.5 of the corresponding value for buildings supported on isolated footings.

Prior to the advent of sophisticated computer-aided analyses, the analysis of mat foundations involved several simplifying assumptions. As a result, it has been common practice to use twice as much reinforcing as the analysis indicated. If different portions of the mat carry significantly different loadings, it is advisable to use control joints. Irregular shapes such as narrow appendages cause problems and must be carefully designed if they cannot be avoided; otherwise, cracking and rotation will occur in the vicinity of the junction of the appendage and the main segment of the mat.

10.4.2 Deep Foundations

As the depth to reach suitable support conditions increases, alternative systems must be considered, such as drilled piers, caissons, and piles. These systems may receive support from end bearing on high-capacity geological strata such as bedrock or other dense strata, or they may develop their capacity through skin friction with the surrounding soil. Because these systems have significant surface areas exposed to the surrounding soil, their capacity may be reduced as the surrounding soil consolidates. Clusters of friction piles tend to act as a unit rather than as isolated individual members.

Deep foundations are somewhat specialized and require considerable design input from the geotechnical engineer. The selection of a system is usually dictated by geotechnical considerations. Timber and steel piles that support pile caps are the most commonly used deep foundations. The capacities of the

piles in these foundations range from relatively low 10-ton values for timber piles to values in excess of 200 tons for steel piles. Piles with 40-ton capacities are the most commonly used steel piles because most building codes require load tests for capacities in excess of 40 tons. The load tests are costly and time consuming. The capacity of piles not subjected to load tests is determined by any of a number of empirical formulas.

Steel wide-flange members and open-ended pipe piles, which, when used, have relatively small steel cross-sections and displace very little soil as they are driven, are thus suitable for driving through soils with dense strata. Closed-end pipe piles displace soil and densify the soil in the immediate vicinity of the member. As clusters of these pipe piles are driven, the soil contained within the pile array becomes relatively dense and causes the entire cluster to act as a monolithic unit. The structural capacity of closed-end piles may be increased by filling the pile with concrete; however, in many cases, the capacity of the pile will be dictated by geotechnical considerations rather than its internal structural capacity. Filling piles with concrete adds considerable stiffness to the member. In cases where concrete fill is used to stiffen the member, proper reinforcement must be provided and the interior of the pile must be cleaned prior to concreting.

Precast prestressed concrete piles are somewhat less commonly used than steel and timber piles in the United States but are popular abroad. When precast piles are used in the United States, they are usually high-capacity, hollow, cylindrical piles with large diameters. The diameters are usually considerably larger than steel-pipe piles. Bridges and piers are candidates for this type of pile. The large diameter helps develop a stiff member, which makes placement easier, especially when underwater placement through considerable distances and soft material is involved. As mentioned, although not especially popular in the United States, solid precast prestressed piles are used. These piles usually have cross-sectional dimensions that more closely approximate steel piles.

The stresses resulting from driving must be carefully controlled with precast piles. The hammer introduces a compressive wave that travels down the pile and reflects back as a tension wave. The precompression supplied by the prestressing strands must be adequate to prevent damage to the pile due to tensile driving stresses. The prestressing tends to close any cracks that develop during the life of the pile. If the pile can be maintained in a crack-free condition, its stiffness is greatly increased. Prestressed piles are sometimes coated for protection. Obviously, any coating is susceptible to damage during driving and should not be depended upon solely for the longevity of the pile. Coatings in general extend the useful life of both steel and concrete used in marine environments, as the most hostile environment is in the splash zone, an area in which the coating is less likely to be damaged by the driving operations.

Lateral load resistance of pile foundations requires careful consideration. In a limited number of conditions, the lateral resistance of the pile foundation is developed by soil pressures reacting against the vertical face of the pile cap. A standard technique is battering the piles to utilize the vertical loads available to provide a horizontal component that resists the applied lateral loads. In lightly loaded structures with batter piles, uplift forces may develop as a result of the lateral loads. In many cases, the geotechnical engineer can determine a *point of fixity* at which the pile can be considered to have a rigid support. This enables the structural engineer to investigate the feasibility of developing lateral resistance using the flexural capacity of the piles. Flexural stresses introduced into the pile caps must be considered when the cantilever approach is used. Special consideration must be given to the proper anchorage of an uplift pile into the pile cap. The problem arises because of the relatively limited depth of penetration of the pile into the bottom of the pile cap. The problem is not as pronounced with respect to steel piles as it is with timber piles. Load-resisting lugs can easily be welded onto steel piles. Timber piles have potential problems due to the parallel orientation of the grain with limited edge distance. In addition to the traditional reinforcing rod inserted through holes drilled through the pile, several anchors are commercially available.

Drilled piers and caissons are concrete foundation elements that may or may not be permanently cased or reinforced. Usually, the decision to case or not is driven by the surrounding soil conditions. Unless the soil has the ability to maintain a vertical cut, casing is usually called for. If any clean-out, bottom preparation, or inspection is required, casing is almost certainly required, even if it is removed as the

concrete is placed. Because most drilled piers and caissons are high-capacity members, verification of the bearing capacity is a must. If verification requires that personnel be lowered into the hole, a minimum diameter of 30 in. should be considered. Verification may include a relatively simple visual confirmation that conditions are as expected or it may entail drilling into the rock to confirm the anticipated properties.

Auger cast piles might be considered for sites where noise, vibrations caused by pile driving, and disturbance of adjacent structures are a concern. An auger cast pile is constructed by drilling into the ground with a hollow-stemmed continuous flight auger. As the auger is withdrawn, a high-slump concrete is pumped down the stem of the auger. Reinforcement placed by hand is generally limited to 20 feet in depth. Reinforcement can be placed at higher depths by a vibrator or prior to concrete placement if specialized drilling equipment is used.

As seismic requirements continue to be refined for almost all geographic regions, there is generally a recognition that lateral loads may be greater than previously anticipated, and the ability to absorb large amounts of seismically generated energy is of paramount structural importance. Batter piles, the most common method for resisting lateral loads, depend on axial transfer of the loads from the structure to the support strata and may experience excessively large loads in a seismic event. It is probable that the design community will move to flexural-resisting elements for substructures as well as superstructures. This will result in large flexural and shear stresses, requiring considerable reinforcing to provide required strength and ductility. Traditionally, piers and caissons have been minimally reinforced, with the reinforcing frequently located in the upper portion of the member to ensure adequate connection to the supported structure. The designer should not be surprised to encounter some resistance from contractors with regard to the amount and detail of the reinforcing required in areas previously considered safe from earthquakes.

Differential settlements must be considered with respect to the type of superstructures supported by the foundations. Simple post-and-beam construction has more tolerance to movement than structures with shear walls or moment frames. Shear-wall structures usually have several isolated, very stiff elements. Excessive differential settlement may cause damage immediately adjacent to the shear walls, as rotations and displacements tend to be concentrated at the perimeter of the shear elements. Although moment frames have the inherent ability to accommodate considerable movement, the permanent stresses introduced into the structure must also be considered in the design of overstress during extreme loading events such as seismic activity, which may cause overload and failure.

In most cases, foundations can tolerate minor cracking; thus, standard ultimate-load analyses are commonly used. Thickness of the members is frequently governed by shear considerations. This is especially true of pile-cap design, which requires that large concentrated loads be safely transferred to the support piles. For those structures that cannot tolerate cracking, thickness of the members must also be checked to ensure that flexural stresses will be below the modulus of rupture.

For these cases, stresses related to volume changes must also be considered. Because foundations should be placed at elevations where the support soil is not subjected to seasonal (or annual) volume changes, there is the potential that the foundations may be placed at or below water level. The construction documents must clearly define requirements to ensure that the concrete is properly placed in these conditions. This is especially true of concrete-placing operations for deep-foundation systems. Consideration must be given to material selection and foundation protection for construction in aggressive soils (such as acid and acid-producing soils) that attack and deteriorate concrete. Chapter 14 in this *Handbook* details the geotechnical engineering of foundations in all their categories.

10.5 Structural Frames

10.5.1 Rigid Frames

It is a common in the design of concrete structures to design members as an isolated entity. When the overall structural system and layout have been determined, a structural analysis is performed to determine the moments, shears, and axial forces in each of the structural members. The individual members are

FIGURE 10.6 Sway of portal frame.

then proportioned to resist these forces. A structural building frame system relies on continuity between beam and column members to distribute and resist shears and moments induced by various loadings. As a building material, concrete naturally lends itself to frame-type construction, as it can easily be shaped, via formwork, to resist the applied loads in an optimal manner. Continuity is achieved, in part, by providing longitudinal reinforcement through the joint. For a concrete frame system to perform as intended, particular attention must be given to the design and detailing of the beam–column joints and to proper construction procedures and placement sequences. Frame connections and construction issues are discussed later in this section.

10.5.2 Braced and Unbraced Frames

Building-frame systems can be divided into two categories: (1) nonsway or braced frames, and (2) sway or unbraced frames. The majority of concrete building structures fall into the braced-frame category. In most cases, the bracing for frames is accomplished with structural walls placed at stairwells, or elevator shafts, where they serve the secondary purpose of providing a certain level of fire protection. In a general sense, a braced frame is defined as a frame in which the majority of side-sway buckling is prevented by diagonals, shear walls, or other bracing members relative to the restraint provided by the frame itself. To better develop an understanding of frame behavior, one must first consider the unbraced frame. Stability in an unbraced frame is dependent on the internal stiffness of the beam and column members that comprise the frame system. Lateral deflection in an unbraced frame consists of a displacement component resulting directly from horizontal loads as well as a component caused by unsymmetrical gravity loads, member properties, or frame geometry. When a building deflects laterally, the weight of the structure acts at an eccentricity to the support locations, introducing secondary bending moments in the beam and column members. This phenomena is known as the *P-delta effect*. Figure 10.6 demonstrates the *P-delta* effects in a typical unbraced frame. In braced frames, *P-delta* effects are generally small enough to be neglected.

10.5.3 Column Proportioning

A major factor affecting the design of unbraced frames is the reduction in axial capacity as a result of *slenderness effects*. For concrete frames, ACI considers a column to be slender if the column experiences more than a 5% reduction in its axial load capacity due to moments resulting from *P-delta* effects. Elastic stability of a column exists until a critical load, corresponding to the Euler buckling load, is reached. This critical load is greatly affected by rotational end restraints and lateral bracing, which alter the length and number of half-sine waves in the deflected shape of the column. To account for various end and bracing

restraints, most codes have adopted the concept of *effective length*. The effective length is the actual length of the column multiplied by a modification factor (k) necessary to produce a column with pinned-end restraints having the same buckling-load capacity.

Lateral drift of columns results in an increase in column moments which reduces the axial capacity of the column. Provided that the axial load is below the critical value, the structure will stabilize with increasing lateral deflection as the load becomes greater. The resulting load-vs.-moment curve is nonlinear, with a stability convergence process that can be described with a second-order differential equation. As a result, the additional forces and moments that result from material nonlinearity, cracking, and P-delta effects are generally considered in what is known as a *second-order analysis*. The 2005 ACI Code allows the use of such nonlinear, second-order analysis and provides a simplified design method for approximating these slenderness effects. The simplified design combines the forces based on a first-order, elastic analysis with a moment-magnifier approach.

To utilize the moment-magnifier design method, one must first establish whether a column is designated as a sway or nonsway column. Usually, this is readily evident by inspection, provided the column is located within a building level where lateral deflection is limited by stiff bracing members such as shear walls. If there is any doubt, ACI Section 10.11.4.1 permits a column to be considered nonsway if there is less than a 5% end-moment increase in the elastic moments due to second-order effects. Having established the type of frame that the column is a part of, the engineer can then design for the magnified moments given by the approximate equations and methods found in ACI Section 10.12 for nonsway columns or in Section 10.13 for sway columns.

10.5.4 Beam Proportioning

Frames and continuous beams are statically indeterminate members. With the faster and more powerful microcomputers available today, moments and shears in such members can be determined using any one of several frame analysis programs. For smaller, less complex structures, other procedures such as traditional elastic analyses (e.g., moment-area, slope-deflection, moment-distribution), plastic analyses, or approximate methods (such as the portal or cantilever methods) can be employed.

The greatest moments in a frame often result because of pattern loadings, also referred to as *skip live-loading* or *checkerboard loading*. Influence lines based on the Mueller–Breslau principle are often used to determine which spans should and should not be loaded to produce the worst-case design moments or shears. An influence line is a graphical representation of a design parameter at a particular point due to a unit load that moves across the structure. To account for the effects of pattern loadings, ACI 318 Section 8.9.2 requires that continuous-beam members must be proportioned to resist loads produced by two cases: (1) the dead load placed on all spans with the live load placed on two adjacent spans, a condition that produces the largest negative moment at the support as well as the worst-case shear force; or (2) the dead load placed on all spans with the live load positioned on alternate spans, a loading that results in the maximum and minimum positive moments at midspan and the maximum negative moment at the exterior support.

For smaller size structures where computer modeling is not warranted, the hand calculations required to produce the moment envelopes for the various loading patterns become quite tedious. To simplify design, the ACI has developed the use of moment and shear coefficients that can be used to approximate actual member forces. The approximate analyses permitted by ACI 318 Code Section 8.3 apply only to braced frames where significant moments due to lateral loads do not exist. The following criteria must be met for the simplified moment and shear coefficients to be valid:

1. There must be two or more spans of approximately equal lengths.
2. The larger of two adjacent spans must not exceed the shorter span by more than 20%.
3. Loads must be uniformly distributed.
4. Unfactored live load must not exceed three times the unfactored dead load.
5. The members must be prismatic.

Provided that the above criteria are met, the approximate equations give slightly conservative design moments and shears. Chapter 35 in this *Handbook* outlines the procedures and presents the equations governing the analysis and design of concrete structural members.

10.5.5 Beam–Column Joints

Considering that joints are often the weakest link in a structural system, considerable research on beam–column and slab–column connections has been conducted that led to the development of the ACI Committee 352 (2002) recommendations for design of monolithic connections. There are several parameters that interact to influence the mechanics of a joint. These parameters include joint shear–stress level, joint confinement, and the bond between the reinforcement and the concrete. ACI Committee 352 has provided design recommendations for ensuring adequate development length and horizontal joint reinforcement and also has set limits on the horizontal shear capacity of the joint, depending on the type and classification. The importance of adequate joint detailing has become increasingly evident in recent years due to research and better understanding of seismic failure modes. Concrete confinement in the form of transverse closed-tie reinforcement can greatly improve the ductility of concrete, which is a highly brittle material.

10.5.6 Construction Considerations

An increased behavioral understanding of reinforced concrete has resulted in more stringent reinforcement–detailing requirements that often make construction more difficult, particularly at beam–column joints where significant rebar congestion occurs. For exterior and knee joints, where the primary longitudinal reinforcement cannot be run continuously through the joint, hooked-bar anchorages must be used. This further increases joint congestion and may prevent adequate concrete placement. Many times, geometric limitations prevent the use of larger diameter reinforcing bars due to lengthy hook extensions and large bend diameters. In such cases, designers must be cognizant of the construction implications that their designs may have. Even with proper design and detailing attention, improper construction techniques can significantly affect the performance of individual members or affect the continuity between them. The concrete placement sequence has significant importance on the behavior of frames. ACI 318 Section 6.4.6 dictates that the column concrete must be placed and allowed to set prior to placing any concrete in the floor supported by those columns. This is to ensure that any settlement or bleeding of the column concrete while in the plastic state occurs beforehand, thus preventing any gaps or cracking at the beam–slab and column interface.

10.6 Concrete Slab and Plate Systems

10.6.1 One-Way Beam–Slab Systems

The selection of a beam–slab structural system is most frequently driven by the geometry of a given column bay. Rectangular bays, with an aspect ratio exceeding 2:1, will function to distribute nearly 100% of the shear and moments in the short direction. Configuring beams in the long-span direction only, with slabs spanning one way, perpendicular to the beams, creates a structural system that maximizes the benefits of each element. In addition, the continuity created by casting the slab system integrally across each beam support allows the framing system to redistribute load between the positive and negative moment zones so as to provide redundancy at the ultimate load state. Finally, deflections are minimized due to the continuity of the system. Under standard loading conditions (see Section 10.2), slabs can be kept thin (see Table 10.1), with reinforcing steel provided primarily in one direction only. Nominal transverse temperature and shrinkage reinforcement must always be provided to prevent cracking. It is important to stress that it is more effective to use smaller diameter bars at closer spacing than larger diameter bars at larger spacing. The former is essential to controlling cracking development in the slabs.

TABLE 10.1 Minimum Thickness h of Nonprestressed One-Way Slabs

Loading Condition	h
Simply supported	$L_n/20$
One end continuous	$L_n/24$
Both ends continuous	$L_n/28$
Cantilever	$L_n/10$

Note: L_n = effective span or cantilever arm.

The distribution pattern of the primary reinforcing steel closely follows the pattern of the bending-moment diagram (see Figure 10.7). Where negative moments are greatest (over the beam supports), top-reinforcing steel is provided. The cutoff point for the top steel occurs where the concrete no longer requires steel to resist tension stresses. The ACI Code requires that reinforcement must extend beyond this point a distance equal to the greater of the effective depth of the slab or $12d_b$, the diameter of the bar. Also, at least 1/3 of the total tension reinforcing provided for negative moment must be extended beyond the point of inflection not less than the effective depth of the slab, $12d_b$, or 1/16 the clear span, whichever is greater. Chapter 12 of the ACI Code gives the expressions for determining the development length required for the various conditions and categories. In practice, the ACI criteria result in extensions of the top reinforcing steel for distances of 1/3 (span) beyond each side of the support (see Figure 10.8). Using the guidelines established in Table 10.1, the resulting slab thicknesses will be sufficiently proportioned to resist shear stresses from typical loadings. Where extremely heavy loads (exceeding 250 psf) are experienced, the slab shear capacity should be checked. In accordance with Chapter 11 of the ACI 318 Code, the critical shear plane is located at a dimension d away from the face of the support for one-way slabs.

FIGURE 10.7 Moments and reinforcement locations in continuous beams.

FIGURE 10.8 One-way slab bar bending and placing detail.

Special detailing requirements are limited in scope for one-way slab design. As long as the load path to the supporting beam element is maintained, the structure will perform as intended. Thus, openings parallel to the slab span are easily accommodated by providing internally reinforced headers along the short edges of the openings. The designer should strive to orient all major openings in a one-way system such that the long dimension is parallel to the span of the slab. No special detailing at columns is required, as the beam element is intended to carry 100% of the load from the slab to the column. One-way slab systems have the following advantages:

- Long-span capability of the beam elements permits wide column spacings and frame elements for lateral resistance.
- Predictable slab thicknesses, reinforcing requirements, and deflection performance allow the designer to concentrate design efforts elsewhere.
- Reinforcing detailing and placement are prioritized in one direction only, reducing complication at the construction site.

One-way concrete-slab systems are frequently used in parking structures, where the predictable traffic patterns require long open-column bays in one direction but permit shorter bays in the other direction.

10.6.2 Flat Plates and Flat Slabs

Where the designer is presented with a fairly regular, essentially square column bay, the most economical concrete structural system available is the two-way column-supported slab. As a monolithic material, the placed concrete naturally spans in two directions. By taking advantage of this natural tendency, the designer can achieve significant economy while maintaining desired deflection control and lateral resistance. Flat plates are distinguished from flat slabs by the treatment at the columns. Both systems are entirely beam free; however, flat slabs employ drop caps or column capitals to assist with shear transfer at columns. Flat plates are flat on their underside, and shear transfer is accomplished by proper proportioning of the concrete plate with the appropriate design and use of shear-moment transfer reinforcement.

Two-way column-supported slabs derive redundancy from the fact that 100% of the applied loads must be carried by the structure in each of the two orthogonal directions. Thus, for a column bay of widths I_a and I_b , the structure is proportioned and designed such that 100% of the load can at any time be carried in either the I_a or the I_b direction. Load transfer in a two-way system is accomplished by effective widths of slab that serve as shallow beams. For analytical purposes, these effective widths are divided into column strips and middle strips. By definition, column strips are widths of slab centered on the column grid line, in both grid directions. The ACI Code specifies that column strips should extend

FIGURE 10.9 Column and middle strips in two-way slabs and plates.

$0.25L_1$ or $0.25L_2$ on each side of the column, whichever is less, where L_1 and L_2 are the adjacent slab spans. Middle strips occupy the region between the column strips, at the centers of the column bays, in both directions, as shown in Figure 10.9.

Chapter 13 of the ACI 318 Code addresses the design of two-way slab systems. The code allows that design may be made by any procedure satisfying conditions of equilibrium and geometric compatibility. The code then describes two alternative design approaches: the direct-design method and the equivalent-frame method. The direct-design method is an empirical method developed essentially from the elastic theory of the distribution of moments in continuous slabs. Strict conformance to the limitations must be maintained or the reliability of the method will be compromised. The slab system must operate within the following constraints if the direct-design method is used:

- There shall be a minimum of three continuous spans in each direction.
- Panels shall be rectangular, with a ratio of longer to shorter span, center-to-center of supports, not greater than 2.
- Successive span lengths center-to-center of supports in each direction shall not differ by more than one third the longer span.
- Offset of columns by a maximum of 10% of the span (in the direction of the offset) from either axis between center lines of successive columns shall be permitted.
- All loads shall be due to gravity only and uniformly distributed over the entire panel. Live load shall not exceed two times the dead load.
- For a panel with beams between supports on all sides, the relative stiffness of beams in two perpendicular directions shall not be less than 0.2 or greater than 5.0.

FIGURE 10.10 Torsional beam element in two-way action.

Using factors provided in the ACI 318 Code, Chapter 13, the total gravity load acting on the slab system is distributed into the column strip and middle strip zones. This method acknowledges that the summation of the negative and positive moments for any given span must equal the simple beam moment for a corresponding span. Consequently, the total static moment acting on any panel is denoted M_o , and the positive and negative moment distribution factors sum to $1.0M_o$. For interior spans, the total static moment (M_o) is distributed 65% to the negative moment and 35% to the positive moment. End-span conditions require reference to the tabular information provided in the ACI Code. After the moment-distribution factor is derived, additional factors are employed to proportion the moments between the column strips and the middle strips.

The equivalent-frame method is also essentially based on elastic theory. The slab is divided into frames comprised of the column grid and the slab on each side, extending to the middle of the panel. Each slab-column frame can be designed separately at each floor level, assuming that the columns are fixed at the floors above and below. Using stiffness coefficients for the various intersecting components at the column junction, inclusive of the stiffness of the torsional beam, a moment distribution is performed. Figure 10.10 illustrates the torsional moment transferred to the slab from the torsional beam. The moment of inertia may be calculated using the gross area of concrete. Determining the distribution of moment through the slabs and columns resolves the flexural phase of the design. The second and perhaps more critical aspect in the design of flat plates or slabs by either method is the shear transfer at the column junction. Because neither the flat-plate system nor the flat-slab system has beams that can transfer load into the columns, all of the load carried by the column strips must be transferred through the slab thickness. In a flat-slab system, drop caps and column capitals can be used to supplement the shear capacity of the slab concrete alone. The designer must consider two forms of shear transfer.

As seen in Figure 10.11, a portion of the unbalanced moment is transferred to the column by a vertical balancing couple in the form of vertical shear acting at the face of the column, while another portion is transferred by a horizontal force couple (flexure) occurring within the slab depth. ACI 318, Chapter 11, indicates that approximately 60% of the unbalanced moment is transferred by flexure, with the balance transferred by shear. These percentages have to be calculated for each case. The designer must remember that the vertical reaction due to gravity loads in the slab must be added to the unbalanced moment forces to gain a complete picture of the slab-column interface.

FIGURE 10.11 Shear-moment transfer mechanism.

For columns that are essentially square in cross-section, such shear failure typically governs the proportioning of the plate or column cap. The shear-failure plane occurs as a 45° crack that forms around the full perimeter of the column. The failure plane is angled upward from the bottom of the column. The critical shear zone for analysis is considered to be a distance $d/2$ from the face of the column, where d is the effective depth of concrete above the reinforcing.

Where the applied shear forces greatly exceed the concrete-slab shear strength, the designer has two primary options. One is to provide additional concrete in a region slightly wider than the critical shear zone; this is accomplished by adding a flat drop cap consisting of several additional inches of concrete. Alternatively, a column capital, shaped like an inverted cone, can be provided to widen the critical shear zone and to thicken the concrete in the zone, thereby increasing the concrete shear capacity. Chapter 35 of this *Handbook* lists the maximum allowable shear capacity (V_c) that can be used in the design for two-way action to determine the thickness of the plate or slab as governed by shear. The other alternative is the use of special steel reinforcing assemblies. Commonly referred to as *shear heads*, these assemblies can consist of steel beams or channels welded in a cross shape, placed on top of the column, and poured monolithically with the slab. Other shear-head assemblies consist of flat steel bars with welded-head shear studs. These assemblies are placed so they overlap the column and extend outward, thus increasing the critical shear zone.

Where significant shear-head reinforcing is required, the slab is proportioned too thin for the applied loads or the tributary areas. Shear failure is a sudden failure mode. The designer must exhibit extreme caution in analyzing shear transfer. Although not in favor for many architectural designs due to infringement of the ceiling plenum space, drop caps provide the designer with a simple but effective means of increasing slab capacities without resorting to complicated reinforcing schemes that are ultimately only as reliable as the installation method. The designer is encouraged to analyze the perimetric punching shear transfer as early in the design process as possible.

A final means of increasing the slab shear capacity, if the other two alternatives are not economically justifiable, is increasing the size of the columns. In practice, this method is only effective when the differential between the applied shear force and the slab capacity is within 20%. In this case, a 4-in. increase in the column dimensions will increase the slab shear capacity sufficiently to support the shear transfer.

As noted earlier, perimetric shear is typically the governing shear condition for design purposes; however, where rectangular columns with an aspect ratio in excess of 2:1 are provided, one-way beam shear can govern the slab thickness. Where applied shear forces exceed the concrete capacity, drop caps can be employed to increase the critical shear zone and the thickness of the concrete. Column capitals are not used for rectangular columns. The designer may find more success in increasing the long dimension of the column, if this option is available.

10.6.2.1 Post-Tensioned Two-Way Plates

Prestressed, post-tensioned, two-way floors are frequently used today, particularly in apartment buildings. The primary advantages of post-tensioning are the ability to use thinner slabs, the crack control derived from the presence of a significant precompression force in the concrete, greater shear capacity as a result of the precompression force, and greater deflection control as a function of reverse cambering. The designer is cautioned that the advantages realized from post-tensioning in the slab elements can quickly be lost in the column elements. The extremely high compression forces generated by the tensioning strands cause large unbalanced moments in exterior columns. To adequately reinforce the columns to resist these forces, much of the available room for shear reinforcing and negative flexural steel is occupied. The designer must carefully detail these conditions to ensure that no conflicts exist among the different types of required reinforcement that could jeopardize the design once it is under construction. The final aspect of two-way column-supported slab design considered here is the transfer of lateral moments between the slab–diaphragm system and the columns. Under uniform gravity loading, flexural stresses are essentially balanced at interior columns, and shear transfer is accomplished via independent analysis. Where unbalanced moments are to be transferred into the columns, the analysis of shear and flexure becomes combined. Analysis of this moment transfer requires calculation of the polar moment of inertia for the column element. Then, by applying the standard stress analysis theory of shear stress and bending stress, the proportion of the slab or drop cap at the column head can be checked. The designer is cautioned that the analysis of punching shear as a function of unbalanced moment transfer is of utmost importance and should be addressed as early in the design process as possible to allow for changes in the structural approach, if necessary. Because slabs tend to be thinner in post-tensioned systems, the analysis of punching shear and unbalanced moment transfer at the columns takes on even greater significance.

10.7 Liquid-Containing Structures

10.7.1 Introduction

Concrete structures for liquid containment consist mainly of water-treatment plants, wastewater-treatment facilities, tanks, and reservoirs. The concrete used for these facilities should be watertight and should be protected against contamination from groundwater. In addition, exposed concrete structures require protection against freeze–thaw damage and environmental effects. In containment concrete, low water permeability and low shrinkage are essential to prevent damage and cracking of concrete. Although proper design, such as specifying proper control joints and reinforcing steel, is important, the most effective way of controlling shrinkage and minimizing water permeability is by designing good-quality concrete mixes. In addition, proper concrete quality, concrete batching, delivery to the site, and placing are essential factors for good quality containment concrete.

The compressive strength of concrete used for containment structures should be a minimum of 4000 psi at 28 days of age. The air content should be $6 \pm 1\%$. The amount of mixing water should be enough to produce a slump of 2 to 3 in. The minimum cement content for a 4000-psi concrete should be 560 lb/yd³. Containment concrete should have a maximum water/cement ratio of 0.45 lb/lb.

The use of a water-reducing admixture generally helps reduce the amount of mixing water used. The use of high-range water reducers may also be used to reduce the amount of mixing water and increase the slump, easing the placement. Slump after the addition of superplasticizers should not exceed 7 in. In warm weather, a high-range water reducer and retarder may be used to prevent quick setting of the cement. For more information on admixture types and their functions, ASTM C 494 as well as reputable admixture manufacturers may be consulted.

To further reduce permeability and increase the density and durability of concrete, the addition of microsilica to the concrete mix may be considered. In general, the addition of 5% microsilica by weight of Portland cement reduces the permeability of concrete considerably. Microsilica-containing concrete is widely used for parking garage floors to reduce chloride infiltration into the slabs.

The size and amount of coarse aggregate used in concrete are also governing factors in controlling the shrinkage and cracking of concrete. The size of aggregate should not exceed 1-1/2 in. (ASTM C33, size #57). The amount of coarse aggregate should be between 1750 and 1850 lb/yd³. The higher the amount of coarse aggregate, the lower the amount of sand, which is a factor in controlling shrinkage. All other concreting practices such as placement techniques, finishing procedures, and curing should be done as per the ACI specifications. The joint type and spacing as well as the reinforcing percentage and the other design details of the project should be designed by the structural engineer.

The most important aspect of concrete tanks is that they must be leak free. This requires that careful consideration must be given to the analysis, detailing, and construction of tanks. The requirement that the tanks be free of leaks leads to the rather obvious conclusion that the stresses in the tank must be below the modulus of rupture. Because reinforcing becomes effective at strains near those that cause cracking in concrete, reinforcing is present in the tanks to resist the tensile stresses if the concrete ruptures, thus averting a catastrophic failure. The thickness of the walls is therefore selected to keep shear and flexural stresses below the cracking point. The ideal configuration for tanks is the circular shape. Resisting loads with tensile members is more efficient than doing so with flexural members. Most of the loads generated by the contents of a circular tank are very efficiently resisted by circumferential tensile forces. When space or process constraints must be considered, rectangular tanks may be the proper choice.

10.7.2 Circular Tanks

The analysis and design procedures for circular liquid-containing tanks are not complicated. They follow the elastic theory of shells (Billington, 1982; Nawy, 2003). The method basically consists of a membrane analysis of the tank with the introduction of shears and moments to account for boundary conditions that are noncompliant with the membrane theory. The Portland Cement Association (PCA) publication *Circular Concrete Tanks Without Prestressing* (PCA, 1992) provides procedures and examples for the design of circular tanks. Much of the information and formulas contained herein are extracted from the PCA pamphlet. There are also computer programs that can analyze these tanks. From a practical standpoint, it should be noted that the base slabs for most tanks are relatively thick for several reasons and the nominal amounts of steel to control volumetric changes of the concrete result in capacities greater than those required by the analysis.

The basic approach to design of a circular tank is to select a wall thickness that is strong enough that the stresses in the wall will always be less than the modulus of rupture of the concrete. Circumferential reinforcing is provided to carry all of the ring tension should the concrete crack. Vertical reinforcing is selected to resist the flexural stresses caused by the support conditions. It is interesting to note that using reduced allowable stresses in the reinforcing steel causes higher stresses in the concrete. The area of reinforcing steel required to resist the ring tension (T) is:

$$A_s = \frac{T}{f_s} \quad (10.5)$$

where A_s is the area of steel required, and f_s is the design stress for the reinforcing steel. The stress in the concrete can be expressed as:

$$f_c = \frac{(CE_s A_s + T)}{(A_c + nA_s)} \quad (10.6)$$

where f_c is the stress in the concrete, C is the thermal coefficient of expansion, A_s is the cross-sectional area of the steel, A_c is the cross-sectional area of the concrete, $n = E_s/E_c$, and E_c and E_s are the moduli of elasticity of concrete and steel, respectively. Inserting varying design stresses for the reinforcing confirms that as the steel design stresses decrease the stresses in the concrete increase. Of interest is the revelation that, as the design stress of reinforcing approaches infinity, A_s approaches zero and the stress in the concrete approaches T/A_c . In other words, the effects of thermal stresses disappear.

FIGURE 10.12 Detailing of wall–base intersection.

Because volumetric changes cause tensile stresses in the concrete, efforts should be made to control shrinkage. Construction joints should be specified on the construction documents. Joint spacings in excess of 30 ft will almost invariably lead to shrinkage cracking. A closer spacing should be considered for relatively low walls because of the circumferential fixity at the base and the unrestrained top surface of the wall. Expansive concrete is an option used by several designers. An alternative to expansive concrete is to attempt to limit those components contributing to shrinkage in the concrete matrix. By limiting the amount of cement, sand, and water in the concrete, major contributors to shrinkage are reduced. The reduction in paste results in reduced workability, which can, at least in part, be addressed by the use of superplasticizing admixtures in the mix. Prestressing is an option for reducing or eliminating tensile stresses in the concrete.

Attention to details is an important part of producing leak-free tanks. In general, it is better to use smaller reinforcing rods with their greater specific area for developing bond, shorter lap splices, and smaller bend radii. Conversely, it is important that the bar spacing allow for effective concrete placement to avoid honeycombing and inadequately consolidated concrete. Most leaks in concrete tanks occur at joints. Acknowledgment of difficulties in placing concrete should be reflected in the design details; for example, to ensure proper water stop installation at the slab–wall intersection, consider lowering the top layer of reinforcing as shown in Figure 10.12. Also, consideration must be given to joint details that do not utilize starter walls as a part of the slab. This is because effective consolidation of concrete, necessary for a leak-free joint, is difficult for these cases. Reinforcing congestion at joints makes proper placement of the concrete difficult and may contribute to honeycombing and leaks.

Prestressed concrete tanks, both pretensioned and post-tensioned, are probably the most efficient leak-proof circular containment vessels. The principles of the shell theory for cylindrical shells applies equally. The design factors used are similar to those for the reinforced concrete already discussed. Two types of prestressing systems are used: (1) circular strand wire-wrapped, such as the preload system used extensively worldwide, and (2) post-tensioned, both horizontally and vertically. Reports by ACI Committees 372 (2003) and 373 (1997) give detailed requirements for maximum allowable stresses and other pertinent provisions for design. Nawy (2003) presents a detailed chapter on the design of prestressed circular tanks of both types, with examples, as well as the design of the cylindrical shell roof of a typical circular tank.

10.7.3 Rectangular Tanks

Performance criteria for rectangular reinforced concrete tanks are usually similar to those of circular tanks—namely, no leakage. The wall thickness of relatively shallow tanks is dictated by the need to keep flexural stresses below the modulus of rupture. The wall thicknesses of deep tanks, such as those associated with pump stations, are often dictated by shear stresses; flexural stresses are usually less than the modulus of rupture cracking stresses. The Portland Cement Association's *Rectangular Concrete Tanks* (PCA, 1998) provides guidelines and design procedures. Extensive additional information is available in the literature (see, for example, Timoshenko and Woinowsky-Krieger, 1959; Young, 1989). The corners of rectangular tanks tend to be subjected to large stresses; hence, considerable attention should be devoted to detailing and joint placement to limit cracking to an acceptable minimum. Construction joint locations must be incorporated into the design documents to limit the effects of volume changes. As the horizontal dimensions of the tanks increase, the effects of the corners diminish, and the wall behaves more like a cantilevered retaining wall. Introduction of counterforts reintroduces two-dimensional behavior and should be considered in long walls. This technique can also be utilized for large-diameter circular reinforced concrete tanks in which the circumferential stresses become exceedingly large. Buried rectangular tanks present a special problem at wall corners. Slabs at the corners of rectangular tanks tend to curl upward; thus, the corners must be properly attached to the walls. Because diagonal cracks occur at the corners, additional diagonal reinforcing steel is usually provided.

10.8 Mass Concrete

10.8.1 Introduction

Large structures such as dams, bridge foundations, mat foundations, nuclear plants, and large-span deep beams require the placement of large quantities of concrete that are required to act in a monolithic manner. The successful placement of mass concrete requires careful planning, mixture design, placement, and consolidation. Quality mass concrete, like other concrete, begins with the proper mixture for the job. Volume changes within the concrete can cause internal cracking, with its attendant reduction in strength and degree of watertightness. To keep shrinkage to a minimum, factors that are major contributors to shrinkage must be controlled. Successful placement of mass concrete requires the prevention of early setting of the cement and shrinkage of the concrete. During the placement of concrete, the temperature increases due to the hydration of the cement; therefore, minimizing the increase of heat of hydration is essential to prevent shrinkage and cracking of the concrete. The publication *Control of Cracking in Concrete Structures* (ACI Committee 224, 2001) deals with the preventive measures necessary to control internal temperature in mass concrete. Concrete used for various large structures has to have excellent control of early setting to prevent shrinkage, cracking, and problems associated with placement and workability of concrete. Among the factors to be considered for mass concrete are the following:

- Engineering design details of mass concrete (this phase of the work requires considerable knowledge and experience of structural engineering)
- Selection of materials and proportioning of concrete mixes
- Control of concrete quality during batching and placement

10.8.2 Materials for Mass Concrete

The following materials are appropriate for mass concrete:

- *Portland cement with low heat of hydration.* It is common to use Type II or Type IV Portland cement (ASTM C 150). The minimum amount of Portland cement should be used to achieve the design strength.
- *Pozzolans* (ASTM C 311 and ASTM C 618). Addition of a pozzolan such as fly ash in the range of 20 to 25% by weight of cement will assist in reducing the heat of hydration and improving workability and long-term strength gain.

- *Aggregates* (ASTM C33). Both fine and coarse aggregates should meet ASTM C 33 requirements. For dams, the coarse aggregate should preferably be size No. 1. In case of structural mass concrete for beams, coarse aggregate should have a nominal size of 1 to 1-1/2 in. The amount of coarse aggregate should be high, approximately 1900 lb/yd³ of concrete. Especially in concrete dams, the ratio of fine aggregate to total aggregate by absolute volume should be low—approximately 25%.
- *Mixing water*. The amount of mixing water to be used should be low to provide a slump of 2 to 3 in.
- *Admixtures*. Admixtures should be used to entrain air and reduce the water/cement ratio. The water reducer should preferably be a Type D water-reducing and retarding admixture, as specified in ASTM C 494.
- *High-range water-reducing (HRWR) admixtures*. Mass concrete to be pumped should be treated with either an HRWR admixture (Type F) or an HRWR and retarding admixture (Type G) as specified in ASTM C 494. The slump before the addition of the superplasticizer should be 2 to 3 in.; after the addition of superplasticizer, the slump should be 5 to 7 in.
- *Coolants*. The temperature of mass concrete for dams should be controlled to be between 40 and 50°F, especially in hot weather conditions. Finely chipped ice may be added to concrete to control the temperature. Other methods of cooling the aggregates, such as keeping them damp and under shaded conditions, will reduce the temperature. When steel forms are used, they should be sprayed with cold water if necessary. Curing the concrete with cold water also will help in controlling the temperature of cast concrete. The maximum temperature for mass structural concrete, such as beams, should be 70°F. In this case also, the use of chipped ice may be considered to lower the concrete temperature.

10.8.3 Concrete Mixture Design

Concrete mixtures used for mass concrete should be proportioned in a qualified laboratory in accordance with ACI Committee 211.1-91 (*Standard Practice for Selecting Proportions for Normal, Heavyweight and Mass Concrete*; reapproved 2002). The materials used in concrete mix designs should be the same materials intended for use in the project. The compressive strength of concrete used for dams generally is low, 3000 psi to 3500 psi. The full design compressive strength is achieved 6 to 12 months after placement. In the case of mass structural concrete, the design compressive strengths are generally between 4000 and 6000 psi. The design strength is based on 28-day age.

10.8.4 Quality Control

Thorough quality control and quality assurance are essential for the proper execution of a mass concrete project. The selection and quality of ingredients to be used, batching, and placing of the concrete should be observed, and the necessary tests should be performed as per the applicable ACI and ASTM specifications. Equipment that allows rapid placement of large concrete quantities should be used to reduce the possibility of cold joints. The typical low-water, low-slump concrete used for mass concreting must be properly consolidated to eliminate cold joints and honeycombing. Segregation of aggregates must be avoided. Large-volume delivery systems are less susceptible to segregation than smaller volume systems. With minimum handling, there is less potential for segregation. Large-volume buckets with their wide discharge openings are effective means of delivering large quantities with minimum segregation. When it has been placed, the concrete must be properly vibrated to knit successive layers together in a joint-free matrix. Transportation of concrete using vibrators should not be done because of the potential for segregation. Preplacement planning must include the involvement of the concrete supplier to resolve potential problems such as truck breakdowns or the opposite—a backup of trucks leading to excessive mix time. Effective communication is an absolute must. Proper equipment maintenance greatly reduces the potential for breakdown. If a pump-delivery system is utilized, consider having a spare unit on-site to ensure an uninterrupted delivery to the point of placement.

10.9 On-Site Precasting and Tilt-Up Construction

On-site precasting is used in lift-slab, tilt-up, and miscellaneous general construction. Lift-slab on-site precasting consists of casting the floor and roof slabs on top of one another so they can be lifted into place once the columns and jacking equipment are in place. Section 10.10 discusses the lift-slab system in more detail, so specifics of the system are not discussed here. Site-casting of the slabs provides economies resulting from:

- Reduced formwork costs, as only edge forms are required and these are reused several times
- Reduced placing costs, as all of the concrete placement is at ground level
- Reduced curing and protection costs due to the limited surface area exposed to the elements
- Reduced reinforcing costs due to the considerable repetition from floor to floor and because the materials do not have to be hoisted to elevated floors
- Uniformly flat soffits of the slabs, thus simplifying design and installation of mechanical and electrical systems
- Favorable fire-resistance ratings that may be obtained without the application of fireproofing to the underside of the slabs

Several of these advantages can also be realized by site-casting specific structural members. In the northeastern portion of the United States, it is not unusual to site-cast concrete columns to be used with structural steel roof systems. The concrete columns provide favorable fire protection ratings while also providing high-capacity concrete members at a price that compares very favorably with structural steel columns. The site-cast columns can be made as durable as steel columns with respect to impact damage from material-handling equipment. The majority of site-cast concrete is used in tilt-up construction. In addition to many of the potential cost savings listed above, tilt-up construction can replace exterior structural steel with concrete bearing walls that can be architecturally treated at a relatively low cost. Figure 10.13 shows the various components and their arrangement along a bearing wall of a tilt-up building. Basically, the system consists of the following steps:

- Prepare the site and cast the footings.
- Cast the slab on grade, omitting a strip several feet wide around the perimeter of the building and erosion-control measures such as draping plastic sheeting over the exposed soil at the perimeter of the building between the exterior footings and the edge of the slab on grade.
- Place edge forms for the wall panels directly on top of the slab on grade.
- Patch any blemishes on the surface of the slab on grade, and temporarily patch all joints occurring within the area of the wall panels as these will read through onto the wall panels.
- Apply a high-quality bond breaker to the slab on the grade surface.
- Apply any architectural finishes that will be exposed on the surface cast against the slab on grade.
- Place reinforcing and tilt-up hardware, such as lift and bracing inserts, and place the concrete, using care to avoid shifting reinforcing, inserts, or architectural finishes.
- Apply curing compound or moist cure wall panels.
- Install bracing inserts in the slab on grade if they have not been previously placed.
- Place leveling pads on footings, and mark for transverse and longitudinal alignment.
- Tilt up wall panels and lift into position using a suitably sized rubber-tired moving crane.
- Brace wall panels to slab on grade using a system of pipe braces and dimensional lumber attached to the wall and slab at the appropriate inserts.
- Stabilize the base of the wall using concrete infill at the oversized shear key in the footing.
- Erect the structural steel; when the entire structure is plumbed and square, weld structure to tilt-up wall panels.
- Backfill around the exterior and interior of the perimeter footings.
- Extend the slab connection reinforcing from the wall panels and place the perimeter strip between the wall and edge of slab on grade.

FIGURE 10.13 Typical panel bracing.

Although greater economies can be realized by using the system for bearing-wall construction, the system also deserves consideration when nonbearing walls are contemplated. The system usually becomes economical when the floor area is 40,000 ft² or more. Obviously, this threshold area will vary from region to region. The important requirement is to have adequate room to precast the panels on the floor slab. Local labor rates and work rules will also affect the viability of the system. In northern regions, it would not be prudent to begin a tilt-up project at the onset of winter or other anticipated extended periods of inclement weather. It is especially important not to leave a slab on grade that is exposed to freezing weather unprotected because of the possibility of the slab heaving. Irregularities in the slab such as this are difficult to remove and will read through to the wall panels. Typically the wall panels are cast so that when lifted the exterior panel face is cast against the slab or facing upward. Tilt-up panels are also cast on concrete site paving in addition to the interior slab on grade. Another option is to use temporary site casting beds or to stack cast the panels.

The exterior face-down casting position provides an opportunity to economically treat the exterior face of the panel if desired. Because the contact surface of the floor slab will in all probability contain blemishes, treatment of the wall panels may be more effective than the elimination of floor blemishes that might very well be acceptable for the intended floor use. Typical finishes for the panels include graphics formed into the surface, accents, aggregate finishes, or combinations thereof. Accent strips are constructed using inexpensive dimensional lumber. The exposed aggregates are placed on a layer of treated sand that is bounded by the accent strips. Prior to placing the surface aggregate the sand receives two applications of bond breaker to prevent the concrete from adhering to the sand or the aggregate. After the sand has been sprayed, the aggregates are carefully spread over the areas to receive the finish.

FIGURE 10.14 Alternative detail of transfer of lateral loads.

Care must be exercised during the placing operations to avoid displacement of the aggregates. Stainless-steel reinforcing accessories must also be utilized, or rust staining of the surface will occur. During the design, reducing thickness to accommodate the surface treatment of the panels must be considered.

Footings supporting the wall panels may either be continuous or discrete. If continuous footings are not utilized, additional horizontal reinforcement near the bottom of the panels must be provided to ensure adequate flexural capacity to enable the panel to span from footing to footing. In many cases, use of continuous footings is an option that results in ease of construction and reduction of potential for differential settlement.

Panel thicknesses are determined by the economics of reduced concrete and panel lift weight vs. additional reinforcing. Panel thickness is also related to the number and arrangement of lift inserts necessary to ensure that the flexural stresses are kept below the cracking level. Allowance for an increase in stress resulting from partial adhesion of the panel to the slab on grade, if a sand or aggregate layer is not used, should also be incorporated into the design. The panels will almost certainly be considered to be slender compression elements, requiring that the effects of panel deflection (P-delta) under lateral loads be considered in the analysis, in addition to global effects as a result of the diaphragm deflection. If the structural framing for the roof utilizes steel joists, the connection of the joist bottom chord to the panels should be avoided as the deflection of the joists will introduce a potentially large moment into the panels through the fixity of the top and bottom chords. It is more economical to consider the additional unsupported height in the design of the panel. If possible, seat the joists at or near the mid-depth of the panels to reduce the eccentricity of the loads supported by the panels.

Lateral loads can be resisted through horizontal diaphragm action in the roof structure. The lateral loads can effectively be transferred from the roof deck to the wall panels as shown in Figure 10.14. The angle is also a cost-effective replacement for a joist placed adjacent to the panel and simplifies roofing details through its zero displacement. Panels at corners should always be connected across the corner joint to ensure alignment. Panel joint connections elsewhere are a function of the need to engage more than one or more panels for overturning shear wall action. In addition, in high seismic areas, the continuous diaphragm chord is typically accomplished by connecting continuous rebar along the top of the panels across the joints.

10.10 Lift-Slab Construction

10.10.1 Introduction

The lift-slab method of construction was first introduced in the 1950s by Phillip N. Youtz, who later joined Thomas B. Slick to refine the design concept and construction techniques of his system. From this research, the original concept of lift-slab construction was introduced. The structural components of lift-slab buildings are no different from conventionally constructed buildings. The difference is how the building is erected. The procedure is to cast the concrete floor slabs, one on top of the other, on the slab on grade and lift them to their final elevation with hydraulic jacks (Russillo, 1988). Lift-slab concrete

construction is seldom used any more, so the following discussion is provided more as a historical reference. The first step is to prepare the site for construction and install the foundation system for the building, using normal construction techniques. The first level of columns is then erected on the foundation with the steel lifting collars in place. The columns are usually two stories high for economy. When all of the columns are in place, the concrete slab on grade is placed, allowed to set, and coated with a separating material. The first steel shear collar is then slid down the column and is aligned on the slab on grade. The slab reinforcing is installed, along with embedded electrical conduit and plumbing lines directly on the slab surface. The edge of the slab is formed, and finally the concrete is placed. The above procedure is repeated for each of the supported floors plus the roof. When the roof slab is completed, it is loaded with the upper column sections and the slab-lifting equipment. The lifting jacks are placed atop each of the columns and are connected to the roof-lifting collar by threaded rods. The roof slab is then lifted to the top of the column section and temporarily secured. With the roof slab in this position, the tops of the columns are braced and the column capacity is increased for the successive lifts. The upper level slabs are then lifted to the underside of the roof and are temporarily secured. The lower level slabs are lifted and are permanently attached to the column sections at their designated elevations. The lifting jacks are removed and the next column sections are erected. The jacks are then placed on top of the next column section, and the lifting sequence is repeated until all the floor and roof slabs are in their final position. When all of the slabs are secured to the columns, the exterior facade can be constructed, and the floors are ready to be fitted out.

10.10.2 Foundations

The process of lifting the precast concrete slabs does not impose any loads on the foundation system that are different from the design service loads. No special foundation requirements are necessary for this type of construction. The foundation type is selected and proportioned based on the geotechnical characteristics of the project site and the dead loads and service live loads anticipated for the occupancy of the building. The concrete slab on grade is to be placed and finished based on the requirements of its end use. Note that the finish of the slab will be reflected on the ceiling above. Any depressions in the slab on grade for floor finishes can be filled with lean concrete to prevent them from being reflected on the ceilings above.

10.10.3 Columns

The columns for lift-slab buildings are usually steel wide-flange shapes, but precast and cast-in-place concrete columns have also been used. Our discussion here is limited to steel wide-flange shapes, although concrete columns are similarly erected. The length of the column sections is usually two stories high and is limited by the design column section and the length of the lifting rods supplied by the contractor. No limiting column-spacing requirements are imposed by the lift-slab process. It is controlled by architectural layout, span of the slabs, and the loads supported by the slab. The lift-slab contractor may, however, limit the total area to be lifted at a time, thus dividing the slab into sections. This is determined by the number of jacks and support equipment available to the contractor. The boundary between two adjacent slabs is known as a *pour strip*. After the slabs are lifted into place, these areas are formed and concrete is placed to complete the floor system.

10.10.4 Supported Slabs

The concrete slabs used at the inception were conventionally reinforced two-way flat slabs. These slabs worked well, were easy to construct, and were sized to eliminate drop panels. This limits formwork to blockouts for the mechanical chases and perimeter-slab edge. The major drawbacks with conventional two-way slabs are that they are thick and heavy and their spans are relatively short. Today, most slabs are two-way flat plates that are post-tensioned. Post-tensioned slabs are thinner for the same loading conditions or have greater capacity for the same span and slab thickness. The slabs are generally the

same, whether the building is lift-slab or conventionally constructed. The advantage is obtained by casting all the slabs at grade level, one on top of the other. It is not necessary for large cranes to hoist material to the elevated floors, a man lift is not required, the time required to move material is reduced, and the fall hazard for the workmen is nearly eliminated.

10.10.5 Lifting Collars

Lifting collars, threaded onto the columns prior to erection, are centered on each column and cast into each of the supported slabs. The original steel castings were found to be expensive and had limited lift capacity. Today, lift collars are exclusively steel sections that are welded with full-penetration welds. The purpose of the lift collar is threefold: It connects the slab to the lifting jack via a threaded rod, attaches the slabs to the columns for load transfer, and acts as shear reinforcement in the slabs (shear heads) to eliminate drop panels in the thinner post-tensioned slabs.

10.10.6 Lifting Jacks

The lifting jacks used to raise the slabs are mounted to the top of each of the columns and are attached to the slab by two threaded rods. The jacks are hydraulic and are driven in such a manner that they lift in unison at a rate of 4 to 10 feet per hour. This is to eliminate damage to the slabs as they are being lifted.

10.10.7 Critical Component Design

The design of the structural components of a lift-slab building is, for the most part, the same as for a conventionally constructed building. The differences occur in the critical components such as the lifting collar, the slab at the column connection, and the columns, which need to be checked for all conditions and end restraints during construction.

10.10.7.1 Columns

The columns of a building utilizing the lift-slab method of construction serve a dual purpose in that they support the building in its final position, braced at each floor by the slab, and they are used to support the lifting jacks during positioning of the slabs. The columns require analysis for all the load cases proscribed by local building codes as well as for construction loads. During jacking of the roof slab, the columns are freestanding, with base fixity achieved by the base plate detail and encasement of the columns by the slab on grade. The stage during which the roof slab is lifted up along the freestanding columns is the most critical condition. The column sections must be sized for this condition as well as for conditions during successive lifts. The first load condition is best checked using Euler's column formula for columns fixed at the base and free at the top:

$$P_{(\text{all})} = \frac{\pi^2 EI}{4L^2 (\text{F.S.})}$$

where:

- $P_{(\text{all})}$ = allowable load (kips).
- E = modules of elasticity (kips/in.²).
- I = moment of inertia (in.⁴).
- L = column height (in.).
- F.S. = factor of safety.

When the roof slab is at the top of the column section and has been secured (temporarily or permanently), the slab connects all of the columns together and fixes the top of the column section. The column condition now becomes fixed at the bottom and fixed against rotation at the top but is allowed to translate laterally. This condition reacts the same way as columns that are pinned at both ends and is analyzed using the following column expression:

FIGURE 10.15 Lift collar in lift-slab construction.

$$P_{(\text{all})} = \frac{\pi^2 EI}{L^2 (\text{F.S.})}$$

The capacity of the columns at this stage quadruples. This extra capacity in the columns may allow a number of slabs to be lifted simultaneously.

10.10.7.2 Lift Collar

Lift collars (see Figure 10.15) must be designed to perform adequately for multiple purposes. The collar is sized to transfer the construction loads imposed on the slabs to the lifting jacks and all of the service loads to the column. Finally, the collar must be sized to reinforce the slab to keep the diagonal tension stresses in the slab below the allowable stress dictated by the building code. The design of the collar also depends on the forces to be transferred from the slab to the column. Depending on the designers assumptions, the forces could be shear only, shear with partial-moment transfer, or shear with full-moment transfer. The design of the lift collar is the responsibility of the lift-slab contractor. The design engineer should note the type of collar desired and anticipated design forces on the design documents.

10.10.8 Applications

The lift-slab method of construction is best suited for buildings whose column layout is ideal for two-way post-tensioned concrete slabs. Although higher structures have been lifted, up to 20-story buildings are the best candidates. The exterior facade does not affect the decision as to whether this system should or should not be used. Constricted construction sites warrant investigation of the lift-slab method because large track-mounted tower cranes are not required. When construction of the superstructure is scheduled to occur during cold seasons, this approach becomes economical in that when the foundation is completed and the columns have been erected a shelter can be constructed and heated to provide a protected work area.

10.11 Slip-Form Construction

10.11.1 Introduction

Vertical slip-form construction is a process of placing concrete continuously with a single form that is constructed on the ground and raised as the concrete is cast. Casting is done at a rate that prevents the formation of a cold joint in previously placed concrete. The result is a continuous placing sequence

resulting in a monolithically erected wall with no visible joints. This construction process utilizes lifting jacks located on the ground or on the working platform that elevates the form and the workers' scaffolding attached with smooth rods or pipes. These rods or pipes are embedded in the hardened concrete. The construction technique is similar to an extrusion process.

The die (slip form) moves upward as it extrudes the concrete wall. The rate of the extrusion process is controlled by the setting time of the concrete and the crew's ability to prepare the wall for the pour. The average time of lift for any project is 6 to 8 in./hr, placing approximately 4- to 10-in. layers of concrete per lift; however, the time varies anywhere from 2 to 4 in./hr for the lower levels of a nuclear reactor containment structure to 20 to 50 in./hr for an underground shaft lining. The project foreman looks for zero slump from the 4- to 10-in. layer below the layer being placed.

It is important to note that, when this construction procedure is utilized, the concrete wall being slipped through supports only its own weight. The jacking rods located in the wall support the weight of the slip-form structure. The concrete keeps the jacking rods from buckling. In some cases, the jacking rods become part of the permanent structure. The other alternative is to have the jacking rods slip through a thin pipe sleeve as the form slips upward. Engineers designing these walls should not rely on the steel rods for reinforcement due to lack of bond between the bars and the concrete.

Slip-form construction, even though in a state of continuous motion, can be interrupted by weekends and evenings simply by extruding the form away from the poured wall as it sets. The form should never be allowed to adhere to the concrete. Slip-form construction is used for various applications, such as bridge piers, building cores, apartment-house shear walls, chimneys, communication towers, cooling towers, and silos, among many other applications. In many cases, the procedure can be used to erect a structure in half the time of conventionally formed work. In addition, the working platforms rise with the form and reduce the labor costs of dismantling and re-erecting scaffolds at each floor. Close inspection of the concrete must be performed at all times to ensure elimination of blowout (concrete plastic state) or bonding of concrete to the slip form during the construction process.

10.11.2 Materials and Methods

The major components of a slip-form assembly consist of lifting jacks and rods, yokes, wales, sheathing, a working platform, and suspended scaffolding (see Figure 10.16). All components, with the exception of the lifting jacks and concrete, climb integrally when the form is elevated. The lateral loads of the form are transferred through the sheathing and wales, which are supported by the yokes. The vertical loads of the scaffolding and platforms, in addition to live loads (equipment), are carried by the wales and transmitted to the yokes and into the jacking rods embedded in the concrete. The weight of the concrete acts as a lateral support to the rods.

The **lifting jacks** provide the forces that lift the forms upward. The three types of jacks are screw, hydraulic, and pneumatic, with hydraulic being the most common. Hydraulic jacks range anywhere from 3 to 25 tons/jack in uplift force. Care must be taken to properly position the jacks. The dead and live loads dictate the size and number of lifting jacks required for the application. All jacks must lift equal weight; otherwise, distortions in the wall will result in excessive stress to the yokes at certain locations. Operations must include quality control to avoid excessive live loads concentrated in an area of the working platform.

Jacking rods require careful design as well. These rods provide the required support of the slip-form structure and are located in the poured concrete wall. If they remain in the wall, they have reduced or minimal bond strength and should not be designed as a typical reinforcing rod. The rods can be salvaged by sliding them through a thin metal sleeve attached to the yoke. The rods must be vertical at all times when placed in the walls. This will prevent buckling of the rods in the concrete as the form rises.

The **yokes** are connected to the lifting jacks and consist of a horizontal member and two yoke legs. Depending on the design of the wall, the yoke should be engineered to compensate for the loads that will be applied to it. The yoke acts as a clamp holding the wales and sheathing in place, and it transfers the weight of the entire slip-form assembly directly onto the vertical jacking rods. In addition, the

FIGURE 10.16 Lifting jack assembly.

yokes support the reinforcing steel of the concrete wall. The yoke has to support the lateral pressure of concrete as per the ACI standard, which is described in the following formula:

$$p = 100 + \frac{6000R}{T}$$

where:

- p = maximum lateral pressure (lb/ft²).
- R = rate of concrete placement (ft/hr).
- T = temperature of concrete forms (°F).

Additional frames or false yokes are sometimes located between the yokes. The primary difference between the two is that the false yokes do not transfer the vertical loads onto the jacking rods; instead, the false yokes only support the lateral loads transmitted through the wales.

The **wales** are the longitudinal supports for the sheathing. An upper and a lower wale are usually located on each side of the concrete wall. More wales should be provided if the form height warrants the additional support. Normally, this is a height exceeding 4 ft. The wales resist the loads and transfer these loads directly to the yokes. The wales must be engineered to withstand the ACI lateral pressure requirement as indicated previously. In addition, ACI Committee 347 (2005) also requires that tolerances be maintained for the finished structure. The variation of wall thickness cannot be greater than $\pm 3/8$ in. for walls up to 8 in. thick or $\pm 1/2$ in. for walls thicker than 8 in.; therefore, good engineering practice must be applied in the design of these forms. As per ACI SP-4, timber wales should be a minimum of two- or three-ply lumber or at least one ply of 2-in. material; when the span between jacks approaches 10 ft, the wales should be braced to act as a truss in the vertical plane between yokes. For curved walls, the minimum depth of segmental wales should be 4-1/2 in. at the center after cutting. Peurifoy (1995) discusses in depth the formwork for concrete structures.

The **sheathing** is the vertical support in direct contact with the concrete. Swelling of sheathing must be controlled because the sheathing is in continuous contact with moist concrete for the duration of the construction. Protecting sheathing prior to construction should be accomplished either by presoaking lumber or with a waterproofing preparation. In many cases, a nonabsorbent surface that can withstand moisture and temperature conditions is selected. Sheathing should be higher on the exterior face of the form to avoid splashing materials onto workers on the scaffolding below. As per ACI SP-4, forms should be constructed of at least 1-in. board, 3/4-in. plywood, 10-gauge steel sheet, or other approved material. The sheathing, when constructed, should have a slight batter to it. This will enable the forms to self-clear. The batter should be tapered inward at the top of the form and tapered outward at the bottom of the form. The middle area of the sheathing is the finished dimension of the concrete wall. The height of the form is usually 4 ft. The sheathing is kept well oiled as it rises to eliminate excessive drag forces. The construction engineer should compensate for this additional vertical load in the design.

The **working platform** houses all of the construction equipment necessary for the form to advance. The platform also keeps the poured walls square. Care should be taken in the design of the platform. A minimum of 75 psf is recommended for design. In addition, concentrated buggy loads must be considered. **Suspended scaffolds** are located below and on either side of the form. They provide a work area that enables work crews to finish the concrete wall that has been placed. Because the concrete is still wet, it is workable.

10.11.3 Advantages and Disadvantages

One disadvantage is that the monolithic pour precludes the placement of floors during the extrusion process. Horizontal reinforcing protruding through the walls cannot be placed until the slip form passes through the wall. Provisions can be incorporated to prepare for floors, corbels, or openings (see Figure 10.17). This is accomplished by blockouts. The crews provide openings or pockets by creating forms within the form. Quality control is of considerable importance. Care must be taken to lift the form at the right time. As a result, the construction procedure requires skilled laborers and experienced project management. Placing concrete too quickly can result in a blowout and too slowly can cause the concrete to adhere to the form, which could damage the wall as well as the form. Construction engineering is an important aspect of the overall procedure. Careful preparation and analysis should be undertaken prior to construction. Temperature and climatic conditions are all factors that must be incorporated in the design of slip-form construction. All of the above incur additional costs for the project as opposed to using conventional forms. Another disadvantage is the difficulty of inspecting the wall, as steel is placed only a few feet above prior to the pour. The advantage of slip-form construction is the speed at which a wall can be erected. A slip-formed wall can eliminate up to 3 months of construction, compared to conventionally formed work, and the wall is free of horizontal joints. The taller the building, the more cost effective the system can be. The level of safety is greatly increased when utilizing the slip-form process. Preparation for the process must be carefully carried out by well-trained and skilled individuals. As a result, all staging is eliminated and the working areas only have to be built once.

FIGURE 10.17 Blockouts for floors, corbels, and openings.

10.11.4 Economy

Slip-forming tall cores (in excess of 12 stories) can greatly reduce the cost of construction. Only one form has to be built which can often be reused for every level to the top. The cost of forms per contact area is greatly reduced. The overall question of cost, however, is difficult to address due to varying costs with regional conditions, available skilled labor, and the complexity of the project. This issue must be evaluated by the conditions that dictate the design and the location of the site.

10.12 Prestressed Concrete

10.12.1 Introduction

When gravity loads are applied to a flatwork element (slab or beam), moments and shears are created within the element. Applied moments are resisted by the development of a force couple within the element section. The couple consists of a tension and a compression force, each occurring on opposite sides of the neutral axis within the section. Shears are resisted by the effective concrete area of the section; at times, supplemental resistance is provided by shear-reinforcing steel.

In conventional concrete design, the moment-resisting couple is essentially the only resistance to bending moments; thus, the proportioning of the section dimensions, in association with the sizing of adequate reinforcing steel, must be sufficient to resist the applied moments, with tension stresses often

being the limiting design criterion. By designing so tension stresses are resisted by mild steel reinforcement, the failure mode of an element will be ductile and gradual, giving ample warning of precipitating failure. This is ensured by designing all beams, slabs, and plates as under-reinforced; that is, the reinforcement percentage does not exceed 75% of the balanced condition—in most cases, not more than 50% to prevent congestion of reinforcement.

Pretensioned (precast) and post-tensioned concrete design, generally grouped as prestressed design, involves an additional form of resistance to the applied moments and shears. By externally applying a compressive force to the element, the stress distribution over the section is dramatically altered. The compressive force acting on the section reduces the tensile stresses at the tension zones, thereby preventing cracking and also increasing considerably the diagonal capacity of the section. This permits the section size to be reduced while keeping the total resulting stress within the allowable range. Chapter 35 of this *Handbook* gives the basic expressions for the stresses and diagrams of stress distribution across the depth of a prestressed beam as affected by the external compressive prestressing force (see also Nawy, 2003, for details regarding the design of prestressed concrete structures).

The use of prestressing methods can allow the designer to reduce section proportions while carrying the same or larger load as a conventionally reinforced concrete section, which results in a corresponding reduction in cost in terms of the gross volume of concrete. The designer must acknowledge that the prestressing equipment, materials, and installation can, in some circumstances, cause the total construction cost to exceed that of conventionally reinforced concrete. Preliminary cost/benefit analysis is advisable before deciding to use a prestressing system, provided that other requirements of span and load might necessitate the use of a prestressed concrete design.

10.12.2 Pretensioned (Precast) Concrete

Prestressed concrete generally falls into two groups: pretensioned or precast concrete and post-tensioned concrete. Precast concrete usually is made in off-site casting plants and may or may not include prestressing. Construction elements ranging from hollow core slabs to T sections to architectural wall panels are regularly precast. Precasting offers the controlled environment of a plant, which results in very consistent production in terms of quality and delivery speed. Precast plants work with heated, steel form beds with polished form surfaces. The quality of the concrete is controlled and is usually 5000 psi or higher. The color, consistency, and dimensions of precast elements are usually of better quality than can be produced in the field. Concrete admixtures, to achieve rapid set and also to gain durability advantages, are frequently added to produce higher quality concrete.

As noted earlier, precast concrete can be either prestressed or not. Conventionally reinforced precast concrete is most frequent in wall panels, columns, and miscellaneous elements such as highway dividers. Prestressed elements are most frequently produced for structures carrying high loads, bridging long spans, or subjected to harsh environments. In these cases, the precompression force improves both load-carrying performance by reducing tension stresses and durability by closing surface cracks on the tension face that might allow the intrusion of corrosive salts or chemicals.

Where prestressing is used in precast applications, bonded prestressing is usually used. Bonded prestressing consists of placing high-tensile-strength (270-ksi) wire strands, or bundles, in the setting beds prior to pouring the concrete. The strands are then tensioned by jacking them tight against a rigid frame at the head and foot of the setting bed. When the required jacking force has been introduced to the strands, fresh concrete is poured into the bed in direct contact with the strands. As the concrete sets, the strands become bonded to the concrete.

The initial jacking force introduced to the strand is released into the precast element via the bond between the strand and the concrete. This produces a fairly even distribution of compressive stress along the length of the member. In addition, because the bond is continuous along the length of the member, a bonded precast element can be cut into smaller pieces without losing the precompression force.

The designer is cautioned that the latter characteristic of precast concrete is only applicable where the strand drape is flat, thus producing an even precompression force over the entire length of the element.

Where the strand drape is not flat (discussed further below), the influence of the jacking process will be to introduce both a precompression force and an internal moment into the element. In such a case, cutting the element could result in the loss of the internal moment, as it would not be resolved by the balancing remainder of the element that has been cut away. In practice, hollow-core plank is frequently cast in long lengths, with an essentially flat strand. The plank is then cut to the appropriate length for project needs. Some forms of wall panel are also produced in this fashion; however, where strict quality control is required to ensure proper architectural appearance, each precast member is usually cast alone.

When designing precast concrete sections, the designer must be cognizant of several forces that act on the member during its life. It is not sufficient to simply analyze the service loads to be applied once the member is situated in its final position. Because concrete cures over a period of time, the relative strength of a concrete member changes as the concrete strength increases; thus, loads that are applied to a member shortly after casting could cause stresses that exceed the capacity of the member at that specific moment in its life.

The designer must therefore consider three types of loads that act on every precast member at some point. First are stripping stresses, created when the casting forms are released. This action causes suction forces that can induce large, concentrated tensile stresses in the concrete. Second are transport stresses, created from lifting and stacking the members for transport around the casting yard and to the job site. Lifting lugs are frequently cast into the precast members to provide a location for the attachment of lifting equipment. The use of strategically located lifting lugs allows the designer to anticipate and design for the stresses that result from moving the members. Last are service stresses, which occur as a result of the design loads that are expected to act on the structure, determined by its use classification. These are the traditional design loads that must always be addressed.

When precast elements arrive at the job site, they are erected piece by piece and bearing pads are used to separate the elements. Precast concrete shop drawings specifically detail all of the connections between the precast pieces and any other structural members. Local stress concentrations must be taken into consideration during the design process to address conditions where ledges or corbels will support adjoining members.

In certain applications of precast concrete, a final cast-in-place concrete topping is applied when the precast superstructure has been erected. This is typical in precast plank or double-tee construction, where a consistent, durable wearing surface is required. The topping course (typically, 2 to 3 in. thick) is sometimes reinforced with welded wire fabric, thus providing catenary reinforcement, which aids in the distribution of loads over the entire floor system.

10.12.3 Post-Tensioned Concrete

While pretensioning is generally conducted in a plant setting, post-tensioning is mostly conducted in the field. The “post” term is something of a misnomer, as the precompression force introduced into the concrete is added prior to the introduction of any load on the structural system. The term has evolved, however, because the procedures occur at the construction site rather than at a precasting plant and thus are “post” because the members are not brought to the site ready to install. Post-tensioning design follows the same procedures and expressions used in the design of pretensioned elements except for prestress losses. By introducing a precompression force into the concrete section, the maximum tensile stress is reduced by the compressive stress, thereby permitting the use of smaller sections that support the same loads as conventionally reinforced concrete members. Construction procedures can be considered an extension of those used in traditional cast-in-place (*situ*-cast) concrete. Formwork must be erected to support the fresh, poured concrete; mild reinforcing steel must be placed to provide system ductility; and site curing procedures must be followed to ensure that quality, final concrete is produced. The concrete stresses permissible in flexural prestressed members occur at three load levels: stresses occurring immediately after prestress transfer, stresses at service load, and stresses at the ultimate load level. Section 18.4 of the ACI 318-05 Code presents the permissible stresses at the extreme fibers of the members for these loading stages. Also, Chapter 11 and Chapter 12 in this *Handbook* and *Prestressed Concrete: A*

Fundamental Approach by Nawy (2003) address most of the design and construction aspects pertinent to pretensioning and post-tensioning beams and one-way and two-way slabs and plates. It is important to recognize that, in two-way slab design, attention must be given to re-entrant corners, large openings, L-shaped plan configurations, balconies, repetitive perimeter openings, or steps in slab elevations. Each of these conditions poses a difficult design problem if conventionally reinforced concrete is used. The problems are multiplied when the system is precompressed and compelled to shorten. Cracks can rapidly develop at corners, and localized crushing of concrete can occur, particularly due to stress concentration at these locations. To counter this condition, significant mild steel reinforcement has to be provided to prevent cracking propagation at the early stages of post-tensioning or loading.

Acknowledgments

Construction of Prestressed Concrete

Ben C. Gerwick, Jr., P.E., S.E.*

In Memoriam

Professor Ben C. Gerwick, Jr., a world authority and pioneer in prestressed concrete, died December 25, 2006, a month after he so graciously expanded, upgraded, and completed the revision to this chapter which he originally wrote for the previous edition of the *Handbook*. He is fondly remembered as a prolific author of papers and books and as a foremost expert in the innovational designs of offshore-prestressed concrete structures.

11.1 Introduction

The effective construction of prestressed concrete structures requires the practical application and implementation of sophisticated engineering technology in a safe and reliable manner under the constraints of time, budget, and the external environment. It incorporates the assembly of materials, equipment, and personnel and the execution of the work so as to attain the results envisioned in the design. The key elements in prestressed concrete construction are the following:

- The production of concrete that has stable, predictable properties, not only of strength but also of creep, shrinkage, elastic modulus, and durability (high strength is essential to attaining efficiency of structural performance)
- The forming (molding) of concrete into the design shape and within the specified tolerances
- The incorporation of mild steel reinforcement, accurately placed and held during concreting
- The placement of high-strength steel wires, strands, or bars to fit the design profile and the stressing and anchoring and corrosion protection of such elements
- Installation of the composite structural elements or assemblages described above, in their final positions, whether they are cast in place or prefabricated

During construction, prestressed concrete passes through a number of steps or stages, each of which must be considered. Then, after attaining the designed state, it undergoes a lifetime of relatively subtle but cumulatively important changes. Although conventional reinforced concrete passes through a similar life history, the changes and the importance of the stages are generally far less dramatic, and the consequences of oversights are not as severe; hence, in this chapter, the emphasis is on the practical attainment of safety and stability. We are working with an active, rather than a passive, structural system.

Environmental conditions are given considerable emphasis. Important prestressed concrete structures have been completed and now serve in Arctic, temperate, and tropical zones. They are successfully employed in the ocean, in the urban environments of large cities, and in remote deserts. Prestressed

concrete is used in buildings; bridges (Figure 11.1); offshore platforms (Figure 11.2); liquefied natural gas (LNG) import facility floating structures; towers; poles; tanks; wind, wave, and current energy structures; and railroad sleepers. Each of these uses has its own special criteria and practices. Each has its own constraints and limitations. The reliable performance of prestressed concrete (that is, its durability) throughout its design life requires careful consideration during design and construction. The requirements for such widespread use can be summed up in a few key words:

- Reliable, stable material properties
- Full consideration of the stages of construction of a prestressed concrete structure
- Durability with regard to long-term performance and serviceability

Various authorities have issued their precepts or commandments. These generally include the following:

- When prestress is applied, the concrete element must be allowed to shorten in the direction of the prestress. If the structure is restrained from shortening, it will not be prestressed.
- When the prestressing tendon is curved, it exerts a radial shear force.
- Prestressing applied to concrete too soon after casting, before it has gained strength and maturity, will lead to excessive creep. Prestress applied too late after concreting may result in extensive shrinkage cracks.
- Prestressing eccentric to the centroid of the concrete section produces bending. This bending (e.g., camber) tends to grow with age due to creep.
- The energy and hence force induced in a prestressing tendon by stressing are very large and result in a temporarily dangerous missile; safety precautions are essential.

11.2 Concrete and Its Components

The concrete material components must meet the general requirements for construction of reinforced concrete structures and, in addition, must usually conform to more stringent requirements to attain the design objectives.

11.2.1 Aggregates

Coarse aggregates are usually siliceous or limestone. Both gravels from riverine deposits and crushed rock are used. Desirable properties are hardness, soundness, nonreactivity, surface roughness, cubic as opposed to plate cleavage, low water absorption, and impermeability. Slightly reactive aggregates may often be utilized in specific applications if the proper chemistry of the cementitious materials is selected. Some limestones are not only porous but also permeable; their use in marine structures requires special actions to preserve durability. Lightweight (ceramic) aggregates are used extensively. Those of high strength, low creep, and low absorption are most appropriate to prestressed concrete application. Fine aggregates may be from natural deposits or they may be crushed from coarse aggregate. In any event, screening will be necessary to ensure a proper proportion of coarse sands and a suitable grading curve, preferably with a low percentage of the fine fractions, as a mix rich in cementitious material will fill the interstices while an excessive percentage of very fine particles will have a high water demand. The aggregates must be clean and free from salt and dirt. They should be properly stored above ground and protected from snow and ice and from excessive heat. Shielding from the sun may be provided by portable sheets of galvanized metal on temporary posts in the aggregate pile. To a large degree, cooling of aggregates may be accomplished by evaporation. A water soaker hose may be effective. Conversely, aggregates should be above freezing when batched. They may be heated by steam. Care must be taken to avoid accumulation of ice in the aggregate, whether by snow or the freezing of condensate, as ice particles may be unintentionally weighed and batched as coarse aggregate. Aggregates, both fine and coarse, should not contain or be encrusted with salts and silt. Washing is usually required, preferably with fresh water; but, if fresh water is not available, even brackish water can be used to remove the condensed salt crystals and silt.

11.2.2 Cementitious Materials

The practical construction of prestressed concrete is based on the use of Portland cement as the principal cementing agent. American Society for Testing and Materials (ASTM) cement Types I, II, and III are used. Type I can be used in geographical areas and applications where sulfate attack is not a problem. Type II, with closer control over the constituent compounds, especially tricalcium aluminate (C_3A), is widely employed where durability is a concern. Fly ash and metakaolin are pozzolanic materials that gain strength over a longer period of time than cement. They can be substituted for up to 20% or more of the cement. The silica of the fly ash binds up the soluble calcium hydroxide, substantially increasing impermeability. It also provides resistance to sulfate attack and alkali-aggregate reactivity while lowering

the heat of hydration and reducing thermal strains. Fly ash requires a separate silo and should be weigh-batched separately from the cement. In some areas, fly ash is interground with the cement. For proper strength gain, continuous moisture is essential over an extended period of up to 30 days. This is usually best obtained by wet curing for 3 days followed by sealing with one or two coats of membrane-sealing compound. Finely ground blast-furnace slag (BFS) can be used with a limited portion of Portland cement to act as an efficient cementitious material with low heat of hydration and low permeability. Mix proportions of BFS to cement range from 50–50% to 70–30%.

11.2.3 Admixtures

Many revolutionary new admixtures are commercially available. The most important are water-reducing agents, especially high-range water reducers (superplasticizers), air-entraining agents, and microsilica, called *silica fume*. Corrosion-inhibiting admixtures, retarding admixtures, pumping aids, and viscosity admixtures are also available. Tests mixes are essential to ensure that the admixtures selected are compatible with the particular cement and other admixtures. The use of high-range water reducers (superplasticizers) is the best way to achieve the low water/cementitious material ratios essential for high-performance concrete. The usable life of high-range, water-reducing admixtures is typically 1-1/2 hours after mixing, so the concrete must be placed and consolidated within that period to prevent sudden premature stiffening. This life can be extended by adding retarders. Some high-range, water-reducing admixtures incorporate a retarder and hence have an extended slump life.

Air entrainment creates tiny air bubbles of proper distribution throughout the concrete, thus enabling the structure to resist a large number of freeze-thaw cycles. Its use is essential in cold regions. Its efficacy is dependent on in-place characteristics. Unfortunately, these can only be verified by microscopic examination of hardened concrete specimens, although other real-time tests give valuable indications as to the entrained air and can be used for control when they have been properly calibrated by a petrographic inspection. Day-to-day control can be exercised by use of a meter that measures the total air content (entrapped plus entrained air) in the fresh concrete mix. Microsilica or silica fume consists of very small particles of silica about 1/100 the size of cement grains which combine with gypsum to produce high early strength, very low permeability, improved bond, and enhanced fatigue endurance. Microsilica also increases electrical resistivity. It is used in percentages (by weight of cement) of 3 to 10%. More than 6% makes the concrete quite sticky and difficult to place and consolidate; however, this property of added cohesiveness can be beneficially used for concrete placed underwater. Microsilica can be introduced as a powder or in a slurry, or, in some cases, can be ground with the cement. If introduced as powder, it must be well mixed. Although most commercially available microsilica is a mineral byproduct of silicon production, rice-husk ash has recently been used as a source, with similar and possibly enhanced properties. Use of high-range, water-reducing admixtures is essential to the incorporation of microsilica in the mix.

Proprietary corrosion-preventing admixtures, based on calcium nitrite, are available. Similar admixtures that reduce the diffusion of chlorides in concrete are commercially available but are relatively expensive. Other thixotropic (viscosity-control) agents are available that promote the initial flow of concrete and self-leveling but gel when movement ceases, thus preventing bleed. They are often used for underwater concreting and for grouting post-tensioning ducts.

11.2.4 Water

Water for prestressed concrete is required to have no more than 650 ppm of chlorides and 1000 ppm of sulfate ion, although in many specifications, the latter is increased to 1300 ppm. Water furnishes the essential electrolyte that initiates the chemical reactions and promotes fluidity (workability) by coating the particles; however, excess water is inimical to strength and durability. For this reason, the water/cementitious materials ratio (w/cm) should be limited to a maximum of 0.42 and preferably 0.40. In practice, w/cm ratios of 0.32 for precast elements and 0.37 for cast-in-place concrete are attainable. In hot weather, ice may be added to the mix in place of water to lower the temperature of the fresh concrete. Alternatively, liquid nitrogen may be injected.

11.2.5 Batching of Concrete

Concrete is weigh-batched in the same manner as in conventional reinforced concrete practice except that in prestressed concrete construction, there are usually more dry components (e.g., cement, coarse aggregate, fine aggregate, fly ash, blast-furnace slag, microsilica) and more wet components in the form of admixtures, each of which must be accurately dosed. The moisture content of the aggregates must be ascertained from free-moisture meters in the bins and corrections made to the amount of water added.

11.2.6 Mixing of Concrete

It is obvious that mixing must be very thorough to blend the many components. For this reason, turbine mixers and shear mixers are favored. Even when the concrete is subsequently transported in ready-mix trucks, premixing at the plant is desirable. The order in which admixtures are added to the mix is important—particularly for air-entrainment agents and superplasticizers, as the latter may inhibit the proper development of entrained air. Adding half the dosage and then mixing for a brief period before adding the remainder can solve the problem in some cases.

11.2.7 Transporting and Placing

Transporting and placing follows conventional practice; ready-mix trucks, concrete pumps, buckets, and conveyors are used. For discharge of stiff mixes from the trucks, screw conveyors may be used. In some high-rise construction using slip forms, where the required rate of concreting at any one location is low, buckets have been used to raise the concrete to elevated hoppers, from which the concrete has been distributed by buggies running on runways. The loss of slump and of entrained air content when pumping concrete to high elevations must be considered.

11.2.8 Consolidation

Internal high-frequency vibration is the typical means of consolidation for cast-in-place concrete. It should also be used to supplement external vibration in all precast concrete elements except very thin (150-mm or 6-in. or less) members, as external vibratory energy is not effective at depth. Self-consolidating concrete (so-called *flowing concrete*) is now being used in thin and congested sections.

11.2.9 Curing

Membrane curing (curing compound) is generally considered to be the most reliable for vertical surfaces. For horizontal surfaces, wet curing is best, although sealing with polyethylene sheets is also widely practiced. Concrete containing fly ash, and especially that containing microsilica, requires special attention to curing to prevent surface crazing. For precast elements and occasionally for cast-in-place segments, steam curing is used to accelerate gain in strength. Steam curing at atmospheric pressure provides both moisture and heat and results in generally superior concrete; however, certain practical precautions are required with steam curing (see PCI, 1999):

- Concrete should have its initial set 3 to 4 hours before the temperature is elevated; otherwise, it may be damaged as it expands.
- The maximum curing temperature should be limited to 60°C (140°F) to prevent long-term development of delayed ettringite.
- Steel forms expand before concrete; hence, changes in section must be detailed to accommodate length change so as not to crack the concrete. Soft rubber gaskets may be used between flanges of forms to absorb their early expansion.
- Concrete, once cured, should not be exposed to cold, drying winds until it has cooled to within about 10 to 15°C (20 to 30°F) above ambient. It is important not only to prevent sudden cooling of the outer surface while the inner core is still hot but also to prevent rapid evaporation of

FIGURE 11.3 Spreading rubberized nylon tarpaulins in preparation for steam curing. (From Gerwick, B.C., Jr., *Construction of Prestressed Concrete Structures*, John Wiley & Sons, New York, 1996. With permission.)

moisture. The latter may require supplemental water or membrane curing. Membrane-curing compounds evaporate with heat; hence, in hot weather a second coat may be required.

In cold weather, and especially with dry winds, the concrete must be protected by insulated forms or blankets (tarpaulins) until the surface temperature is no more than 15°C (30°F) above that of the core (Figure 11.3); otherwise, cracking will occur due to the early contraction of the outer layer.

11.2.10 Testing

Testing of high-strength and high-performance concrete is a demanding technology, requiring trained personnel and sophisticated equipment. Specimens must be taken and prepared carefully if the results are to be meaningful. Cylinders should be vibrated with a pencil vibrator in steel molds, because plastic and cardboard molds will give erroneously low results. The cylinders should be subjected to the same temperature regime as the structural element—for example, placed under the steam hood near each end and at the center of the bed. When removed, cylinders should be placed in a water bath containing lime and kept at 20°C (70°F) until one day before the test. They should then be removed to dry out before testing. Ends of the cylinders should be rubbed smooth to remove any surface irregularities. Numbers should never be etched in the top surface! Cylinders should be carefully capped with new capping compound or ground smooth to test without capping. Similarly, cubes, where used, should be ground and tested without capping. Be sure there is a strong screen around the testing machine, as high-strength concrete fails explosively. Testing of other properties is even more complex. Air-entrainment characteristics are determined by microscopic petrographic examination of thin slices cut from a core in the hardened concrete. Impermeability is very difficult to measure at the upper limits associated with high-performance concrete. The validity of the rapid chloride permeability tests of both ASTM and British Standards has recently been questioned. On many important projects involving prestressed concrete, various properties are specified. These include permeability and determination of the extent of microcracking. In practice, some of the values specified have proven to be extremely difficult to attain in the field. The contractor should therefore start the mix development and testing program at the earliest possible moment, working in cooperation with the engineer and technicians so as to avoid delays and rejections.

FIGURE 11.4 T-headed bars lock against reinforcing steel to provide high shear capacity and confinement.

11.3 Reinforcement and Prestressing Systems

11.3.1 Reinforcing Steel

Because in prestressed concrete structures the role of primary reinforcement has largely been replaced by prestressing steel, an unfortunate tendency has been to denigrate the importance of supplementary conventional reinforcing. Conventional reinforcement fulfills the essential functions of distribution and resistance in the orthogonal directions to the prestressing, most typically in the transverse direction. It serves to augment prestressing steel in critical areas of concentrated stress. It serves as confinement, resisting the bursting and delamination stresses due to prestressing itself (Figure 11.4). It also resists punching shear under concentrated loads.

The role of reinforcing steel is secondary to the structural behavior and is concerned with stress distribution and crack prevention, so close spacing with small bars is preferable to large, widely spaced bars. Confining reinforcement usually consists of spirals, although hoops (welded rings) perform best under ultimate loads. Mechanically headed bars (Figure 11.5) have been used on a number of recent major structures. Subject to the design engineer's approval, bundling of bars may be acceptable, especially in cast-in-drilled shafts and columns. This clustering of bars together often facilitates concrete placement. For splices, mechanical splices are best, although lap splices may be used.

Reinforcing bars typically develop anchorage by having an embedment length that extends beyond the location of high stress, preferably terminating in a confined zone or core. Bends, such as those of stirrups, are only about 70% effective in ultimate capacity, as the concrete under the bend crushes at high stress. Headed bars typically anchor the bar, develop its full strength, and permit the use of larger bars or those with higher yield strength. They are much easier to install than stirrups and reduce congestion of steel bars. It is a serious mistake by both designer and constructor to reduce anchorage lengths to the absolute minimum permitted by code or specifications, as practicable placement tolerances frequently result in inadequate length for anchorage. A typical concern arises with the provision of *cover*—that is, the thickness of concrete outside the reinforcing bars. Because cover is a major factor in durability, as well as in mechanical behavior, it is normally specified to a tolerance of -6 mm ($-1/4$ in.).

Main bars should be tied with wire at every intersection. Stirrups or hoops must be tied to the longitudinal bars at three intersections so as to prevent displacement along the bars during concreting (a typical problem in concreting that has serious consequences). Lap splices in reinforcement are another

FIGURE 11.5 Mechanically headed bars used to replace conventional closed stirrups.

source of difficulty. These can be more easily achieved if the bar is a little longer than the minimum required by code. The designer or the code should specify whether or not the overlapping bars must be tied together with soft iron wire. In general, this is good practice. Compression splices are rendered most efficient by being well tied together at both ends; otherwise, the concrete may locally crush under one or both bar ends. Lap splices, especially those in tension, must be confined on both orthogonal axes, transverse and through thickness.

Reinforcing bars require support. Both concrete dobie blocks and plastic chairs are used and are left in place in the completed concrete structure. Reinforcing bars are frequently epoxy coated to protect against corrosion. The electrostatic fusion process is most widely used. Problems sometimes occur with insufficient thickness of epoxy over the lugs of the deformations. Regardless of the method of manufacture or whether the bars are bent before coating or bent afterward, there will be some scratches and some “holidays” due to handling and placement. Fiber slings and pads must be used. Abraded areas must be touched up in the field after placing. Special care must be taken to ensure that the reinforcing steel is stored in a salt-free area before concreting—that is, where seawater chlorides cannot be carried by fog or spray to contaminate bars. In critical areas and special applications, corrosion-resistant or stainless-steel reinforcement is utilized, enabling a reduction in cover and providing long-term durability.

11.3.2 Prestressing Tendons and Assemblies

Prestressing tendons are made of cold-drawn wire, both parallel and stranded, or rods of high-yield strength steel. Bars and rods consist of heat-treated alloys, which have been prestretched beyond yield and tempered in the manufacturing process. They are rolled with spiral threads, either cut in upset ends or continuously rolled so the threads also act as deformations. Cold-drawn wire is typically low alloy that has been tempered. Wires are generally wound into seven-wire strands and prestretched. The seven-wire strand, with an outside strand diameter of 12 to 15 mm (0.5 to 0.6 in.) is most typical for both the pretensioning and post-tensioning systems discussed in Sections 11.5 and 11.6. For pretensioning, the strands are directly embedded in the concrete, gaining anchorage by bond on the twisted surface. For special applications, such as railroad ties (sleepers), a wire with a deformation is stranded into one outer layer of the strand to shorten the stress transfer length. For post-tensioning, anchorages are locked to a socket by serrated wedges, locking into a female sleeve. High-strength bars are used primarily for short

FIGURE 11.6 Seven-wire prestressing strand is shipped in coils to the precast concrete plant or jobsite. (Photograph courtesy of VSL Corporation, Campbell, CA.)

tendons. Wedges can be used to anchor bars although threaded connections are more often employed. These permit restressing to counter the set typical of wedge anchors.

Bars, wires, and strands are usually left *black*, or uncoated. They may be galvanized for corrosion protection; hot-dip process galvanizing appears to be most reliable. A chromate wash applied at the end of the galvanizing process will passivate the zinc and inhibit the liberation of individual hydrogen atoms that results from reaction with the alkali cement. Evidence indicates, however, that the protection resulting from galvanizing has a limited life of 10 to 15 years in seawater. Individual strands that are sheathed in plastic are now available. They are then bundled into tendons for post-tensioning application. Epoxy coating is occasionally applied to steel strands. Sand is dusted on while the epoxy is still wet to improve bond.

Prestressing steels, which are under high sustained stress, are subject to a long-term plastic rearrangement of molecules known as *stress relaxation*. This can produce long-term losses in prestress of the member up to 13%. By a special tempering process, the stress relaxation may be reduced significantly, to about 6%. Seven-wire strand has approximately 30% voids as compared to a solid bar of the same external diameter. *Compact strand* is available, in which the wires are shaped so they fit tightly together. This allows an approximately 15% increase in total force to be obtained within the same external dimensions and is a valuable technique for solving space problems in highly stressed members and in repairs. Prestressing wire and strand are shipped in coils that are wrapped with heavy, water-resistant paper (Figure 11.6). If the cover is torn, the entire coil may be corroded at regular intervals. Bars and rods are similarly shipped in bundles, wrapped for protection from moisture. For protection against corrosion, vapor-phase-inhibiting crystals may be inserted in the package. More frequently, however, the tendons are coated with water-soluble oil.

FIGURE 11.7 High-strength alloy steel bars are used to prestress this wall to enable it to resist the pressures of Arctic sea ice. (From Gerwick, B.C., Jr., *Construction of Prestressed Concrete Structures*, John Wiley & Sons, New York, 1996. With permission.)

11.3.3 Anchorages and Splices

The anchorages and splice hardware for prestressing systems consist of cast alloy steels, machined to accurate dimensions with very close tolerances to provide a positive grip to the tendons under high forces (Figure 11.7). The anchorage includes, either separately or monolithically, a bearing plate that transfers force to the concrete. The concrete at the anchorage, being under a force that is typically several times its uniaxial compressive strength, must be confined, either by a ring integral with the anchorage or by hoops or spiral. The anchorage may also include the socket and wedges for gripping the tendon. Anchorages must be transported, stored, and handled with extreme care. Some European specifications require storage in a heated, dehumidified, warehouse. Anchorage assemblies must be clean and free from foreign material, except the grease specified by the system manufacturer. Damaged or visually defective anchorages should never be used. A failure may result in the other anchorage and the tendon being ejected at high velocity. Splices of prestressing tendons are similar to anchorages in that they anchor to both ends of the tendons. It is fundamental that the splice be free so as to allow the tendon to elongate upon stressing; thus, a recess or opening must be temporarily left in the concrete at the splice location. Post-tensioned anchorages are either encased or recessed for reasons of durability, fire protection, and appearance. A recessed pocket is formed in the end block with protruding steel ties that are temporarily bent aside. The surfaces of the pocket or recess are coated with bonding epoxy or latex, then a fine (small coarse aggregate) concrete is placed in a manner so as to eliminate a shrinkage and bleed pocket at the top. After the form is stripped, the joint may be sealed with a penetrant epoxy.

FIGURE 11.8 Ducts for post-tensioning may be of steel or plastic. (Photograph courtesy of VSL Corporation, Campbell, CA.)

11.3.4 Ducts

For post-tensioning, ducts are used to preform holes in the concrete structure during casting so that later, after the concrete has hardened, tendons may be inserted and stressed. Several types of ducts have been used, including steel pipe, semirigid steel ducting made of strips spirally wound to lock to each other, thin flexible metal tubular ducting, and plastic (Figure 11.8). Ducts are usually circular in cross-section, although flat ducts with a rectangular cross-section are used where the concrete cross-section and crossing bars or tendons constrict the available space.

Flexible metal ducts, made of thin corrugated steel and usually galvanized for temporary corrosion protection, are used for tendons of sharp or reversing curvature. These ducts are readily wound in coils and can be spliced by a short overlapping sleeve of similar material. These ducts are very flexible, so that they develop unwanted local curvature, called “wobble.” This can be prevented by insertion of a mandrel of smaller diameter, for example, electrical conduit. After the concrete has been placed, the mandrel is drawn forward and backward to prevent any bond with mortar that may have leaked into the duct, and then removed.

Semirigid metal ducts are bright steel strip, wound spirally with crimped overlaps (Figure 11.9). This ducting has less wobble but still requires use of a mandrel in those applications where even slight deviations have serious consequences. This material is normally furnished in straight lengths but can still be deviated over large-radius curves, depending on the sheet thickness used. Semirigid and flexible ducts are neither watertight nor mortar tight. If a mandrel is not used, a wire or single strand should be run back and forth to clean out any mortar leaking in from the concreting operation. For long, straight runs, especially long vertical runs, thin-walled pipe with screwed splice fittings is employed. Wall thicknesses of 1 to 2 mm are typically used. Splicing of metallic ducts is done by sleeving, with an adequate overlap of at least two diameters and taping with waterproof tape; however, the latter has not proven to be fully reliable. Heat-shrink tape is now preferred.

Steel ducts may be epoxy coated externally where used in zones vulnerable to corrosion, such as transverse post-tensioning of bridge decks in geographical areas where salts are applied to prevent icing. Plastic ducts of polyethylene or polystyrene, with corrugations inside and out, are increasingly employed because they are watertight and grout tight, have controllable flexibility, and give long-term corrosion protection to the tendons. They can readily be fabricated to exact length and can be spliced, either by fusion or by use of sleeves and glue or heat-shrink tape. Plastic ducts should have a minimum thickness of 2 mm; plastic ducts are available both as circular tubes and as rectangular flat ducts.

FIGURE 11.9 Both longitudinal and transverse ducts in place to receive tendons after concrete has been placed and cured.

When a plastic duct is installed on a profile or plan that is curved and wires or strands are later pushed in, the duct may be cut by abrasion, resulting in subsequent grout leakage. Ribbed ducts, in which the strand or wire will bear on enlarged ribs, have been used successfully to overcome this problem, as has lubrication with water-soluble oil. The ribs or corrugations enhance the bond between a plastic duct and the surrounding concrete. Use of 3- to 4-mm-thick plastic duct and pulling-in of the tendon as a bundle with a protective nose-piece (“Chinese finger”) will also minimize the problem of abrasive cutting.

The integrity of ducts, after installation in the concrete, is critical to the successful completion of prestressing. The duct location and the tolerances determine the subsequent profile of the tendon. Any blockage, as by in-leakage of mortar during concreting or out-leakage and crossover of grout from one duct to an adjacent one, will prove very costly, time consuming, and, in some cases, impracticable to correct.

11.4 Special Provisions for Prestressed Concrete Construction

11.4.1 Concreting in Congested Areas

It is typical of much prestressed concrete construction that certain zones, such as the ends of girders and locations of deviation of prestress, are heavily congested (Figure 11.10). Such areas may include, for example, zones in which post-tensioning anchorages, trumpets, spiral confinement, and transverse and vertical reinforcing steel bars compete for the limited space available. At the same time, such zones may make the highest demand on the concrete for compressive and tensile strength. Placing concrete of the required quality, without any voids, honeycomb, or segregation requires one or more of the following techniques:

- Bundling of reinforcing steel bars, especially stirrups, or substitution of headed reinforcement to give more clearance for the concrete
- Changing the concrete mix to reduce the maximum size of the coarse aggregate (e.g., to 10 mm), while increasing the cement content as necessary to obtain the required strength
- Use of flowing concrete
- Prior to concreting, marking the location of reinforcing steel on the forms to enable subsequent insertion of the vibrator

FIGURE 11.10 Congestion of conventional reinforcement and multi-axial prestressing ducts creates problems for concrete placement. (From Gerwick, B.C., Jr., *Construction of Prestressed Concrete Structures*, John Wiley & Sons, New York, 1996. With permission.)

- Prior to concreting, insertion of tremie tubes through the reinforcement, gradually withdrawing these as the concrete is placed
- Prior to concreting, inserting the vibrator within a tube that penetrates through reinforcement (Figure 11.11), gradually withdrawing the tube as the concrete is placed, allowing the vibrator to consolidate concrete below the tube
- In extreme cases, precasting of the end block in the horizontal position, then setting the end block in the forms and joining it to the cast-in-place concrete by protruding reinforcing dowels and the axial post-tensioning

11.4.2 Special Reinforcement at Location of Curvature of Prestressing Tendons

At locations where the centroid of prestressing deviates sharply in relation to the centroid of the concrete section, high radial stresses are introduced. These may cause cracking or, in extreme cases, actual pullout of the concrete in punching shear. It is important to tie this zone to the main concrete section. Typical zones where this phenomenon occurs and has led to damage in the past are at intermediate anchorages, especially where the anchorages are in bolsters or blisters protruding from the concrete section, and at deviation points for deflected-strand pretensioning. Similar conditions exist where external post-tensioning is constructed alongside an existing concrete section but is eccentric to it. In all of the above cases, U-stirrups or the equivalent are required. Their legs must be anchored deeply within the concrete core, preferably in a compressive zone.

11.4.3 Special Reinforcement to Distribute Anchorage Zone Strains

It has long been recognized that the concentrated forces at anchorages of post-tensioning tendons creates radial bursting forces that lead to cracking in the immediately surrounding concrete. All commercial producers of prestressing systems include appropriate confining reinforcement. Not so well recognized is that in the zone between two anchorages, or between the ends of two groups of pretensioned strands, splitting tension is developed. This requires distributed reinforcement to prevent detrimental cracking. When prestressing tendons are anchored at locations other than the ends of the member (e.g., the intermediate anchorages of continuity tendons or dead-end anchorages), the concrete behind the anchorage is subject to tension as the concrete in front of the anchorage tries to shorten. Either adjacent

FIGURE 11.11 Vibrating concrete in order to ensure thorough consolidation below ducts. (From Gerwick, B.C., Jr., *Construction of Prestressed Concrete Structures*, John Wiley & Sons, New York, 1996. With permission.)

prestressing tendons or conventional reinforcing bars are required to distribute these stresses back into the body of the concrete behind.

In vertical walls and webs, looped U-tendons are often used to provide prestress against shear. These situations occur in the vertical walls of silos, offshore platforms, and bridge piers and in the web of deep girders. Adjacent U's must overlap at the bottom; if the adjacent U's are separated, then high-tensile strains exist between them that can lead to cracking. Orthogonal reinforcing steel bars are needed. Additional bars for the above cases should be well distributed over the zone where the potential crack will initiate. The number and size of bars, while calculable by finite-element methods, are often determined on an empirical basis—for example, by provision of enough conventional reinforcement to transfer 50% of the prestress force to the zone behind. Failure to counter the tensile forces and strains can lead not only to cracking but also to a serious reduction in shear capacity.

It can be argued that the above problems are the responsibility of the design engineer; however, the counter-argument is that these local strains are associated with the anchorages of the prestressing system, which are typically selected by the contractor or a subcontractor and, hence, to some degree, are their responsibility. In any event, the occurrence of the cracking, etc. described above may initially be blamed on the constructor and may have serious cost consequences. Conversely, the extra reinforcing required is minimal compared with the overall project; therefore, it appears prudent for the constructor to ensure that it is provided. The matter should be resolved before the concrete is cast.

11.4.4 Embedments

Steel embedment plates are frequently installed in the sides or surfaces of prestressed concrete members. Frequently, these are square plates. As a result of at least three phenomena, cracks often originate at the corners:

- *Steam curing*—The steel plate expands rapidly as the temperature rises, before the concrete expands and before it gains strength.
- *Concrete shrinkage*—The concrete surrounding the embedment is subject to both setting and drying shrinkage.
- *Strains at sharp corners*—Such strains arise due to prestress.

FIGURE 11.12 Sylhan Viaduct in the French Alps combines high performance, high-strength concrete truss members with external tendons inside trussed extension. (Photograph courtesy of Bouygues, Paris, France.)

Solutions that will prevent or minimize such cracks are as follows:

- Place soft wood or a neoprene strip around the embedment, which will later be removed and filled with epoxy, latex, cement mortar, or an equivalent material.
- Round the corners of embedment plates.
- Install short diagonal bars across corners.

11.4.5 High-Performance Concrete

The criteria for high-quality concrete has been presented in general terms in Section 11.2. High performance, above the range normally associated with high-quality reinforced concrete, is often required for prestressed concrete members (Figure 11.12). Typical high-performance requirements specify very high strength (above 60 MPa, or 8700 psi), enhanced impermeability (less than 10^{-10} m/sec), special requirements limiting microcracks, high abrasion resistance, and high tensile strength (above 4 MPa, or 600 psi). The attainment of these requires advanced concrete technology and strict control of field construction practices, including:

- Rescreening and rewashing of aggregates
- Selection of aggregates with surface roughness (e.g., crushed rock and crushed sand)
- Smaller coarse aggregate sizes
- Higher sand content
- Higher cement content
- Replacement or addition of fly ash
- Alternatively, use of blast-furnace-slag cement
- Addition of silica fume (microsilica)
- Use of a high-range, water-reducing agent or higher than normal doses of conventional water-reduction agents
- Special admixtures related to specific properties desired
- Precooling of concrete mix
- Curing practices

FIGURE 11.13 Prestressed lightweight concrete girder being prepared for shipment by rail. (From Gerwick, B.C., Jr., *Construction of Prestressed Concrete Structures*, John Wiley & Sons, New York, 1996. With permission.)

As stated in Section 11.2.3, development, testing, and approval of special mixture designs take time and therefore should be initiated as early as possible. Extensive treatment of this subject is given in Chapter 2.

11.4.6 Lightweight Concrete

Prestressed lightweight concrete has a substantial history of very satisfactory performance in highly demanding structures, including bridge girders (Figure 11.13) and offshore structures. In several important cases, beneficial properties other than light weight have been the rationale for selection. These properties include:

- Durability
- Insulation
- Fire resistance
- In conjunction with silica fume, enhanced fatigue resistance

Structural lightweight concrete has often been selected to reduce the inertial mass of structures in seismic regions and to reduce draft of floating structures. The performance of lightweight concrete is highly dependent on the specific aggregates selected, which in turn depends on the raw materials (clay or shale), the manufacturing process, and the temperature and duration at which they are fired in the kiln. Unfortunately, because of the previous widespread use of low-quality, lightweight aggregates for less-demanding applications, such as fireproofing, and because of the wide range of properties covering lightweight aggregates, most current codes require increased allowances for creep and shrinkage. It should be noted, however, that careful selection of the highest quality lightweight aggregates and the use of some natural sand can keep creep and shrinkage within the same ranges as with natural stone aggregates. Some properties of these high-quality lightweight concretes are inherently less than those of hard-rock (conventional) concrete of the same strength; these include modulus of elasticity, shear strength, and tensile strength. High-performance lightweight concrete has a unit weight of only 75 to 80% of conventional hard-rock concrete; however, compressive strengths of up to 62 MPa (9000 psi) can be obtained by the use of natural sand for the fine aggregate and the addition of microsilica. Microsilica is especially beneficial to lightweight concrete because it chemically bonds with aggregate particles which in turn gives better fatigue endurance under cyclic loads.

11.4.7 Modified-Density Concrete

By using natural sand to replace the lightweight fine aggregate in part or whole and using 50 to 60% of hard-rock coarse aggregate (by volume), a concrete having about 85 to 90% of the density of all-hard-rock concrete can be produced that has almost the same properties, including modulus, shear, and tensile strength as the comparable all-hard-rock concrete. This mixture has been used on a number of offshore structures where weight was critical for draft and stability.

11.4.8 Composite Construction

Composite steel–concrete construction is widely used for high-speed-railroad bridges in Germany, as well as for major bridges elsewhere. Composite construction has also been proposed for offshore structures where the membrane characteristic of the steel plate and its two-dimensional tensile reinforcement properties can be combined with the shell action of the concrete to resist concentrated forces. Connectors used to ensure shear transfer have included welded studs, shear rings, and special shear ribs. Prestressing has been suggested as a potentially synergistic way in which to utilize composite properties, as the steel is kept from local buckling if it is properly anchored to the concrete. The shear on the connectors that is created by the prestressing must be considered. The tendons must be located with consideration of the various moduli of elasticity. Composite construction using half-depth precast prestressed slabs and beams with structural concrete topping has been widely utilized for floor slabs of buildings and for decks of short-span bridges. Shear transfer may be accomplished by the roughened concrete surface alone in the case of light live loads or by means of reinforcing ties. Cleanliness of the surfaces and proper preparation (e.g., saturated or surface damp) are important to ensure bond. The constructor must ensure that the specified degree of roughness of the lower slab or beam is attained. Steel ties are very effective. Typically, the precast member is longitudinally pretensioned. Conventional reinforcing in the topping slab is used to distribute forces transversely and to provide live-load continuity, although in certain instances, especially bridge and wharf decks, the composite system has also been post-tensioned transversely. The designer of such a transversely post-tensioned structure must have adequately considered the effects of differences in moduli and the inherent eccentricity of two orthogonal layouts of tendons. In areas where significant eccentricity is unavoidable, use of steel ties will prevent delamination.

11.4.9 Architectural Prestressed Concrete

Many applications of prestressed concrete have a criterion for architectural and esthetic appearance. Prestressing can be used to help attain the criterion by preventing cracking. One- and two-way prestressing has been utilized for this purpose (Figure 11.14). Care must be taken that neither the ends of pretensioned strands nor the anchorages of post-tensioned tendons can rust and stain the surface. Pretensioned strands can be cut back by a small flame torch or by a welding rod and then plugged with latex cement mortar or a light colored epoxy mortar. Post-tensioned anchors should be recessed and later filled with concrete or mortar. In some cases, epoxy mortar is used. These plugs should be tied to the parent concrete by steel ties; otherwise, cracks may occur around the plugs and allow corrosion products to leach out. Alternatively, in some architectural applications, the architect has elected to emphasize the anchorage, in which case, heavy galvanizing or epoxy coating has been pre-applied.

Some architectural panels incorporate ceramic tiles as facing elements with a backing of concrete. Prestressing locks the ceramics in place and prevents cracking, which otherwise might reflect through the face. Great care must be taken in locating the tendons to offset the difference in modulus of the facing from that of the backing. Some architectural treatments of concrete involve processes that are corrosive to prestressing steel. Acid washing or etching is especially dangerous as residue may remain in ducts and recesses. Joints between segments require special attention if they are to be blended into the overall members. Any epoxy residue must be removed. Use of white cement as part of the mortar mix will help to prevent discoloration, as patches tend to be darker than the surrounding concrete. Steam curing may adversely affect colored concrete; condensation may drip onto colored concrete and leave unsightly marks.

FIGURE 11.14 Two-way pretensioned concrete wall units serve both structural and architectural purposes in the construction of new university building.

Microsilica or antibleed admixtures can be used to prevent unsightly bleed holes. Fly ash or microsilica can be used to prevent efflorescence. These can also be used to reduce permeability and thus minimize the unsightly fungus growth that occurs in semitropical and humid environments.

11.5 Post-Tensioning Technology

11.5.1 Principles

With post-tensioning, the concrete sections are cast first with all conventional passive reinforcement, then, after the concrete has gained sufficient strength, tendons are placed, usually through holes formed by ducts. These tendons are stressed so as to react against the concrete and precompress it. The concrete must be free to shorten under the precompression. The tendons are then anchored, and corrosion protection, such as grout or grease, is installed. There are many variations on the above procedures, of which the most common and important are described here.

11.5.2 Storage of Tendons and Anchorages

Tendons and anchorages are high-strength steel, accurately made to very close tolerances. As such, they are subject to corrosion in storage or, even more insidious, to contamination that will lead to hidden long-term corrosion. Tendons and anchorages should be stored in a covered area, fully protected from the weather and raised off the ground. Some specifications require that the storage facility be dehumidified.

FIGURE 11.15 U-duct is specially fabricated to hold vertical tendons in webs of bridge girders. (Photograph courtesy of VSL Corporation, Campbell, CA.)

Usually, heat is applied to keep the relative humidity well below 50%. In some countries, including the United States and Canada, open storage is acceptable, provided the material is up off the ground and dry. Among the many cases of corrosion of tendons due to inadequate storage are the following:

- Tendons were stored in mud adjacent to a roadway on which salt was applied to prevent icing.
- Tendons were stored on a beach and subject to immersion at high tide.

11.5.3 Installation of Ducts and Anchorage Bearing Plates

Ducts, whether of steel strip or plastic, must be carefully placed to true profile and rigidly held so as not to be displaced during concreting. Their location and alignment determine the position of the tendons that are later installed. Ducts must be kept free from dents and flattening; otherwise, they will not permit the free installation of the tendons. Dents, bulges, and burred ends must not be allowed to occur during the subsequent placing of reinforcement, and care must be taken in the use of the vibrator when consolidating the concrete. Preferably, ducts should be supported on saddles of plastic or steel, rather than bearing directly on the reinforcing steel, which may dent the duct when the load of fresh concrete impinges on it. It is particularly difficult to align ducts accurately across splices. A temporary internal mandrel may be used to ensure proper alignment across splices. Sleeves, overlapping at least two diameters on each end, should be sealed with heat-shrink tape. Screw fittings can be used on ducts comprised of pipe. Although waterproof tape and epoxy have been used to seal overlapping sleeves, tests and experience have shown that these are not as reliable as the heat-shrink tape. The duct cross-section should be about twice the gross cross-section of the tendons and should allow 6-mm (1/4-in.) clearance all around to permit proper encasement in grout. The preferred anchorage for post-tensioning tendons is a recess pocket formed in the end of the concrete member. This is boxed out with forms attached to the end form.

When the duct is placed, the trumpet and bearing plate are attached by screws and sealed to prevent mortar inflow. This rigid attachment serves to ensure that the bearing plate is truly normal to the design tendon axis. Vent tubes and grout tubes must be properly affixed to the duct and taped securely to prevent rupture or leakage. Vents are installed at the high points of upward-curving tendons or at about 20-m intervals on near-horizontal ducts. A tube is also installed at each end just behind the bearing plate to act as an inlet when injecting grout and as a vent at the far end. Drains are used at low points in the tendon profile. They should be used at the bottom of U-ducts installed vertically, such as, for example, in the webs of girders (Figure 11.15 and Figure 11.16). The drain tube may also function as an intermediate grout tube. For the primary prestressing of major structures, such as bridge girders, provision of at least one extra longitudinal duct on each side will facilitate corrective action in case of excessive creep or blockage of a duct. Ducts should preferably be delivered to the job site with plastic covers already fitted. If not, covers should be fitted during installation to keep foreign material, including rain, from entering the duct.

11.5.4 Installing and Stressing Tendons

Groups of steel strands and bundles of steel wires can be preassembled with a nose-piece attached. A pull-wire is fed through the duct; one means to feed it through the duct is to blow it by compressed air acting on a rubber ball. A line is attached to the ball which can then be used to pull in the pull wire. The nose-piece is often a Chinese finger grip of spirally wound wire. The bundle is then pulled through the duct. It is usually more efficient, however, to push strands through one at a time, using a pushing feeder of mechanically driven rolls. The end of the strand is fused together by a torch so the individual wires do not separate. Water-soluble oil is brushed onto the strand as it enters the duct. When all of the strands have been pushed through the duct and through holes in the anchorages, they are pulled to a nominal tension by a single-strand jack and temporarily wedged. This ensures that all strands are of the same length. See Figure 11.17 for a graphic representations of the sequence. A multistrand jack is then fitted so as to extend the tendons to their designed stressing level, which is usually about 72% of the ultimate strength. The wedges are hydraulically pushed home (Figure 11.18). When there is considerable curvature in the tendon, the tendon is stressed from both ends. Cycling it by pulling from first one jack and then the other reduces frictional loss. Final stress in the tendon should match theoretical elongation, using calculations based on the modulus of elasticity as furnished by the manufacturer. The modulus varies with the lay of the strand. Allowable tolerance is usually set at 5%. Where this value is exceeded, the cause should be determined. It may be excessive friction, in which case adding water-soluble oil and cycling can help, or the cause may be in the assumed modulus. These data are recorded for each tendon. After the jack is removed, the ends should now be protected from rain and spray by a covering of polyethylene or similar material.

11.5.5 Scaffolding and Falsework for Post-Tensioned Cast-in-Place Construction

A great many building and bridge structures are constructed on scaffolding and falsework. After the cast-in-place concrete has gained strength, the structure is post-tensioned. This prestressing redistributes the dead loads, typically raising the span off of the central scaffolding and transferring it to the end supports.

FIGURE 11.17 Sequence for stressing post-tensioning tendon. (Photograph courtesy of VSL Corporation, Campbell, CA.)

FIGURE 11.18 The stressing operation. (Photograph courtesy of VSL Corporation, Campbell, CA.)

In the typical case, this redistribution and induced camber are beneficial to the construction process, making it easier to remove the scaffolding; however, the constructor must ensure that any temporary supports at the reaction points are capable of taking the increased dead load and lateral forces imposed on them. Prestressing also shortens the span. If one end is on neoprene bearing pads it will be free to move. The intermediate scaffolding will be distorted by the shortening but is usually able to accommodate this because of its height and flexibility; however, this should be verified in each case. If the ends are fixed, then the act of prestressing pulls the supports toward each other. The stiffer support will take most of the force and in turn will counter the prestressing, reducing its efficacy. Because of creep, the problem gets more severe as time goes on. This situation has unfortunately arisen on a substantial number of building projects where the effects were not adequately foreseen, resulting in spalling at the edges of bearing seats and, in at least one case, splitting of a stiff column. If a permanent connection must be made at both ends, and the supports do not have adequate flexibility to accommodate the shortening with only small opposing force, then it is best to temporarily place one end on a neoprene pad or sliding bearing, then fix it after the elastic shortening and early creep have taken place. Of course, long-term creep may still cause problems, but its magnitude will be less. Neoprene strips should be used at the edges of the bearing surface to allow minor rotation and to minimize the tendency to spall.

11.5.6 Corrosion Protection of Tendons

The standard method of providing corrosion protection of tendons is by injection of cement grout. If properly done, this encapsulates the strands and penetrates between the wires of the strands. In the case of ducts no larger than two times the gross area of the tendon, cement and water are the principal components of the grout. Sand or other fines are incorporated only in the rare cases of very large ducts. Water-reducing admixtures are necessary for corrosion protection. Fly ash may be used to replace up to 20% of the cement. Thixotropic admixtures are very valuable in reducing bleed, which leads to voids at high spots in the profile. Thixotropic grouts require a positive-displacement pump for injection. Special grouting admixtures have proven very successful for promoting full filling of ducts and preventing bleed pockets. Expansive admixtures, such as aluminum powder have been used but have sometimes created problems with excessive pressure and with the control of expansion. A thixotropic antibleed admixture is believed to be more effective.

The grout should be injected from one end. The first grout ejected from a vent is dark due to the water-soluble oil. Grout should be wasted until the ejected material has the same color and consistency as the grout to be injected. When the grout ejected from the first vent is deemed satisfactory, that vent is closed. When the end vent is discharging satisfactory grout, that vent is closed. This forces the grout through the tendon anchorages and seals the strands at these critical locations.

Vertical ducts present a special problem in that the strands act as wicks, promoting bleed. Use of a thixotropic admixture helps but is not always 100% effective. One solution is to have an extra hole in the top anchorage plate, through which a tube leads to a small tank above. This tank or receptacle is filled during grouting; the grout then can feed down to fill the duct as the column of grout subsides. Silica fume, as an admixture, also reduces bleed; however, the combination of silica fume and thixotropic or anti-washout admixture is frequently too viscous for effective injection. The anchorage pockets then must be completed. Preferably, small-sized bars have been placed that can be bent down into the pocket. The anchorage pockets should be filled with a fine concrete—that is, one made with small-size coarse aggregate, say 8 to 10 mm (pea gravel)—and a mix rich in cement. Silica fume may be added to minimize bleed. Frequently, the surface of the anchor and the pocket is coated with bonding epoxy. In other cases, latex-modified concrete is used to improve bond.

Shrinkage should be prevented by using the window-box technique, in which the concrete is filled to an elevation higher than the pocket, so if bleed occurs the grout will feed down into the space. Any excess concrete can be easily chipped off after a day or so. The joint around the pocket may be painted with an epoxy that has high capillarity and can be sucked into any shrinkage crack.

VSL External Post-Tensioning System Components

FIGURE 11.19 External tendons. (Photograph courtesy of VSL Corporation, Campbell, CA.)

In a number of cases, especially nuclear reactor containments, the tendons and the anchorages are encapsulated in grease instead of cement grout. The grease is injected in much the same manner as grout and periodically examined; also, where necessary, additional grease is injected. This technology is now giving way to an advanced system in which each strand of the tendon is sheathed in polyethylene and grease is injected so the strand is free to move within the sheath. This protection is very positive. A cluster of such sheathed strands is fed into a duct. They are then stressed and the duct is grouted or grease is injected, thus achieving a multiple protection system. The critical zone in such a system is at the anchorage, where the strands must be bared for the wedges to grip them. Caps with grease or grout fittings are provided that screw onto the anchorage so they too may be injected after stressing.

11.5.7 External Tendons

The term *external tendons* is used to describe post-tensioning tendons that are not directly incorporated into ducts in the concrete. Usually, these tendons are placed inside the box of a trapezoidal box girder, but they may also be outside. External tendons are unbonded. They are anchored at blisters or bolsters, usually near the ends of the member, and may be deviated at intermediate points along the profile. The tendons are typically encased in a heavy polyethylene sheath. At deviation points, a steel sleeve may be used to prevent the tendon from cutting into the polyethylene. The polyethylene sheath may be continued through the steel sleeve. The steel sleeve is preformed to the design radius. It should have belled ends to prevent stress concentrations (Figure 11.19). Large radial forces at the deviators must be resisted by proper reinforcing details. Deviators must be adequately anchored to the webs or flanges. One problem frequently encountered with external tendons is the failure to leave enough space at the anchorages in which to place a large multistrand jack on the prescribed angle. This must be considered in the working drawings.

11.6 Pretensioning Technology

11.6.1 General

Pretensioning denotes the process by which tensioned high-strength steel wires or strands are incorporated in a concrete segment. The process is relatively simple in concept, economical, and technically efficient; however, it requires a major plant facility that is able to temporarily restrain the forces in the tensioned

FIGURE 11.20 Stretching strands down pretensioning bed.

tendons until the concrete cast around them has gained sufficient strength to effectively bond the tendons and transfer their force to the concrete. The process lends itself to prefabrication—that is, precasting. Most precast pretensioned concrete is produced in permanent plants; however, for large projects, especially in remote areas, contractors have found it practical to set up job-site plants. Although the process is adaptable to a wide range of shapes and configurations, economy favors the use of standardized members fabricated on a repetitive process with a fixed cycle. The principal standardized members produced are piles, bridge girders, building floor slabs, roof slabs, wall panels, railroad ties (sleepers), and poles. Nonstandardized but repetitive segments that lend themselves to pretensioning include stadium seats.

11.6.2 Description of Process

In its simplest form, the pretensioning facility consists of a casting slab or bed on which the segments will be fabricated, reaction frames or stands at the end to temporarily resist the tendon forces, hydraulic jacks for tensioning, tarpaulins or hoods to cover the segments during curing, and lifting equipment to remove the completed segments for storage and shipment.

11.6.3 Tendon Installation and Stressing

The tendons most commonly employed are seven-wire strands with a nominal diameter of 15 mm (0.6 in.), an ultimate tensile strength of 1900 MPa (270,000 psi), and a 0.2% offset yield strength, which is 80% of ultimate. These strands are spaced apart to develop bond for stress transfer and are arranged in appropriate patterns to develop the design compressive stress in the concrete cross-section. Multi-wedge strand anchors are used to temporarily grip the ends of each strand so the jacks can impart the desired force and elongation. Both single-strand and multistrand jacks are used. After the strands are properly stretched, they are anchored to the stands at each end of the bed (Figure 11.20 and Figure 11.21). When

FIGURE 11.21 Fully extended jacks impart prestress to pretensioning strands. (From Gerwick, B.C., Jr., *Construction of Prestressed Concrete Structures*, John Wiley & Sons, New York, 1996. With permission.)

strands are stretched with a multiple jack, very large forces are stored. To prevent serious accidents, nuts should be progressively run up on the extension arms of the jack to limit travel in the event of a loss of hydraulic pressure. The achievement of the proper prestress can be determined both by gauge pressure readings of calibrated jacks and by the elongation. Most specifications require that these deviate not more than 5%. Variations are caused by difference in moduli of the strands or by frictional restraint at the ends and intermediate supports. It is important to keep foreign materials such as oil and grease off of the strands. Welding should never be permitted on or near the tendons as it will destroy the special properties that have been induced by cold drawing of the wires. Unstressed reinforcing steel can usually be most easily placed after the strands are tensioned. The entire reinforcing assembly can then be held in proper position by tying it to the strands or by using plastic chairs and dobie block or by hanging it from overhead spreader bars with plastic wires.

11.6.4 Forms

The forms for concrete segments are typically made of steel. Because the forms are standardized members, they minimize the effort and time required to set them in place and subsequently strip them. For some configurations, the forms may be fixed and tapered so the segment can be removed without moving the forms. For other shapes, mechanical means may be used to close and open the forms. The end gates of the forms are especially critical, as they must allow the strands, and perhaps some reinforcing bars, to pass through without leakage; hence, they may have to be made up in small pieces. Rubber gaskets can be used to seal around the strands and at the sides. For some products, such as piles, it is important that the head be normal, or square, to the longitudinal axis. This can best be achieved by making the end gates up in pairs, spread apart and rigidly held in a frame.

11.6.5 Concreting

The concrete mix is designed to gain strength rapidly so the tendons may be released, transferring their force into the concrete; the segment is then removed to storage. The strength required for release is controlled by two factors: (1) adequate bond strength to limit the transfer length at the ends of the member, and (2) adequate strength to minimize the creep under sustained stress. Typical release strengths

FIGURE 11.22 Concreting and finishing operations.

range from 20 to 30 MPa (3000 to 4300 psi). Concreting follows normal practices of placement (Figure 11.22). External vibrators are often used; they may be moved progressively to brackets on the steel form or permanently mounted on them. They produce excellent consolidation and drive water and air bubbles from the outer exterior 100 to 150 mm (4 to 6 in.) of concrete thickness. For members thicker than about 200 mm (8 in.), internal vibration is also required, even with so-called flowing concrete; otherwise, in densely reinforced and congested zones, such as the end blocks of girders and the heads and tips of piles, honeycomb and rock pockets may occur.

11.6.6 Curing

To gain strength rapidly, accelerated curing is usually applied, which provides heat and moisture. Most commonly, such curing will consist of low-pressure steam. Ideally, adequate strength will be gained in 8 to 12 hours, enabling a daily cycle of production. Forms must be free when the tendons are released, as the concrete will shorten. If the forms are locked to the concrete (for example, by a change in the cross-section), then they also will be forced to shorten. A variety of means are used to prevent damage to the forms. Safe removal can be effected by lifting, sliding, or hinging. If tapered and smooth, of constant cross-section, and sufficiently rugged, then the concrete member may partially slide in the form. Multiple short forms may be designed to slide on the bed.

11.6.7 Release of Prestress

After curing is complete, the tendons are released from the stands, transferring force into the concrete. The concrete shortens under compressive stress. To ensure behavior as a prestressed concrete member, the shortening must not be restrained. In practice, when heavy segments are cast, the friction between the segment and the soffit of the forms may restrict the shortening. In many cases, this problem may be overcome by initially lifting one end of the segment before the other, thus allowing the member to shorten and become prestressed before the full load is realized. Any discontinuity in the cross-section, whether inherent in the design or accidental, such as a fin due to leakage from the forms, may prevent shortening. At this early stage the concrete segment is subject to drying shrinkage and thermal shrinkage, so cracks may occur. Also, steel forms expand under steam or heat curing more rapidly than concrete, forcing a crack. To prevent cracks at changes in cross-section, soft neoprene or rubber gaskets may be installed to

accommodate the dimensional changes. Covering and insulation of the surfaces after curing will postpone drying and thermal shrinkage strains until the concrete has more tensile strength.

Release of the prestensioning into the segments is preferably accomplished by use of a hydraulic jack. This requires reinstalling the jack, exerting a slight additional pull to loosen the wedges, then slowly backing down on the force, allowing the strands to slacken. Even then the friction of heavy concrete segments on the bed or in the forms may prevent their movement and prevent release of prestress into the individual segments. The release then is accomplished by burning the strands. This should be done in a balanced pattern, using low heat (yellow flame) and then cutting with the blue flame. The intention is to reduce the stress gradually. A sudden shock release increases the development length over which the prestress force is transferred to the concrete.

Over this transfer length, particularly near the ends of the segment, the prestress compression is not uniform over the concrete cross-section. Tension develops between strands and especially between groups of strands. Orthogonal reinforcement, in the form of short bars or mesh, is often needed at the ends to prevent splitting cracks. Although this supplemental reinforcement should be part of the design, in practice it is often left up to the fabricator and thus must be considered when preparing shop drawings for fabrication.

11.6.8 Cycle

The typical cycle in precast prestensioned fabrication is as follows:

- 4:00 a.m. Terminate steam-curing cycle.
- 5:00 a.m. Remove test cylinders from under the tarpaulins for testing; replace tarpaulins.
- 6:00 a.m. Test cylinders, and verify that the required release strength has been obtained.
- 6:30 a.m. Remove tarpaulins.
- 7:00 a.m. Detension tendons, and cut strands between segments.
- 8:00 a.m. Lift products out to storage, and store on timber sleepers at correct points to minimize deflection due to creep.
- 8:30 a.m. Clean forms.
- 9:00 a.m. Stretch new strand tendons the length of the bed.
- 10:00 a.m. Equalize lengths with single-strand jack.
- 10:30 a.m. Stress strands.
- 11:00 a.m. Place reinforcing steel, and place end stops or gates.
- 1:00 p.m. Place concrete, consolidate, and finish.
- 2:00 p.m. Cover progressively to prevent premature drying out.
- 6:00 p.m. Turn on low-pressure steam, raising temperature 1°C every 2 minutes to 60°C (140°F). Hold temperature constant until 4 a.m.

Obviously, times and operations have to be adjusted to fit individual products and reinforcing steel patterns.

11.6.9 Tendon Profile

The efficient design of many segments, such as slabs, beams, and girders, requires that the profile of the tendons follow a path other than a straight line. This means that the strands must be deflected. Deflection has been accomplished in a number of ingenious ways. One such way is described in the following. Strands are initially stressed to a precalculated reduced stress. They are then pulled down or up at specific points, forcing the strands into a series of chords approximating the design path (Figure 11.23). This, of course, raises the stress in the strands to near the desired value. The jack then brings the stress to the design level. By this method, frictional losses and variations of stresses between segments are minimized. Another method is to pull the tendons over a series of rollers, set at selected deviation points; unfortunately, the frictional losses with this method are cumulative and result in unequal tendon stresses in the several segments.

FIGURE 11.23 Deflecting pretensioned strands with special hold-down devices. (Photograph courtesy of Ben C. Gerwick, Inc., San Francisco, CA.)

The hardware at the deviation points can be likened to the arrow in a stretched bow; thus, they are points of danger to personnel during placement of reinforcement and subsequent concreting until the concrete has at least reached final set. These points should be clearly marked with red paint on the tops of the forms, and all personnel must be kept clear. This is especially important for the vibrator operator.

The release of a member made with deflected strands requires special consideration. If the deflected strands are released first, the pull-down devices hold the segment tightly against the casting bed, preventing shortening and effective transfer of prestress. Conversely, if the deviation points are released first, the resulting upward force in an unstressed member could break it. For this reason, the first method is used—that is, first releasing the longitudinal strands and then releasing the pull-downs at the deviation points. In some advanced installations, provisions have been incorporated to allow limited longitudinal movement at the deviation points.

11.7 Prestressed Concrete Buildings

11.7.1 General

Buildings represent perhaps the largest overall use of prestressed concrete and certainly the most diversified use of precast pretensioned concrete segments. Standardized modular configurations have been extensively employed for roof slabs, floor panels, beams, and wall panels. Cast-in-place post-tensioned concrete has been widely used for floor slabs, especially of lift-slab construction and for heavy beams and girders. Post-tensioning permits the full integration of slabs, beams, and girders. Similar monolithic construction is attained with precast pretensioned construction by jointing and cast-in-place infill and topping. Because the construction process differs significantly between the two processes, they are treated separately in the following sections; however, the two systems may be combined in any particular building.

11.7.2 Precast Pretensioned Concrete

The most widely employed precast concrete segment is the double-tee (Figure 11.24). It is used for roof slabs and wall panels. In combination with cast-in-place topping, double-tees are used for floor slabs. Widths are modular; in the United States, this means either 4 or 8 ft (1.22 or 2.44 m).

FIGURE 11.24 Double-tee precast, pretensioned concrete slab. (From Gerwick, B.C., Jr., *Construction of Prestressed Concrete Structures*, John Wiley & Sons, New York, 1996. With permission.)

11.7.2.1 Manufacture

The precast segments are cast in steel forms with tapered legs. The taper plus the slight flexibility of the steel forms permit the segments to be lifted out, or stripped, without adjustment to the forms. Inserts can be placed in the bottom of the legs to reduce their depth for shorter spans. Straight strands are employed for short spans, and deflected strands are employed for longer and more heavily loaded spans. Because the typical deflecting forces are low, much less than with bridge girders, the system of pushing up at the ends while holding down at the middle or third points is commonly employed. Shear reinforcement may be in the form of bent reinforcing bars or welded wire mesh. A few widely spaced strands may be run in the top slab to prevent shrinkage cracking. Transverse bars or diagonal bars will provide cross-slab reinforcement and can anchor embedments for connection between flanges of adjacent slabs. Where topping is to be placed for composite behavior, the top surface is roughened with a transverse broom finish. When double-tee segments are employed for walkways and small bridges, the legs are usually wider and deeper to accommodate the necessary strands and shear reinforcement. For longer spans, single tees with deeper and thicker stems are used (Figure 11.25). Another form of slab, the hollow-core slab (Figure 11.26), is made by several proprietary processes, resulting in a flat top and bottom with multiple longitudinal holes. Both lightweight and conventional concrete are used in manufacture. For lightweight concrete, the replacement of part or all of the fines with natural sand will reduce problems of creep and shrinkage.

11.7.2.2 Erection

Precast segments are typically transported by truck and erected by a large truck crane with extended outriggers. Proper procedures and safety practices must be followed to ensure safe and efficient operations. The Prestressed Concrete Institute has published a manual, *Erection Safety for Precast and Prestressed Concrete* (PCI, 1995), that includes sections on the following important aspects:

- Preplanning of the erection
- Site conditions
- Cranes
- Equipment
- Rigging

FIGURE 11.25 Single-tee slab for longer spans.

FIGURE 11.26 Hollow-core floor slabs.

- Tools
- Unloading
- Lifting
- Fall protection
- Setting/connecting/releasing

Preplanning of the erection is proving especially valuable to contractors, who use it to determine access for cranes and trucks, the swing of the crane and segment in three-dimensional space, and the sequence of erection and means for accurate positioning. Temporary bracing and staying may be required. Marking the exact seats of segments beforehand saves valuable time in the final positioning. Connecting or jointing details are quite critical. Tolerances must be considered, both relative to adjacent segments and cumulative. Details of embedment of strands or reinforcing or welding and bolting have proved to be very important, especially when the structures are subjected to dynamic loads such as earthquake, hurricane, and tornado.

FIGURE 11.27 Erecting a tapered double-tee floor slab in circular parking garage.

Large truck cranes with outriggers are the most commonly used means of erection (Figure 11.27). It is essential that the outriggers be properly supported by timber mats or the equivalent to prevent settlement during the swing of the load. Care must be taken to ensure that neither the boom nor the rigging swing into already erected elements. Adequate room must be available for the counterweight during swing. Tower cranes are also employed; the weight of the units determines their capacity and reach.

Because of the large number of relatively light segments that are typically erected in a building, attention must be given to the detailing and construction of the lifting inserts. These must be compatible with the hooks and slings employed by the rigger, and they must be properly anchored into the member to resist inclined as well as vertical forces. Local pullout can cause a serious accident. Adequate factors of safety must be provided to take care of the dynamic amplification of lifting and minor accidental lateral impact.

When a cast-in-place concrete topping slab is placed on top of precast pretensioned slabs, the latter often require temporary shoring to sustain the dead load of the fresh concrete without excessive deflection (Figure 11.28). This shoring is typically made tight and the grade adjusted by the use of either wedges or screw jacks. These must be set in such a manner that they do not become loose or tip while the top concrete is being placed. The shores react against a lower slab, which may have been placed only a week before, in which case the topping may not have adequate strength. Serious progressive collapses have occurred when the shoring has not been carried far enough or was not strong enough to carry the accumulated loads. Other serious collapses have occurred when the shoring was removed too early. The in-place strength of concrete should be ascertained by companion cylinders stored alongside or through nondestructive testing (e.g., Schmidt hammer). Particular care must be taken during winter when low temperatures delay the strength gain.

Creep must be considered by both the designer and erector, as lengths and camber will change with time. For that reason, it is desirable to let the precast segments mature a reasonable length of time before erection (e.g., 1 to 3 months). Rigid welded connections at both ends are to be avoided. Bearing slabs must be of adequate length and adequately reinforced. Neoprene bearing pads will allow minor rotation and shortening. Shear at the ends of slabs becomes increasingly critical with time due to the tensile stresses induced by creep and the increase in the transfer length of pretensioned strands with time. The erector needs to consider this when preparing the shop drawings.

Camber is affected by a number of factors, including eccentricities of prestressing, the modulus of elasticity of the concrete, creep, differential temperature from top side to bottom, and differential moisture. The cumulative effect of these factors and of various tolerances may create difficulties, especially in

FIGURE 11.28 All precast, pretensioned building of the Marin County Civic Center in California nears completion.

thin, highly stressed slabs such as those most often employed in roofs. These difficulties may in turn cause problems in waterproofing. In extreme cases, loss of camber may lead to ponding of rainwater, which in turn increases downward deflection and ponding of more water, leading to progressive collapse. The camber of adjacent segments may not fully match. Adjacent sections usually can be pulled to match with minimal force, provided the differences in camber and the stiffness of the members are not too great. Where excessive force is required, typically more than 100 kg (220 lb), the design engineer should be consulted. Excessive camber may be reduced by tensioning of embedded polyethylene-sheathed and greased strands installed for this contingency.

11.7.3 Cast-in-Place Post-Tensioned Buildings

Both bonded and unbonded tendons are employed for cast-in-place post-tensioned buildings. Unbonded tendons are extensively used in flat slabs, both lift slabs and cast-in-place slabs. The advent of polyethylene-sheathed and greased strands has made this process reliable and durable. The details of this type of construction are presented in Chapter 10 and Chapter 12. Conventional post-tensioning in ducts, with subsequent encasement of the strands in grout, is typically employed for deep beams and girders. In parking garages, this method is often employed for the ramp (Figure 11.29). For lift-slab construction and wherever precast columns are used, post-tensioning through the columns is desirable to ensure shear friction transfer from the slab, so as to offset subsequent shrinkage. A key detail in post-tensioned building construction is the protection of anchorages to prevent moisture in leakage and to safeguard against fire. Both conventional and polyethylene-sheathed tendons have bare strands through anchorage zones; thus, this is the most vulnerable area for potential corrosion. Recessed anchorages, filled with concrete and tied to the structural slab, are the most reliable.

11.8 Prestressed Concrete Bridges

11.8.1 General

Prestressed concrete has been quite successfully used in the field of bridges, ranging from low- to medium-span precast pretensioned bridges to post-tensioned girder spans 250 m (820 ft) in length and, beyond that, to cable-stayed concrete bridges 600 m (2000 ft) long (which are a derivative form of post-tensioning).

FIGURE 11.29 Cast-in-place concrete floor slab will be post-tensioned in both directions. (Photograph courtesy of VSL Corporation, Campbell, CA.)

Prestressed concrete bridges are now used worldwide in remote developing countries as well as in the urban centers of highly developed countries. Prestressing has proven very versatile in its application and can be used to solve many complex problems of curvature and skewness. It has become the standard by which alternative materials and systems are measured. This success, however, has not come without some problems. Some of these are common to all reinforced concrete—for example, the corrosion of steel in bridge decks on which salts are applied to prevent icing. Many of the problems peculiar to prestressing are due to the widespread adoption of this new technology, sometimes without proper attention to details of design and workmanship. Although in most cases these problems were resolved on the site, they have proven costly and cause delays to the constructor. Fortunately, most problems are now in the past, in that we understand their causes and have adequate solutions available.

11.8.2 Precast Pretensioned Bridge Girders

The precast, pretensioned I-beam girder is widely used for trestle-type bridges, viaducts, and overcrossings (Figure 11.30). This element has proven to be adaptable to mass production, with resultant economies and reductions in cost. The girders are manufactured on long-line pretensioning beds, with deflected strands as described in Section 11.6. They are then transported, principally by truck and dolly, so the support is within 1 m (3 ft) of each end. Long and deep-webbed girders are hog-rodged to prevent buckling during transport.

Girders must be positively restrained against tipping. At this stage, there is no additional dead load from the slab acting; hence, the girder stresses are usually within safe limits only when they are near vertical. If tipped too far, they may fail explosively due to overcompression in the top flange. Blocking and chaining are used to prevent tipping. (Note that wire rope stretches under sustained and repeated loads, so chains or structural members are the only safe means for providing restraint.)

The girders are usually erected by crane. When one crane is used, slings leading at 45° to the horizontal or more (60° is preferable) are employed. This limits the height to which the girders can be lifted. These slings develop a horizontal thrust due to their angle, which may overload the compression flange of the girder, especially because of the low buckling resistance of the girder in the y - y (transverse) direction. To overcome this problem, a spreader beam with vertical slings from the girder to the beam is often used (Figure 11.31). The axial compression of the spreader is then utilized to resist that imposed by the inclined slings. A pipe strut is usually used for the spreader beam, but trusses are employed for very long girders.

FIGURE 11.30 Precast, prestensioned I-girder for high-level bridge across the Napa River in California.

FIGURE 11.31 Erecting precast girder using trussed spreader beam. (From Gerwick, B.C., Jr., *Construction of Prestressed Concrete Structures*, John Wiley & Sons, New York, 1996. With permission.)

The process of lifting and setting precast girders is a demanding one due to the dynamic forces caused by inertia and swinging, as well as to long and high lifts. Most erection is carried out by crawler and truck cranes; the latter use their outriggers for stability.

The picking inserts in the girders must be properly anchored deep into a compressive zone and must be capable of taking the force at an angle. Slings must be properly designed to meet the amplified load due to angle. Both must be adequate for the dynamics of inertia force and acceleration. The latter is especially critical when floating equipment is used for lifting due to the potential dynamic motion of the barge hull. The rules of crane and rigging safety must be carefully followed.

When bridge girders are erected, they are initially vulnerable to tipping. Tipping may be caused by girders being set on a superelevation, by wind, or by contact with a line from a second girder while it is being lifted. For this reason, long and deep I-beam girders should be braced as soon as they are set. Cast-in-place decks are designed to act compositely with the precast girders. To ensure full transfer of horizontal and vertical shear across the joint, the top flange of the precast girder is roughened and multiple stirrups are employed to tie the girder and deck together. Transverse diaphragms are cast between the end blocks of the girders and sometimes at intermediate locations, although the latter have proven to be less prevalent than was necessary in the early years of this new technology. Experience and tests have shown that the deck slab provides adequate transfer in most cases.

Girders are usually set on neoprene bearing pads. To facilitate accurate and rapid setting, it is helpful to mark a line on the pad for the planned ends of the girder, so no further measurements in either direction need to be made. The cantilever suspended span concept has been used to extend the span of precast prestressed girders. The two side spans are continued over the main piers and are haunched and prestressed for negative moment. Either pretensioning or post-tensioning may be used to provide the required moment capacity. The suspended span, designed for simple span behavior, is then installed. At the interim stage, when the side spans are set but do not have the relieving load of the suspended span, they may be overstressed by the prestressing. This can be countered by the addition of mild steel reinforcement at the bottom of the haunch or by the use of temporary counter prestress.

In the typical bridge, the deck acts as the compressive flange, while the web transmits the shear to the bottom flange. The bottom flange has to have enough prestress to resist both superimposed dead load and design live loads. The top flange has to be large enough to accommodate the tendons necessary to sustain the dead-load compression. In longer girders, this frequently results in temporary excessive precompression in the bottom flange. Enlarging the bottom flange results in a *bulb tee*, which has the desired stress characteristics at all stages and provides the necessary room for the prestressing tendons. Other cross-sectional shapes have been employed for shorter span bridges. These include the double-tee and the triple-tee, or M shape. The typical double-tee used in buildings has a rather narrow web, which may not provide adequate cover for durability or adequate strength for shear. Special forms with a wider web may be used.

Precast prestressed slabs are also employed for short spans and have the advantage of minimum depth and a flat underside. For slightly longer spans, hollow cores may be formed to reduce weight. These slabs may also have a cast-in-place composite topping. To temporarily support the load of fresh concrete, the precast member may require shoring at its midspan or third points.

11.8.3 Post-Tensioned Girders, Cast-in-Place on Falsework

This is a widespread application of prestressed concrete. Falsework shoring is set up, is adequately supported on the ground (or on the new foundations or on piling), and is capable of resisting the dead load of the concrete with minimal deflection. Provision should be made to offset the calculated deflection, whether it be elastic bending of falsework beams or elastoplastic deformations of the ground support. It is important that the shores be adequately braced for both transverse and longitudinal movement during casting of the concrete (Figure 11.32) and subsequent stressing.

For continuous structures, the concrete is usually cast in progression from the center of the span to each end, so as to reach its deflected profile prior to casting the concrete over the piers, thus preventing cracking in the negative moment zone. As the cast-in-place sections are prepared, the ducts are placed to the required profile and alignment. At vertical construction joints, the sections are spliced. Because splices and construction joints are a principal source of problems that occurred in the early years of this technology, attention must be paid to the details, as described in Section 11.3.4. This includes accurate prolongation of the profile across the joint (e.g., by the use of mandrels), the application of heat-shrink tape to the ends of splice sleeves, and proper preparation of the construction joint surfaces (Figure 11.33).

In the negative moment zone, over the piers, the design often calls for several ducts with their tendons lined up one above the other in groups of two, three, or more. Space between these ducts may be very

FIGURE 11.32 Structural steel falsework supports high-level cast-in-place post-tensioned bridge (Ma Wan Viaduct, Hong Kong).

FIGURE 11.33 Draping ducts for cast-in-place post-tensioned bridge (I-205 north approach, Columbia River Bridge between Washington and Oregon). (From Gerwick, B.C., Jr., *Construction of Prestressed Concrete Structures*, John Wiley & Sons, New York, 1996. With permission.)

limited, so the potential exists for an upper duct to pull through into the one below. To prevent this, small reinforcing bar hairpins may be placed transversely, between each pair of ducts. In extreme cases, the lower tendon must be stressed first and grouted, then the second tendon is stressed and grouted, and so on. It generally proves economical and practicable to space the tendons so the shear strength (in double shear) of the concrete and the dowel effect of the transverse bar are adequate to resist the radial component of the tendon force.

As cautioned in Section 11.4.9, the design of supporting falsework must consider not only the stage when the concrete is cast, and hence imposes its dead load on the supports, but also the stage when the prestressing force has transferred the dead load, distributing it with concentrated forces under the zones of concave curvature downward while relieving the load on the zones of convex curvature.

The cumulative effect of shortening between joints of multispan continuous girders must be considered. Intermediate supports must be able to accept the curvature imposed by this shortening or, better, be temporarily freed from it by temporary devices that allow the girders to move the short increment of prestress deformation. Stressing from each end will minimize the actual movements over the intermediate piers. Some very important bridges of moderate span have been cast-in-place and post-tensioned with temporary support on a steel deck truss. When the span is post-tensioned, it rises up off the truss so it is independently supported directly on the piers. The truss can now be slid forward past the pier to the adjacent pier and the process repeated for the adjacent span. This results in a series of simple spans that can subsequently be made continuous for live load by post-tensioning for negative moment over the supports. To facilitate the sliding of the truss from one span to the next, the pier must have an appropriate configuration, such as a division into two shafts between which the truss slides or the provision of steps on the outside of the piers on which individual trusses may be slid forward.

Transverse post-tensioning of the deck is increasingly employed, especially for box girders with cantilevered deck flanges. Because space is limited, ducts must be kept small. Rectangular ducts encasing four side-by-side strands are frequently employed. Tendons may have a dead-end anchorage in the concrete at one end and a stressing anchorage in a pocket at the other end. To provide additional corrosion protection, plastic ducts may be used. In other cases, plastic-sheathed and greased strands are employed with special care being taken to protect the anchorages.

The primary longitudinal post-tensioning tendons are located in the upper flange in the negative moment region near the piers. This means that the transverse tendons should go over them above the webs and under them near the transverse centerline. This is a three-dimensional problem of location, and some eccentricity is unavoidable. To prevent delamination, hairpin dowels at 600-mm (24-in.) spacing may suffice.

11.8.4 Post-Tensioned Precast Segmental Bridges

The concept here is that short segments of the full cross-section of the bridge are cast in a prefabrication site or casting yard. These segments are then transported to the site and erected on falsework or on a truss, as described in the previous section. The segments are then jointed and post-tensioned. Because the segments are cast as relatively small, discrete units, it is possible to obtain close tolerances for reinforcing and duct placement, as well as for finished concrete dimensions. The ability to obtain high-strength and high-performance concrete is enhanced. At the same time, segments are kept to a reasonable size for transport and erection. After erection, segments are carefully aligned to the correct profile; thus, dead-load deflection is taken care of prior to stressing.

Joints may be constructed by a variety of means. Cast-in-place joints, typically 500 to 1500 mm (1.6 to 5 ft) in width, can be constructed in which the reinforcing steel is made continuous by lap splices, welded splices, or couplers. Ducts can be readily spliced by sleeves and sealed by heat-shrink tape. Thin grouted joints, typically 75 mm (3 in.) in thickness, were used in the past but have not proven to be successful because of difficulty with duct continuity.

Vertical joints usually require shear keys. In the past, trapezoidal keys were widely used, but experience has shown them to be subject to diagonal cracking at the corners. Installing a short diagonal bar across the potential crack is one solution. More recently, curved shear keys, corrugated on a large pitch, have been used for both cast-in-place and precast concrete segments.

Dry joints have been used for many bridges in which the precast concrete deck girder segments have been match cast. Match casting consists of constructing each successive segment with its trailing edge cast against the leading edge of the preceding segment (Figure 11.34 and Figure 11.35); thus, a perfect fit is ensured. Ducts are extended from the first segment to the second by use of a mandrel.

FIGURE 11.34 Precast concrete segments are match-cast in elevated cells to facilitate their alignment and movement.

FIGURE 11.35 Precast match-cast segment for viaduct in Riyadh, Saudi Arabia. Note shear keys and anchor blocks (blisters). (Photograph courtesy of CCC Group, Athens, Greece.)

Some problems with fit have occurred with match casting when steam curing has been employed. The segments tend to warp in unequal fashion with the heat. To prevent this, it is best to steam cure the first and second segments together, prior to separation. A bond breaker must be used on the common joint surface. After separation, a light sand blasting, wire brushing, or water-jet blasting can be employed to clean the mating surface.

With dry joints, a thin O-ring seal can be placed in a recess around each duct to seal against grout leakage and cross-over of grout between ducts. Alternatively, thorough swabbing of the duct may suffice but the results need to be verified. Dry or match-cast joints have been greatly improved by the use of epoxy glue on the mating surfaces. Typically, during erection, the second segment of the joint is raised. It is positioned by the use of two mating dowels, either cast in the segment or temporarily affixed to the top. After verifying proper fit, the segments are moved apart and epoxy glue is applied with a gloved

FIGURE 11.36 Cast-in-place cantilever segmental construction for the I-205 Columbia River Bridge.

hand. Because epoxy is incompatible with free moisture, the surface must be protected from rain, etc. during this process. The second segment is again pulled into contact with the first and a temporary precompression is applied by stressing bars at the top, bottom, and both sides. The precompression on the concrete surface of the joint should be 0.3 MPa (44 psi). The epoxy sets under the applied pressure. Many such matings have been successfully made using only epoxy glue to seal the ducts at the joint; however, use of a thin O-ring gasket is believed to be a conservative and justified step to prevent inadvertent blockages in later grouting.

Assembly of complete and multiple spans has been successfully carried out both by erection on falsework and by lifting up a completed span with one or two crane barges. In some instances, the full span, less the two pier-head segments, has been assembled, jointed, and prestressed on a barge, then lifted up from the preset pier heads. Prestressing such an assembly on a barge requires the consideration of the extreme loads imposed on the barge deck at the girder ends due to the post-tensioning. Additional posting or support of the deck may be required.

11.8.5 Cast-in-Place Cantilever Segmental Bridge Construction

This process has been successfully employed on spans up to 200 m (660 ft) and more (Figure 11.36). With cable-stayed concrete segmental bridges that employ the external tendon principle, much longer spans—500 m (1600 ft) and longer—have been attained. The concept is to cast two segments, one on each side of a pier. The casting is followed by prestressing the segments over the pier to resist the negative moment in cantilever. Two more segments can then be cast and post-tensioned, and so on. Each stage must be carefully analyzed to ensure adequate prestressing for the dead load of that segment plus the forms and the weight of the next segment during its casting. Because it is generally not feasible to cast two segments simultaneously, one on each side of the pier, the pier shaft must be adequately reinforced to withstand, out of balance, the temporary bending that is induced. These cantilevered decks are typically extended to near midspan. After a waiting period, to allow as much of the creep as practical to take place, the two extended arms are locked together and a closure pour is made.

At the initial stage of this process, a pier-cap segment is first constructed which is temporarily locked by vertical post-tensioned bars to the pier shaft. A small skid derrick is then erected on the pier-cap segment. The derrick lifts up a prefabricated form for the first cantilevered segment. Reinforcing steel and ducts are placed and the segment concreted. The concrete mix is designed to attain adequate strength

for prestressing within 1 to 3 days. This segment is then post-tensioned to the pier cap segment, and the skid derrick is moved out onto it and temporarily bolted to the deck. This leaves room on the pier cap to install a second small skid derrick headed in the other direction. It now raises the forms and constructs and stresses its cantilevered segment. Now the process can proceed in parallel on each arm of the deck. A typical cycle requires 4 to 7 days for each pair of segments. In many designs for continuous bridges, a hinge is required near the quarter point. To permit the cantilever segmental process to continue past the hinge, it is temporarily locked with removable post-tensioning bars. In other designs, a hinge is placed at midspan. To prevent undesirable movements as heavy live loads cross the hinge, complex devices that transfer shear but no moment are installed.

The cantilever segmental process is very demanding for the contractor; accurate and thorough quality control are essential. Prestressing ducts must be accurately placed to close tolerances and rigidly held in position so as not to be displaced during subsequent concreting and vibrating. At the ends of each segment, the ducts are held in exact location by the end bulkhead of the form. To ensure that the profile of a duct is continuous across the joint, without a small, sharp bend, a pipe mandrel should be inserted which can be extended into the duct in the next segment when it is formed. Pipe mandrels also serve the secondary purpose of ensuring that the duct remains clear and open when adjacent tendons are grouted. Each time a form is extended from the preceding segment, it is purposely set sufficiently high at its leading end to counter the deflection under the weight of the fresh concrete. Concrete placement should proceed from the outer end back toward the previously completed segment.

Segments are typically very congested by conventional reinforcement in three directions and longitudinal and transverse post-tensioning tendons. Near the piers, vertical post-tensioning tendons are often installed as well. This congestion makes concreting difficult. Fortunately, the use of high-range, water-reducing admixtures (superplasticizers) makes obtaining a very workable mix feasible while still achieving high early strength and high long-term strength.

Because of the congestion in the deck near the pier, the horizontal section through the middle of the top deck may have a greatly diminished concrete section; the area is largely occupied by closely spaced longitudinal and transverse ducts. Thus, horizontal shear transfer across this section is diminished and may result in laminar cracking due to the unavoidable eccentricities in the prestressing centroid in the two directions. This problem has been successfully prevented in a number of cases by provision of small-diameter hairpin stirrups in the deck at a nominal spacing of about 0.6 m (24 in.) in each direction. Whereas laminar cracking should be considered for design, it should also be considered by the contractor because laminar cracking is not readily apparent at early ages and repairs are very difficult, usually requiring stitch bolting. Creep and shrinkage, as well as elastic deformations, affect the profile of the completed bridge; thus, it is necessary to take accurate readings at the same time each day, preferably early in the morning before the heat of the sun distorts the structure. This allows corrections to be calculated by the engineer and implemented on the next segment.

In lieu of the temporary support of forms by a small skid derrick or overhead frame, a gantry may be used, extending over at least 1-1/2 spans. This gantry is moved forward after the two cantilever arms are completed on one pier. When its leading edge reaches the next pier, temporary supports are placed, allowing the gantry to move forward one half span farther. The rear end of the gantry, now over the first pier, is locked to it by post-tensioning bars. The gantry can now support the forms and the fresh concrete of the cantilever segments as they are constructed.

Earlier, the installation of near-vertical tendons in the webs was mentioned. These tendons resist the high shear forces near the piers. Frequently, these are installed in U-shaped ducts, with the two anchors in the deck slab. During construction, these ducts must be covered to prevent rain and curing water from entering as well as to protect them from being clogged by debris. Even soda bottles have been found wedged in the U at duct bottoms! Grouting of these vertical ducts must employ the special procedures discussed in Section 11.5 to ensure complete filling of the duct.

Continuity tendons are installed after the closure has been completed. They are designed to provide positive moment capacity over the mid-portion of the span. Typically, their anchorages are in bolsters (blisters) on the webs or bottom flange and the tendons are installed in the bottom flange. Anchorage

FIGURE 11.37 Erecting precast match-cast segment in cantilever construction.

bolsters should be staggered in balanced pairs, with adequate longitudinal spacing and reinforcing to distribute the tensile strains behind them. Proper reinforcing details are also required to resist the pullout forces of the sharp curvature at these anchorages.

11.8.6 Precast Cantilevered Segmental Construction

In this type of construction, the segments are prefabricated in a casting yard, using the match-cast process. They may be cast as individual segments (short-line-process) that are subsequently placed against their partner for concreting or by the long-line method, where the entire girder is cast with segments separated by a bond breaker. Care is taken to ensure the correct positioning of the longitudinal ducts and their extension into the next segment through the use of pipe mandrels (Figure 11.37). The erection process in the field may proceed in a manner similar to that described for cast-in-place segments. In this case, the skid derricks or frames must lift a segment that is positioned directly underneath and raise it into position. Epoxy glue is then applied to the faces of the segments. The tendons are then installed and stressed. The process is inherently very rapid, in that a pair of segments can be completed each day. In some cases, using multiple shifts, two pairs of segments have been completed per day.

The gantry scheme of erection is especially well adapted for this concept. The precast segments can be transported along the completed deck, oriented at right angles to their final position. They can be lifted by the rear end of the gantry and run forward to their final location, where they are turned 90° for erection. Usually, a longer gantry is used, extending over 2-1/2 or even 3 spans. This enables the work to proceed further ahead while previous spans are being post-tensioned and grouted and closures are being effected. If the gantry has adequate capacity, several segments may be suspended from it, thus minimizing the amount of post-tensioning required. If the gantry is of adequate length and strength so it can support the entire double cantilever midspan to midspan, then the required post-tensioning will be reduced to that required for the permanent structure. Because the segments are precast and the concrete has attained greater maturity, the creep and shrinkage are reduced. Nevertheless, the profile and alignment have to be checked daily. Minor corrections can be made as needed by the insertion of wire mesh shims. Alternatively, corrections may be accomplished by additional post-tensioning. A few more strands may be inserted in an existing duct, compact strands may be used, or an additional tendon may be placed in a spare duct.

One significant disadvantage of precast segmental construction is the lack of mild steel reinforcement across the joints, which would minimize crack width under ultimate load conditions as well as improve

stress distribution. This is especially needed at the ends of transversely cantilevered deck flanges, where shear lag may reduce the effective prestress. The latter problem can be resolved by including a high-strength bar in the end of each flange that is stressed at each segment. Couplers can be used to extend the bar from one segment to the next.

Perhaps the best means of providing the desired monolithic behavior and ductility is to include additional ducts, spaced out over the contact surfaces where no primary tendons cross, and to install unstressed strands and grout them so as to provide a nominal steel area across the joint, which is adequate to ensure that if the joint does open the steel, both stressed and passive, is not elongated beyond yield strain. Another method is to provide mild steel dowels in slots or holes across each joint that are subsequently grouted.

11.8.7 Incremental Launching

The incremental launching method is suitable for straight bridges (on a tangent) and for bridges of a constant circular alignment and superelevation; unfortunately, it is unsuitable in its current state of development for constructing spirals. The bridge may be on a straight-line profile or a constant vertical curve. With this process, all work is carried out from one end, in a job-site facility. A segment, typically 6 m (20 ft) long, is cast to its full cross-section. A second segment is then cast immediately behind and post-tensioned to the first. Both segments are seated on bearing plates of stainless steel that slide on Teflon® with a friction coefficient of 0.03 to 0.05. Large hydraulic jacks are installed below the first segments and arranged so they can pull the two segments forward.

As each succeeding segment is cast, it is post-tensioned to the preceding assemblage, and they are pulled forward as a group. Obviously, because the leading segments overhang the abutment, they must be counterbalanced by the segments still at the casting site. A trussed steel nose extension is attached to the leading segment. When the nose reaches the next pier, it is guided onto Teflon® and stainless-steel bearings. The nose is slightly tapered so it can engage the sliding bearings. Despite the elastic downward deflection, the nose raises the bridge to grade as it progressively slides past the second pier. Side guides should be provided at each pier bearing to prevent the bridge from creeping laterally. This is especially important when the bridge is superelevated or on a curved alignment. Because all work is carried out at one location, it is feasible to provide an enclosure so work can be carried out regardless of weather conditions.

Stage post-tensioning is critical to this method. During launching, because the girders are alternating between positive and negative moment, the post-tensioning must be more or less concentric. For the final service condition, after the bridge is in final position, the centroid of prestress must be raised over the piers and deflected downward over the central portion. To physically accomplish this, several methods have been employed. Through the use of external tendons located inside the box of a box girder, the tendons are jacked to their required profile, then secured to the webs with stirrups and concreted in place. This requires an accurate computation of the increase in the stress due to deflection. The process is conceptually similar to the deflection of pretensioned strands. Additional prestressing tendons with exaggerated profile are added to move the centroid of the total prestress to the desired location. These additional tendons can be internal tendons (i.e., in preplaced ducts) or external tendons inside the central opening of the box girder.

11.8.8 Lift-In and Float-In Erection

Lift-in and float-in erection are processes in which the span is **preassembled** and post-tensioned, either on a barge or on shore, then transported to the specific site and positioned beneath the piers. For the lift-in process, heavy lift jacks can be placed on the pier caps so as to raise the complete span. When the span is to be erected one girder at a time, the lifts may be made by skid derricks on top or by floating cranes below. On overland projects, the bridge span may be constructed at ground level and then raised by lift jacks to the pier tops, then a cast-in-place closure is constructed. This closure should incorporate

FIGURE 11.38 Full-width, full-length bridge span for the Great Belt Western Bridge in Denmark is prefabricated on land.

FIGURE 11.39 Erecting one of the 124 spans of the Great Belt Western Bridge in Denmark; each is 100 m long and weighs 7000 t.

a shear key or keys. The lifted-in span is connected to the pier caps by post-tensioning through the pier cap. Float-in spans are similar, except that in this case, the tide plus ballasting or deballasting may be used to place the span onto the pier caps. This concept is most suitable for low-level bridges and trestles. Float-in may also be used with a large crane on a catamaran-type barge (see Figure 11.39). The crane picks the girder, and the barge then moves to straddle the pier. The crane then lowers the girder onto its bearing. This process has been used for very large spans over 100 m in length and up to 8000 t in weight (Figure 11.38 through Figure 11.41).

FIGURE 11.40 Construction of one of the five bridges of the King Fahd Causeway connecting Bahrain to Saudi Arabia.

FIGURE 11.41 Prestressed concrete girders being erected at Prince Edward Island Bridge in eastern Canada.

11.8.9 External Tendons for Bridges

This relatively new technology was introduced in Section 11.5.7. External tendons are located outside the concrete cross-section of the bridge girder, although they may be inside the box of a box girder. External tendons may constitute the entire primary post-tensioning or a portion of the total, the remainder being internal, grouted tendons. The external tendons are anchored at or near the ends in typical recessed pockets. The tendons themselves are multistrand cables encased in a polyethylene sheath. At several locations along the span, either at third or quarter points, the tendons are deviated to the correct profile by structural concrete deviators—that is, partial diaphragms anchored to the webs. Because the forces on these deviators are concentrated, the deviators must be heavily reinforced themselves as must their ties to the concrete webs.

The bending at the deviator must be over a curve of substantial radius to minimize the normal bearing stress on the strands that acts concurrently with the axial elongation changes under varying live load. A steel sleeve with belled ends is used, which is pre-bent to the required radius. The polyethylene duct may be spliced to the steel section or run through this sleeve. Steps to minimize cutting of the plastic when pulling in the strands must be taken. These include pulling as a bundle with protective nose piece, pulling slowly, and use of a thicker plastic duct. The strands are grouted in the duct. The duct is usually left free in the steel sleeve.

One of the advantages of using external tendons in bridges is the ability to remove and replace one or two tendons at a time. This is feasible only if the anchorages are accessible for removal and subsequent replacement and restressing. Anchorages may have screwed-on, grease-filled caps. Although such replacement is frequently a design criterion for bridges that will be treated with salts in the winter to prevent icing, and therefore exposed to a very corrosive environment, the protection afforded by polyethylene sleeves and caps plus grout is believed to be essentially permanent. The use of external tendons has also been applied to concrete truss spans, in which the truss members can be used as the deviators. In this case, because the tendons are exposed to daylight, the polyethylene should be pigmented to minimize ultraviolet degradation of the polyethylene.

11.9 Prestressed Concrete Piling

11.9.1 General

Prestressed concrete piling are used on a very large scale as bearing piles for building foundations, as bridge superstructures, and as support for wharves and quays and tanks and towers. They have been used for offshore terminals and for fender piles and sheet piles for quays and bridge piers (Figure 11.42, Figure 11.43, and Figure 11.44). Piles up to 600 mm (24 in.) in cross-section and, occasionally, to 800 mm (36 in.) are typically pretensioned, using standard pretensioning practices as described in Section 11.6. Further specifics for manufacture of piles will be given later in this section. Cylinder piles, 800 to 1650 mm (36 to 66 in.) in diameter have been produced both by pretensioning and by post-tensioning, the latter again using standard post-tensioning processes. Fender piles and sheet piles are usually pretensioned. Sheet piles may incorporate sheathed and greased tendons arranged in a vertical profile to suit the final service conditions. They are stressed from the top only after the sheet pile is at final grade.

11.9.2 Durability of Piles

Piling for most land foundations, such as for the support buildings, are generally fully embedded in a benign environment of soil below the water table with little oxygen; hence, corrosion of steel has not been a problem. Exceptions may arise when piles are driven through garbage dumps or highly corrosive soils. For piling that extends above the permanent water table, durability must be considered. At sites up to 70 km (42 miles) from the sea and especially in arid zones, chlorides pose a threat to the steel. Corrosion has occurred in serious amounts in the Middle East for piles in both water and land foundations. Preventing corrosion of prestressing steels and conventional reinforcing in marine environments requires

FIGURE 11.42 Prestressed concrete cylinder pile for pier of Napa River Bridge in California. (From Gerwick, B.C., Jr., *Construction of Prestressed Concrete Structures*, John Wiley & Sons, New York, 1996. With permission.)

FIGURE 11.43 Spreading spirals along tensioned strands of prestressed concrete piling.

a dense, highly impermeable mix of at least 350 kg/m^3 (600 lbs/yd^3) of cement containing at least 5 to 10% C3A, with a low water/cementitious materials ratio, preferably less than 0.43. Fly ash may be used to replace 15 to 20% of the cement. In marine installations subject to freezing, the problems of freeze-thaw

FIGURE 11.44 Placing inserts for lifting piles in pretensioned concrete piles.

attack may be especially severe. High tide and waves saturate the concrete, while low air temperatures cause the concrete to freeze during low tide. Some sections of the pile may see two cycles of freeze–thaw a day throughout the depth of winter. Substantial air entrainment is required, with the proper spacing factor and specific surface, as shown by petrographic analysis of hardened specimens or cores. Coatings other than those that breathe water vapor can be counterproductive, as the moisture migrates to the cold face and is trapped behind the impermeable coating, where it then freezes, popping the cover off. Thus, high strength, high impermeability, minimum water absorption by aggregates, low water/cementitious materials ratios, and adequate air entrainment are all required for this environment.

11.9.3 Manufacture

The manufacture of pretensioned piling is a mass-production process, typically involving a small number of standardized cross-sections; hence, economy of production is of great importance. Forms may be double or quadruple so that two to four lines can be manufactured simultaneously. Preferably, the forms are designed so as to require minimal effort for setting and release. Flexible steel side panels may be held in position during concreting by intermittent straps across the top which are easily removed to lift out the hardened pile. Or, the side forms may be stiff enough to hold the fresh concrete without significant deflection yet be tapered so the member may be lifted out directly. A draft of 1 on 50 is usually adequate for steel forms of moderate stiffness. For hollow-core and cylinder piles, the two upper sloping surfaces may be formed by portable panels that clamp to the fixed form and use a neoprene gasket between (Figure 11.45). Alternatively, the upper sloping forms may be hinged.

The internal voids of hollow-core and cylinder piles have been formed in many ways. All of the methods used face the problem of keeping the void form accurately centered so it will not float up when the concrete is vibrated. One method that has proven capable of consistently producing high-quality cylinder piles is to use an internal steel form that is collapsible. A form segment is typically half the length of a pile, so after lift-out of the completed pile each half-length segment may be retracted.

In a typical manufacturing sequence, the internal void forms are set up in the lower half of the fixed outer form and are then blocked up. Coiled spreading spirals of an appropriate amount are then set at the ends of the piles (Figure 11.43). The strands are pulled down the bed, through the coiled spiral but outside the inner void form. The strands are now properly spaced around the circle and tensioned with a single-strand jack. They may be fully tensioned to the desired value (70 to 75% of ultimate) or only

FIGURE 11.45 Closing up forms during manufacture of pretensioned cylinder piles.

FIGURE 11.46 View of end-gates separating piles during manufacture. Note heavy spiral to resist driving stresses as well as plastic hinging during earthquakes.

partially tensioned, with the remaining tension applied by a large jack. The spirals are then distributed to their correct spacing and tied to the strand as needed.

At appropriate stages, end forms (end gates) are set in place; these are usually fabricated in several segments. Rubber or plastic stops are used to seal against mortar leakage where the strands penetrate the end gates (Figure 11.46). The upper side forms are set in place and the pile is ready for concrete. In a properly designed pile, the spirals or hoops will be very closely spaced at the head and tip. Additional longitudinal bars or tubes may also be inserted at the pile head. The head and tip are zones where the highest concrete quality is essential, so vibration must be thorough. To permit this, the spirals may be bundled and a pencil vibrator used to penetrate between them.

After the piles in a line have been cast and cured, the upper forms are laid back, the strand tension is released, and the strands are cut between piles. This is an especially critical time for cylinder piles, as well as for all large piles, in that the upper surface of the pile is now exposed to both rapid drying

FIGURE 11.47 Pretensioned hollow-core piles in storage.

shrinkage and thermal shrinkage as the top cools off while the warm bottom half and inside is still protected by the forms. Application of membrane-curing compounds and blanketing the pile will prevent the longitudinal cracks that often occur, especially in winter and on windy days.

Cylinder piles are also manufactured by sliding a long internal mandrel along the bed to form the void. The mandrel may be coated so it slides with minimal friction. The rate of progress is matched by the stiffening of the concrete to prevent slumping of the top as the tail end of the mandrel passes. Internal heat has been used to accelerate the rate of stiffening. During the main part of the mandrel slide or slip, the cement paste from the concrete will lubricate the mandrel, but at the beginning it is necessary to coat the mandrel with fluid paste or at least to wet it. Particular attention has to be given to the ends of the piles to prevent the drag of the mandrel from causing cracks or spalls. Slumping of the top and displacement of the strands will cause eccentricity in the cross-section and even delamination, which may then lead to breakage or spalling during driving, as well as reduce the performance of the piles under lateral loads. The bottom strands must be supported in such a way as to maintain their cover. Also, cylinder piles are manufactured by the assembly of short concrete pipe segments. Jointing can be by epoxy or by a 200-mm-wide cast-in-place joint. The pile is then tensioned by running strands through preformed holes, and the tendons are grouted. This process has been used for cylinder piles from 1 m to 3.5 m in diameter.

Piles are lifted from the forms by one of several means. Except in the splash and tidal zone of marine piles (and to a lesser extent the submerged zone), lifting inserts or bundled loops of strand may be used (Figure 11.44). Lifting inserts must be adequately embedded in the pile. Spacing of these inserts may be designed to minimize negative bending moments. Because these negative moments peak at the lifting points and the load is augmented by friction in the forms for large and heavy piles, short lengths of mild-steel bars may be incorporated in the top of the pile.

Where inserts are not permitted, a thin band may be preplaced in the forms, enabling the pile to be raised a short distance by a jacking frame so it can be progressively blocked about 50 mm (2 in.) above the soffit. A lifting wire rope choker can then be inserted so slings from an overhead gantry or crane can lift the pile clear. Piles should be blocked at the same picking points while they are in storage to prevent development of a sweep due to creep. While in storage, the projecting ends of the strands, especially those at the pile head, should be burnt back into the concrete (Figure 11.47). A daub of epoxy mortar may be applied if desired. During load-out and transport, piles should be supported so they do not develop a net tension in the concrete (Figure 11.48). For truck transport, the dynamic amplification must be considered, especially for the overhanging ends.

FIGURE 11.48 Loading heavy prestressed cylinder piles on barge by rolling.

FIGURE 11.49 Pretensioned hollow-core piles driven to support new pier in San Francisco Bay.

11.9.4 Pile Installation

Although one of the primary benefits of prestressing for piles is that they can be driven in a wide range of soil conditions and achieve the required penetrations, even though this requires prolonged hard driving, a number of very specific steps can be taken to prevent pile damage or breakage. Lofting the pile (that is, lifting it from the horizontal to the vertical) typically requires two or more lifting points (Figure 11.49). The slings or lines to these points will typically be at an angle, and this angle will vary during the lift. This means that the vertical components of the force in the lines will be different; thus, the situation differs from that in the manufacturing yard where all lifting forces are normal to the pile. Fortunately, it turns out that in most cases the maximum moments in the pile occur during initial lofting, so the calculation of angles and resultant moments and stresses is relatively

FIGURE 11.50 Lifting prestressed concrete pile into position for driving.

simple. A dynamic amplification factor should be applied to the dead load of the pile. For very long piles, the moments and stresses should be checked through the several stages of lofting from horizontal to vertical.

Most cases of damage to prestressed concrete piles occur during the initial and early phases of driving. This is a consequence of the fact that the tension capacity of the pile is limited to the sum of the precompression due to prestress and the tensile strength of the concrete; the latter is less than 10% of the compressive strength. High tensile stresses during driving are due to a rebound wave of the pile hammer blow from the pile tip in soft driving, when the tip has little or no resistance. Consider the following three typical cases. First consider a pile driven by a diesel hammer (Figure 11.50). Initially, the pile tip is in soft clay or mud. To start the diesel hammer, it has to be raised to almost full stroke, typically about 2-1/2 m (8 ft). Thereafter, in soft driving, the diesel hammer automatically delivers soft blows, but that first blow at full stroke is the one that cracks the pile. The tensile rebound wave is greater than the tension capacity of the pile. This cracking may or may not be noticed, so driving continues. Eventually, the pile encounters hard driving, and the hammer delivers maximum compressive stresses across the cracks. This leads to local crushing at the crack and eventually to fatigue of the strands. Finally, the pile plunges, obviously broken somewhere below ground. Typically, the hard driving is blamed, but the initial damage was done on the first blow (Figure 11.51).

A second case arises when the pile is driven through compacted soil that overlies softer materials such as mud. The pile is subjected to hard driving when in the compacted soils. Then it suddenly breaks through and plunges 3 m (10 ft) or more. The single hammer blow, with little tip resistance, is what has caused the cracking. A somewhat similar situation arises when the pile is required to penetrate a

FIGURE 11.51 Driving long prestressed concrete piling for major naval facility in Puget Sound, Washington.

hard stratum. The contractor employs jetting to reduce the end bearing. Prolonged jetting erodes a hole. The pile drives through with relative ease due to the low tip resistance. In this case, the tension is exacerbated by the fact that the pile is gripped by skin friction along its sides while there is essentially no resistance at the tip, so the compressive wave from the hammer blow is literally driving the end off. In all of these cases, the actual breakage may not occur until there is subsequent sustained hard driving. Prevention of damage due to tensile rebound stresses begins with placing a cushion block on top of the concrete pile. This block is contained within the driving head or helmet on which the pile hammer ram delivers its blow. The material and thickness of this pile cushion block is selected so as to attenuate the peak compressive force, which lasts only a few milliseconds during each blow. When properly selected, this cushion block can actually aid penetration by lengthening the period of application of compressive force while reducing its peak. The best material, after thousands of trials, has proven to be softwood, such as pine or spruce, laminated in multiple layers. To hold this softwood block together, plywood sheets may be nailed top and bottom and inserted in between every third or fourth lamination. The required thickness varies with the pile, the soil, and the hammer. Thicknesses of 150 to 350 mm (6 to 14 in.) are typical. The cushion block compresses during driving. Except when it breaks into pieces and falls out or catches fire and burns up, it is not necessary to replace the block during the driving of any one pile. Exceptions occur for piles in highly stratified ground, where soft soils lie below hard soils. A new cushion block should be used for each pile. Even if the cushion block appears undamaged, its attenuating compressibility has been greatly reduced. For the typical case of a diesel hammer driving a pile whose tip is in soft mud, the pile may be driven down to moderate tip resistance by using the diesel hammer as a drop hammer—that is, raising the ram half distance and dropping it to prevent the damage resulting from a high starting blow. For the second case, predrilling through the fill is indicated. In both cases, the pile may be pulled down through the soft soil by a line rigged to the hoist engine.

The third case is more complex, especially where penetration of the intermediate hard stratum proves difficult and requires extensive jetting. Steps that may be used are as follows:

- Increase prestress; however, this is costly and piles may have already been cast.
- Limit the jetting at the tip but increase the jetting higher up along the sides to reduce skin friction.
- Install a new, thick cushion block when driving through the hard stratum and before re-driving the pile.
- Prebore by jet or auger to break up the hard stratum.

Hundreds of thousands of prestressed concrete piles have been driven successfully without breakage, provided they had the required design and a suitable cushion block was used.

The design prestress should ensure that, if a crack does occur for any reason, the steel strand will not be stressed beyond yield. Cracking will occur when the residual prestress in the concrete (after losses that have occurred to that date) plus the effective tensile strength of the concrete exceed the yield strength of the strand. To prevent this requires an adequate area of steel strand plus any supplemental reinforcement.

Values of 5 MPa (725 psi) have been successfully used for hundreds of thousands of prestressed concrete piles driven in normal soils, where moderate to hard resistances were encountered throughout the driving cycle. Values of 7 to 8 MPa (1000 to 1160 psi) have been used for piles subject to potentially severe tensile rebound stresses; however, the calculated value is extremely sensitive to the assumed tensile strength of the concrete, which is progressively degraded by repeated hammer blows in soft soil. Prestress as high as 10 MPa (1450 psi) may be employed for sensitive conditions and piles with high importance, for instance, large-diameter cylinder piles.

Driving of a concrete pile produces high axial compression, which is additive to the prestress. The Poisson effect develops high transverse (circumferential) strain, typically about 0.22 that of the axial compression. Because this often exceeds the tensile strain capacity of the concrete, longitudinal cracks develop. These can be resisted by spirals or hoops. The matter is complicated by the cover, so the confining reinforcement has to bond to the concrete cover (e.g., through adhesion); thus, epoxy-coated spirals, if used, must have sand embedded in the epoxy.

To prevent the pile head from spalling, additional spiral confinement should be placed close to the head. This can be a circular hoop placed just beneath the chamfer at the corners of the head, perhaps 50 mm from the head, and of adequate diameter to extend to the sides, as cover is not normally a requirement at this location. The tip of the pile should be square, not pointed or wedge shaped, because these shapes tend to wedge the pile out of vertical and, in the case of batter piles, out of proper inclination. Extra spiral, similar to that for the pile head, will prevent local spalling when rip-rap or boulders may be encountered.

11.10 Tanks and Other Circular Structures

The first application of prestressing technology was circular tanks, for which circumferential wrapping with high-strength wire under tension was used to create precompression in the walls of the tank. Walls were cast in place using jump forms or slip forms. When cast-in-place walls are employed, concrete construction may be by slip forms. Flowing, self-consolidating concrete may be more readily placed, especially in thin, heavily-congested walls. Today, such walls are often made of precast concrete staves, set vertically and joined by grout infill or, with wider openings, concrete infill. The wires or strands are then wound under tension. These are then encased by mortar, usually applied pneumatically by a wet shotcrete process. Placing and tensioning of the wires are almost always performed by a specialist contractor using a proprietary process. Both black and galvanized wires are used. In this section, only those elements of work performed by the general contractor are discussed.

The circular wall is usually set on neoprene pads to permit inward deformation under prestressing and hence the development of a state of prestress in the concrete at the base. In seismic regions, special shear keys or restrainer strands connect the base slab and the walls. The details must be executed with great care, not only to ensure safety during earthquakes but also to ensure proper performance and leak

tightness under normal service conditions. When precast staves are used, they are erected to true position and verticality and temporarily supported by tilt-up braces. By marking the location of each stove or panel beforehand, minor errors in position will be minimized and prevented from accumulating.

Tanks may also be prestressed by internal post-tensioning. If the joints between panels are relatively wide, 200 mm or more, they may be treated like similar joints between bridge segments, with overlapping reinforcing and sleeving of ducts so that they may be internally post-tensioned. Anchorages are in blisters spaced at 120°, so each tendon covers 240° and alternate tendons overlap. Blisters must be adequately tied to the wall by stirrups to resist the radial stresses. Tendons are usually stressed from both ends to offset the friction due to curvature.

The joints between panels are filled with high-strength grout or concrete. This grouting is very critical as it must fill the complete joint with a high-strength material that will be able to withstand 70% or so of the ultimate strength of the wall panels, applied within a short period after grouting. The encasement with wet shotcrete is then applied, first by washing the wall with fresh water to remove any contaminants, such as wire-drawing lubricant or water-soluble oil, then by applying a flash coat of neat cement grout, and finally by placing several coats of shotcrete. Where the tanks are to be backfilled (i.e., buried tanks), a coating of epoxy asphalt is also applied. The long-term performance of shotcrete is determined by its impermeability and is dependent to a large degree on the expertise of the nozzle man, who must direct his spray at a slight angle so rebound is not entrapped.

A critical location in tank construction lies at the top of the wall, where any small crack, even a microcrack, between wall concrete and shotcrete can result in progressive corrosion due to moisture infiltration and freeze-thaw attack. This location should be covered by monolithic concrete or epoxy asphalt, as specified or approved by the design engineer. The walls of tanks that will contain sewage or organic materials, hot chemicals, etc. must be free from cracks such as those due to drying shrinkage or thermal strains. Coating the interior surface with a suitable polyurethane material, durable to the contained fluids and able to span minor cracks, should be considered. Where a circular structure such as a penstock is in contact with the soil, or backfilled, epoxy asphalt coatings may provide protection against contamination and penetration of salts from the soil. In freeze-thaw or deep-freeze environments, a special problem arises from the fact that the concrete is saturated and the freeze front will form in the middle of the wall. This can lead to delamination and the spalling of the exterior concrete. An internal coating or membrane appears to be essential.

Containments for nuclear power reactors and for high-temperature gas reactors are usually thick-walled structures with either internal post-tensioning or exterior wrapping. The construction of these structures is similar to that of tanks, but the walls are much thicker and of higher strength concrete, the reinforcing is much denser and more complex, and the post-tensioning ducts and anchorages are very thickly congested. A thin ductile steel liner or membrane must be attached. Because thermal strains in the thick concrete wall have to be minimized, the fresh concrete mix should be precooled using ice or liquid nitrogen, and walls should be protected or insulated after the forms are stripped.

Prestressed concrete tanks may be used as primary or secondary barriers for containment of cryogenic liquids such as liquefied petroleum gas and liquefied natural gas. These applications are highly specialized, especially in providing critical design details for base and roof connections adequate to accommodate the thermal shortening; hence, they require specialty contractors.

11.11 Prestressed Concrete Sleepers (Ties)

Sleepers are a mass-produced element made complex by the need to anchor prestress in a short length, to vary the prestress profile to match the moments, to affix the rail, and to develop adequate electrical resistivity (Figure 11.52). Pretensioned concrete sleepers have been used for the Amtrak from Boston to Richmond as well as on heavy-rail coal railroads in the Southwest and Metro systems nationwide. Their heavy weight is of benefit to anchor welded rail. They must be durable under conditions of freeze-thaw and saltwater dripping from refrigerated cars. Chemistry of the cement and concrete requires careful control because some problems have occurred when durability was not adequately considered. Microsilica

FIGURE 11.52 Pretensioned concrete sleepers (“ties”) being fabricated.

FIGURE 11.53 Offshore LNG Import Terminal under construction; it will be towed to the Adriatic and be seated as a gravity-based structure (GBS). (Photograph courtesy of Exxon-Mobil, Irving, TX.)

(silica fume) has been used to provide the necessary high strength, bond strength, and impermeability as well as electrical resistivity. To provide adequate bond, the lay of the strand may be shortened or deformations provided in the strand during manufacture. Any corrosion-protection oil must be soluble. Sleepers can also be manufactured by post-tensioning.

11.12 Prestressed Concrete Floating Structures

Concrete has been utilized for floating structures ever since World War I, initially prompted by war-time shortages of steel but subsequently used for reasons of economy and performance, the latter being primarily structures that do not require mobility. It especially lends itself to offsite prefabrication of bridge piers, offshore platforms, floating bridges, and, most recently, river navigation structures (Figure 11.53, Figure 11.54, Figure 11.55). Permanently floating concrete structures include barges for support of construction operations, floating breakwaters, floating oil storage, and floating marine terminals. The U.S. Navy is currently testing a half-scale floating pier module in San Diego Bay. The benefits of prestressing have been

FIGURE 11.54 Arco Sakti Ardjuna en route to Java Sea.

FIGURE 11.55 Temporary post-tensioned segment of the Oresund Tunnel exiting assembly basin. (Photograph courtesy of Oresundbro Konsortiet, Copenhagen, Denmark.)

the ability to resist the cyclic bending, shear, and torsional stresses in the hull due to the waves. Other benefits are the minimization of cracking, the resistance to fatigue, and the resistance to thermal strains. Prestressing is used to connect prefabricated elements and subassemblies. In recent years, renewed interest is being exhibited in mobile vessels, either towed or self-propelled. The main deterrent to such use has been the much greater weight compared to steel vessels. With the advent of high- and ultra-high-performance concretes and corrosion-resistant tendons and reinforced concrete, vessels can be constructed with thinner sections, hence less weight and smaller draft.

11.13 Prestressed Concrete Pavements

Prestressed concrete pavements have been used for major airport runways, taxiways, heavy industrial floors, container terminal yards, etc., especially where it is desirable to minimize irregularities and provide a truly level surface during service. Post-tensioning is usually employed and is centered in the concrete cross-section. Because the pavement is subject to water collection, major changes in temperature, etc., providing a crack-free structure is important. Cracks prior to stressing must be avoided by such means as precooling the mix, placing concrete at night, and covering the concrete for several days with ponding, wet burlap, or polyethylene. To permit shortening under prestress, the slab is usually placed on a bed of sand 50 mm (2 in.) thick that is covered by a polyethylene sheet. Splices in post-tensioning ducts and couplers in bar tendons are made at the longitudinal joints. These construction joints are an obvious location of leakage and subsequent corrosion and so must be made with great care. The edges of slabs tend to warp upward due to thermal strains. Many designs incorporate an edge beam so the weight of the concrete offsets the thermal strains and any design eccentricities in the centroid of prestressing.

11.14 Maintenance, Repair, and Strengthening of Existing Prestressed Concrete Structures

11.14.1 Maintenance

Although prestressed concrete structures, properly designed and constructed, have proven highly durable in a wide range of environments, in numerous cases corrosion has seriously damaged both the conventional reinforcing steel and the prestressing tendons. The most prevalent cases are the following:

- Decks of prestressed concrete bridges to which deicing salts have been applied during winter
- Decks of parking structures where tires have carried salts from the adjoining streets
- Piling and the underside of wharf decks of coastal marine structures in tidal and splash zones
- Unbonded tendons, wrapped in paper and bitumastic, in an area near the seacoast where chlorides are present in the fog
- Walls of graving docks that are intermittently flooded by seawater and then dewatered for extended periods of time

In the above microenvironments, chloride contamination is the principal cause of corrosion. Chloride ions penetrate the concrete to the reinforcing and prestressing steel and depassivate it. With the presence of water and the permeation of oxygen, electrochemical corrosion proceeds. Carbonation from CO₂ in the atmosphere can cause similar corrosion attacks but the penetration is slower and more easily prevented. Prevention of these attacks must be primarily focused on initial design and construction, where steps can be implemented to make the concrete more impermeable, to give adequate cover over the steel, and to limit cracking.

The lives of existing prestressed concrete structures that have not been significantly damaged may be prolonged by a rigorous maintenance program. The following program may serve as a checklist:

- Wash down concrete surfaces on which salt has been deposited by spray, accident, or intention.
- Periodically treat the surfaces with silane to render them relatively impermeable to water that contains chlorides.
- Seal static cracks with epoxy injection or coatings.
- Seal active cracks with flexible membranes, such as polyurethane, which have crack-spanning ability.
- Where feasible, reduce the relative humidity in enclosures to below 50%; this is applicable to such structures as seawater pump rooms.
- Apply penetrating corrosion inhibitors; these are a relatively new development that may work in special cases, particularly where the concrete can be dried so water in the pores does not impede penetration of the corrosion inhibitor.

FIGURE 11.56 Attaching plastic sleeve to repair damaged prestressed concrete pile.

- Where applicable, keep the structure flooded with water, even seawater, to maintain the concrete fully saturated. The oxygen content of seawater is only a few percent of the oxygen content in the atmosphere, and oxygen does not penetrate saturated concrete very rapidly. This applies to prestressed concrete penstocks, conduits, sewers, and piping, especially during the period between completion of construction and initiation of service.
- Repair and seal laminar cracks by stitch bolting and epoxy injection.
- Where freeze–thaw attack is eroding the cover of concrete over the reinforcement, provide insulation and coating or covering.
- Install a cathodic protection system, connected to both the reinforcing steel and the prestressing steel. This step is normally instituted after serious corrosion of the reinforcement or prestressing has developed but can be provided for by bonding of the steel and by installing studs for future electrical connection if needed.

11.14.2 Repairs

In many cases, serious damage to a prestressed concrete structure will have only penetrated to the conventional mild steel, causing delamination, spalling, and cracking; thus, conventional repairs can be instituted. These include removal of the damaged concrete, cleaning of existing rebar, replacement of badly corroded rebar, and patching with new concrete or mortar. The problem that often arises is that the new salt-free concrete becomes cathodic to the adjoining chloride-contaminated concrete, leading to accelerated corrosion at the periphery of the patch. Various techniques have been developed to prevent or minimize this process, such as fastening zinc bracelets to the ends of the rebar or coating of the bars by zinc silicate. For concrete piles that are suffering visible deterioration to the concrete cover in the tidal and splash zones, it is necessary to shut off further ingress of seawater with its dissolved ions of sulfate and chloride. Although coatings and jackets have been used in the past with marginal results, the current state of the art is encasement in a sleeve of high-density polyethylene (HDPE) with an inner wrap of felt impregnated with a petrolatum jelly that blocks all further inflow of seawater and air (see Figure 11.56). The following section primarily addresses the repair of those structures in which the prestressing tendons have become corroded.

Prior to undertaking repairs, the existing structure should be adequately shored. The shores must extend down to firm and adequate support. In cases where the damage is due to corrosion, after the structural situation is rectified cathodic protection may be applied to prevent further corrosion. In the case of exposed beams, new external tendons can be installed on each side. They are tied to the existing beam by drilled and grouted dowels and then encased in new concrete.

Bolting steel plates on the bottom and sides of existing beams or gluing on carbon-fiber sheets provides external strengthening sufficient to offset the loss of prestress. The structure then becomes essentially a reinforced concrete structure instead of a prestressed concrete structure. The current state of the art is to affix carbon-fiber strips by epoxy glue.

For temporary repairs to badly corroded structures, structural steel beams may be placed to provide additional support in critical areas. Wedging or shimming may be used to ensure contact and predeflect the steel. Cathodic protection or coatings may be applied for corrosion protection of the steel. Overlays of concrete with new tendons, such as polyethylene-encased and greased strands, may be used in certain cases. In cases where the damage to the tendons is localized, new short tendons, such as bars, may be placed in adjacent slots cut in the concrete, anchored at the ends, and stressed at the center by special center-pull jacks. Where tendons in a deck are corroded but the concrete is still sound, slots may be cut and new tendons installed, stressed, and encased in concrete one at a time. Existing tanks may be repaired by additional circumferential prestressing, followed by shotcrete to give corrosion protection to the new tendons. Righthand–lefthand threaded coupler sleeves may be used to splice the bars.

11.14.3 Strengthening Existing Structures

This is the arena where prestressing has a major role to play, as it is ideally adapted to providing greater strength and correcting unacceptable deflections. Post-tensioning by means of external tendons has been used to correct excessive sag in long-span bridges and to provide additional load capacity. It has been used to transversely tie cantilevered additions to existing bridges to widen them. When new structural elements are added adjacent to existing structures, post-tensioning can tie them so both new and old deform together, sharing the load. In these cases, post-tensioning has been applied either by drilling holes through the existing structure or by placing external tendons. The external tendons must be adequately tied to the existing concrete by dowels. Post-tensioning is extensively employed to strengthen existing buildings and bridges for earthquake resistance. It has been used effectively to transfer the loads from existing columns to new underpinning. Construction follows the general guidelines for post-tensioning with the following special provisions:

- Seats for anchorages must be carefully prepared by mortar or grout to ensure that the anchor plates can be fully seated on a plane normal to the trajectory of the tendon. The concrete beneath must have the ability to accept high compressive stress without bursting or cracking due to the concentrated load; thus, it may be necessary to remove and replace defective concrete. Adequate confining reinforcement is essential.
- Where external tendons are placed and are to be bonded to the existing concrete, the surface should be roughened and cleaned and a bonding epoxy applied.
- Adequate corrosion protection and, where applicable, fireproofing must be provided for the anchorages.
- In planning for strengthening, consideration must be given to access for the jacks and bearings for them to react against.
- The retrofitted structure must be able to accommodate the elastic and plastic shortening due to prestress.

11.15 Demolition of Prestressed Concrete Structures

Buildings and bridges must eventually be demolished and removed to make room for larger structures or other uses. Such demolition can be piecemeal, using the time-honored methods of headache ball, concrete saw, drill, and burning torch, or by more modern approaches that use diamond saws, hydraulic jacks (feathers) or controlled explosives that can topple the entire structure within a matter of seconds, turning it into rubble. Prestressed concrete structures require special considerations, due to the fact that tremendous amounts of energy are stored in the stressed tendons. Sudden release can produce a missile

FIGURE 11.57 Heidrun is the world's first permanently floating semi-submersible offshore oil platform; it is shown here under construction in Norway.

that can fly 100 m or more with a velocity sufficient to penetrate a board fence. More serious is the potential for injury to workmen or the public.

When removing a structure in stages, it is usually necessary to shore under the span being demolished to prevent its collapse. The shores should be wedged up to fit tightly against the member to prevent erratic loading as the tension is released. Heavy timbers or blasting mats should be placed behind the end anchorages to absorb impact energy. Post-tensioned tendons and especially unbonded tendons must be destressed gradually. One method is to heat the tendon with the yellow flame of a burning torch, allowing it to slowly elongate. The other, applicable to large post-tensioning tendons, is to cut one wire at a time. Controlled heating is the most reliable method.

When the precompression in the structural element is fully released, the element will transfer its load onto the shores, so they must be designed to take the resultant loads. Bonded, post-tensioning, multi-strand tendons are more difficult to release. Because their transfer length is typically short, they have to be cut at frequent intervals, but the projectile phenomenon is not as great a factor. When demolishing by explosives, millisecond delays should be used to ensure that unbonded tendons are cut close behind the anchorages prior to the release of the main spans. Demolition of a small area to repair a damaged zone should follow isolation of the concrete by a saw cut, so spalling, etc. will not extend farther than intended. Stitch bolts through the thickness may be installed around the periphery. The concrete can then be removed by a small chipping gun or jet blast of water, taking care not to seriously damage the tendons. The tendons may be clamped at their ends or bonded by epoxy injection if they have not already been bonded by grout. They are then heated to relieve tension and cut for splicing or other remedial repair.

11.16 The Future of Prestressed Concrete Construction

Prestressed concrete is now accepted for a wide range of applications such as those described in the preceding chapters. It not only enhances the tensile capacity of the structural elements but also enables the control of deformations and service performance. It prevents cracking, thus enhancing durability (Figure 11.57 and Figure 11.58). In the future, it will give an expanding capability to the architect and his structural engineer. Magnificent buildings and bridges will be translated from creative ideas into

FIGURE 11.58 Rion-Antirion cable-stayed bridge across Gulf of Corinth, Greece.

realities. Mass production of prefabricated elements, both prestressed by themselves and prestressed to create a monolithic whole, will be even more widely employed. The continued creative imagination and innovation of designers, and constructors will allow the horizon to expand exponentially.

Acknowledgments

12.1 Developments in Unbonded Post-Tensioning

12.1.1 Introduction

During the last three decades, unbonded post-tensioning has progressively become the predominant construction choice for commercial concrete buildings in the United States. The utilization of unbonded tendons is now standard practice for concrete structures. Because of their excellent performance record and their economical and versatile application, the total use of unbonded tendons increased from approximately 7500 tons in 1976 to over 180,000 tons of prestressing steel in 2005, adding up to over 1 billion square feet of slab constructed with unbonded post-tensioning. Early applications of unbonded tendons and their limitations in design and construction were soon succeeded by well-established analysis, design, detailing, and field procedures. Driven by durability considerations, post-tensioning

* Principal Consultant, FBA, Inc., Hayward, California, and Vice President of the American Concrete Institute; expert in analysis, design, evaluation, and retrofit of post-tensioned concrete structures.

FIGURE 12.1 Unbonded monostrand tendon.

manufacturers have implemented product improvements for corrosive environments. The most meaningful testimony for unbonded post-tensioned construction is the successful performance of over 1 billion square feet of concrete construction.

The four common types of tendon systems are monostrand tendons, single-bar tendons, multistrand tendons, and multiwire tendons. During the 1960s and early 1970s, several proprietary tendon systems were used for concrete building structures. Unbonded single-strand or monostrand (1/2-in.-diameter, seven-wire) tendons with various types of sheathing applications were used predominantly over construction using unbonded single-bar tendons in plastic (or metal) ducts and unbonded button-head wire tendon. The application of unbonded monostrand tendons offers an economical and versatile application for post-tensioning thin slabs and narrow beams. Together with the small tendon diameter, positioning monostrand tendons horizontally, side by side (maximum bundle of four), provides the maximum possible offset from the neutral axis (eccentricity) within a member cross-section. In addition, the monostrand post-tensioning system utilizes compact anchorage devices and anchor recess pocket formers, together with small, lightweight stressing jacks, thus permitting the stressing operation to be executed with hand-carried equipment. The relatively simple components of unbonded tendons, their proven performance, and the economical advantages they offer positioned unbonded post-tensioning to record an average annual growth of over 8.5% between 1986 and 2004, according to the *Post-Tensioning Manual*, 6th ed., hereafter referred to as the PTI Manual of the Tensioning Institute (PTI, 2006).

The use of 5/8-in.-diameter single-bar tendons (smooth rods) was discontinued due to the labor and material costs involved in splicing the standard bar length. In contrast, unbonded multiwire tendons (button-head wire tendons) were used until the mid-1970s for beams and transfer girders, which required large localized forces. The economical application of multistrand tendons has continued until today. Multistrand tendons originally intended as bonded tendons but kept ungrouted for surveillance (nuclear) are specifically excluded and not part of this review.

12.1.2 Unbonded Post-Tensioning System Technology

In the United States, the first unbonded monostrand tendons were used in the mid-1950s for building construction using greased and paper-wrapped seven-wire strand. The spirally applied continuous paper strip was intended to be a bond breaker between the strand and concrete, and the grease coating assumed the role of corrosion protection. Plastic sheathing introduced during the mid- to late 1960s assumed the roles of (1) bond breaker, (2) protection against damage by mechanical handling, and (3) providing a barrier against intrusion of moisture and chemicals. The strand coating, commonly referred to as *grease*, reduces the friction between the strand and the sheathing and provides protection against corrosion (Figure 12.1). Three principal polyethylene coating applications were used for several years—namely, a plastic tube into which the grease-coated strands were pushed (stuffed or push-through tendons); a continuous polyethylene strip positioned parallel with the strand, wrapped around the coated strand, and sealed with a seam along the longitudinal axis of the strand (heat sealed); and the extrusion of polyethylene over the coated strand. Primarily used in Canada until approximately 1990, the stuffed or push-through tendons were discontinued during the early 1970s in the United States. Heat-sealed

FIGURE 12.2 Unbonded tendon evolution: (a) paper-wrapped, (b) plastic sheath types, (c) encapsulated system, and (d) electrically isolated tendon.

fabrication of monostrand sheathing was supplied until the early to mid-1990s. In corrosive environments, stuffed and heat-sealed tendons have the inherent shortcoming of either trapping or allowing access of corrosive substances in the oversized sheathing. Extruded polyethylene sheathing has demonstrated excellent performance since its first introduction in 1969. The extrusion process applies the sheathing, eliminating voids between the sheathing and the grease coating. The extrusion sheathing application, with encapsulation of anchor zones for corrosive environments, has been used almost exclusively in the United States since the latter part of the 1990s until today. Again, the sheathing progression for most parts of the United States was paper-wrapped, stuffed or push-through, heat-sealed, extruded, encapsulated, and, for special applications, electrically isolated sheathing (Figure 12.2). Electrically isolated monostrand tendons have had limited application (Schupack, 1980).

12.1.2.1 Material Specifications

12.1.2.1.1 Prestressing Steel

Prestressing steel properties have essentially remained unchanged, conforming to ASTM A 416 Grade 250 or 270. The seven-wire low-relaxation strand, with a nominal diameter of 0.5 in. and a specified tensile strength of 270 ksi, is typically anchored near 70% of its ultimate strength. The material should be packaged at the source in a manner that prevents physical damage to the strand during transportation and protects the material from deleterious corrosion during transit and storage.

12.1.2.1.2 Anchorages

Tendon anchorages and couplings should be designed to develop the static and fatigue strength requirements of Section 2.2.1.1 and Section 2.2.1.2 of the Post-Tensioning Institute's *Specification for Unbonded Single-Strand Tendons* (PTI, 2000) and Section 4.1 of *Acceptance Standards for Post-Tensioning Systems* (PTI, 1998). Castings should be nonporous and free of sand, blow holes, voids, and other defects. The average compressive concrete bearing stress of anchorages should not exceed the limits set forth in Section 2.2.1.3 of the referenced specifications. For wedge-type anchorages, the wedge grippers should be designed to preclude premature failure of the prestressing steel due to notch or pinching effects under the static or dynamic test load conditions stipulated under Section 2.2.3 (PTI, 2000) and Section 4.1 (PTI, 1998), for both stress-relieved and low-relaxation prestressing steel materials. Anchors intended for use in corrosive environments should include design features permitting a watertight connection of the sheathing to the anchorage and a watertight closing of the wedge cavity for stressing and nonstressing (fixed) anchorages. Intermediate stressing anchorages should be designed to permit complete watertight encapsulation of the unbonded tendon.

12.1.2.1.3 Sheathing

Sheathing for unbonded single-strand tendons should be made of a material with the following properties:

- Sufficient strength to withstand unrepairable damage during fabrication, transport, installation, concrete placement, and tensioning
- Watertightness over the entire sheathing length
- Chemical stability, without embrittlement or softening over the anticipated exposure temperature range and the service life of the structure
- Nonreactivity with concrete, steel, and the tendon corrosion-preventive coating

Minimum thickness of the sheathing used in all environments and all applications other than ground-supported post-tensioned slabs for residential and light commercial construction should be 0.050 in. for polyethylene or polypropylene with a minimum density of 0.034 lb/in.³, or equivalent if other materials are used. Minimum thickness of sheathing used in ground-supported post-tensioned slabs for residential and light commercial construction should be 0.040 in. for polyethylene or polypropylene with a minimum density of 0.034 lb/in.³, or equivalent if other materials are used (Section 2.3.2.1 in PTI, 2000).

12.1.2.1.4 Corrosion-Preventive Coating

The corrosion-preventive coating material should have the following functions and properties:

- Provide corrosion protection to the prestressing steel.
- Provide lubrication between the strand and the sheathing.
- Resist flow within the anticipated temperature range of exposure.
- Provide continuous nonbrittle coating at lowest anticipated temperature of exposure.
- Be chemically stable and nonreactive with prestressing steel, sheathing material, and concrete.

The film should be an organic coating with appropriate polar, moisture-displacing, and corrosion-preventive additives. According to Section 2.4.3 of *Specification for Unbonded Single-Strand Tendons* (PTI, 2000), the minimum weight of post-tensioned coating material on the prestressing strand should be not less than 2.5 lb per 100 ft for 0.5-in.-diameter strand and 3.0 lb per 100 ft for 0.6-in.-diameter strand. The amount of coating material used should be sufficient to ensure essentially complete filling of the annular space between the strand and the sheathing. The coating should extend over the entire tendon length.

12.1.3 Durability of Unbonded Tendons

Post-tensioned concrete members inherently provide enhanced durability due to the limitation of cracks that provide access to reinforcement for corrosive agents. The use of post-tensioning typically eliminates most slab joints, which, if not eliminated, may give corrosive agents access to beams and columns. The excellent durability performance of existing concrete structures in corrosive environments reflects the potential of unbonded monostrand tendons. Most of these structures were built without specific durability design and construction considerations. The visual inspection of a 15-year-old parking structure in Baltimore, Maryland, following demolition confirmed that no significant corrosion had occurred on the unbonded tendons over the 15-year service life (Suarez and Posten, 1990).

The distinguishing characteristic of an unbonded tendon is that, by design, it does not form a bond along its length with the surrounding concrete. The axial force in the stressed tendon is transferred to the concrete primarily by the anchors provided at each end. Because the force of an unbonded tendon is primarily resisted by the anchors at each end, the long-term integrity of tendons and anchors throughout the service life of an unbonded tendon are of concern.

The Post-Tensioning Institute originally published *Specification for Unbonded Single-Strand Tendons* in 1993; the second edition, published in 2000, includes special durability requirements for tendons used in structures exposed to aggressive environments. These specifications provide for watertight encapsulation of the strand within the tendon sheathing over its entire length, including watertight

Notes:

1. Locate anchor at bulkhead per project plans.
2. Install grommet flush between bulkhead and anchor for tight seal.
3. Slide sleeve tight against anchor. Be sure no bare strand is exposed. Tape if necessary.
4. After pouring, at time of stressing, remove grommet and insert wedges.
5. After stressing, cut strand to within 1/8" of end of end cap and grease end cap prior to inserting it tight against anchor.
6. Patch stressing pocket per project plans.

Item	Description

6	End cap

FIGURE 12.3 Encapsulated system for tendons in corrosive environments (stressing end).

enclosure of the tendon anchorage device (Figure 12.3). The specifications further require the use of a specially formulated corrosion-inhibiting grease and include many other secondary provisions to ensure enhanced durability.

Nevertheless, some buildings constructed with unbonded tendons have suffered durability shortcomings. A survey of 215 concrete structures in Toronto, Ottawa, and Montreal concluded the following: “The evidence indicates that durable structures can be built, and that poor performance must be attributed to design and construction practices whose effectiveness falls short of that required by the environment” (Litvan and Bickley, 1987). A map that divides the United States into five principal environmental zones is available to help with understanding and evaluating environmental considerations when selecting appropriate unbonded tendon systems. The selection of zones was in part based on the geographical use of deicing salts and presence of airborne salts from oceans. Detailed information on the zoning requirements and related system recommendations can be found in Walker (1990).

To improve the quality and consistency of unbonded post-tensioned tendons, the Post-Tensioning Institute developed plant certification requirements and issued in 1998 *Acceptance Standards for Post-Tensioning Systems*. To further a better understanding of the durability aspect, the Post-Tensioning Institute issued the second edition of *Specification for Unbonded Single-Strand Tendons* in 2000. The specifications provide for tendons in both normal and aggressive environments.

12.2 General Notes and Standard Details

12.2.1 General Notes

This section is intended to offer a sample layout of general notes for the construction of an unbonded post-tensioned concrete structure, typically outlined on structural drawings. The sample notes are limited to the post-tensioning activity of the concrete frame or member only. The notes are neither considered complete nor applicable for every project that includes the construction of unbonded post-tensioned members; however, with minor revisions and additions and deletions, the notes have been used by the author on over 500 concrete structures. The design engineer should be aware that the concrete frame may develop cracking as a result of concrete creep, shrinkage, temperature deformation, and elastic shortening on members that are partially or fully restrained from movement. For this reason, notes should be added on the drawings that disclose the likelihood of potential concrete cracking and allow for a funding mechanism for crack repair in the form of a postconstruction material maintenance allowance.

12.2.1.1 General

Material, installation, stressing, and finishing specifications. The tendon shall meet the requirements set forth in *Specification for Unbonded Single-Strand Tendons* (PTI, 2000).

Marking of tendon location. If desired by the owner, the tendons may be marked using the dye-transfer method or by paint marking the formwork along the tendon lines just prior to placement of concrete. The paint transfers to the concrete soffit to permanently locate tendons (Section 6.4, PTI, 2006).

Power-driven fasteners. No power-driven fasteners or inserts shall be shot or drilled into the post-tensioned slab after concrete is placed without the written authorization of the engineer.

Openings. All openings, penetrations, and inserts shall be preplanned to the fullest extent possible. No changes shall be made in the field without prior approval of the engineer.

Formwork. For multilevel structures, the formwork shall extend beyond the slab edge, or scaffolding shall be provided to allow adequate room for the stressing operation.

Shop drawings. The contractor shall submit shop drawings showing tendon layout, dead-end and stressing-end locations, and tendon support layouts with details necessary for installation to the engineer for approval. The contractor shall supply the engineer with two sets of shop drawings a minimum of three weeks prior to fabrication. The review of shop drawings by the engineer is only for general compliance with the structural drawings and specifications. A set of approved shop drawings must be filed with the city engineer by the contractor.

Post-tensioned slab review. The tendon and mild reinforcement layout of a post-tensioned slab shall be reviewed by the engineer or the engineer's designated representative prior to concrete pour. The engineer shall be notified at least 48 hours in advance.

Field foreman. The field foreman responsible for the placement, stressing, and finishing of all break post-tensioning material shall have a minimum of five (5) years of specialized experience in this capacity for this type of construction.

12.2.1.2 Materials

Strand quality. One sample of each reel or heat shall be tested by an approved laboratory. Test results or mill certificates shall be submitted to the engineer before stressing of tendons. Post-tensioning tendons shall be stress relieved or be of low-relaxation quality and shall conform to the following:

PT hardware quality. All anchorages, couplers, and miscellaneous hardware shall be standard products and approved by governing agencies and the engineer.

Tendons. Unbonded strands shall be encased in slippage sheathing that shall consist of a sealed durable waterproof plastic tubing (minimum thickness as specified by PTI) capable of preventing the penetration of moisture and cement paste and that will contain a rust-inhibiting grease coating.

Tears in the sheathing shall be repaired to restore the watertightness of the sheathing. The sheathing application shall be limited to the extrusion process. Tendons shall be secured during shipping and supported during handling to avoid damage to the tendon sheathing. During shipping and storage, the tendons shall be covered or protected to avoid moisture access to post-tensioning material.

12.2.1.3 Installation

Installation of unbonded tendons. If the post-tensioning supplier does not install the material supplied, detailed instructions for the installation and stressing of tendons shall be furnished. The contractor responsible for hiring the independent post-tensioning placer shall ensure that the installation crew meets the standards set forth above. The supplier shall provide technical assistance necessary to properly install, stress, and finish all post-tensioning material.

Tendons. Tendons shall be shop fabricated with preassembled fixed-end anchorages. Anchor casting with plastic pocket formers shall be used at all stressing ends to recess the anchor in enough concrete to achieve required cover.

Banded layout. The banded tendon placement layout shall be used for two-way post-tensioned slabs.

Tendon placement. Care shall be taken that tendons are located and held in their designated positions. Tolerances for the location of the prestressing steel shall not be more than $\pm 1/8$ in. vertically, except as noted or approved by the engineer. Access to stressing ends shall be maintained where shown.

Strand bundles. The maximum allowable number of strands per bundle is four (4) for slabs and six (6) for beams.

Tendons over columns. For two-way slab construction, a minimum of two (2) tendons in each orthogonal direction shall be placed directly over the supporting column.

Tendon adjustments. Small deviations in the horizontal spacing of the slab tendons will be permitted when required to avoid openings, inserts, and dowels with specific locations. Where locations of tendons seem to interfere with each other, one tendon may be moved horizontally to avoid the interference.

Twisting. Twisting or entwining of individual wires or strands within a bundle or a beam shall not be permitted.

Vertical profiles. Profiles shall conform to controlling points shown on the drawings and should be in approximate parabolic drape between supports, unless noted otherwise. Low points are at midspan unless noted otherwise. Harped tendons shall be straight between high and low point controls.

Horizontal profiles. Should the tendons be horizontally curved to miss an opening or other obstructions, tendon bundles shall be flared with a minimum distance of 2 in. between each individual tendon while horizontally curved. In addition, #3 hairpins at 12 in. on-center for each tendon shall be installed, transferring the horizontal radial force via the hairpin mild reinforcing to the concrete.

Prestress cover. All dimensions showing the location of prestressing tendons are to the center of gravity (CGS) of the tendon unless noted otherwise.

Minimum chairing. Tendons shall be secured to a sufficient number of positioning devices to ensure correct location during and after the placing of concrete and shall be supported at a maximum of 3 ft, 6 in. on-center. Chairs greater than 2.5 in. shall be stapled to the formwork.

Support bars. Support bars located at the face of drop panels shall be #6 or greater. Drop panels greater than 4 ft in width shall have additional #6 or greater support bars at the center, with a maximum support bar spacing of 4 ft for larger panels. All other support bars shall be minimum #4 bars. Continuous support bar lap splices shall be 24 in. minimum.

Anchors. Anchorages shall be recessed a minimum of two (2) in. Place two (2) #4 bars continuous behind all anchorages unless otherwise noted. Splices shall be 24 in. minimum and staggered. Special anchorage zone reinforcement shall be provided for groups of six or more anchors for 1/2-diameter strand tendons spaced at 12 in. or less on center.

Blockouts. All pockets or blockouts required for anchorage shall be adequately reinforced so as not to decrease the strength of the structure. All pockets should be waterproofed to eliminate water leakage through or into the pocket.

Pipes and conduits. Plastic or metal conduits may be embedded in the slab providing that the following criteria are met:

- A. Plumbing pipe and electrical conduit layout proposed to be within the slab cross-section must be specifically approved by the engineer of record.
- B. Maximum pipe or conduit size shall be 1.5-in. diameter (O.D.), located within the middle third of the slab cross-section, and supported independently from all reinforcement.
- C. Center-to-center spacing of conduits shall not be less than three (3) times the diameter of the largest conduit.
- D. No aluminum pipes, conduit, or embedment shall be permitted in post-tensioned concrete slabs.
- E. Conduits must not interrupt the post-tensioned tendon layout or profile.
- F. No pipe or conduit may be placed within the column shear cone.
- G. It is undesirable to have excess amounts of conduit entering the slab from one location. If this condition exists, the conduits must be fanned out immediately.

Penetrations. Penetrations shall not be permitted in beams or drop caps unless permitted on post-tensioning drawings or typical details.

12.2.1.4 Concrete Placement

Concrete consolidation. The contractor shall take precautions to ensure complete consolidation and densification of concrete behind all post-tensioning anchorages.

Concrete placement. When concrete is placed in post-tensioned slabs, special care shall be taken at all column drop caps (panels). Insert the pump hose into the column drop panel below reinforcement and fill until concrete reaches the top reinforcing layer. Monitor concrete elevation to avoid flotation of top reinforcing. After the drop panel is full of concrete, place concrete over the top reinforcing layer to specified slab thickness. Vibrate adequately in and around column drop panels.

Pumped concrete. If concrete is placed by the pump method, horses shall be provided to support the hose. The hose shall not be allowed to ride on the tendons.

Chlorides. Grout or concrete containing chlorides shall not be permitted.

12.2.1.5 Stressing of Tendons

Tendon stresses. Such stresses shall conform to the following:

- Maximum tendon jacking stress, 216 ksi
- Maximum tendon stress at anchorage immediately after prestress transfer, 189 ksi

Effective force. Forces shown on structural drawings are effective forces after all losses. All losses (short- and long-term losses) due to creep, shrinkage, tendon relaxation, and elastic shortening, including friction losses and losses due to wedge seating, may be assumed as 14 ksi. Thus, the effective force per tendon may be assumed to be 24.8 kips for stress-relieved tendons and 26.8 kips for low-relaxation tendons, when tendon length is less than 100 feet. For variance from this value or for tendons over 100 feet, the post-tensioning supplier shall provide friction and long-term loss calculations for the engineer's approval. Friction losses may not be averaged or assumed to redistribute along the tendon length. The available effective force shall be established at a location along the tendon length where the force demand meets the minimum effective tendon force.

Concrete strength at stressing. Prior to transfer of prestress, concrete shall reach a minimum compressive strength of $f'_c = 3000$ psi. Minimum concrete strength shall be established by breaking concrete test cylinders. The stressing shall not commence until concrete reaches the specified strength; however, tendons shall be stressed within 72 hours after concrete reaches the minimum specified strength to mitigate early-age concrete cracking. This may not apply to stage stressing of transfer floor or mat foundations.

Calibration. The ram and attendant gauge used shall have been calibrated within sixty (60) days of use.

Tendon stressing. The stressing operation shall be done by jacking under the immediate control of a person experienced in this type of work. Continuous inspection and recording of elongations are required during all stressing operations.

Stressing sequence. In general, uniformly distributed tendons shall be stressed before concentrated beam strip (banded) tendons, and slab tendons shall be stressed before beam tendons. Additional stressing sequence requirements shall be as specified below.

Two-Way Slab Sequence

1. Stress continuous distributed tendons
2. Stress continuous banded tendons
3. Stress added distributed tendons
4. Stress added distributed tendons
5. Stress added slab tendons

One-Way Slab and Beam Sequence

1. Stress temperature tendons
2. Stress continuous slab tendons
3. Stress beam tendons
4. Stress transfer girder tendons

Elongation. Individual tendon field readings of elongations and/or stressing forces shall not vary by more than $\pm 7\%$ from the calculated required values shown on the shop drawings. If the measured elongations vary from calculated values by more than $\pm 7\%$, the contractor shall provide friction calculations and/or other justification, to the satisfaction of the engineer, for the discrepancies.

Member forces. The post-tensioned force provided in the field for each structural member shall not be less than the values noted on the structural drawings. In this context, structural members are beams or slabs, whether with banded or distributed tendons, each serving its respective tributary area.

Tendon ends. Do not burn off tendon ends until the entire floor system has been satisfactorily stressed and the engineer's approval is obtained.

Anchor protection. The stressing end anchors and wedges shall be spray-painted with rust-inhibiting paint or a similar coating for corrosion protection prior to grouting of recess pockets. Install grease caps within 24 hours after cutting tendon tails.

Grouting of stressing pockets. Stressing pockets shall be filled with nonshrink grout after stressing, tendon end cutting, painting, and grease capping to stop moisture access to the strand.

Deshoring. Slabs or beams may be deshored when all tendons have been satisfactorily stressed and the engineer's approval is obtained, unless shoring is required to carry floors of multiple levels (reshoring). In areas supporting a partial span, such as near a pour strip or construction joint, the shoring in the partial span and immediate back span shall stay in place until the remaining section of the span has been poured and stressed or cured.

Inspection for prestressing steel. Continuous special inspection shall be provided during placement of reinforcing steel, tendon supports, and prestressing steel. Tendon location and integrity of the protective wrapping for post-tensioned tendons shall be inspected prior to placement of concrete. During stressing of post-tensioned tendons, the special inspection shall include recording of field-measured elongation and jacking force for each tendon.

Admixtures. No admixtures shall be added to the concrete mix without the approval of the engineer, unless noted otherwise. Admixtures concrete containing chlorides shall not be used in post-tensioned slabs.

Special notes to the owner. Under normal conditions, and for conventional buildings, reinforced concrete as well as post-tensioned concrete develops cracks. The cracks are due to inherent shrinkage of concrete, creep, and the restraining effects of walls and other structural elements to which the beams/slabs are tied. The early-age concrete cracks that may develop are usually of a cosmetic nature. The slab typically retains its serviceability and strength capability. Due to special features of unbonded post-tensioning, it is possible that a number of hair cracks, which would normally spread over a wide area, will integrate into a single crack with a width exceeding 0.01 in. It is emphasized that, although special efforts are made to reduce the potential causes and number of such cracks, it is not practical to provide total articulation between

the floor system and its supports and thereby achieve complete inhibition of all cracks. Most early-age cracks develop during the first two (2) years after construction of the floor system is complete. Cracks that are wider than 0.01 in. may have to be pressure epoxied. Refer to the notes under the Material Allowances section. The objective of providing joints is to allow movement. Movements due to creep and shrinkage may be noticeable at joints for up to two (2) years after construction, beyond which movements due to variations in temperature will persist. In aggressive environments, cracks should be repaired at the time they are first noticed.

12.2.1.6 Material Allowances

The contractor shall include in the project budget material allowance for the engineer to use at the engineer's discretion during construction to address unforeseen conflicts. Any materials not used by the engineer shall be credited back to the individual (owner, developer) funding such allowances.

Reinforcement allowance. The contractor shall provide an amount of reinforcement as specified by the engineer of record for the engineer to use at the engineer's discretion during construction. (Example: The contractor shall provide 2000 lb plus 0.05 lb per square foot of elevated concrete slab of reinforcement for the engineer to use at the engineer's discretion during construction.)

Post-tensioning allowance. The contractor shall provide an amount of post-tensioning material as specified by the engineer of record for the engineer to use at the engineer's discretion during construction. (Example: The contractor shall provide 1000 lb plus 0.02 lb per square foot of elevated concrete slab of post-tensioning material for the engineer to use at the engineer's discretion during construction.)

Pressure epoxy allowance. The contractor shall include an amount for pressure epoxy injection of cracks that may develop in the structure during the first two (2) years. (Example: The contractor shall include the cost of \$0.10 per square foot of elevated concrete slab for pressure epoxy injection of cracks that may develop in the structure during the first 2 years.)

12.2.2 Standard Details

In accordance with standard industry procedures for most construction-related work, details for unbonded post-tensioned members are first developed by the design engineer or architect. The details typically show the member geometry, reinforcing layout (location of tendons and mild reinforcing), and other embedments. After the construction contract is awarded, the post-tensioning supplier commonly prepares more project-specific drawings, called *shop drawings*. The shop drawings for post-tensioning materials are normally prepared in much more detail than the design drawings. Typically, they are submitted for review and approval to the design engineer or agency before fabrication of the tendons is initiated. It is essential that details of the post-tensioning tendons, nonprestressed reinforcement, ducting for electrical or mechanical service, and other embedment items be reviewed and coordinated during the detailing stage. It is not uncommon for final details for different material trades to be shown on different shop drawings, indicating incompatible or conflicting layout. In most cases, details can be rather easily adjusted at the shop-drawing stage to accommodate all embedded items. When conflicts do arise during the development of shop drawings or during construction, the tendon layout should govern over other elements or embedments conflicts. Many specialized structural details have been developed for the construction of unbonded post-tensioned members. The following selected details illustrate typical design and detailing practices for most common applications of unbonded post-tensioning in building construction.

12.2.2.1 Tendon Anchorage Zone

The anchorage zone, probably the most critical concrete region, has to retain the tension force of unbonded tendons during the service life of the post-tensioned structure. Figure 12.4 shows typical details of stressing and dead ends. Unless otherwise detailed on the design or post-tensioning installation drawings, banded tendon anchorage zones in normal weight concrete for groups of six or more 1/2-in.-diameter single-strand tendons with anchor spacing of 12 in. or less should be reinforced in accordance

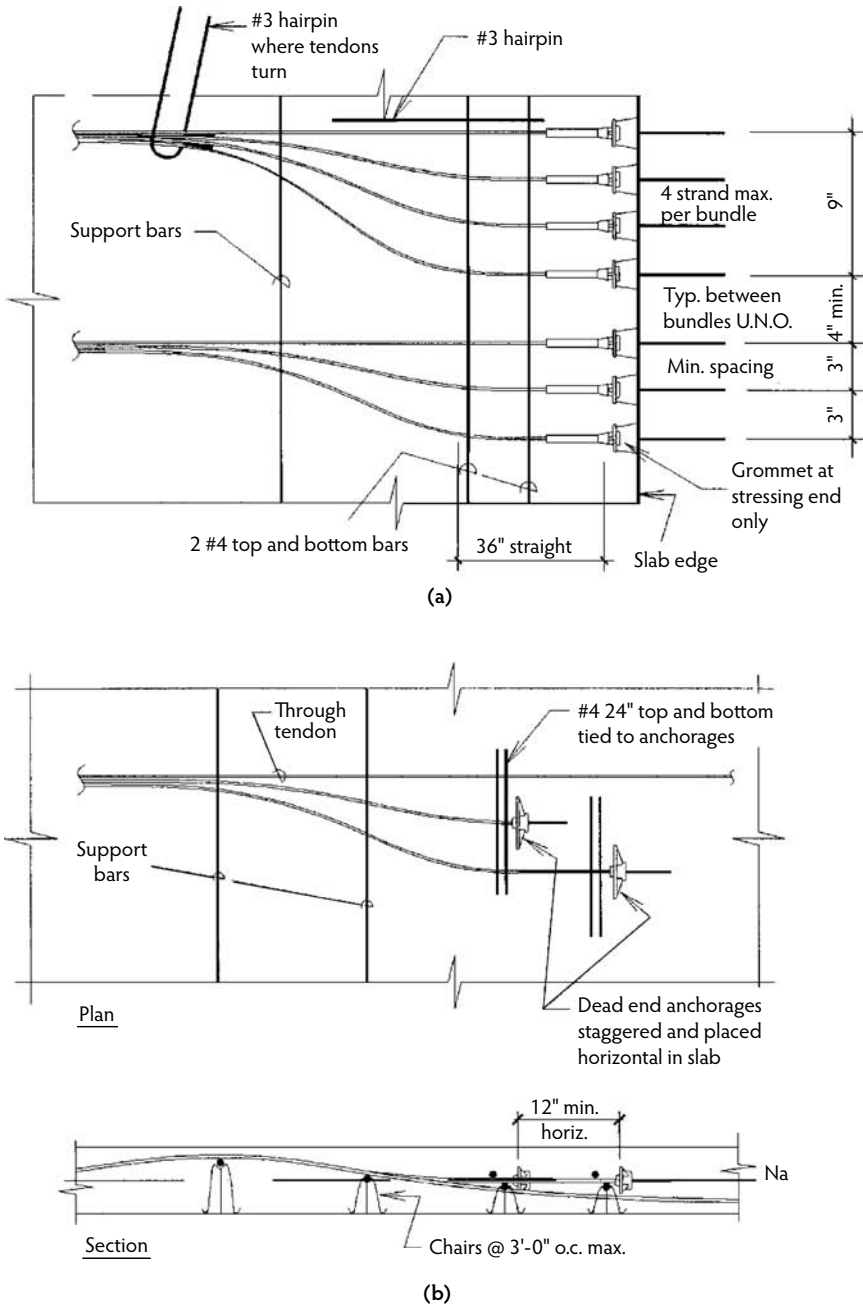

FIGURE 12.5 Flaring of tendon bundles and fixed-end tendon staggering: (a) flaring of banded tendons at the slab edge in a corrosive environment, and (b) placement of added tendons.

tendon support bars must be stable and properly secured to ensure a firm tendon profile during the concrete pour. Also, large tendon bundles, such as multiple bundles of six tendons, that are not properly spaced and layered may result in tendons bunching up at locations of curvature (high and low points) and developing splitting forces in the concrete beam. The use of tendon support bars, which guide the installation crew in the appropriate spacing of tendon bundles, has successfully addressed this concern (Figure 12.11).

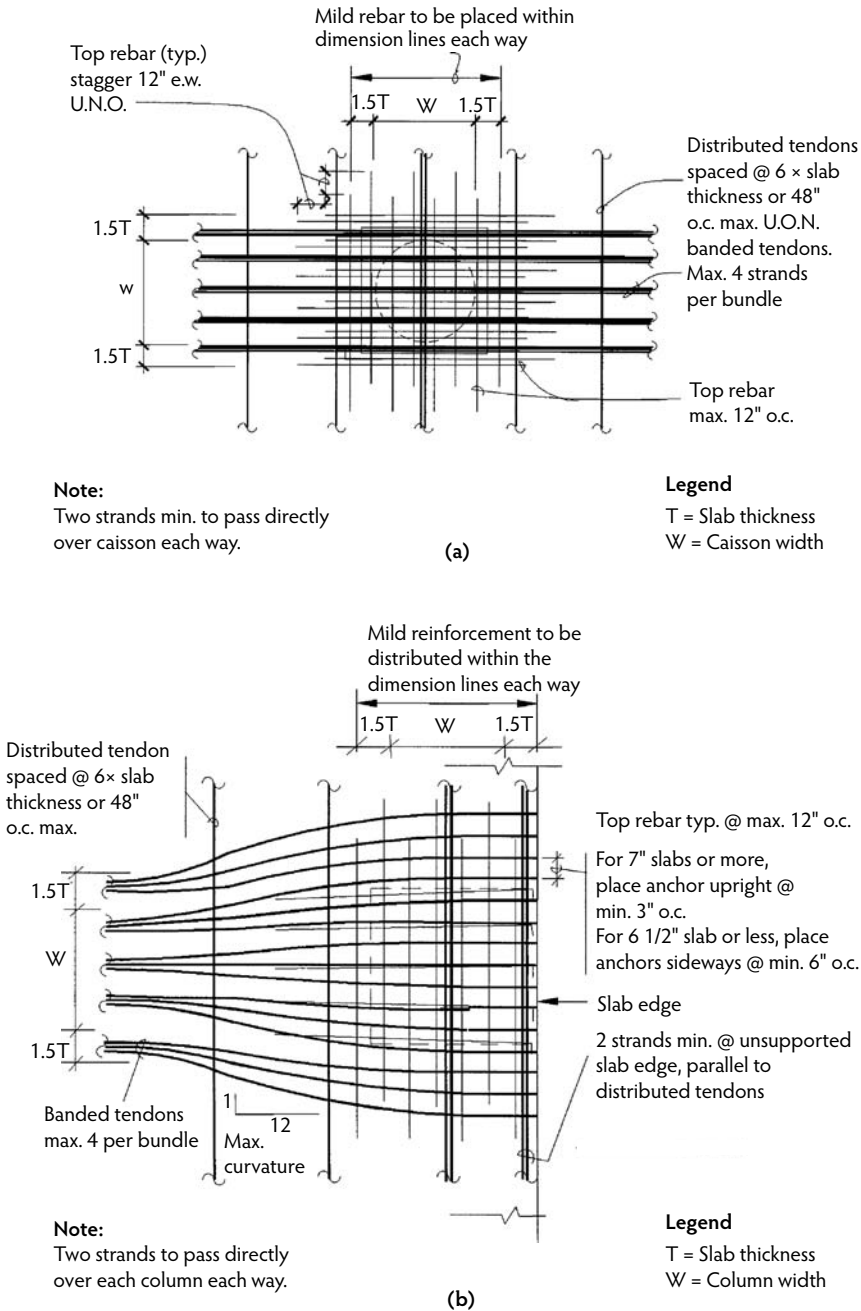

FIGURE 12.6 Typical two-way slab tendon layout: (a) top reinforcement at interior columns, and (b) top reinforcement at exterior columns.

12.2.2.4 Joints

Section 12.3 discusses in detail the types and optimum locations for joints to mitigate the restraint effects of post-tensioned members. In addition to restraint considerations, joints may have to be located to limit concrete pour size (Figure 12.12a) or allow for intermediate stressing (Figure 12.12b). The selection of pour-strip location and duration of pour-strip opening shall be based on a numerical shortening evaluation of the structure. A sample reinforcing layout for a typical interior stressing blockout and a 3-foot-wide

Note: A minimum of two tendons shall be placed in each direction directly over column.

(a)

Note: A minimum of two tendons shall be placed in each direction directly over column.

(b)

FIGURE 12.7 Typical two-way slab tendon layout: (a) typical interior column, and (b) typical drop-panel section.

pour strip is shown in Figure 12.13. The preceding discussion emphasizes that the successful performance of an unbonded post-tensioned structure is directly related to the understanding and extent of detailing of specific performance considerations.

12.2.3 Typical Field Shortcomings: Problems and Solutions

12.2.3.1 Preventing the Most Frequent Problems

Prior to placing the concrete, the post-tensioning installation should be checked for the following. The area behind the anchors (18 in. behind the anchor at 45° angles on each side, as shown in Figure 12.14) should be free of sleeves, blockouts, large conduit, or any other voids or congestion that could

FIGURE 12.8 Layers in typical two-way slab tendon layout: (a) section through banded tendon at column, and (b) section through distributed tendon at column.

allow the concrete to crush or form a void in this high-stress zone. If penetrations must be positioned within the 45° region, steel pipe inserts must be used as specified by the engineer. Frequently, the electrical, mechanical, and plumbing contractors place their sleeves just before the pour, after the

Note:
Keep tendon groups uniformly spaced throughout the length of beam.

(a)

Note:
At conditions where there are two types of added bars (top or bottom), the longer bars shall be placed first.

FIGURE 12.12 Joint locations: (a) construction joint with no intermediate stressing, and (b) construction joint with intermediate stressing in a corrosive environment.

tendon-placement inspection. While checking the anchor zones, make sure a sufficient strand tail extension is protruding through the edge form. It is typically much easier to adjust the tendon by a few inches prior to placing the concrete than it is to use splices and special equipment to stress a short tendon later.

For an encapsulated system, the sheathing should be connected to the anchor according to the manufacturer's recommendation to ensure that there will be no exposed strand and to provide continuous protection. In normal environments, however, because there is no connection between the anchor and the sheathing, special care should be taken to minimize the length of greased strand behind the anchor. The maximum length of greased strand should not exceed 1 in. If concrete is cast against unshathed strand, the rifling pattern of the strand will be cast in the concrete, forming spiral grooves that twist the strand when stressed. The spiraling of the strand will cause the stressing jack to spin at the end of the stressing cycle and could injure the person operating the stressing equipment or break the hydraulic supply hoses on the jack. Even if no one is harmed, the twisting motion of the strand through the jack grippers causes premature wear. It is important to tape wrap exposed strands before the concrete pour, as the fix is costly once the concrete has hardened.

- Notes:**
1. Cut stressed strands; grease and place end cap.
 2. Continue all interrupted bars shown in plans through the blockout.
 3. Fill blockout with nonshrink concrete of same strength as slab, minimum.

(a)

- Notes:**
1. Retain shoring until closure concrete reaches slab's design strength or 14 days.
 2. Closure strip to be poured with non-shrink concrete not less than \times days after stressing.
 3. Roughen & clean joints & wet prior to placing concrete.
 4. Eliminate accidental misalignment between edge of slabs that are to be joined with a closure strip. Use mechanical methods such as jacking, if necessary.
 5. Raise edge of slab 1/4" @ closure to allow for settlement.
 6. Provide waterproofing membrane if required for water-tightness.
 7. Cut stressed strand tails; grease and place end cap.

(b)

FIGURE 12.13 Sample reinforcing layouts: (a) stressing blockout and (b) closure strip in a corrosive environment.

If more than 1 in. is exposed, repair the sheathing right up to the back of the anchors. If this area is difficult to access due to bursting steel or other obstructions, make a circular cut on the sheathing 18 to 24 in. back from the anchor, slide the sheathing forward until it touches the anchor, and then repair the bare spot at a location away from the congestion. The second option has the advantage of leaving the most critical area (that zone 12 in. behind the anchor) covered with good sheathing.

The quality of the installation can be jeopardized by people walking on the placed cable before a pour. The pocket former must be held tight against the anchors so concrete slurry does not leak into the anchor cavity. This can happen if the concrete vibrator bounces the edge form and separates the pocket former from the anchors. There is no substitute for having the anchors tightly attached. If a small amount of post-tensioning coating is applied to the tip of the pocket former before inserting it in the anchor cavity, it will make a seal between the two pieces that will keep concrete slurry out even if a small gap develops.

- Notes:** 1. Penetrations with dimensions greater than 12" require trim reinforcement.
 2. Sweat PT tendons (where possible) to avoid conflict between PT anchors and openings.

FIGURE 12.14 Openings at post-tensioning anchorage.

FIGURE 12.15 Split troubleshooting anchor.

12.2.3.2 Slipping Strand and Jack Hang-Up

When wedges fail to hold the strand, the most common cause is concrete slurry in the wedge seat of the anchor cavity. If a separation between the pocket former and the anchor occurs, concrete slurry can flow into the anchor cavity and set up in the form of a ring around the strand at the back of the anchor. This will stop the wedges from penetrating into the anchor the proper distance and result in strand slippage. If the elongation requires more than one cycle of the stressing equipment, it can cause the jack to become locked onto the tendon. On the first cycle, the wedges usually hold because they do not have to be fully seated and the pressure is low. On the second cycle, the wedges bottom out on the concrete slurry and the strand will be free to slide back into the concrete, stripping the teeth on the wedges and hanging up the jack. Several different methods can be used to detension the tendon, thereby releasing the jack, depending on individual site conditions as follows. A second jack should not be used on the back of the one that is hung up to detension it. Once the jack is hung up, a troubleshooting split anchor (Figure 12.15) must be inserted behind the nosepiece of the jack bearing on the anchor cast in the concrete but in front of the gripper block of the jack to free up the jack.

During this procedure, do not exceed the recommended gauge stressing pressure. Open the jack just enough to insert the troubleshooting split anchor on the strand. Insert the wedges in the troubleshooting anchor and slowly release the pressure on the jack until the stress in the strand is taken up by the troubleshooting anchor. Continue closing the jack until the jack grippers in the jack gripper block are released from strand. Extend the jack fully and then retract the jack approximately 2 in. Engage the jack grippers and extend the jack to stress the strand again and release the wedges in the troubleshooting anchor. (Applying a thin coat of Never-Seez® or a similar product on the back of the wedges will make them easier to remove during this step.) Slowly release the pressure in the jack and let the strand slide back into the concrete slab until fully relaxed. (If the jack bottoms out before the strand is relaxed, simply repeat all the steps of the sequence.) When the jack is fully released, remove it and the wedges from the anchor in the slab. It is not uncommon to find that the wedge seating was either restricted by a small film of concrete slurry around the tapered sides of the anchor cavity or a ring of concrete formed around the strand at the back of the anchor. If necessary, remove the debris by scraping or chipping the slurry out of the anchor. Because the area is very congested, a small screwdriver may be the proper tool for this procedure. After removal of all debris, clean the wedge seat of loose materials and dust using compressed air. Insert a new pair of wedges and stress the tendon.

12.2.3.3 Honeycomb in Concrete

Rock pockets, sand pockets, or voids should be repaired prior to the stressing operation. Remove all loose material and dust prior to repair. Wet the concrete surface before repair. When patching, use a high-strength, nonshrink concrete grout mix with an epoxy binder. Grout strength should equal or exceed specified concrete strength. *Do not* use grout that contains calcium chloride or other materials containing chloride. When the patch has attained proper strength, the stressing operation may proceed. It is essential to repair honeycomb in anchorage zones to avoid blowouts. After detensioning of tendons, all loose material and dust should be removed until sound concrete surfaces are encountered. Stress tendons after the repaired area reaches the minimum concrete compressive strength specified. Prior to stressing, check the quality of the patch by tapping it with a hammer to sound for voids. A hollow sound indicates a poor patch that is not suitable for stressing.

12.2.3.4 Splicing Tendons

Tendons are sometimes too short to reach an edge form because of misplacement or misfabrication. If the tendon is in one pour only and not continuous, every effort should be made to replace the short tendon with a tendon of proper length instead of using couplers. If tendons are continuous from another pour, thus making tendon couplers necessary, the engineer of record and the post-tensioning material supplier should be notified. The coupler location should be determined by the post-tensioning material supplier such that the coupler is centered in the member and not at a point of tendon curvature. Couplers should not be located side by side. If more than one tendon requires splicing, couplers should be staggered at half-bay increments per tendon group.

A PVC pipe of sufficient inside diameter to hold the coupler and of sufficient length to allow for subsequent elongation movement should be used. Also, an additional piece of sheathed strand of sufficient length to reach the edge form is required, along with two pocket formers. Post-tensioning coating should be used to fill the void in the PVC pipe. The tapered tip of the pocket former that normally fits inside the anchor cavity can be cut off when being used for splicing, thereby reducing the length of the PVC pipe needed. The original strand is first cut with a saw or abrasive plate at the coupler location, and one pocket former is placed on the strand. The strand should be marked before coupling to make certain that the proper length of strand has been fully inserted into the coupler. The coupler is then coupled to the original strand. The PVC pipe is placed over the coupler. The second pocket former is placed over the new strand (the strand is marked) and inserted into the coupler. A pocket former is taped to one end of the PVC pipe, which is then packed tightly with post-tensioning coating, allowing no air voids. The second pocket former is affixed to the PVC pipe, completing a tightly sealed coupler.

The tendon coupler's location within the PVC pipe must permit the coupler to move the required elongation amount in the direction of stressing. Allowance for movement in both directions must be provided when the tendon is to be stressed from both ends. Conservatively, a minimum of 1.5 times the total expected elongation at the splice location should be allowed for. A dark crayon or paint mark on the deck will facilitate locating the coupler after the pour, should that become necessary if the above procedure was not properly followed.

12.2.3.5 Tendons Too Short to Stress Using Normal Stressing Procedure

Short tendons can result from an incorrect tendon-fabrication cutting list, misfabrication, misplacement, or a job-site mistake such as cutting tendons off prior to stressing. During stressing, most conditions may be addressed with special equipment that can be obtained from the post-tensioning material supplier. If a tendon is too short to be stressed using a standard jack, in some cases a short tendon can be stressed by simply removing the nose piece and using jack feet. When using jack feet, care should be taken to center the jack with the tendon before applying pressure. If the tendon is stressed without being centered on the anchor, it will rub on the side of the anchor, and inserting one of the wedges may be impossible. This will cause the other wedge to be drawn all the way to the back of the anchor cavity, breaking or damaging the strand. Without the hydraulic-seating attachment, the wedges will have to be inserted and seated using a hand-seating tool and a hammer. Tendons that are too short for the above procedure will have to be stressed using a coupler with a short piece of strand fixed on one end of the coupler. Tendons that were cut with a torch prior to stressing have lost some of the temper in the steel due to the heat. If the jack grippers or the coupler grip near the previously heated area, the tendon may slip at a very low pressure. If this condition exists, make the first pull as short as possible (so the stressing pressure is kept low), install the wedges in the anchor, and regrip the tendon farther away from the end that was heated.

12.2.3.6 Lift-Off Procedures

The purpose of a lift-off is to verify the force of a tendon after it has been stressed. A lift-off may be required when the recorded elongation is out of code-recommended tolerance. Project specification may call for a selected force verification using the lift-off method. A lift-off test may be conducted by use of the standard hydraulic stressing jack on previously stressed and anchored monostrand post-tensioning tendons to determine the residual effective force in the tendon at the anchorage. The lift-off test is preferable and most easily done before the stressing tails of the tendons have been cut off. While it may be possible to conduct a lift-off test after the stressing tails have been cut off, this possibility is determined by the length of tendon protruding beyond the wedges in the stressing pocket as well as the possibility of connecting the hydraulic jack to this length of tendon (this may be dangerous). When the tendon is initially stressed and anchored, the wedge seating that occurs develops a mechanical-friction force between the strand, wedges, and anchorage casting. During the lift-off test, it is necessary to stress the tendon in excess of the residual effective tendon force at the anchorage by an amount equivalent to this mechanical-friction force to break the wedges loose and determine the force remaining in the tendon. This process will be reflected during the lift-off test by stressing to a level (reflected on the gauge attached to the ram) sufficient to break the wedges loose and a subsequent reduction in the gauge pressure to reflect the residual force in the tendon. It should be understood that the lift-off test determines the residual force in the tendon at the anchorage. Determination of the force level in the tendon at other locations requires detailed consideration of friction and wedge-seating effects.

12.2.3.7 Cracked Wedges

Hairline cracks may appear in the case-hardened surface of wedges due to deformation of the wedges around the strand at the time of seating. These cracks do not affect the integrity of the post-tensioning system.

12.2.3.8 Shooting Power-Driven Fasteners

The structural designer of an unbonded post-tensioned member should offer detailed information regarding the limited application of power-driven fasteners that may be used on a particular project

member. Frequently, developers are concerned about damage to tendons if future plumbing penetrations are added. This problem can be solved for structures in which changes are anticipated. The dye-transfer technique relies on the dye color marked on the forms to transfer to the concrete soffit after the member is poured. Alternatively, markers may be installed to visually mark the location of each band and tendon bundle.

12.2.3.9 “Hazardous” Statement

The procedures described in this part of Section 12.2.3 may be hazardous. Only qualified experienced personnel, with a minimum of 5 years of specialized experience in the installation and repair of unbonded post-tensioned systems, should attempt these procedures.

12.3 Evaluation and Rehabilitation of Building Structures

12.3.1 Evaluation

Even though concrete is considered to be one of the most durable construction materials, building structures must be evaluated during their useful life for various reasons. Some of the more common reasons may include deterioration (serviceability shortcomings, loss of strength), change in loading of a structure, building modification, overloading (disaster), or simply as an assurance evaluation. The evaluation of an existing unbonded post-tensioned elevated floor system may be divided into three principal activities: (1) examination of the existing floor system and structure (conditional survey), (2) diagnosis, and (3) prognosis or findings. All three steps are necessary before a repair or retrofit can be outlined. The level of evaluation may vary from simple nondestructive examinations and preliminary calculations for initial reporting to rigorous destructive testing with detailed analytical diagnosis of the structure.

12.3.1.1 Examination of an Existing Unbonded Post-Tensioned Floor System

As part of the structural assessment, the engineer should initially complete a detailed survey of the structural floor framing system, geometry, and the “as-is” condition of the structure, including environmental impact. This stage includes the collection of existing information about the structure, surveying the floor system for signs of distress, and establishing a listing of proposed nondestructive and destructive testing based on the distress observed and information gathered. To establish as-built data, the examination should consider the material properties and the detailed survey of the condition of each material and the material configuration or quantity.

The physical testing of concrete may include verification of the concrete compressive strength, material uniformity, mix properties, permeability, and aggregate type. In addition, chemical testing may be performed to establish the concrete constituents, which are used in the evaluation of concrete reactivity or concrete resistivity. The tests should determine the amount of chloride, sulfate, or other materials that may result in a chemical attack on the concrete section of concern. Properties such as the tensile strength of the mild steel and post-tensioning strands may be of interest. Should the tendon anchorage zones be of concern, it may be necessary to test individual elements of the anchorage system.

The material-condition survey of the examination may focus on locations of primary distress but should extend to the comparative performance of the entire structure. Concrete voids (consolidation), delamination, spalling, discolored concrete, chemical attack, excessive air voids, and cracking should be investigated to determine the extent, formation, and amount of concrete damage within the distressed concrete area. In addition to selectively locating the position and amount of reinforcing steel and post-tensioning, the level of deterioration, as a result of corrosion, should be assessed. Specifically, post-tensioned slab edges should be surveyed for exiting tendons or loose grout plugs at stressing ends. The removal of grout plugs at tendon-stressing ends may allow visual assessment of the anchorage zone. Along the tendon length, removal of the tendon sheathing may be necessary to view the condition of the high-strength strand wires at high and low points.

In addition to the factual material-condition review of structural members, the survey should include a performance survey. Besides the typical serviceability considerations, this would include the performance review of joints, hinges, attachments, locations of movement, and locations of restraint. As part of the material-condition survey, each distress location should be assessed using time as one of the evaluating parameters.

12.3.1.2 Diagnosis

After all project documents have been collected and reviewed and after detailed inspection and testing of the floor system of the structure have been performed, the formal process of analytically assessing the existing unbonded post-tensioned floor member takes place. First, the floor framing system should be checked for adequate strength. The selected modeling must accurately represent the actual geometry and boundary conditions using the two-dimensional simple beam frame or the equivalent frame slab strip for a two-way slab. The calculated elastic factored-load moments may be increased by the code-permissible plastification, commonly referred to as *redistribution of moments*. The elastic support moments may be raised or lowered to the maximum percent of the code-permissible redistribution for each respective support. This band of the factored-load moment demand yields a range of acceptable solutions.

After establishing the band of acceptable moment-demand solutions, determine the capacity of the existing structure at critical points. Select a redistribution based on the capacities of the existing structure and the permissible percentages computed, and, finally, establish whether or not the redistribution made on the basis of the existing capacities falls within the permissible range. The demand-vs.-capacity check should include consideration of possible strength loss due to distressed member cross-sections. For conditions where the demand design strength exceeds the capacity of the member, refer to Section 12.3.3, below. For unbonded post-tensioned slabs in particular, extensive destructive testing should be conducted to confirm that calculated member capacity is based on the observed quality and quantity of the tendon.

Serviceability of the unbonded floor system should then be reviewed. Sectional stress checks at critical locations and immediate and long-term deflections should be calculated. The observed distress may reveal a direct relationship to the original design, material sections, construction, or applied loads and maintenance. In most cases, serviceability limitations, such as durability or deferred maintenance shortcomings, initiate concerns that are typically answered by evaluations. The more common serviceability shortcomings include corrosion of strands and anchorage zones, as well as broken strand wires and tendon concrete cover at high and low points.

12.3.1.3 Findings

Assessing a post-tensioned member, particularly one showing signs of distress, is not simply a matter of conservatively selecting the desired material properties and load flow path, as is the case for a newly designed member. After an analytical model representing the unbonded post-tensioned member has been developed, it should be used to perform a detailed review. The objective is to explore the consequences of variation in tested material properties, assumed loading and load distribution, boundary conditions, extent of distress, and rate of material deterioration. As part of a member evaluation process, it is common to apply various modeling techniques in the process of understanding how the structure behaves and where hidden strength reserves may be available. After the diagnosis of the structural element is completed, the engineer should have developed a clear understanding of how the structure behaves and be clear on the causation of distress, including future behavior, considering time and site-specific adverse environmental conditions as additional dimensions. Based on the preceding description, it is obvious that the prognosis is based on a multitude of variables that may only be understood by a reviewer with extensive experience in the evaluation of unbonded post-tensioned concrete structures. In closing, it should be noted that the review or evaluation of an existing post-tensioned member requires the highest degree of professional expertise, knowledge, and integrity from the assessing engineer.

FIGURE 12.16 Tendon exiting at slab edges.

12.3.2 Repair

Unbonded post-tensioned concrete members are considered one of the more difficult structural members to assess for repair or retrofit. It is not uncommon for engineers who are not experienced with unbonded post-tensioning to misinterpret the distress observed. The author frequently encounters assessment reports of crack development that conclude that cracks may have developed as a result of member strength deficiency, where, in fact, the cracks may have developed as a result of reverse tendon-profile curvature or restraint member effects. Even if the assessing engineer correctly found the cause of concrete cracking of the post-tensioned member, the effects that the distress has on the structure and its repair may be grossly misjudged. For this reason, it is not uncommon for proposal requests for evaluation and repair to require the contractors to have a minimum of 5 years of specialized experience in designing, analyzing, and repairing unbonded post-tensioned members. This is a fundamental consideration before assessing the repair of a member. The common repairs outlined below may be used to address distress resulting from poor detailing or construction execution and deterioration of the materials.

12.3.2.1 Blowout

The sudden exiting of a tendon at the slab edge or at tendon profile high or low points, during or after stressing, is typically referred to as *tendon blowout*. In contrast, if the concentrated precompression force behind tendon anchors or the reverse tendon-profile curve causes the sudden disintegration of a localized concrete pocket, it is typically referred to as *concrete blowout*.

12.3.2.1.1 Typical Examples of Tendon Blowout

Tendon blowouts are typically recorded either at the slab edge or on the slab surface or soffit. During the installation of mechanical, electrical, or structural elements, should the contractor partially rupture or cut the unbonded tendon, the tendon tail may eject from the slab edge. The amount of existing slab edge is primarily related to the type of sheathing that was supplied. Extruded tendon should typically result in minimal tendon exiting (up to 3 ft) at slab edges (Figure 12.16). If unbonded tendons are used with a stuffed or heat-sealed sheathing application, the tendon exiting during a sudden release of stored energy may be unpredictable. The minimal void between the sheathing and the creased strand (of stuffed or heat-sealed tendons) limits the internal friction, allowing the stored energy to travel past the existing location. During a sudden release of the entire tendon force, the strand may exit vertically (also known as *vertical tendon blowout*) at locations of minimal concrete cover, typically the high and low points of

FIGURE 12.17 Vertical loop resulting from exit of seven-wire strand.

FIGURE 12.18 Tendon blowout resulting from strands riding on each other.

profiled tendons, due to the vertical component of the draped profile. The seven-wire strand may exit, resulting in a 1- to 3-ft vertical strand loop (Figure 12.17). Conditions noted above may be a result of the accidental cutting of a strand or due to deterioration of the member. *Horizontal tendon blowouts* are typically found where horizontal tendon curves around openings are not detailed and executed correctly. Tendons are typically installed side by side in groups of two to four unbonded tendons. The tension force allows the strands to ride on each other in the horizontal radial plane, creating a splitting force that can result in a tendon blowout (Figure 12.18). Tendon groups should be reduced and limited to groups of two maximum over the length of the horizontal curvature. In addition, adequate reinforcing steel (U-pins) should be added to account for and tie back the centrifugal forces.

FIGURE 12.19 Pulverized concrete behind tendon anchor due to low concrete strength.

FIGURE 12.20 Pulverized concrete behind tendon anchor due to voids.

12.3.2.1.2 Typical Examples of Concrete Blowout

Concrete blowouts are most frequently recognized during the tendon-stressing operation. The anchoring of tendon forces tests the compressive strength of the concrete pocket immediately behind the tendon anchorage. A simple void, rock pocket, low concrete strength, or lack of reinforcing behind the tendon anchor may cause the concrete to pulverize, resulting in a concrete blowout. Figure 12.19 and Figure 12.20 show pulverized concrete behind the tendon anchor due to low concrete strength and voids, respectively. Most concrete blowouts are recognized during the stressing operation or within several months of stressing the tendons. In addition, tendons that are stretched over a longer distance near the concrete surface (i.e., with minimal concrete cover) and that have a reverse tendon-profile curvature may split the concrete section over the distance of reverse curvature to allow the tendon to straighten. This may take place during the stressing operation or at a later date if the concrete section experiences additional concrete stresses due to loading.

12.3.2.1.3 How to Repair Concrete Blowout

Depending on the location and severity of the blowout, adjacent tendons may have to be detensioned before concrete removal can begin. After detensioning (as necessary), the damaged concrete is removed in sufficient amounts to expose any damaged strands and allow the resetting of the anchorages. In some cases, it may be necessary to use couplers in the repair to increase tendon length due to strand damage. It is important that the back side of the opening be cut square and perpendicular to the tendon to avoid slippage of the concrete patch during stressing. Remove all loose debris and clean the surface of dust. Make sure all the anchor zone reinforcements have been replaced, and fill the area to be repaired with a high-strength, nonshrink concrete grout mix. *Do not* use grout that contains calcium chloride or other materials containing chlorides. Stress the tendons only after the grout patch has attained the required design strength as approved by the engineer of record.

12.3.2.2 Tendon Rupture

Tendons may rupture partially if only one wire is damaged or totally when several wires are damaged, causing the remaining wires to fail under sustained tension load. The cause of tendon rupture for tendons should be determined. One of the most critical actions for unbonded post-tensioned structures is to immediately determine the extent of damage. If corrosion is the leading cause of the damage, several tendons should be spot checked to establish the extent of damage to each tendon and the slab area or beams in which damage has been recorded. If preliminary calculation indicates that the loss of the ruptured tendons affects the strength of the unbonded post-tensioned member, the member should immediately be shored. Destructive testing to recover representative strand samples should be considered to record the tendon location, wire condition at the location of rupture, concrete cover, type of sheathing, condition of the crease, remaining cross-sectional area of the seven-wire strand, and other project-specific conditions. When the extent of damage and type of tendon sheathing have been identified, strand replacement or splicing of tendons may be considered.

Strand rupture or breakage can also occur from misalignment of wedges, the anchor to the strand not being perpendicular, overstressing, or internal damage to the tendon. Misalignment of wedges occurs when the two or three parts of the wedges are offset prior to stressing. The wedges can pinch one or more wires due to different circumstances. Internal damage to the tendon could be caused by nicks in the strand or heating of the strand due to torch cutting of adjacent objects prior to concrete placement. Damage can be caused after concrete placement by drilling, saw cutting, or shooting power-actuated studs into the concrete.

If a strand does not hold, remove the wedges, clean the cavity, install new wedges, and restress. Overstressing of a tendon can occur by misreading the pressure gauge or using a jack and gauge that are out of calibration or that are not a matched set. The strand may either break or be stressed beyond yield. If the strand breaks, the engineer of record will determine how the structure is affected and whether replacement is necessary. If the wedges hold and the strand does not break, it is usually preferable to leave the tendon in the overstressed condition. Attempts to detension the tendon may damage tendon or break it necessitating replacement of the strand.

Prior to replacement of existing strands, adjacent strands may have to be detensioned. After exposing stressing and dead ends, it may be advantageous to weld a 1/4-in. wire rope to the existing damaged strand tail, allowing repulling of the new strand. If the existing strand is ruptured, not allowing the rethreading of a wire, the new strand may have to be pushed into the sheathing void by hand. Strand replacement can be effectively executed for unbonded monostrand tendons with heat-sealed or stuffed sheathing. The slightly oversized sheathing typically can accommodate new strands. For long tendons or tendons with extruded sheathing, a smaller size strand, such as 7/16- or 3/8-in.-diameter strands, may be selected. Strand replacement for tendons with paper-wrapped sheathing is nearly impossible. For all strand replacement, adequate creasing application should take place as part of the strand installation procedure.

The substitution of the original 1/2-in.-diameter strand with a smaller strand may be acceptable for the following reasons. Most older structures used stress-relieved type strands that are typically replaced by new low-relaxation strands. Strain tempering is very effective in improving the stress-strain characteristics and has the additional advantage of substantially reducing time-dependent losses due to

FIGURE 12.21 Beam cracking due to incorrect tendon profile high point placement.

relaxation of the strand. Stress-relieved type strands may experience over 10% more loss in stresses due to relaxation than do low-relaxation strands. The stress loss due to concrete shortening may not have to be compensated for.

12.3.2.3 Cracking of Concrete Members

12.3.2.3.1 Crack Development

The most frequent crack development is typically due to restraint of adjoining members. This phenomenon is extensively covered in Chapter 35 of this book. Crack development due to the incorrect installation of the tendon profile or anchors and overbalancing of the member self-weight is in most cases misinterpreted. The incorrect placement of an unbonded tendon profile high point near the quarter span of a beam instead of over the column support has resulted in notable beam cracking approximately two beam depths away from the support (Figure 12.21). In this case, even though the inspection reports and survey of the installation crew confirmed correct placement of the tendons, destructive testing revealed the misaligned tendon profile (Figure 12.22). A simple realignment of the tendon profile reconditioned the beam for its intended life cycle. The layout of unbonded tendons should incorporate appropriate locations for the dead ends and stressing ends of the tendon. The localized concrete zone surrounding groups of added tendons may be subjected to high-tension stresses, which, if combined with flexural stresses, may result in crack development. Figure 12.23 illustrates a significant crack that developed in a post-tensioned beam at the location of added tendon dead ends. The dead ends were not staggered, allowing a load distribution as called for in the standard details.

12.3.2.3.2 Repair of Cracks

The objectives of crack repair on structures with cracks caused by restraint effects tendon profiles or for cracks in anchorage zones, which were surveyed by the author, served the following purposes:

- In most cases, repair was conducted as a precautionary measure to eliminate the exposure of reinforcements and post-tensioning to weather and moisture. In some cases, it was performed to stop leakage.
- It was rarely necessary to carry out repairs to restore structural strength.
- Occasionally, repairs were conducted for aesthetic reasons.

Which cracks should be repaired? Cracks that are determined to be of structural significance should be repaired regardless of width and location. Most such cracks are due to poor design, deficient detailing, or bad workmanship. Cracks that affect the serviceability of a structure, such as deflection and local distress,

FIGURE 12.22 Misaligned tendon revealed by destructive testing.

FIGURE 12.23 Crack in a post-tensioned beam where tendon dead ends were added.

may be left unrepaired if the diminished serviceability is acceptable and the repair is not cost effective. Under normal conditions of service, shortcomings due to deterioration may be encountered if cracks exceed 0.01 in. in width. Such cracks should be sealed to prevent intrusion of moisture and possible oxidization, loss of steel area, and possible spalling. Cracks in structures exposed to especially adverse conditions should be sealed, even if they are less than 0.01 in. in width. Also, cracks that show rust stain should be sealed.

When should cracks be repaired? Restraint cracks are best repaired after the shrinkage and creep shortenings are essentially complete. Generally, a lapse of approximately 2 years after construction is adequate, after which cracks may be repaired. A time delay in sealing of cracks is only justifiable if corrosion considerations permit. Cracks caused by reverse tendon profile should not be repaired until the reverse profile is relieved, neutralizing the cause of cracking.

How should cracks be repaired? Among the numerous reports on methods for sealing cracks in prestressed concrete structures, the most common and effective procedure is the injection of an epoxy resin compound under pressure into the cracks to fill in the crack voids. For details, consult the

manufacturer's literature. For cracks that are nonworking (that is, they no longer move), the best sealing method is to inject the cracks with an epoxy resin of low viscosity. This is done in such a manner that the cracks filled with the resin and the concrete on each side of the cracks are reunited by the gluing action of the resin. Another method is to rout a groove along the crack throughout its entire length and fill the groove with an epoxy compound. The latter scheme is not recommended in highly corrosive environments. Cracks that are working (that is, they open and close as a result of loads, temperature, etc.) cannot normally be successfully sealed with epoxy compounds but must be sealed with flexible sealant that can withstand the movements to which the cracks are subjected.

12.3.3 Retrofitting Concrete Structures Using Unbonded Post-Tensioning

From the mid-1980s to the mid-1990s, a series of natural disasters tested the performance of existing structures on the west and east coasts of the United States. As a result, building-code revisions addressed improved strength and serviceability considerations. The perception of building performance during recent disasters, the ever-changing building codes, and the gradual deterioration of existing structures have sparked increased public interest in the retrofitting of structures. The objective of retrofitting a structure is to modify or improve the strength and serviceability of the existing member. The options of strengthening an existing concrete floor system for gravity loads include the following:

- Adding drop caps, drop panels, or beams at the slab soffit
- Slab overlay that supports the existing slab dead load
- Increase in or jacketing of existing beams, girders, and columns
- Adding columns or remove and replace existing columns
- Adding a gridwork of beams at the slab soffit
- Attaching externally applied metal plates to the existing concrete slab
- External prostrating

The options outlined in the following sections are limited to members being retrofitted with unbonded post-tensioning. It is understood that other elements or connections may have to be strengthened (columns, walls, and foundations and their connections) within the structure as a result of the external tendon retrofit application. The application of external prestressing for nonprestressed or prestressed floors is a widely used retrofit option for gravity-load strengthening and serviceability. The following section differentiates between gravity-load strengthening and serviceability considerations.

12.3.3.1 External Prestressing for Gravity-Load Strengthening

A strength requirement ensures that all elements of the building provide an adequate factor of safety against injury or material damage in the event of a code-specified overload. Slabs with inadequate strength or slabs that are subject to overload initially exhibit significant crack formation in tandem with noticeable deflections. If a thorough evaluation indicates inadequate member capacity for code-predicted factored load demand, the member should be subject to strength retrofit. Using an external unbonded post-tensioning retrofit scheme, the author has used two principal approaches to compensate for the strength shortfall of the existing structure—namely, direct-member strengthening (for one-way slabs and beams) and indirect-member strengthening (for two-way slabs).

Direct-member strengthening is typically used for one-way members such as one-way slabs and beams. First, the engineer should establish the capacity of the existing member and scale the strength shortfall by comparing the established capacity with the load demand. The strength-shortfall compensation may be readily supplied by attaching externally stressed unbonded tendons on each side of a beam. The tendons should be profiled (typically, harped with one or two deviators) so as to uplift or unload the beam equal to or more than the amount of load that the existing capacity cannot safely sustain. The external tendons are only intended to supplement the existing capacity. It may be difficult to establish the capacity of damaged structures or members with highly deteriorated reinforcing. In such cases, the

external post-tensioning may be considered to take all loads. Where anchors are attached to columns or beams, the applied load is retained in the form of precompression in the existing member. The installation of deviators (deflector saddles) or anchors should miss all main member reinforcing.

Indirect-member strengthening, typically used for two-way slabs, takes advantage of the possibility of alternate load passes by using the capacity of the existing structure. Initially, a two-way member may be examined, using code-factored loading, to establish the as-is failure mechanism and locations of hinge formation. The objective is to search for and select an alternative failure mechanism that is capable of safely sustaining the factored loading. Through the addition of external applied post-tensioning upward forces, the failure mechanism may be altered to accomplish this objective. External prestressing, if used to supplement the strength of the member, should be encased in fire-retardant material that meets the fire-resistivity or rating requirements for the particular application.

12.3.3.2 External Prestressing for Serviceability

Serviceability describes the in-service functionality of a building for its users. Excessive out-of-level floors, inadequate drainage, perceived vibration, perceived sagging of ceiling lines, exposure of reinforcement to corrosive elements due to excessive crack widths, and unsightly cracks are the primary serviceability considerations. Serviceability may be influenced by original design, material selection, construction, applied loads, and maintenance. When a structure reflects signs of serviceability shortcomings, such as excessive deflections or cracking, external prestressing has been effective as a corrective retrofit. For example, the installation of tendons at the underside of a slab or at each side of a beam, profiled to result in upward forces where desired, may be an effective and economical retrofit solution. For cracks or deterioration of members, additional work may be required beyond the application of external post-tensioning. The retrofitting of nonprestressed members, using external forces to counteract excessive elastic deflection and plastic deformation, may have to be analyzed using specialized software to model the time-dependent creep deformation. If the application of external tendons is used solely for the purpose of improving serviceability shortcomings in a structure with adequate strength to sustain the code-predicted factored loading, then the tendons may not require corrosion protection if they are aesthetically acceptable.

12.3.3.3 Retrofit Application of External Unbonded Post-Tensioning

The principal considerations for the selection of a retrofit scheme are performance, durability, economy, and appearance. The performance records of external prestressing on hundreds of retrofitted structures across the United States and its versatile and economical application have resulted in today's frequent use of this system. External tendons may be threaded through existing concrete members (such as walls or beams), directly attached to existing elements, or routed over deflector supports. When selecting a particular tendon layout support system, access, available space, fire protection requirements, and aesthetics must be considered. The following section is intended to offer selected examples of the external prestressing installation application. The information on member selection and connections, shown in the details, offers project-specific design information prepared by the author which may not be applicable to other retrofit projects.

12.3.3.3.1 Beam Retrofit

During the course of evaluating the nonprestressed beams of a private parking structure in Woodland Hills, California, excessive post-elastic deformation and concrete cracking were recorded. The use of bundled unbonded tendons on each side of the beam, with one deviator at midspan, was selected to utilize the upward force component to instantly neutralize elastic deflection and to remove the postconstruction plastic deformation (creep) to near zero within a 10-year period after the retrofit was successfully installed. A time-dependent analysis was performed to establish the deformation of the nonprestressed beams during their predicted useful life. A typical elevation and details of tendon attachments are shown in Figure 12.24 and Figure 12.25. An alternative connection of external unbonded tendons is shown in Figure 12.26.

FIGURE 12.24 Schematic of external tendons profiled on each side of the beam: (a) typical elevation, and (b) section.

FIGURE 12.25 Retrofit details.

12.3.3.3.2 Slab Retrofit

During the final construction stages of a hybrid structure (a three-story residential wood framing over a one-story concrete garage) located in Glendale, California, excessive deflection and cracking of the elevated concrete slab were recorded. An initial document review revealed that inadequate reinforcement was specified in the original design. The nonprestressed cast-in-place concrete slab was supported on an array of orthogonally spaced concrete columns. The first-mode failure mechanism of parallel hinge line formation was altered by the introduction of external upward forces along said hinge line (Figure 12.27).

FIGURE 12.26 Alternative connection of external unbonded tendons.

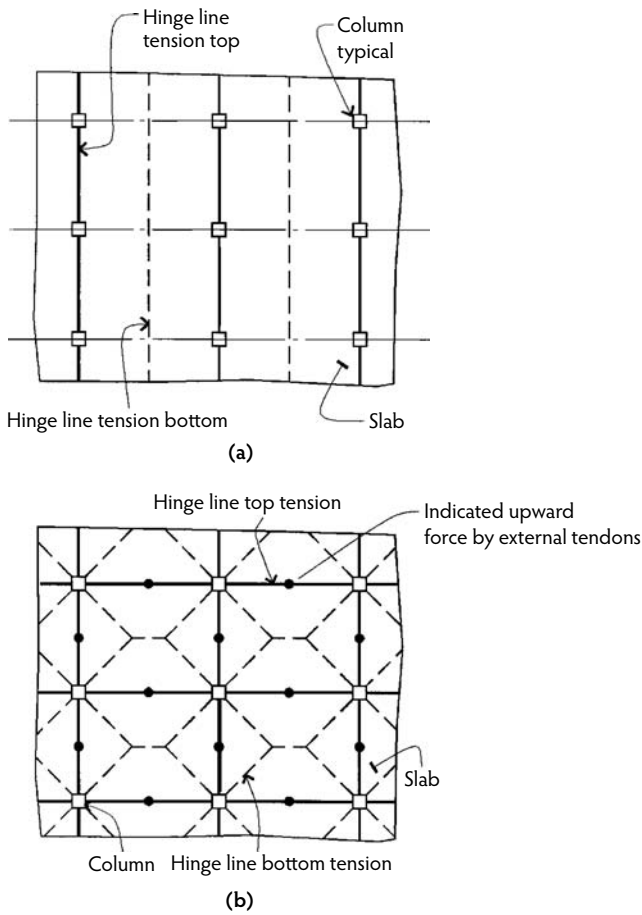

FIGURE 12.27 Simplified failure mechanisms of column-supported slabs: (a) failure mechanism as constructed, and (b) new failure mechanism after retrofitting the slab.

The upward force was calculated, utilizing the existing slab’s capacity, allowing for an alternative failure mechanism with a significantly higher capacity limit. Three principal external tendon layout support systems were proposed.

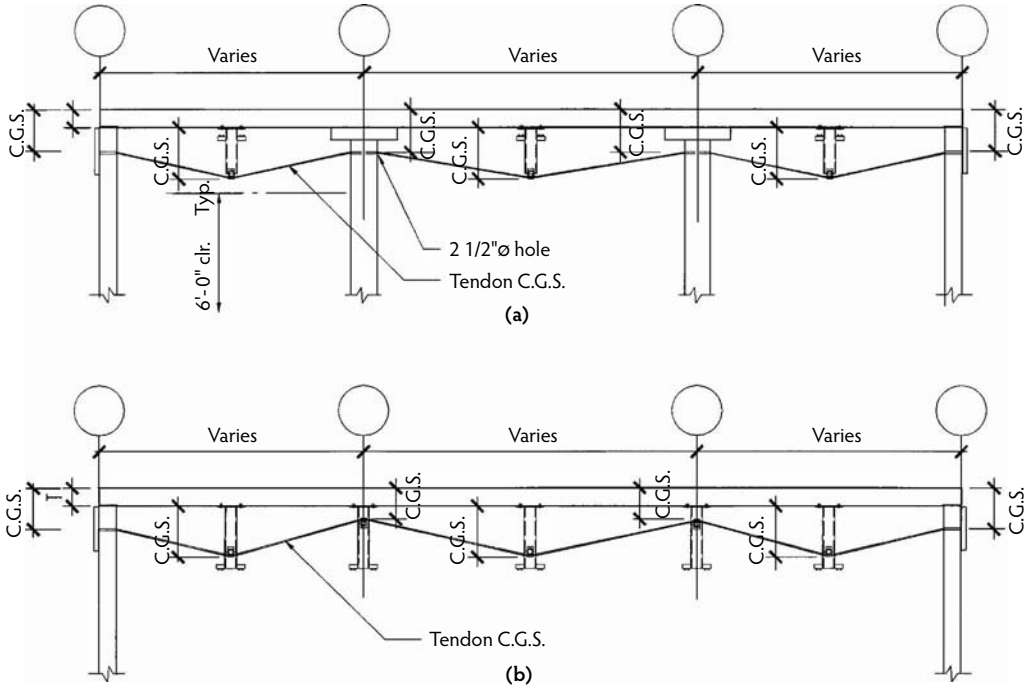

FIGURE 12.28 External tendon layout support systems: (a) typical harped tendon layout at column lines, and (b) typical harped tendon layout at midspan.

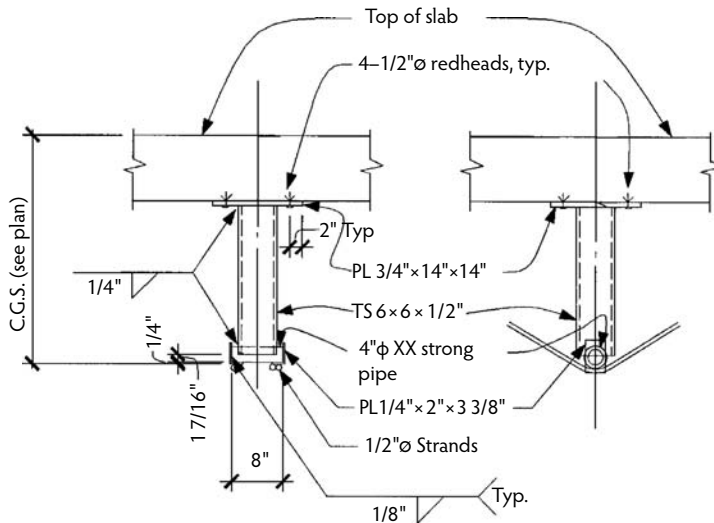

FIGURE 12.29 Typical saddle detail.

The first system consists of simple steel tube deviator or saddle supports anchored at each end of the structure (Figure 12.28 and Figure 12.29). The fabrication and application of this externally applied system can be readily installed around utility pipes and other obstructions. This layout should be considered if adequate headroom is available, allowing for large harped-profile shapes; however, short spans may result in large tendon angular changes over the deviator, which may result in localized damage to the tendons. Aesthetics considerations may be difficult to satisfy, especially if the entire system requires fire-protection coating (Figure 12.30).

FIGURE 12.30 Fire-protection coating.

FIGURE 12.31 Schematic of external tendon at column line: (a) typical elevation, and (b) typical tendon deviator detail.

The second option may allow for using more tendons with a less vertically harped profile and tendons anchored in added drop panels at columns (Figure 12.31). The advantage of this option is that tendons may be discontinued at column lines for localized application, and it may be installed in areas with limited headroom. The concrete for the added column capitals may have to be poured through access holes from above the slab. A fire-protective coating must be applied if external tendons are required to supplement strength shortcomings.

FIGURE 12.32 Retrofit beam and details: (a) typical beam elevation, (b) section 1-1, and (c) rebar through beam.

The third option was added to address fire protection and aesthetic considerations. The objective of this option is to install additional unbonded tendons without the structure retrofitting becoming visible. The tendons are installed within a reinforcing cage reflecting the intended vertical profile (Figure 12.32 to Figure 12.34). A concrete beam is poured at each column grid line to encase the tendons, offering fire protection and concealing the retrofit approach in concrete, hiding the afterthought even to a trained eye. Enough tendons must be selected to balance the dead load of the added concrete beam in addition to achieving the required upward force. The beams are isolated from the existing slab with contact at midspan for upward load transfer. The concrete for the added beams may have to be poured through access holes from above the slab. As this option addresses the durability and aesthetics of the retrofit effectively, the economic penalty of adding a grid of concrete beams may not be of great significance.

12.4 Demolition of Post-Tensioned Structures

12.4.1 Introduction

The purpose of this section is to address the concerns of the industry, primarily contractors and engineers, regarding the unique properties of prestressed concrete that must be addressed to safely demolish structures that contain unbonded prestressing systems and devices. The scope of this section is limited to the structural engineering considerations that must be made to properly evaluate prestressed structures for demolition and not for the purpose of mandating regulatory requirements.

FIGURE 12.33 Details of retrofit using external tendons: (a) plan, (b) section 1-1, and (c) post-tensioning anchor orientation.

FIGURE 12.34 Tendons installed within a reinforcing cage.

The reader is advised to refer to those publications prepared by OSHA (promulgates rules and regulations regarding health and safety in the workplace) and the American National Standards Institute (provides standards for safety during construction and demolition operations). In addition, the National Association of Demolition Contractors' publication *Demolition Safety Manual* covers the use of demolition equipment and safety procedures to be followed for all forms of structures to be demolished including precast and prestressed concrete structures. The recommendations are presented for the guidance and information of professional engineers, who must add their engineering judgment to the application of these recommendations.

12.4.2 Structural Evaluation

The demolition of an unbonded post-tensioned structure should be carefully evaluated by an engineer to ensure safety during all phases of the demolition operation. Shoring that is to be used to support the structure during all phases of demolition, including tendon destressing, should be designed to accommodate vertical loads and horizontal loads, including any associated structural deflections. It is important to account for the loss of strength in multiple spans (over the tendon length) when detensioning unbonded tendons. It is important to secure the slab edge, as the release of energy stored in each tendon can result in sudden exiting of the strand at stressing ends.

12.4.2.1 Material Considerations

Wood and steel structures allow the demolition contractor to stage the demolition sequence and procedures based on the member strength and configuration. Concrete structures have inherent uncertainties with regard to the location, size, splice, prestressing force, and quantity of tensile reinforcing beyond the information provided by original construction documents. The layout and amount of mild and prestressed reinforcing in the continuous beams of frames must be reviewed, accounting for the altered modeling of a span by a span-demolition sequence.

12.4.2.2 Identification of Structural System Used

It is necessary to review available records relating to the design and construction of the building or structure to be demolished. These include design drawings, shop drawings, project specifications, field reports, repair records, job photographs, and correspondence. These records should be retained by the building owner; they may also be available from the engineer or architect of record or the contractor and should be on file with the local building department.

12.4.2.3 Condition Survey of Building or Structure

Prior to demolition operations, an engineering condition survey of the premises should be performed to determine the type and condition of the structural elements to prevent a collapse of any portion of the structure. This survey should include adjacent structures, overhead and underground utilities, and sidewalk vaults that may be affected by the demolition operations. All necessary permits and notices to adjacent owners and utilities should be obtained. The condition survey should include intrusive probes of the slab, girder, and column connections of critical elements to verify both their presence and their condition.

12.4.2.4 Determination of the Condition of Critical Elements

All structural elements reviewed should be to ensure that sufficient load-carrying capacity and stability is maintained for each stage of demolition. Strength capacity may be affected when adjacent supports and lateral load-resisting elements such as shear walls are removed. Strength reduction may already be diminished due to previous damage from fire, corrosion, age, and improper and undocumented alterations to the structure. All structural elements reviewed should be for the controlled release of stored energy in cutting tendons, especially the unbonded tendons. The location and direction of the anchor wedge seating of the intermediate anchors and splices may be of great interest to avoid a progressive collapse in a multi-frame structure. Stability requirements for each stage of demolition should be evaluated. Locations of stair and elevator towers may be isolated from the primary structure and may require special attention. A structural analysis may be required to determine unbalanced post-tensioning thrusts on framed elements, shear forces on wall systems, cantilever construction, continuously designed floor elements, and locations of critical tensile stresses in post-tensioned concrete elements due to temporary loading and unloading conditions. The presence of wind forces and other environmental effects should be considered in the analysis, including temporary crane and equipment loads that may be supported on the structure. The prime concern to be addressed in all demolition of post-tensioned concrete buildings and prestressed elements is the sudden release of stored energy caused by either removing the adjacent concrete cover or

cutting or burning the stressed tendon strands, either intentionally or accidentally, which may cause a sudden uncontrolled collapse to occur. In addition, the possibility exists that anchors and tendons may be released suddenly, resulting in steel ejection at slab edges or blowouts along the tendon length.

12.4.2.5 Preparation of Demolition Plan

A written plan for controlled demolition operations should be prepared that includes the following:

- Identification of anchorage layout within the structure
- Site protection and barriers
- Sequence of dismantling structural elements and demolition of entire assemblies
- Location of all temporary shores and supports
- Location of all equipment loads
- Sequence of cutting strands
- Sequence of cutting partial structural elements
- Control of other site operations
- Preparation of demolition sequence and procedural drawings
- Predemolition survey

12.4.3 Deconstruction Analysis

Mass concrete demolition prior to the mid-1980s was typically executed by positioning equipment such as the crane and impact ball outside the collapse envelope of a structure. This was considered nonengineered demolition or removal of concrete. The demolition contractor's survey of available documents and field conditions were the primary basis for equipment selection and the removal sequence or procedure.

Engineered demolition involves the analytical evaluation of a concrete structure during all stages of demolition to verify the adequacy of its strength and stability. The deconstruction analysis is essentially the reverse process of the original construction of a structure, with revised partial framing and alternative load patterns. Engineered demolition is mandatory for post-tensioned structures if the operator is on the structure or is within the collapse envelope of the structure to be demolished. The contractor should seek experienced engineering advice. The process of engineered demolition should, at a minimum, include a thorough review of the existing condition of a structure, its proximity to other structures, any utilities above and below grade, the preparation of the demolition sequence, the procedures, the assignment of equipment to be used, an analysis of all actual altered structural models, and a stability analysis of the structure considering the member demand (all demolition-load combinations) and the member capacity (remaining concrete cross-section, tendon profile, tendon layout, and location of anchors). Absent design guidelines for engineered demolition of concrete structures, several state agencies have agreed on minimum considerations. The following guidelines have been used on over 50 major engineered demolition projects since 1990.

The intent of the stability analysis is to confirm that the structure to be demolished has the capacity during all stages of demolition to safely support the weight of equipment or other demolition-related loading such as debris loading. The analysis is limited to a strength review only; no serviceability stress checks are considered. Strength-reduction factors are employed as recommended for new construction. Concrete configuration, reinforcing quantity, size of bars, splice locations, and prestressing forces are obtained from the as-built drawings. To calculate the demand or required strength (U), live loads are magnified by a load factor of 1.3 ($U = 1.0D + 1.3L$), except as noted below. The live-load factor is assumed to include an adequate increase for impact loading as the equipment live load is a well-defined load. Where supporting members show minor visual damage such as cracking at beam-column joints or questionable rebar configuration, the live-load factor is increased to 2.0. For damaged sections of the structure, shoring should be considered and installed to support the dead and live load of its respective tributary area. Minimum temporary lateral-load capacity of the structures to be demolished is defined as a horizontal

force, applied at the center of mass of a section, equal to 2% of its own weight. Pinned joints of supporting elements may require lateral bracing during demolition. Adequacy of the structure or a member of a structure to be demolished is established when the capacity/demand ratio is equal to or exceeds 1.0.

12.4.4 Methods of Demolition

The following demolition methods may be used on prestressed concrete structures where applicable and permitted by local regulations.

12.4.4.1 Ball and Crane

The method requires the controlled swing (choking) or dropping of a steel headache ball from a crane. The chief advantage is that the workers are outside of the building collapse envelope during this work. A disadvantage is that it cannot be used on tall structures and on those structures that are close to adjacent ones or in congested urban areas.

12.4.4.2 Explosives

Explosives require experienced personnel to detonate critical building elements to effect a proper controlled collapse of the structure. The chief advantage is that this is a fast method of demolition. Disadvantages include ground and air vibration effects that may damage adjacent facilities. Users of this method should consider the stored energy effects of prestressed concrete when determining the charge levels of the explosives being used. Due to the sudden stored-energy release of unbonded tendons, explosives have limited application for purposes of demolition.

12.4.4.3 Pressure Bursting

This method utilizes hydraulic bursters, gas expansion bursters, and hydraulic jacks to break the concrete into sections. This method is not frequently used and is limited to mass concrete, areas of limited direct access, and other unique conditions.

12.4.4.4 Thermal Lance

This method uses a steel rod in conjunction with oxygen or acetylene to melt concrete aggregates to form a series of boreholes that permit further demolition by other methods such as pressure bursting or the use of hand tools.

12.4.4.5 Torch

Typically, an acetylene torch is used to cut strands by heating the strands, resulting in a yielding behavior of the steel section. This tool is also frequently used to cut reinforcement during demolition as it may interfere with demolition equipment access. Acetylene torches are an effective tool to cut steel embeds and structural steel section connected to the concrete structure.

12.4.4.6 Diamond Saws and Drills

Using diamond plate saws is an effective way to cut a large concrete slab into smaller sections that can be removed and transported. The most common application is to sever concrete to be removed from slab sections that will remain. Line drilling by using cores can be used in slabs and beams.

12.4.4.7 Hand-Held Percussion Tools

These are typically operated from a compressor and are used locally to remove concrete from tendons and reinforcing steel to permit access for torches and other saws to cut the reinforcement.

12.4.4.8 Pneumatic and Hydraulic Breakers

These are large pieces of equipment, such as excavators, special pulverizers, and shear or hammer attachments. They can extract and demolish thick floors with a maximum boom reach of up to 85 ft. Hydraulic crushers are used extensively because the pulverizer separates and processes the base materials during the demolition of a floor or wall.

12.4.4.9 Water Jetting

High-pressure water cuts and removes aggregate from concrete. Very high pressures can cut steel. The disadvantage is that large volumes of water are required during the demolition.

12.4.4.10 Other Methods

Other methods include chemical reactions, cutting by lasers, plasma-arc thermal cutting, and variations of methods previously described.

12.4.5 Other Considerations

12.4.5.1 Type of Construction

The type of original framing and erection should be investigated, as lift-slab framing or other types of unique erection require special attention. Multistory buildings must be shored to allow the dead load of the uppermost slab (slab to be removed) to be distributed to several levels below using reshoring. The deconstruction of a post-tensioned building must consider the reverse construction sequence and reverse removal of structural members of the original construction.

12.4.5.2 Proximity to Other Buildings

Adjacent buildings and structures must be protected during all phases of the demolition. Adequate dust and noise control should be addressed. Adequate limits can be selected for dust and noise and be monitored to satisfy other property owners in densely populated areas. If applicable, vibration measurements should be taken.

12.4.5.3 Accessibility of the Exterior Slab Edge and Beam Ends

Exterior wall assemblies, cladding, or other facades should be safely removed to provide access to exterior slab edge strips and beam ends.

12.4.5.4 Interior Closure Strips

These strips should be carefully opened to release tendon stresses, if applicable. Controlled cutting of one side of the closure strip at a time is required so as not to adversely affect the adjacent concrete slab area of the other side of the closure strip. Adequate shoring of both sides of the closure strip may be required before any cutting proceeds when structural drawings and shop drawings are not available.

12.4.5.5 Intermediate Stressing Joints or Construction Joints

Intermediate stressing joints can be an advantage during the deconstruction of a building. When tendons are severed, the loss of strength may be limited to an area before or after the intermediate stressing joint location. It is imperative for the engineer to understand the location and direction of the intermediate stressing anchor to confirm the direction in which the strength of the slab is retained during detensioning. (See also the description of interior closure strips in Section 12.4.5.4.)

12.4.5.6 Height of Structure

Special consideration for high-rise construction containing prestressed elements may be necessary. Any and all interferences (e.g., power lines), adjacent buildings, and debris disposal during demolition must be carefully considered. It is not uncommon for high-rise structures to be removed in small sections, level by level, similar to a reverse sequence or operation of the original building construction. Any and all elements must be secured during the removal process to minimize the effects of falling debris.

12.4.5.7 Condition of Concrete

A strength evaluation of the *in situ* concrete is advisable to determine the stability of remaining elements of the structure and to determine limits of possible deterioration that has occurred within the structure.

12.4.5.8 Condition of Reinforcement

A strength evaluation of floor systems may be required where severe deterioration of reinforcement has occurred. The designer may use a load test or other methods outlined in Chapter 20 of *Building Code Requirements for Structural Concrete* (ACI Committee 318, 2008).

12.4.5.9 Shoring Requirements

Adequate shoring is required for all phases of demolition. The design of shoring and reshoring is one of the most critical aspects of a demolition plan. A detailed sequence of shoring installation and removal must be offered to give guidance to the contractor and to retain structural stability during all phases of demolition. The shoring plan and installation and removal sequence must be submitted to the local building officials for approval.

12.4.5.10 Protection of Personnel and Public

Adequate site supervision, sidewalk bridges, barriers, and other protective devices should be employed. It is advisable to retain a safety officer on site at all times during the demolition of a concrete structure. Due to the large potential variation between actual construction and old as-built drawings, the engineer (or designated representative) designing the deconstruction of a post-tensioned building should consider remaining on-site at all times to confirm compliance with the removal and demolition sequence. This allows the engineer to verify that as-built conditions match assumptions made on a continuous basis.

12.4.5.11 Partial Demolition

Where a structure is to undergo partial demolition to alter or maintain adjacent parts, special consideration to demolition procedures is required. Lack of consideration for impact loads and sudden stress release may damage existing concrete. The reduction of mechanical energy from pneumatic hammers in areas to be preserved may be limited to 1200 ft-lb or less so as not to fracture sound concrete unnecessarily.

12.5 Defining Terms

Added tendons—Tendons, usually short in length, placed in specific locations, such as end bays, to increase the structural capacity at that location without having to use full-length tendons.

Anchor, trouble-shooting—See troubleshooting anchor.

Anchorage—A mechanical device comprised of all components required to anchor the prestressing steel and permanently transmit the prestressing force to the concrete.

Anchorage, dead-end—See dead-end anchorage.

Anchorage, intermediate—See intermediate anchorage.

Anchorage, live end—See live-end anchorage.

Anchorage zone—The region in the concrete adjacent to the anchorage subjected to stresses (forces) resulting from the prestressing force.

Anchor—For monostrand tendons, normally a ductile iron casting that houses the wedges and is used to transfer the prestressing force to the concrete.

Back-up bars—Reinforcing steel used to control the tensile splitting forces in the concrete resulting from the concentrated anchor force developed by the stressed tendons.

Bearing plate—A metal plate that bears directly against concrete and is part of an overall anchorage system.

Blowout—A blowout is a concrete failure that occurs during or after stressing; a blowout may be explosive in character.

Bonded tendon—A tendon in which the annular spaces around the prestressing steel (strands) are grouted after stressing, thereby bonding the tendon to the concrete section.

Bulkhead—See edge form.

Bursting steel—Reinforcing steel used to control the tensile bursting forces developed at the bearing side of the anchor as the concentrated anchor force from the stressed tendon spreads out in all directions.

Cantilever—Any rigid horizontal structural member projecting beyond its vertical support.

Casting—See anchor.

Chair—Hardware used to support or hold prestressing tendons in their proper position to prevent displacement before and during concrete placement.

Chuck, single-use splice—See coupler.

Coating—Material used to protect against corrosion and reduce the friction of the prestressing steel.

Coupler—A device, normally spring loaded, for connecting two strand ends together, thereby transferring the prestressing force from end to end of the tendon.

Creep—The time-dependent deformation (shortening) of prestressing steel or concrete under sustained stress (load).

Dead-end anchorage—The anchorage at the end of the tendon that is usually installed before the tendon arrives at the project site and that is not used for field stressing of the tendon.

Detensioning—A means of releasing the prestressing force from the tendon.

Edge form—Formwork used to limit the horizontal spread of fresh concrete on flat surfaces such as floors.

Effective prestress—The prestressing force at a specific location in a prestressed concrete member after all prestress losses have occurred.

Elastic shortening—The shortening of a member that occurs immediately after the application of the prestressing force.

Elongation—Increase in the length of the prestressing steel (strand) under the applied prestressing force.

Encapsulated system—A system that provides watertight connections at all stressing, intermediate, and dead ends and that has the wedge-cavity side of the anchorage covered by a watertight cap filled with a corrosion-protective coating material.

Fixed-end anchorage—See dead-end anchorage.

Friction loss—The stress (force) loss in a prestressing tendon resulting from friction created between the strand and sheathing due to the wobble or profile of the tendon during stressing.

Friction, wobble—See wobble friction.

Hand-seating tool—A small, hand-held device used to properly align (seat) the wedges in the anchor prior to attaching the jack to the strand for stressing.

Initial prestress—The stress (force) in the tendon immediately after transferring the prestressing force to the concrete. This occurs after the wedges have been seated in the anchor.

Installation drawings—Drawings furnished by the post-tensioning material supplier showing information such as the number, size, length, marking, location, elongation, and profile of each tendon to be placed.

Intermediate anchorage—An anchorage, located at any point along the tendon length, that can be used to stress a given length of tendon without the need to cut the tendon; normally used at concrete pour breaks to facilitate the early stressing and removal of formwork.

Jack—A mechanical device (normally hydraulic) used for applying force to the prestressing tendon.

Jack-gripper plates—Steel plates designed to hold the jack grippers in place in the jack.

Jack grippers—Wedges used in the jack to hold the strand during the stressing operation.

Jacking force—The maximum temporary force exerted by the jack while introducing the prestressing force into the concrete through the tendon.

Kip—One kip = 1000 lb force.

Live end—See stressing end.

Live-end anchorage—The anchorage at the end of a tendon that is used to stress the prestressing steel (strand).

Monostrand—A single strand.

Multiuse splice chuck—A coupler that uses three-piece wedges and is made of heavier material for repeated use.

Nosepiece—The front part of the jacking device that fits into the stressing pocket to align the jack with the anchor.

Split donut—See troubleshooting anchor.

Split pocket former—A temporary device used at the intermediate end during casting of concrete to provide an opening in the concrete for access by the installer and the stressing equipment to the anchorage area.

Stage stressing—Sequential stressing of tendons in separate steps or stages in lieu of stressing all the tendons during the same stressing operation.

Strand—High-strength steel wires twisted around a center wire. For unbonded tendons, seven-wire strand conforming to ASTM A 416 is used almost exclusively.

Stresses—Internal forces acting on adjacent parts of a body.

Stressing end—The end of the tendon at which the prestressing force is applied.

Stressing equipment—Consists normally of a jack, pump, hoses, and a pressure gauge.

Stressing force—See jacking force.

Tendon—A complete assembly consisting of anchorages, prestressing steel (strand), protective coating, and sheathing; the tendon imparts the prestressing force to the concrete.

Tendon, bonded—See bonded tendon.

Tendon, unbonded—See unbonded tendon.

Tensile stresses—Internal forces directed away from the part of a body on which they act.

Tension—The effect of tensile forces on a body.

Trouble-shooting anchor—A special anchor used for structural modification or repair of existing tendons. The anchor consists of a removable segment that allows it to slide onto an existing strand; the segment is then returned and tightened by a screw or bolt.

Unbonded tendon—A tendon in which the prestressing steel (strand) is prevented from bonding to the concrete and thus is free to move relative to the concrete; therefore, the prestressing force is permanently transferred to the concrete by the anchorage only.

Wedge set—The relative movement of the wedges into the anchor cavity during the transfer of the prestressing force to the anchorage, resulting in some loss of prestressing force.

Wedges—Pieces of tapered metal with teeth that bite into the prestressing steel (strand) during transfer of the prestressing force. The teeth are beveled at the front end to ensure gradual development of the tendon force over the length of the wedge. Two-piece wedges are normally used for monostrand tendons.

Wobble friction—The friction caused by the unintended horizontal deviation of the tendon.

Note: Local practices, customs, and usage may employ terminology, jargon, and nicknames different from the terms and definitions set forth in this chapter. Check with the local engineering community or other qualified person to clarify terms and definitions.

13.1 Introduction

Concrete has a long history and a significant and successful presence in offshore and marine applications. Throughout this chapter, reference will be made to things that are onshore, inshore, and offshore. *Onshore* is connected to the land, such as a pier or bridge might be. *Inshore* means that the location is away from the land but is close enough to the shore to be in protected waters with respect to the open sea. *Offshore* means that it is located in the open sea. The term *owner* is also used. The owner of an offshore, inshore, or onshore structure can be a single company, a collection of companies who retain varying percentages of the operation but who have designated a single company to operate and maintain the facility, or some level of government ownership.

Offshore concrete structures are generally understood to be those structures exposed to an open-sea environment (ACI Committee 357, 1989; FIP, 1985). They are designed to remain permanently or semi-permanently fixed to the seabed by gravity, piles, or anchors or to remain afloat and moored. They are

* President, Hoff Consulting LLC, Clinton, Mississippi; past-president, American Concrete Institute; past chairman, Commission 10 (Construction), Fédération Internationale du Béton(fib); past chairman, Materials Directoraté of ASCE; expert on offshore concrete platforms and marine structures and on concrete behavior under severe conditions.

often associated with the exploration and production of hydrocarbons but may have many other specialized uses. Inshore concrete structures are also exposed to seawater but are not necessarily exposed to the harsh environmental loads experienced by offshore structures. They also are designed to remain permanently or semipermanently fixed to the seabed by gravity, piles, or anchors or to remain afloat and moored. Onshore concrete structures may or may not be exposed to seawater. They are commonly referred to as *marine structures* and include berthing and mooring structures for marine transportation, seawater crossings for inland transportation, structures for marine navigation, facilities for shipbuilding and ship repair, shore protection and recreational facilities, wave attenuation structures, floating plants and pump stations, and other special structures. Most of these structures have a direct connection to the land. Marine structures on rivers have the same or similar design and structural requirements as marine structures in contact with the sea but generally do not require as strict durability considerations depending on the environmental exposure.

Like most other types of concretes, those for use in offshore structures are usually made with local materials by local labor in conformance to local guidelines or specifications; thus, they can vary widely in quality. Depending on the particular application, their strengths can vary from 25 to 65 MPa (3600 to 9500 psi). All such concretes must be extremely durable. Once in service, maintenance becomes very difficult due to the hostile environment and is very expensive. Some offshore concrete platforms have design lives of 50 to 70 years.

The use of concrete in marine structures dates back to the ancient Greeks and Romans, and remains of some of their constructions still exist. The first use of reinforced concrete in a floating vessel is attributed to Lambot who, in 1848, constructed a boat by applying sand-cement mortar over a framework of iron bars and mesh. One of Lambot's boats survives today in a museum in France. The use of concrete as a hull construction material for commercial vessels began at the end of the 19th century (Harrington, 1987). Initial applications were generally used worldwide and consisted of concrete barges and pontoons. The first reinforced concrete seagoing ship was the *Namsenfjord*, constructed in Norway in 1917 by N.K. Fougner. Fougner went on to build several larger self-propelled reinforced concrete vessels. The first concrete platform for oil and gas production in the Gulf of Mexico was installed in 1950. Since that time, more than 1000 functionally similar concrete structures have been built in that area (Norwegian Contractors, 1991a). The first concrete gravity-base structure in U.S. waters was installed in 1978 (Huntman et al., 1979). The first large offshore concrete platform for the North Sea (Ekofisk Tank) was installed in 1973. Three concrete caisson structures, functionally similar to the Ekofisk Tank, were built in Brazil in 1977 and 1978 for South American offshore waters (Anon., 1988a). In recent years, similar offshore concrete structures have been built for use in Germany, the Netherlands, Australia, the Philippines, Nigeria, Russia, Italy, and Canada. Significant offshore and inshore floating concrete structures have been built for use in Japan, Indonesia, and the Congo.

13.2 Types of Concrete Structures

Offshore, inshore, and onshore structures can generally be either bottom founded or floating. Many of the bottom-founded structures are also required to float at various stages of their life. The following descriptions of various types of platforms are very brief but are meant to give the reader a feeling for the enormous versatility that can be realized when concrete is used.

13.2.1 Bottom-Founded Structures

Bottom-founded structures can be further identified as:

- Gravity-base structures
- Concrete cylinder pile-supported structures
- Floatable/bottom-founded concrete-hull structures

Examples of each are shown in Figure 13.1, Figure 13.2, and Figure 13.3.

FIGURE 13.1 Typical gravity-base structure.

FIGURE 13.2 Typical cylinder-pile-supported platform.

The gravity-base structure (GBS) (Figure 13.1) maintains its position on the sea bottom because of its very large weight. The sliding force and over-turning moment due to the maximum environmental loads are resisted by the weight of the concrete, the operating weights on the structure, and any additional ballast weight that is contained within the structure. This type of structure is common for hydrocarbon exploration and production. The produced oil must be temporarily stored before being removed to a tanker or pipeline. The practical range of water depths for these platforms is 40 to 350 m (130 to 1150 ft). These structures are built at onshore or inshore locations and floated out to their final location. They can also be refloated

FIGURE 13.3 Floatable/bottom-founded structure. (Figure courtesy of Production Management Structural Systems, New Orleans, LA.)

when platform removal is required (Anon., 1990a). More detailed descriptions of these types of platforms can be found in ACI Committee 357 (1989, 1990) and FIP (1985). Figure 13.4 shows the wide variety of offshore concrete platforms that were built in Hinna, Norway, using a construction dry dock and a deep-water fjord for multistage construction.

Concrete-cylinder-piled structures (Figure 13.2) were the earliest type of concrete offshore platform used. The first platform of this type in the Gulf of Mexico was installed in 1950. More than 1000 of these platforms have been installed in Lake Maracaibo in Venezuela (Norwegian Contractors, 1991a). They consist of an array of prestressed concrete piles that are driven into the seabed. The piles are arranged so a prefabricated template deck can be placed over the array to form the working surface of the platform. The decks can be made of concrete or any other suitable construction material. Concrete jackets are often placed around the piles in the splash zone and boat-impact region of the platform. Steel cross bracing between piles may also be used to stiffen the overall arrangement when the piles become fairly long. The practical range of water depths for these platforms is from 5 to 20 m (16 to 65 ft). The use of concrete cylinder piles is also common for the support of docks, wharves, bridges, and roadways over water.

Floatable/bottom-founded concrete hull platforms generally consist of a barge-like concrete hull that is designed to float. Extending upward from the hull are posts or columns that act as the support frame for the platform (Figure 13.3 and Figure 13.5). These posts or columns can be made of concrete or steel. The hull is floated to its desired location and then water-ballasted down until it sits on the seabed. It is then pinned to the seabed by spud piles around its perimeter. These piles maintain the position of the platform and help resist sliding and overturning, as the platform does not have sufficient on-bottom weight by itself. Once the hull is piled into position, the topsides deck and equipment are usually added using a crane barge. This type of platform has many variations. It can accommodate some subsea storage of oil in the hull. The practical range of water depths for these platforms is from 4 to 30 m (13 to 98 ft).

FIGURE 13.4 Concrete structures constructed at Hinna, Norway. (Figure courtesy of Dr. techn. Olav Olsen, Lysaker, Norway.)

FIGURE 13.5 Eighteen-year-old floatable/bottom-founded platform after refloating and relocation to wet dock for equipment modifications.

Platforms of this type that are in use in the Gulf of Mexico have, on numerous occasions, been refloated and reused at different locations. Table 13.1 provides a listing of this type of structure constructed by one firm for the Gulf of Mexico and shows typical concrete hull dimensions, and Table 13.2 provides a summary of larger platforms built in various locations around the world.

In the 1990s, there was considerable interest around the world in developing offshore reinforced concrete liquefied natural gas (LNG) receiving terminals. These terminals are bottom-founded structures that would allow the berthing of ocean-going LNG carriers and subsequent off-loading of the LNG into the concrete terminal. The LNG would then be re-gasified on the structure and sent through pipelines

TABLE 13.1 Summary of Floatable/Bottom-Founded Concrete Hull Structures for the Gulf of Mexico Constructed by One Contractor between 1984 and 1989

Year Installed	Location	Water Depth		Hull Dimensions (width × length × height)	
		m	ft	(m × m × m)	(ft × ft × ft)
1984	Eugene Island, Block 45	6.1	20	17.7 × 17.7 × 3.7	58 × 58 × 12

Gerwick, Inc., San Francisco, CA, for Norwegian Contractors, Joint Industry Project on Concrete for Gulf of Mexico, Floating Production Platforms, 1991.

to shore, where it would be introduced into various distribution or end-use systems. The use of an offshore terminal eliminated the need for deep-water harbor facility and satisfied many concerns of the general public about having a terminal near their homes. Various concepts were proposed; some had the LNG contained in tanks or membranes within the reinforced concrete structure, others had the LNG stored in the concrete in direct contact with the concrete, and some had LNG tanks partially contained in a concrete barge with the top of the tanks extending above the barge. The LNG, at a temperature of -167°C (-269°F), could be placed against the concrete with no adverse effects. Onshore LNG storage tanks with the LNG in direct contact with the concrete walls have been built in Philadelphia, Pennsylvania, and in Spain in the 1970s and have provided excellent service to date. Figure 13.6 shows an artist's concept of a proposed offshore reinforced concrete LNG terminal. Figure 13.7 and Figure 13.8 show the Isola di Porto Levante LNG terminal that will be located approximately 17 km (10.6 miles) off the coast of Italy in the North Adriatic Sea in 30 m (98 ft) of water. The structure was built in Spain and towed to the project site and is expected to begin operation in 2008.

Other types of bottom-founded concrete structures that are fabricated elsewhere and floated to their final location before installation include bridge piers, sea walls, river navigation structures, dams, and marine caissons. These precast structures are usually thin-shell floating structures with internal ballasting compartments. The innovative methods used for these types of structures offer substantial benefits in cost, construction time, risk reduction, and facility utilization while reducing environmental impact.

13.2.2 Floating Structures

Floating structures are those structures that will perform their operational function while in a floating mode. These structures require a permanent mooring system. In general, the current family of floating concrete structures includes:

- Concrete tension-leg platforms (TLPs)
- Deep-draft concrete floaters (DDCFs)
- Industrial plantships
- Floating bridges
- Floating piers and docks

Examples of each are shown in Figure 13.9 through Figure 13.17. Large concrete buoy-type floating structures have also been conceptualized.

Concrete tension-leg platforms (TLPs) (Figure 13.9) derive their name from the fact that they are fastened to large anchors on the seabed by long tethers that have a predetermined amount of tension in them. These tethers, which originate at the corners of the platform, keep the floating platform in a very precise position. The platform itself can have various configurations but generally resembles the semisubmersible drilling rigs that are common throughout the offshore petroleum industry. It consists of an

FIGURE 13.9 Concrete tension leg platform (TLP).

to be carried. Current designs have ranged as high as 50,000 tonnes (55,000 tons). A variation of the DDCF is the spar buoy platform (Figure 13.11). Because of the low center of gravity and heavy weight of the concrete, it is relatively insensitive to the motion of the sea. The spar buoy platform can accommodate crude storage, if desired. It also requires a mooring system (Anon., 1991).

Industrial plantships (Figure 13.12) are custom-built prestressed concrete barges that provide a support surface for the processing equipment, work and storage areas, and living quarters necessary for offshore oil and gas production or for any other industrial applications. Process applications for reinforced concrete plantships include fertilizer production, manufacturing plants, refineries, desalinization plants, electrical power stations, chemical treatment facilities, tidal power generation facilities, and liquefied natural gas (LNG) and liquefied petroleum gas (LPG) terminals.

For hydrocarbon production, drilling is usually not done from these barges but is done from special drilling vessels or jack-up rigs. The production wells are usually located on a nearby unmanned fixed platform. The entire barge or selected portions of the barge can be built in concrete. A mooring system must be provided for the barge. Produced oil and other partially processed fluids can be accommodated in the barge; large floating concrete oil-storage facilities have been built in Japan. The size of the barges

is influenced by the sea states in which they must operate and the amount of working area they must provide. The water depth in which a barge can operate is a function of the draft of the barge and the operational sea states. A notable production/storage concrete barge is the Ardjuna Sakti LPG barge currently on station in the Java Sea (Figure 13.13) (Anderson, 1977). A thoroughly developed concept for the production of LNG is shown in Figure 13.14. For this structure, the gas wells are drilled from the floating reinforced-concrete barge. The vapor gas is then processed into liquid form and stored in the reinforced concrete hull until it can be off-loaded into LNG tankers that moor adjacent to the barge. More detailed information on concrete barge-like structures and concrete hulls can be found in ACI Committee 357 (1988, 1989) and Harrington (1987).

The concept of floating bridges goes back to ancient times, when river crossings were frequently accomplished by adjoining rafts of floating timber or by placing a hard surface over boats or pontoons that were in contact with each other from one side of the river to the other. These generally were temporary, seasonal structures. The use of floating concrete elements in modern times for water crossings has provided an optimum and cost-effective solution for some difficult sites and for special applications.

In the United States, two well-known examples of floating bridges are the Hood Canal Bridge (Abrahams and Belvedere, 1984; Nichols, 1964) and the Ford Island Bridge (Abrahams and Wildon 1998). The Hood Canal floating bridge crosses Puget Sound in Washington (Figure 13.15). The structure was originally opened for traffic in 1960 and was modified from 1979 to 1982, with portions being reconstructed and replaced. The bridge is 2347 m (7863 ft) long, including approach ramps. The floating concrete portion is 1973 m (6471 ft) long and consists of normal weight, prestressed concrete pontoons having a compressive strength at 10 days age of 21 MPa (3000 psi). The pontoons were built in a graving dock in Seattle and towed to the site in 1959 (Anon., 1983).

The Ford Island Bridge, across Pearl Harbor to connect Ford Island and the island of Oahu in Hawaii, was completed and opened in 1998. The bridge includes a causeway 305 m (1000 ft) long, a 1219-m (4000-ft) fixed trestle, and a movable section 315 m (1035 ft) long. The moveable section consists of two steel transition spans and a 284-m (930-ft) floating drawspan with its two ends extending under the transition spans. The floating drawspan is made up of three floating concrete modules, each 94.5 m (310 ft) long, 15.2 m (50 ft) wide, and 5.3 m (17.5 ft) deep. The pontoon modules were constructed with a combination of precast and cast-in-place concrete. Each pontoon was post-tensioned longitudinally. The three pontoons were tied together with high-strength bolts to provide the entire drawspan. Figure 13.16 shows the precast prestressed floating drawspan being retracted under the bridge spans so a large Navy vessel can pass through. The floating section was fabricated in Tacoma, Washington, and towed to Hawaii for on-site assembly and installation.

Another example is the use of floating concrete pontoons in the very deep fjords of Norway. The width and depth of the fjords often make it too expensive to use typical bridge piers to support the bridge deck or long-span bridge elements. Figure 13.17a shows the Norhordland Bridge across the Salhus fjord in Western Norway. It is a combined floating bridge and cable-stayed bridge that was opened in 1994. The total length of the bridge is 1616 m (5302 ft), with a floating portion that is 1246 m (4088 ft) long. The superstructure is supported by 10 floating concrete pontoons designed in lightweight aggregate concrete (LWAC) with a density of 1900 kg/m³ (118.6 lb/ft³) and a concrete cube strength of 70 MPa (10150 psi). The pontoons are 42.0 m (138 ft) long and 20.5 m (67 ft) wide, with each side curved with a radius of 10.25 m (33.6 ft); each pontoon has nine compartments. Figure 13.17b shows construction of the pontoons in a dry dock. They were floated from the dry dock to the bridge site for installation.

Numerous concrete floating piers, docks, and quays exist throughout the world. They vary in size from small fishing boat docks to very large docks for container ships, ferry boats, and cruise ships. They typically are moored in such a manner that allows them to move up and down with tidal fluctuations or seasonal changes in water level. One example is a precast, prestressed concrete container dock at Valdez, Alaska (Figure 13.18) (PCI, 1982). The dock is 30 m wide, 210 m long, and 9 m deep (100 × 700 × 30 ft) with a mooring system to hold it in place and a fender system that protects both the dock and the ships during berthing operations. The segments of the dock were fabricated in Tacoma, Washington, and towed to Valdez, where they were joined together on-site.

FIGURE 13.18 Valdez, Alaska, floating container pier.

Another example is the twin ferry terminals on either side of Burrard Inlet in Vancouver, British Columbia, Canada (ABAM, 1986b). Each terminal is E-shaped in plan and consists of four cellular concrete modules post-tensioned together to form a single integrated unit. The concrete modules were cast in a graving dock and post-tensioned together prior to floating them out. While they were afloat, the decking of the individual modules was completed. The completed modules were joined together by post-tensioning through the cast-in-place joints. Normal weight concrete with a 28-day design compressive strength of 48 MPa (7000 psi) was used throughout.

Figure 13.19 shows the floating pier that was installed at the entrance to the Harbor at Monaco on the Mediterranean Sea. This very large structure was built in Spain and towed to its present site. In addition to providing a berth for ships, it also includes car parking in the structure.

13.2.3 Other Structures

Concrete subsea oil-storage tanks (Anon., 1984, 1986, 1988b) (Figure 13.20) have been proposed for use in water depths ranging from 20 to over 400 m (65 to over 1300 ft). These tanks can be built like the base of a GBS but are fully submerged to the seabed, where they function as a gravity-base structure. Concrete wall caissons (Figure 13.21) have been used to provide retaining walls for earth-filled islands. These islands provide the working surface for oil and gas exploration and production. The caissons are built as floating units, towed to location, joined into a unit, and then ballasted to the seafloor. The framework of the caissons then forms the perimeter of an island. A hydraulic fill is usually used to fill the interior. When the use of the caisson-retained island is complete, the caissons can be refloated and disassembled, and nature is allowed to reclaim the island. A notable application was the Tarsuit Caisson Retained Island (Fitzpatrick and Stenning, 1983), where the caisson was made of lightweight aggregate concrete. Concrete caissons for an artificial island were a strong contender for development of the Wytch Farm prospect in the offshore southern United Kingdom (Anon., 1990b). The use of caissons for artificial islands is generally limited to water depths of less than 15 m (50 ft). Reinforced concrete segments were used to construct an underwater tunnel to connect Amsterdam with surrounding areas (Gimsing and Iversen, 2001). The reinforced concrete segments were constructed in a dry dock and assembled into units 135 m (440 ft) long that were then floated to the tunnel site. The Oresund Crossing, a fixed traffic link between Denmark and Sweden, used 20 precast concrete segments to form a 4050-m (13,290-ft) immersed tunnel. The tunnel segments were fabricated in a casting yard in the Copenhagen North Harbor and towed approximately 16 km (10 miles) to the project site for immersion. Figure 13.22a shows the Bjorvika project in Oslo, Norway, that used a submerged concrete tunnel to connect two existing rock tunnels (Maage et al., 2007). The immersed tunnel, which is 675 m (2215 ft) long, is divided into six segments that were produced in a dry dock on the West coast of Norway (Figure 13.22b). After floating from the dry dock, they were then towed approximately 800 km (500 miles) to the project site.

Concrete has been used for the base of flare towers and offshore loading buoys. An entire flare boom tower made of concrete was proposed for the *Slieper* platform in Norway, and concrete anchors for the *Snorre* TLP have been built (Anon., 1990c). The *Maureen* offshore development uses a concrete offloading buoy. *Oseberg II* in the North Sea utilizes concrete subsea wellhead protectors (Norwegian Contractors, 1990). The potential for concrete use is great and is limited only by the ingenuity of the concrete designer and constructor.

As many oil and gas fields are depleted, it is necessary to remove offshore steel platforms due to the OSPAR Convention. For the North Sea alone, this represents a market value of some \$US10 billion. This market potential initiated the development of a robust, inexpensive reinforced concrete heavy lifter (MPU Heavy Lifter) (Maage and Olsen, 2000; Olsen, 2000; www.mpu.no). It is a concrete, U-shaped semisubmersible that utilizes the simple principle of Archimedes to lift straight up (Figure 13.23). Construction of the Heavy Lifter was begun in 2007.

Holland Symposium on Advances in Concrete Technology*, 9th CANMET/ACI International Symposium on Fly Ash, Silica Fume, Slag and Natural Pozzolans in Concrete, Warsaw, Poland, 2007.)

13.3 Concrete Quality

There is a perception that all concrete used in offshore and inshore platforms is something unique and special and requires a technology that is beyond normal practice for concrete construction. If *normal practice* means the practice applied to residential construction, then this perception is correct. If *normal practice* means practices applied to any major civil-engineering structure such as a building or bridge, then this perception is wrong. There is nothing unique or special in the application of proper batching, delivery, consolidation, and curing of properly proportioned concrete mixtures. In general, the recommended practices for concrete construction, including materials selection and mixture proportioning, that exist in the various building codes, specifications, and standard practices of most developed countries

FIGURE 13.23 Reinforced concrete MPU Heavy Lifter. (Figure courtesy of Dr. techn. Olav Olsen, Lysaker, Norway.)

are entirely sufficient for use in the offshore concrete industry. Somewhat different values for the water/cementitious materials ratio, cementing material content, and concrete cover over reinforcing bars may be required because of marine exposure, but these values are well documented. Examples are given in Table 13.3 and Table 13.4.

The concrete provided for offshore North Sea platforms has seen a gradual evolution of cube compressive strength from 50 to 70 MPa (7200 to 10100 psi) (Moksnes, 1989). Table 13.5 shows the strength development for platforms built by one North Sea contractor. The unique environment in which this concrete is used demands such high quality of concrete. The Ravenspurn North platform (Jackson and Bell, 1990; Roberts, 1990) was built in a more moderate environment in the southern part of the North Sea and required only 50-MPa (7250-psi) concrete, which was delivered from local ready-mix suppliers. The early concrete platforms made in the Gulf of Mexico used concrete with cylinder compressive strengths from 25 to 35 MPa (3600 to 5000 psi). Samples from some 33-year-old platforms in the Gulf of Mexico showed an increase in strength from 50 to 69 MPa (7200 to 10,000 psi) over the life of the structure (Hoff, 1991a; Tate and Core, 1989). The actual strength required for a given structure depends on a large number of factors but is significantly influenced by environmental and operating loads. When these loads are small, the strength of the concrete can usually be consistent with that commonly made in the region of the construction.

13.4 Concrete Materials

As noted in Section 13.1, the constituents of the concrete can be local materials. They must be evaluated, however, to ensure that they have the proper concrete-making characteristics and that they will be durable in the environment in which they are used. Most offshore concrete platforms have a service life of 20 years or more. Because of their offshore location, they are not easily accessible for remedial work when problems occur. To eliminate the high cost of future offshore repair work, the materials used and the resulting concrete must be virtually maintenance free for the service life of the structure.

The durability of offshore and marine Portland cement concrete is generally defined as its ability to resist weathering action, chemical attack, abrasion, or any other process of deterioration while still retaining its original form, quality, and serviceability when exposed to its environment. This includes resistance to deterioration from freezing and thawing action; chemical attack by the constituents of the seawater; physical abrasion due to wave action, floating or suspended solids and debris, and floating ice; corrosion of steel or other metals imbedded in the concrete; and chemical reactions associated with aggregates in the concrete (Tate and Core, 1989). When considering these deteriorating actions collectively, it can be easily deduced that the most aggressive exposure that a concrete can

TABLE 13.3 Summary of Relevant Code Requirements for Water/Cement Ratio, Cement Content, and Compressive Strength

Codes ^a	Exposure Zones		
	Submerged	Splash	Atmospheric
<i>ACI 357</i>			
Maximum water/cement ratio	0.45	0.40	0.40
Minimum cement content, kg/m ³ (lb/yd ³)	356 (600)	356 (600)	356 (600)

^b If subject to abrasion.

^c 320 kg/m³ (540 lb/yd³) for a maximum aggregate size of 40 mm (1.57 in.); 360 kg/m³ (610 lb/yd³) for a maximum aggregate size of 20 mm (0.78 in.). Cylinder strength is assumed to be 80% of specified cube strength.

routinely experience is in a tidal zone in freezing weather. For most offshore structures, the most prevalent of the destructive mechanisms is the corrosion of reinforcing bars associated with ingress into the concrete of chlorides from the seawater.

Portland cements should have as low a tricalcium aluminate (C_3A) content as is practical with the local cement production. This helps to reduce the possibility of attacks from sulfates. The total alkali of the cement, calculated as sodium oxide, should not exceed 0.60% to minimize any potential for reactivity with the aggregates. The cement should have some finely divided siliceous material added to it (Hoff, 1991a). This includes natural pozzolans, fly ash, granulated slag, or condensed silica fume. These products contribute to the formation of a dense binder that inhibits the migration of the seawater into the concrete. They also combine with the alkalis to reduce the amount of available alkalis.

TABLE 13.4 Summary of Relevant Code Requirements for Minimum Concrete Cover

Codes ^a	Exposure	
	Splash or External Atmospheric	Other
ACI 357		
Untreated reinforcing bars	65 mm (2.6 in.)	50 mm (2.0 in.)

Coarse aggregates can be either normal-density gravel or crushed stone or good-quality lightweight aggregate. The aggregates should be evaluated with respect to their potential for reactivity with the alkalis in the cement. Those aggregates that are potentially reactive should not be used. Aggregates from areas in close proximity to the sea should be checked for concentrations of sea salts. These salts

must be washed from the aggregate before it is used. Fine aggregates can be either natural or manufactured sands. They, too, must be nonreactive and free from deleterious materials. In no instance should seawater or brackish water be used to make the concrete. All mixing water should be potable. Washing of aggregates should also be done with potable water.

Chemical admixtures are essential for the production of durable marine concrete. Air entrainment is necessary when cycles of freezing and thawing can occur. High-range, water-reducing admixtures (HRWRAs), commonly called *superplasticizers*, are required for both consolidation assistance and for improved durability. A HRWRA will allow mixing water reductions of up to 30% without sacrificing workability. This water reduction significantly reduces the permeability of the concrete and contributes to a densification of the binder fraction of the concrete.

13.5 Concrete Properties

Of importance to structural designers are the properties of construction materials at an age when appreciable loads are applied to the structure. For most offshore structures, maximum loadings occur when the structure is put into service. This can vary from 1 to 5 years from the start of construction, depending on the size and complexity of the structure and its ultimate use. The properties of hardened concrete that are used by the designers of offshore concrete platforms include:

- Compressive strength
- Tensile strength
- Modulus of rupture
- Modulus of elasticity
- Poisson's ratio
- Stress-strain relationships
- Fatigue strength
- Absorption
- Shear strength
- Creep and shrinkage
- Shear-friction capacity
- Bearing strength
- Thermal properties such as the coefficient of thermal expansion, thermal conductivity, specific heat, and diffusivity

The numerical value of each of these properties is generally not critical because the design process can usually use whatever values the selected concrete produces. The specific properties, however, may not always be complementary; for example, a very high compressive strength concrete (e.g., 65 MPa, or 9400 psi) may allow compressive structural members to be reduced in cross-section for a given loading. If, however, the corresponding increase in the modulus of elasticity of that concrete allows cracking to occur at lower strain levels, then additional reinforcement may be required to reduce the cracking. Because the cross-section has now been reduced, the additional reinforcing steel adds to the congestion within the wall and makes concrete placement more difficult. The cost of the in-place reinforcing steel may also be more than the reduction in cost due to using less concrete. Trade-offs between the various properties of the concrete should be attempted, where possible, to achieve the most efficient and cost-effective design.

All of the hardened concrete properties should be determined at advanced ages for the specific concrete to be used in an offshore structure. Unfortunately, this is not always possible, and early-age properties (e.g., at 28 days) are often used. This gives the design a conservative flavor, but it may add substantial costs to the structure. There is a risk associated with extrapolating early-age data, particularly with high-strength concretes, because the improvement of concrete properties with age may not always follow assumed trends. Other properties of the concrete that are of concern to the constructor rather than the designer include:

- Workability
- Pumpability
- Unit weight
- Air content
- Consolidation
- Thermal gradients
- Finishing

The interrelationship of these properties is a complex problem. Of utmost importance is the unit weight of the concrete. For a structure of given dimensions and configuration that may also be required to carry a fixed amount of dead load while floating, variations in the concrete unit weight may adversely affect the floating stability of the structure, causing it to sink or overturn. The in-place unit weight, in turn, is affected by the mixture ingredients, their proportions, and the void content, which is both a function of the entrained air content and the entrapped air or voids remaining after consolidation. A mixture that does not have adequate workability to surround the high levels of reinforcing bars that may occur could result in additional voids in the concrete. The absorption values determined on the hardened concrete are applied to the hardened density of the concrete to establish what the concrete density is when the structure is in the water. If the actual density varies significantly, so will the actual absorption values, which will be different from those used in the design process.

As described later, the typical structural members in an offshore structure and in some inshore structures are quite thick. Because most offshore codes require fairly high cement contents (see Table 13.3) for durability purposes, the possibility of significant heat development within the concrete exists. Limiting values for the maximum placing temperature and the maximum heat rise are contained in the codes. Even when meeting these requirements, care must be exercised to minimize thermal gradients so thermal cracking of the structural members does not occur.

The finish of the concrete surface of an offshore structure may seem like a noncritical item, but a poor finish can have several undesirable effects besides poor appearance. For most offshore structures, the governing design load is caused by the forces from sea waves acting on the surface of the structure. Rough surfaces tend to gather more wave forces and thus reduce the factor of safety planned for a structure. In cold climates, an initially rough surface tends to degrade faster when subjected to cycles of freezing and thawing because there are receptacles in the surface of the concrete where water can collect and freeze. In ice-congested waters, ice moving against and past a structure tends to abrade rough surfaces faster than smooth surfaces (Hoff, 1991a).

Other properties of the concrete that are usually not of concern to either the designer or the constructor are durability properties. These are of concern to the owner, as the offshore structure is usually part of a profit-making venture that has a prescribed lifetime. Some of the durability aspects of the concrete, such as freezing and thawing resistance, are addressed in the code requirements. Matters such as the air-void system in hardened concrete as defined by the spacing factor, the specific surface, and voids per millimeter (inch) have specific requirements that must be met. Guidance is also provided in the codes to prevent or mitigate such deleterious effects as sulfate attack and alkali-aggregate reactivity through proper materials selection.

Chloride-ion permeability of the concrete should also be evaluated to ensure that a satisfactory concrete is being provided to resist reinforcing-bar corrosion. Although minimum concrete cover over the reinforcing bars is specified for a given exposure zone (see Table 13.4), this may have to be increased if the concrete to be used in the platform does not have adequate resistance to chloride-ion penetration.

The abrasion resistance of the concrete to waterborne sediments, debris, floating objects, and ice is usually not specified as it is a rather site-specific phenomenon. In offshore areas where significant abrasion can occur, such as in ice-congested waters, the resistance of the concrete to the abrading medium must be evaluated and loss rates for the concrete surface determined (Hoff, 1988). Once these rates are known, measures to accommodate or eliminate the losses, such as additional concrete cover or steel plates in the abrasion zone, respectively, can be implemented.

An evaluation of all of the above concrete properties for a specific concrete for a specific structure is the ideal situation, but it has not often been done. When actual numerical values are not available, conservative approximations are chosen, and these result in a satisfactory, but not necessarily cost efficient, design. One study that addressed most of the properties noted above was performed on high-strength lightweight aggregate for use in offshore Arctic structures and is described in ABAM (1983, 1984, 1986a).

13.6 Design Considerations

As noted in Section 13.2, concrete offshore structures can be bottom founded or floating. With the exception of a structure that has a base made entirely from prestressed concrete piles, most of the other bottom-founded structures are in a floating mode at some time in their early life. These structures must then include design provisions for both bottom-founded operational loads and those loads associated with the behavior of the structure as a ship. Design codes and guidelines for offshore concrete structures have been developed by various regulatory agencies and standards groups. A listing of some of the major codes and regulations is given in Table 13.6. These are constantly being upgraded as technology advances. In general, detail design of the individual elements of an offshore concrete structure for such things as shear, tension, flexure, compression, eccentric loads, etc. is not significantly different than for any other type of concrete structure. It is only the types of loads, their frequency and duration, and their magnitude that differ from ordinary civil-engineering structures.

The principal loads the offshore structure encounters are permanent loads, variable functional loads, environmental loads, accidental loads, and deformation loads. These various loads are combined in a realistic way to determine their net effect. Permanent loads include the weight of the structure, any permanent equipment, ballast that will not be removed, and the external hydrostatic seawater up to mean sea level. Variable functional loads are the loads associated with the normal operation of the structure. Loads in this category that are unique to offshore structures include variable ballast, installation and drilling loads, vessel impact, fendering and mooring, weight of petroleum products temporarily stored in the platform, helicopter loads, and crane operations. Environmental loads include waves, wind, current, ice and snow, and earthquake. Accidental loads include fire, explosion, ship impact, unintentional flooding, unintentional ballast distribution, and changes in presupposed pressure differences. Examples of deformation loads include prestressing, concrete shrinkage, and thermal gradients.

The geotechnical considerations offshore are much more complex than onshore. For bottom-founded structures, this is an extremely critical area of design. The anchors and moorings of floating structures are also significantly influenced by the subsea soil conditions. Seismically active areas warrant special consideration. Specialists in subsea foundation problems, not onshore foundation specialists, should always be chosen to work on this part of the design problem.

For the first structure in countries or regions that have never used offshore concrete structures before, initially it is best to use the design expertise of companies or firms that have prior experience with these structures. Such firms exist in North America, Europe, Scandinavia, the United Kingdom, and Japan. By involving local design firms in partnerships with these experienced firms, the philosophy and mechanics of the design process can be transferred to the local regions.

13.7 Safety Considerations

Modern offshore concrete platforms are designed with sufficient redundancy to resist major accidental loads. Concrete has exceptionally good impact resistance, and only a few isolated instances of structural damage due to ship impact have been reported. Sufficient ductility can be designed into structural concrete elements to eliminate the problem of progressive collapse. The fire resistance of concrete is well known, with concrete often being used to protect steel from fires in many major structures. A summary of the service record of concrete platforms in the North Sea can be found in Hoff (1986). Floating concrete structures are designed for one-compartment damage stability, which means that any local damage that causes leakage of the sea into the hull will not cause the floating structure to be at risk. Similar criteria are applied to bottom-founded structures so they are not at risk while in their floating mode. Bottom-founded structures, such as that shown in Figure 13.1, have the unique capability of having each of their shafts or towers operate independently of the others. All living quarters and other major personnel areas can be isolated on top of one shaft and kept removed from the more dangerous areas where drilling and processing of hydrocarbons take place. All areas can be connected by bridges. This is a significant advantage over a structure where most of the supporting structural members are tied together in some fashion and collectively support all of the operations of the platform. In the event of a major fire or explosion in or on shafts where hydrocarbons are present, living quarters would not be affected, and successful evacuation of the GBS-type platform could take place.

13.8 Construction Practices

No unique construction practices are required to build structures such as those described above. The good practices employed for any major civil-engineering project are sufficient for building an offshore, inshore, or onshore concrete platform. This gives the owner flexibility in selecting construction contractors. The large offshore concrete platforms of the North Sea have been constructed using predominantly slipforming (Moksnes et al., 1987). It has been demonstrated that North Sea slipforming techniques can be satisfactorily applied to offshore concrete construction in the hotter climate of the Gulf of Mexico

(Norwegian Contractors, 1991b). The small barge-like platforms in the Gulf of Mexico are cast in place (Harrington, 1987). The Hibernia platform (Michel, 1989) for the east coast of Canada, which was completed in 1996, was originally planned to be jump formed but was ultimately slipformed. Precast elements have been used in some structures (Yee et al., 1984). The method of construction can be anything that works and should be left to the discretion of the contractor.

The concrete can be delivered to the form by pump, boom, conveyor, bucket, buggy, barrow, or, again, anything that works. Sophisticated distribution systems normally are not needed. The distribution of the concrete into the slipforms used on North Sea structures has been by wheelbarrow. Proper and sufficient consolidation of the concrete is essential. The equipment and procedures to do this already exist. Adequate curing must be provided. This includes protection from early freezing in regions where this is a possibility.

Two items of offshore concrete construction that differ from most onshore concrete construction are the thickness of the concrete elements and the amount of reinforcing steel that is used. The thinnest concrete walls are usually 350 mm (13 in.). The thickest walls can be several meters (more than 6 ft) thick. Typical wall thicknesses are 500 to 600 mm (20 to 24 in.). Temperature control of the concrete in these thick walls is essential to eliminate thermal cracking problems. Reinforcement densities typically average 400 kg/m³ (676 lb/yd³). Extremes in critical areas have been as great as 1100 kg/m³ (1859 lb/yd³). The proportioning of the concrete and the consolidation methods must be tailored to ensure that the reinforcing steel is completely encapsulated by the concrete. In general, the maximum size aggregates used in these structures has been 19 mm (3/4 in.) or less to allow the concrete to move around the large amounts of reinforcing bars. The use of high-range water reducers (superplasticizers) is a necessity. Prestressing is also used in almost every structure. This is to ensure watertightness of the concrete. The amounts of prestressing are structure and location specific. Standard prestressing materials and practices can be used for these structures, keeping in mind that the work will be done in a marine environment. Special care must be taken to protect the end anchorages of the prestressing from the corrosive environment of the sea.

13.9 Construction Locations

Bottom-founded and floating offshore concrete structures can be constructed, either partially or completely:

- In dry docks or graving docks
- On submersible barges
- On skid ways
- In precast facilities onshore

Precast facilities are used principally for the precast concrete piles and template decks. These facilities can also be used to prefabricate substantial portions of a structure. The prefabricated elements are then transported to and assembled at other locations. For construction of the concrete Arctic drilling structure Glomar Beaufort Sea I, also known as the CIDS (concrete island drilling system), most of its interior concrete elements were made in a prefabrication facility (Yee et al., 1984). The actual method selected depends greatly on the existing site facilities where construction is planned and on the economics of the project.

13.9.1 Dry-Dock Construction

The principal method of construction used for large North Sea concrete platforms is to begin the construction in a dry dock or graving dock. Figure 13.24 shows the construction sequence. When the base of the structure has become stiff enough and has sufficient buoyancy, the dock is flooded and the base is allowed to float. It is then towed from the graving dock to a deeper water location where it is temporarily moored. Construction then continues at that location. Depending on available water depths, this location can be close to the shore or a great distance away. If the structure is located close enough to shore to be reached by a floating or fixed bridge, materials and personnel can reach the structure directly from the shore. Office facilities and concrete production facilities can remain onshore. If the

FIGURE 13.24 Dry-dock construction scenario.

structure is located some distance away from the shore, it will be necessary to have adjoining barges that support offices, materials lay-down areas, concrete batching plants, and other essential equipment. Concrete materials are obtained directly from supporting ships. Work crews are shuttled back and forth from the shore by crew ships. Figure 13.8 shows partial concrete construction of the Isola di Porto Levante LNG terminal built in a dry dock in Spain. When the concrete construction is complete, the structure may be moved to an even deeper water location, where it is mated with the topsides equipment and hook-up of the equipment begins.

FIGURE 13.25 Principal components of the Ravenspurn North concrete platform. (Figure courtesy of Ove Arup & Partners, London.)

It generally costs less to construct a GBS entirely in a dry dock rather than partially in the dry dock, at a wet dock, or at a jetty mooring. Productivity is generally higher in the dry dock, and specialized equipment is minimized. Construction risk is usually lower. For smaller concrete platforms, the platform can be built entirely in the dry dock with sufficient buoyancy to be floated out and towed to the final location. The Ravenspurn North platform (Moksnes, 1989; Roberts, 1990) and all the barge-like platforms (see Figure 13.3 and Figure 13.5) built for the Gulf of Mexico have been constructed in this manner. Figure 13.25 shows an exploded view of various components of the Ravenspurn North platform (Ove Arup & Partners, 1990). It has been reported (Anon., 1989) that, in Europe, concrete GBSs for water depths from 100 to 150 m (330 to 490 ft) can be constructed entirely in a dry dock. The limit is governed by a combination of gate width and sill draft. As noted above, the total support for complete dry dock construction is land based, and the process is very similar to constructing a concrete building. Very large platforms can also be built in this manner but require the use of auxiliary buoyancy compartments for flotation. These compartments can be designed to be removed after platform installation or can be left in place. Some small platforms have also used additional buoyancy compartments to satisfy installation requirements.

A major expense in the construction of a concrete platform is the development of a dry dock if one does not exist or the modification of existing dry dock facilities to accommodate the construction. This expense can include land procurement; excavation, cofferdam construction; dewatering systems; dredging of channels for float out; construction of supporting quays, docks, and wharves; and overall infrastructure upgrades to improve project support (e.g., roads, bridges, power supply, water supply, sewage treatment). These costs can easily reach 80% of the project cost in remote areas.

FIGURE 13.26 Barge construction scenario.

13.9.2 Construction on Barges

To eliminate much of the costs associated with the construction of a dry dock, the construction of some or all of the platform on submersible barges is a practical solution. Such an approach eliminates the need for a dry dock and thus greatly expands the potential number of construction-site locations. Figure 13.26 shows a typical barge construction scenario. Any location with sufficient water depth for barge and supply-ship operation is a possible construction site. Preferably, this site should be in sheltered waters and not subject to severe seas. The number of barges required will depend on the size of the structure and the capacity of the barges. Specially built barges are always a solution, but it may be more economical to weld together a sufficient number of smaller, standard-size barges to accomplish the same objective. When the barges have been assembled to provide the working platform, construction then proceeds on the barges as it would on land. Construction support will depend on the water depths available. Initially, construction can probably begin with the barges moored adjacent to the shore so all construction support can come directly from the land. Figure 13.27 shows the concrete tether anchors for the Snorre tension-leg platform (TLP), which were constructed entirely on barges with direct land support. If the platform is small, the entire platform can be built on the barges at one location. If the platform is large, only a portion would be built on the barges. That portion would be floated off the barges and temporarily moored, and construction would be completed while the portion is in a floating mode.

13.9.3 Skid-Way Construction

Skid ways exist in almost all marine fabrication yards. A skid way is basically a structural slab having a small slope that extends from a construction area down into the sea. Structures that are built on the skid way can be gravity assisted as they are moved down the slope and into the sea. The structures can be self-floating or can be skidded onto barges. Skid ways can be gravity assisted as they are moved down the slope and into the sea. The structures can be self-floating or can be skidded onto barges. For a concrete GBS, the structure can be built either in part or in its entirety on the skid way (Ben C. Gerwick, Inc., 1989). Small structures (Figure 13.28) are the most likely candidate for this type of construction. Because the weight of a complete large concrete structure is so great, there is probably an upper limit where any

FIGURE 13.27 Snorre TLP foundation anchors. (Figure courtesy of Norwegian Contractors, Stabekk, Norway.)

FIGURE 13.28 Skid-way construction. (Figure courtesy of Ben C. Gerwick, Inc., San Francisco, CA.)

given skid way could not be used without significant structural upgrading. This upgrading may not be cost effective but does warrant consideration. The base of most concrete structures can probably be constructed on a skid way to a level where the structure would be self-floating. It can then be skidded into a floating mode and towed to a deeper water site for mooring and completion.

13.9.4 Site Limitations

The principal limitation for any construction site is access to the open sea or to maintained ship channels. As most of the structures will float at some time during their construction and installation phases, water of sufficient depth for them to float and be towed to their final location must exist in close proximity to the construction site. Dredging of new channels is very expensive and may not be possible due to physical, environmental, or political reasons. Most large structures with deep drafts have been completed while in a floating mode. When this is done, the deep-water requirement is further constrained because the deep-water location must be in a relatively mild environment with respect to wind, waves, and current. It is also desirable to have the deep-water location close enough to shore that materials supply and construction crew changes can be made without having to stockpile large amounts of material offshore or provide temporary offshore quarters for personnel. Both of these aspects of construction can add

greatly to the cost of the project. If a dry dock is required and must be built, the supporting infrastructure must be carefully studied before a site is selected. If the site is not convenient to major population areas, the site development will have to include such things as accommodations for work crews, dining facilities, water supply, sewage disposal, recreation facilities, communication facilities, transportation, and all the other things required for a small city. As noted above, the existence of skid ways in operating shipyards does not necessarily mean they can be used for concrete structures because they may be undersized or structurally inadequate. Dredged channels leading away from skid ways most likely will not be of sufficient depth for the draft of larger concrete platforms, and some additional dredging may be required.

13.10 Marine Operations

The subject of marine operations is outside the scope of this chapter, but it should be noted that offshore development and marine operations go hand in hand. The construction and installation of any type of offshore concrete platform will involve significant marine operations (FIP, 1991). The structure itself must float, be towed, and perhaps be submerged for final installation. The structure may have its topside equipment installed in a mating operation. In this operation, the structure is ballasted down until it is almost submerged. The assembled topside equipment is then floated over the submerged structure. Deballasting is initiated, and as the structure rises it picks the topside up off the barges. Deballasting is continued until the structure reaches its final draft for towing operations. Hook-up of the topside to the structure is then performed. This mating is a critical marine operation. Marine operations are expensive and may require special vessels. Fortunately, many good specialist firms or consultants with offshore structure installation experience exist around the world, and they should be consulted for this aspect of the use of concrete platforms.

13.11 Cost Considerations

The costs of an offshore structure are usually dictated by the complexity of the structure, the location where it will be built, and the methods of construction used. These structures have the potential for low capital costs because the materials are local and the labor skill level usually does not have to be high. When properly made, concrete can be virtually maintenance free, thus producing an attractive life-cycle cost. Detailed cost discussions are beyond the scope of this chapter, but a cost philosophy for these structures is described in des Desert and Gifford (1989) and Hoff (1991b).

13.12 Summary

The information presented in this chapter is intended to provide a general overview of what is required in the use of concrete for offshore structures. A significant amount of information on the subject is distributed throughout the literature but has not yet been assembled in a useful textbook form. Concrete is the material of choice for permanent constructions in all regions of the world. It can be produced with local labor and local materials. The potential exists for its use in the offshore oil and gas industry in developing regions of the world and in existing offshore regions where steel structures have been predominately used before. The use of concrete for these structures generally must be sold to owners or developers who are used to dealing with steel structures. Concrete technology is well established for use in offshore structures. No special materials are required, the concrete quality is not unusual, design requirements are well established, competent offshore concrete design firms exist in many regions of the world, no special construction practices are required, flexibility exists in construction-site selection, capital costs can be low, and life-cycle costs can be very attractive. Because of the severe environment that exists offshore, durability aspects of concrete will require special attention. The potential for the use of concrete in offshore structures is great and is limited only by the ingenuity of the concrete designer and constructor and their ability to sell their ideas to the owners.

14.1 Foundation Engineering

Geotechnical engineering is a branch of civil engineering in which technology is applied to the design and construction of structures involving earthen materials, and there are many branches of geotechnical engineering. Surficial earthen material consists of soil and rock; soil and rock mechanics are fundamental studies of the properties and mechanics of soil and rock. Foundation engineering is the application of

* Professor of Civil Engineering at University of South Florida, Tampa; expert in various areas of geotechnical engineering, including foundation design, numerical modeling, and soil stabilization.

FIGURE 14.1 Equipment for sieve analysis.

the principles of soil mechanics, rock mechanics, and structural engineering to the design of structures associated with earthen materials. It is generally observed that most common foundation types supported by intact bedrock present no compressibility problems; hence, when designing common foundation types, the foundation engineer's primary concerns are the strength and compressibility of the subsurface soil and, whenever applicable, the strength of bedrock.

14.1.1 Soil Classification

14.1.1.1 Mechanical Analysis

According to texture or the feel, two different soil types can be identified: (1) coarse-grained soil (gravel and sand), and (2) fine-grained soil (silt and clay). Whereas the engineering properties (primarily strength and compressibility) of coarse-grained soils depend on the size of individual soil particles, the properties of fine-grained soils are mostly governed by moisture content. Hence, it is important to identify the type of soil at a given construction site, because effective construction procedures invariably depend on the soil type. Soil engineers use a universal format called the *unified soil classification system* (USCS) to identify and label soil. The system is based on the results of common laboratory tests of mechanical analysis and Atterberg limits (Bowles, 1986). To classify a given soil sample, mechanical analysis is conducted in two stages: (1) sieve analysis for the coarse fraction (gravel and sand), and (2) hydrometer analysis for the fine fraction (silt and clay). Of these, sieve analysis is conducted according to ASTM D 421 and D 422 procedures, using a set of U.S. standard sieves (Figure 14.1). The most commonly used sieves are numbers 20, 40, 60, 80, 100, 140, and 200, corresponding to sieve openings of 0.85, 0.425, 0.25, 0.18, 0.15, 0.106, and 0.075 mm, respectively.

During the test, the percentage (by weight) of the soil sample retained on each sieve is recorded, from which the percentage (R%) passing (or finer than) a given sieve size (D) is determined. On the other hand, if a substantial portion of the soil sample consists of fine-grained soils ($D < 0.075$ mm), then sieve analysis has to be followed by hydrometer analysis (Figure 14.2). This is performed by first treating the fine fraction with a deflocculating agent such as sodium hexametaphosphate (Calgon®) or sodium silicate (water glass) for about half a day and then allowing the suspension to settle in a hydrometer jar kept at a constant temperature. As the heavier particles settle, followed by the lighter ones, a calibrated ASTM 152H hydrometer is used to estimate the fraction (R%) still settling above the hydrometer bottom at any

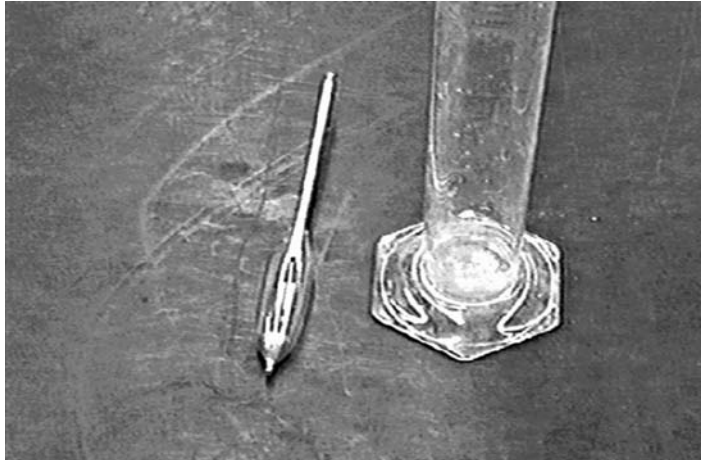

FIGURE 14.2 Equipment for hydrometer analysis.

FIGURE 14.3 Grain-size distribution curves.

given stage. Further, the particle size (D) that has settled past the hydrometer bottom at that stage in time can be estimated from Stokes' law. It can be seen that $R\%$ is the weight percentage of soil finer than D .

Complete details of the above tests are provided in Bowles (1986). For soil samples that have significant coarse and fine fractions, the sieve and hydrometer analysis results ($R\%$ and D) can be logically combined to generate grain (particle) size distribution curves such as those indicated in Figure 14.3. From Figure 14.3, it can be seen that 30% of soil type A is finer than 0.075 mm. (U.S. No. 200 sieve), with $R\% = 30$ and $D = 0.075$ mm being the last pair of results obtained from the sieve analysis. In combining sieve analysis data with hydrometer analysis data, one has to convert the $R\%$ (based on the fine fraction only) and D obtained from hydrometer analysis to $R\%$ based on the weight of the entire sample to ensure continuity of the curve.

FIGURE 14.4 Variation of the fine-grained soil properties with water content.

FIGURE 14.5 Equipment for the plastic limit test.

As an example, let the results from one hydrometer reading of soil sample A be $R\% = 90$ and $D = 0.05$ mm. To plot the curve, one needs the percentage of the entire sample finer than 0.05 mm. Because what is finer than 0.05 mm is 90% of the fine fraction (30%) used for hydrometer analysis, the converted $R\%$ for the final plot can be obtained by multiplying 90% by the fine fraction of 30%. Hence, the converted data used in Figure 14.3 are $R\% = 27$ and $D = 0.05$ mm.

14.1.1.2 Atterberg Limits

As mentioned earlier, properties of fine-grained soils are governed by water; hence, the effect of water on fine-grained soils has to be considered in soil classification. This is achieved by employing the Atterberg limits or consistency limits. The physical state of a fine-grained soil changes with increasing water content, as shown in Figure 14.4, from a brittle to a liquid state. Theoretically, the plastic limit (PL) is defined as the water content at which the soil changes from *semisolid* to *plastic* (Figure 14.4). For a given soil sample, this is an inherent property that can be determined by rolling a plastic soil sample into a worm shape to gradually reduce its water content by exposing more and more of an area until the soil becomes semisolid. This change can be detected by the appearance of cracks on the sample. According to ASTM 4318, the plastic limit is the water content at which cracks develop on a rolled soil sample at a diameter of 3 mm; thus, the procedure is one of trial and error. The apparatus (ground glass plate and moisture cans) used for the test is shown in Figure 14.5, but the reader is also referred to Bowles (1986) and Wray (1986) for details.

On the other hand, the liquid limit (LL), which is visualized as the water content at which the state of a soil changes from *plastic* to *liquid* with increasing water content, is determined in the laboratory using Casagrande's liquid limit device (Figure 14.6). This device is specially designed with a standard brass cup where a standard-sized soil paste is laid during testing. In addition, the soil paste is grooved in the middle by a standard grooving tool, thereby creating a gap with standard dimensions. The brass cup is then made to drop through a distance of 1 cm on a hard rubber base. The number of drops (blows) required to close the above gap along a distance of 1/2 in. is counted. Details of the test procedure can be found in Bowles (1986). ASTM 4318 specifies the liquid limit as the water content at which closing of the standard-sized gap is achieved in 25 drops of the cup; therefore, one has to repeat the experiment for different trial water contents, each time recording the number of blows required to close the above

FIGURE 14.6 Equipment for the liquid limit test.

standard-sized gap. Finally, the water content corresponding to 25 blows can be interpolated from the data obtained from all of the trials. The plasticity index (PI) is defined as follows:

$$PI = LL - PL$$

14.1.1.3 Unified Soil Classification System

In the commonly adopted unified soil classification system (USCS) shown in Table 14.1, the aforementioned soil properties are effectively used to classify soils. Example 14.1 below illustrates the classification of the two soil samples shown in Figure 14.3. Defining the following two curve parameters is necessary to accomplish the classification:

Coefficient of uniformity: $C_u = D_{60}/D_{10}$

Coefficient of curvature: $C_c = (D_{30})^2/(D_{60} \times D_{10})$

where D_i is the diameter corresponding to the i th percentage on the grain-size distribution curve.

Example 14.1

Soil A. The percentage of coarse-grained soil is equal to 70%; hence, soil A is a coarse-grained soil. The percentage of sand in the coarse fraction is equal to $(70 - 30)/70 \times 100 = 57\%$. Thus, according to the USCS (Table 14.1), soil A is a sand. If one assumes clean sand, then:

$C_c = (0.075)^2/(2 \times 0.013) = 0.21$ does not meet criterion for SW.

$C_u = 2/0.013 = 153.85$ meets criterion for SW.

Hence, soil A is a poorly graded sand (SP).

Soil B. The percentage of coarse-grained soil is equal to 32%; hence, soil B is a fine-grained soil. Assuming that LL is equal to 45 and PL is equal to 35 (then PI is equal to 10) and using Casagrande's plasticity chart (Table 14.1), it can be concluded that soil B is a silty sand with clay (ML).

14.1.2 Strength of Soils

The two most important properties of a soil that a foundation engineer must be concerned with are strength and compressibility. Because earthen structures are not designed to sustain tensile loads, the most common mode of soil failure is shear; hence, the shear strength of the foundation medium constitutes a direct input to the design of concrete structures associated with the ground.

TABLE 14.1 Unified Soil Classification System

Major Divisions		Group Symbols (τ)		Typical Names		Laboratory Classification Criteria	
1	2	3	4	5	6	7	8
<p>Coarse-grained soils: More than half of the material is larger than No. 200 (75 μm) sieve size (75 μm) sieve size cannot be seen with the naked eye.)</p>	<p>(Particles smaller than the No. 200 sieve cannot be seen with the naked eye.)</p> <p>Gravels: More than half of gravel fraction is larger than No. 4 (4.75 mm) sieve size</p> <p>Sands: More than half of coarse fraction is smaller than No. 4 (4.75 mm) sieve size</p>	<p>Clean gravels (few or no fines)</p> <p>Gravels with fines (appreciable amount of fines)</p> <p>Clean sands (few or no fines)</p> <p>Sands with fines (appreciable amount of fines)</p>	GW	Well-graded gravels, gravel-sand mixtures, few or no fines	<p>Determine percentage of gravel and sand from grain size curve. 14.1.2.1 Effective Stress Concept

Pores (or voids) within the soil skeleton contain fluids such as air, water, or other contaminants. Any load applied on a soil is partly carried by such pore fluids in addition to being borne by the soil grains; therefore, the total stress at any given location within a soil mass can be expressed as the summation of the stress contributions from the soil skeleton and the pore fluids as:

$$\sigma = \sigma' + u_p \quad (14.1)$$

where:

- σ = total stress (above atmospheric pressure).
- σ' = stress in soil skeleton (above atmospheric pressure).
- u_p = pore (fluid) pressure (above atmospheric pressure).

The stress in the soil skeleton, or the intergranular stress, is also known as the *effective stress*, as it indicates that proportion of the total stress carried by grain-to-grain contacts.

In the case of **dry soils** in which the pore fluid is primarily air, if one assumes that all pores anywhere within the soil are open to the atmosphere through interporous connectivity, then from Equation 14.1 the effective stress would be the same as the total stress:

$$\sigma' = \sigma \quad (14.2)$$

On the other hand, in completely wet (**saturated**) soils, the pore fluid is mostly water, and the effective stress is completely dependent on the *pore water pressure* (u_w). Then, from Equation 14.2:

$$\sigma' = \sigma - u_w \quad (14.3a)$$

Using the unit weights of soil (γ) and water (γ_w), Equation 14.3a can be modified to a more useful form as shown in Equation 14.3b:

$$\sigma'_{v0} = \gamma z - \gamma_w d_w \quad (14.3b)$$

where:

- z = depth of the location from the ground surface.
- d_w = depth of the location from the groundwater table.

Finally, in **partly saturated soils**, the effective stress is governed by both the pore water and pore air pressures (u_a). For unsaturated soils that contain both air and water with a high degree of saturation (85% or above), Bishop and Blight (1963) showed that:

$$\sigma = \sigma' + u_a - \chi(u_a - u_w) \quad (14.4)$$

where ($u_a - u_w$) is the soil matrix suction that depends on the surface tension of water and χ is a parameter in the range of 0 to 1.0 that depends on the degree of saturation. One can verify the applicability of Equation 14.3a for saturated soils based on Equation 14.4, as $\chi = 1$ for completely saturated soils.

14.1.2.2 Determination of Shear Strength

The shear strength of soils is assumed to originate from the strength properties of cohesion (c) and internal friction (ϕ). Using the basic Coulomb's friction principle, the shear strength of a soil can be expressed as:

$$\tau_f = c + \sigma \tan \phi \quad (14.5)$$

However, it is also known that the magnitudes of the soil shear strength properties vary with prevailing drainage conditions and to a minor extent with the stress level; hence, it is important to characterize the strength properties in terms of the drainage condition (drained or undrained) employed during testing. A wide variety of laboratory and field methods are used to determine the shear strength parameters c and ϕ of soils. The triaxial test, the standard penetration test (SPT), and the static cone penetration tests (CPTs) are the most common ones used in foundation engineering.

FIGURE 14.7 Schematic diagram of triaxial cell.

FIGURE 14.8 Triaxial testing apparatus.

14.1.2.3 Triaxial Tests

In this test, a sample of undisturbed soil retrieved from a site is tested under a range of pressures that encompass the expected field stress conditions due to the building. Figure 14.7 is a schematic diagram of the important elements of a triaxial setup, and the actual testing apparatus is shown in Figure 14.8. From the discussion of soil strength, it can be seen that the type of soil and the field-loading rate have a bearing on selection of the laboratory drainage conditions and hence the loading rate. Accordingly, three types of triaxial tests are commonly conducted: (1) consolidated drained (CD) tests, (2) consolidated undrained (CU) tests, and (3) unconsolidated undrained (UU) tests. In CU and CD tests, the pressure exerted on the cell fluid is used to consolidate the soil sample back up to the *in situ* stress state before applying the axial compression. On the other hand, in UU tests, the cell pressure is applied with no accompanying consolidation merely to provide a confining pressure. Computations involving CU and UU tests are given in Example 14.2 and Example 14.3, and the reader is referred to Holtz and Kovacs (1981) for more details regarding the testing procedure.

TABLE 14.2 Measured CU Triaxial Test Data

Test	Cell Pressure (kPa)	Deviator Stress at Failure (kPa)	Pore Pressure (kPa)
1	20	20.2	5.2
2	40	30.4	8.3

FIGURE 14.9 Stress states at failure: (a) total stresses (kPa); (b) effective stresses (kPa).

FIGURE 14.10 Mohr circle diagram for a consolidated undrained (CU) test.

Example 14.2

Assume that one conducts two CU triaxial tests on a sandy clay sample from a tentative site to determine the strength properties. The applied cell pressures, deviator stresses, and measured pore pressures at failure are given in Table 14.2. The strength parameters can be easily estimated using the Mohr circle method as follows:

- *Total strength parameters.* The total stresses (σ_1 and σ_3) acting on both test samples at failure are indicated in Figure 14.9a. Accordingly, the Mohr circles for the two stress states can be drawn as in Figure 14.10. Then, the total strength parameters (sometimes referred to as the *undrained strength parameters*) can be evaluated from the slope of the direct common tangent, which is the Coulomb envelope (Equation 14.5) plotted on the Mohr circle diagram:

$$c_u = 4.0 \text{ kPa and } \phi_u = 13.2^\circ$$

It is obvious that the generated pore pressure has been ignored in the above solution.

- *Effective strength parameters.* The effective stresses (σ_1' and σ_3') on both test samples at failure, computed by subtracting the pore pressure from the total stress, are indicated in Figure 14.9b. The Mohr circles corresponding to the two stress states are drawn in Figure 14.10. The effective

TABLE 14.3 Measured UU Triaxial Test Data

Test	Cell Pressure (kPa)	Deviator Stress at Failure (kPa)	Pore Pressure (kPa)
1	40	102.2	N/A
2	60	101.4	N/A

**FIGURE 14.11** Mohr circle diagram for an unconsolidated undrained (UU) test.

strength parameters (sometimes referred to as the *drained strength parameters*) can be found from the slope of the Coulomb envelope for effective stresses plotted on the Mohr circle diagram:

$$c' = 5.5 \text{ kPa and } \phi' = 13.7^\circ$$

Example 14.3

Assume that one wishes to determine the strength properties of a medium stiff clayey foundation under short-term (undrained) conditions. An effective method for achieving this is to conduct a UU (quick) test. For the results presented in Table 14.3, the undrained strength parameters have to be estimated. Because the pore pressure generation is not monitored in these tests, only the total stresses can be plotted, as in Figure 14.11. It can be seen that the deviator stress at failure does not change with the changing cell pressure during this type of test. This is because the soil samples are not consolidated to the corresponding cell pressures during UU (unconsolidated undrained) tests; therefore, the soil structure is unaffected by the change in cell pressure. Hence, the following strength parameters can be obtained from Figure 14.11:

$$c_u = 50.6 \text{ kPa and } \phi_u = 0^\circ$$

The reader should note that the subscripts *u* are used to distinguish the UU test parameters.

14.1.2.2.1 Selection of Triaxial Test Type Based on the Construction Situation

The CD strength is critical for consideration of long-term stability. Examples of such situations include:

- Slowly constructed embankment on a soft clay deposit
- Earth dam under steady-state seepage
- Excavation of natural slopes in clay

On the other hand, CU strength is more relevant for the following construction conditions:

- Raising of an embankment subsequent to consolidation under its original height
- Rapid drawdown of a reservoir of an earthen dam previously under steady-state seepage
- Rapid construction of an embankment on a natural slope

FIGURE 14.12 Standard penetration test hammer.

FIGURE 14.13 Split spoon sampler.

Finally, the UU strength is applicable under the following conditions:

- Rapid construction of an embankment over a soft clay
- Large dam constructed with no change in water content in the clay core
- Footing placed rapidly on a clay deposit

14.1.2.4 Standard Penetration Test

The standard penetration test (SPT) is the most common field test used to estimate the *in situ* shear strength of foundation soil. In this test, a 140-lb hammer (Figure 14.12) that falls 30 in. is used to drive a standard split spoon sampler (Figure 14.13) 18 in. into the ground. The number of hammer blows necessary to achieve the last 12 in. of penetration is recorded as the blow count (N). Although it is relatively easy to perform, SPT suffers because it is crude and not repeatable. The basic principle underlying the SPT test is the relation between the penetration resistance and shear strength of the soil, which can be visualized as a unique relationship. Because the penetration resistance is obviously affected by the overburden, the following correction is applied before determining the soil properties:

TABLE 14.4 Relation between SPT Blow Count and Friction Angle of Granular Soils

Description	Very Loose	Loose	Medium	Dense	Very Dense
Relative density (D_r)	0	0.15	0.35	0.65	0.85
SPT N'_{70}					
Fine	1–2	3–6	7–15	16–30	?
Medium	2–3	4–7	8–20	21–40	>40
Coarse	3–6	5–9	10–25	26–45	>45
ϕ					
Fine	26–28	28–30	30–34	33–38	—
Medium	27–28	30–32	32–36	36–42	<50
Coarse	28–30	30–34	33–40	40–50	—
γ_{wet} (kN/m ³)	11–16 ^a	14–18	17–20	17–22	20–23

^a Excavated soil or material dumped from a truck has a unit weight of 11 to 14 kN/m³ and must be quite dense to weigh much over 21 kN/m³. No existing soil has a $D_r = 0.00$ nor a value of 1.00. Common ranges are from 0.3 to 0.7.

Note: Empirical values for ϕ and D_r and unit weight of granular soils are based on a normally consolidated (approximately, $\phi = 28^\circ + 15^\circ D_r, \pm 2^\circ$) SPT at about 6-m depth.

TABLE 14.5 Relation between SPT Blow Count and Unconfined Compression Strength of Clay

Consistency of Saturated Cohesive Soils ^a		N'_{70}	q_u (kPa)	Remarks
Very soft	NC ↓ Young clay	0–2	<25	Squishes between fingers when squeezed
Soft		3–5	25–50	Very easily deformed by squeezing
Medium		6–9	50–100	?
Stiff	Increasing OCR ↓ Aged/cemented	10–16	100–200	Difficult to deform by hand squeezing
Very stiff		17–30	200–400	Very difficult to deform by hand squeezing
Hard		>30	>400	Nearly impossible to deform by hand

^a Blow counts and OCR division serve as a guide; in clay, exceptions to the rule are very common.

Source: Bowles, J.E., *Foundation Analysis and Design*, McGraw-Hill, New York, 1995. With permission.

$$N' = \sqrt{\frac{1}{\sigma'_v}} N \quad (14.6)$$

where σ'_v is the effective overburden stress (in tons per square feet) computed as follows:

$$\sigma'_v = \gamma z - \gamma_w d_w \quad (14.7)$$

where:

γ = unit weight of soil.

z = depth of test location.

γ_w = unit weight of water.

d_w = depth of test location from the groundwater table.

Once the corrected blow count (N'_{70}) is determined, one can find the strength parameters based on the empirical correlations shown in Table 14.4 and Table 14.5. The subscript 70 indicates 70% efficiency in energy transfer from the hammer to the sampler. This value has been shown to be relevant for the North American practice of SPT. It should be noted that the undrained strength (c_u) of a saturated clay is one half the unconfined compression strength (q_u).

FIGURE 14.14 Cone and sleeve.

FIGURE 14.15 Cone penetration test equipment. (From Stinnette, P., Geotechnical Data Management and Analysis System for Organic Soils, Ph.D. dissertation, University of South Florida, Tampa, 1996.)

14.1.2.5 Static Cone Penetration Test

The cone penetration test (CPT) has been gaining popularity as a more reliable and repeatable alternative to SPT. In this test, a standard cone and a sleeve (Figure 14.14) are advanced at a steady rate (1 cm/sec) into the ground while the cone resistance (q_c) and the sleeve friction (f_s) are electronically measured. The entire cone apparatus and the associated computing facilities are usually trunk mounted, as shown in Figure 14.15. A typical cone profile obtained from a University of South Florida organic soil research site is shown in Figure 14.16. Because it measures the two parameters q_c and f_s , CPT is a useful tool for identifying soil type as well as for evaluating soil properties. A convenient parameter termed the *friction ratio* (F_R) is defined for this purpose as:

$$F_R = \frac{f_s}{q_c} \tag{14.8}$$

Figure 14.17 shows a simple chart that can be used for soil classification using CPT data. Currently, it is commonplace to have cone tips fitted with transducers that can produce a continuous record of the ground pore pressures at various depths. Using CPT data, the undrained strength of a clay can be obtained as:

$$s_u = \frac{qt - p_0}{N_{kT}} \tag{14.9}$$

FIGURE 14.16 A typical cone profile. (From Mullins, A.G., Field Characterization of Dynamic Replacement of Florida Soils, Ph.D. dissertation, University of South Florida, Tampa, 1996.)

where:

$$q_T = q_c + u_c(1-a) \quad (14.10)$$

$$N_{mT} = 13 + \frac{5.5}{50} PI \quad (14.11)$$

and p_o and u_c are the effective overburden pressure and the pore pressure, respectively, measured in the same units as s_u and q_c ; a is taken as the approximate diameter ratio $(d_1/D)^2$ (Figure 14.14).

On the other hand, the friction angle of a granular soil can be obtained from q_c (in megapascals) based on the following approximate expression:

$$\phi = 29 + \sqrt{q_c} \quad (14.12)$$

For gravel and silty sand, corrections of $+5^\circ$ and -5° , respectively, have to be made.

14.1.3 Compressibility and Settlement

Soils, like any other material, deform under loads; hence, even if the integrity of a structure is satisfied, soil supporting the structure can undergo compression, leading to structural settlement. For most dry soils, this settlement will cease almost immediately after the particles readjust to attain an equilibrium with the structural load. This immediate settlement is evaluated using the theory of elasticity; however, if the ground material is wet, fine-grained (low permeability) soil, then the settlement will continue for a long period of time with slow drainage of water until the excess pore water pressure completely dissipates. This is usually evaluated by Terzaghi's consolidation theory. In some situations involving very fine clays and organic soils, settlement continues to occur even after the pore water pressure in the foundation vicinity comes to an equilibrium with that of the far field. Secondary compression concepts are required to estimate this secondary settlement.

FIGURE 14.17 Soil classification using CPT data. (From Bowles, J.E., *Foundation Analysis and Design*, McGraw-Hill, New York, 1995. With permission.)

14.1.3.1 Estimation of Foundation Settlement in Granular Soils

Very often, settlement of footings founded on granular soils is determined based on the plate load tests discussed in Section 14.2. The most commonly adopted analytical methods for settlement evaluation in granular soils are based on the elastic theory; however, one must realize that reliable estimates of elastic moduli and Poisson’s ratio values for soils are not easily obtained. This is mainly because of the sampling difficulty and, particularly, the dependency of the elastic modulus on the stress state. Reliable field methods for obtaining elastic moduli are also scarce. The following expressions can be used to find the immediate settlement:

$$s_e = f \frac{B_{q_0}}{E_s} (1 - \mu_s^2) \frac{\alpha}{2} \tag{14.13}$$

where:

- s_e = immediate (elastic) settlement.
- f = 0.5 or 1.0 (depending on whether s_e is at the corner of the foundation).
- B = width of foundation.
- q_0 = contact pressure (P/BL , where L is the length of the foundation).
- E_s = elastic modulus.
- α = a factor to be determined from Figure 14.18.

Another widely used method for computing granular soil settlements is the Schmertmann and Hartman (1978) method based on the elastic theory:

$$s_e = C_1 C_2 (\bar{q} - q) \sum_0^z \frac{I_z}{E_s} \Delta z \tag{14.14}$$

where:

- C_1 = foundation depth correction factor = $1 - 0.5[q/\bar{q} - q]$.
- C_2 = correction factor for creep of soil = $1 + 0.2 \log(\text{time in years}/0.1)$.

- \bar{q} = stress at foundation level.
- q = overburden stress.
- I_z = strain influence factor in Figure 14.19.

The elastic properties necessary to manipulate the above expressions are provided in Table 14.6 and Table 14.7. Furthermore, some useful relationships that can provide the elastic properties from *in situ* test results are given below:

$$E_s \text{ (tsf)} = 8N \tag{14.15}$$

and

$$E_s = 2q_c \tag{14.16}$$

A comprehensive example illustrating the use of the above relations is provided in Example 14.4.

14.1.3.2 Estimation of Foundation Settlement in Saturated Clays

The load applied on a saturated fine-grained soil foundation is immediately acquired by the pore water, as illustrated in Figure 14.20a; however, with the dissipation of pore pressure resulting from drainage of water, the applied stress (total stress) is gradually transferred to the soil skeleton as an effective stress

TABLE 14.6 Elastic Properties of Geomaterials

Soil	E_s (MPa)
<i>Clay:</i>	
Very soft	2–15
Soft	5–25
Medium	15–50
Hard	50–100
Sandy	25–250
<i>Glacial till:</i>	
Loose	10–150
Dense	150–720
Very dense	500–1440
Loess	15–60
<i>Sand:</i>	
Silty	5–20
Loose	10–25
Dense	50–81
<i>Sand and gravel:</i>	
Loose	50–150
Dense	100–200
Shale	150–5000
Silt	2–20

Note: Value range for the static stress-strain modulus E_s for selected soils (see also Table 5.6). The value range is too large to use an “average” value for design. Field values depend on stress history, water content, density, and age of deposit.

(Figure 14.20b). The long-term soil skeleton rearrangement taking place during this process is termed the *consolidation settlement*. The soil properties required for estimation of the magnitude and rate of consolidation settlement can be obtained from the laboratory one-dimensional (1-D) consolidation test. Figure 14.21 shows the consolidometer apparatus where a saturated sample (2.5-in. diameter and 1.0-in. height) is subjected to a constant load while the deformation and sometimes the pore pressure are

FIGURE 14.20 Illustration of consolidation settlement: (a) subsurface profile, (b) effective stress distribution, and (c) pore pressure distribution.

FIGURE 14.21 Laboratory consolidometer apparatus. (Figure courtesy of the University of South Florida, Tampa.)

monitored until consolidation is complete. A detailed description of this procedure can be found in Bowles (1986). The sample is tested in this manner for a wide range of stresses that encompass the expected foundation pressure. Using Terzaghi’s 1-D consolidation theory, the relationship shown in Table 14.8 between the degree of consolidation U (settlement at any time t as a percentage of the ultimate settlement) and the time factor T can be derived for a clay layer subjected to a constant pressure increment throughout its depth.

Figure 14.22 shows the results of a consolidation test conducted on an organic soil sample. The coefficient of consolidation (C_v) for the soil can be obtained from these results using Casagrande’s logarithm-of-time method (Holtz and Kovacs, 1981). Using this method, from Figure 14.22 one can estimate the time for 90% consolidation as 200 sec. Then, by using the following expression for the time factor, one can estimate C_v as 2.5×10^{-4} in.²/sec, because $U = 90\%$ when $t = 200$ sec:

$$T = \frac{C_v t}{H_{dr}^2} \tag{14.17}$$

TABLE 14.8 Degree of Consolidation vs. Time Factor

0.8	0.567
0.9	0.848
0.95	1.163
1.0	∞

where H_{dr} is the longest drainage path in the consolidating soil layer. It should be noted that the water in the laboratory soil sample drains through both sides during consolidation, so $H_{dr} = 0.5$ in.

When the above consolidation test is repeated for several other pressure increments, doubling the pressure each time, variation of the post-consolidation (equilibrium) void ratio e with pressure p can be observed using the following relation between e and the sample strain computed from the monitored sample deformation:

$$\frac{\Delta e}{1 + e_0} = \frac{\Delta H}{H} \tag{14.18}$$

where e_0 and H are the initial void ratio and the sample height, and ΔH and Δe are their respective changes. A typical laboratory consolidation curve (e vs. $\log p$) for a clayey soil sample is shown in Figure 14.23. The following important parameters can be obtained from Figure 14.23:

- Recompression index (C_r) = $(1.095 - 1.045)/(\log 60 - \log 10) = 0.064$.
- Compression index (C_c) = $(1.045 - 0.93)/(\log 120 - \log 60) = 0.382$.
- Preconsolidation pressure (p_c) = 60 kPa.

FIGURE 14.22 Settlement vs. logarithm-of-time curve. (From Stinnette, P., Engineering Properties of Florida Organic Soils, Master’s project, University of South Florida, Tampa, 1992.)

FIGURE 14.23 Laboratory consolidation curve (*e* vs. $\log p$).

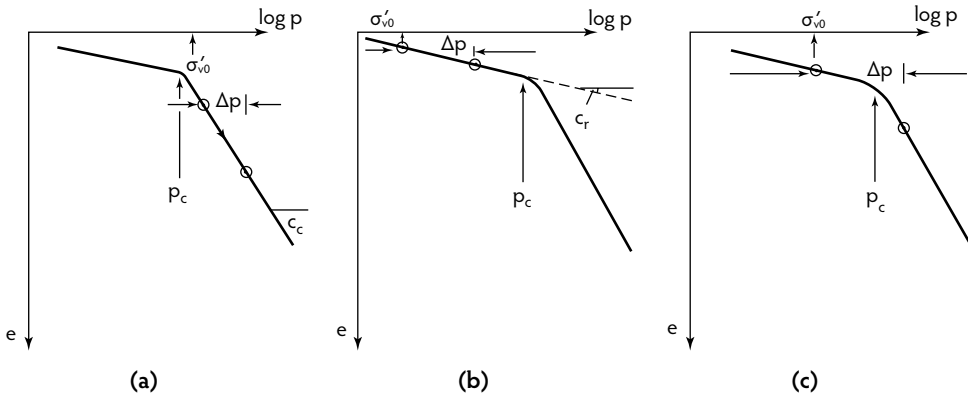

FIGURE 14.24 Illustration of the use of the consolidation equation: (a) case 1, (b) case 2, and (c) case 3.

All of the above information can be used to estimate the ultimate consolidation settlement of a saturated clay layer (of thickness H) due to an average pressure increase of Δp . The ultimate consolidation settlement (s_{con}) can be expressed by the following, depending on the individual case, as illustrated in Figure 14.24:

Case 1 ($\sigma'_{v_0} > p_c$):

$$s_{con} = \frac{C_c H}{1 + e_0} \log \frac{\sigma'_{v_0} + \Delta p}{\sigma'_{v_0}} \tag{14.19}$$

Case 2 ($\sigma'_{v_0} + \Delta p < p_c$):

$$s_{con} = \frac{C_r H}{1 + e_0} \log \frac{\sigma'_{v_0} + \Delta p}{\sigma'_{v_0}} \tag{14.20}$$

Case 3 ($\sigma'_{v_0} + \Delta p > \sigma'_{v_0}$):

$$s_{con} = \frac{C_r H}{1 + e_0} \log \frac{p_c}{\sigma'_{v_0}} + \frac{C_c H}{1 + e_0} \log \frac{\sigma'_{v_0} + \Delta p}{p_c} \tag{14.21}$$

The average pressure increase in the clay layer can be accurately determined by using Newmark's chart, shown in Figure 14.25. When the footing is drawn on the chart to a scale of $OQ = d_c$ (the depth of the midplane of the clay layer from the footing bottom), Δp can be evaluated by:

$$\Delta p = qIM \tag{14.22}$$

FIGURE 14.25 Newmark's chart. (From Holtz R.D. and Kovacs W.D., *An Introduction to Geotechnical Engineering*, Prentice Hall, Englewood Cliffs, NJ, 1981. With permission.)

where q , I , and M are the contact pressure, the influence factor (specific to the diagram), and the number of elements of the chart covered by the drawn footing, respectively.

Example 14.4

Assume that it is necessary to compute the maximum differential settlement of the foundation shown in Figure 14.26, which also shows the SPT, elastic moduli (using Equation 14.15 for sands and 33% of the estimate for clay), and unit weight profiles as well as the strain influence factor plot. For the above data:

Contact pressure (\bar{q}) = $200/(1.5)^2$ kPa = 88.89 kPa.

Overburden pressure at footing depth (q) = 16.5×1.0 kPa = 16.5 kPa.

Immediate Settlement. Areas of the strain-influence diagram covered by different elastic moduli are:

$$A_1 = 0.5(0.75 \times 0.6) + 0.5(0.25)(0.533 + 0.6) = 0.367 \text{ m}$$

$$A_2 = 0.5(1.5)(0.533 + 0.133) = 0.5 \text{ m}$$

$$A_3 = 0.5(0.5)(0.133) = 0.033 \text{ m}$$

FIGURE 14.26 Settlement computation.

Then, by applying Equation 14.14, one obtains the immediate settlement as:

$$S_{\text{center}} = \left[1 - 0.5 \left\{ 16.5 / (88.89 - 16.5) \right\} \right] \left[1.0 \right] \left[88.89 - 16.5 \right] \left[0.367(1.0) / (11.5 \times 10^3) + 0.5 / (10.7 \times 10^3) + 0.033 / (2.57 \times 10^3) \right] = 5.87 \text{ mm}$$

From Equation 14.13, s_{corner} can be deduced as $0.5(5.87) = 2.94 \text{ mm}$.

Consolidation Settlement. As for the consolidation settlement, the average stress increase in clay can be obtained as:

$$\Delta p_{\text{center}} = 4 \times 19 \times 88.89 \times 0.001 = 6.75 \text{ kPa}$$

$$\Delta p_{\text{corner}} = 58 \times 88.89 \times 0.001 = 5.2 \text{ kPa}$$

On the other hand, the average overburden pressure at the clay layer is found from Equation 14.3b as:

$$\sigma'_{v0} = 16.5(2) + 17.5(1.5) + 18.0(1.0) - 9.8(2.75) = 54.8 \text{ kPa}$$

From Figure 14.24, one observes that the relevant expression for this situation is Equation 14.21, and by using the above estimates the consolidation settlement is found as:

$$s_{\text{center}} = \left[0.064 / (1 + 1.06) \right] (2.5) \log(60 / 54.8) + \left[0.382 / (1 + 1.06) \right] (2.5) \log \left[(54 + 6.75) / 60 \right] = 0.0819 \text{ m} = 8.19 \text{ mm}$$

As for the corner, the applicable expression from Figure 14.24 is Equation 14.20; hence,

$$s_{\text{corner}} = \left[0.064 / (1 + 1.06) \right] (2.5) \log \left((54.8 + 5.2) / 54.8 \right) = 3.06 \text{ mm}$$

Therefore, the total settlement at the center of the footing will be 30.39 mm (1.12 in.), while that at the corner will be 6.0 mm (0.24 in.).

Total Settlement Check. Most building codes stipulate the maximum allowable total settlement to be 1.0 in., so the above value is unacceptable.

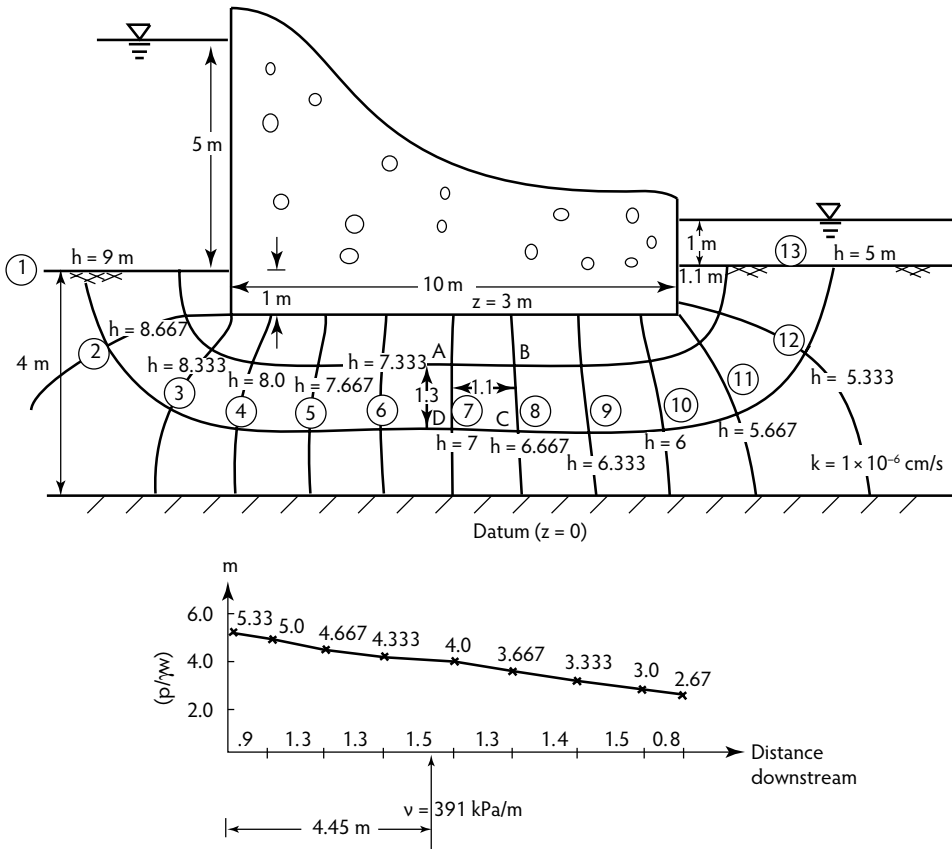

FIGURE 14.27 Seepage under a concrete dam.

Differential Settlement Check. The differential settlement is equal to $(s_{\text{center}} - s_{\text{corner}})$ distance from center to corner, or $(30.39 - 6.00)/1.06 \times 1000 = 0.023$. According to most building codes, the maximum allowable differential settlement to prevent structural cracks in concrete is 0.013; hence, the above design fails the differential settlement criterion.

14.1.4 Groundwater and Seepage

Stability analysis of water-retaining concrete structures requires that the uplift forces exerted on them be evaluated. These structures often exist in groundwater flow regimes caused by differential hydraulic heads; hence, an analysis of groundwater seepage has to be performed invariably when estimating the uplift forces. The most common and the simplest means of seepage analysis is the method of *flownets*. In this method, two orthogonal families of equipotential and flow lines are sketched in the flow domain (Figure 14.27) using the following basic principles. A *flow line* is an identified or a visualized flow conduit boundary in the flow domain. On the other hand, an *equipotential line* is an imaginary line in which the total energy head is the same.

14.1.4.1 Rules Governing the Construction of a Flownet

1. Equipotential lines do not intersect each other.
2. Flow lines do not intersect each other.
3. Equipotential lines and flow lines form two orthogonal families.
4. To ensure equal flow in the drawn flow conduits and equal head drop between adjacent equipotential lines, individual flow elements formed by adjacent equipotential lines and flow lines bear the same height/width ratio (typically 1.0).

With seepage velocities being generally very low, the pressure (p) exerted by seeping water contributes along with the potential energy to the total head (energy/unit weight) of water as:

$$h = \frac{p}{\gamma_w} + z \quad (14.23)$$

The quantity of groundwater flow at any location in a porous medium such as soil can be expressed by D'Arcy's law as:

$$q = kiA \quad (14.24)$$

where k is the coefficient of permeability (or hydraulic conductivity) at that location, and i , the hydraulic gradient, can be expressed by:

$$i = \frac{dh}{dx} \quad (14.25)$$

The following example illustrates the flownet method of seepage analysis and evaluation of uplift pressures. For more accurate and rigorous methods, the reader is referred to Harr (1962).

Example 14.5

Assume that it is necessary to establish the pressure distribution on the bottom of the dam shown in Figure 14.27 and the seepage under the dam shown in Figure 14.27. As the first step in the solution, a flownet has been drawn to scale, following the rules above. Using the bedrock as the datum for the elevation head, total heads have been assigned using Equation 14.23 for all of the equipotential lines as shown. It is noted that the head drop between two adjacent equipotential lines is:

$$(9 \text{ m} - 5 \text{ m})/12 = 0.333 \text{ m}$$

Then, by applying Equation 14.23 to the points where the equipotential lines and the dam bottom (B_c) intersect, the following expression can be obtained for the pressure distribution, which is plotted in Figure 14.27:

$$p = \gamma_w(h - 3.0)$$

Then, the total upthrust can be computed from the area of the pressure distribution as .34 kPa/m acting at a distance of .45 m downstream.

By applying Equation 14.25 to the element ABCD, one obtains:

$$i = (5.333 - 5.0)/1.1 = 0.302$$

Because $k = 1 \times 10^{-6}$ cm/s, one can apply Equation 14.24 to obtain the quantity of seepage through ABCD as:

$$q_1 = 1s(10^{-9})(0.302)(1.3)(1) \text{ m}^3/\text{s}/\text{m} \text{ (because AD = 1.3 m)}$$

Because all of the conduits must carry equal flow (see rule 4 of the flownet construction):

$$q = 3 \times (10^{-9})(0.302)(1.3)(1) \text{ m}^3/\text{s}/\text{m} = 1.18 \times 10^{-9} \text{ m}^3/\text{s}/\text{m}$$

Note the following important assumptions made in the above analysis:

1. The subgrade soil is homogeneous.
2. The bedrock and concrete dam are intact.
3. There is no free flow under the dam due to **piping** (or erosion).

Thus, the design and installation of an adequate pore-pressure monitoring system that can verify the analytical results are essential. A piezometer with a geomembrane/sand filter that can be used for monitoring pore pressures is shown in Figure 14.28.

FIGURE 14.28 Piezometer probes. (From Thilakasiri, H.S., Numerical Simulation of Dynamic Replacement of Florida Organic Soils, Ph.D. dissertation, University of South Florida, Tampa, 1996.)

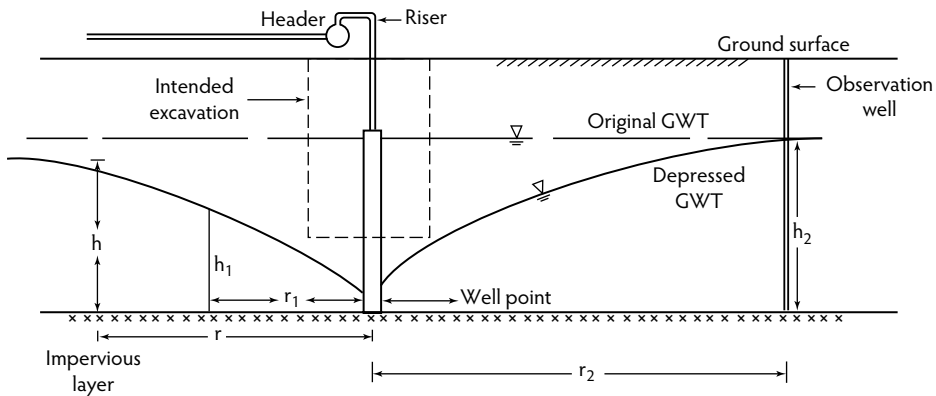

FIGURE 14.29 Dewatering of excavations.

14.1.5 Dewatering of Excavations

Construction in areas of shallow groundwater requires dewatering prior to excavation. Although contractors specialized in such work determine the details of the dewatering program depending on the field performance, a preliminary idea of equipment requirements and feasibility can be obtained by a simplified analysis. Figure 14.29 shows the schematic diagram for such a program and the elevations of the depressed water table at various distances from the center of the well. Observation wells (or bore holes) can be placed at any location, such as those shown at distances of r_1 and r_2 , to monitor the water table depression. When analyzing a seepage situation like this, Dupuit (Harr, 1962) assumed that: (1) for a small inclination of the line of seepage, the flow lines are horizontal, and (2) the hydraulic gradient is equal to the slope of the free surface and is invariant with depth. For discharge through any general section such as an

FIGURE 14.30 Typical cross-section of a geomembrane-lined landfill. (From Koerner, R.M., *Designing with Geosynthetics*, 3rd ed., Prentice Hall, Upper Saddle River, NJ, 1994. With permission.)

observation well, one can write the following expression for the flow by combining Equation 14.24 and Equation 14.25:

$$q = k \left(-\frac{dh}{dx} \right) h \quad (14.26)$$

Noting that q and k are constants throughout the flow regime considered, Equation 14.26 can be integrated between distances of r_1 and r_2 to obtain:

$$q = \frac{\pi k (h_1^2 - h_2^2)}{\ln(r_1/r_2)} \quad (14.27)$$

By defining the extent of dewatering, using parameters r_1 , r_2 , h_1 , and h_2 , one can utilize the above expression to determine the capacity requirement of the pump.

14.1.6 Environmental Geotechnology

The amount of solid waste generated in the United States was expected to exceed 510M tons by the year 2000 (Koerner, 1994); thus, the immediate need for construction of adequate landfills cannot be over-emphasized. Although the construction of landfills involves political and legal issues, properly designed, constructed, and maintained landfills have proven to be secure, especially if they are provided with lined facilities. These are installed on the bottom or sides of a landfill to control groundwater pollution by the liquid mixture (**leachate**) formed by the interaction of rainwater or snowmelt with waste material. Types of liners for leachate containment are basically: (1) clay liners, (2) geomembranes, and (3) composite liners consisting of geomembranes and clay liners. Of these, until recently, the most frequently used liners were clay liners, which minimized leachate migration by achieving permeability values as low as 5×10^{-8} to 5×10^{-9} cm/sec; however, due to the large thickness requirement (0.6 to 2 m) and chemical activity in the presence of organic-solvent leachates, geomembranes have been increasingly utilized for landfills.

14.1.7 Design of Landfill Liners

As shown in Figure 14.30 and Figure 14.31, the important components of a solid material containment system include: (1) a leachate collection/removal system, (2) a primary leachate barrier, (3) a leachate detection/removal system, (4) a secondary leachate barrier, and (5) a filter above the collection system to prevent clogging. Some of the design criteria are as follows (Koerner, 1994):

- The leachate collection system should be capable of maintaining a leachate head of less than 30 cm.
- Both collection and detection systems should have 30-cm-thick granular drainage layers that are chemically resistant to waste and leachate and that have a permeability coefficient of not less than 1×10^{-2} cm/sec or an equivalent synthetic drainage material.
- The minimum bottom slope of the facility should be 2%.

FIGURE 14.31 Typical cross-section of a clay/geomembrane-lined landfill. (From Koerner, R.M., *Designing with Geosynthetics*, 3rd ed., Prentice Hall, Englewood Cliffs, NJ, 1994. With permission.)

4.1.7.1 Design Considerations for Clay Liners

In the case of clay liners, the U.S. Environmental Protection Agency (EPA) requires that the coefficient of permeability be less than 10^{-7} cm/sec. This can be achieved by meeting the following classification criteria:

- The soil should have at least 20% fines (see Section 14.1.1.1, Mechanical Analysis).
- The plasticity index should be greater than 10 (see Section 14.1.1.2, Atterberg Limits).
- The soil should not have more than 10% gravel-size (>4.75 mm) particles.
- The soil should not contain any particles or chunks of rock larger than 50 mm.

It is realized that liner criteria can be satisfied by blending available soils with clay minerals such as sodium bentonite.

4.1.7.2 Design Considerations for Geomembrane Liners

Geomembranes are mainly used in geotechnical engineering to perform the functions of: (1) separation, (2) filtration, and (3) stabilization. In this application of geotextiles, the functions of separation and, to a lesser extent, filtration are utilized. Due to the extreme variation of solid-waste leachate composition from landfill to landfill, the candidate liner should be tested for permeability with the actual or synthesized leachate. In addition to the permeability criterion, other criteria also play a role in geomembrane material selection. They are as follows:

- Resistance to stress cracking induced by the soil/waste overburden
- Different thermal expansion properties in relation to subgrade soil
- Coefficient of friction developed with the waste material that governs slope stability criteria
- Axisymmetry in tensile elongation when the material is installed in a landfill that is founded on compressible subgrade soils

In selecting a geomembrane material for a liner, serious consideration should also be given to its durability, which is determined by the possibility of leachate reaction with the geomembrane and premature degradation of the geomembrane. For more details on geomembrane durability and relevant testing, the reader is referred to Koerner (1994). According to U.S. EPA regulations, the required minimum thickness of a geomembrane liner for a hazardous waste pond is 0.75 mm.

14.2 Site Exploration

In addition to screening possible sites, a thorough site study can reveal plenty of vital information regarding the soil and groundwater conditions at a tentative site, leading to more efficient selection of foundation depth and type as well as other construction details; hence, a site investigation that includes a subsurface exploration can certainly aid in economizing the time and cost involved in foundation construction projects. An exhaustive site study can be separated into two distinct phases: (1) preliminary investigation, and (2) detailed investigation. In the preliminary investigation, one would attempt to obtain

TABLE 14.9 Approximate Spacing of Boreholes

Type of Project	Spacing (m)
Multistory	10–30
One-story industrial plants	20–60
Highways	250–500
Residential subdivisions	250–500
Dams and dikes	40–80

as much valuable information about the site as possible at the least expense. Useful information regarding the site can often be obtained from the following sources:

- Local department of transportation (DOT) soil manuals
- Local U.S. Geological Survey (USGS) soil maps
- Local U.S. Army Corps of Engineers hydrological data
- U.S. Department of Agriculture (USDA) agronomy maps
- Local university research publications

A preliminary investigation also involves site visits (or reconnaissance surveys) where one can observe such site details as topography, accessibility, groundwater conditions, and nearby structures (especially in the case of expected pile driving or dynamic ground modification). Firsthand inspection of the performance of existing buildings can also add to this information. A preliminary investigation can be an effective tool for screening all alternative sites for a given installation. A detailed investigation has to be conducted at a given site only when that site has been chosen for the construction, as the cost of such an investigation is enormous. This stage of the investigation invariably involves heavy equipment for boring; therefore, at first, it is important to set up a definitive plan for the investigation, especially in terms of the bore hole layout and the depth of boring at each location. Generally, there are rough guidelines for bore hole spacing, as indicated in Table 14.9.

In addition to planning boring locations, it is also prudent on the part of the engineer to search for any subsurface anomalies or possible weak layers that can undermine construction. As for the depth of boring, one can use the following criteria:

1. If bedrock is in the vicinity, continue boring until sound bedrock is reached, as verified from rock core samples.
2. If bedrock is unreachable, one can seek depth guidelines for specific buildings such as those given by the following expressions (Das, 1995):

$$D = 3S^{0.7} \text{ (for light steel and narrow concrete buildings).}$$

$$D = 6S^{0.7} \text{ (for heavy steel and wide concrete buildings).}$$
3. If none of the above conditions is applicable, then one can explore up to a depth at which the foundation stress attenuation reduces the applied stress by 90% ($\Delta p/\sigma'_{v0} = 0.1$ in Example 14.4). This generally occurs around a depth of $2B$, where B is the minimum foundation dimension.

Hand augers and continuous flight augers (Figure 14.32a) can be used for boring up to a depth of about 3 m in loose to moderately dense soil. For extreme depths, a mechanized auger (Figure 14.32b) can be used in loose to medium dense sands or soft clays. When the cut soil is brought to the surface, a technically qualified person should observe the texture, color, and type of soil found at various depths and prepare a bore-hole log identifying the soil types at the different depths. This type of boring is called **dry sample boring** (DSB). On the other hand, if relatively hard strata are encountered, investigators have to resort to a technique known as **wash boring**. Wash boring is carried out using a mechanized auger and a water-circulation system that aids in cutting and drawing the cut material to the surface. A schematic diagram of the wash-boring apparatus is shown in Figure 14.33, and the Florida Department of Transportation drill rig, which utilizes the above technique, is shown in Figure 14.34.

(a)

(b)

FIGURE 14.32 Drilling equipment: (a) hand-auger, and (b) mechanized auger. (Figure courtesy of the University of South Florida, Tampa.)

In addition to visual classification, one has to obtain soil type and strength and deformation properties for a foundation design; hence, the soil at various depths has to be sampled as the bore holes advance. Easily obtained disturbed samples suffice for classification, index, and compaction properties, while triaxial, and consolidation tests require carefully obtained undisturbed samples (samples with minimum disturbance). Disturbed granular or clayey samples can be obtained by attaching a standard split spoon sampler (Figure 14.13) to the drill rods. An undisturbed clay sample can be obtained by carefully advancing and retrieving a Shelby tube (Figure 14.35) into a clay layer; however, if one needs to evaluate a granular material for strength, settlement, or permeability, then *in situ* tests have to be performed due to the difficulty in obtaining undisturbed samples in such soils. In this regard, the reader is referred to the *in situ* tests shown in Table 14.10. A description of the plate load test is presented in Section 14.2.1.

FIGURE 14.33 Schematic diagram of wash boring.

TABLE 14.10 Recommended *In Situ* Tests

Evaluation Parameter	Test
Permeability	Field pumping test ^a
Settlement	Plate load test ^b
Shear strength	SPT or CPT ^c

- ^a In Section 14.1.5, Dewatering of Excavations.
- ^b In Section 14.2.1, Plate Load Tests.
- ^c In Section 14.1.2, Strength of Soils.

14.2.1 Plate Load Tests

Plate load apparatus consists of a set of steel plates of standard diameters (12 in., 18 in., etc.), a hydraulic loading and recording mechanism, a reaction frame, and a deflection gauge (Figure 14.36). During the test, the plate is laid at the tentative foundation depth and gradually loaded while the magnitude of the load and plate deflection at different stages is recorded. Figure 14.37 shows a typical plot of plate load results on a sand deposit. When one scrutinizes Figure 14.37, it can be seen that the ultimate bearing capacity of the plate can be estimated from the change in gradient of the load–deflection curve; hence, the bearing capacity and the settlement of a tentative foundation can be predicted in the following manner, based on the results of a plate load test performed on that location. In the following expressions, the subscripts *f* and *p* refer to the foundation and the plate, respectively.

Ultimate bearing capacity in clayey soils:

$$q_{u(f)} = q_{u(p)} \tag{14.28}$$

Ultimate bearing capacity in sandy soils:

$$q_{u(f)} = q_{u(p)} \left(\frac{B_f}{B_p} \right) \tag{14.29}$$

where *B_p* and *B_f* refer to the plate diameter and the minimum foundation dimension, respectively.

One can deduce the above expressions based on the basic expression for the bearing capacity of shallow footings (Section 14.3, Equation 14.32) when one realizes that predominant contributions for bearing capacity in clay and sand are made by the terms involving *B_c* and *N_γ* terms of Equation 14.32, respectively.

FIGURE 14.36 Plate load test.

Settlement of a footing under a given contact pressure (q) can be estimated by the corresponding plate settlement (s_p) (Figure 14.37) using the following expressions:

Immediate settlement in clayey soils:

$$s_f = s_p \left(\frac{B_f}{B_p} \right) \quad (14.30)$$

Immediate settlement in sandy soils:

$$s_f = s_p \left(\frac{2B_f}{B_f + B_p} \right)^2 \quad (14.31)$$

14.3 Shallow Footings

A shallow spread footing must be designed for a building column to transmit the column load to the ground without exceeding the bearing capacity of the ground and causing an excessive settlement (Figure 14.38). Plate-load test results clearly demonstrate the existence of a maximum stress (approximately 10 psi in Figure 14.37) that can be imposed on a plate without causing excessive settlement. This maximum stress is termed the *bearing capacity* of a foundation.

14.3.1 Bearing Capacity of Shallow Footings

To avoid catastrophic bearing failures, shallow footings are proportioned based on the bearing-capacity criterion. Two expressions extensively used to evaluate the ground bearing capacity are provided below.

14.3.1.1 Terzaghi's Expression

$$q_{\text{ult}} = s_c c N_c + q N_q + s_\gamma (0.5 B \gamma) N_\gamma \quad (14.32)$$

FIGURE 14.37 Typical plate load test results. (From A.G. Mullins, A.G., Field Characterization of Dynamic Replacement of Florida Organic Soils, Ph.D. dissertation, University of South Florida, Tampa, 1996.)

FIGURE 14.38 Schematic diagram of a shallow footing.

14.3.1.2 Hansen's Expression

$$q_{ult} = s_c d_c i_c c N_c + s_q d_q i_q q N_q + s_\gamma d_\gamma i_\gamma 0.5 B \gamma N_\gamma \tag{14.33}$$

where:

- $N_c, N_q,$ and N_γ are bearing capacity factors (Table 14.11).
- s coefficients are shape factors based on B/L (Table 14.12).
- d coefficient are depth factors based on D_f/B (Table 14.12).
- i coefficients are inclination factors based on load inclination ϕ (Table 14.12).
- γ is the unit weight of soil in the footing influence zone.
- c and ϕ are the shear strength parameters of the soil.

Thus, to avoid bearing-capacity failure:

$$\frac{q_{n,ult}}{F} > \frac{P}{A} \tag{14.34}$$

where:

- $q_{n,ult}$ = net ultimate bearing capacity based on Equation 14.35.
- P = structural load.
- A = footing area.
- F = safety factor.

$$q_{n,ult} = q_{ult} - q \tag{14.35}$$

TABLE 14.11 Bearing Capacity Factors

ϕ	Terzaghi's Expression			Hansen's Expression		
	N_c	N_q	N_γ	N_c	N_q	N_γ
0	5.7	1.0	0.0	5.14	1.0	0.0

TABLE 14.12 Shape, Depth, and Inclination Factors

	Hansen's Expression	Terzaghi's Expression
	$S_q = 1 + (B/L) \tan\phi$ $S_\gamma = 1 - 0.4(B/L)$	1.0 for strip footings 0.6 for circular footings 0.8 for square footings
Depth	For $D_f/B < 1$: $d_c = 1 + 0.4(D_f/B)$ $d_q = 1 + 2 \tan\phi(1 - \sin\phi)^2(D_f/B)$ $d_\gamma = 1$ For $D_f/B > 1$: $d_c = 1 + 0.4 \tan^{-1}(D_f/B)$ $d_q = 1 + 2 \tan\phi(1 - \sin\phi)^2 \tan^{-1}(D_f/B)$ $d_\gamma = 1$	
Inclination	$i_c = i_q = (1 - \beta/90^\circ)^{2a}$ $i_\gamma = (1 - \beta/\phi)^{2a}$	

^a Here, β is the load inclination to the vertical.

Example 14.6

Proportion a suitable footing for a 1000-kN vertical column load on a sandy ground where the SPT results are as indicated below. Assume that the groundwater table is at a depth of 0.5 m below the ground surface.

Elevation (m)	N
1.0	5
2.0	7
3.0	10
4.0	12
5.0	12

An average N value has to be determined from the above data within the influence zone of the footing. For this, one has to assume a footing size, as the influence zone depends on the size of the footing, so assume a circular footing of diameter 1.5 m placed at a depth of 1 m from the ground surface. As indicated in Figure 14.39, the influence zone extends from $0.5D_f$ above the footing (i.e., elevation -0.5 m) to $2B$

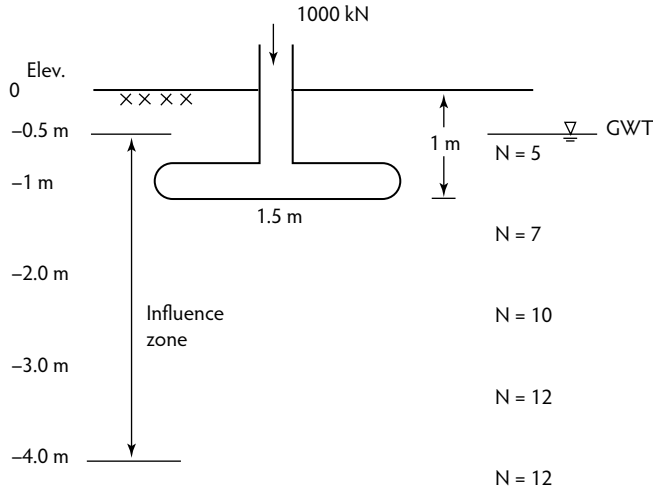

FIGURE 14.39 Foundation influence zone.

below the footing (i.e., -4.0 m). Then, by averaging the corrected N values within this range, one can obtain the average N' as worked out in the table below:

Elevation (m)	N	σ'_v (kPa)	C_N	N'
1.0	5	12.1	2.81	14
2.0	7	19.3	2.23	15.6
3.0	10	26.5	1.9	19
4.0	12	33.7	1.69	20.3

Note: Average $N' = [14(1.0) + 15.0(1.0) + 19(1.0) + 20.3(0.5)]/3.5 = 17$.

Note that the vertical effective stresses (σ'_v) are obtained using Equation 14.3 and assuming unit weights of 17.0 kN/m^3 and 9.8 kN/m^3 , respectively, for sand and water, while C_N is obtained using Equation 14.6.

Then, from Table 14.4, a ϕ of 37° can be found. This yields interpolated values $N_c = 60$, $N_q = 49$, and $N_\gamma = 57$ from Table 14.11 (Hansen's factors). The following factors can also be evaluated from Table 14.12:

$$s_c = 1.816, \quad s_q = 1.657, \quad s_\gamma = 0.6$$

$$d_c = 1.266, \quad d_q = 1.176, \quad d_\gamma = 1.0$$

$$i_c = 1.0, \quad i_q = 1.0, \quad i_\gamma = 1.0 \text{ (because the load is applied vertically)}$$

The following quantities are also needed for Equation 14.35:

$$q = \sigma'_v \text{ at the foundation level} = 12.1 \text{ kPa}$$

$$\gamma = \gamma' \text{ (because the foundation is fully submerged)} = 17.0 - 9.8 = 7.2 \text{ kN/m}^3$$

Finally, by substituting the above values in Equation 14.33, one obtains the ultimate bearing capacity as:

$$q_{n,ult} = (1.657)(1.176)(12.1)(49 - 1) + (0.5)(0.6)(1.0)(1.5)(7.2)(57) = 1316.7 \text{ kPa}$$

Note that the cohesion term is dropped due to negligible cohesion in sandy soils. Then, using Equation 14.34, one obtains a safety factor of $1316.7(1000/1.5/1.5) = 2.96$, which provides an adequate design; hence, a 1.5×1.5 -m footing at a depth of 1.0 m would suffice. Note that, if the groundwater table was well below the footing (usually greater than $2B$), then one would revise the following quantities as:

$$q = \sigma_v' \text{ at foundation level} = 17 \text{ kPa}$$

$$\gamma = \text{kN/m}^3$$

If the groundwater table was below the footing but still near it (a distance of d below), one can use the following approximation to evaluate the γ term:

$$\gamma = \gamma' + \frac{(\gamma_{\text{dry}} - \gamma')d}{2B} \quad (14.36)$$

As an example, if the groundwater table was 2.0 m below the ground, one can assume a γ_{dry} of 16.5 kN/m³ to modify the above two quantities as:

$$q = \sigma_v' \text{ at foundation level} = 16.5 \text{ kPa}$$

$$\gamma = 7.2 + (16.5 - 7.2)(1.0)/2(1.5) = 10.3 \text{ kN/m}^3$$

14.3.2 Footings with Eccentricity

If a footing has to be designed for a column that carries an axial load (P) as well as a moment (M), or an eccentric axial load, the resulting contact pressure distribution is as shown in Figure 14.40a. One realizes, however, that this is statically equivalent to the uniform distribution shown in Figure 14.40b; hence, a simple method of computing the bearing capacity is to assume that only the portion of the footing containing the column at its center contributes to bearing capacity. When designing such a footing, modified dimensions (B' and L') have to be used in Equation 14.32 or Equation 14.33, where B' and L' are defined as follows:

$$B' = B - 2e_x$$

$$L' = L - 2e_y$$

Example 14.7

Check the adequacy of the footing shown in Figure 14.41 for the soil data obtained from the UU test in Example 14.3 ($c_u = 50.6$ kPa). From Figure 14.41:

$$e_x = M_x/P = 50.0 \text{ kNm}/250.0 \text{ kN} = 0.2 \text{ m}$$

$$e_y = M_y/P = 62.5 \text{ kNm}/250.0 \text{ kN} = 0.25 \text{ m}$$

Then, $B' = 1.1$ and $L' = 1.1$. Because $\phi = 0^\circ$, one obtains $N_c = 5.14$, $N_q = 1.0$, and $N_\gamma = 0.0$ from Table 14.11; hence, the only significant term in Equation 14.33 is the cohesion term, and only the relevant factors are computed as follows:

$$S_c = 1 + 1.0/5.14 = 1.195$$

$$d_c = 1 + 0.4(1.0/1.5) = 1.267$$

$$i_c = 1.0$$

$$q_{ult} = 1.195(1.267)(50.6)(5.14) = 393.78 \text{ kPa}$$

Finally, the safety factor can be computed as:

$$F = (393.78)(1.1)(1.0)/250 = 1.733$$

Because the safety factor has to be more than 2.5, this is not a safe design. This factor can be improved by increasing the dimensions to about 2.0×2.0 m, depending on the available space.

FIGURE 14.40 Simplistic design of an eccentric footing: (a) pressure distribution due to an eccentric load, and (b) equivalent pressure distribution.

FIGURE 14.41 Design of an eccentric footing: (a) plan, and (b) elevation.

14.3.3 Presumptive Load-Bearing Capacity

The building codes of some cities suggest bearing capacities for a certain building site based on the classification of the predominant soil type at the site. Table 14.13 presents a comprehensive list of presumptive bearing capacities for various soil types; however, it should be noted that these values do not reflect the foundation shape, depth, load inclination, location of the water table, and settlements that are associated with the sites. For this reason, the use of these bearing capacities is primarily advocated in situations where a preliminary idea of the potential foundation size is needed for the subsequent site investigation.

14.4 Mat Footings

Because mat footings are larger in dimension than isolated spread footings, they are commonly used for transferring multiple column loads to the ground to prevent bearing-capacity failures. Thus, an ideal application of a mat footing would be on relatively weak ground. However, if the ground has sufficient strength to produce adequate bearing for isolated spread footings, a mat footing will be an economical alternative only if the combined area of the spread footings is less than 50% of the entire building plan area.

14.4.1 Design of Rigid Mat Footings

14.4.1.1 Bearing Capacity of a Mat Footing

One can use Equation 14.32 or Equation 14.33 to proportion a mat footing if the strength parameters of the ground are known. However, because the most easily obtained ground strength parameter is the standard penetration blow count (N), an expression is available that uses N to obtain the bearing capacity of a mat footing on a granular subgrade. This is expressed as follows:

TABLE 14.13 Presumptive Bearing Capacities

Soil Description	Presumptive Bearing Capacities from Indicated Building Codes (kPa)

Source: Bowles, J.E., *Foundation Analysis and Design*, McGraw-Hill, New York, 1995. With permission.

$$q_{n,\text{all}} = \frac{N}{0.08} \left(1 + \frac{1}{3.28B} \right)^2 \left(1 + \frac{0.33D_f}{B} \right) \left(\frac{s}{25.4} \right) \quad (14.37)$$

where:

$q_{n,\text{all}}$ = net allowable bearing capacity (kPa).

B = width of footing.

s = settlement (mm).

D_f = depth of footing (mm).

Then, the following condition has to be satisfied to avoid bearing failure:

$$q_{n,\text{all}} > \frac{P}{A} \quad (14.38)$$

in which the use of a safety factor is precluded by employing an allowable bearing capacity.

Example 14.8

Figure 14.42 shows the plan of a column setup where each column is 0.5×0.5 m in section. Design an adequate footing if the corrected average SPT blow count of the subsurface is 10 and if the allowable settlement is 25.4 mm (1 in.). Assume a foundation depth of 0.5 m. The bearing capacity can then be computed from Equation 14.37 as:

$$q_{n,\text{all}} = 10 \left[1 + 0.33(0.5)/5.0 \right] \left[1 + 0.3/5.0 \right] / (0.08) = 136.87 \text{ kPa}$$

FIGURE 14.42 Illustration of a mat footing.

FIGURE 14.43 Free-body diagram for strip BCGF (Figure 14.42).

By applying Equation 14.38:

$$4000 / (5.0 + 2e)^2 < 136.87$$

$$e > 0.2029 \text{ m}$$

Hence, the mat can be designed with a 0.25-m edge space as shown in Figure 14.42.

For the reinforcement design, one can follow the simple procedure of separating the slab into a number of strips as shown in Figure 14.42. Each strip (BCGF in Figure 14.42) can be considered as a beam. The uniform soil reaction per unit length (w) can be computed as $(4000)(2.5) / [(5.5)(5.5)] = 330.5 \text{ kN/m}$. Figure 14.43 indicates the free-body diagram of the strip BCGF (Figure 14.42). It can be seen from the free-body diagram that the vertical equilibrium of each strip is not satisfied because the resultant downward load is 2000 kN, as opposed to the resultant upward load of 1815 kN. This discrepancy results from the arbitrary separation of strips at the midplane between the loads where nonzero shear forces exist. In fact, one realizes that the resultant upward shear at the boundaries BF and CG (Figure 14.42) account for the difference—that is, 185 kN. To obtain shear and moment diagrams of the strip BCGF, one can add this to modify them as indicated in the figure. This was achieved by reducing the loads by a factor of 0.954 and increasing the reaction by a factor of 1.051. The two factors were determined as follows:

- For the loads, $[(2000 + 1815)/2] / 2000 = 0.954$
- For the reaction, $[(2000 + 1815)/2] / 1815 = 1.051$

FIGURE 14.44 Distribution of shear on strip BCGF (Figure 14.42).

FIGURE 14.45 Distribution of moment on strip BCGF (Figure 14.42).

The resulting shear and moment diagrams are indicated in Figure 14.44 and Figure 14.45. Now, using Figure 14.44 and Figure 14.45, we can determine the steel reinforcements as well as the mat thickness. This estimation is not repeated here as it can be found in other chapters of this book.

14.4.1.2 Settlement of Mat Footings

The settlement of mat footings can also be found using the methods that were outlined in Section 14.1.3 (Compressibility and Settlement), assuming that they impart stresses on the ground in a manner similar to that of spread footings.

14.4.2 Design of Flexible Mat Footings

Flexible mat footings are designed based on the principle of slabs on elastic foundations. Because of their finite size and relatively large thickness, one can expect building foundation mats to generally exhibit rigid footing behavior; therefore, applications of flexible footings are limited to concrete slabs used for highway or runway construction. The most significant parameter associated with the design of beams on elastic foundations is the radius of relative stiffness ($1/\beta$) given by the following expression:

$$\frac{1}{\beta} = 4 \sqrt{\frac{Eh^3}{12(1-\mu^2)k}} \quad (14.39)$$

where:

E = elastic modulus of concrete.

μ = Poisson's ratio of concrete.

k = coefficient of subgrade reaction of the foundation soil usually determined from the plate load test (Section 14.2.1) or Equation 14.40.

h = slab thickness.

$$k = \frac{E_s}{B(1-\mu_s^2)} \quad (14.40)$$

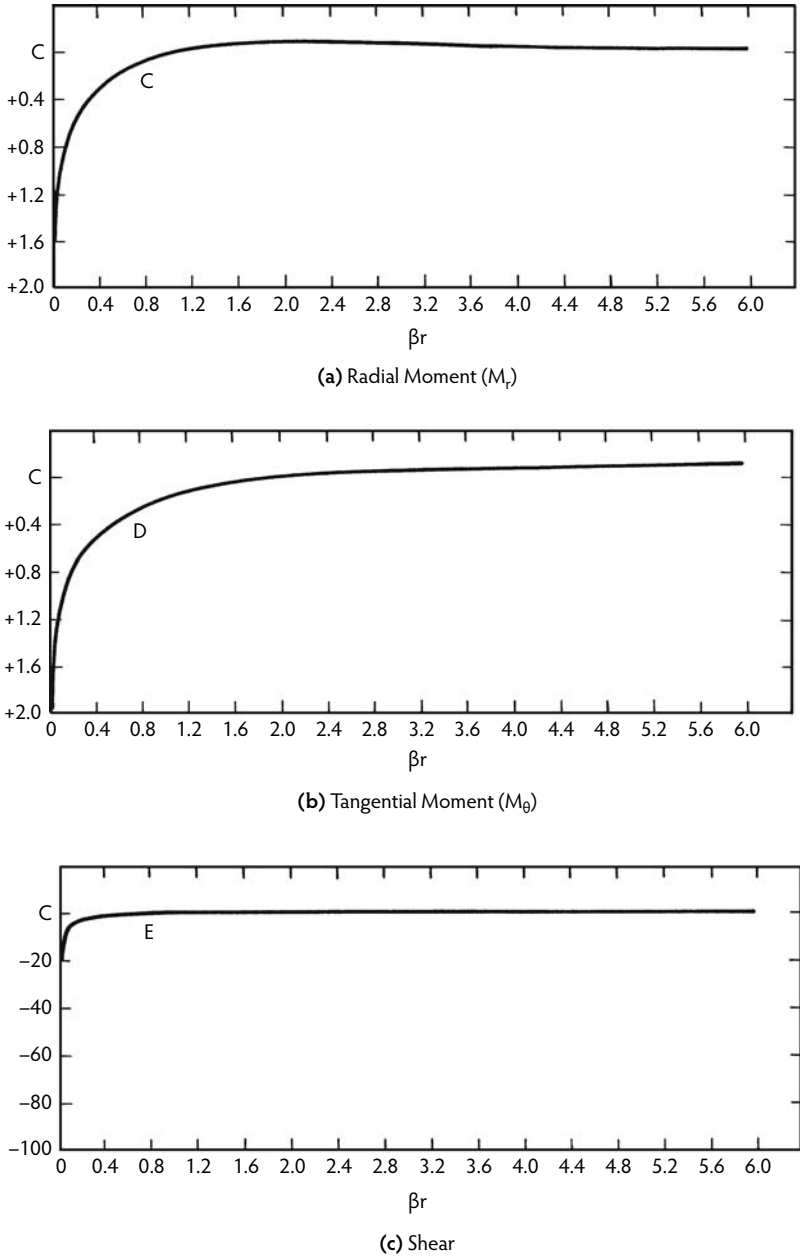

FIGURE 14.46 Radial and tangential moments and shear coefficients in a slab under point load. (From Scott, R.F., *Foundation Analysis*, Prentice Hall, Englewood Cliffs, NJ, 1981. With permission.)

where:

E_s = elastic modulus of subgrade soil.

μ_s = Poisson's ratio of subgrade soil.

When β has been evaluated for a particular mat, the shear, moment, and reinforcing requirements can be determined from nondimensional charts that are based on the solution for a concentrated load (P) applied to a slab on an elastic foundation. The following expressions can be used, along with Figure 14.46, for the evaluation:

FIGURE 14.47 Influence chart for determining moment at the edge of a slab. (From Pickett, G. and Ray, G.K., *Am. Soc. Civ. Eng. Trans.*, 116(2425), 49-73, 1951.)

$$M_r = -\frac{P}{4}C \tag{14.41a}$$

$$M_\theta = \frac{P}{4}D \tag{14.41b}$$

$$V = -\frac{P\beta}{4}E \tag{14.42}$$

FIGURE 14.48 Illustration of an infinite flexible slab.

TABLE 14.14 Flexible Footing Moments

Distance from A (ft)	C Coefficient for Load at A	C Coefficient for Load at B	C Coefficient for Load at C	Moment (kip-ft)
0.0	1.6	0.18	0.0	122.5
1.0	0.8	0.25	0.02	32.25
2.0	0.5	0.4	0.05	84.38
3.0	0.4	0.5	0.08	92.5
4.0	0.25	0.8	0.1	121.88
5.0	0.18	1.6	0.18	222.5
6.0	0.1	0.8	0.25	121.88
7.0	0.08	0.5	0.4	92.5
8.0	0.05	0.4	0.5	84.38
9.0	0.02	0.25	0.8	32.25
10.0	0.0	0.18	1.6	122.5

The moment due to a distributed load can be obtained by drawing the contact area on an influence chart, such as the one shown in Figure 14.47, and then using Equation 14.43. It should be noted that the scale for the drawing should be selected such that $1/\beta$ is represented by the distance l shown in Figure 14.47:

$$M = \frac{P(1/\beta)^2 N}{10,000} \tag{14.43}$$

where:

P = distributed load.

N = number of elements covered by the loading area drawn.

Example 14.9

Plot the shear and moment distribution along the columns A, B, and C of the infinite slab of 8-in. thickness shown in Figure 14.48. Consider it to be a flexible footing. Assume a coefficient of subgrade reaction of 2600 lb/ft³. Because $E_c = 5.76 \times 10^8$ psf and $\mu_c = 0.15$, then one can apply Equation 14.39 to obtain $\beta = 0.1156$ ft⁻¹. Using the above results, Figure 14.46a, and Equation 14.41a, Table 14.14 can be developed for the radial moment (the moment on a cross-section perpendicular to the line ABC in Figure 14.48). These moment values are plotted in Figure 14.49.

14.5 Retaining Walls

When designing a retaining structure, one must ascertain that its structural capacity is adequate to withstand any potential instability that can be caused by the lateral earth pressures of the retained backfill; hence, a major step in the design of a retaining structure is the evaluation of the magnitude, direction, and the line of action of the lateral force. Most of the methods available for analyzing lateral earth pressures assume a yielding soil mass in the vicinity of the retaining structure, so the solutions are based on the limit equilibrium. The magnitude of the lateral force depends on the soil failure mechanism. The mechanism in which the backfill yields with the outward movement of the wall is known as the *active*

FIGURE 14.49 Moment distribution on a flexible slab (in kip-ft).

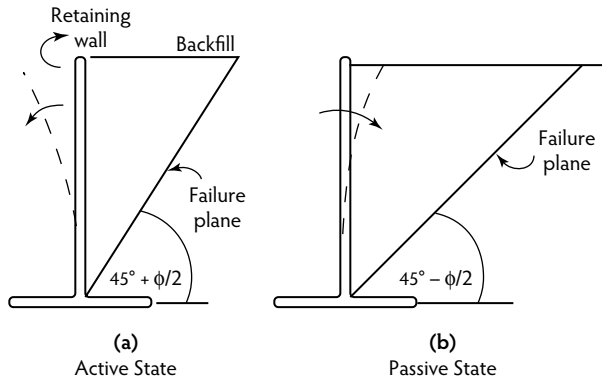

FIGURE 14.50 Illustration of (a) active and (b) passive states.

failure mechanism (Figure 14.50a), while the yielding of soil due to inward wall movement is termed the *passive failure mechanism* (Figure 14.50b). Also indicated on Figure 14.50 is the orientation of the failure planes for each condition in the case of a smooth, vertical wall supporting a horizontal backfill. The two most widely used analytical methods are illustrated below.

14.5.1 Determination of Earth Pressures

14.5.1.1 Rankine Method

The Rankine method of analysis can be employed for the relatively simple case of a smooth, vertical wall supporting a homogeneous backfill. A modified form of Rankine’s original analysis allows one to obtain the active and passive earth pressure distributions by using the following expressions:

$$\sigma'_a = \sigma'_v K_a - 2c\sqrt{K_a} \tag{14.44}$$

and

$$\sigma'_p = \sigma'_v K_p - 2c\sqrt{K_p} \tag{14.45}$$

where the subscripts *a* and *p* stand for active and passive states, respectively, and the coefficients of earth pressure K_a and K_p can be determined from the following expressions:

$$K_a = \cos\beta \frac{\cos\beta - \sqrt{\cos^2\beta - \cos^2\phi}}{\cos\beta + \sqrt{\cos^2\beta - \cos^2\phi}} \tag{14.46}$$

FIGURE 14.51 Illustration of the Earth's pressure distribution.

and

$$K_p = \cos\beta \frac{\cos\beta + \sqrt{\cos^2\beta - \cos^2\phi}}{\cos\beta - \sqrt{\cos^2\beta - \cos^2\phi}} \tag{14.47}$$

where:

β = inclination of the backfill.

c, ϕ = soil strength parameters.

The direction of the resultant lateral pressure and the line of action are indicated on Figure 14.51.

Example 14.10

Determine the lateral pressure on the retaining wall shown in Figure 14.51. Assume active conditions. By using Equations 14.46, one obtains $K_a = 0.38$. Then, by using Equation 14.44,

At $z = 0.0$ m, $\sigma'_a = -2(10)(0.616) = -12.32$ kPa.

At $z = 2.0$ m, $\sigma'_a = 0.6$ kPa.

At $z = 8.0$ m, $\sigma'_a = 19.3$ kPa.

The line of action of the effective force can be found by discretizing the pressure diagram into five segments as shown in Figure 14.51:

Segment	Area (A)	Centroidal Distance (z)	Az
1	-11.77	0.64	-7.49
2	0.027	1.97	0.053
3	112.2	6.0	673.2
4	3.6	5.0	18.0

Hence,

$$z = (-7.49 + 0.053 + 673.2 + 18.0) / (-11.77 + 0.027 + 112.2 + 3.6) = 6.57 \text{ m}$$

In obtaining the total force on the wall, one should remember to include the water pressure in segment 5 in addition to the effective force.

FIGURE 14.52 Illustration of the application of Coulomb's analysis.

14.5.1.2 Coulomb Method

The Coulomb method of analysis is an attractive alternative to the Rankine method due to its ability to handle more complex cases involving rough, nonvertical retaining walls. The relevant equations for lateral earth pressure coefficients are given below:

$$K_a = \frac{\sin^2(\alpha + \phi)}{\sin^2 \alpha \sin(\alpha - \delta) \left[1 + \frac{\sin(\phi + \delta) \sin(\phi - \beta)}{\sin(\alpha - \delta) \sin(\alpha + \beta)} \right]^2} \quad (14.48)$$

$$K_p = \frac{\sin^2(\alpha - \phi)}{\sin^2 \alpha \sin(\alpha + \delta) \left[1 + \frac{\sin(\phi + \delta) \sin(\phi + \beta)}{\sin(\alpha + \delta) \sin(\alpha + \beta)} \right]^2} \quad (14.49)$$

where α and δ are the inclination of the wall face to the horizontal and the angle of wall friction, respectively. As illustrated in Figure 14.52, the direction of the resultant lateral force changes when conditions change from active to passive states, with the line of action remaining on the generators of the friction cone. The above coefficients can be used in conjunction with Equation 14.44 and Equation 14.45.

On the other hand, if $\alpha = 90^\circ$, and $\beta = \delta = 0^\circ$, it can be easily shown that Equation 14.48 and Equation 14.46 reduce to:

$$K_a = \frac{1 - \sin \phi}{1 + \sin \phi} \quad (14.50)$$

Hence one can see that Rankine's and Coulomb's analytical predictions agree only when earth pressures are predicted on smooth, vertical walls supporting horizontal backfills. In this case, the direction of the lateral force is horizontal.

Example 14.11

Use the Coulomb method to determine the lateral earth pressure on the wall shown; assume passive conditions. Because the angle of wall friction (δ) is not specified in this problem, it would be adequate to assume that $\delta = (2/3)\phi = 13.33^\circ$. Substituting $\alpha = 70^\circ$, $\phi = 20^\circ$, $\delta = 13.33^\circ$, and $\beta = 0^\circ$ in Equation 14.49, one would obtain $K_p = 1.968$. With $c = 0.0$, and a surcharge of q , Equation 14.45 reduces to the following:

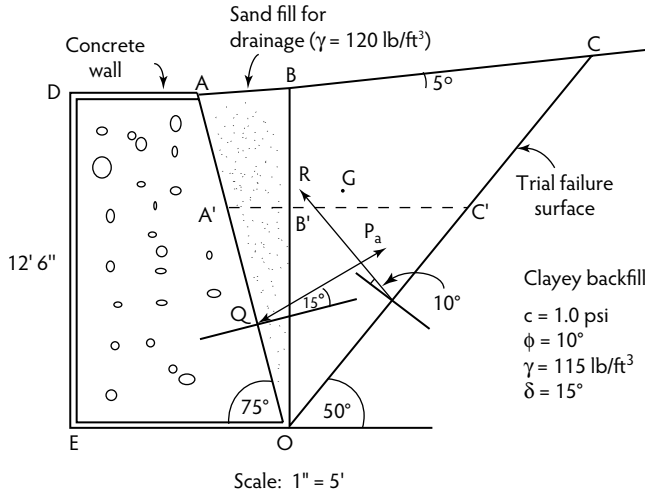

FIGURE 14.53 Trial wedge method.

$$\sigma'_p = (\sigma'_v + q)K_p \tag{14.51}$$

where $\sigma'_v = 120z$, and $q = 610$ psf. Then, one would obtain the passive pressure distribution as:

$$\sigma_p = 236.16z + 1200 \tag{14.52}$$

and the resultant lateral force will be 44.568 kips/ft acting at a distance of 6.0 ft above the base, as shown in Figure 14.52.

14.5.1.3 Trial-Wedge Method

When the backfill is nonhomogeneous or if there is a finite or a concentrated surcharge on the backfill, the above methods cannot be used to determine the earth pressures. In such situations, the lateral force on a retaining wall can be estimated by the graphical construction of the force polygon for a selected potential failure wedge. The following example is provided to illustrate this technique.

Example 14.12

Use the trial-wedge solution to estimate the active soil pressure on the retaining wall shown in Figure 14.53:

- Step 1. Select a trial failure surface. An appropriate initial estimate would be the one corresponding to a smooth vertical wall with a horizontal backfill indicated in Figure 14.50. Hence, in this case, select a surface with an inclination of $45^\circ + (10^\circ/2) = 50^\circ$ to the horizontal (OC).
- Step 2. In the case of active conditions, estimate the depth up to which tension develops ($= 2c/\gamma K_a$) and demarcate the area of tension cracks. In this case, the vertical depth of tension cracks is 4.4 ft, and the tension crack area is indicated by $A'B'C'$. Therefore, an effective cohesive force is developed on the OC surface only up to C' . This will have a magnitude of $OC' \times 1 \times 5 \text{ ft} \times 1.5 \times 144 \text{ psf} = 1.526$ kips.
- Step 3. Estimate the total weight of the failure wedge. If there is a water table, submerged unit weights must be used under the water table to account for buoyancy. In this case, the weight of AOC can be estimated as $(0.5 \times 12.6 \times 3.1 \times 120) + (0.5 \times 12.6 \times 11.5 \times 115) = 10.675$ kips.
- Step 4. Draw a force polygon assuming the indicated directions for the two other forces (active force on the wall and the reaction from the intact soil mass). In this case, these are designated as P_a and R on Figure 14.54.
- Step 5. Estimate P_a from the force polygon. In this case, $P_a = 5.25$ kips.

FIGURE 14.54 Force polygon.

- Step 6. Repeat the above procedure for a number of different trial failure planes. Estimate the minimum lateral force to be the actual P_a and consider the corresponding trial failure plane to be the actual failure plane.
- Step 7. If G is the centroid of the actual failure wedge, obtain the line of action of P_a from the point Q on the wall such that QG is parallel to the failure surface OC .

14.5.2 Design of Concrete Retaining Walls

The two basic types of concrete retaining walls are the *gravity* type and the *cantilever* type. The following conditions must be satisfied when designing a concrete retaining wall:

- Stability against overturning due to earth pressure
- Stability against base sliding due to earth pressure
- Prevention of any possible tensile stresses in the base soil

In addition to these design criteria, the design must also provide for a good drainage system and adequate bearing (see Section 14.3.1, Bearing Capacity of Shallow Footings) and no excessive settlements (see Section 14.1.3, Compressibility and Settlement).

14.5.2.1 Design of a Cantilever Retaining Wall

The basic design of a cantilever retaining wall is illustrated by the following example.

Example 14.13

Design a suitable cantilever retaining wall to support the backfill shown in Figure 14.55. Bowles (1995) recommended the tentative dimensions shown in Figure 14.56 for a cantilever retaining wall. Based on Bowles' recommendations, the dimensions shown in Figure 14.55 are assumed for the retaining wall. In computing the lateral pressure on the wall, it is usually assumed that the wall section starts at the cross-section CG shown in Figure 14.56; hence, the active wall pressure can be evaluated, using either of the described methods, as 4.496 kips/ft at a height 5 ft from the base. Despite the passive force due to the soil berm on the toe, practitioners generally neglect it for a conservative design. The weights of the different retaining wall components are computed as follows:

$$w_1 = (5.0 \times 13.5 \times 120)/1,000 = 8.1 \text{ kips/ft}$$

$$w_2 = (9.0 \times 1.5 \times 150)/1,000 = 2.025 \text{ kips/ft}$$

$$w_3 = (1.0 \times 13.5 \times 150)/1,000 = 2.025 \text{ kips/ft}$$

$$w_4 = (0.5 \times 0.5 \times 13.5 \times 150)/1,000 = 0.506 \text{ kips/ft}$$

The locations of the respective centroids from the toe are indicated below:

Element	Weight (w_i)	Centroidal Distance (x_i)	$w_i x_i$
1	8.1	6.5	52.65
2	2.025	4.5	9.11
3	2.025	3.5	7.09
4	0.506	2.83	1.43

FIGURE 14.55 Tentative design dimensions for a cantilever retaining wall. (From Bowles, J.E., *Foundation Analysis and Design*, McGraw-Hill, New York, 1995. With permission.)

FIGURE 14.56 Cantilever retaining wall design.

Stability Against Overturning. The factor of safety against overturning can be computed as:

$$F_1 = \frac{\text{Stabilizing moment}}{\text{Overturning moment}} = \frac{(52.65 + 9.11 + 7.09 + 1.43)}{4.496 \times 5} = 3.13$$

This is adequate, as it is greater than 1.5.

Stability Against Sliding. The normal reaction on the base is equal to $\Sigma w_i = 12.656$. Thus, the maximum frictional force on the base is equal to $12.656(\tan\phi) = 6.449$ kips/ft. Then, the safety factor against sliding can be computed as:

$$F_2 = \frac{\text{Stabilizing force}}{\text{Sliding force}} = \frac{6.449}{4.496} = 1.43$$

This is also acceptable, as it is greater than 1.25.

Check for Tension in the Base Soil. The eccentricity on the base produced by the above forces is equal to $0.5(8.1 \times 2.0 - 2.025 \times -0.506 \times 1.67 - 4.496 \times 5)/(12.656) = e = -0.723$ m. For tension not to develop in the base soil, $e < B/6$. Because $B/6.0 = 1.5$, the base tension criterion is also satisfied by this design (Figure 14.57).

FIGURE 14.57 Design details.

FIGURE 14.58 Load, shear, and moment diagrams for the retaining wall stem.

Reinforcement Requirements. To determine reinforcement requirements, the shear and bending moment diagrams can be drawn separately for the stem and the base (Figures 14.58 and 14.59). It should be noted that the maximum shear and moment in the stem occurs at its base and are 3.045 kips/ft and 16.412 kip-ft/ft, respectively. The reader should note that, when obtaining the shear and moment diagrams for the base, the base soil pressure is represented by a uniform distribution within a distance of B' (equal to $B - 2e$), as this is statically equivalent to an eccentric force of 12.656 kips/ft. A maximum shear force of 3.743 kips/ft is produced at the base. The reader should also note that in the moment diagram, within the stem area of the base, an unbalanced stem moment of 16.512 kips/ft (Figure 14.58) is gradually transferred to the base. Further, the heel of the base will have a moment of 4.2 kip-ft/ft due to the earth pressure distribution on the base thickness as shown in the load distribution diagram (Figure 14.59a). This information can be utilized for reinforcement design.

Drainage Design. The interested reader is referred to Bowles (1995) for further design details; however, one should remember the following preliminary guidelines:

- Provide a compacted free-draining soil layer adjacent to the retaining wall if the backfill material is clayey in nature.
- Provide a perforated collector drain with an appropriate soil or geomembrane filter at the base of the retaining wall.
- Make provisions for drainage outlets known as **weep holes** in the stem with a soil or geomembrane filter at the wall face to prevent clogging.

14.5.3 Effect of Water Table

In many instances, the soil behind an earth-retaining structure is submerged. Examples include seawalls, sheet pile walls in dewatering projects, and offshore structures. Another reason for saturation of backfill material is poor drainage, which leads to an undesirable buildup of water pressure behind the retaining

FIGURE 14.59 (a) Load, (b) shear, and (c) moment diagrams for the retaining wall base.

wall. Drainage failure often results in subsequent failure and collapse of the earth-retaining structure. In cases where the design considers the presence of a water table, the lateral earth pressure is calculated from the effective soil stress. Oddly enough, this leads to a *reduction* in effective horizontal earth pressure, as the effective stresses are lower than their total counterpart; however, the total stresses on the wall increase due to the presence of the hydrostatic water pressure. In other words, while the effective horizontal stress decreases, the total horizontal stress increases.

14.5.4 Reinforced Walls

14.5.4.1 Geogrid-Reinforced Walls

With the increased availability of high-strength geogrid materials in the 1990s, geogrid-reinforced walls were introduced as an alternative to metallic strip reinforcement. They provide increased interface area (because the coverage area can be continuous), better interlocking with the backfill (due to the geometry of the openings), resistance to corrosive environments, and lower cost. The most common type of geogrids used in earth reinforcement is the uniaxial type, due to its high strength and stiffness in the main direction. Facing panel units may be connected to the geogrid using a steel bar interwoven into the grid (known as a Bodkin connector) or, more recently, through special plastic clamps that tie into a geogrid section embedded in the concrete panel.

Among the concerns associated with the use of geogrids in heavily loaded walls (such as bridge abutments) are the time-dependent stress relaxation (creep deformation), installation damage, and chemical degradation. It is, therefore, crucial to determine the design strength of the geogrid considering the various reduction factors due to creep, installation damage, chemical degradation, and biological

FIGURE 14.60 Geotextile-reinforced wall with wrapped-around facing.

degradation (Gunaratne, 2006). In addition, it is extremely important to ensure that the geogrid is fully stretched during installation and compaction of the subsequent soil layer; otherwise, significant deformation is required before tensile stresses and interface friction are mobilized. A closely related problem that has been identified is the difficulty in keeping the facing elements plumb during installation, especially when close tolerance is required in tall walls.

Design and construction procedures for geogrid reinforced walls are almost identical to reinforced earth walls. One distinct exception is that the strength of the geogrid is expressed in terms of force per unit length, and the associated horizontal spacing (s_h) is taken as a unit length in all calculations. Another difference is that, because of the effective interlocking of the soil particles within the geogrid openings, the interface friction angle is usually equal to the internal friction angle of the soil.

14.5.4.2 Geotextile-Reinforced Walls

Unlike metallic and geogrid reinforcement, typical geotextile-reinforced wall designs do not require facing elements. Instead, the geotextile layer is wrapped around the compacted soil at the front to form the facing (Figure 14.60). The finished wall must be covered with shotcrete, bitumen, or gunitite to prevent ultraviolet radiation from reaching and damaging the geotextile. Such walls are usually constructed as temporary structures or where aesthetics are not of prime importance; however, it is possible to cover the wall with a permanent faux finish that blends with the surrounding environment. The design procedures for geotextile-reinforced walls are also identical to those described earlier for steel and geogrid reinforcement. The interface friction angle between the soil and the geotextile sheet is typically equal to $1/2$ to $2/3\phi$. In addition, the overlap length (L_o) must be determined from the following equation:

$$L_o = \frac{s_v \times \sigma_{h,z}}{2\sigma_{v,z} \times \tan\phi_i} \times FS_{\text{overlap}} \quad (14.53)$$

where s_v is the vertical spacing of the geotextile and z is any given depth. The minimum acceptable overlap length is 1 m.

14.5.5 Sheet Pile Walls

14.5.5.1 Cantilever Sheet Piles

A conceptual representation of the lateral earth pressure acting on a cantilever sheet pile is shown in Figure 14.61. Only active pressure is present on side A, from the ground surface to the depth of excavation. Below the excavation depth, passive conditions are assumed to act on side B of the sheet pile, while active conditions persist on side A, up to point O, where a reversal of conditions occurs. Point O can be viewed roughly as the point of rotation of the sheet pile in the ground. Such rotation is necessary to achieve static equilibrium of the system. Below point O, active conditions develop on side B while passive earth pressures are present on side A. Cantilever sheet pile design typically involves the determination of the embedment depth (D), given other geometric constraints of the problem as well as soil properties. Therefore, the first step is to calculate the magnitude of the horizontal stresses

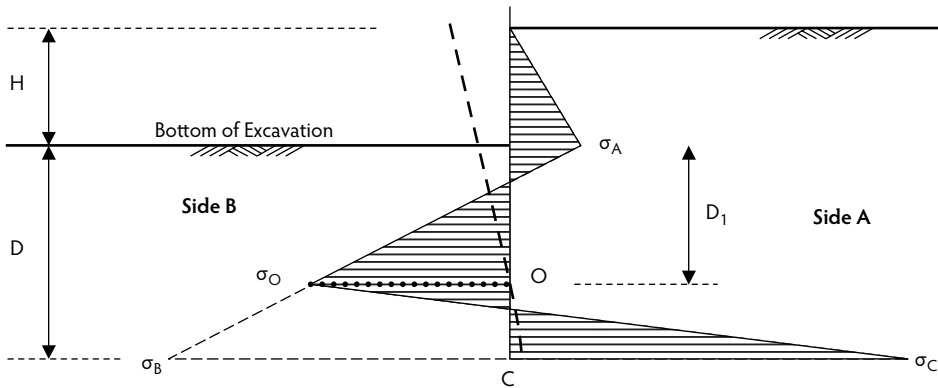

FIGURE 14.61 Conceptual representation of lateral earth pressure on a cantilever sheet pile wall.

σ_A , σ_B , and σ_C . The value of σ_A is readily calculated as the active earth pressure acting at depth H . The magnitudes of σ_O and σ_B must be calculated as a function of the embedment depth (D) and the depth to the rotation point (D_1), both of which are unknown. The value of σ_O is calculated assuming passive conditions on side B and active conditions on side A. Similarly, σ_B is calculated with passive earth pressure on side A and active earth pressure on side B. Two equilibrium conditions are to be satisfied: The sum of the horizontal forces and the sum of the moments in the system must be equal to zero. By solving both equilibrium equations, the two unknowns, D and D_1 , can be determined. As force and moment calculations become complex, it is often convenient to determine the value of σ_C , which is the hypothetical lateral earth pressure at depth D that corresponds to passive earth pressure on Side B and active earth pressure on Side A.

14.5.5.2 Anchored Sheet Piles

For large excavation depths, the inclusion of an anchor tie rod is necessary to reduce the moment on the sheet pile wall; otherwise, unreasonably large cross-sections may be required to resist the moment. Anchored sheet piles may be analyzed using either the free earth support or the fixed earth support method. Under free earth support conditions, the tip of the sheet pile (Figure 14.62) is assumed to be free to displace and rotate in the ground. Only active earth pressures develop on the tie-back side, while passive pressures act on the other side. No stress reversal or rotation points exist down the embedded depth of the sheet pile. In contrast, the tip of fixed-earth support sheet piles is assumed to be restricted from rotation. Stress reversal occurs down the embedded depth, and the sheet pile is analyzed as a statically indeterminate structure.

To design free earth support sheet piles, typically the depth of the anchor tie rod must be known. Equilibrium conditions are checked in terms of horizontal forces and moments, and the force in the tie rod as well as the depth of embedment are calculated accordingly. Alternatively, the maximum allowable force in the tie rod may be given, while the depth of the tie rod and the embedment depth of the sheet pile are unknowns. It is usually convenient to sum the system moments about the connection of the tie rod with the sheet pile to eliminate the tensile force in the tie rod from the equation.

The necessary anchor resistance in the tie rod is supplied through an anchor plate or deadman located at the far end of the tie rod (Figure 14.62a). To ensure stability, the anchor plate must be located outside the active wedge behind the sheet pile, which is delineated by line AB from the tip. In addition, this active wedge must not interfere with the passive wedge through which the tension in the tie rod is mobilized, which is bounded by the ground surface and line BC. Therefore, the length of the tie rod (L_t) is calculated from:

$$L_t = (H + D) \tan(45 - \phi/2) + D_1 \tan(45 + \phi/2)$$

FIGURE 14.62 Conceptual representation of lateral earth pressure on tie-rod-anchored sheet pile walls: (a) free earth support; (b) fixed earth support.

Example 14.14

For the sheet pile wall shown in Figure 14.62a, determine the depth of embedment (D) and the force in the tie rod. The soil on both sides of the sheet pile is well-graded sand, with a unit weight $\gamma = 19 \text{ kN/m}^3$ and an internal friction angle of 34° . The tie rods are spaced at 3 m horizontally and are embedded at a depth $H_1 = 1 \text{ m}$. The height of the excavation $H = 15 \text{ m}$.

Solution

The active force (P_a) on the right side is calculated from:

$$P_a = \frac{1}{2} K_a \gamma (H + D) = \frac{1}{2} \times 0.283 \times 19 \times (15 + D) = 40.328 + 2.689D$$

The passive force (P_p) on the right side is calculated from:

$$P_p = \frac{1}{2} K_p \gamma D = \frac{1}{2} \times 3.537 \times 19 \times D = 33.60D$$

The sum of the moments about point O is:

$$(40.328 + 2.689D) \left(\frac{2}{3} \{15 + D\} - 1 \right) - (33.60D) \left(15 + \frac{2}{3} D \right) = 0$$

Solving for D , we obtain:

$$D = 0.77 \text{ m}$$

FIGURE 14.63 Examples of braced excavations.

FIGURE 14.64 Approximate earth pressure diagrams for use in designing braced excavations: (a) sand; (b) soft to medium clay; and (c) stiff fissured clay.

The tension in the tie rods per meter width of the sheet pile wall is then calculated from the equilibrium of the horizontal forces:

$$T(\text{per m}) = (40.328 + 2.689 \times 0.77) - (33.60 \times 0.77) = 16.3 \text{ kN/m}$$

The force in each tie rod is calculated by multiplying the result by the horizontal spacing:

$$T = 3 \times 16.53 = 50 \text{ kN}$$

Theoretical depth D is multiplied by a safety factor of 1.2, thereby giving a total embedment depth of 0.92 m, which is rounded to 1.0 m.

14.5.6 Braced Excavations

Excavations in urban environments are constrained by the lack of adjacent space for installing tie rods or ground anchors. Where cantilever sheet piles are impractical, it becomes imperative to provide support to the sheet piles through internal bracing and struts. Examples of typical braced excavations are shown in Figure 14.63. It is important to ensure that the bracing system is stiff enough to prevent or minimize adjacent ground movement and strong enough to resist the earth pressure associated with such restricted deformations. Construction is usually initiated by driving the sheet piles or lateral support system, then excavating gradually from the ground level down. Rows of bracing or lateral support are installed as the excavation progresses down. The earth pressure developing in the case of braced excavations is different from the theoretical linear increase with depth described earlier for conventional retaining walls. In braced excavations, the lateral earth pressure is dictated by the sequence of excavation, soil type, stiffness of the wall and struts, and movement allowed prior to installing the struts. Although accurate determination of the distribution of earth pressure in braced cuts is almost impossible, Terzaghi et al. (1996) provided approximate methods based on actual observations for use in strut design (Figure 14.64). In the case of sands, the envelope of the apparent earth pressure is constant and equal to $0.65 K_a \gamma H$, where H is the depth of the excavation. In the case of soft/medium clays and stiff fissured clays, the diagrams shown in Figure 14.64b and Figure 14.64c are used, respectively. It is

FIGURE 14.65 Construction of soil-nailed wall.

imperative, however, to monitor the development of forces in the struts and deformations along the depth of the braced cut during construction. Forces in the struts and deformations must be continuously adjusted to comply with design specifications.

14.5.7 Soil Nail Systems

Soil nailing is a technique for stabilizing steep slopes and vertical cuts. The technique relies on driving soil nails, which are steel rods 25 to 50 mm in diameter, into a vertical or steep cut at a 15° angle as excavation proceeds (Figure 14.65). Alternatively, the soil nails may be installed through drilling and grouting. Conceptually, the method differs from tie-back anchored walls in that no prior driving or installation of an earth retaining wall (sheet pile, soldier piles, or slurry wall) is conducted. Instead, the exposed soil surface is kept from caving in by installing a wire mesh on which the soil nails are connected through face plates. The technique works best in cohesive soils, as significant unraveling may occur in sandy soils. The wire mesh is then covered with shotcrete, and excavation proceeds to the next level. Soil nail walls are typically used as temporary earth-retaining systems, although they have been used successfully as permanent structures. When analyzing soil nail systems, global stability is considered. Conventional methods for slope stability analysis are used, with the tension in the soil nails contributing to the stability of the slope. Typically, the method of slices is chosen, and the forces acting on each slice, including the tensile resistance of the soil nail, are included. The global stability of the reinforced soil mass is then assessed, and a factor of safety is calculated. The length of the soil nails is determined accordingly, so as to satisfy equilibrium of the slope or vertical cut.

14.5.8 Drainage Considerations

Proper drainage of backfill materials is a crucial component of retaining wall design. In general, cohesive backfills are highly undesirable because of their poor drainage, loss of strength and increase in density upon wetting, and high coefficient of active earth pressure. This is particularly important in the case of mechanically stabilized earth (MSE) walls, where only select backfill material may be used. Acceptable soil types for such purpose are SW (well-graded sand), GW (well-graded gravel), and SP (poorly graded sand). The vast majority of current design codes prohibit the use of cohesive materials as backfill in MSE walls. In addition, proper drainage provisions must be included in the design. This entails the inclusion of drains and filters in the cross-section, such as those shown in Figure 14.66. While graded sand constituted the majority of filters and drains in the past, geosynthetics (geotextiles, geonets, and geocomposites) are used in almost all projects today. To select the proper filter material, the acceptable apparent opening size (O_{95}) of the geosynthetic must be first determined. Current guidelines require that O_{95} be smaller than $2.5D_{85}$, where D_{85} is the grain size corresponding to the 85th percentile of the grain size distribution of the soil. Geonets selected for drainage must have a maximum flow rate that is greater than the anticipated flow rate in the structure.

FIGURE 14.66 Drainage provisions in cantilever retaining wall.

14.6 Pile Foundations

A pile foundation can be employed to transfer superstructure loads to stronger soil layers deep underground; hence, it is a viable technique for foundation construction in the presence of undesirable soil conditions near the ground surface. However, due to the high cost involved in piling, this method is only utilized after other less costly alternatives, such as combined footings and ground modification, have been considered and ruled out for the particular application. On the other hand, piles may be the only possible foundation construction technique in the case of subgrades that are prone to erosion and in offshore construction.

14.6.1 Advantages of Concrete Piles

Depending on applicability, one of the three different pile types: timber, concrete, or steel, is selected for a given construction situation. Concrete piles are selected for foundation construction under the following circumstances:

- Heavy loads must be supported in maritime areas where steel piles can easily corrode.
- Stronger soil types are located at a relatively shallower depth that are easily accessible to concrete piles.
- Bridge piers and caissons require large-diameter piles.
- A large pile group is needed to support a heavy extensive structure so the total expense can be minimized.
- Minipiles are necessary to support a residential building on a weak and compressible soil.

The disadvantages of concrete piles are that they are damaged by acidic environments (organic soils) and undergo abrasion due to wave action when used to construct offshore structures.

14.6.2 Types of Concrete Piles

The two most common types of concrete piles are precast and cast *in situ*. Of these, precast piles may be constructed to specifications at a casting yard or at the site itself if a large number of piles is needed for the particular construction. In any case, handling and transportation can cause intolerable tensile stresses in precast concrete piles; hence, one should be cautious in handling them so as to minimize bending moments in the pile. Cast *in situ* piles are of two classes: (1) cased type, which are piles that are cast inside a steel casing that is driven into the ground, and (2) uncased type, which are piles that are formed by pouring concrete into a drilled hole or into a driven casing before the casing is gradually withdrawn.

FIGURE 14.67 Load-bearing capacity of a pile.

14.6.3 Estimation of Pile Capacity

The pile designer should be aware of the capacity of a pile under normal working conditions (**static**) and when it is driven (**dynamic**).

14.6.3.1 Static Pile Capacity

The ultimate working load that can be applied to a given pile depends on the resistance that the pile can produce in terms of side friction and point bearing (Figure 14.67); hence, the expression for the allowable load on a pile will take the following form:

$$P_a = \frac{P_{pu} + P_{su}}{F} \quad (14.54)$$

where:

- P_{pu} = ultimate point capacity.
- P_{su} = ultimate side friction.
- F = safety factor.

The ultimate point capacity component in Equation 14.54 corresponds to the bearing capacity of a shallow footing expressed by Equation 14.55, which is a modified form of Equation 14.32:

$$P_{pu} = A_p \left[cN_c^* + q(N_q^* - 1) \right] \quad (14.55)$$

where:

- A_p = area of the pile cross-section.
- q = vertical effective stress at the pile tip.
- c = cohesion of the bearing layer.
- N_c^*, N_q^* = bearing capacity factors modified for deep foundations (and a B/L ratio of 1.0).

The bearing capacity factors for deep foundations can be found in Figure 14.68. Using the above bearing capacity factors is more involved than in the case of shallow footings because, in the case of deep foundations, the mobilization of shear strength also depends on the extent of the penetration of the pile into the bearing layer. In granular soils, the depth ratio at which the maximum strength is mobilized is called the **critical depth ratio** $(L_v/D)_{cr}$. Figure 14.69 shows $(L_v/D)_{cr}$ for the mobilization of N_c^* and N_q^* for different values of ϕ . According to Meyerhoff (1976), the maximum values of N_c^* and N_q^* are usually mobilized at depth ratios of $0.5(L_v/D)_{cr}$. An interpolation process must be followed to evaluate the bearing capacity factors if the depth ratio is less than $0.5(L_v/D)_{cr}$. This is illustrated in Example 14.15.

FIGURE 14.68 Bearing capacity factors for deep foundations. (From Das, B.M., *Principles of Foundation Engineering*, PWS Publishing, Boston, MA, 1995. With permission.)

FIGURE 14.69 Variation of critical depth ratio with φ. (From Das, B.M., *Principles of Foundation Engineering*, PWS Publishing, Boston, MA, 1995. With permission.)

Point Capacity in Sands. In the case of sandy soils where the cohesive resistance is negligible, Equation 14.55 can be reduced to:

$$P_{pu} = A_p q (N_q^* - 1) \tag{14.56}$$

where the limiting point resistance is:

$$P_{pu_{max}} = A_p 50N_q^* \tan \phi \text{ (kN)}; P_{pu_{max}} = A_p N_q^* \tan \phi \text{ (kips)} \tag{14.57}$$

Point Capacity in Clays. The most critical design condition in clayey soils is the undrained condition where the apparent angle of internal friction is zero. Under these conditions, it can be seen that Equation 14.55 reduces to:

$$P_{pu} = A_p (9.0c_u) \quad (14.58)$$

where c_u is the undrained strength.

Skin-Friction Capacity of Piles. The skin-friction capacity of piles can be evaluated by means of the following expression:

$$P_{sf} = \int_0^L p f dz \quad (14.59)$$

where:

- p = perimeter of the pile section.
- z = coordinate axis along the depth direction.
- f = unit skin-friction at any depth z .
- L = length of the pile.

Unit Skin Friction in Sandy Soils. Because skin friction in granular soils is due to the frictional interaction between piles and granular material, the unit skin friction can be expressed as:

$$f = K \sigma'_v \tan \delta \quad (14.60)$$

where:

- K = earth pressure coefficient (K_0 for bored piles and $1.4K_0$ for driven piles).
- δ = angle of friction between the soil and pile material (usually assumed to be $2/3\phi$).
- σ'_v = vertical effective stress at the point of interest.

It can be seen from the above expression that the unit skin friction can increase linearly with depth; however, practically, a depth of $15B$ (where B is the cross-sectional dimension) has been found to be the limiting depth for this increase.

Skin Friction in Clayey Soils. In clayey soils, on the other hand, skin friction results from adhesion between soil particles and the pile; hence, the unit skin friction can be simply expressed by:

$$f = \alpha c_u \quad (14.61)$$

where **adhesion factor** α can be obtained from Figure 14.70.

Example 14.15

Estimate the maximum allowable static load on the 200-mm-square driven pile shown in Figure 14.71. From Table 14.14 and Table 14.15, the following strength parameters can be obtained, based on the SPT data given:

Soil Layer	Representative N'	Cohesion (c) (kPa)	Friction (ϕ) ($^\circ$)
Loose sand	5	0.0	28
Clay	8	40.0	0
Medium dense sand	20	0.0	38

Computation of Skin Friction in Loose Sand. Applying Equation 14.60, one would obtain:

$$f = 1.4K_0(17.0)z \tan \delta$$

up to a depth of -30 m (i.e., 15.0×0.2) and constant thereafter. Assuming $\delta = 2/3(\phi) = 19^\circ$ and $K_0 = (1 - \sin \phi)OCR = 0.574$, because the overconsolidation ratio (OCR) = 1.0 for normally consolidated soils, one obtains:

FIGURE 14.70 Variation of α with undrained strength. (From Das, B.M., *Principles of Foundation Engineering*, PWS Publishing, Boston, MA, 1995. With permission.)

FIGURE 14.71 Illustration of the computation of pile capacity.

TABLE 14.15 Comparison between Maintained Load and Quick Load Tests

Test Parameter	Maintained Load Test	Quick Load Test
Test load	200% of design load	300% of design load or up to failure
Load increment	25% of the design load	10–15% of the design load
Load duration	Up to a settlement rate of 0.001 ft/hr or 2 hr, whichever occurs first	2.5 min
Test duration	48 hr	3–5 hr

$$f = 4.203z \text{ kPa, for } z < 3 \text{ m} \quad \text{and} \quad f = 12.6z \text{ kPa, for } z > 3 \text{ m}$$

Computation of Skin Friction in Clay. Applying Equation 14.61, one obtains:

$$f = \alpha(40)$$

where $\alpha = 1.0$ from Figure 14.70, so:

$$f = 40 \text{ kPa}$$

The dense sand layer can be treated as an end-bearing layer, so its skin-frictional contribution cannot be included. Because the pile perimeter is constant throughout the depth, the total skin-frictional force (Equation 14.59) can be computed by multiplying the area of the skin-friction distribution shown in Figure 14.68 by the pile perimeter of 0.8 m. Hence,

$$P_{sf}(0.8) [0.5(3)(12.6) + 12.6(1) + 40(6)] = 217.2 \text{ kN}$$

Computation of the Point Resistance in Dense Sand. From Figure 14.69, $(L/D)_{cr} = 15$ for $\phi = 30^\circ$. For the current problem, $L/D = 1/0.2 = 5$. Because, in this case, $L/D < 0.5(L/D)_{cr}$, N_q^* can be prorated from the maximum N_q^* values given in Figure 14.68. Thus,

$$N_q = \left[(L/D) / 0.5(L/D)_{cr} \right] (N_q^*) = 5/7.5 \times 300 = 208$$

Note that $N_q^* = 300$ was obtained from Figure 14.68. Also,

$$A_p = 0.2 \times 0.2 = 0.04 \text{ m}^2$$

$$q = \sigma'_v = 17.0(4) + (17.5 - 9.8)(6) + (18.0 - 9.8)(1) = 122.4 \text{ kPa}$$

Then, by substituting in Equation 14.56:

$$P_{pu} = 0.04(208 - 1)(122.4) \text{ kN} = 974.3 \text{ kN}$$

but

$$P_{pu\max} = 0.04(5)(208) \tan 38^\circ = 271.8 \text{ kN} \quad \therefore P_{pu} = 271.8 \text{ kN}$$

Finally, by applying Equation 14.55, one can determine the maximum allowable load as:

$$P_{\text{all}} = (271.8 + 217.2) / 4 = 122.3 \text{ kN}$$

14.6.4 Computation of Pile Settlement

In contrast to shallow footings, a pile foundation settles not only because of the compression the tip load causes on the underlying soil layers but also because of the compression caused by the skin friction on the surrounding layers. The elastic shortening of the pile itself is another source of settlement. In addition, if an underlying saturated soft clay layer is stressed by the pile, the issue of consolidation settlement will also have to be addressed. In this section, only the immediate settlement will be analytically treated, as a computation of consolidation settlement of a pile group is provided in Example 14.16. According to Poulos and Davis (1990), the immediate settlement of a single pile can be estimated from the following expressions:

$$s = \frac{PI}{E_s d} \tag{14.62}$$

and

$$I = I_o R_k R_h R_v \tag{14.63}$$

FIGURE 14.72 Influence factor I_o . (From Poulos, H.G. and Davis, E.H., *Pile Foundation Analysis and Design*, Krieger, Melbourne, FL, 1990. With permission.)

FIGURE 14.73 Correction factor for pile compressibility. (From Poulos, H.G. and Davis, E.H., *Pile Foundation Analysis and Design*, Krieger, Melbourne, FL, 1990. With permission.)

where:

- I_o = influence factor for an incompressible pile in a semi-infinite medium with $\nu_s = 0.5$ (Figure 14.72).
- R_k = correction factor for pile compressibility $k (= E_p/E_s)$ (Figure 14.73).
- R_h = correction factor for a finite medium of thickness h (Figure 14.74).
- R_ν = correction factor for the Poisson's ratio (ν_s) of soil (Figure 14.75).
- E_s = elastic modulus of soil.
- E_p = elastic modulus of pile material.
- d = minimum pile dimension (pile diameter).

FIGURE 14.74 Correction factor for layer thickness. (From Poulos, H.G. and Davis, E.H., *Pile Foundation Analysis and Design*, Krieger, Melbourne, FL, 1990. With permission.)

FIGURE 14.75 Correction factor for Poisson ratio. (From Poulos, H.G. and Davis, E.H., *Pile Foundation Analysis and Design*, Krieger, Melbourne, FL, 1990. With permission.)

14.6.5 Pile Groups

For purposes of stability, pile foundations are usually constructed of pile groups that transmit the structural load through a pile cap, as shown in Figure 14.76. If the individual piles in a group are not ideally placed, the individual influence zones will overlap, as shown in Figure 14.76. This will be manifested in the following group effects, which have to be considered when designing a pile group:

- The bearing capacity of the pile group will be different (generally lower) than the sum of the individual capacities, due to the above interaction.
- The group settlement will also be different from individual pile settlement due to additional stresses induced on the piles by the neighboring piles.

Both topics are discussed in the following sections, and illustrative examples are provided.

FIGURE 14.76 Illustration of the group effect.

14.6.5.2 Bearing Capacity of Pile Groups

The efficiency of a pile group is defined as:

$$\eta = \frac{\text{Ultimate capacity of the pile group } (P_{g(u)})}{\text{Sum of individual ultimate } (\sum P_{(u)i})} \tag{14.64}$$

where η is the group efficiency. Due to the complexity of individual pile interaction, the literature does not indicate any definitive methodology for determining the group efficiency in a given situation other than the following common Converse–Labarre equation, which is applied for clayey soils:

$$\eta = 1 - \frac{\xi}{90} \left[\frac{(n-1)m + (m-1)n}{mn} \right] \tag{14.65}$$

where:

- $\xi = \tan^{-1}$ (diameter/spacing ratio).
- $n =$ number of rows in the group.
- $m =$ number of columns in the group.

Although the above expression indicates that the maximum possible efficiency is about 90%, reached at a spacing/diameter ratio of 5, the results from experimental studies (Bowles, 1995; Das, 1995; Poulos and Davis, 1990) have shown group efficiency values of well over 100% under certain conditions, especially in dense sand. This may be explained by possible densification accompanied by pile driving in medium-dense sands. Computation of group capacity is illustrated in Example 14.16.

14.6.5.3 Settlement of Pile Groups

One method for determining the immediate settlement of a pile group is by evaluating the interaction factor (α_F), defined as follows:

$$\alpha_F = \frac{\text{Additional settlement caused by adjacent pile}}{\text{Settlement of pile under its own load}} \tag{14.66}$$

The settlement of individual piles can be determined on the basis of the method described in Section 14.6.4. Then, once α_F is estimated from Figure 14.77, one can easily compute the settlement of each pile in a group configuration. At this point, the issue of the flexibility of the pile cap has to be considered. This is because if the pile cap is rigid (thick and relatively small in area), it will ensure equal settlements throughout the group by redistributing the load to accommodate equal settlements. On the other hand, if the cap is flexible (thin and relatively extensive in area), all of the piles will be equally loaded, which results in different settlements.

FIGURE 14.77 Determination of α_F factor for (a) $L/D = 10$, (b) for $L/D = 25$, and (c) for $L/D = 50$. L = pile length; D = pile diameter; k and v_s are as defined in Equation 14.58. (From Poulos, H.G. and Davis, E.H., *Pile Foundation Analysis and Design*, Krieger, Melbourne, FL, 1990. With permission.)

FIGURE 14.78 Illustration of pile group load attenuation: (a) plan, and (b) elevation.

Under conditions that require the estimation of consolidation settlement under a pile group, one can assume that the pile group acts as a large single footing and use the principles discussed in Section 14.1.3 (Compressibility and Settlement). However, the difference in load attenuation between a shallow footing and a rigid pile group with substantial skin friction is accounted for by assuming that the load attenuation originates from the lower middle-third of the pile length, as shown in Figure 14.78b.

Example 14.16

The pile group (six 1 × 1-ft piles) shown in Figure 14.78 is subjected to a load of 80 kips. A compression test performed on a representative clay sample at the site yielded an unconfined compression strength of 3 psi and an elastic modulus of 8000 psi; a consolidation test indicated no significant overconsolidation, with a compression index of 0.3 and a water content of 15%. Estimate the safety of the pile foundation and its settlement. The undrained strength is 0.5 (unconfined compression strength) = 1.5 psi = 216 psf.

Computation of Skin Friction of a Single Pile. Using Equation 14.61, $f = 1.0(216)$ psf. From Equation 14.60, the resultant skin-frictional force = $216(4)(50) = 43.2$ kips.

Computation of End-Bearing of a Single Pile. Using Equation 14.58, $P_{pu} = (1)(9)(216) = 1.944$ kips (in fact, one could have easily expected the insignificance of this contribution due to the frictional nature of the pile). Thus, the ultimate capacity of the pile is 45.14 kips.

Estimation of Group Efficiency. Using Equation 14.65), $\eta = 1 - [(3 - 1)(2) + (2 - 1)(3)](\zeta)/[90(3)(2)] = 0.8$. Then, using Equation 14.64, the group capacity can be obtained as $0.8(45.14)(6) = 216$ kips; hence, the safety factor is 2.7.

Estimation of Single Pile Immediate Settlement. The relative stiffness factor for a rigid pile (K) is $E_{\text{concrete}}/E_s = 4,000,000/8000 = 500L/D = 50/1 = 50$.

- From Figure 14.72, $I_o = 0.045$.
- From Figure 14.73, $R_k = 1.85$.
- From Figure 14.74, $R_h = 1.00$.
- From Figure 14.75, $R_v = 1.00$ (undrained $\nu = 0.5$).

Substituting in Equation 14.62:

$$s = P(0.045)(1.85)(0.8)(1.00)/(8000 \times 12) = 0.032 \times 10^{-5}P \text{ in.}$$

where P is the load on a single pile in kips.

Analysis of Group Settlement. If the cap is assumed to be rigid, then the total settlement of all six piles must be identical. The total settlement consists of both immediate settlement and consolidation settlement; however, only an average consolidation settlement can be computed for the entire pile group based on the stress attenuation method (Figure 14.78) assuming equal consolidation settlement. Thus, one has to assume equal immediate settlements as well. Because of their positions with respect to the applied load, it can be seen that piles 1, 3, 4, and 6 can be considered as one type of pile (type 1) carrying identical loads, while piles 2 and 5 can be categorized as type 2. Thus, it will be sufficient to analyze the behavior of pile types 1 and 2 only. Assume that the loads carried by type 1 and 2 piles are P_1 and P_2 , respectively. Then, for vertical equilibrium:

$$4P_1 + 2P_2 = 80 \text{ kips} \tag{14.67}$$

Using Figure 14.78a, the interaction factors for pile types 1 and 2 due to other piles can be obtained as follows:

Pile Type 1		
Pile i	s/d for Pile i	α_F from Pile i
1	0	—
2	4	0.4
3	8	0.3
4	8.94	0.25
5	5.67	0.35
6	4	0.4
$\alpha = 1.7$		
Pile Type 2		
Pile i	s/d for Pile i	α_F from Pile i
1	4	0.4
2	0	—
3	4	0.4
4	5.67	0.35
5	4	0.4
6	5.67	0.35
$\alpha = 1.9$		

Then, using Equation 14.66, the total settlement of pile type 1 is estimated as $(1 + 1.7)P_1(0.032 \times 10^{-5})$, and the total settlement of pile type 2 would be $(1 + 1.9)P_2(0.032 \times 10^{-5})$. By equating the settlement of pile types 1 and 2 (for equal immediate), one obtains:

$$2.7P_1 = 2.9P_2 \tag{14.68}$$

$$P_1 = 1.074P_2$$

By substituting in Equation 14.67,

$$\begin{aligned}2(1.074P_2) + P_2 &= 40 \\P_2 &= 12.706 \text{ kips} \\P_1 &= 13.646 \text{ kips}\end{aligned}$$

Hence, immediate settlement of the pile group is equal to $2.9(0.032)(10^{-5})(12.706)(10^3) = 0.012$ in.

Computation of Consolidation Settlement. On the basis of the stress attenuation shown in Figure 14.78b, the stress increase on the midplane of the wet clay layer induced by the pile group can be found as:

$$\Delta\sigma = 80,000/[(8 + 20.835)(4 + 20.835)] = 111.71 \text{ psf}$$

The initial effective stress at the above point is equal to $(115 - 62.4)(54.165) = 2849$ psf. From basic soil mechanics, for a saturated soil sample $e = \omega G_s = 0.15 \times 2.65 = 0.4$, assuming that the solid specific gravity (G_s) is 2.65. Then, by applying Equation 14.19, one obtains the consolidation settlement as:

$$s_{ult} = (0.3)(41.67)(1/1 + 0.4)\log[1 + 111.71/2849] = 0.149 \text{ ft} = 1.7889 \text{ in.}$$

Hence, in this case the consolidation settlement is predominant.

14.6.6 Verification of Pile Capacity

Several methods are available to determine the load capacity of piles. The commonly used methods include: (1) the use of pile-driving equations, (2) the use of the wave equation, and (3) full-scale load tests. A brief description of the first two methods is provided in the next two sections.

14.6.6.1 Use of Pile-Driving Equations

In the case of driven piles, one of the very first methods used to determine the load capacity was using numerous pile-driving equations. Of these equations, one of the more popular is the Engineering News-Record (ENR) equation, which expresses the pile capacity as follows:

$$P_u = \frac{EW_h h}{S+C} \frac{W_h + n^2 W_p}{S + CW_h + W_p} \quad (14.69)$$

where:

- n = coefficient of restitution between the hammer and the pile (<0.5 and >0.25).
- W_h = weight of the hammer.
- W_p = weight of the pile.
- S = pile set per blow (in inches).
- C = 0.1 in.
- h = hammer fall.
- E = hammer efficiency (usually estimated by monitoring the free fall).

It can be seen how one can easily compute the instant capacity developed at any given stage of driving by knowing the pile set (S), which is usually computed by the reciprocal of the number of blows per inch of driving. To avoid damage to the pile and the equipment, it should be noted that, when driving has reached a stage where more than 10 blows are needed for a penetration of 1 in. ($S = 0.1$ or refusal), further driving is not recommended.

14.6.6.2 Use of the Wave Equation

With the advent of modern computers, use of the wave equation method for pile analysis, as introduced by Smith (1960), became popular. Smith's idealization of a driven pile is elaborated in Figure 14.79. The governing equation for wave propagation can be written as follows:

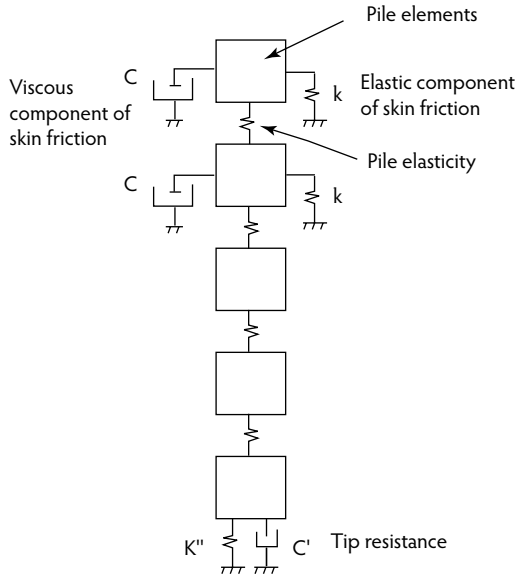

FIGURE 14.79 Idealization of a driven pile.

$$\rho A \frac{\partial^2 u}{\partial t^2} dz = AE \frac{\partial^2 u}{\partial z^2} dz - R(z) \tag{14.70}$$

where:

- ρ = mass density of pile.
- A = area of cross-section of pile.
- u = particle displacement.
- t = time.
- z = coordinate axis along the pile.
- $R(z)$ = resistance offered by any pile slice (dz).

The above equation can be transformed into the finite-difference form to express the displacement, the force, and the velocity, respectively, of a pile element i at time t as follows:

$$D(i,t) = D(i,t - \Delta t) + V(i,t - \Delta t) \tag{14.71}$$

$$F(i,t) = [D(i,t) - D(i+1,t)]K \tag{14.72}$$

$$V(i,t) = V(i,t - \Delta t) + \frac{\Delta t g}{\omega(i)} [F(i-1,t) - F(i,t) - R(i,t)] \tag{14.73}$$

where:

- $K = EA/\Delta x$.
- $\omega = \rho \Delta x A$.
- Δt = selected time interval at which computations are made.

Idealization of Soil Resistance. In Smith's model, the point resistance and the skin friction of the pile are assumed to be viscoelastic and perfectly plastic in nature; therefore, the separate resistances can be expressed by the following equations:

$$P_p = P_{pD} (1 + J V_p) \tag{14.74}$$

FIGURE 14.80 Assumed viscoelastic perfectly plastic behavior of soil resistance.

and

$$P_s = P_{sD} (1 + J'V_p) \tag{14.75}$$

where:

- P_{pD}, P_{sD} = resistances at a displacement of D .
- V_p = velocity of the pile.
- J and J' = damping factors.

The assumed elastic, perfectly plastic behavior for P_{pD} and P_{sD} are illustrated in Figure 14.80. When implementing this method, the user must assume a value of total resistance (P_u), a suitable distribution of the resistance between the skin friction and point resistance (P_{pD} and P_{sD}), the quake (Q in Figure 14.80), and damping factors J and J' . Then, by using Equations 14.71 to 14.73, the pile set S can be determined. By repeating this procedure, a useful curve between P_u and S , which can eventually be used to determine the resistance at any given set S , can be obtained.

Example 14.17

For simplicity, assume that a model pile is driven into the ground using a 1000-lb hammer dropping 1 ft, as shown in Figure 14.81. Assuming the following data, predict the velocity and the displacement of the pile tip after three time steps.

- $J = 0.0$ s/ft, $J' = 0.0$ s/ft.
- $Q = 0.1$ in.
- $\Delta t = 1/4000$ sec.
- $R_{pu} = R_{su} = 50$ kips.
- $k = 2 \times 10^6$ lb/in.

As shown in Figure 14.81, assume the pile consists of two segments ($i = 2$ and 3) and the time step to be $1/4000$ sec. Then, the following boundary conditions can be written:

$$\begin{aligned} D(1,0) &= D(2,0) = D(3,0) = 0 \\ F(1,0) &= F(2,0) = F(3,0) = 0 \\ V(1,0) &= (2gh)^{1/2} = 96.6 \text{ in./sec} \end{aligned}$$

After the First Time Step. From Equation 14.71,

$$\begin{aligned} D(1,1) &= D(1,0) + V(1,0)\Delta t = 1 + 8.0498(1/4000) = 0.024 \text{ in.} \\ D(2,1) &= D(3,1) = 0 \end{aligned}$$

From Equation 14.72,

$$\begin{aligned} F(1,1) &= [(D(1,1) - D(2,1))]k = (0.024 - 0)(2)(106) = 48 \times 103 \text{ lb/in.} \\ F(2,1) &= F(3,1) = 0 \end{aligned}$$

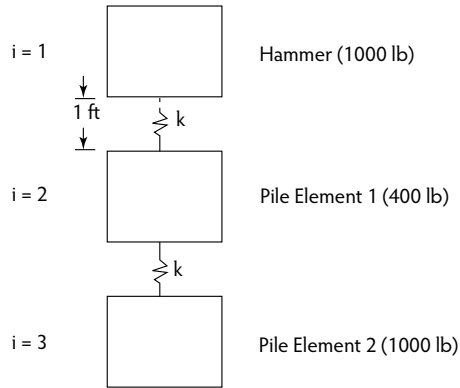

FIGURE 14.81 Application of the wave equation.

From Equation 14.73,

$$V(1,1) = V(1,0) + (1/4000)(388.8)(0 - 48,000)/1000 = 91.93 \text{ in./sec}$$

$$V(2,1) = 0 + (1/4000)(388.8)[48,000 - 0 - R(1,1)]/400 = 11.664 \text{ in./sec}$$

$$V(3,1) = 0.0$$

After the Second Time Step. By repeating the above procedure, one obtains the following results:

$$D(1,2) = D(1,1) + V(1,1)\Delta t = 0.024 + 91.93(1/4000) = 0.047 \text{ in.}$$

$$D(2,2) = D(2,1) + V(2,1)\Delta t = 0 + 11.664(1/4000) = 0.0029 \text{ in.}$$

$$D(3,2) = 0$$

$$F(1,2) = [D(1,2) - D(2,2)](2)(10^6) = 88,200 \text{ lb/in.}$$

$$F(2,2) = [D(2,2) - D(3,2)](2)(10^6) = 5900 \text{ lb/in.}$$

$$F(3,2) = [D(3,2) - D(4,2)](2)(10^6) = 0$$

$$V(1,2) = V(1,1) + 9.72(10^{-5})[F(0,2) - F(1,2)] = 91.93 + 9.72(10^{-5})(0 - 88,200) = 83.35 \text{ in./sec}$$

$$V(2,2) = V(2,1) + 24.3(10^{-5})(88,200 - 5900 - 1450) = 31.3 \text{ in./sec}$$

$$V(3,2) = 0 + 9.72(10^{-5})(5900 - 0 - 0) = 0.56 \text{ in./sec}$$

After the Third Time Step. By repeating the above steps, one obtains the following results:

$$D(1,3) = D(1,2) + V(1,2)\Delta t = 0.047 + 83.35(1/4000) = 0.0678 \text{ in.}$$

$$D(2,3) = D(2,2) + V(2,2)\Delta t = 0.0029 + 31.3(1/4000) = 0.0078 \text{ in.}$$

$$D(3,3) = 0 + 0.56(1/4000) = 0.00014 \text{ in.}$$

$$F(1,3) = [D(1,3) - D(2,3)](2)(10^6) = 120,000 \text{ lb/in.}$$

$$F(2,3) = [D(2,3) - D(3,3)](2)(10^6) = 15,320 \text{ lb/in.}$$

$$F(3,3) = [D(3,3) - D(4,3)](2)(10^6) = 280 \text{ lb/in.}$$

$$V(1,3) = V(1,2) + 9.72(10^{-5})[F(0,3) - F(1,3) - R(1,3)] = 71.69 \text{ in./sec}$$

$$V(2,3) = V(2,2) + 24.3(10^{-5})(210,000 - 15,320 - 3900) = 55.79 \text{ in./sec}$$

$$V(3,3) = 0.56 + 9.72(10^{-5})(15,320 - 70 - 70) = 2.04 \text{ in./sec}$$

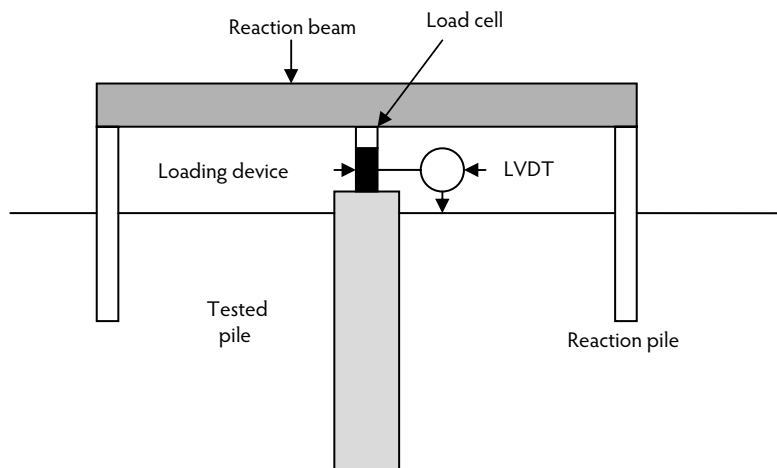

FIGURE 14.82 Schematic of pile load test set-up.

This computational procedure must be repeated on the computer until the bottom pile segment does not move during a given time step and the velocities of all of the pile segments become zero.

14.6.6.3 Pile Load Tests

The most reliable method of verifying the capacity of a driven or a bored pile is a full-scale load test. In a load test, a prototype pile is driven at the construction site and gradually loaded while the load and the corresponding deflections up to failure are monitored. Because this is an expensive test, it is usually justified on a few test piles when a pile group is to be installed under similar soil conditions.

The static pile load test is the most common method for testing the capacity of a pile, and it is also considered to be the best measure of foundation suitability to resist anticipated design loads. Procedures for conducting axial compressive load tests on piles are presented in ASTM D 1143 (Standard Test Method for Piles Under Axial Compressive Load). The most common tests are the *maintained load test* and the *quick load test*; a third test, the *constant rate of penetration test*, is generally performed only on friction piles. These tests involve the application of a load capable of displacing the foundation and determining its capacity from its response. Various approaches have been devised to obtain this information. When comparing these approaches, they can be sorted from simplest to most complex in the following order: static load test, rapid load test, and dynamic load test. These categories can be delineated by comparing the duration of the loading event with respect to the axial natural period of the foundation ($2L/C$), where L represents the foundation length and C represents the strain wave velocity. Tests with a duration between $10L/C$ and $1000L/C$ are denoted as rapid load tests. Although there are various set-ups for this test, the basic principle is the same, in that a pile is loaded beyond the desired strength of the pile (Figure 14.82). There must be an anchored reaction system of some sort that allows a hydraulic jack to apply a load to the pile to be tested. Ideally, a test pile should be loaded to failure, so the actual *in situ* load is known. The load is added to the pile incrementally over a long period of time (a few hours), and the deflection is measured using a laser sighting system. The pile can be instrumented with load cells at varied depths along the pile to evaluate the pile performance at a specific location. Instrumentation of the pile load cells, strain gauges, etc. can provide a great deal of information. All of the data, including time, are collected by a data acquisition unit for processing with software.

If a load test is performed on a pile immediately after installation, irrespective of the surrounding soil type, such a test would underestimate the long-term ultimate carrying capacity of the pile; therefore, a sufficient time period should be allowed before a load test is performed on a pile. Moreover, the additional capacity due to the long-term strength gain allows the designer to use a factor of safety on the lower side of the normal range used. Establishing a trend in the strength gain of driven piles with time will boost

the confidence of the designer to consider such an increase in the capacity during design and specifying the wait period required from the time the pile is installed before performing a pile load test. Although the above procedures are generally applicable for pile tension tests, additional loading procedures are found in ASTM Standard D 3689 (Standard Method of Testing Individual Piles Under Static Axial Tensile Load) for the pile tension test.

Two methods of pile load test interpretation are discussed in this *Handbook*: (1) Davisson's offset limit method, and (2) De Beer's method. In Davisson's method, the failure load is identified as corresponding to the movement that exceeds the elastic compression of the pile, when considered as a free column, by a value of 0.15 in. plus a factor depending in the diameter of the pile. This critical movement can be expressed as follows:

For piles of 600 mm or less in diameter or width,

$$S_f = S + (3.81 + 0.008D) \quad (14.76)$$

where:

- S_f = movement of pile head (in mm).
- S = elastic deformation of total pile length (in mm).
- D = pile diameter or width (in mm).

For pile greater than 600 mm or less in diameter or width,

$$S_f = S + (0.033D) \quad (14.77)$$

In De Beer's method, the load and the movement are plotted on a double logarithmic scale, where the values can be shown to fall on two distinct straight lines. The intersection of the lines corresponds to the failure load.

The elastic displacement of a pile can be expressed as:

$$\delta = \frac{1}{EA_p} \int_0^L P(z) dz \quad (14.78)$$

It is apparent that determination of elastic settlement can be cumbersome even if one has knowledge of the elastic properties of the subsurface soil. This is because the actual axial load distribution mechanism or the load transfer mechanism is difficult to determine. Generally, one can instrument the pile with a number of strain gauges to observe the variation of the axial load along the pile length and hence determine the load transfer. If the reading on the i th strain gauge is ϵ_i , then the axial load at the strain gauge location can be expressed as:

$$P_i = EA\epsilon_i \quad (14.79)$$

where:

- E = elastic modulus of the pile material.
- A_p = cross-sectional area of the pile.

Hence, the elastic displacement of the pile can be approximated by:

$$s = \sum \epsilon_i (\Delta L) \quad (14.80)$$

where ΔL is the interval at which the strain gauges are installed.

Example 14.18

A static compression load test was performed on a 450-mm-square prestressed concrete pile embedded 20 m below the ground surface in a sand deposit (Figure 14.83). The test pile was equipped with two telltales extending to 0.3 m from the pile tip. A summary of data from the load test is provided in Table

FIGURE 14.83 Pile load test results (Example 14.18).

TABLE 14.16 Load Test Data for Example 14.18

14.16. Determine the failure load and the corresponding side friction and end-bearing. Based on Davisson’s method (Figure 14.84), the failure load can be determined as 1.3 MN. Based on De Beer’s method (Figure 14.85), the failure load can be determined as 1.1 MN.

Another frequently used, nondestructive experimental method for estimating the capacity of a pile is the pile-driving analyzer (PDA) method. In this method, an accelerometer and a strain gauge are attached to the top of the driven pile to monitor the particle velocity and longitudinal stress during shock wave propagation following a hammer blow. By analyzing these records using the wave equation method (Section 14.6.6.2), one can closely predict the resistance mobilized during a given stage of driving. Details of this method can be found in Rausche et al. (1972).

FIGURE 14.84 Determination of pile capacity, Davisson's method.

FIGURE 14.85 Determination of pile capacity, De Beer's method.

14.7 Caissons and Drilled Piers

Both caissons and drilled piers are very large-diameter concrete bored piles that can be used in lieu of pile groups to transmit structural loads to bedrock. The term *caisson* is reserved for drilled piers involving a waterway. Construction of caissons and drilled piers is more easily accomplished than driving a group of piles in stiff soils such as dense sands and stiff clays. An added advantage is that installation of drilled piers and caissons precludes disturbance to nearby structures and ground movement. On the other hand, construction of caissons and drilled piers may involve ground loss and consequent settlements that require careful monitoring and supervision.

14.7.1 Estimation of Bearing Capacity

In rare situations when drilled piers are founded on stiff sand or clay, the bearing capacity of the pier can be estimated based on the procedure outlined in Section 14.6.3; however, the bearing capacity factors for drilled piers should be somewhat lower than those for driven piles due to the fact that it is more difficult for bored piles to mobilize the ultimate shear strength. This is especially the case for drilled piers

FIGURE 14.86 Vesic's bearing capacity factor N'_q for deep foundations. (From Das, B.M., *Principles of Foundation Engineering*, PWS Publishing, Boston, MA, 1995. With permission.)

founded on sand where Equation 14.55 is applicable. Das (1995) suggested using Vesic's N'_q values, given in Figure 14.86, for computing the bearing capacity using Equation 14.55. In most cases however, drilled piers and caissons are embedded in sound bedrock, so the load bearing capacity criteria have to be adjusted accordingly. The following stepwise procedure can be utilized for drilled pier design in rock.

14.7.1.1 Selection of Diameter

The pier diameter can be estimated using the compressive strength (f'_c) of concrete as:

$$\beta f'_c = \frac{P_o}{\pi \frac{D^2}{4}} \tag{14.81}$$

where:

- β = strength reduction factor (code recommended value is 0.25).
- P_o = allowable (working) load.
- D = pier diameter.

14.7.1.2 Maximum Embedment Length

The maximum length of embedment (L_{max}) can be estimated by assuming that the overlying soil exerts negligible friction and the pile tip carries zero load. Thus,

$$L_{max} = \frac{P_o}{\pi D \tau_{all}} \tag{14.82}$$

FIGURE 14.87 Drilled pier/rock interface.

where:

L_{max} = maximum required length of embedment.

τ_{all} = allowable shear stress between pile and rock.

The allowable shear stress on the concrete–rock interface can be expressed as (Goodman, 1980):

$$\tau_{all} = \frac{q_u}{20F} \tag{14.83}$$

where:

q_u = minimum of the unconfined compression strengths of rock and concrete.

F = safety factor.

Check for Rock-Bearing Capacity. The normal stress at a depth of z in a concrete pier embedded in rock (Figure 14.87) can be obtained from the following expression (Das, 1995):

$$\sigma_z = \frac{P_w}{(\pi/4)D^2} \exp \left[-\frac{2\mu_c \tan \delta}{1 - \mu_c + (1 + \mu_r) \frac{E_c}{E_r}} \frac{2z}{D} \right] \tag{14.84}$$

where:

δ = angle of friction between rock and concrete.

μ_c and μ_r = Poisson’s ratios of concrete and rock.

E_c/E_r = moduli ratio of concrete to rock.

For z , one can assume any design embedment depth $L (<L_{max})$ and compare the normal stress at the tip of the pier with the maximum allowable bearing capacity of rock.

Check for Adequate Shear. One can estimate the average shear stress induced in the pier–rock interface by assuming a uniform shear stress distribution (τ). Then it can be seen that:

$$\tau = (P_w - \sigma_z (\pi/4)D^2) \frac{1}{\pi DL} \tag{14.85}$$

Finally, τ can be compared with τ_{all} in Equation 14.83.

Example 14.19

Design a suitable drilled pier to carry a load of 1000 tons with the following data:

Moduli ratio of concrete–rock = 1.5.

Friction angle at concrete–rock interface = 35°.

Allowable compressive strength of rock = 0.65 kips/in.².

Allowable compressive strength of concrete = 3 kips/in.².

Unconfined compression strength of rock = 4.3 kips/in.².

Determine the Pier Diameter. From Equation 14.81,

$$\begin{aligned}\pi D^2/4 &= 1000(2000)/(0.25)/(3 \times 1000) \\ D &= 4.85 \text{ ft}\end{aligned}$$

Determine Maximum Pier Length. From Equation 14.83,

$$\tau_{\text{all}} = 4.3/20/3 = 0.072 \text{ kips/in.}^2 \text{ (assuming } F = 3.0)$$

Then, from Equation 14.82,

$$L_{\text{max}} = 2000(2000)/[\pi(4.85 \times 12)(.072 \times 1000)] = 12.66 \text{ ft}$$

Check for Bearing on Rock. Assume an embedment depth of 7 ft and Poisson's ratios of rock and concrete to be 0.3 and 0.15, respectively. Then, by applying Equation 14.84,

$$\sigma_z = 44.78 \text{ tons/ft}^2 = 0.62 \text{ kips/in.}^2 < 0.35 \text{ kips/in.}^2$$

The bearing is adequate.

Check for Shear. Shear force on the shaft = 1000 – 44.78(π)(D)²/4 = 173 tons. Average shear stress = 173/(π)(D)(7) = 1.622 tons/ft² = 0.0225 kips/in.² < 0.072 kips/in.². Thus, design a pier of 4.85 ft in diameter embedded to 7.0 ft.

15.1 Introduction

Specialized construction applications are considered to be those that contain materials that are not routinely used in conventional structural or mass concrete (ACI 116R, 1990), those that are not proportioned using procedures given in the American Concrete Institute Standard Practice 211.1 (ACI 211.1, 1991), or those that are placed with equipment or by methods that require additional attention from the contractor to ensure the required quality is achieved. The techniques of mixing, batching, transporting, consolidating, protecting, and placing concrete have drastically changed during the past few decades. The reasons for these drastic changes include the following:

- Owners demanded that cost escalation of new construction must be kept under control.
- These demands required the development of accelerated construction techniques and new materials.
- Governmental agencies initiated regulations that required better protection of the environment.
- Construction had to be accomplished with fewer workers; consequently, new techniques being developed had to use innovative equipment and materials.

Some of the more successful specialized construction techniques, primarily relating to the use of hydraulic-cement concrete, that are covered in this chapter include:

- Preplaced-aggregate concrete
- Underwater concreting
- Conveying concrete by pumping
- Vacuum processing
- Cement mortar and plastering
- Self-consolidating concrete (SCC)
- Mass concrete
- Roller-compacted concrete (RCC)

Research has resulted in many new types of equipment, materials, admixtures, and improvements in older types, thereby permitting concrete construction to be accomplished more quickly and, consequently, more economically, with better control and superior quality. The use of admixtures, both mineral and chemical, has greatly expanded the utilization of concrete in new construction techniques, has extended the life of freshly mixed concrete for as long as the user desires, and has allowed concrete to be dropped through water without segregating or separating. Admixtures have allowed concrete to be used in corrosive environments without corrosion of the reinforcing steel and to be used in freezing and thawing environments without the previously experienced rapid deterioration. They have also allowed concrete to attain much greater compressive strength with higher moduli of elasticity for use in high-rise concrete structures. These vastly improved capabilities have been accomplished to keep hydraulic-cement concrete competitive as a primary construction material. This competitiveness has to be maintained for concrete to remain the most cost-effective construction material in the world. Without the progress of concrete technology, the industry will flounder and more exotic construction materials will be developed as alternatives.

15.2 Preplaced-Aggregate Concrete

15.2.1 General

Preplaced-aggregate concrete (PA) (ACI 116R, 1990) is concrete produced by placing coarse aggregate in a form and later injecting a hydraulic cement, sand, and fly-ash grout, usually with chemical admixtures, to fill the voids. Smaller-size coarse aggregate (less than 1/2 in.) is not used in the mixture to facilitate grout injection (ASTM C 926, 2006). Much of the information presented on preplaced-aggregate concrete has been taken from the U.S. Army Corps of Engineers' *Standard Practice for Concrete for Civil Works Structures* (U.S. Army Corps of Engineers, 1994).

One of the primary advantages claimed for PA concrete is that it can easily be placed in locations where conventional concrete would be extremely difficult to place. The primary use of PA concrete is in the repair of existing concrete structures. PA concrete may be particularly suitable for underwater construction, for placements in areas with closely spaced reinforcing steel and cavities where overhead contact is necessary, and in areas where low-volume change of the hardened concrete is desired. PA differs from conventional concrete in that it contains a higher percentage of coarse aggregate, as the coarse aggregate is placed directly into the forms, with coarse aggregate having point-to-point contact rather than being contained in a flowable plastic mixture.

Hardened PA concrete properties are greatly dependent on the properties of the coarse aggregate. Drying shrinkage of PA concrete may be less than 50% that of conventional concrete, which partially accounts for the excellent bond between PA concrete and existing roughened concrete. The compressive strength of PA concrete is dependent on the quality, proportioning, and handling of materials but is generally comparable to that achieved with conventional concrete. The frost resistance of PA concrete is also comparable to conventional air-entrained concrete, assuming that the grout mixture has air content, as determined by ASTM C 231 (2004), of approximately 9%.

Preplaced-aggregate concrete may be particularly applicable to underwater repair of old structures and new underwater construction where dewatering may be difficult, expensive, or impractical. Bridge piers and abutments are typical of applications for underwater PA concrete construction or repair. ACI 304R (1989) provides an excellent discussion of PA concrete.

15.2.2 Applications

Preplaced-aggregate concrete has been used successfully on various types of projects, including those in the following construction categories:

- Underwater construction of and/or repair of bridge piers
- Resurfacing of lock chambers and guide walls
- Massive fills in permanent sheet-piling piers and cofferdams
- Construction of atomic-reactor shields
- Resurfacing of dam spillways

Preplaced-aggregate concrete is not used frequently, perhaps due to concern on the part of the construction industry that the technology exceeds the industry's normal capabilities; however, successful PA projects can be accomplished by any construction entity that has a knowledgeable concrete technologist on staff.

15.2.3 Materials and Proportioning

Intrusion grout mixtures should be proportioned in accordance with ASTM C 938 (2002) to obtain the specified consistency, air content, and compressive strength. The grout mixture should also be proportioned such that the maximum water/cement ratio complies with the same ratio that conventional concrete would be required to have for the same environmental exposure and placing requirements. Compressive-strength specimens should be made in accordance with ASTM C 943 (2002). Compressive-strength testing of the grout alone should not be used to estimate the PA concrete strength because it does not reveal the weakening effect of bleeding; however, such testing may provide useful information on the potential suitability of grout mixtures.

The ratio of cementitious materials to fine aggregate will usually range from about 1 for structural preplaced-aggregate concrete to 0.67 for massive concrete sections. A grout fluidifier meeting the requirements of ASTM C 937 (2002) is commonly used in the intrusion grout mixtures to offset bleeding, to reduce the water/cement ratio while still providing a given consistency, and to retard stiffening so handling times can be extended. Grout fluidifiers typically contain a water-reducing additive or admixture, a suspending agent, aluminum powder, and a chemical buffer to ensure timed reaction of the aluminum powder with the alkalis in the hydraulic cement.

Products proposed for use as fluidifiers that have no prior record of successful use in PA concrete can normally be accepted based on successful field use. ASTM C 937 (2002) requires that intrusion grout, made as prescribed for acceptance testing of fluidifiers, have an expansion within certain specified limits that may be dependent on the alkali content of the cement used in the test. Experience has shown, however, that because of differences in mixing time and other factors, expansion of the field-mixed grout ordinarily will range from 3 to 5%. If, under field conditions, expansion of less than 2% or more than 6% occurs, adjustments to the fluidifier should be made to bring the expansion to within these limits. The fluidifier should be tested under field conditions with job materials and equipment as soon as practicable so sufficient time is available to make adjustments to the fluidifier, if necessary. If the aggregates are potentially reactive, the total alkali content of the hydraulic cement plus fluidifier added to increase expansion should not exceed 0.60%, calculated as equivalent sodium oxide by mass of cement. The grout submitted for use may exhibit excess bleeding if the ratio of its cementitious material to fine aggregates is different from that of the grout mixture used to evaluate the fluidifier. Expansion of the grout should exceed bleeding, as desired, at the expected in-place temperature. Grouts should be placed in an environment where the temperature will rise above 40°F, as expansion caused by the fluidifier ceases at temperatures below 40°F.

This condition is normally readily obtainable when preplaced-aggregate concrete is placed in massive sections or placements are enclosed by timber forms. When an air-entraining admixture is used in the PA concrete, adjustments in the grout mixture proportions may be necessary to compensate for the significant strength reduction caused by the combined effects of entrained air and the hydrogen generated by the aluminum powder in the fluidifier; however, these adjustments must not reduce the air content of the mixture to a level that compromises its frost resistance. The largest practical nominal maximum size aggregate (NMSA) should be used to increase the economy of the PA concrete. A 1.5-in. NMSA will typically be used in most PA concrete, although provisions are made for the use of 3-in. NMSA when it is considered appropriate. It is not expected that many situations will arise where the use of aggregate larger than 2 in. will be practical and economical. Pozzolan is usually specified to increase flowability of the grout.

15.2.4 Preplacing Aggregate

Because excessive breakage and objectionable segregation are to be avoided, it is necessary to preplace the coarse aggregate in the placement with extreme care. The difficulties are magnified as the nominal maximum size of the aggregate increases, particularly when two or more sizes are blended; therefore, proposed methods of placing aggregate should be carefully established to ensure that satisfactory results will be attained. Coarse aggregate must be prewashed, screened, and saturated immediately prior to placement to remove dust and dirt and to eliminate coatings and undersized particles. Washing aggregate in forms should never be permitted because fines may accumulate at the bottom.

15.2.5 Contaminated Water

Contaminated water is a matter of concern when PA concrete is placed underwater. Contaminants present in the water may coat the aggregate and adversely affect setting of the cement or bonding of the mortar to the coarse aggregate. If contaminants in the water are suspected, the water should be tested before construction begins. If contaminants are present in such quantity or of such character that the harmful effects cannot be eliminated or controlled, or if the construction schedule imposes a long delay between aggregate placement and grout injection, then PA concrete should not be used.

15.2.6 Preparation of Underwater Foundation

The cleanup of foundations in underwater construction when the foundation material is glacial till or similar material is always difficult. The difficulty develops when, as a result of prior operations, an appreciable quantity of loose, fine material is left on the foundation or in heavy suspension just above

the foundation. The fine material is displaced upward into the aggregate as it is being placed. The dispersed fine material coats the aggregate or settles and becomes concentrated in void spaces in the aggregate just above the foundation, thus precluding proper intrusion and bond. Care must therefore be exercised to ensure that as much loose, fine material is removed as possible before placement of the aggregate.

15.2.7 Pumping

Pumping of grout should be as continuous as practical; however, minor stoppages are permissible and ordinarily will not present any difficulties when proper precautions are taken to avoid plugging of grout lines. The rate of grout rise within the aggregate should be controlled to eliminate cascading of grout and to avoid form pressures greater than those for which the forms were designed. For a particular application, the grout injection rate will depend on form configuration, aggregate grading, and grout fluidity.

15.2.8 Joint Construction

A cold joint is formed in PA concrete when pumping is stopped for longer than the time it takes for the grout to harden. When delays in grouting occur, the insert pipes should be pulled to just above the grout surface before the grout stiffens and then rodded clear. When pumping is ready to resume, the pipes should be worked back to near contact with the hardened grout surface, and then pumping should be resumed slowly for a few minutes. Construction joints are formed similarly by stopping grout rise approximately 12 in. below the aggregate surface. Care must be taken to prevent dirt and debris from collecting on the aggregate surface or filtering down to the grout surface.

15.2.9 Grouting Procedure

The two patterns for grout injection are the horizontal layer and the advancing slope. Regardless of the system used, grouting should start from the lowest point in the form.

- *Horizontal layer.* In this method, grout is injected through an insert pipe that raises the grout until it flows from the next insert hole, 3 to 4 ft above the point of injection. Grout is then injected into the next horizontally adjacent hole, 4 or 5 ft away, and the procedure is repeated sequentially around the member until a layer of coarse aggregate is grouted. Successive layers of aggregate are grouted until all aggregate in the form has been grouted.
- *Advancing slope.* The horizontal-layer method is not practical for construction of slabs having large horizontal dimensions. In such situations, it becomes necessary to use an advancing-slope method of injecting grout. In this method, intrusion is begun at one end of the form and pumping is continued until the grout emerges on the top of the aggregate for the full width of the form and assumes a slope that is advanced and maintained by pumping grout through successive rows of intrusion pipes until the entire mass is grouted. In advancing the slope, the pumping pattern is begun first in the row of holes nearest the toe of the slope and continued row by row up the slope (opposite to the direction of advance of slope) to the final row of pipes. This process is repeated, moving ahead one row of pipes at a time as the intrusion is completed.
- *Grout insert pipes and sounding devices.* The number, location, and arrangement of grout insert pipes will depend on the size and shape of the work being constructed. For most work, grout insert pipes will consist of pipes arranged vertically and at various inclinations to suit the configurations of the work. Grout pipes are generally either 3/4, 1, or 1-1/2 in. Normally, either a 3/4- or 1-in. diameter would be necessary for structural concrete having a maximum size aggregate of 1-1/2 in. or less. If the preplaced aggregate has a maximum size larger than 1-1/2 in., then the grout insert pipes should have a diameter of 1-1/2 in.

Intrusion points should be spaced about 6 ft apart; however, spacing wider than 6 ft may be permissible under some circumstances, and spacing closer than 6 ft will be necessary in some situations. Normally, one sounding device should be provided for every four intrusion points, but fewer sounding devices

may be permissible under some circumstances. There should always be enough sounding devices, and these should be so arranged that the level of the grout at all locations can be accurately determined at all times during construction. Accurate knowledge of the grout level is essential to accomplish the following tasks:

- Check the rate of intrusion.
- Avoid getting the grout too close to the level of the top of the aggregate when placement of the aggregate and intrusion are progressing simultaneously.
- Avoid damage to the work that would occur if a plugged intrusion line was washed out while the end of the line was within the grout zone.

Sounding devices usually consist of wells (slotted pipes) through which the level of the grout may be readily and accurately determined. If sounding devices other than wells are considered, conclusive demonstrations should be performed to verify that such devices will readily and accurately indicate the level of the grout at all times.

15.2.10 Finishing Unformed Surfaces

If a screeded or troweled finish is required, the grout should be brought up to flood the aggregate surface, and any diluted grout should be removed. A thin layer of pea gravel or 3/8- to 1/2-in. crushed stone should then be worked into the surface by raking and tamping. After the surface has stiffened sufficiently, it may be finished as required. A finished surface may also be obtained on PA concrete by adding a bonded layer of conventional concrete of the prescribed thickness to the surface. The surface should be adequately prepared prior to applying the topping.

15.3 Underwater Concrete

15.3.1 General

(See ASTM C 150, 2007; ASTM C 231, 2004; ASTM C 943-02, 2002.) Until recently, underwater concreting was defined as tremie concrete only, but now, due to research in the use of admixtures, new procedures have been developed so freshly mixed concrete can now be placed by dropping it through water without the use of a tremie. Although this system is discussed here, it is recommended that, unless absolutely necessary, the concrete should be deposited through a tremie or possibly a pump line.

Placement of concrete underwater requires conveying freshly mixed concrete from the surface of a liquid environment to a location underneath that surface in such a way that the concrete is not damaged by segregation or separation. During administration of the U.S. Army Corps of Engineers' Repair, Evaluation, Maintenance and Rehabilitation (REMR) research program (Scanlon et al., 1983), it was discovered that the cost of dewatering an underwater area to be repaired increased the cost of the repair by 100% when compared to making the same repair in dry conditions.

Generally, many organizations avoid placing concrete underwater, as the probability of major problems occurring is excessive. Also, many owners desire to actually see the concrete that has been placed so they have a better understanding of the appearance and quality. Underwater concreting normally cannot be observed due to the water. Underwater concreting can be a very successful operation, but it is absolutely necessary for the contractor to pay close attention to details.

At times it is physically or economically impracticable to expose a foundation prior to concrete placement. At such times, suitable underwater placing procedures such as pumping or use of tremies or special concrete buckets should be employed. Research has provided techniques for placing freshly mixed concrete through water without the use of a pump line, tremie, or bucket, and innovative antiwashout chemical admixtures have been developed that permit freshly mixed concrete to be dropped through water without segregation or separation (see Figure 15.1). Although these are proprietary admixtures, practically all of the chemical admixture companies provide versions to the industry.

FIGURE 15.1 Clearness of underwater concreting.

15.3.2 Structures Conducive to Underwater Placement

Underwater concreting is appropriate for all types of structures: massive sections, walls, slabs, foundations, piers, caissons, stilling basins, cofferdams, conduits, and many others. It is obvious that underwater concreting is most advantageous for relatively large structures such as bridge piers, cofferdams, thick walls, and large foundations. In this chapter, we discuss the use of tremies, buckets, pumps, aqua valves, and, of course, antiwashout admixtures.

15.3.3 Available Methods

Use of the tremie is currently the most often utilized technique for placing concrete under water. A tremie is defined by the American Concrete Institute in ACI 116R (1990) as a pipe or tube through which concrete is deposited under water, having at its upper end a hopper for filling and a bail for moving the assemblage, as shown in Figure 15.2. Underwater bucket placing consists of lowering a special bucket

FIGURE 15.2 Tremie concreting operation.

containing freshly mixed concrete to the bottom of the foundation and opening the bucket slowly to permit the concrete to flow out gently without causing turbulence or mixing with the water. One of the most troublesome problems associated with using a tremie is controlling the head pressure on concrete in the tremie pipe so the pipe does not empty itself too quickly and allow water to enter the pipe from the bottom. Fortunately, a concrete pump can be used to overcome this problem. A concrete pump permits the pump line to remain full at all times, and the end of the pump line can remain very deep in the fresh concrete, preventing the intrusion of water into the pump line. We will now discuss underwater placement techniques in greater detail.

15.3.4 Bucket Placement

The buckets used for underwater placement of freshly mixed concrete should have drop-bottom or roller-gate openings. The gates should be able to be opened from above water. If air is used to open the bucket, the air should discharge through a line to the surface to prevent water disturbance. The top of the bucket must be covered to prevent water from washing the surface of the freshly mixed concrete. One way is to cover the top with canvas or plastic sheets; the covering should be as watertight as possible. Special buckets designed for the underwater placement of concrete have sloping tops that minimize the water surge. The first bucket of concrete should be slowly lowered to the bottom of the foundation and allowed to rest on the bottom. The gates should be opened slowly to permit the concrete to flow out gently, without causing turbulence or mixing with the water. Additional buckets should land on the previously placed concrete and slightly penetrate the surface so opening the gates and releasing the fresh concrete will result in even less turbulence. The operation is continued until all of the concrete has been placed. An example of concrete placed underwater with buckets is the foundation for the San Francisco–Oakland Bay Bridge, which has a 240-ft-deep foundation.

15.3.5 Tremie

The tremie process is the underwater placing technique used most frequently by contractors. Figure 15.2 depicts a conveyor being used to feed concrete to the tremie hopper for distribution down the tremie pipe in a massive placement. The tremie consists of a vertical pipe through which concrete is placed. The concrete flows from the bottom of the tremie pipe. After the original placement, the end of the tremie pipe is kept submerged in the fresh concrete at all times. The first concrete placed is the concrete that will most likely end up on top of the placement in small-diameter placements. It has been observed that, in a 36-in. caisson, the first cubic yard of grout placed ends up on top of the placement and then is allowed to overflow the top of the caisson until the caisson is filled with concrete. This assures the contractor that there will be no voids in the placement, and when the tremie pipe is removed slowly a good job is almost guaranteed. The discharge end of the pipe should always remain buried in the freshly placed concrete after the initial placement. A tremie pipe should be made of heavy-gauge steel to withstand all stresses induced by the handling operation. The pipes should have a diameter large enough to ensure that aggregate bridging will not occur. Normally, pipes should be between 8 and 12 in. in diameter for concrete containing up to 2 in. NMSA. Pipe sections in increments of 10 ft should be used; for deep placements, the tremie should be fabricated in sections with joints that permit the upper sections to be removed as the placement progresses; otherwise, the hopper will become too elevated for efficient discharge from a ready-mix truck. The joints between sections of pipe must be watertight and capable of being disconnected rapidly so no major interruptions occur during placement of the concrete.

15.3.6 Basic Tremie Methods

The two basic methods of initiating concrete placement when using the tremie method underwater are the **wet-pipe** and **dry-pipe** methods. The wet-pipe method refers to initiating placement with the open-ended tremie pipe on the bottom and with the pipe filled with water. To keep the concrete being delivered from being washed out by the water in the pipe, a plug or go-devil is placed at the upper level of the

water in the pipe before the concrete is discharged into the tremie. When the concrete is discharged into the tremie, the plug or go-devil is between the water and the fresh concrete, preventing the fresh concrete from being washed out.

The weight of the concrete (approximately 140 lb/ft³) pushes the water, which weighs approximately 64 lb/ft³, down the tremie pipe. When the concrete, which has never been in contact with the water, arrives at the bottom, it pushes the plug or go-devil out of the pipe, and the concrete is deposited on the bottom of the placement. Many go-devils are designed so they are lighter than water and float to the top to be used at a later time. When the fresh concrete begins to flow from the end of the tremie, the end of the pipe should stay submerged in the concrete. Continuing to deposit fresh concrete into the tremie hopper causes the concrete to continue flowing through the pipe. The end of the tremie pipe should be kept at a depth in the freshly deposited concrete that permits the concrete to flow at a slow speed through the pipe.

If the concrete flows out of the pipe so the concrete load in the pipe is less than the water load outside the pipe, and if the pipe is not adequately embedded in the freshly placed concrete, then water may refill the pipe. This will not happen if the end of the tremie pipe is adequately embedded in the freshly placed concrete. If the crane operator holding the tremie and hopper feels that the fresh concrete is being completely discharged onto the bottom, the operator should immediately drop the pipe so it will be more deeply embedded. This may prevent the water from getting into the empty pipe. If water does not get into the empty pipe, concrete placement can continue, but if water does get into the pipe it will be necessary to restart the placement by reinserting the plug or go-devil as during initiation of the placement. An ideal tremie placement is one where the initial concrete placed is the concrete that ends up on top. This will only occur when the placement area is relatively small (say, 4 ft²). The dry-pipe method requires a tremie pipe that is watertight, including the sectional pipe joints. In this method, a pressure-seal plate is attached to the bottom of the tremie pipe in such a way that the water pressure makes the end completely watertight and the interior of the pipe is completely empty and free of any water. Such a method requires that the walls of the pipe be heavy enough to overcome the buoyancy of the water; otherwise, it would be impossible to lower the tremie pipe to the bottom of the placement.

When the end of the tremie pipe with a pressure-seal plate is placed on the bottom, freshly mixed concrete can be introduced into the pipe. After the pipe is sufficiently filled with concrete, the pipe can be slowly raised, which releases the pressure-seal plate due to the weight of the concrete. After the initial discharge of fresh concrete on the bottom, the placement continues exactly as in the wet-pipe method. One drawback to the dry-pipe method is that the pressure-seal plate has to be left in the placement; however, it can be retrieved if a rope or cable is attached in such a way that the cable is on the outside of the tremie pipe. Another technical drawback is that, should the tremie seal be lost (water gets into the pipe), a plug or go-devil would be required to reinitiate the start of the placement.

15.3.7 Mixtures for Underwater Placements

Concrete must be proportioned for very workable concrete if it is to be placed underwater. The slump should be controlled at approximately 7 in. Normally, the hydraulic-cement content should be around seven bags per cubic yard. The maximum size aggregate should be 1-1/2 to 2 in., and the fine aggregate (fine) content should be around 45% of the total aggregate content. The concrete should be air entrained at about 6 to 7%. Any application that improves the workability of concrete should be considered. This includes pozzolans, natural aggregates in lieu of crushed stone, and use of chemical admixtures to extend the setting time and permit additional water reduction.

15.3.8 Use of Antiwashout Admixtures

(See ACI 304.1, 1995; ACI 524R, 1992; ASTM C 937, 2002; ASTM C 938, 2002; Neeley, 1988.) Many of the companies dealing with the manufacture of concrete construction materials have developed admixtures for use in concrete that permit the concrete to be placed underwater without the use of a tremie.

FIGURE 15.3 Relationship of slump, slump-flow value, and spread value.

These materials are referred to as *antiwashout admixtures*. Japan has been a leader in this new concrete technology, although it is believed that Japan obtained its knowledge from a product that was originally used in Germany. Figure 15.1 depicts the clearness with which concrete containing an antiwashout admixture can be discharged under water. Other terms for this type of concrete are *nondispersible concrete* and *colloidal underwater concrete*. The admixture that provides the clearness of this special concrete is known as a nondispersible underwater concrete admixture, but in the United States it is referred to as an antiwashout admixture. This innovative admixture was developed in West Germany around 1981. The admixture is intended to prevent washout of cementitious material and dispersion of aggregate during underwater placement of concrete. The admixture serves to increase the viscosity and the water retention of the concrete matrix. The antiwashout admixtures currently being marketed in Japan use cellulose or acrylic as the primary ingredient. Admixtures containing acrylic use a polyacrylamide polymer as the primary ingredient. Admixtures containing cellulose use a nonionic water-soluble cellulose ether, which has a hydroxide ion (OH) base and is almost like water. Hydroxyethylcellulose (HEC), hydroxyethylmethylcellulose (HEMC), and hydroxypropylmethylcellulose (HPMC) are among the various admixtures used. When dissolved, their viscosities differ considerably according to polymerization, molecular weight, and type of substituent. They dissolve in water rapidly when placed in a high-pH environment such as concrete. They are also not susceptible to chemical changes within concrete-like reactions, gelation, or decomposition.

15.3.9 Characteristics of Antiwashout Underwater Concrete

Antiwashout underwater concretes have slightly different properties than ordinary hydraulic cement concrete because of the effect of the admixture. Fresh antiwashout concrete can be characterized by the following properties.

15.3.9.1 Flowability

Because of the increased viscosity of antiwashout underwater concrete, the slump transformation takes place over several minutes. The slump is ultimately 8 to 10 in. To have a better understanding of the flowability of this type of concrete, a slump-flow value or a spread value determined by the German Standard DIN 1048 is more suitable than a slump value. The relationship of these values is demonstrated in Figure 15.3. Table 15.1 provides criteria for the relationship between flowability and conditions of execution.

TABLE 15.1 Criteria of Relationship Between Flowability and Conditions of Execution

Slump Flow Value (cm)	Softness	Conditions for Applications	Conditions for Execution
40	Hard consistency	When it is desired to keep the flow small, such as the execution of a slanted path	Concrete pump pressure transmission boundary
45	Medium consistency	General case	Less than 50-m concrete pump pressure transmission distance
50	Medium soft consistency	When excellent filling capability is needed	Concrete pump pressure transmission distance of 50–200 m
55	Soft consistency (plastic concrete) Supersoft consistency	When excellent flowability is especially needed, such as in reinforced concrete members of dense fiber and filler for narrow and deep supersoft consistency holes	

15.3.9.2 Air Content

Mortar and concrete mixed with cellulose ether have greatly increased air content; therefore, such antiwashout admixtures contain an air-detraining admixture to reduce the air content of the concrete to between 3 and 5%. From a petrographic standpoint, the bubble-spacing factor of concrete containing the antiwashout admixture is about the same as concrete without the admixture, but the freezing and thawing resistance tends to be somewhat low.

15.3.9.3 Bleeding

Concrete containing the antiwashout admixture retains more of the mixing water. Because the normal amount of admixture used is more than double the amount required to prevent bleeding, very little, if any, bleeding occurs in antiwashout underwater concrete. This lack of bleeding is responsible for the small reduction in quality of the concrete and increases the need for reinforcing steel.

15.3.9.4 Setting Time

The use of antiwashout cellulose admixtures affects the setting time of underwater concrete. When a cellulose antiwashout admixture is used, the setting time (ASTM C 191, 2007) is greatly extended; therefore, the antiwashout admixture contains an accelerating admixture. The most common accelerating admixture amounts are adjusted to result in a final setting time of from 5 to 12 hours. Antiwashout admixtures containing acrylic have no effect on the setting time. When an air-entraining, water-reducing admixture is added to the antiwashout admixture, the setting time is slightly extended, but the increase in setting time for the normal admixture amounts is less than 5 hours. Specialty admixtures can extend the setting time for underwater antiwashout concrete by 30 hours or more.

15.3.9.5 Underwater Dispersion Resistance

The dispersion resistance of concrete during an underwater placement operation is evaluated by such tests as the cementitious materials outflow rate, the change of water permeation rate, the turbidity of the water, the change of pH value, and the change of composition. The rate of dispersion is decreased as the quantity of antiwashout admixture in the underwater concrete is increased.

15.3.10 Characteristics of the Hardened Concrete

15.3.10.1 Compressive Strength

The relationship between the compressive strength of concrete containing no antiwashout admixture and concretes containing various amounts of cellulose antiwashout admixture is shown in Figure 15.4. Generally, the compressive strength of a test specimen fabricated in air is lowered by an increase in the

FIGURE 15.4 Relationship of quantity of cellulose admixture and concrete compressive strength.

quantity of admixture, but in some instances the compressive strength has increased slightly. Test specimens fabricated underwater are made by placing concrete into water that is 12 to 20 in. deep. The compressive strength of such specimens increases with an increase in the quantity of antiwashout admixture used; consequently, the compression strength ratio of test specimens made underwater increases compared to those made in air as the quantity of admixture increases. The amount of admixture to be used is determined by the flowability required, depth of the underwater placement, horizontal flow distance, desired water cementitious materials ratio, and, of course, the quantity of cementitious materials to be used. In general, the compressive strength ratio referenced above can be expected to range from 0.8 to 0.9.

15.3.10.2 Miscellaneous Strength and Other Characteristics

The ratio of tensile strength and flexural strength to compressive strength of an underwater fabricated test specimen is identical to that of specimens fabricated in ordinary dry concrete. The modulus of elasticity is the same or slightly less than that of ordinary concrete. The unit volume of water in antiwashout underwater concrete is much greater than that of ordinary concrete. Because water retention is so high, drying shrinkage is large at 20 to 35%. Also, creep in air appears to be somewhat greater than in ordinary concrete.

15.3.11 Characteristics of the Horizontal Flow Time of Nondispersible Underwater Concrete

Qualitative changes in antiwashout underwater concrete can be made by adding a water-reducing admixture, which causes the concrete to flow longer distances. Underwater concrete with water-reducing admixtures has been shown to have a slump flow of 50 to 60 cm, a cement content of 364 to 430 kg/m³, and a water/cement ratio of 0.48 to 0.60. The final flow gradient was 1/125 to 1/500. Even though the

TABLE 15.2 Combinations of Antiwashout and Water-Reducing Admixtures

Antiwashout Admixtures	Water-Reducing Admixtures
Cellulose	Melamine sulfonate (triazine)
Acrylic	Naphthalene sulfonate Melamine sulfonate (triazine) Acrylic Polycarbonic acid

concrete surface was virtually horizontal, qualitative changes were recognizable when the flow distance exceeded 10 m. The area near the edge of the concrete may suffer a drop in unit weight and modulus of elasticity as well as in compressive strength because the quantity of aggregate declines. The greatest flow distance is best determined by fully considering proportions and placement conditions.

15.3.12 Principal Considerations

Because antiwashout underwater concrete has a high viscosity, the mixer load is increased by 25 to 50%, so the capability of the mixer and the quantity of materials mixed must be considered. Use of a water-reducing admixture causes a decline in dispersion resistance and some extension of the time of setting. In some instances, a specific flowability cannot be obtained by combining the water-reducing admixture and the antiwashout admixture; therefore, the types of water-reducing admixture and their recommended dosages must be considered. Table 15.2 illustrates the various combinations of types of antiwashout admixtures and water-reducing admixtures ordinarily used. Because the dispersion resistance is high, blockage will occur in pump lines only if problems are encountered within the pressure transmission tube during the pumping pressure period. Qualitative changes in the concrete should not occur before or after the pressure is transmitted. Due to high viscosity, however, pressure transmission resistance is 2 to 4 times that of ordinary concrete. It has been reported that the pressure transmission capacity of the squeeze-type pumps is inferior to that of the piston-type pumps, an aspect that must be considered.

15.3.13 Summary

Antiwashout underwater concrete is being considered for use in many underwater structures and other large-scale projects. Under current conditions, several problems remain, such as: (1) differences in performance of the more than ten kinds of admixtures currently being marketed, (2) differences in mixing methods and placement methods used by various contractors, and (3) inappropriateness of the antiwashout concrete for use in above-water structures due to its drying shrinkage and poor resistance to freezing and thawing. It is recommended, therefore, that the engineer and contractor fully understand the quality of the antiwashout underwater concrete and the procedures involved in the placement of this relatively new and innovative material.

15.4 Vacuum Processing

15.4.1 General

The ACI report 116R (1990) defines vacuum concrete as concrete from which excess water and entrapped air are extracted by a vacuum process before hardening occurs. This process is administered by applying a vacuum to formed or unformed surfaces of ordinary concrete immediately or very soon after the concrete is placed. Additional compaction of the concrete is the primary result of vacuum processing. As the water and entrapped air are removed, the mortar is subjected to consolidation; the

concrete becomes denser because approximately 40% of the water close to the surface has been removed. Entrapped air is also removed, resulting in a concrete surface that is more resistant to freezing and thawing, especially if the concrete originally contained entrained air of at least 9% of the paste fraction. The air, being noncontinuous, is removed from the surface and not from the interior. The depth of water extracted and the amount of water removed depend on the coarseness of the mixture, mixture proportions, and the number of surfaces to which the vacuum is applied. The depth of water extraction can, under good conditions, extend to 12 in., and the amount of water extracted a few inches below the surface can be equal to one third of the mixing water. Removal of an average of 20% of the water down to a depth of 6 in. from the surface is common. The best results from vacuum processing occur when (1) the mixture contains a minimum amount of fines, (2) the vacuum can be applied promptly while the concrete is still plastic, and (3) the concrete near the vacuum panel can be vibrated during the first few minutes of the vacuum treatment. Vacuum procedures result in concrete with higher strength and greater durability. The Bureau of Reclamation (1992) found that vacuum processing increased the 3-day strength of one concrete from 800 psi to 1800 psi. Although vacuum processing improves the surface of hardened concretes, the improved appearance is normally not adequate justification for use of the process. Vacuum processing improves durability, but this should not be used as justification not to use air entrainment. Vacuum treatment has been used to increase the resistance of concrete surfaces to high-velocity liquid flow, but its use should not justify reduced efforts to perfect alignment of flow lines.

15.4.2 Concrete Mixtures

It is not absolutely necessary that special concrete mixtures be used when vacuum processing of the concrete surface is planned. This is not to say that slight changes in the normal mixtures should not be considered. The best results are obtained when the fines are at a minimum; in other words, vacuum processing seems to work best when the mixture is relatively lean and contains a minimum amount of fine aggregate (sand) that is on the coarse side of the grading. Sticky mixtures with an excess of fines do not respond well to vacuum treatment. The treatment is also more effective at low ambient temperatures. One of the primary goals of concrete construction is to place concrete in a uniform fashion so the finished results will be uniform. The vacuum should be applied soon after placing the concrete while the concrete is still plastic. The concrete should be highly workable, and during the first few minutes of the vacuuming process the concrete should be slightly vibrated, permitting the small channels left by the water removal to close, thus improving the watertightness.

15.4.3 Early Equipment

During early use of the vacuum process, the vacuum was applied to the concrete surface by vacuum hoses attached to special vacuum mats or form panels. The mats for unformed surfaces were usually reinforced plywood faced with two layers of screen wire covered by muslin. For unformed curved surfaces, such as the buckets of dams, flexible steel that could adapt to the curved surface was used in lieu of plywood. Sometimes, a fiberglass cloth without screen backing was used for the lining of steel forms for concrete pipe. The equipment was very cumbersome and required much preparation time. In addition, it was expensive and complicated. As a result, use of the equipment was not very inviting, and very little use was made of the process.

15.4.4 New Equipment

Vacuum equipment has since been simplified, and its use, especially in Europe, has greatly increased. The vacuum process is now being used more frequently in the United States. The panels have been replaced by vacuum pads that are flexible, light, and easy to handle (see Figure 15.5). This newer system greatly improves the handling, and the system is much more efficient and cost effective.

FIGURE 15.5 Distribution of vacuum pads on newly placed concrete slab.

FIGURE 15.6 Vacuum pump used in vacuum processing.

15.4.5 Procedure

After the concrete slab is vibrated, the surface is immediately covered with a base filter pad and a suction mat connected to a vacuum pump. The pump (see Figure 15.6) creates a vacuum under the pad. The vacuum causes the atmospheric pressure to compress the concrete, and the water is extracted. The base pad is designed to distribute the vacuum under the entire surface evenly and permit water to pass through. The vacuum is applied for approximately 4 minutes for each inch of slab thickness. After the pads and mats are removed, the surface is normally firm enough to walk on, and finishing is then performed with specially designed, low-amplitude, high-frequency disk floats. Following finishing, the slabs are preferably cured with water, but practically any method that prevents the concrete from additional drying can be used. Because internal water has been removed from the concrete, it is best to ensure that adequate water is available for hydration of the cement; consequently, water curing is best.

15.4.6 Conclusions

For attaining a highly impervious concrete floor, vacuum processing is a viable method, but, just as for all processing methods, options such as using low water/cement ratios and adequately air-entrained concrete and incorporating proper curing and protection techniques must be considered during construction. Do not depend 100% on vacuum processing to provide the high-quality, low-permeability, smooth floor that is desired; quality concrete materials must be used, and proven mixing, transporting, placing, finishing, curing, and protection procedures also have to be followed.

15.5 Portland Cement Plaster Construction

15.5.1 General

Portland cement plaster construction, commonly referred to as *stucco*, has been around for many years, but it has normally been considered an art rather than a science. The knowledge necessary to apply Portland cement plaster was previously acquired by learning from others and not from technical literature. ACI Report 524R, *Guide to Portland Cement Plastering*, was developed in 1992. Before then, little information was available to engineers who wished to include this subject in project specifications; consequently, the U.S. Army Corps of Engineers initiated worldwide studies to identify the problems associated with defective concretes and Portland cement plaster construction.

15.5.2 Most Frequently Found Problems

During visits to the various sites around the world, numerous installations were inspected where the design and the workmanship for stucco were excellent. The recurring problems that were found can be separated into three categories:

- Questionable design
- Incomplete specifications or specifications lacking in detail
- Inadequate inspection and poor workmanship

The following general procedures must be fully considered when contemplating a Portland cement plaster construction project:

- Quality plaster is essential to any successful installation. The plaster must develop adequate tensile strength to resist imposed stress and have sufficient resiliency to accommodate expansion and contraction. Consistency in the batching operation is as important to the development of quality plaster as the ingredients and quantities.
- The most important ingredient is the aggregate. Aggregate should conform to specifications. The physical properties of aggregate that have the most pronounced effect on plaster are grading, shape and denseness of the particles, and particle surface characteristics (roughness and porosity).
- Curing procedures play a vital role in reducing shrinkage cracking by permitting the plaster to dry slowly and uniformly. Fog curing requires the application of a fine mist at intervals related to job conditions. The purpose of curing is to maintain enough water within the plaster to keep the interior relative humidity above 80% during the specified curing period.
- It is acceptable to place a second coat of plaster as soon as the first coat is strong enough to withstand the pressure of the second application. When plaster is applied to a solid backing such as block, concrete, or wire lath backed with rigid sheathing, both base coats can be applied in one day and the finish coat on the following day. Or, successive coats can be applied on consecutive days.

15.5.3 Technical Aspects of Portland Cement Plaster

The desirable properties of fresh Portland cement plaster can be summarized by the following properties:

- *The ability to stick to the particular substrate*—The primary concerns in this area relate to the influence of the aggregate, the water/cement ratio, and the absorptive characteristics of the substrate or base.
- *The ability of the fresh plaster to stick to itself*—The plaster should not sag, slough, or separate (delaminate).
- *The ability to be placed, shaped, floated, and tooled*—The plaster should already have the first two properties; plaster without these abilities is generally incorrectly proportioned or possibly incorrectly mixed.

Hardened Portland cement plaster should have excellent durability against weathering, should be highly impermeable, and should be resistant to temperature changes. Such plaster should also be highly resistant to the action of freezing and thawing. Plaster should be air entrained for better freeze–thaw resistance and better impermeability, which provides protection from acid rain and aggressive chemicals. Hardened Portland cement plaster should also be proportioned for high tensile strength. Properly proportioned plasters that have been properly cured should have acceptable tensile strength.

15.5.4 Portland Cement Plaster Materials

The cement used in Portland cement plaster may be practically any type or class of cementitious materials conforming to the various ASTM Standards, such as:

- Portland cement (ASTM C 150, 2007)
- Blended cements (ASTM C 595, 2007)
- Masonry cement (ASTM C 91, 2007)
- Plastic cement (ASTM C 926, 2006)

Should the aggregates be potentially reactive, low-alkali cements should be used, and air-entraining cements should be used, when possible. Lime conforming to the requirements of Type S, ASTM C 206 (2003) or ASTM C 207 (2006) should be used along with an air-entraining admixture when possible. Lime is necessary only when regular cement is used.

The aggregates should be either natural or manufactured fine aggregate (sand) complying with the requirements of ASTM C 897 (2005). Lightweight aggregates such as perlite or vermiculite may be used but should not be used in base courses when conventional-weight aggregate plaster is to be applied as a finish coat. Perlite or vermiculite aggregates have low resistance to freezing and thawing. Sand should be washed clean; should be free of organic matter, clay, and loam; and should be well graded.

The water used should be as good as water used in hydraulic-cement concrete. Drinking water is normally all right to use. The water should comply with the requirements of ASTM C 191 (2007) for setting time and ASTM C 109 (2007) for strength. Calcium chloride should not be used in Portland cement plaster because of the embedded metals. Should chemical admixtures be considered for use, be sure they do not contain chlorides and they are not corrosive. Accelerating admixtures that do not contain chlorides or other corrosive materials are available and could be used.

15.5.5 Proportioning

As stated earlier, Portland cement plastering (stucco) is thought of as an art and not a science. The industry does not seem to want to join the 21st century, as materials are still proportioned by shovel. Measurement of sand is accomplished by counting the number of shovels of sand per bag of cement and seven No. 2 shovels are equated to one cubic foot of sand. The quantity of water is determined by the

appearance of the plaster in the mixer. Some project specifications require the use of a cone for measuring the slump; the cone is 6 in. high by 4 in. in diameter at the bottom and 2 in. in diameter at the top. Many specifications permit a slump of 1-1/2 to 3 in. for either hand- or gun-applied plaster. Plasticizers are also normally required, and again the quantity is determined by the appearance. When plastic or masonry cements are used, the addition of plasticizers is not necessary. When Portland or blended cements are used, it may be necessary to add plasticizer to up to 20% by weight of the cementitious material. Avoid sloppy and overwatered mixtures, as they tend to cause segregation and separation of materials. Proportioning Portland cement plaster drastically affects the final quality and serviceability of the hardened plaster. Proportions of the ingredients should be in accordance with project specifications, local building codes, and ASTM C 926 (2006).

15.5.6 Mixing

Experience dictates that a particular sequence for mixing should be followed: The water should be added first, followed by 50% of the sand, the cement and any admixtures, and finally the remaining 50% of the sand. Normal mixing time is approximately 3 to 10 minutes. Excessive mixing should be avoided because it could be detrimental to the quality of the plaster.

15.5.7 Bases for Plaster

Metal plaster bases come in three types. One type is woven-wire plaster base, which is fabricated galvanized steel wire that is reverse twisted into a hexagonal mesh pattern and normally comes in rolls or sheets. Expanded-metal diamond mesh lath is fabricated from coils of steel that are slit and then expanded to form a diamond pattern (chicken wire). The third type is welded-wire lath, which is fabricated from at least 15-gauge copper-bearing, cold-drawn galvanized steel wire.

15.5.8 Weather Barrier Backing

Several materials are being used as weather barrier backing, including waterproof paper or felt meeting the requirements of Federal Specifications UU-B-790, Type II, Class D. The paper should be free of holes and breaks and should weigh at least 14 lb per 108-ft² roll. A large number of accessories are required to obtain a proper plaster job. Accessories establish plaster grounds and transfer stresses in critical areas of plaster elements. Portland cement plaster should not be considered to be part of the load-bearing members; the plastering project should be designed so the plaster is not placed under stress. To construct a successful plaster project, all locations—corners and joints (expansion and contraction)—must contain the correct accessories to prevent the plaster from experiencing the normal stress that would occur at these locations. Special accessories are made for corners; they may be expanded flange corner beads, welded or woven wire, vinyl bead, or expanded-metal corner lath. The corner reinforcement must be designed so plaster can be applied without hollow areas. Inside corner joints must have accessories designed to provide stress relief at internal angles. Casing beads, often called *plaster stops*, should be installed wherever plaster terminates or joins a dissimilar material. Plaster screeds are used to establish the thickness of the plaster or to create decorative motifs. Ventilating screeds contain perforated webs that permit air to pass freely from the outside. Additional screeds include drip screeds that are installed on outside plaster ceilings to prevent the water that runs down the face of the structure from penetrating the plaster soffits and the ceiling. Weep screeds are normally installed at the foundation plate line and function as a plaster stop, permitting trapped moisture to escape from the space between the backing paper and the plaster.

15.5.9 Sample Panels

Sample panels or mock-ups should always be constructed, especially on large jobs where all the plastering will not be performed by one crew of plasterers. These panels or mock-ups should include examples of all joints, windows, doors, corners, and, in general, all conditions to which the plaster will be exposed.

Sample panels should be constructed until the results describe the desired quality and appearance expected of the structure. The panels should be kept close to the project so workers and supervisors can verify that the previously approved results are being obtained.

15.5.10 Surface Preparation

Concrete surfaces to which plaster will be applied should be straight, true to line, and plane. Concrete surfaces should be cleaned or roughened to increase the likelihood of a good chemical and mechanical bond. The concrete surface should be cleaned with a cleaning agent to remove most surface contaminants. Other methods of cleaning might include the use of wire brushes, hammers or chisels, water blasting, or light sandblasting.

15.5.11 Application of Plaster

Prior to beginning to apply plaster, the substrate must be prepared as described above. It is also necessary to verify that the lath and backup paper have been installed along with the necessary accessories. After the required substrate treatment has been verified, proper application procedures must be followed. The project specifications will normally require or allow the plaster to be applied by hand or by machine. When hand application is permitted, the plasterer applies the plaster to the surface using a trowel. The plasterer determines the amount of water required to obtain the desired consistency of the plaster. Plaster pumps are sometimes required for plaster application. In this case, batches of plaster are prepared in a mixer, and the individual performing the mixing operation is responsible for batching the correct quantities of cement, sand, and water. The quantity of water is determined by the mixer operator. The plaster is placed in a hopper and pumped onto the surface through a hose and nozzle. The nozzle operator controls the spray pattern by adjusting the air jet, air pressure, and nozzle orifice.

15.5.12 Types of Application

Portland cement plaster is normally applied in either two or three coats. The three coats are referred to as the *scratch coat*, *brown coat*, and *finish coat*. The scratch coat should be thick enough to result in a good bond to the substrate; on substrates containing metal laths, this coat should fully cover the lath. The scratch coat should be scored horizontally so mechanical bonding is improved. When the specification requires a delay between application of the scratch coat and the brown coat, it is necessary to cure the scratch coat by moist curing. If no delay is required, then the brown coat should be applied as soon as possible to secure a good bond. The brown coat should be applied when the scratch coat is rigid enough to receive the brown coat without cracking. The brown coat normally contains more sand than the scratch coat. The required thicknesses are established either in the local specifications or by construction codes. In some cases, the brown coat is the finish coat. Where a finish coat is specifically required, it is normally proportioned to provide a particular texture, color, or appearance. Prior to applying the finish coat, the brown coat must be moist cured for at least 2 days. Finish coats can be applied and finished in numerous aesthetically pleasing patterns. Smooth troweled surfaces are not recommended because of their tendency to crack. Finish coats must not be burnished; burnishing will almost always induce cracking. Moist curing is an absolute necessity.

15.6 Self-Consolidating Concrete (SCC)

15.6.1 Introduction

Self-compacting concrete (SCC) or self-consolidating concrete, as it is referred to by ASTM Subcommittee C09.47, can be defined as concrete that does not require compaction or vibration. Because of its high viscosity, SCC can flow freely without segregation. SCC is able to flow under its own self-weight into corners of formwork and through closely spaced reinforcement with little or no vibration or compaction.

This leads to lower energy cost, lower stress on the formwork, reduced labor costs, and elimination of potential human error in the consolidation of the concrete. The concrete becomes more consistent, as the cementitious paste and aggregates are equally dispersed. As a result, both SCC mechanical properties and durability are improved over normal or conventional concrete, and it has enjoyed increased popularity in Europe and Japan (Okamura, 1997); however, the use of SCC in the United State remains limited. Part of the reason is because of the limited knowledge and experience regarding its use, as well as its high initial cost. Nevertheless, the Federal Highway Administration (FHWA) is leading an effort to promote the use of SCC in transportation structures in the United States, and SCC has been used by several state departments of transportation, such as those in New York, New Jersey, and Virginia.

The proper use of SCC requires: (1) good understanding and knowledge of the new generation of superplasticizers and chemical admixtures, (2) control of the constituent materials and water content of the concrete, (3) familiarity with and understanding of the acceptance of fresh and hardened concrete, (4) documentation of properties and durability, (5) use and implementation of proper casting methods, (6) control of pressure on the formwork, and (7) contingency plans for repair of defects and for interrupted casting (Suksawang et al., 2005).

15.6.2 Mix Design

Fresh concrete can easily attain high flowability by simply increasing the water-to-binder (w/b) ratio; however, increasing the w/b ratio alone could lead to concrete segregation and less durability. Thus, to successfully develop SCC, mineral and chemical admixtures, such as pozzolans, limestone filler, superplasticizer, and viscosity-modifying admixtures (VMAs), must be added to the mix design to prevent segregation and enhance the durability of SCC. In addition, the absolute volume of coarse aggregates also must be limited to reduce interparticle friction and allow the SCC to flow under its self-weight without segregation (Okamura, 1997). Also, a reduction in the volume of coarse aggregate would have to be balanced by an increase in the volume of cement paste, which would result in higher material costs and an increase in the capillary pores. One solution to decreasing the paste volume is to use a VMA that reduces interparticle friction and increases flowability, so the volume of coarse aggregates could be increased. Despite this solution, concrete producers and owners still have questions regarding the use of VMAs because little information on its long-term effects and the effects of various chemical admixtures on SCC is available. An alternative solution is to use pozzolans, such as fly ash or dust powder, to replace the cement content (Persson, 2001; Zhu and Bartos, 2003). The pozzolanic materials not only reduce the cement content but also fill the capillary pores, thus making the concrete denser and increasing its durability. Moreover, some pozzolans, such as fly ash and slag, can also increase the flowability of concrete, which reduces the amount of superplasticizers required and lowers production costs. However, any decrease in the volume of coarse aggregate and any increase in the volume of cementitious paste will greatly affect the mechanical properties of SCC. Also, most of these mix designs are based on Japanese and European experiences. SCC mix designs using raw materials in the United State are limited. The cementitious materials typically consist of ordinary Portland cement (OPC), silica fume (SF), fly ash, and slag. Fine and coarse aggregates consist of river sand and crushed aggregates. The size and type of coarse aggregates influence concrete consolidation and distribution. In addition, several admixtures such as high-range, water-reducing agents and air-entraining agents (AEAs) are also used in SCC mix designs. Viscosity-modifying admixtures can also be used to increase flowability without segregation, which allows the volume of coarse aggregates to be increased.

15.6.3 Testing Methods and Specifications

For SCC to become a standard concrete mixture, acceptance tests on fresh and hardened SCC to evaluate its physical and mechanical properties must be established to ensure a level of comfort for the contractors, designers, and owners (Persson, 2001). As mentioned earlier, SCC does not require compaction; therefore, the rheological characteristics of SCC are very important, as its consolidation depends on its rheological performance. In ordinary concrete, adequate slump in conjunction with good consolidation practice will

FIGURE 15.7 Self-consolidating concrete (SCC) spread test.

FIGURE 15.8 J-ring test for SCC.

yield a dense concrete structure with few air voids. The external forces due to vibration compensate for the variations in plastic concrete, so the rheology of concrete can be ignored; hence, only the slump test is performed for testing fresh ordinary concrete. In SCC, however, the rheological characteristic cannot be ignored, because the concrete must meet certain rheological requirements. The plastic concrete is generally described as a Bingham fluid, where the concrete behavior is characterized by its shear yield stress and plastic viscosity. For SCC, the shear yield stress has to be lower than ordinary concrete for the concrete to self-compact (Khayat, 1999). The rheology of concrete could be measured using a concrete rheometer, which measures the shear yield stress and viscosity of concrete. The problem with doing so is that the device is very expensive, and the test is impractical to perform at a job site, so other practical fresh concrete testing methods similar to the slump test of ordinary concrete have been developed. These tests include: (1) the spread test, (2) the L-shaped or U-shaped box, (3) the V-funnel (4) the J-ring, and (5) sieve stability. Figure 15.7, Figure 15.8, and Figure 15.9 illustrate the various tests for fresh SCC (Suksawang et al., 2005, 2006). It must be noted, however, that these tests do not measure the rheology of concrete but instead are used to simulate actual environment and field conditions. Furthermore, not

FIGURE 15.9 L-box test for SCC.

FIGURE 15.10 SCC in drilled shafts.

enough data are available to correlate these tests with the rheology of concrete, especially for mix designs that use raw materials available in the United States. Hardened SCC is subjected to the same tests used for normal concrete, such as compressive strength, elastic modulus, shrinkage, freeze–thaw, rapid chloride permeability, and scaling, among others.

15.6.4 Applications

Because of its ability to flow easily in highly congested areas, SCC is now being considered for structural members with high volumes of steel reinforcement. In addition, SCC is becoming more attractive because it offers accelerated construction schedules, reduced noise levels, and smooth surface finishes. The first SCC application in Japan was in buildings in 1990. Since then, it has been used in bridge towers, bridge girders, bridge decks, box culverts, anchorages, and immersed tunnels. Lightweight SCC was also used in bridge girders (Okamura and Ouchi, 2003). In the United States, SCC has been used in nonstructural elements such as noise walls and parapets. The New York State Department of Transportation is already using SCC in bridge decks, and the New Jersey Department of Transportation is using SCC in drilled shafts. Figure 15.10 shows SCC pours in drilled shafts. Durability issues in SCC and its mechanical properties compared to those of normal concrete are being evaluated by many researchers; however, these studies are still limited and do not address all of the durability issues for highway structures. In addition, current prediction equations for the mechanical properties of normal or conventional concrete still must be validated for their applicability and accuracy in predicting properties of SCC mixes.

15.7 Mass Concrete

15.7.1 Introduction

Mass concrete is defined in ACI Committee 116 (1990) as “any concrete with dimensions large enough to require that measures be taken to cope with generation of heat from hydration of the cement and attendant volume change to minimize cracking.” Mass concrete according to the Portland Cement Association (PCA,

1987) can be any placement of normal concrete that has minimum dimension equal to or greater than 3 ft. Many structural elements require the use of large amounts of concrete, such as abutments, shear walls, tanks, mat foundations, large-diameter drilled shafts, footings, transfer girders, and dams. The biggest concerns with mass concrete are the maximum temperatures generated and the maximum temperature differentials. Several factors influence temperature changes, including the size of the component, the amount of reinforcement, the ambient temperature, the initial temperature of the concrete at time of placement, and the curing program. To minimize the effects of high thermal loads in mass concrete, engineers use various methods to apply mass concrete. These methods include refining concrete mix proportions, protecting exposed surfaces and formwork from extreme environmental factors, using aggregates with desirable thermal properties, precooling the concrete constituent materials prior to mixing, using internal pipes to cool the concrete itself after placement, and placing the concrete in several lifts or pours.

15.7.2 Methods of Controlling Temperatures

Some mix designs for mass concrete include supplementary cementitious materials in the mix, including slag cement or fly ash. The Slag Cement Association offers some guidance on specifying slag cement for mass concrete. The American Coal Ash Association also offers information on the benefits and specification of fly ash. Many state departments of transportation specify 35°F (19°C) as the maximum differential temperature between the core and the surface and 135°F (57°C) as the maximum concrete temperature (Gajda and Alsamsam, 2006). This is difficult to achieve unless other measures are used to control the heat of hydration. Many argue that this limit is arbitrary and should not be put in the specifications; rather, the maximum differential temperature should be calculated using ACI guidelines given in ACI 207.2R (Anon., 2001). Using less cement content and adding fly ash or ground granulated blast-furnace slag to replace some of the cement or using aggregates with low coefficient of thermal expansion can help reduce the rise in temperature and the temperature differential in mass concrete. In addition to controlling the mix design, other temperature control methods include precooling the concrete mix using shading and sprinkling of the aggregates, using cold water in the mix, and post-cooling of concrete using cooling pipes (Gajda and Alsamsam, 2006). Placing concrete in several lifts has also been used, but precautions should be taken to avoid cold joints. Slag and fly ash should be used with caution, but slag and fly ash can be useful for small mass concrete pours with temperature control.

Modeled temperatures in a 10-ft slab with 600 lb/yd³ of cementitious materials made up of 65% Type II cement and 35% fly ash Type F are shown in Figure 15.11. The figure shows the variations in temperature vs. time for different locations in the slab as well as variations in the differential temperatures in the concrete with time (Gajda and Alsamsam, 2006). Figure 15.12 shows the temperature change with time for the massive footing shown in Figure 15.13. For this massive concrete pour, an optimal mix design was used along with cooling pipes to cool the concrete after the pour (Gajda, 2003).

15.8 Roller-Compacted Concrete

15.8.1 Introduction

Roller-compacted concrete (RCC) is a type of concrete that exhibits zero slump and requires no vibration or forms; paving machines and compaction rollers compact the concrete after placement. Newer generations of paving machines, however, can achieve compaction of RCC during placement without the need for any additional compaction (see http://www.cement.org/pavements/pv_rcc_pcc.asp). Applications of this type of concrete include pavements, dams, and industrial sites with large areas, such as maintenance yards, military fields, container and truck distribution areas, and precast yards. RCC is an attractive material because of its easy preparation and placement, speed of construction, reduced labor requirements, and high strength. With its low water/cement ratio and high density, RCC has high strength and good durability; however, it requires special equipment for placement and lacks a smooth surface finish. The material was developed in the mid-1970s by Canadian builders for the logging industry. Today, RCC is a competitive material that is widely used in many projects all over the world.

FIGURE 5.11 Modeled temperatures for 10-ft slab with 600 lb of cement materials per cubic yard (65% Type II OPC and 35% fly ash). (From Gajda, J. and Alsamsam, E., *Engineering Mass Concrete Structures*, Seminar Development Series, Portland Cement Association, Skokie, IL, 2006.)

FIGURE 15.13 Overview of footing and pier prior to footing placement. (From Gajda, J., *Concrete Technol. Today*, 24(3), 34–37, 2003.)

15.8.2 Mix Design, Placement, and Curing

Mix design for RCC uses a low water-to-binder ratio, making it a dry mix with zero slump. The aggregates are a blend of various sizes chosen to achieve a well-graded aggregate mix. Typical maximum coarse aggregate size is 3/4 in. Aggregate sizes larger than 3/4 in. could result in segregation and less density. Gravel aggregates or crushed stone are typically used for coarse aggregates, and natural sand or river sand is used for fine aggregates (PCA, 2000). RCC is placed in various thicknesses and various widths. Thicknesses can be as thin as 5 in. and as thick as 12 in. for slabs; the width depends on the paving machine used. Placement can also be achieved by spreading the RCC mix and then applying compaction; however, care must be taken to ensure that the spread is continuous and the compaction process is uniform. Precaution should be taken when placing RCC in hot weather—when the temperature increases, the mix tends to lose more moisture. Contractors should maintain the required moisture of the mix by either increasing the moisture content in the mix or delaying the moisture loss by using admixtures or cooling methods. Like regular concrete, RCC should be cured. Improper curing could lead to severe dryness and incomplete hydration of cement, resulting in weaker RCC and cracking. Curing is typically applied for 7 days after placement. Plastic sheets and wet burlap can be used similar to regular concrete (PCA, 2000).

15.8.3 Testing Methods for RCC

The moisture content and densities of RCC are important properties that must be verified for acceptance. ASTM Subcommittee C09.45 is in charge of developing standard test procedures for measuring RCC properties. ASTM Subcommittee C09.45 developed ASTM Standard C 1170 (2006), a test method for determining the consistency of concrete using a vibrating table and a surcharge and determining the density of the consolidated concrete specimen. They also developed ASTM Standard C 1040 (2005), a standard test method for in-place density of unhardened and hardened concrete, including roller-compacted concrete, by nuclear methods using gamma radiation.

16.1 Introduction

Concrete has been used as a construction material in a wide variety of structures ranging from buildings and parking structures to bridges, dams, earth-retaining structures, pressure vessels, tanks, boats, and offshore platforms. Today, it is the most widely used construction material. As with other forms of infrastructure, there is an ever-increasing need to evaluate and repair concrete structures. Repairs may be required for a variety of reasons, ranging from a change in the space requirements of the structure to the deterioration of concrete and corrosion of the steel reinforcement. Although most concrete structures have good long-term performance records, deterioration problems have occurred because of poor construction practices, poor design, lack of quality materials, and aggressive environmental exposure. Perhaps the most-cited statistic in the technical concrete literature concerns the extent of deterioration of this

* Principal of WDP & Associates, Inc., Austin, Texas, and chairman, ACI Committee 318; expert in structural design both in reinforced and prestressed concrete and in retrofit of concrete structures.

country's roads and bridges, often referred to as the nation's highway infrastructure. The American Association of State Highway and Transportation Officials (AASHTO) rates 40% of U.S. highways as below minimum standards of engineering. According to the U.S. Department of Transportation, 230,000 out of the 575,000 bridges on primary and secondary roads are structurally deficient or functionally obsolete. It has been estimated that between \$18 billion and \$21 billion is spent by owners for repair, protection, and strengthening (Strategic Development Council, 1996). The value of the concrete-based infrastructure in the United States is estimated to be \$8 trillion. And, as was so simply put in a Smithsonian article, "a lot of that concrete needs fixing" (Wolkomir, 1994).

Repair of structural concrete—that is, repair of structures in which concrete is the principal load-carrying material—can be classified into three major categories: *rehabilitation*, where repairs are conducted to extend the service life of the structure; *restoration*, where repairs are effected to upgrade the functionality or change the use of the structure; and *strengthening*, to restore the intended load capacity of the structure or perhaps, as in the case of restoration, increase its capacity because of an anticipated change in use. As can be surmised, the boundaries between rehabilitation, restoration, and strengthening of concrete structures often overlap. The principal objectives of a repair are to ensure safety and structural integrity, extend useful life, improve aesthetics, change use, or to improve serviceability. The design of repairs must, therefore, address strength, durability, and serviceability analogous to the limit states considered in the design of a new structure.

It is not the intent of this chapter to present a comprehensive treatise of all aspects of the repair of concrete structures. Detailed information is available in the literature with regard to concrete preparation, repair materials, and execution of repair construction. Rather, the objective is to present the structural concepts concerning concrete repair that include evaluation procedures and general design concepts. The structural guidelines presented are generally applicable to all types of concrete structures, including bridges, buildings, water-containing structures, parking garages, and special structures. A detailed case study of an infrastructure repair project is presented to demonstrate the importance of proper evaluation within the context of a repair project. This comprehensive case study also illustrates the various structural analysis and design techniques that are sometimes necessary to ensure a cost-effective solution in a large-scale infrastructure repair project.

16.2 Limit States Design for Repair

To repair a concrete structure, it is important to understand what has "failed." Perhaps one of the simplest definitions of what might constitute failure of a structure can be inferred from the definition of limit states given by the structural sage, Professor J.G. MacGregor (1976), who stated: "When a structure becomes unfit for its intended use, it is said to have reached a limit state." Thus, the inference is that when a structure can no longer perform in its intended function this, in essence, constitutes failure. The three generally recognized limit states for concrete structures are:

- Serviceability limit state
- Ultimate limit state
- Durability limit state

Although concrete building codes such as ACI 318-08 (ACI Committee 318, 2008) may not have code provisions and standards that explicitly guard against failure for all of these limit state categories, they do so implicitly. When concrete structures suffer from premature deterioration caused by steel reinforcement corrosion, this is generally thought to affect their durability. A concrete structure designed for an intended life of 40 years could be considered to reach the durability limit state if severe corrosion and attendant distress were manifested, for example, in only 15 years. But, as conceptually illustrated in Figure 16.1, it is difficult to separate the pernicious effects of corrosion on durability, serviceability, and strength because the deterioration that results from corrosion not only compromises durability but clearly can

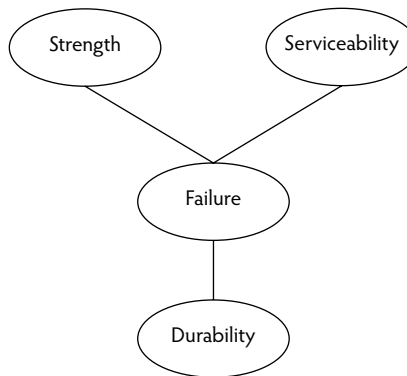

FIGURE 16.1 Limit states in structural concrete repair.

also impair the serviceability and strength of the structure. In fact, there is a confluence of limit states with regard to the effects of deterioration in structural concrete. It is therefore necessary to design concrete repairs to satisfy all three limit states.

16.3 Evaluation

Prior to undertaking repairs to concrete structures, a condition assessment to determine the existing conditions and nature and causes of observed distress must be conducted; otherwise, the absence of this information could lead to a high risk of failure of the repair. The extent of the condition assessment depends largely on the objectives of the repairs. The factors that affect the repair objectives include safety and structural integrity, the desired service-life extension, change in intended use or loading requirements, serviceability, aesthetics, and cost. Internationally recognized organizations, such as the American Society of Civil Engineers (ASCE) and the American Concrete Institute (ACI), have published guidelines for condition assessment of structures (ASCE, 2000).

The Strategic Highway Research Program (SHRP) was established in 1987 by Congress to improve the performance and durability of the nation's highway systems (TRB, 1986). As part of this effort, a number of nondestructive evaluation (NDE) tools were developed that have been implemented by states and local government agencies, by industry, and by private sectors. Some of the methods developed by SHRP include alkali-silica reactivity (ASR) test methods and a rapid method for determining chloride content and the rate of corrosion of steel reinforcement in hardened concrete. These, along with other existing and emerging NDE techniques, have aided in diagnosing problems, specifying repairs, and quantifying the extent of adverse conditions and deterioration.

A condition assessment of a concrete structure may be necessary even if repairs are not contemplated. In some cases, condition assessment is required for determining the load rating of a structure. Moreover, a condition assessment may be conducted in an ongoing inspection program simply to show that a structure is structurally sound. In fact, the Federal Highway Administration (FHWA) has mandated biennial inspections for bridges since 1968. Traditionally, a condition assessment of a concrete structure generally meant a visual examination of the structure along with select coring of various concrete elements for compressive strength testing, perhaps a petrographic analysis, and sounding by chain drag. Although these techniques are still helpful and largely necessary, over the past two decades other very valuable and practical nondestructive evaluation methods have been developed. These newer generation nondestructive methods greatly improve and increase the efficiency of the condition assessment process for concrete structures. Some of these recently developed nondestructive evaluation technologies allow for relatively rapid inspection of damage and deterioration of concrete structures.

The objectives of this section are to summarize selected nondestructive evaluation methods that can be used as an aid in conducting condition assessment of concrete structures, highlight some of the more recently developed methods, and discuss the relative merits of various NDE methods. For our purposes, NDE is defined as any test or method that yields information regarding the quality of a structure or portion thereof that does not impair the serviceability of the element or structure. Destructive testing in the sense of removing samples from a structure or element, such as coring, is considered a nondestructive test for the purposes of this discussion. The techniques and methods discussed are generally applicable to all types of concrete structures.

16.3.1 Information Gathering

Prior to the field-investigation component of the evaluation, it is important to gather as much information as possible related to the original design and construction. This includes gathering structural and shop drawings, project specifications, and construction records. Records such as concrete batch tickets, test reports, and weather and daily logs can be particularly useful if there is observed deterioration, cracking, or other types of service-performance problems. These types of original construction documents should be perused to ascertain if existing conditions are related to original construction problems or perhaps to design deficiencies.

16.3.2 Visual Inspection

Despite the advances in nondestructive evaluation methods, visual inspection is still an integral part of a condition assessment and, in fact, is the most widely used form of NDE. It is always the first step in condition assessment of a structure. The forms of distress and deterioration that should be recorded in the field evaluation and some of the associated causes are summarized in Table 16.1. In some select cases, the evaluation may be concluded with a simple visual inspection; however, in more cases than not, some form of nondestructive testing (NDT) is required to determine the cause of the observed deterioration, assess its implications and the extent to which it affects structural integrity, and develop appropriate repair and maintenance strategies to meet the client's budget.

16.3.3 Testing

The types, location, and size of material samples should be consistent with the size of the structure so the results are statistically meaningful; for example, determining chloride-ion content at only one or two locations in a bridge deck will not provide sufficient data to draw statistically significant conclusions. Table 16.2 summarizes some methods of field and laboratory testing that may be conducted to aid in the condition assessment of a concrete structure. Selection of the appropriate test method to determine a particular characteristic depends on several factors, including desired sensitivity and cost. At a minimum, the concrete strength and condition and location of the reinforcement should be assessed to generally characterize the strength, safety, and integrity of the structure. Other testing is then conducted to determine the extent of deterioration and to establish causes. Establishing the cause of deterioration is an important element in developing appropriate repair strategies within prescribed budget limitations. The test methods for evaluating concrete structures described in Table 16.2 are well documented in the literature (e.g., ACI 228.2R). Because of their relative virtues and effectiveness, two of the test methods—impact-echo and surface-penetrating radar (SPR)—are briefly described to illustrate the power and versatility of selected nondestructive testing technologies for evaluating structural concrete.

16.3.3.1 Impact-Echo

In the impact-echo technique, a transient stress pulse is introduced into a test object by mechanical impact on the surface as illustrated in Figure 16.2. The stress pulse propagates into the object along spherical wave fronts as P- and S-waves and along the surface of the object along a circular wave front as an R-wave. The P- and S-waves are reflected by internal cracks or interfaces and by the external

TABLE 16.1 Forms of Concrete Distress and Deterioration Noted in a Visual Condition Assessment

Description	Typical Causes
Cracking	Plastic shrinkage Drying shrinkage Restraint Subgrade support deficiencies Absence or location of vapor barrier Expansion Corrosion of reinforcing steel/prestressing steel or other embedded metal Components Thermal loading Vehicular impact Overloading Aggregate reaction
Scaling	Inadequate air content Finishing problems Freeze-thaw cycling Chemical deicers
Spalling	Aggregate reaction Corrosion Freeze-thaw cycling Construction Poor preparation of construction joints Early-age loading
Disintegration	Frozen concrete Freeze-thaw cycling Low strength Chemical attack Sulfate attack
Honeycombing and surface voids	Poor placement Poor consolidation Congested reinforcement
Discoloration and staining	Different cement production Different water-cement ratios Corrosion Aggregates Use of calcium chloride Curing Finishing Nonuniform absorption of forms
Efflorescence	Calcium carbonate and other mineral deposits caused by leakage

boundaries of the object. The arrival of these reflected waves at the surface where the impact was generated produces displacements that are monitored by a transducer. If the transducer is placed close to the impact point, the waveform is dominated by displacements caused by P-wave arrivals.

Because it is difficult and time consuming to analyze time-domain waveforms to determine the arrival times of reflected waves and thereby calculate the depth of reflecting interfaces, waveforms are transformed into the frequency domain using the fast Fourier transform (FFT) technique (Sansalone and Carino, 1986, 1988). The resulting amplitude spectrum is used to identify the dominant frequencies present in the waveform. Because these frequencies are produced by multiple wave reflections between interfaces, they can be used to determine if a structure is solid or if flaws exist within the structure. Each type of structure—plate (bridge deck, slab), bar (beam, column), hollow cylinder (pipe, shaft line), etc.—exhibits a characteristic frequency response when subjected to impact. The presence of a flaw affects this response.

TABLE 16.2 Selected Tests for Condition Assessment of Concrete Structures

Mechanical/Physical/ Chemical Property	Test Type	Reason for Test
Compressive strength	Swiss hammer (ASTM 805) Windsor probe (ASTM C 803) Core for compression testing (ASTM C 42) Ultrasonic pulse velocity (UPV) (ASTM 597)	Strength of in-place concrete; comparison of concrete strength in different locations (UPV and Swiss hammer provide relative differences in strength only)
Reinforcement location	Pachometer Radiography Radar (ASTM D 4748)	Steel location and distribution; concrete cover
Corrosion potentials	Half-cell potential (ASTM C 876) Linear polarization (SHRP S-330)	Identification of location of active reinforcement corrosion; corrosion rate
Chloride ion content	Acid-soluble, by titration (ASTM C 1152)	Susceptibility of steel reinforcement to chloride-induced corrosion
pH	Phenolphthalein; direct measurement with pH meter	Assess corrosion protection value of concrete with depth and susceptibility of steel reinforcement to corrosion; depth of carbonation
Air content; cement and aggregate properties; scaling	Petrographic examination of concrete core removed from structure (ASTM C 856)	Assist in determination of cause(s) of distress; degree of damage; quality of concrete when originally cast
Alkali-silica reactivity; freeze-thaw susceptibility	(ASTM C 457)	—
Permeability	Electrical indication of concretes Ability to resist chloride ion penetration (ASTM C 1202) (AASHTO T277) Resistance of concrete to chloride ion penetration (90-day ponding test) (AASHTO T259) Absorption test (ASTM C 642)	Establish relative susceptibility of concrete to chloride ion intrusion; assess effectiveness of chemical sealers, membranes, and overlays in repair

In a plate, the impact-echo is dominated by reflections between the top and bottom surface of the plate or from a defect if one exists. Knowing the P-wave speed (to determine the P-wave speed, a test must be carried out over a portion of the test object of known thickness) in the test object (C_p), the depth (T) to a reflecting interface can be calculated as:

$$T = \frac{C_p}{2f_p} \quad (16.1)$$

where f_p is the frequency of P-wave reflections from the interface. In plates, wave reflections from the side boundaries do not have a significant effect on the response.

An impact-echo test system is composed of three components: an impact source, a receiving transducer, and a waveform analyzer or a portable computer with a data acquisition card that can sample at a frequency of at least 500 kHz. The duration of the impact determines the frequency content of the stress waves generated by the impact. Impacts with shorter durations contain higher frequency (shorter wavelength) components, which are required for testing thinner structures or detecting smaller or shallow flaws. Hardened steel spheres on spring steel rods are used as impact sources. The impact durations produced by impactors generally range from about 10 to 80 μ s.

Figure 16.3 shows the impact-echo test results from a 20,000-ft² industrial concrete overlay delaminated from a structural slab at an industrial facility. Impact-echo was used to identify the delaminated repairs,

TABLE 16.2 (cont.) Selected Tests for Condition Assessment of Concrete Structures

Mechanical/Physical/ Chemical Property	Test Type	Reason for Test
Alkali-silica reactivity	SHRP rapid test (SHRP-C/FR-91-101)	Establish in field if observed deterioration is due to alkali-silica reactivity
Location of delaminations, voids, and other hidden defects	Limited information of shallow defects from sounding (ASTM D 4580), impact-echo, infrared thermography (ASTM D 4788), pulse echo, surface-penetrating radar (ASTM D 4748), impulse response	Assessment of reduced structural properties; extent and location of unobserved damage and defects
Steel area reduction; defect identification	Invasive probing	Observe and measure rust and area reduction in steel; observe corrosion of embedded post-tensioning components; verify location and extent of deterioration; provide more certainty in capacity calculations
Concrete component thickness	Impact-echo radar (ASTM D 4748); invasive probing	Verify thickness of concrete; provide more certainty in capacity calculations
Local or global strength and behavior	Load test; strain measurements; acceleration; deformation; displacement measurements	Uncertainty in integrity and behavior; ascertain acceptability without repair or strengthening; determine accurate load rating
Tensile strength	Pull-off tests (ASTM C 1583) Splitting tests (ASTM C 496) Tension tests	Assess tensile strength of concrete and steel; relative quality of material
Material property determination	Density (ASTM C 642) Moisture content (ASTM C 642) Shrinkage (ASTM C 341) Dynamic modulus (ASTM C 215) Modulus of elasticity (ASTM C 469)	Determine mechanical properties of materials and volumetric properties

Note: ASTM, American Society for Testing and Materials Testing Standards; AASHTO, American Association of State Highway and Transportation Officials Testing Standards; SHRP, test methods developed as part of the Strategic Highway Research Program.

which appear as dark areas in the map. The test results facilitated the selective removal of the delaminated areas, lowering the cost of the repair work. Chapter 19 provides more detailed information regarding the impact-echo testing system.

16.3.3.2 Surface-Penetrating Radar

Surface-penetrating radar (SPR) is a nondestructive evaluation technique that utilizes electromagnetic energy to locate objects, subsurface flaws, or interfaces within a material. The system utilizes a high-frequency dipole antenna to transmit a train of discrete amplitude modulation (AM) radiowave pulses. A second antenna, housed next to the transmitting antenna, is used to receive the scattered pulses as they return to the surface of the material. The radar unit detects back-scattered radiation that is reflected at the boundary between differing dielectric media. By measuring the time it takes to receive the reflected signal, the depth of an embedded object or interface may be determined. A real-time visual display of the material cross-section is recorded as the antennae are moved along the surface. The output is fed to sampling circuitry before being digitally processed by a computer. The color and intensity of the patterns in the output are related to the amplitude of the reflected signals. Figure 16.4 illustrates SPR scanning and sample signal output. The bands of alternating light and dark areas that appear in the remainder of the output correspond to the positive and negative reflections of the input wave from subsurface objects. Reflections from a lower dielectric media to a higher one, such as from concrete to steel, will undergo a phase inversion, or reversal, and the boundary will show up as a bright signal (assuming the input wave

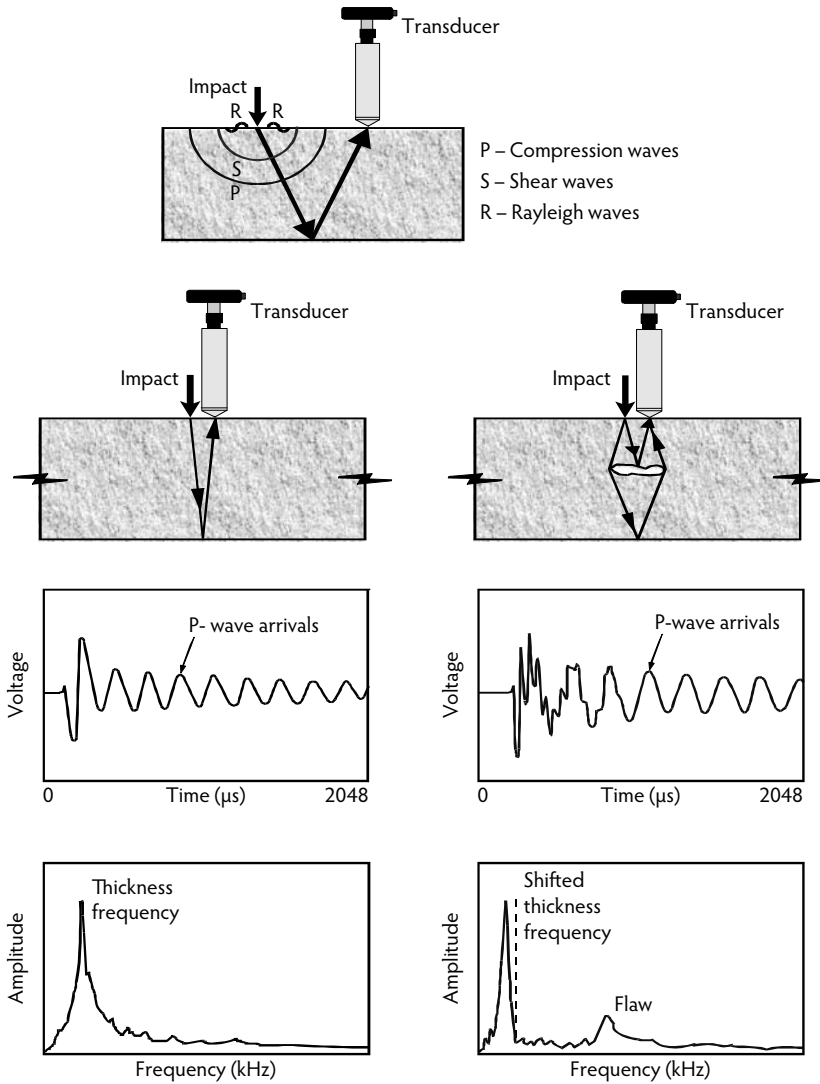

FIGURE 16.2 Schematic of the impact-echo technique applied to a concrete structure.

is dark). Conversely, the boundary from concrete to air (higher dielectric to lower) will show up as a dark signal. SPR antennae are specifically tuned to detect cylindrical objects, such as rebar, conduit, pipes, etc. These types of features show up as hyperbolas, or arch shapes, on the data record, as seen in Figure 16.4. Steel shows up more distinctly than other media due to the high reflective property of electrically conductive materials, and, as a result, SPR is particularly well suited for locating mild reinforcing steel in concrete.

16.4 Structural Implications

Results from field and laboratory observations and testing must be assessed to determine the cause of the observed deterioration. In addition, findings from the investigation results must be assimilated to determine their effects on strength, serviceability, and durability of the structure. As previously discussed, each of these factors must be considered for a successful concrete repair. The strength and integrity of

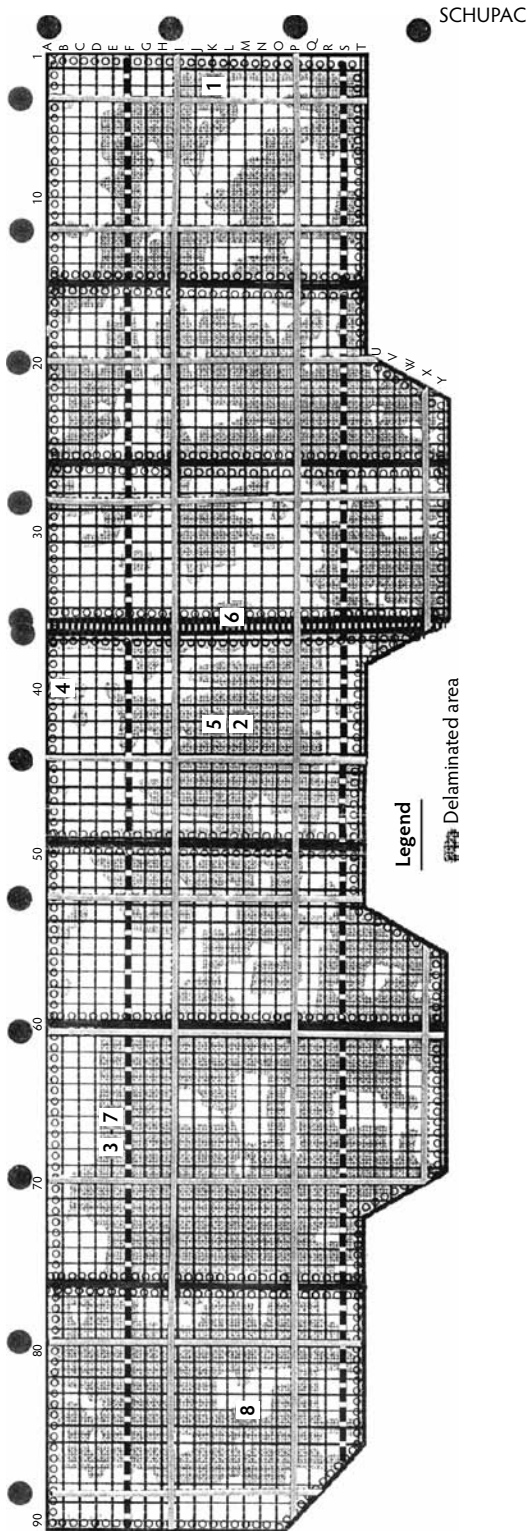

FIGURE 16.3 Results from impact-echo testing on an industrial lab showing areas of delamination.

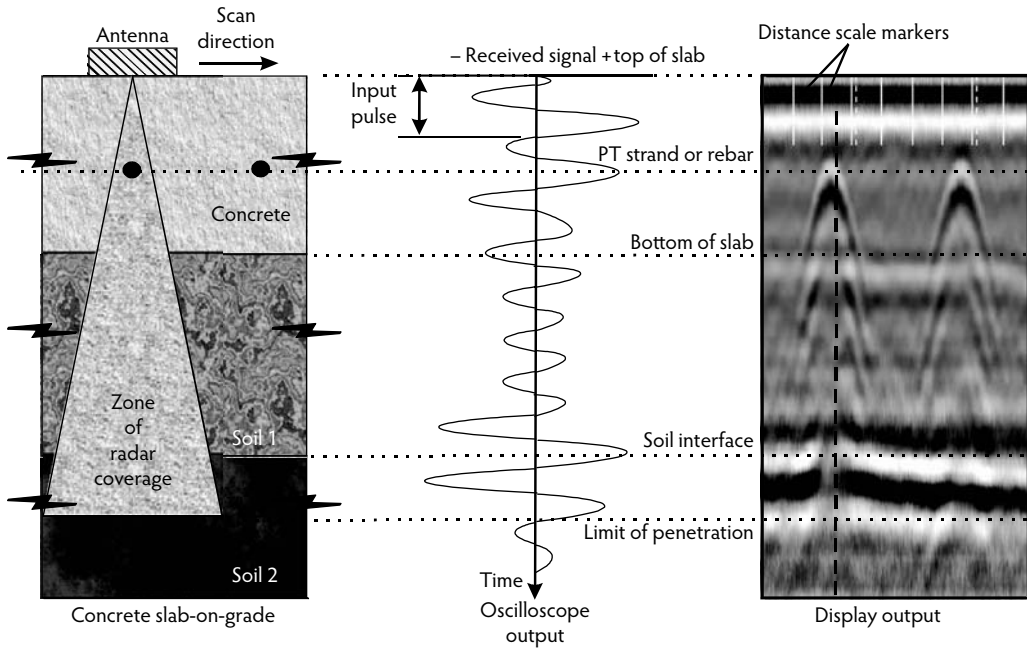

FIGURE 16.4 Schematic of surface penetrating radar technique applied to a concrete structure.

concrete structures suffering from deterioration can be assessed using conventional analysis techniques for concrete structures utilizing quantitative assessments of reduced material properties as determined in the investigation. This requires some judgment about the extent of deterioration. It is prudent to reduce the capacity-reduction (ϕ) factors in the ACI Building Code (ACI Committee 318, 2008), as they were calibrated for material variations that occur in new concrete construction. Several technical committees within ACI are examining this issue of ϕ -factor selection for repair and strengthening designs. Depending on the conditions and factors involved, a ϕ factor as low as 0.5 may not be unreasonable. In extreme cases, where analysis of a structure with reduced properties may be inappropriate or produces questionable results concerning integrity and safety, load testing of the structure is an option. Load testing can be expensive and must be conducted with extreme caution, particularly on deteriorated and suspected grossly deficient structures. In some cases, however, it may be the only viable alternative for demonstrating the integrity of a repaired structure (Poston and Irshad, 1996).

16.5 Repair Principles

Various organizations such as the American Concrete Institute (ACI) and the International Concrete Repair Institute (ICRI) have developed guidelines for the repair of concrete structures. These include technical and construction-related guidelines for, among other things, preparing the surfaces of deteriorated concrete and selecting and specifying materials for repair. These are valuable resources that describe in detail the proper construction-preparation techniques for good concrete repair. The reader is referred to the ICRI documents listed at the end of this chapter and the *Concrete Repair Manual* (ACI, 2002) for additional information on these construction-related aspects of concrete repair. The principles presented in this section are generally applicable for all structural concrete, including conventionally reinforced, prestressed, or partially prestressed structures; however, some of the more unique aspects of repairing unbonded post-tensioned concrete structures are presented in Section 16.6.

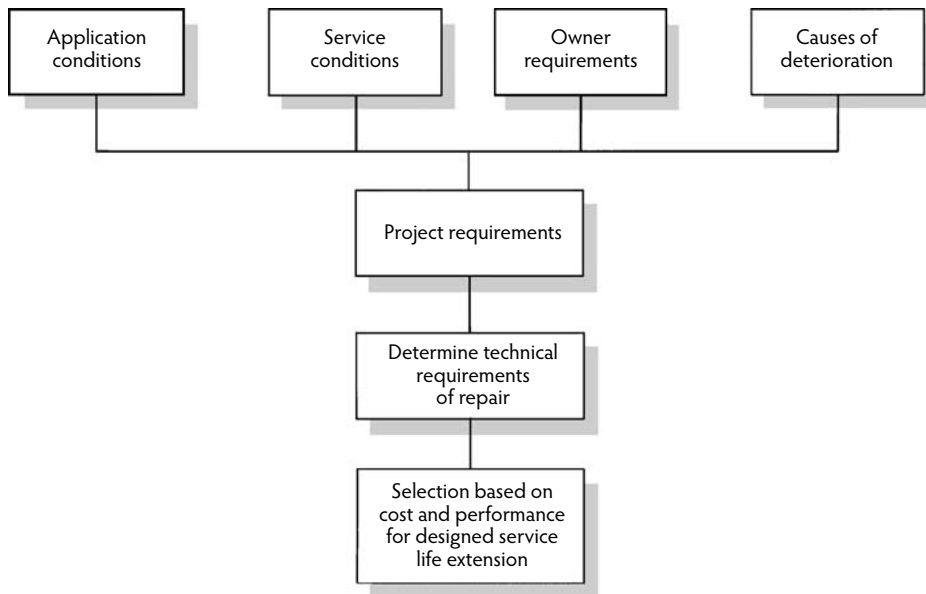

FIGURE 16.5 Representation of material selection process.

16.5.1 Material Selection

A general axiom in the repair of concrete structures is to use a material of physical and mechanical characteristics similar to those of the existing parent material. One of the most important mechanical properties to match, but which is often overlooked, is the coefficient of thermal expansion. As an example, epoxy concrete used in a repair exposed to large temperature differentials, such as on a parking garage deck, is not appropriate, as deformation of the epoxy is much greater than that for concrete. As shown in Figure 16.5, the process of selecting concrete materials for repair must include identification of the causes of deterioration, service conditions, owner requirements, and the application conditions. Thus, this somewhat complex selection process must consider constructability and service issues guided by the owner's needs and the engineering requirements of the repair. The final selection of a repair material is based on the relationship between cost and performance. ICRI Guideline No. 03733 (ICRI, 1996) provides in-depth information for the process of selecting repair materials.

16.5.1.1 Bond Strength

In almost all cases, one of the most important properties for repair is the bond strength (see Figure 16.6) between the repair material and the existing concrete substrate. Bond failures are generally a result of dimensional incompatibility between the repair material and the existing substrate, such as from drying shrinkage (McDonald et al., 2002). The failure is generally not a direct result of lack of bond strength. The relative dimensional changes that can occur, such as those illustrated in Figure 16.7, can affect the repair. Bond can be reduced and shrinkage cracks can appear; thus, the durability of the repair is compromised (McDonald et al., 2002).

16.5.1.2 Dimensional Compatibility

Drying shrinkage of the repair concrete is one of the important factors that influence the dimensional behavior. The existing concrete substrate has already experienced most of its time-dependent effects such as drying shrinkage and creep. The repair concrete that is then added must also undergo its shrinkage; consequently, it is very important to identify and select a low-shrinkage material. The time required for

FIGURE 16.6 Bond strength, an important property for the success of break repair.

FIGURE 16.7 Dimensional changes in repair material that have resulted in restrained shrinkage cracks.

a material to achieve dimensional stability is dependent primarily on the ambient temperature and humidity. It is important to adequately cure the repair to mitigate shrinkage cracking. It is recommended that the repair concrete material be limited to less than 0.05% shrinkage at 28 days as measured by ASTM C 157 (McDonald et al., 2002). Other properties of the repair material that are important in achieving dimensional compatibility include the coefficient of thermal expansion, modulus of elasticity, and creep, both compressive and tensile. In general, these properties in the repair material should reasonably match those of the existing concrete to achieve dimensional compatibility. By matching these properties, cracking in the repair will be mitigated. This will help ensure long-term durability of the repair.

16.5.1.3 Durability Considerations

The durability of the concrete repair is its ability to resist structural loading and environmental conditions without degradation and deterioration. The environmental conditions that may affect durability include weathering, temperature changes, chemical attack, and abrasion, among others. It is essential that the cause and extent of deterioration of an existing concrete structure be identified. Based on this information, a strategy can be identified to satisfy the durability limit state of the repair.

Material properties that can affect the durability of a repair include permeability, water-vapor transmission, freeze–thaw resistance, scaling resistance, sulfate resistance, abrasion resistance, and alkali–silica reaction. Permeability is the rate of transmission of a liquid through the concrete. In general, the lower

FIGURE 16.8 Provision for vapor transmission in repair.

the permeability, the better the protection against the ingress of aggressive elements such as chloride ions from chemical deicers and from diffusion of carbon dioxide leading to carbonation. Water-vapor transmission can lead to failure of a repair that uses an impermeable barrier. The movement of vapor in the concrete can become trapped at the interface of a permeable concrete and an impermeable barrier, such as a membrane, leading to debonding. As shown in Figure 16.8, the repair must make provision for this vapor transmission, such as by adding vents to allow the vapor to escape or by providing materials that allow vapor transmission such as chemical sealers or silicone-based coatings. The selected repair material must have adequate freeze–thaw resistance to ensure long-term durability. The cyclic freezing and thawing of concrete that is critically saturated leads to a deterioration of the paste matrix. Repair materials that have entrained air or that have been proven through laboratory testing to provide freeze–thaw resistance should be specified. In industrial applications, abrasion resistance is an important durability consideration. The resistance to abrasion is governed principally by the hardness, quality, and strength of the aggregate.

16.5.1.4 Mechanical Properties

Repair materials must be capable of resisting the internal stresses generated by loading and volume changes. The mechanical properties of the repair material are generally selected to match those of the existing concrete. This ensures compatibility of strains under load. The principal mechanical properties that should be examined in the repair design include compressive strength, tensile strength, modulus of elasticity, and coefficient of thermal expansion. In some circumstances, Poisson's ratio and flexural strength are also important mechanical properties for repair design.

16.5.1.5 Placement

The placement of the repair material and field conditions can greatly affect the type of repair procedure and material selection. Characteristics such as slump, pumpability, rate of strength gain, heat of hydration, set time, and characteristics in hot or cold weather can affect material selection. Conventional ready-mixed or machine-mixed concrete is the repair material of choice for existing-concrete deterioration that goes through, or mostly through, the structural element and beyond the reinforcement, or if the area to be repaired is large. Affected areas should be excavated until there is no question as to the soundness of the concrete. The excavation and repair area should avoid sharp angles that produce stress concentrations. Forms should maintain their shape during casting and maintain existing lines of the structure. For small repair areas that are relatively deep, rodding a very stiff, low water/cement ratio, dry-pack mortar is the method of choice. The rodding should be done in thin lifts, rodding the dry pack between successful lifts. If large volumes of repair are required in tight places, preplacing aggregate followed by pumping of grout is a good repair method. This usually requires specialized equipment and experience. For large-quantity shallow overhead and vertical repairs, shotcrete is an excellent choice. It bonds very well and is capable of supporting itself without a form. The nozzlemen must have good experience to control rebound that can lead to pockets of sandy layers. Mobilization costs require the repair project to be of reasonable size to justify using shotcrete. Repair of shallow areas of limited size are well suited for proprietary prepackaged

repair materials. These prepackaged materials often contain polymers to enhance the bond of the material to the existing concrete substrate; however, it has been observed that some prepackaged repair materials have excessive shrinkage characteristics and thus are dimensionally incompatible with concrete.

16.5.2 Preparation

In general, deteriorated concrete should be removed to sound concrete substrate. Partial-depth repairs are desirable because less demolition is required, no formwork is required for horizontal repairs, and they are generally less costly; however, if repair is required on two sides of a slab or wall, then full-depth removal is preferable. Saw cuts around the perimeter of the repair are advisable, particularly in the case of slabs to eliminate feather edges. After deteriorated concrete is removed, the surfaces to be bonded should be thoroughly cleaned, such as by wet sandblasting, then all loose particles should be vacuumed or pressure blown from the repair area. The surface should be thoroughly wet. The repair material should be placed when the surface has no standing water. A bonding agent such as a cement slurry coat or epoxy is normally not necessary but should be utilized if the manufacturer of a prepackaged material recommends their use.

16.5.3 Cleaning and Protecting Reinforcement

Prior to placing the repair material, steel reinforcement and other metal components should be cleaned of corrosion and other scale. Mechanical abrasion can be used, although sandblasting is preferable if environmental conditions permit. There are various components on the market for coating the reinforcement. These include epoxy, zinc-rich compounds, and cement-based coatings. Epoxy and some of the zinc-rich compounds can act as bond breakers and therefore, must be applied carefully. Recent findings regarding epoxy have raised questions about the appropriateness of its use. It has been speculated that the application of epoxy on reinforcing steel in an area under repair results in accelerated corrosion in surrounding areas, sometimes referred to as the *anodic ring effect*.

16.5.4 Curing

All concrete repairs must be properly cured to ensure hydration of the cement and strength gain and to minimize shrinkage and cracking. Curing should follow the same good practices as for new construction.

16.5.5 Crack Repair

Whether a crack in concrete should be repaired to restore structural integrity or merely sealed is dependent on the nature of the structure and the cause of the crack and on its location and extent. If the stresses that caused the crack have been relieved by its occurrence, the structural integrity can be restored with some expectation of permanency. In the case of working or moving cracks, such as cracks that open and close because of temperature changes, the only satisfactory solution is to seal them with a flexible or extensible material. ACI 224.1R (ACI Committee 224, 1998) provides comprehensive information on crack repair. Cleaning of the crack is essential before any treatment takes place. All loose particles and foreign material must be removed. The method of cleaning is dependent on the size of the crack and the nature of the contaminants. It may include compressed air, sandblasting, or routing. Restoration of cracks without restoration of structural integrity requires the use of materials and techniques similar to those used in sealing joints. Typically, the cracks are routed and a urethane sealant is applied. A bond breaker should be used on the bottom of the routed crack so bonding occurs on only two sides.

16.5.6 Corrosion Protection

Various corrosion protection strategies are being used in repair and new construction projects. Their selection depends on the type of structural system, exposure conditions, service life, and, naturally, costs. Selected corrosion protection strategies are summarized in Table 16.3.

TABLE 16.3 Selected Corrosion Protection Strategies for Concrete Structures

Strategy	Selected Types of Materials	Range of Additional Unit Costs
Reinforcing steel coatings	Epoxy	\$0.25–\$0.75/lb of steel
Corrosion inhibitors	Admixed in concrete	\$10.00–\$20.00/yd ³ concrete
Chemical sealers	Methacrylate, silane	\$0.50–\$1.00/ft ² of concrete surface
Elastomeric membranes	Urethane, neoprene	\$2.50–\$3.50/ft ² of concrete surface
Low-permeability concrete overlays	Fly ash and microsilica	\$6.00–\$8.00/ft ²
Cathodic protection	Impressed current	\$10.00–\$15.00/ft ² of concrete surface
Low-permeability polymer overlays	Epoxy, methacrylate	\$2.00–\$3.00/ft ² of concrete surface

FIGURE 16.9 Strengthening using bolted and epoxied steel plates.

FIGURE 16.10 Strengthening using steel subframing.

16.5.7 Strengthening

A repair that has been conducted for understrength concrete structures resulting from deterioration or upgrading of load capacity is the addition of auxiliary bonded reinforcement or addition of members. The strengthening may take one of the following forms: wire mesh or reinforcing bars added to the understrength area and bonded to existing concrete using shotcrete, latex-modified concrete, or other means; structural steel plates epoxied and bolted through deficient structural concrete to increase capacity, as shown in Figure 16.9; the addition of supplemental steel subframing, as shown in Figure 16.10; the use of external post-tensioning, as shown in Figure 16.11; or the use of bonded carbon fiber applied to the concrete surface. Depending on conditions, there may be a need for corrosion protection and fireproofing. The requirements for engaging all or some of the superimposed loads on the structure must be carefully reviewed. Generally, it is preferable to preload the structural member being strengthened to

FIGURE 16.11 Strengthening using external post-tensioning.

some degree. The amount of preloading depends on whether the deficiency is under service or ultimate loads or both. In some cases, no preloading is required and the strengthening is only effected to ensure that the structural element can achieve ultimate strength.

16.6 Repair of Unbonded Post-Tensioned Concrete Structures

Prestressed concrete is a type of reinforced concrete construction in which steel reinforcement is tensioned so permanent internal compressive stresses in the concrete improve the response of a member of structure to loading. Compared to conventionally reinforced concrete, prestressed members typically have greater load capacity or deflect less for the same load. Two different procedures are used for prestressing concrete structures. In pretensioned concrete, the general repair principles presented in Section 16.5 are applicable. Figure 16.12 illustrates post-tensioning, where the steel is tensioned after the concrete has been cast and gains strength. Metal or plastic ducts are used to prevent bond with multistrand tendons, whereas for single-strand tendons plastic sheathing is used. The prestressing force is transmitted to the concrete through bearing at mechanical anchorages. Tendons are usually stressed from one anchorage, known as the live end, or from both end anchorages if stress losses due to friction and curvature are significant. Pockets for stressing anchors are usually grouted to protect the hardware. If the duct is filled with a conventional grout, then bonding or partial bonding of the steel to the concrete is achieved. This is referred to as *bonded post-tensioned concrete*. In unbonded post-tensioned concrete, the duct remains unfilled after anchoring so the steel is not bonded to the concrete and is permanently free to move. Unbonded post-tensioning systems are more common in North America. Unbonded post-tensioning is used for applications ranging from buildings, bridges, and parking structures to pressure vessels, tanks, and earth-retaining structures. Steel used for unbonded applications includes high-strength wires, strands, and threaded bars. The most commonly used unbonded tendon is the monostrand system, which has a seven-wire, 0.5- or 0.6-in.-diameter, 270-ksi strand, as shown in Figure 16.13. The steel is covered with a corrosion-inhibiting grease or other coating and enclosed in a plastic sheath or a plastic or metal duct.

More than 2.0 billion square feet of unbonded post-tensioned concrete structures have been constructed in the United States since the mid-1960s. There is an ever-increasing need to repair and strengthen these structures to extend their service lives and to restore structural integrity. The need for repair and strengthening is primarily due to one or more of the following reasons: the strand is unintentionally damaged or cut, such as when coring concrete to install a mechanical pipe; there is a change in load or the space requirements of a structure, such as adding a stairwell; improper design or construction resulting in inadequate structural capacity; and corrosion of the prestressing strand or mechanical anchorages.

Prior to repairing an unbonded post-tensioned concrete structure, it is important to conduct a comprehensive engineering evaluation using the techniques previously discussed to determine the causes of observed problems. Because of the potential for tendon release, caution must be exercised during the evaluation and repair phases. The methods for assessing an existing unbonded post-tensioned concrete

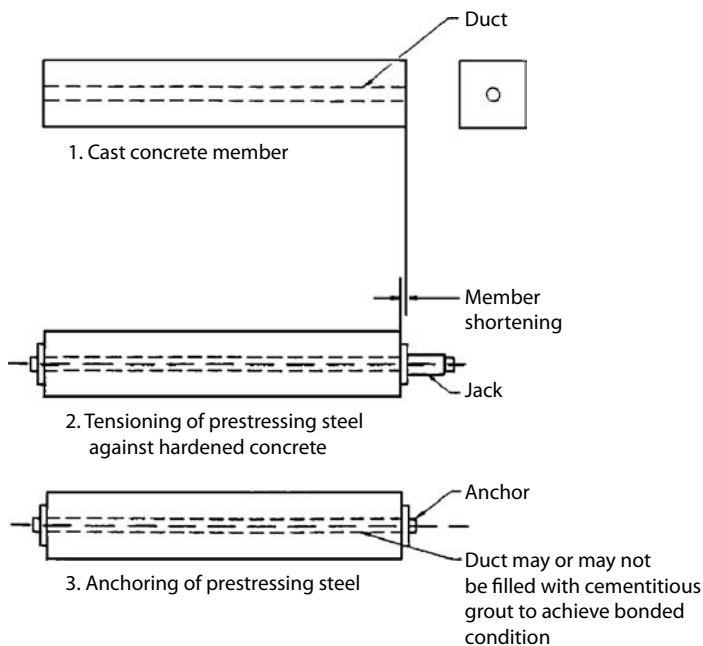

FIGURE 16.12 Post-tensioned concrete.

FIGURE 16.13 Plastic sheath filled with grease containing unbonded monostrand.

structure are, for the most part, the same as for a concrete structure constructed with mild steel reinforcement; however, the repair of existing unbonded post-tensioned structures is different in many respects.

The repair of unbonded post-tensioned concrete structures cannot be easily divided into categories where a certain type of repair is best for a certain type of problem. The type of repair depends on the expected cost of the repair, cause of the problem, the need to maintain service of the structure, whether the repair is to a beam, slab or other structural member, and many other factors. Moreover, once repairs begin, the owner, engineer, and repair contractor must be able to adapt to unobserved latent defects and changed conditions. The most important axiom in the repair of unbonded post-tensioned structures is to expect the unexpected. The general types of repair of unbonded post-tensioning are classified as (1) do nothing, (2) tendon splice or replacement, and (3) strengthening by adding bonded reinforcement, structural members, or external post-tensioning to improve or increase structural capacity. If the repair is due to a corrosion problem, it is likely that other concrete repairs will be necessary because of the deterioration that is generally attendant with corrosion. As with all types of concrete repair, extreme caution should be exercised by all individuals during the investigation, demolition, and repair. The need for shoring and the sequence of repair should be thoroughly thought out prior to starting any work.

16.6.1 Do Nothing

On some occasions nothing needs to be done for a failed post-tensioned strand. If it is known unequivocally that one strand or possibly two have been accidentally severed, then these strands can be pulled out and not replaced. Section 18.20.4 of the ACI Building Code (ACI Committee 318, 2005) allows the total loss of prestress due to unreplaced broken tendons that does not exceed 2% of the total prestress. Thus, for example, in the case of a post-tensioned slab structure that might contain hundreds of tendons in a single floor, the loss of one strand without replacement would be acceptable and would not be considered to have a significant impact on structural integrity.

16.6.2 Tendon Splice or Replacement

Tendon splice or replacement is the most common form of repair to an unbonded concrete structure. This type of repair is generally cost effective when the number of tendons to be spliced or replaced is limited, although there have been several notable examples where the tendons in an entire structure have been replaced (Aalami and Swanson, 1988). Tendon replacement may include replacement of the strand or one or more of the anchorages, depending on access for retensioning and anchorage condition. This option is the repair method of choice if the strand has been severed or if corrosion is localized. The cost of tendon splicing or replacement can range between \$1500 and \$5000 per strand, depending on the difficulty of the repair and the number of strands required. If the strand to be spliced or replaced is already severed, then the repair is somewhat simplified. If the strand is still tensioned, then the following procedure is required:

- Choose a point in the structure in which the tendon is more accessible. If the location of the problem and thus the splice point is known, then choose that point. Locate the tendon by use of a pachometer. In more complicated repairs, radiography or SPR may be warranted.
- Make a shallow saw cut in the concrete surrounding the tendon that defines the limits of the concrete to be removed.
- Remove the concrete around the tendon by light chipping hammer or jackhammer.
- If the strand is to be respliced, it is preferable to install a temporary anchorage. After placing the temporary anchorage, the strand may then be cut using a grinder. If a temporary anchorage is impractical, then, exercising extreme caution by making sure no one is in the area of the entire tendon length, the strand may be cut using a grinder. After cutting through just two wires of a seven-wire strand, the strand will yield and then fracture, with an attendant loud noise from the energy release. In some cases, controlled heating of the strand over a length of several feet may be preferred. This is the case when sudden detensioning can push out wedges at inaccessible anchorages, making restressing of the tendons impossible. Heating can result in less shock and more control in the detensioning process.
- If the existing strand is to be replaced or partially replaced, the strand piece to be removed can now be pulled from the anchorage. A new strand, coated with a corrosion-inhibiting grease, can then be threaded through the existing duct. A special type of splicing hardware allows for retensioning at the point of splice. This is beneficial when access to the end anchorages does not allow the use of a standard hydraulic stressing jack.

When stressing has been completed, the concrete can be recast in the excavation. As previously discussed, it is generally preferred to use a concrete of similar strength and modulus as the existing concrete. Exposed reinforcing steel should be cleaned and coated for corrosion protection. Exposed concrete surfaces should be sprayed with water prior to casting concrete. Curing should follow established good practices. In some cases, the entire post-tensioning strand may have to be replaced because of corrosion. In other cases, such as in buildings where access for splicing may be difficult, anchorages at the edge of a member can become the splice point. If the existing anchorage is not easily accessible for jacking, then a new anchorage can be added for ease of constructability.

FIGURE 16.14 New anchorages and bursting steel.

It is important to emphasize that if the strands are still tensioned and the anchorages are still engaged, do not try to release the stress by jack-hammering around the anchorage. This is very dangerous. Instead, as previously noted in the procedure for splicing, cut a slot in the concrete away from the anchorage zone. Making sure that no one is in the way of the tendon trajectory at the ends of the structure or above or below, the strands can be detensioned using a grinder or by heating at the control point. Again, expect a loud noise when several of the wires of the seven-wire strand have been cut. Removal of the anchorages can begin by first placing a shallow saw cut around the boundary of the anchorage zone. The concrete can then be removed by light chipping. The anchorages and strand can then be removed.

Figure 16.14 shows an arrangement of new corrosion-protected anchorages in place. Note that new mild reinforcement for control of anchorage zone bursting stresses has been placed just in front of the anchorages. In this case, the replacement anchorages are epoxy coated, and the plastic transition trumpets are attached integrally to the anchorages and the extruded sheathing to prevent water intrusion. The trumpet is filled with a corrosion-resistant grease. To expedite retensioning of the replaced tendons, a high-early-strength concrete may be used. In no circumstances should it contain calcium chloride as an accelerator. Many of these high-early-strength concrete materials can gain enough strength (>4000 psi) in 24 hours to allow retensioning the next day.

16.7 Construction Issues

The disruption caused by repairs to an existing structure depends on the degree of deterioration, the type of the structure being repaired, time of day when the construction is being done, expertise of the selected contractor, and other factors. Disruption to the owners and users of the structure is virtually unavoidable. Disruption, however, can be minimized with a carefully thought out and detailed schedule that is issued by the contractor to the affected parties. Generally, by breaking the project into workable units that are taken out of service one at a time, completed, then brought back into service is preferable to taking all of the affected areas out of service. Repairs of this nature cost more but allow for continued use of at least a portion of the structure. Historically, the knowledge level of repair contractors was not what might have been expected, but today many more competent and knowledgeable contractors are available for conducting specialized concrete repairs. This has resulted in high-quality, cost-competitive structural concrete repairs.

16.8 Long-Term Repair Performance

The question most often asked by owners relates to the anticipated long-term performance of repair alternatives. If this question can be answered with certainty and repair and maintenance costs are known, then it is a relatively simple matter to conduct a benefit/cost analysis. Of course, how long something will last depends on numerous variables, such as quality of repair, exposure conditions, maintenance, and a host of other factors, most of which are difficult to define. As part of a repair program, costs for a return after the first year to conduct an engineering inspection of the repairs should be included. If the budget permits, embedded sensors, such as wires to measure half-cell potentials, and a corrosion-rate probe should be included to monitor the repairs. All structures require maintenance. This is even more true with a repaired structure. Depending on the nature of the effected repairs, annual maintenance costs on the order of 1 to 5% of the repair costs may be appropriate for maintaining the repaired structure.

16.9 Case Study

To illustrate some of the general principles involved in structural concrete repair, a detailed case study of a large infrastructure rehabilitation project is presented here. This case study of an existing seawall clearly shows the value of conducting an informed evaluation prior to undertaking the repair design. It demonstrates the necessity of determining the cause of deterioration and selecting a multifaceted repair approach to meet the expressed objective of extending the service life for 30 more years. Utilizing a comprehensive approach in this infrastructure repair project ultimately saved the funding public agencies \$6 million on a \$15 million project.

16.9.1 Background

The 7.5-mile Marina del Rey Seawall was constructed in western Los Angeles, California, during the late 1950s and early 1960s as a means of reclaiming a low-lying swamp area for dry-land uses. Over \$5 billion of infrastructure has developed in and around this area. The original construction was high quality for the time. The vertical flexural reinforcement in the cantilevered wall has been subjected to aggressive saltwater exposure, principally through a construction joint located near the base of the wall (see Figure 16.15). The long-term exposure to seawater has led to chloride-induced corrosion of the reinforcing steel crossing the construction joint and attendant concrete deterioration on the hidden (land) side of the wall. Because of the nonredundant nature of the cantilever wall system, loss of primary vertical reinforcement at the wall base by corrosion results in a loss of overall structural integrity. In February 1986, a failure mechanism (see Figure 16.16) that resulted from severe corrosion of the vertical reinforcement occurred when an isolated 60-ft wall panel collapsed. An engineering investigation into the collapse concluded that the failure was caused by corrosion of the reinforcing steel due to exposure to natural seawater. No other factors were identified as having contributed to the collapse. To address concerns about the integrity of the seawall panels, a restoration program with three distinct focuses was developed by various public agencies:

- Utilize an impressed current cathodic protection system to mitigate active corrosion of the seawall reinforcing steel.
- Utilize a drilled caisson strong-back system to reduce reliance on the vertical reinforcing steel that had been subjected to corrosion and to upgrade the seismic behavior of the system. The strong-back concept was successfully installed during a trial repair in the marina.
- Conduct nondestructive impact-echo testing to locate areas where corrosion damage had occurred. This would allow for categorization of repairs based on the extent of delamination and concerns for life safety in areas of high public exposure. The impact-echo technique had been proven to be successful in locating corrosion-deteriorated areas in the seawall.

Figure 16.17 shows a schematic representation of the multifaceted seawall rehabilitation strategy. Each of the three distinct focuses of the restoration program is represented in this figure.

FIGURE 16.15 Typical reinforcing details of Marina del Rey Seawall. (From the original project drawings, October 1959.)

FIGURE 16.16 Failure of an isolated 60-ft wall panel due to corrosion.

FIGURE 16.17 Schematic representation of proposed rehabilitation strategy for Marina del Rey Seawall.

16.9.2 Repair Strategy

Prior to development of the strong-back concept, several repair strategies were considered. The repair strategies included utilization of rip-rap ballast on the sea side of the wall, installation of precast panels anchored to caissons, and the use of soil tie backs. These preliminary designs were abandoned because they were cost prohibitive or failed to adequately address the seismic upgrading of the wall. As part of the strategic planning, it was decided that the rehabilitation must address the need to prevent additional corrosion damage along the base of the seawall, to upgrade the capacity of the seawall due to the loss of strength caused by the corrosion of the primary vertical reinforcing steel, and to provide seismic resistance that was not originally considered in the seawall design.

16.9.2.1 Full Damage along the Base of the Seawall

On the basis of the results of preliminary impact-echo testing and select concrete coring, significant reinforcing steel corrosion and attendant concrete deterioration were found to be present along the base of the seawall. Corrosion of reinforcing steel along the base of the seawall was determined to be the cause of the isolated seawall panel collapse in 1986. Because of these factors, all repair strategies had to assume that the vertical reinforcing steel at the vulnerable construction joint had lost capacity to carry tension if corrosion deterioration was found to be present; therefore, under a fully repaired condition, the connection between the wall and the footing was assumed to be hinged and only capable of transmitting shear across the joint.

16.9.2.2 Service Life of Repairs

The Marina del Rey Seawall had been in service for over 30 years. This was consistent with the expected design life of concrete structures. Much of this nation's concrete infrastructure is now routinely being rehabilitated because replacement is becoming more and more cost prohibitive. At the time of the evaluation, the seawall concrete was not showing any significant signs of visible deterioration due to abrasion, sulfate attack, or other mechanisms. Previous testing had shown levels of chloride-ion penetration

sufficient to cause chloride-induced corrosion; however, it was strongly believed that an effective rehabilitation strategy implemented in a timely fashion would extend the life of the seawall by another 30 years or more. To ensure a minimum 30-year life extension of the seawall, the repair strategy had to mitigate corrosion of the vertical reinforcing steel and provide a load path for forces originally carried by the deteriorated reinforcing steel. Corrosion engineers had indicated that the impressed current cathodic protection system would fully mitigate the corrosion of the vertical reinforcing steel. In essence, it was indicated that the corrosion would virtually stop and the corrosion rate would be essentially zero. The strong-back repair system had been shown to be effective in carrying loads in a panel with existing deterioration along the wall base. With the implementation of these rehabilitation measures, the service life of the seawall could clearly be extended by 30 years or more.

16.9.2.3 Strategic Ordering of Repairs

Because of life safety concerns and budget constraints, a strategic ordering of repairs was developed. This logical ordering of repairs was developed to ensure that areas of high public access, such as parks, were given high priority in the ordering of repair to address life safety concerns. Because only a portion of the needed funding was in place at the time, the repairs were categorized to address budget constraints. Impact-echo test results were evaluated to locate wall panels with significant deterioration that would be categorized as the highest priority.

16.9.3 Life-Cycle Cost Analysis

Because of the complex interaction of concrete corrosion and repair issues, life safety considerations in the marina area, and the budget constraints of the various municipal and state agencies involved, a life-cycle cost analysis of the marina seawall refurbishment project was requested. The principal objective of this analysis was to consider and prioritize various facets of the seawall refurbishment project so critical decisions could be made with due consideration of the concerns of all agencies and with respect to a logical and strategic ordering of the repairs. Figure 16.18 shows a schematic representation of the interaction of issues that were considered in the Marina del Rey Seawall rehabilitation project.

16.9.3.1 Life Safety Issues

The Marina del Rey area serves as a mixed-use residential and recreational area. Present in the marina are boat yards, restaurants, parks, and residential areas. It was anticipated that the areas of public exposure would be of high priority in the seawall repairs. Use of impact-echo testing in these areas further prioritized the repair sequencing on the basis of the amount of damage detected in panels in public areas. Significant damage detected in areas of high public exposure were naturally categorized as higher priority.

16.9.3.2 Seismic Upgrade

In addition to considering the corrosion-induced deterioration, the engineering design for the Marina del Rey Seawall refurbishment project mandated upgrading the seismic capacity of the seawall. The original design did not consider seismic loading. Development of the seismic retrofit included consideration of the degree of corrosion-induced deterioration as determined by impact-echo testing. This deterioration was modeled as a loss of vertical reinforcing steel capacity at the base of the seawall. As the degree of deterioration increased, additional caissons (strong-backs) were required to upgrade the capacity of the seawall. The wall was upgraded to survive the maximum credible seismic event even though damage would be expected. The proposed strong-back repair strategy minimized the risk of wall collapse during the maximum credible earthquake.

16.9.3.3 Sequence and Ordering of Testing

To provide information on the deterioration level at various locations in the marina, a sequence of impact-echo testing was developed. The sequence and ordering prescribed that a small number of panels should initially be tested in all basins. The preliminary testing provided an initial deterioration assessment for the various structural engineering tasks.

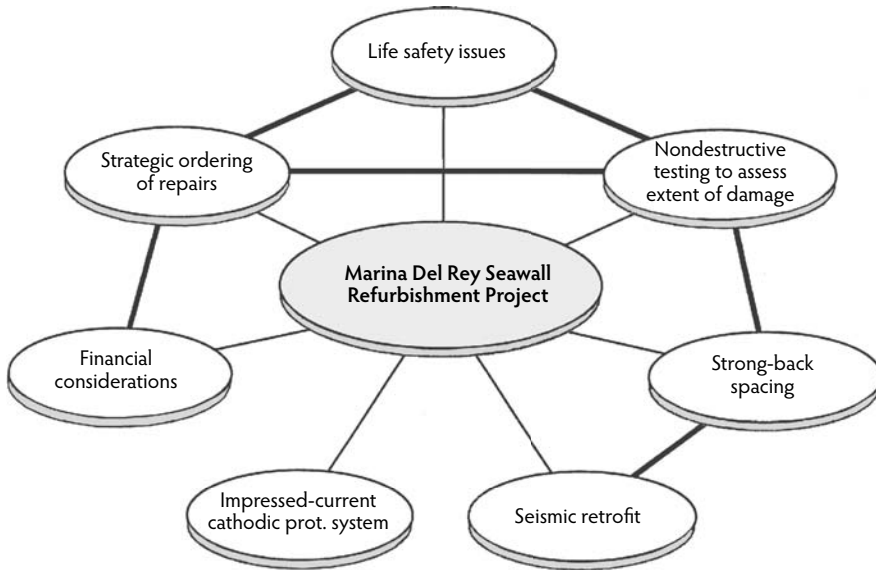

FIGURE 16.18 Interaction of issues being considered in the Marina del Rey Seawall refurbishment project.

16.9.3.4 Deterioration Ratings

Impact-echo testing was used to locate areas where physical manifestations of corrosion damage were present. This information was used to develop deterioration ratings that correlated to the number of caissons required. Both the effects of continuous damage and isolated damage were considered. Using corrosion damage models, ratings were developed to distinguish the number of caissons required at varying levels of deterioration. The models were based on estimated lengths of continuous or intermittent damage along the construction joint. As impact-echo testing results became available, modifications were made to the preliminary damage models. Using the corrosion-damage models previously discussed, caisson spacing parameters were developed. The parameters delineated when additional caissons were required due to the extent of corrosion damage and to minimize the risk of collapse during the maximum credible earthquake.

16.9.3.5 Design Guidelines

The following criteria were agreed upon by the various public agencies involved for developing the life-cycle cost analysis:

- Maximum credible seismic event—0.5-g lateral acceleration
- Surcharge loading—2 ft of soil
- Design life for all rehabilitation measures—30 years

No guidelines were established for a serviceability-level seismic event. In essence, the seismic retrofit strategy was to minimize the risk of collapse during the maximum credible seismic event. Damage to the wall during the maximum credible earthquake would be expected and acceptable. After completion of the life-cycle analysis, the parameters were modified to reflect further refinement and development of the analysis models based on the results obtained from the geotechnical investigation and impact-echo testing.

16.9.4 Impact-Echo to Assess Deterioration

Various studies were conducted as part of the strategic planning of the Marina del Rey Seawall refurbishment project. Numerous nondestructive test methods were reviewed as candidates for assessing deterioration of the seawall due to corrosion-induced delaminations. The majority of nondestructive

testing techniques for assessing reinforcing steel corrosion, such as measurement of half-cell corrosion potentials and chloride-ion content, provide only limited, indirect information about whether or not corrosion is occurring. These testing measures do not provide an assessment of the amount of corrosion damage or the degree of concrete deterioration present.

Stress-wave propagation methods known as *pulse-echo* and *pitch-catch* were reviewed as candidates for detecting damage on the soil side of the wall in the vicinity of the construction joint. These methods had limitations that made them impractical for use on the seawall as constructed. During the project development, the transient stress-wave method known as impact-echo was examined as a possible candidate for nondestructively determining the location of corrosion-induced deterioration. This method was determined to be well suited for finding flaws in concrete. The reader is referred to Section 16.3.3.1 for a description of the impact-echo method.

It is important to note that, although impact-echo is effective for finding flaws in concrete structures, such as the corrosion-induced delaminations on the soil side of the wall near the level of the construction joint at the base of the wall, it cannot assess the amount of deterioration in terms of degree of steel-reinforcement corrosion. In this case, impact-echo was used to locate the manifestation of corrosion—that is, the attendant delamination of the concrete caused by reinforcing steel corrosion—but it was not used to assess the degree of corrosion. This implies that, when using the impact-echo method, if a delamination or defect is found it is assumed that the reinforcing steel at this location is in essence completely corroded. There could have been some measure of steel area that was still effective, but for condition-assessment purposes, the steel was assumed to be ineffective for developing a tension force and thus incapable of carrying moment at the base of the wall. This was a conservative assumption in the context of the rehabilitation design.

16.9.5 Reliability in Assessing Deterioration

16.9.5.1 Previous Trial Studies on the Seawall

It is generally beneficial in larger projects to conduct trial testing and, in some cases, repairs to prove the veracity of the methods. This approach provides confidence for all parties concerned prior to spending large sums of money. In the case of the seawall project, previous studies that assessed the efficiency of using impact-echo to detect corrosion-induced deterioration on the unobservable soil side of the seawall clearly indicated the veracity of the method. Concrete coring at select locations of delaminations located by the impact-echo method demonstrated the reliability of the procedure for detecting damage.

16.9.5.2 Test Locations

A visual examination in a trial study that sliced a piece of the wall clearly showed that the damage caused by corrosion of the vertical reinforcing was in the range of about 10 to 20 cm (4 to 8 in.) above the construction joint. The average of this range was 6 in., which was used to define the height of impact-echo testing in the field-test program. It is also important to note that a trial study indicated that the corrosion appeared isolated to the local region near the construction joint. All seawall panels were tested about 6 in. above the construction joint as part of the field evaluation; however, select panels were tested on a two-way horizontal and vertical grid to confirm that the damage was generally confined to the region near the construction joint. Figure 16.19 presents a schematic representation of the approximate area of influence during impact-echo testing for the geometry of the wall and assumed type of corrosion-induced delamination. Note that the influence area is on the order of 27 in.; thus, testing on 25-in. centers provided for about a 2-in. overlap. Based on generalized stress-wave propagation principles, there was assurance that most delaminations were located and that finding the delaminations was independent of whether the test was conducted directly over a reinforcing bar. The 25-in. spacing used in the evaluation program was determined to be sufficient to detect most of the damage that was present.

FIGURE 16.19 Influence area of impact-echo test on seawall for anticipated corrosion-induced break delamination.

16.9.6 Cathodic Protection

The galvanic corrosion of reinforcing steel in concrete is an electrochemical process in which the reinforcing steel reacts with water and oxygen to form iron-oxide products (rust). For galvanic corrosion to occur, four elements must be present. The elements are anodes (locations where corrosion activity occurs), cathodes (areas that are protected by the corrosion activity at anodes), a metallic path between the anodes and cathodes, and an electrolyte. The metallic path is provided by the horizontal and vertical reinforcing steel mat. Moisture in the soil backfill, seawater, and moist concrete all serve as the electrolyte. The corrosion cell is driven by the differences in electrical potential that exist between the anodic and cathodic areas. Figure 16.20 shows a schematic representation of the electrochemical process of corrosion of reinforcing steel.

Cathodic protection (CP) is an electrochemical technique in which external anodes are added to the electrochemical cell present in the seawall. The addition of external anodes to the seawall structure resulted in the shift of electrical potentials at the reinforcing steel from anodic (actively corroding) to cathodic values (noncorroding). Figure 16.21 shows a schematic representation of both sacrificial anode and impressed current cathodic protection systems. Two types of cathodic protection systems were considered for the Marina del Rey Seawall. A galvanic or sacrificial anode system utilizes metal (typically zinc) anodes attached directly to the reinforcing steel grid. When connected to the reinforcing steel grid, the sacrificial anodes corrode instead of the reinforcing steel. Corrosion of the sacrificial anode results in electrons traveling to the reinforcing steel, which further prevents corrosion of the seawall reinforcing steel. Sacrificial anode systems are best suited to areas of low electrical resistivity or to submerged areas. An impressed current cathodic protection system is similar to a sacrificial anode system, except that an external power supply is used to provide the electrical potential that drives the corrosion cell.

The seawall rehabilitation concept required that the horizontal (temperature and shrinkage) reinforcing steel carry the redistributed moments resulting from the caisson installation. This required protecting both the horizontal and vertical reinforcing steel from long-term corrosion. An impressed current cathodic protection system was determined to be better suited for long-term corrosion control. This was because of the location of the seawall above the mean low water level and the measured soil resistivities. A successful application of an impressed current cathodic protection system must ensure the electrical continuity of all protected areas. Reinforcing steel in both the horizontal and vertical directions was tested to ensure connectivity.

After installation of an impressed current cathodic protection system, the rate of reinforcing steel corrosion is effectively reduced to zero. This has been proven time and again in actual field applications. To mitigate corrosion, cathodic protection must have an electrolyte present. In the seawall, the seawater below the water table and the moist soil acted as the electrolyte. An electrolyte allows the flow of the

FIGURE 16.20 Schematic of electrochemical corrosion of reinforcing steel in concrete.

FIGURE 16.21 Schematic representation of cathodic protection systems.

impressed current from the sacrificial anode to the reinforcing steel in the seawall. In areas where concrete delaminations have occurred due to corrosion, the cathodic protection system will protect the existing reinforcing steel if sufficient electrolyte is present at these locations. The cathodic protection system cannot protect areas where an air gap is present between delaminated concrete and the reinforcing steel; however, this condition was not considered likely to be present to any significant degree.

The Marina del Rey Seawall refurbishment project was designed to provide a minimum 30-year life extension to the seawall. Accordingly, all facets of the rehabilitation strategy were designed for the ultimate serviceability and durability limit state to reflect a minimum 30-year life cycle. After installation of the cathodic protection system, no further reinforcing steel corrosion was expected to occur; thus, the 30-year service life was clearly attainable. The steel was, in essence, kept in its existing condition without further corrosion.

16.9.7 Structural Analysis

This section summarizes the results from various structural analyses that were conducted on a typical 60-ft wall panel. Analyses were conducted to assess the integrity of the existing wall without the strong-back system in place for various postulated damage models. Parametric analyses were then conducted for a typical seawall panel that incorporated different combinations of strong-backs (caissons) for postulated damage models and included the loads resulting from the assumed maximum credible seismic event.

FIGURE 16.22 Representation of the nonlinear model used for analysis of a typical seawall panel.

16.9.7.1 Integrity of the Typical Existing Panel

Analyses were conducted to assess the integrity of a typical 60-ft wall panel in its current condition for various assumed damage models. The threshold damage in terms of the degree of corrosion necessary to cause collapse of a typical wall panel was then established by examining the results of these analyses:

- *Nonlinear analysis model.* To assess the integrity of a typical 60-ft seawall panel, as constructed for various assessed-damage models, a nonlinear analysis of the typical wall section was undertaken. The analytical model used a tangent stiffness formulation. Incremental loads were applied to the structure, then the incremental displacements and forces were calculated and added to the previous displacements and forces to obtain the new displacements and forces. The stiffness method is used to calculate incremental displacements from applied loads, and incremental forces are then computed from the displacements. The model uses a linear formulation that has been modified to include various nonlinear effects. The nonlinearities include second-order deflection effects (P-delta), geometric nonlinearity, and material nonlinearity. Analytically, failure occurs when defined material strength limits are exceeded or by the instability of the structure. Because the seawall was originally designed principally as a cantilever retaining wall, only a typical 1-ft width of wall was required to represent its behavior under lateral load. Figure 16.22 shows a schematic representation of the nonlinear model used for the wall. The reinforcing steel was terminated (cut off) at the appropriate wall height location as indicated in Figure 16.15. The wall taper was also duly accounted for in this analysis. The base of the wall was assumed to be fixed.
- *Loading.* Figure 16.23 summarizes the load conditions for which a typical seawall panel was analyzed under anticipated actual operating service load conditions. Note that these were not

FIGURE 16.23 Estimated operating service wall loads.

design loads—they represented an assessment of the probable operating loads on the wall as might exist on a typical existing wall panel. For purposes of this analysis, no earthquake loading was considered.

- *Effect of reinforcing steel loss.* Analyses were conducted for the typical seawall panel assuming an average net section loss of reinforcing steel at the construction joint due to corrosion. Incremental lateral loads were applied to the wall for various cases of assumed reinforcing steel loss until a failure occurred. The loads due to the surcharge and water table were applied first, then the lateral earth pressure was incrementally applied until failure occurred. The parameters of interest in this type of analysis are the load necessary to cause failure compared to the probable in-service lateral earth pressure (see Figure 16.23) and the expected horizontal deflection at the tip of wall before collapse occurs (see Figure 16.24).

Table 16.4 summarizes the results of the nonlinear analysis of the wall for various postulated scenarios of the degree of corrosion of the vertical steel at the construction joint. The results of the analysis of the wall as constructed (0% loss of the reinforcing steel) indicated that the wall had adequate integrity for the probable existing operating loads if seismic loads were not considered. This suggested that, for wall panels determined to have little or no damage as established by impact-echo testing, some measure of strengthening to upgrade the wall for seismic loading was still needed. The analyses clearly revealed that, as the percentage loss of reinforcing steel due to corrosion increases, the load to cause failure and the associated horizontal wall deflection at the top of the wall at failure decreases. Further, the analysis results indicated that an average of about 60% (actual value, 62%) of the reinforcing steel at the construction joint must be lost to corrosion for failure of the wall to occur under current probable operating-load conditions.

FIGURE 16.24 Horizontal deflection of wall just before failure.

This model assumes that the corrosion damage is uniformly distributed along the wall, which may not be the case. Contiguous damage would be even more detrimental than the uniform damage implicit in this analysis. This suggests that if impact-echo testing revealed that the wall along the construction joint indicated evidence of randomly distributed corrosion-induced delaminations (say, to about the 40% level), then the panel could be approaching collapse conditions and would naturally be of the highest priority in terms of repair sequencing.

The nonlinear analysis results also clearly indicated that there would be very little visual evidence of distress before failure occurred. Table 16.4 indicates that the horizontal deflection at the top of the wall is about 3/4 in. just before failure, assuming no corrosion damage; however, for the case of 62% average loss of reinforcement due to corrosion, the calculated horizontal movement at the top of the wall is only about 3/8 in. just before collapse occurs. This small amount of relative movement between adjacent wall panels over time would likely not be perceptible due to the observed construction tolerances and to wall rotations that may have occurred because of differential soil settlement. This analysis clearly indicated that there would be very little warning before failure.

TABLE 16.4 Summary of Nonlinear Analysis of Typical Wall Panel in Service

Assumed Percent Loss of Steel Reinforcement Due to Corrosion of Construction Joint	Ratio of Failure Load to Probable In-Service Lateral Earth Pressure	Horizontal Deflection at Top of Wall before Collapse (in.)
0	2.8	0.74 \approx 3/4
20	2.4	0.74 \approx 3/4
50	1.5	0.45 \approx 1/2
62	1.0	0.41 \approx 3/8
80	0.5 ^a	0.24 \approx 1/4

^a Indicates section fails at about one half of the present estimated operating service loads.

FIGURE 16.25 Seawall with strong-back retrofit.

FIGURE 16.26 Finite-element model of a typical wall panel for a case with six caissons.

16.9.7.2 Finite-Element Analysis of the Wall With and Without a Strong-Back System

To evaluate the capacity of a typical 60-ft seawall panel for various reinforcing steel corrosion damage models and to assess the effect of strong-back spacing, a parametric study was conducted using linear elastic finite-element analysis techniques.

16.9.7.2.1 Model

A typical 60-ft seawall panel with the proposed strong-back retrofit is shown in Figure 16.25. To evaluate the effects of reinforcing steel corrosion and strong-back spacing on the seawall stem, a finite-element model was developed for the stem using four node isotropic plate elements. A finite-element model with six caissons installed is shown in Figure 16.26. It should be noted that the finite-element model took advantage of geometric symmetry about the centerline of the 60-ft seawall panel. For this analysis, it was assumed that loading, strong-back spacing, and reinforcing steel corrosion damage were symmetrical about the centerline of the seawall. For simplicity, only one half of the seawall was modeled for the parametric study using appropriate boundary conditions at the plane of symmetry. For comparison, a typical horizontal moment dithering for the half-model using symmetry and for a model of the full 60-ft seawall panel is shown in Figure 16.27. Note that the computed moments are identical, indicating the validity of the symmetry model. A 6×6 -in. element grid was used for the model. Element thickness varies to correspond with the taper in the face of the seawall.

FIGURE 16.27 Horizontal moments from the full and symmetric models (ft-lb/ft).

Because the capacity of a typical seawall panel is dependent on the strength of the stem, it was not necessary to model the seawall footing. Instead, boundary elements were used to model the interface between the seawall stem and footing. To model the condition of no loss of reinforcing steel at a particular node, a boundary condition constraining translation and rotation about the three axes was assumed. To model the condition of total loss of reinforcing steel at a particular node, a boundary condition constraining translation, but not rotation, about the three axes was assumed. Also, the interface between the seawall and the strong-back system was modeled using translational boundary elements with an assumed spring constant. For this analysis, explicit modeling of the caisson was not necessary. A tie-back spring constant was assumed to connect the wall to a rigid element (the caisson). A spring constant of 200 kips/in. was assumed. Five tie backs were assumed for each caisson location, spaced 1 ft, 6 in. on-center starting 2 ft from the top of the wall.

FIGURE 16.28 Preliminary design earth-pressure loads.

16.9.7.2.2 Loading

The loads imposed on the stem of the seawall are primarily due to lateral earth pressure. Using Rankine theory, the active lateral earth pressure diagram shown in Figure 16.28 was developed, using the following parameters derived from a comprehensive geotechnical investigation:

- Soil friction angle (ϕ) = 32
- Unit weight of soil (γ) = 125 pcf
- Unit weight of water (γ_w) = 62.4 pcf
- Active pressure coefficient (K_A) = 0.31
- 2-ft soil surcharge load

To determine earthquake loads, a seismic analysis was performed using a procedure by Mononobe and Okabe, as described in the AASHTO Specifications (1992). This procedure, which uses an equivalent static loading, replaces the active soil coefficient (K_A) with a seismic active soil coefficient (K_{AE}). Using a horizontal acceleration of 0.5 g based on a geoseismic study of the area, K_{AE} was calculated to be 0.62. The following design load combinations were calculated in accordance with Appendix C of the ACI Building Code (ACI Committee 318, 2005):

$$U = 1.7H \tag{16.2}$$

$$U = 0.75(1.7H + 1.7(1.1E)) \tag{16.3}$$

where:

- U = required strength to resist factored loads.
- H = earth pressure.
- E = lateral earth pressure due to earthquake loading.

TABLE 16.5 Moment and Shear Capacities of a Typical Undamaged Wall Panel

Inches	Vertical Moment		Horizontal Moment		Shear (lb/ft)
	Negative (ft-lb/ft)	Positive (ft-lb/ft)	Negative (ft-lb/ft)	Positive (ft-lb/ft)	
0	-12,229	6292	-3636	2534	4190
6	-11899	6292	-3531	2534	3230
12	-11569	6292	-3426	2534	3980
18	-7133	6292	-3321	2534	3870
24	-6928	6292	-3216	2534	3760
30	-6723	4058	-3111	2534	3660
36	-6518	4058	-3006	2534	3550
42	-6313	4058	-2901	2534	3440
48	-2442	4058	-2796	2534	3330
54	-2362	1642	-2691	2534	3230
60	-2282	1642	-2586	2534	3120
66	-2202	1642	-2481	2534	3010
72	-2122	1642	-2376	2534	2900
78	-2042	1642	-2271	2534	2800
84	-1962	1642	-2166	2534	2690
90	-1882	1642	-2061	2534	2580
96	-1802	1642	-1956	2534	2470
102	-1722	1642	-1851	2534	2370
108	-1642	1642	-1746	2534	2260

The seismic load combination in Equation 16.3 resulted in forces approximately 60% larger than the load combination in Equation 16.2, which considers only the static lateral earth pressure. Thus, the load combination in Equation 16.3 governed the analysis. The appropriate load combinations were used in conjunction with the lateral earth pressure diagram shown in Figure 16.28 to determine the pressure loads used in the finite-element analysis.

16.9.7.2.3 Wall Capacities

Moment and shear capacities were calculated for the stem of the seawall in accordance with the ACI Building Code and are summarized in Table 16.5. These capacities were calculated using the reinforcing steel details shown on the original plans, and $f' = 4000$ psi and $f_y = 40,000$ psi. Review of the original construction records indicated a concrete strength of 3000 psi as used in the original seawall design. The results of compressive-strength tests conducted during the field investigation indicated an average compressive strength of 4400 psi for the concrete at the time of the evaluation some 35 years later. These test results justified the use of 4000 psi as the *in situ* concrete compressive strength for the repair design.

16.9.7.2.4 Analysis Results

Various combinations of reinforcing steel corrosion damage scenarios and strong-back spacing were analyzed using the finite-element model and load combinations previously discussed. A summary of the cases analyzed is presented in Table 16.6. The results of each analysis case were examined and compared with the moment and shear capacities listed in Table 16.5. Vertical and horizontal shears and moments were examined separately, similar to the ACI analysis procedures used for two-way slab design. Sample outputs of horizontal and vertical moments are shown in Figure 16.29 and Figure 16.30, respectively, for Case 8 (six strong-backs, 100% corrosion of vertical reinforcing steel, and load combination (Equation 16.2)).

Negative horizontal moments that occur at strong-back locations were redistributed, as allowed by Section 8.4 of the ACI Building Code. A maximum redistribution limit of 40% was also examined in lieu of the more restrictive 20% limit imposed by ACI. With the lower reinforcement ratio of the horizontal reinforcing steel, it was believed that the wall would exhibit adequate ductility to allow this larger redistribution limit with the caissons in place. For the final design, a detailed moment-curvature analysis of the wall ductility generally confirmed this assumption.

TABLE 16.6 Summary of Finite-Element Analysis Cases

Case Number	Corrosion of Vertical Steel at Construction Joint (%)	Load Combination	Number of Strong-Backs
1	0	1	None
2	0	2	None
3	0	2	2
4	0	2	3
5	0	2	4
6	100	2	4
7	100	2	5
8	100	2	6
9	100	2	7
10	8 (5 ft at one end)	2	4
11	17 (5 ft between strong-backs)	2	4
12	17 (10 ft at one end)	— ^a	None
13	17 (8 ft at one end)	— ^a	None

^a Anticipated actual operating service-load conditions.

FIGURE 16.29 Horizontal moments for case 8 (ft-lb/ft).

- *Case 1.* The Case 1 analysis examined a typical seawall panel with no corrosion of vertical reinforcing steel, no strong-backs, and no earthquake loading. The average vertical moments were typically slightly below the calculated capacities; however, an 8.5% overstress occurred at the interface with the footing, and a 17% overstress occurred 1 ft, 6 in. above the footing. Considering that a larger value of compressive strength was used for the analysis than was originally specified, the overstress indicated that either the load assumptions or the design procedures used for the analysis were more conservative than those used for the original design. Hand calculations were also done for this case and were used to verify the results of the finite-element analysis.

FIGURE 16.30 Vertical moments for case 8 (ft-lb/ft).

- *Case 2.* The Case 2 analysis examined a typical seawall panel with no corrosion of vertical reinforcing steel and no strong-backs for earthquake loading. The average vertical moments were larger than the wall capacity from the intersection with the footing to a height of 5 ft, 6 in. above the footing. The overstress at the interface of the footing was 71%. The results of this analysis indicated the need for a retrofit to address earthquake loading even if there was no corrosion damage.

Using the strong-back retrofit concept, the next three cases were used to determine the minimum number of strong-backs required for earthquake loading, assuming no corrosion of vertical reinforcing steel:

- *Case 3.* The Case 3 analysis examined a typical seawall panel for earthquake loading assuming no corrosion of vertical reinforcing steel and strong-backs placed 15 ft from each end. By inspection of the horizontal and vertical moments, it was clear that two strong-backs would be ineffective for reducing the vertical movement to an acceptable level.
- *Case 4.* The Case 4 analysis examined a typical seawall panel for earthquake loading assuming no corrosion of vertical reinforcing steel and three strong-backs placed at a spacing of 20 ft. The average vertical moment at the base of the seawall for a middle strip equal to half the distance between strong-backs was 13,840 ft-lb/ft, which was 13% larger than capacity. In addition, considering a 40% moment redistribution, the average positive and negative moments for the top 4.5 ft of the seawall were 2710 ft-lb/ft and -2460 ft-lb/ft, respectively, resulting in overstresses of 7% and 11%. A more detailed analysis of earthquake loading, soil properties, and surcharge loading provided justification for reducing the load level, thus it was determined that three strong-backs would provide the required lateral-load resistance.
- *Case 5.* The Case 5 analysis examined a typical seawall panel for earthquake loading assuming no corrosion of vertical reinforcing steel and four strong-backs placed at a spacing of 15 ft. The average vertical moment at the base of the seawall for a middle strip equal to half the distance between strong-backs was 13,220 ft-lb/ft, which was 8% larger than capacity. However, considering a 35% moment redistribution, the average positive and negative moments for the top 4 ft, 6 in. of the seawall were 2430 ft-lb/ft and -2250 ft-lb/ft, respectively, both less than the average capacities for

these regions. Although the vertical moment at the base is slightly overstressed, the horizontal moment capacity was considered adequate when considering a 35% moment redistribution. Based on analysis of the results for Case 5, the installation of a minimum of four strong-backs at each typical panel would be required for the assumed earthquake loading.

The next four cases were used to determine the maximum number of strong-backs required for earthquake loading assuming 100% corrosion of the vertical reinforcing steel:

- *Case 6.* The Case 6 analysis examined a typical seawall panel for earthquake loading assuming 100% corrosion of the vertical reinforcing steel and four strong-backs placed with a spacing of 15 ft. By inspection of the positive and negative horizontal moments, it was clear that both were significantly overstressed.
- *Case 7.* The Case 7 analysis examined a typical seawall panel for earthquake loading assuming 100% corrosion of the vertical reinforcing steel and five strong-backs placed at a spacing of 12 ft. As with Case 6, inspection of the positive and negative horizontal moments made it clear that both were significantly overstressed.
- *Case 8.* The Case 8 analysis examined a typical seawall panel for earthquake loading assuming 100% corrosion of the vertical reinforcing steel and six strong-backs placed at a spacing of 10 ft. The average positive and negative moments for the top 4 ft, 6 in. of the seawall assuming a 40% redistribution were 3500 ft-lb/ft and -2340 ft-lb/ft, respectively, resulting in overstresses of 38% and 6%. Considering the level of overstress of both the horizontal positive and negative moments, the installation of six strong-backs would not be sufficient to resist the loadings assumed in the preliminary study. Again, it was later determined that six strong-backs was the maximum number required for a given 60-ft seawall panel when more refined soil parameters became available.
- *Case 9.* The Case 9 analysis examined a typical seawall for earthquake loading assuming 100% corrosion of the vertical reinforcing steel and seven strong-backs placed at a spacing of 8 ft, 6 in. The average positive and negative moments for the top 4 ft, 6 in. of the seawall using a 35% redistribution were 2480 ft-lb/ft and -2000 ft-lb/ft, respectively, both less than the average capacities for these regions.

Based on analysis of the results for Case 9, a maximum number of seven strong-backs would be required for the assumed earthquake loading; therefore, it was determined that for the loading conditions each seawall panel required the installation of seven strong-backs, depending on the amount of vertical reinforcing steel corrosion. This requirement was relaxed to three to six caissons on the basis of the results from the soil investigation and refinements in the seismic and surcharge loadings. Case 10 and Case 11 examined the effect of a continuous strip of reinforcing steel corrosion damage on strong-back spacing:

- *Case 10.* The Case 10 analysis examined a typical seawall panel for earthquake loading assuming 5 ft of continuous (8%) corrosion of the vertical reinforcing steel at the end of a panel and four strong-backs placed at a spacing of 15 ft. Based on the analysis of this case, 5 ft of continuous corrosion of the vertical steel at the end of a panel required an additional strong-back.
- *Case 11.* The Case 11 analysis examined a typical seawall panel for earthquake loading assuming 5 ft of continuous (8%) corrosion of the vertical reinforcing steel, centered between two strong-backs, assuming four strong-backs placed at a spacing of 15 ft. The average positive and negative moments for the top 4 ft, 6 in. of the seawall using a 40% redistribution were 3850 ft-lb/ft and -2380 ft-lb/ft, respectively, resulting in overstresses of 52% and 7%. Considering this level of overstress of both the horizontal positive and negative moments, it was determined that 5 ft of continuous damage between strong-backs required a strong-back spacing of less than 15 ft.

The Case 12 and Case 13 analyses examined a typical seawall panel with no strong-backs using the anticipated actual operating service load conditions to determine the amount of continuous vertical

reinforcing steel damage at one end that would lead to a failure (“unzipping”) of the panel. In this case, failure would occur by progressive yielding of the noncorroded vertical reinforcing adjacent to the damaged area that continued to the opposite end of the panel.

- *Case 12.* The Case 12 analysis examined 10 ft of continuous damage from one end. On the basis of the results of this analysis, it was determined that continuous damage of 10 ft or more was sufficient to cause a progressive failure of the seawall panel.
- *Case 13.* The Case 13 analysis used the same assumption as Case 12, except that continuous damage of 8 ft from one end was examined. On the basis of the results of this analysis, it was determined that continuous damage of less than 8 ft would not cause a progressive failure of the seawall panel.

16.9.8 Life Safety Implications

To address life safety concerns, a multifaceted restoration program was developed by various local and state agencies. The plan utilized an impressed current cathodic protection system to mitigate active corrosion of the reinforcing steel. A strong-back system was developed to upgrade the seismic behavior of the seawall and the integrity lost by corrosion of the reinforcing steel. A minimum of three caissons was determined to be necessary to upgrade the seismic capacity of the seawall to satisfy current building-code requirements. The number of additional caissons was directly proportional to the extent of corrosion damage along the base of the seawall. For the case of full damage along the seawall (worst-case scenario), analysis indicated that six caissons were required to provide satisfactory capacity. To determine the extent of the corrosion damage along the base of the seawall, a program of nondestructive impact-echo testing was conducted. Because of budget constraints of the various municipal and state agencies involved, guidelines for prioritization of the repairs were needed. These guidelines helped to ensure that life safety considerations were of paramount importance with respect to the prioritization of repairs.

The budget constraints of the municipal and state agencies involved in the Marina del Rey Seawall restoration program required a prioritization of repairs based on two criteria: (1) the extent of damage along the base of the seawall panel, and (2) the degree of public exposure of an individual seawall panel. To simplify the categorization of public exposure, use of two categories was proposed. A public exposure categorized as high was limited to areas where a seawall panel collapse would result in a high probability of personal injury. All other areas were categorized as low exposures.

Analysis indicated that a 60% loss of reinforcing steel might result in the collapse of the seawall panel at its actual operating service load levels. This was based on the assumption of uniformly distributed corrosion damage across the base of the seawall. Analysis also indicated that contiguous damage from the end of a seawall panel was more severe in nature than uniform damage. For the purposes of categorizing the extent of damage, the adoption of a dual-criteria classification was proposed. The classification assigned the panels to one of three categories, as described in Table 16.7. Wall panels were placed into the appropriate damage category if either criteria in Table 16.7 was satisfied. The use of 40% of total wall damage was recommended as the maximum allowable to provide some additional measure of conservatism. During the impact-echo testing, panels classified in the high-damage category were immediately brought to the attention of the public agencies involved.

Due to the financial considerations, a phased construction schedule was proposed. To minimize public exposure to the potential collapse of a seawall panel, repairs in areas of high public exposure with high priority and intermediate damage levels were classified as the highest priority. Other areas were categorized into two additional groups based on public exposure and degree of deterioration. Table 16.8 specifies the repair prioritization groupings that were made.

16.9.9 Cost Savings

Structural analysis of the Marina del Rey Seawall indicated that the number of caissons required to upgrade the capacity of the seawall for seismic loads was directly related to the amount of corrosion

TABLE 16.7 Prioritization Based on Degree of Wall-Panel Damage

Percent of Total Wall Damage	Number of Feet of Continuous Damage	Corrosion Damage Category
>40	>8	High
20–40	4–8	Intermediate
<20	<4	Little or no damage (seismic upgrade required)

TABLE 16.8 Repair Priority

Damage Category	Public Exposure	
	High	Low
High	Highest priority	High priority
Intermediate	Highest priority	High priority
Little or no damage (seismic upgrade required)	Priority	Priority

TABLE 16.9 Caisson Requirements Based on Degree of Damage

Degree of Damage	Number of Caissons Required
High	6
Intermediate–high	5
Intermediate–low	4
Little or no damage (seismic upgrade only)	3

TABLE 16.10 Cost Savings Resulting from Impact-Echo Testing

Caissons required, assuming 100% damage	3971
Caissons required utilizing impact-echo testing results	2473
Caissons saved as a result of impact-echo testing	1498
Estimated construction cost per caisson	\$3900
Construction savings resulting from impact-echo testing	\$5,842,000

damage present at the construction joint. This indicated that a categorization of seawall panels into logical groupings, based upon the extent of damage detected by impact-echo, could provide a significant cost savings during the construction phase of the project.

Based on the extent of damage detected during impact-echo testing, the seawall panels were placed into three categories: high damage level, intermediate damage level, and little or no damage present (only seismic upgrade required). The number of caissons required for panels in the high-damage and little-to-no-damage categories was fairly well established. In the intermediate-damage category, a further breakdown of the category was possible. The division of the intermediate-damage category into two groups resulted in four families of repairs, categorized in terms of the number of caissons required to provide the upgraded seismic capacity and to address the loss of strength due to corrosion. The categories, or families, of repair are summarized in Table 16.9. Panels at the intermediate-damage level were placed into separate categories based on the results of impact-echo testing and further structural analysis that examined the effects of localized corrosion damage and distribution of damage on the repaired system. After completion of the seawall testing and extensive structural analysis, a construction cost savings estimate was made. This estimate is shown in Table 16.10. The cost savings were based on comparing the number of caissons required to strengthen the walls, assuming 100% corrosion damage, to the number of caissons used in the repair scheme. A savings of \$5.8 million was realized by conducting impact-echo testing. On an economic basis, the merits of using nondestructive testing in this infrastructure repair project are clearly seen.

16.9.10 Conclusions

The Marina del Rey Seawall had been in service as a mixed-use residential and recreational area for over 30 years, and \$5 billion of infrastructure had been built around the area. To ensure its continuing service for at least another 30 years or more, an extensive restoration program was developed to mitigate the ongoing corrosion of the seawall reinforcing steel, to upgrade the seismic capacity of the seawall, and to restore the integrity of seawall panels that had been lost due to corrosion. The following are the more salient conclusions from the presentation of this case study:

- Analysis of the seawall indicated that, with increasing levels of reinforcing steel corrosion, the ductility of the wall decreased. At an assumed 60% loss of reinforcing steel due to corrosion at the seawall base, a failure was possible at the operating service load levels on the seawall. The horizontal deflection of the top of the wall prior to failure was determined to be approximately 3/8 in. for the case of 60% reinforcing steel loss. This would provide little warning of pending failure.
- The finite-element analysis clearly indicated the need for strong-back installation to seismically upgrade the seawall panels; however, the number of caissons required beyond the number necessary for seismic resistance increased as the amount of corrosion damage increased. Between three and six caissons were required to provide adequate lateral load resistance depending on the degree of corrosion damage detected.
- Threshold criteria were established to prioritize the repairs. The categorization was based primarily on life safety concerns in areas of high public exposure. Seawall panels that were determined to have a high degree of deterioration and that were located in areas of high public exposure were classified as the highest priority.
- On the basis of the cost estimate for caisson installation and the estimated number of panels that required only seismic-capacity upgrades, a substantial cost savings was realized with the performance of nondestructive impact-echo testing. Some \$5.8 million was saved by conducting this testing.

17.1 Introduction

Restrained volumetric changes result in strains and ensuing stresses that lead to cracking. For a concrete system to be viable long term, it is essential to reduce the magnitude and extent of cracking by imposing artificial crack locations through the use of joints that relieve the stress levels and sometimes reduce them to a negligible magnitude. In essence, such joints can be viewed as artificial cracks. This chapter utilizes American Concrete Institute (ACI) committee reports and standards on this subject as a background, particularly ACI 224.3R, *Joints in Concrete Construction* (ACI Committee 224, 1995), and ACI 350, *Environmental Engineering Concrete Structures* (ACI Committee 350, 2006). Informational discussions on this subject are also utilized from the references provided at the end of the chapter.

It is important to note that the type of joint utilized depends on the function it must serve. As a general classification, the following are the types of joints commonly used today:

- *Construction joints*
- *Contraction joints* (secondary movement joints)
- *Expansion joints* (principal movement joints; sometimes referred to as *isolation joints*)

Drying shrinkage, carbonation, irreversible creep, fluctuating ambient temperature changes, and externally imposed loads are all factors that induce tensile stress conditions exceeding the modulus of rupture

* Distinguished Professor, Civil Engineering, Rutgers University, The State University of New Jersey, Piscataway, New Jersey, and ACI honorary member; expert in concrete structures, materials, and forensic engineering.

of concrete, resulting in cracking. An example of the magnitude of strains developed by direct elastic strains from external loads and the resulting volumetric changes for a normal concrete specimen subjected to 900-psi (6.2-MPa) compression is presented below (Nawy, 2008):

$$\text{Immediate elastic strain:} \quad \epsilon_e = 250 \times 10^{-6} \text{ in./in.}$$

$$\text{Shrinkage strain after one year:} \quad \epsilon_{sh} = 500 \times 10^{-6} \text{ in./in.}$$

$$\text{Creep strain after one year:} \quad \epsilon_{cr} = 750 \times 10^{-6} \text{ in./in.}$$

$$\text{Total strain:} \quad \epsilon_T = 1500 \times 10^{-6} \text{ in./in.}$$

If the element is 12 ft (3.65 m) long, the resulting dimensional change is $1500 \times 10^{-6} (12 \times 12) = 0.22$ in. A rise in temperature of 65°F results in an additional change of $65(5.5 \times 10^{-6} \text{ in./in.})(12 \times 12) = 0.05$ in. to give a total dimensional change of $0.22 + 0.05 = 0.27$ in. If the element is restrained as part of a monolithic concrete structure, as is usually the case, this element will be subjected to a significant tensile force that will cause extensive cracking or even failure. Some of these cracks can be prevented from opening by providing continuous horizontal and vertical reinforcement in the structure that would resist the tensile forces in the orthogonal directions.

Cracking resulting from these unavoidable strain gradients has always been a significant factor that the designer must consider in any structural design; hence, the use of joints is inevitable. It would be rare to find a structural system of reasonable size that is constructed without the use of construction joints, contraction (control) joints, expansion (isolation) joints, and shrinkage strips—separately or in combination (Fintel, 1974). If, apart from construction joints, other types of joints are to serve as stress relievers, it can be assumed that if enough reinforcement is provided in the direction of the induced forces to prevent the cracks from opening, then no joint would be needed; however, it would be economically prohibitive to do so as the volume of reinforcement required to perform this task would be significant.

Because the induced forces are highly indeterminate, engineering judgment has to be exercised in interpreting the imprecise guidelines in codes and the literature which often render conflicting solutions. This chapter attempts to synthesize in a compact manner the generally accepted industry approaches for the design of joints in concrete.

17.2 Construction Joints

For many structures, construction joints are required to accommodate the construction sequence for placement of concrete. The amount of concrete that can practically be placed in any operation is a function of the batching and mixing capacity and the time available for placing the concrete in the particular segment that is placed. The construction joint is the separating plane between the old (parent) concrete and the new concrete batch. As a result, the spacing of the construction joints must not interfere with flexural and shear continuity through the interface between the parent concrete and the concrete that is placed thereafter. To achieve this continuity, the hardened concrete must be clean and free of laitance if even a few hours elapse between successive placements. The ACI 318 Building Code stipulates that existing concrete should be moistened thoroughly before placement of the fresh concrete so the parent and the new concrete can achieve full monolithic behavior (ACI Committee 224, 1995; ACI Committee 318, 2008). Because the spacing of the construction joints is determined by the volume of the batch, it is often advisable in large area walls to have the construction joint coincide with the contraction (movement) joint. A spacing of 20 to 30 ft (6.1 to 9.1 m) for contraction joints in reinforced concrete continuous walls is often chosen. It is thus logical to use the contraction joint as a construction joint, with a spacing of 20 to 30 ft, depending on the number of openings in the wall. Figure 17.1 shows two types of construction joints: a butt joint in structural slabs and a tongue-and-groove joint with the option of a water stop for use in a liquid-retaining structure.

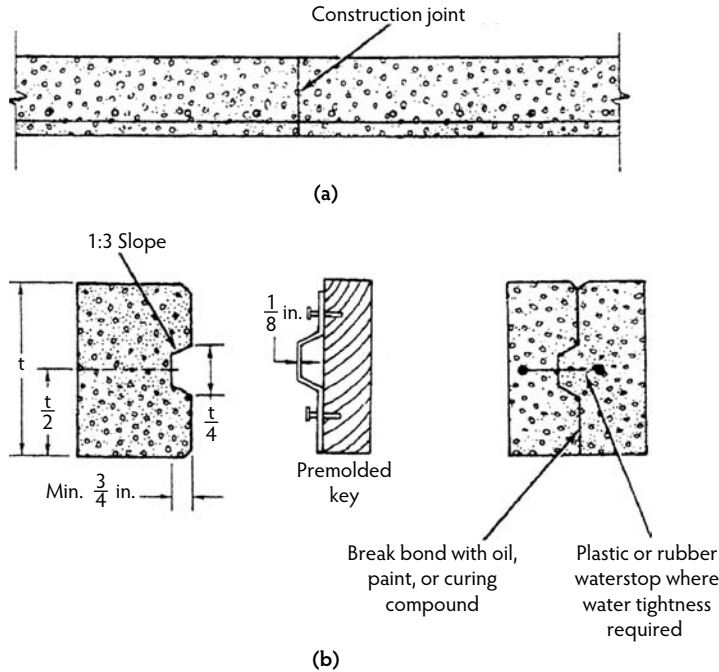

FIGURE 17.1 Typical construction joint assembly: (a) butt joint, (b) tongue-and-groove joint.

17.3 Contraction Joints

Tensile stresses result from drying shrinkage and ambient temperature drops in restrained concrete elements that are prevented from contracting. These tensile stresses resulting from the incipient volumetric change can be reduced to tolerable levels through the use of contraction joints, sometimes referred to as *control joints*. Typically, four methods are commonly used to create contraction joints in concrete surfaces: forming, tooling, sawing, and placement of joint formers (ACI Committee 224, 1995). To form a plane of weakness at the designed spacing, the joints are imposed during concrete placement by tacking rubber, plastic, wooden, or metal strips or caps to the inner faces of the forms to create notches, such as those shown in Figure 17.2.

17.3.1 Formed Contraction Joints

Joint formers can be used to create contraction joints as well as expansion (isolation) joints. Expansion joints usually have removable caps over the expansion joint material. After the concrete hardens, the cap is removed and the void space is caulked and sealed. Joint formers can be either rigid or flexible. Contraction joints are not meant to be isolation joints but are merely made by forming a weakened plane in the concrete with a rigid plastic strip. These strips are essentially T-shaped elements that are inserted to a proper depth into the freshly placed concrete, usually with a bar cutter. The cap must be pulled out prior to bullfloating or troweling the concrete surface. When such joints are formed at construction joint locations in concrete slabs and walls, they serve both as construction and contraction control joints. Tongue-and-groove joints can be made with preformed metal or plastic strips or built to job requirements. The strips have to be securely fastened so they cannot be dislodged during the process of concrete placement and consolidation. Prefabricated circular forms can be used as column isolation joints; these one-piece elements are left in place.

FIGURE 17.2 Contraction joint types. (From ACI Committee 224, *Joints in Concrete Construction*, ACI 224.3R-95, American Concrete Institute, Farmington Hills, MI, 1995, pp. 1-44; ACI Committee 302, *Guide for Concrete Floor and Slab Construction*, ACI 302.1R-89, American Concrete Institute, Farmington Hills, MI, 1989.)

TABLE 17.1 Contraction Joint Spacings

Author	Spacing
Merrill (1943)	20 ft (6 m) for walls with frequent openings 25 ft (7.5 m) for solid walls
Fintel (1974)	15–20 ft (4.5–6 m) for walls and slabs on grade; recommends joint placement at abrupt changes in plan and at changes in building height to account for potential stress concentrations
Wood (1981)	20–30 ft (6 to 9 m) for walls
PCA (1982)	20–25 ft (6 to 7.5 m) for walls depending on number of openings
ACI 302.1R (1989)	15–20 ft (4.5–6 m) recommended until 302.1R-89, then changed to 24 to 36 times slab thickness
ACI 350R (1983)	30 ft (9 m) in sanitary structures
ACI 350 (2006)	Joint spacing varies with amount and grade of shrinkage and temperature reinforcement
ACI 224R (1992)	One to three times the height of the wall in solid walls

17.3.2 Tooled Joints

These contraction joints are tooled into the concrete surface during the finishing operations. A groove is formed to cause a weakened plane, which controls the location of the developing crack. Grooving tools with blades 1-1/2 to 2 in. (40 to 50 mm) in depth are used. The groove should be at least the thickness of the concrete. Cracks may develop within such a groove, although they also can occur at adjacent locations. At a tooled contraction joint, reinforcement in the concrete element should be reduced to *at least* 50% of the designed steel reinforcement or discontinued altogether (ACI Committee 350, 2006). As the distance between tooled joints increases, the volume of steel reinforcement not crossing the joint should be increased to control the tensile stresses that are developed. Often, tooled joints are of insufficient depth to function properly.

17.3.3 Sawed Joints

Sawed joints can reduce the intensity of labor required during the finishing process, but the necessary work and power equipment has to be available within a short period of time after the concrete hardens—namely, as soon as practicable. The most favorable time is when the generated heat of hydration renders the concrete temperature at its peak, but the concrete has to be hardened enough that the surface is not damaged during the cutting operation. As with tooled joints, saw-cut grooves should be made at least 1/4 the depth of the member. Various types of sawing equipment and techniques are available, including diamond-studded blades and abrasive blades. If abrasive blades are used, it is important to set a limit on the magnitude of wear that is acceptable for blade replacement. A drawback to the use of sawed joints is the large equipment clearance required; for example, it is difficult to place the saw at a slab edge where it abuts a wall. Based on industry experience a contraction joint spacing not to exceed 25 ft (7.5 m) is advisable; however, guidelines on joint spacing are diverse and conflicting. Table 17.1 summarizes various recommendations for contraction joint spacing. The focus should be on what spacing will result in an as narrow and aesthetically acceptable crack width and appearance as possible.

17.3.4 Contraction Joint Effectiveness

The effectiveness of a contraction joint is governed by whether any reinforcement passes through it. ACI 318 and ACI 350 consider a contraction joint to be fully effective when no reinforcing bars traverse the joint. For a partially effective contraction joint, a maximum 50% of the design reinforcement is allowed. Any reinforcement exceeding this limit would render the joint useless in controlling the volumetric change cracking in the structural system. It is therefore essential to provide a complete break in the reinforcement

TABLE 17.2 Expansion Joint Spacings

Author	Spacings
Lewerenz (1907)	75 ft (23 m) for walls
Hunter (1953)	80 ft (25 m) for walls and insulated roofs 30–40 ft (9–12 m) for uninsulated walls
Billig (1960)	100 ft (30 m) maximum building length without joints; recommends joint placement at abrupt changes in plan and at changes in building heights to account for potential stress concentrations
Wood (1981)	100–120 ft (30–35 m) for walls
Indian Standards Institution (1964)	148 ft (45 m) maximum building length between joints
PCA (1982)	200 ft (60 m) maximum building length without expansion joint
Kaminetsky (2001)	100 ft (30 m) maximum in environmental structures (see also Table 17.5)

at the joint. It is recommended that bars should be stopped at 1-1/2 to 2 in. (3-1/2 to 5 cm) away from the joint at both sides of the joint line. A bond breaker should be placed between successive placements at contraction and construction joints, similar to expansion joints, and should pass through the entire structure in one plane. If the joints are not aligned, movement at a joint could induce cracking in an unjoined portion of the structure until the crack intercepts another joint (ACI Committee 224, 1995).

17.4 Expansion Joints

17.4.1 Structural Response

Expansion joints are effective isolation joints that divide a structure, including its foundation, into separate isolated units. This becomes necessary in large structural systems where continuity restraint induces significant stresses and large forces due to temperature changes, including ambient temperature variations, during a 24-hour period. The resulting cracking becomes considerably magnified at the lower segment of a wall if it is highly restrained by monolithic attachment to the stiff foundation slab, particularly in liquid-retaining structures. Such structures usually have high walls and stiff thick foundation slabs and cannot tolerate seepage caused by wide cracks that can be avoided. Expansion joints serve to isolate segments that are affected by large dimensional changes due to expansion, contraction, and differential settlement and also prevent cracking when walls change in direction. As an example, the contraction or elongation of a 190-ft (58-m) long wall in an environmental structure subjected to an ambient temperature change of 60°F (34°C) using a concrete coefficient of expansion of $5.5 \times 10^{-6}/^{\circ}\text{F}$ ($9.9 \times 10^{-6}/^{\circ}\text{C}$) would undergo a dimensional change equal to $5.5 \times 10^{-6} \times 60(190 \times 12) = 0.75$ in. (19 mm). Because the wall is monolithically cast with the stiff foundation slab, the lower wall segment will develop severe vertical cracking, as the upper segments are less restrained and can move relatively more freely. To avoid such long-term failure, expansion joints are vital. The joint width should be sufficient to prevent portions of the structure on either side of the joint from coming in contact.

17.4.2 Expansion Joint Width

The width of expansion joints can vary between 1 and 6 inches (25 and 150 mm), with 2 in. (50 mm) being typical. Such joints also serve an additional function as construction joints. As discussed in the case of contraction joints, no definitive standards are available that address the necessary spacing of expansion joints. A rule-of-thumb approach and good engineering judgment should be relied upon when specifying joint widths. Table 17.2 provides general guidelines for recommended spacings in various systems under different conditions.

FIGURE 17.3 Example of a dowel bar assembly. (From ACI Committee 224, *Joints in Concrete Construction*, ACI 224.3R-95, American Concrete Institute, Farmington Hills, MI, 1995, pp. 1–44.)

FIGURE 17.4 Isolation joint between a supported floor and a wall. (From ACI Committee 224, *Joints in Concrete Construction*, ACI 224.3R-95, American Concrete Institute, Farmington Hills, MI, 1995, pp. 1–44; PCA, *Building Movements and Joints*, Portland Cement Association, Skokie, IL, 1982.)

17.4.3 Expansion Joint Details

It is important to stress that the joint should extend through the entire height of the structure and through its foundation slab. Column footings should preferably not be placed at a joint. As in the case of construction joints, no reinforcement bars should pass through the joint but should terminate 2 in. (50 mm) from both faces of the joint. Dowels with breakers can be used to maintain plane (Fintel, 1974). The expansion joint can be covered, filled with a mastic filler, or left open. In the case of liquid-retaining structures, appropriate water stops have to be well designed, detailed, and properly installed to ensure complete liquid-tightness throughout the life of the structure. The water stops should also be suitable for minor foundation adjustments. Figure 17.3 shows a dowel assembly for an expansion joint, and Figure 17.4 illustrates an isolation joint between a supported slab and a wall.

17.4.4 Expansion Joints in Environmental Concrete Structures and Minimum Reinforcement Requirements

17.4.4.1 Expansion Joint Spacing

As previously discussed, expansion joints are isolation joints that divide a long structure into two segments joined by a resilient water stop and sealants. The water stop is designed to allow for anticipated movements in the structure. ACI 350R (ACI Committee 350, 2006) stipulates that “in general, expansion joint spacing preferably should not be greater than 120 ft (36 m)”;

however, engineering practice over the decades and effluent leakage failures have revealed that this spacing limit is too excessive. A modification of the ACI

TABLE 17.3 Recommended Joint Width and Spacing

Temperature Range	Spacing Between Expansion Joints			
	12 m (40 ft) cm (in.)	18 m (60 ft) cm (in.)	24 m (80 ft) cm (in.)	30 m (100 ft) cm (in.)
Underground, 4.44°C (40°F)	1.27 (1/2)	1.50 (3/4)	2.22 (7/8)	2.54 (1)
Partly protected, above ground, 26.7°C (80°F)	1.90 (3/4)	2.22 (7/8)	2.54 (1)	— ^a
Unprotected, exposed roof slabs, 48.9°C (120°F)	2.22 (7/8)	2.54 (1)	— ^a	— ^a

^a Not recommended

350 standard given in Table 17.3 recommends joint spacings and widths, with a maximum spacing of 100 ft (30 m); otherwise, wide liquid-leaking cracks could develop that would render the structure ineffective for retaining treated effluent. Even so, current engineering practice, given the reinforcement percentage values set in ACI 350, often specifies an expansion joint spacing not to exceed 80 ft (24 m). It should be emphasized that the actual width of the joint should be at least *twice* the expected movement.

17.4.4.2 Reinforcement

Prevention of liquid leakage is a major factor to be considered when designing liquid-retaining structures such as water tanks and towers, water-treatment facilities, aeration tanks, and biofords, among others. Such structures are designed for both strength and long-term serviceability. Service stress levels in the concrete and the steel reinforcement are kept low—for example, 20,000 psi (138 MPa) in the reinforcement. The volumetric change reinforcement percentage to be used in such structures has to be higher than in non-liquid-retaining structures. The shrinkage and temperature reinforcement in such specialized structures stipulated by ACI 350 is shown in Figure 17.5 and tabulated in Table 17.4, based on provision of full contraction joints in the walls and the slab foundation. If partial contraction joints as described in Section 17.3 are used, a maximum 50% of wall reinforcement is permitted to cross the contraction joint (ACI Committee 350, 2006). The spacing of these joints is permitted to be up to 30 ft by ACI 350; yet, it is preferable not to exceed 20- to 25-ft spacing to reduce the width and extent of volumetric change cracking. Although the maximum percentage in Figure 17.5 and Table 17.4 is given as 0.5% for 40-ft movement joints, the high rigidity of the foundation slab at the wall joint renders this percentage inadequate. The relative lower flexibility of the wall as compared to the stiff foundation slab at the lower wall segment renders the joint totally rigid with a low magnitude of rotation at the joint, because the wall is almost fixed at the base and free at the top. As a result, vertical cracking, and wide cracks develop, and the liquid-retaining structure becomes heavily permeable. To prevent vertical cracking at the lower quarter segment of the wall, more than 0.5% reinforcement would be needed for walls with expansion joints spaced in excess of 40 to 50 ft. It is the opinion of the author that a percentage ratio in the range of 1.0 to 1.25% for horizontal reinforcement at the lower 15 to 20% of the wall height is necessary to prevent the often excessive cracking at lower segments of a wall. This need arises because the flexible wall element is rigidly held by its monolithically supporting rigid foundation, so as to eliminate the consequent leakage of the retained liquid and its environmentally hazardous effects.

17.4.4.3 Expansion Joint Stops and Fillers

Liquid-tightness is vitally necessary in environmental structures to maintain their long-term integrity. A joint sealant at the liquid face and a suitable water stop made of high-quality rubber or plastic is necessary. As described in ACI 224 (ACI Committee 224, 1995), liquid stops and sealants can be chosen from a variety of alternatives. Rubber water stops allow more joint movement than polyvinylchloride (PVC) water stops. Either type should be at least 9 in. (225 mm) wide to provide adequate concrete embedment, and they should be 3/8 to 1/2 in. (9 to 12 mm) thick. To allow movement at the joint, a preformed joint filler should ideally be able to compress to half of its original width and be able to re-expand to fill the

FIGURE 17.5 Shrinkage and temperature reinforcement for environmental engineering concrete structures. (From ACI Committee 224, *Joints in Concrete Construction*, ACI 224.3R-95, American Concrete Institute, Farmington Hills, MI, 1995, pp. 1–44; ACI Committee 350, *Code Requirements for Environmental Engineering Concrete Structures and Commentary*, ACI 350, American Concrete Institute, Farmington Hills, MI, 2006.)

TABLE 17.4 Minimum Shrinkage and Temperature Reinforcement

joint as the joint enlarges. According to ASTM Standards D 994, D 1751, and D 1752, cork, rubber, foam, and other products conforming to these standards should perform satisfactorily in permitting such levels of movement. Figure 17.6 presents optimal expansion joint water stop detail and illustrates a typical expansion joint for a non-liquid-retaining structure.

17.4.5 Seismic Joints

Seismic joints are wide expansion joints intended to separate portions of buildings that are dissimilar in mass and stiffness. They are designed to allow adjacent units to respond to a seismic wave without the structural units banging against each other. The width of the joint should be equal to the sum of the total displacement at the particular affected level from the base of the two adjacent units, but no less

FIGURE 17.6 Expansion joint details: (a) liquid-retaining structures, (b) non-liquid-retaining structures. (From ACI Committee 224, *Joints in Concrete Construction*, ACI 224.3R-95, American Concrete Institute, Farmington Hills, MI, 1995, pp. 1–44; ACI Committee 302, *Guide for Concrete Floor and Slab Construction*, ACI 302.1R-89, American Concrete Institute, Farmington Hills, MI, 1989.)

than 1 in. for the first 20 ft of height and 1/2 in. for each additional 10 ft of height. The details of the joint should permit a doubling of the joint opening as a minimum when subjected to the seismic wave (Fintel, 1974). Because a seismic joint as a separation joint is normally wider than 2 in. (50 mm), it has to be adequately and aesthetically covered. Figure 17.7 provides suggested configurations for the plate closure at the floor and at the wall–slab separation.

17.5 Joints in Slabs on Grade and Pavements

17.5.1 Slabs on Grade

Slab movements are the result of four actions: volumetric change due to drying or shrinkage, temperature changes, stresses due to applied stationary or moving loads, and slab settlement. When movement is restrained, the slab will have to crack when the tensile stress in the concrete exceeds its modulus of rupture. The ensuing cracks may appear at any time and at any location; hence, joints become necessary to ensure that cracks form at the imposed, prescribed locations. A slab on grade with the minimum initial construction cost is unreinforced and with closely spaced joints, but unreinforced concrete may not be economical over the long term and would often require a larger thickness of the slab. Yet, joint construction and maintenance usually increase costs and must be considered in the design of joint spacing. It is always important to consider the relationship between initial construction costs and recurring costs, including slab reinforcement, use of shrinkage-compensating cement in the concrete, post-tensioning, and special-use considerations of the finished slab, such as flat slabs (ACI Committee 224, 1995). Typical placement of joints in slabs on grade in a typical structure with columns is shown in Figure 17.8 and discussed in the following sections.

17.5.1.1 Contraction Joints

Contraction joints should be provided in slabs on grade to accommodate shrinkage and temperature expansion and contraction, as well as to relieve the resulting internal stresses. As discussed in ACI Committee 224 (1995), a concrete slab on grade does not dry uniformly throughout its depth because

FIGURE 17.7 Seismic separation joints in concrete structures: (a) isolated floor plate closure, (b) building separation floor plate closure at the structure wall. (Adapted from Fintel, M., Ed., *Handbook of Concrete Engineering*, Van Nostrand Reinhold, New York, 1974, pp. 94–110.)

the temperature gradient is different at the slab top and bottom surfaces. The top surface of the slab dries faster than the lower surface, resulting in warping of the slab and intense curling at corners and at some joint boundaries. Use of dowelled joints, proper distribution and an adequate percentage of reinforcement, or thickening of the slab edges can reduce the level of deformation and possibly eliminate cracking in the slab on grade. Additionally, it is advisable to provide contraction joints at locations of change in subgrade slab support to reduce the possibility of cracking in those transition areas, in addition to providing contraction joints at column lines. It is recommended that joints be spaced in such a manner that the slab on grade is divided into small rectangular areas, preferably squares, but the recommended ratio of the long to short side should not exceed a value of 1.25 to 1.5. As a general guideline, the spacing of contraction joints in slabs on grade should be 24 to 36 times the slab thickness in both directions

FIGURE 17.8 Location of types of joints in slabs on grade. (From ACI Committee 224, *Joints in Concrete Construction*, ACI 224.3R-95, American Concrete Institute, Farmington Hills, MI, 1995, pp. 1–44; ACI Committee 350, *Code Requirements for Environmental Engineering Concrete Structures and Commentary*, ACI 350, American Concrete Institute, Farmington Hills, MI, 2006.)

unless intermediate cracks are acceptable (ACI Committee 302, 1989). A greater spacing is permitted for low-slump concrete with aggregate size larger than 3/4 in. (20 mm).

Several types of contraction joints can be used, such as sawed joints, hand-tooled or preformed joints, keyed joints, or dowelled joints. Figure 17.2 illustrates these types of joints. Sawed joints are the most common method of making contraction joints in slabs on grade by saw-cutting the hardened concrete. Hand-tooled joints are produced by hand-tooling or by inserting plastic strips before finishing. If floor slabs are so thick that insertion of preformed strips or hand tooling becomes cumbersome, premolded inserts can be placed at the bottom of the slab. Sometimes it is preferable to use keyed joints to ensure full load transfer. In such cases, a full-depth premolded joint can be inserted in the slab on grade. This process is required in cases where movement between sections of the slab exceeds the level of movement chosen for adequate load transfer through aggregate interlock. Load transfer in keyed joints can also be accomplished through the insertion of full-depth preformed keys at the time of concrete placement so the slab will have a tongue-and-groove joint when the concrete is cast on both sides of the joint. The keyway can be formed through the use of beveled wood strips with premolded keys or the use of metal forms. Keyed contraction joints should not be used for slabs on grade less than 6 in. (150 mm) thick (ACI Committee 224, 1995).

Dowelled joints are used in heavily loaded slabs on grade with a high percentage of reinforcement for adequate load resistance and crack control requirement. Load transfer at the contraction joint is accomplished through the use of steel dowels, such as the dowel assembly shown in Figure 17.3. The dowels have to be centered at the joint and must not bond to the concrete on at least one side to enable horizontal movement. Greasing the dowels or coating them with a bond-breaker plastic will prevent them from bonding with the concrete. Table 17.5 gives recommended dowel spacing.

17.5.1.2 Expansion Joints

Expansion joints are isolation joints that allow horizontal and vertical movement between slabs and adjoining structures (e.g., walls, columns, footings) or in especially loaded areas such as heavy machinery foundations. Movement of the structural elements supported by or adjoining the slabs on grade differs from that of the slab itself because of differences in support conditions, in environmental effects, and in the way the stresses develop due to loading, particularly the rigid connections at column and wall joints. Lack of adequate isolation or separation joints in these areas of stress concentration result in cracking. The joints in their different categories separate the reinforcement, mechanical connection, or keyways

TABLE 17.5 Dowel Length and Spacing for Slabs on Grade

Slab Thickness		Dowel Diameter		Total Dowel Length ^a	
in.	mm	in.	mm	in.	mm
5	125	3/4	20	16	400
6	150	3/4	20	16	400
7	175	1	25	18	450
8	200	1	25	18	450
9	225	1-1/4	30	18	450
10	250	1-1/4	30	18	450
11	275	1-1/4	30	18	450

^a Allowance made for joint openings and minor errors in positioning dowels.

Note: Recommended dowel spacing is 12 in. (300 mm) on-center. Dowels must be carefully aligned and supported during concreting operations. Misaligned dowels cause cracking.

Source: Data from ACI Committee 224, *Joints in Concrete Construction*, ACI 224.3R-95, American Concrete Institute, Farmington Hills, MI, 1995, pp. 1–44; ACI Committee 302, *Guide for Concrete Floor and Slab Construction*, ACI 302.1R-89, American Concrete Institute, Farmington Hills, MI, 1989.

across the entire joint and ensure that no bond interaction between adjacent segments is present. An example of a dowel bar assembly for isolation joints is shown in Figure 17.3, and a typical isolation (or, more correctly, expansion joint) is shown in Figure 17.4. The isolation material filling the joint between the slab on grade and the adjoining structural element has to be wide enough to permit both vertical and horizontal movement (ACI Committee 224, 1995; PCA, 1982). It is important to emphasize that joints have to be adequately sealed to improve joint performance. Sealing joints prevents water and deleterious materials from entering the joints and causing damage through corrosion of reinforcement or freezing, for example. ACI 302.1R (ACI Committee 302, 1989) stipulates that joints in industrial and flat floors subject to hard-wheeled traffic have to be adequately filled with a durable hard material such as epoxy to give adequate support for the joint and provide good resistance to wear and tear. The joint material should have an elongation of at least 6% and should be applied in joint locations where further movements are unlikely. It is recommended that the filling epoxy be applied from 3 to 6 months after slab placement (ACI Committee 224, 1995). In summary, it is extremely important for the subgrade to be stable and that soils such as silts and clays are removed to sufficient depths before a stabilized subgrade is placed; otherwise, failure of joints develops and accelerates with time.

17.5.1.3 Special Considerations

17.5.1.3.1 Shrinkage-Compensating Cement Concrete

Concrete made with shrinkage-compensating cement is sometimes used in large slab areas or slabs on grade with a reduced number and enlarged spacing of joints. The use of such a concrete could significantly improve the performance of these slabs by offsetting shrinkage through expansion of the concrete. Gulyas (1984) noted that the use of shrinkage-compensating cement causes greater expansion in the top half of the slab depth than in the bottom half. As a result, less curling is noticed as compared to slabs constructed of normal Portland cement concrete. This difference in shrinkage level between the top and bottom of the slab concrete section seems to be caused by differences in the restraint imposed by the subgrade on the lower surface of the slab. The reduced curling leads to better long-term performance of slabs on grade; in such cases, the additional costs incurred by the use of shrinkage-compensating cement would be justified over the long term.

17.5.1.3.2 Post-Tensioning

Post-tensioning is a technique that can eliminate cracking of slabs on grade or significantly control the extent of cracking caused by restrained drying shrinkage and temperature variations normally occurring during the initial few days after concrete placement. This technique is used for the construction of large areas of slabs without any joints—for example, 100 to 250 ft (30 to 60 m) of slab length without separation

FIGURE 17.9 Various types of pavement joints. (From ACI Committee 224, *Joints in Concrete Construction*, ACI 224.3R-95, American Concrete Institute, Farmington Hills, MI, 1995, pp. 1–44.)

joints. Prestressing induces large compressive forces in the longitudinal direction and prevents any developing cracks from opening. The construction joints in such slabs on grade will open wider than slabs reinforced with conventional steel reinforcement.

17.5.2 Pavements

Pavements are usually thick rigid slabs that have to carry heavy vehicular loads. As in the case of slabs on grade, cracks in pavements are generated as a result of restrained drying shrinkage and temperature variation. They also occur primarily during the first few days after the concrete is placed, namely while the initial curing is taking place. Sometime, blow-ups can occur if the open joint is full of debris and traffic loads are present. The differential temperature gradient through the slab thickness and the restraint imposed by the subgrade on the bottom surface of the slab result in curling of the slab, particularly at the joint. The weight of the pavement slab itself can cause the slab to be subjected to tensile stresses at its lower face that are magnified by additional tensile stresses due to vehicular traffic loads. Such tensile stresses are expected to result in transverse and longitudinal cracks that generate from the lower surface of the slab in contact with the yielding subgrade, with longitudinal cracks developing from warping, curling, ambient temperature changes, and moisture loss (ACI Committee 224, 1995).

To minimize cracking in rigid pavements, it becomes necessary to use both transverse and longitudinal joints in reinforced as well as unreinforced concrete slab pavements. The joints should be designed to transfer loads between adjacent segments and to systematically open and close. Also, all joints have to be properly sealed, as for slabs on grade, to prevent liquids and deleterious materials from entering the joint and corroding the reinforcement; trapped water could freeze in cold temperatures and result in continuous deterioration of the pavement and its ultimate failure. It is important for contraction and expansion (isolation) joints to be well designed so they can help maintain the integrity of the pavement. Figure 17.9 gives recommended pavement joints (ACI Committee 224, 2005). As in the case of slabs on grade, contraction joints have to be provided, as shown in Figure 17.9, with a groove of at least 1/4 to 1/3 the slab thickness. For cut grooves, concrete should be sawed as soon as possible after hardening. The load transfer in Figure 17.9a is accomplished by aggregate interlock of the cracked lower portion of the slab. When dowel bars are used for joint interlock, they are usually spaced at 12 in. (300 mm) mid-depth in the pavement slab, as shown in Figure 17.9c. The dowels can be coated with paraffin-based lubricant, asphalt emulsions, form oil, or grease to prevent bonding of the concrete. Expansion joints, on the other hand, are constructed with a clean break as a total separation through the entire depth of the pavement slab (Figure 17.9d). Sometimes, the slab is thickened at the expansion joint as shown in Figure 17.9h. When keyed construction joints are used (Figures 17.9e,f), it is recommended that be placed in alternative lanes. Again, it should be emphasized that all joints in pavement slabs must be sealed with appropriate filler material as described in Section 17.5.1 for slabs on grade.

18.1 Categories of Construction Automation

Concrete construction automation is a broadly defined planning and technical endeavor that includes two distinct areas. The first is development of programmable (i.e., robotic) hardware for the execution of construction work tasks; significant progress has been achieved in equipment navigation, locomotion systems, and concrete-placement systems. The second is development of computer-based tools for efficient and optimal planning, design, construction, and operation of concrete structures. Of particular importance is the development and practical application of tools for design visualization, quantity takeoff and cost estimation, generation of work schedules and job cost reports, design–construction integration, construction task planning, optimal resource management, and design for constructability and maintainability of concrete structures.

18.2 Automated Construction Equipment and Related Hardware

Construction robotics are now beyond the initial design and academic discourse stages, which was not the case throughout the 1980s and early 1990s (Skibniewski, 1988, 1996). A number of institutions worldwide have developed prototype hardware for various applications that are now in field testing or

FIGURE 18.1 Takenaka Corp. concrete screeder: (a) top and side views; (b) detail.

initial implementation stages. Currently, the most mature applications of robotics in concrete construction include concrete screeding, surface finishing, scrubbing, and cleaning. Japanese construction firms that have developed their own prototypes of such machines include Obayashi Corp., Taisei Corp., Takenaka Corp., and Shimizu Corp.

An automatic concrete screeder has been developed by Takenaka Corp. (see Figure 18.1). The girder-mounted machine has an automatically controlled screeding tool that operates sequentially along a girder running over a self-shifting rail. When the tool reaches the edge of the rail, the rail is shifted forward automatically after invoking the rail-shifting function on the machine controller. The entire screeder has a modular design and can be manually assembled on the construction site. Assembly and disassembly can be accomplished by two or three workers in about 4 hours. The screeding tool includes a screw to perform concrete leveling by transporting surplus concrete to the side. This is done using a vibrating board that ensures an adequately horizontal surface when the concrete is shifted to the side. The maximum weight of the screeding tool is approximately 130 kg. The girder support structure for the trowel is also

FIGURE 18.1 (cont.) Takenaka Corp. concrete screeder: (c) operational steps.

modular, with parts ranging from 2 to 3 m in width. The traveling saddle for the trowels is located under the girder. The maximum weight of the girder components is approximately 50 kg. The control system for the screeder includes an inclinometer, a laser leveling device, and a rotary encoder (Okuda et al., 1992). The screeding capacity of the machine is approximately 350 m² of a slab area per hour, or 35 m³ of fresh concrete mix per hour on a slab with a thickness of 18 cm.

An example of a concrete surface finishing robot, the *Flatkin* by Shimizu Corp., is shown in Figure 18.2. The Flatkin consists of travel rollers, a power trowel, a controller, and a guard frame. A pair of travel rollers is attached at the bottom of the main body of the robot. The robot can move back and forth or left and right, using DC motors to drive the rollers. The power-trowel mechanism has three supporting arms. Each arm has a rotating trowel assembly with three trowels each. A gasoline engine is

FIGURE 18.2 Concrete surface finishing robot by Shimizu Corp.

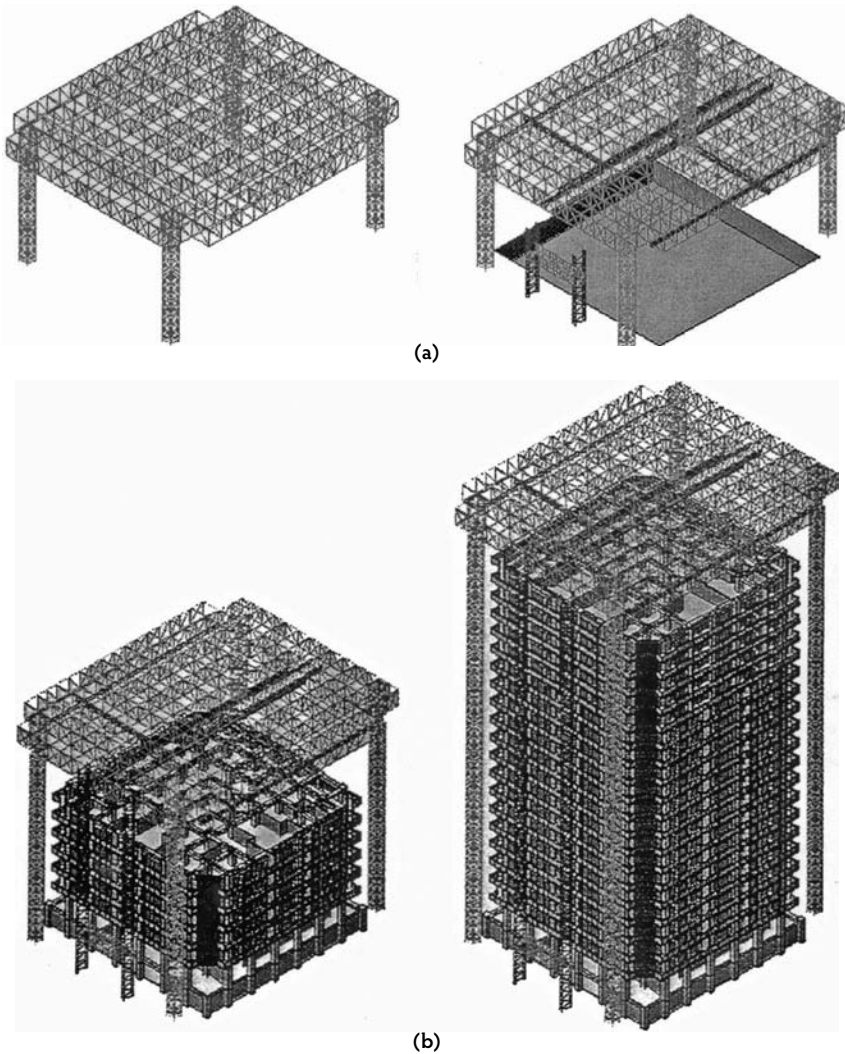

FIGURE 18.3 High-rise building automation by Obayashi Corp.

FIGURE 18.3 (cont.) High-rise building automation by Obayashi Corp.

used as a power unit to drive the trowel assemblies, so the trowel assemblies rotate around the axis and simultaneously rotate around the entire traveling device. The ratio of the rotation speed of the trowels to the revolution speed of the robot around its own axis is approximately 10 and above. The angle between the concrete surface and the trowel can be adjusted by a cam mechanism. This angle is usually changed depending on the hardness of the concrete surface to be finished. The robot is equipped with a guard frame with a touch sensor mounted as a safety device. In addition to the engine for the trowel, the robot has a small generator that enables the elimination of electric power cables, thereby increasing its mobility. The Flatkin can be operated by radio remote control, which is a useful feature for changing the trowel blade positions depending on the hardness of concrete encountered in a given work area. The robot work output is approximately 600 to 700 m² of concrete surface area per day, utilizing two operators in the process. The productivity of the robot is four to five times higher than that of human workers utilizing mechanized walk-behind trowels and manual tools (Ueno et al., 1988).

A partially automated overhead construction factory system for high-rise reinforced concrete frame buildings had been developed by Obayashi Corp. Their *Big Canopy* system integrates a synchronously climbing canopy that houses semiautomated overhead cranes, prefabricated concrete paneling components, computerized management of storage and retrieval of materials on-site, and a semiautomated structural assembly (see Figure 18.3). The canopy covers the entire story of the building being erected to protect workers from severe weather and to produce a safer work environment. Tower crane posts are used as four columns that support the canopy. Raising of the canopy is performed by the climbing facility of the tower cranes. Safety of motion is maintained by synchronized control. A high-speed construction lift and three hoist cranes are combined to deliver the structural components and materials for assembly. The material is raised to the working floor by the lift and passed to the hoist on the delivery girder. The movement of the hoist is fully automated for maximum work efficiency. Upon completion of the building construction, the canopy is disassembled on the top of the building. The external frame is then lowered and then safely disassembled on the ground.

Among the automated surveying technologies relevant to concrete construction, the Consortium for Advanced Positioning Systems (CAPS) has engineered an application of a laser-based positioning device called *Odyssey*[™], developed by Spatial Positioning Systems, Inc. (SPSi) (Figure 18.4). The system has two primary components: transmitters and receivers. At least two transmitters are required to provide

FIGURE 18.4 Laser-based positioning system. (Photograph courtesy of Spatial Positioning Systems, Inc., Blacksburg, VA.)

positioning signals to a receiver; however, any number of receivers can utilize the positioning signals simultaneously. The transmitters can be set up at convenient locations and generally aimed at the work site. Existing benchmarks are used to calibrate the system using any local coordinate system. Each receiver is composed of two lenses mounted on a pole, a processor, a data entry and retrieval system, and a power supply.

The two lenses form a line, and the position of the lenses and the known geometry of the pole allow the point of position measurement to be projected to the end of the pole. Because the position of the tip of the pole does not change if the pole is slanted, rotated, turned upside down, or sideways, the position of any point that the user touches with the receiver is accurately and instantly measured. SPSi system software provides basic functions such as distance between two points, areas, volumes, or angles, although the integrated site positioning system combines real-time coordinate data from the Odyssey™ system with computer-aided design (CAD) design data. The combination of real-time coordinate measurement and CAD representation allows field position and graphical design data to be provided simultaneously to the user. A variety of applications for this system exist in new construction as well as in retrofit projects; for example, in facility characterization, the comparison of as-designed with as-built physical parameters is a large application area in itself. Other applications include industrial plant outage planning and simulation, modular planning, fabrication and construction, consistent site control during construction, providing plant database baselines, and real-time position feedback for automated construction equipment (Beliveau, 1996).

18.3 Economics and Management of Robots

The most decisive factor when considering using a robotic application in construction is its impact on the overall cost of the concrete construction process (Skibniewski, 1988). The promising areas of application are in tasks where the work volume, high repetition, and simple control requirements result in promising robot automation potential. Such tasks include concrete surface treatment (e.g., cleaning, painting, sandblasting), inspection (e.g., nondestructive testing of concrete and reinforcement steel and assessment of ceramic tile adhesion to concrete surfaces), and concrete placement.

Robot-related costs to be reconciled during the analysis include capital costs and operating costs. The capital costs include research and development expenditures (hardware and software, work-system engineering, calibration, and field hardening). Operating costs include energy, maintenance, downtime, repair, tooling, setup, dismantling, transportation, operator, and other related expenditures. Robot-related benefits include construction labor and material savings, improved work quality, extension of work activity into additional locations and time periods, and possibly improved productivity. Details of the economic analysis of construction surface finishing tasks can be found in Skibniewski (1988).

As can be expected from the conditions under which the construction industry operates, the most important decision factor for robot implementation will be a short-term profit potential resulting from labor savings through productivity improvement and possibly through increased construction quality. Most conservative construction firms will be unlikely to invest in robot research and development and will rely on robotics technology developed by commercial robotic systems houses. Such robots will then be either sold or leased by commercial vendors operating in the construction equipment market.

A major difficulty that construction firms will initially face is estimating the robot costs and benefits, as outlined above. The estimation process will improve as more experience with particular robot applications is gained. Detailed information on the cost and benefit items for various robot applications in typical job-site settings can accelerate the pace of robotization if it is made available to all interested construction firms. Future construction robot equipment vendors will be well positioned to fulfill this function in cooperation with robot system developers and manufacturers. When more robotics become available for use on construction sites, significant challenges to both management and technical staff will emerge. For the reasons outlined above, robots must be managed wisely and perform at a high quality level to ensure maximum economic benefits for the contractor's firm.

Despite a number of advantages over traditional methods of performing construction tasks, robots are currently, and will continue to be in the near future, in short supply in comparison to other construction equipment. Thus, robots should be regarded as a scarce resource and their use should be maximized to their full operating potential. By maximizing robot capabilities on as many construction projects as possible, the economic benefits of robot use can be easier to attain; consequently, robot development costs can be recovered faster, and robot use can spread to other applications and types of construction tasks. A hypertext-based optimization program called the *Construction Robotics Management System* (CREMS) has been developed for that purpose. As shown in Figure 18.5, it consists of four modules: Construction Task Analysis, Robot Capability Analysis, Robot Economic Evaluation, and Robot Implementation Logistics (Skibniewski and Russell, 1991).

Automation in construction still constitutes a difficult technical and managerial challenge; however, potential benefits may be significant in this industry. Due to the lack of investment in research and development by construction firms in most industrialized countries except Japan, in combination with other factors, the industry has been experiencing difficulties in introducing and adopting new technologies at the project site level. To facilitate a more comprehensive impact of automation on the construction industry in the future, further research and development are essential. In particular, more attention should be focused on the redesign of construction sitework environments to enable direct technology transfer from other industries to construction, rather than on development of customized automated construction equipment that would closely resemble the humanlike performance of traditional construction tasks (Skibniewski and Nof, 1989). Sound methodologies for systematic technology transfer and

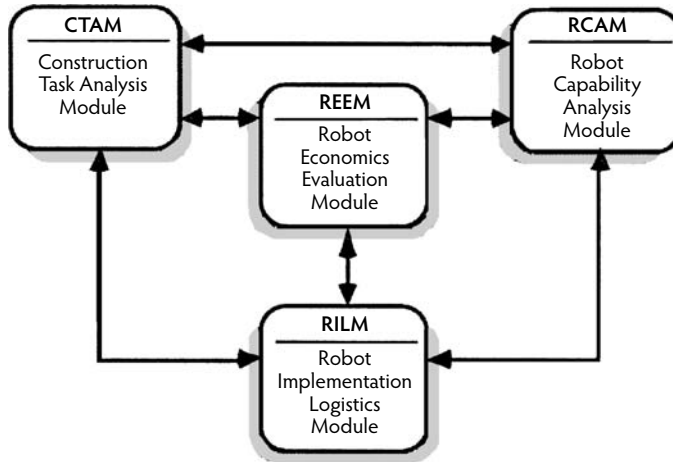

FIGURE 18.5 Construction robotics equipment management system.

evaluation are also necessary (Gaultney et al., 1989), particularly those utilizing the recent advances in computing technologies (Hijazi and Skibniewski, 1989). Better quality constructed products will increase the competitiveness of concrete construction firms involved and can ultimately lead to greater demand for their services. As research and development of construction robotics systems continue, the latest developments are regularly reported in annual symposia on automation and robotics in construction (see, for example, Cho et al., 2006) and in *Automation in Construction*, a bimonthly international research journal published since 1994.

18.4 Computer-Aided Design

18.4.1 Traditional Architectural CAD Modeling

Reinforced concrete (RC) structural facility delivery processes include the design and drafting of various sectional views, on drawing sheets, as two-dimensional drawings. Even a small design modification requires time-consuming redrawing of various sectional views, along with detailed rebar specifications. The emergence of traditional computer-aided design (CAD) systems changed the time-consuming manual design and drafting process into a series of keystrokes and mouse drags-and-clicks on a computer. As basic operations such as drawing and erasing a line, arc, etc. are much faster on a computer, traditional CAD systems reduced the costs of redrawing that resulted from design modifications. Traditional CAD systems require manual interpretation of the information pertaining to a given RC structural facility; for example, a given RC structural component such as beam is represented by several projections along with a set of symbols. This representation process requires manual interpretation not only during the design stage, which provides input of geometric and symbolic information, but also during the construction stage, which reproduces the exact shapes and configurations intended during the design stage. Further, the shapes and configurations are manually interpreted during the design and construction stages by different sets of people with widely varying knowledge and skills. In cases of complex reinforcement configurations—resulting from either the shape of the structure or special requirements such as earthquake resistance—total misinterpretation of shapes and configurations is possible during the construction stage, resulting in costly redesigns and rework. More advanced solid-modeling approaches, currently not prevalent in the RC structure domain, employ specialized representation schemes that would facilitate the interpretation process by capturing the shape information pertaining to a given design object. A brief discussion of various solid-modeling approaches is provided below.

18.4.2 Solid Geometric Modeling

A solid geometric model is an unambiguous and informationally complete mathematical representation of the physical shape of an object in a form that a computer can easily process (Mortenson, 1985). Topology and algebraic geometry provide the mathematical foundation for solid modeling. Computational aspects of solid modeling include data structures and algorithms from computer science and application considerations from the design and construction of engineering projects. The following techniques are available for the solid modeling of civil engineering facilities (Requicha, 1980):

- Primitive instancing
- Cell decompositions
- Spatial occupancy enumeration (SOE)
- Constructive solid geometry (CSG)
- Sweep representations
- Boundary representation (B-Rep)

18.4.2.1 Primitive Instancing

The primitive instancing modeling technique consists of an independent approach to solid-object representation in the context of the group technology (GT) paradigm. The modeling approach is based on the notion of families of objects, each member of the family being distinguishable by a few parameters. Columns, beams, and slabs can be grouped as separate families in the case of general buildings. Each object family is called a **generic primitive**, and individual objects within a family are called **primitive instances** (Requicha, 1980).

18.4.2.2 Cell Decompositions

Cell decompositions are generalizations of triangulations. Using the cell decomposition modeling technique, a solid may be represented by decomposing it into cells and representing each cell in the decomposition. This modeling technique can be used for the analysis of trusses and frames in industrial and general buildings, bridges, and other civil-engineering structures. In fact, the cell decomposition technique is the basis for finite-element modeling (Mortenson, 1985).

18.4.2.3 Spatial Occupancy Enumeration

The spatial occupancy enumeration (SOE) technique is a special case of the cell decomposition technique. A solid in the SOE scheme is represented using a list of spatial cells occupied by the solid. The spatial cells, called **voxels**, are cubes of a fixed size that lie in a fixed spatial grid. Each cell may be represented by the coordinates of its centroid. Cell size determines the maximum resolution. This modeling technique requires large memory space, thereby leading to inefficient space complexity; however, this technique may be used for motion planning of automated construction equipment under the complete information model (Requicha, 1980).

18.4.2.4 Constructive Solid Geometry

Constructive solid geometry (CSG), often referred to as **building-block geometry**, is a modeling technique that defines complex solids as a composition of simpler primitives. Boolean operators are used to execute the composition. CSG concepts include regularized Boolean operators, primitives, boundary-evaluation procedures, and point membership classification. CSG representations are ordered binary trees. Operators, which may consist of rigid motion, regularized union, intersection, or difference, are represented by nonterminal nodes. Terminal nodes are either primitive leaves, which represent subsets of three-dimensional (3D) Euclidean space, or transformation leaves, which contain the defining arguments of rigid motions. Each subtree that is not a transformation leaf represents a set resulting from applying the motional and combinational operators to the sets represented by the primitive leaves. The CSG modeling technique can be adopted to develop computer-aided design and drafting (CADD) systems for civil-engineering structures. It can be combined with primitive instancing that incorporates the group

technology paradigm to assist the designer. Although the CSG technique is most suitable for design-engineering applications, it is not suitable for construction-engineering applications as it does not store the topological relationships required for construction process planning (Requicha, 1980).

18.4.2.5 Sweep Representation

The sweep representation technique is based on the idea of moving a point, curve, or surface along a given path. The locus of points generated by this process results in one-dimensional, two-dimensional, and three-dimensional objects, respectively. Two basic ingredients are required for sweep representation: an object to be moved and a trajectory to move it along. The object can be a curve, surface, or solid. The trajectory is always an analytically definable path. The two major types of trajectories are translational and rotational (Mortenson, 1985).

18.4.2.6 Boundary Representation (B-Rep)

The boundary-representation modeling technique involves representing the boundary of a solid by decomposing it into a set of faces. Each face is then represented by its bounding edges and the surface on which it lies. Edges are often defined in the two-dimensional parametric space of the surface as segments of piecewise polynomial curves. A simple enumeration of the faces of a solid is sufficient to unambiguously separate the solid from its complement; however, most boundary-representation schemes store additional information to aid feature extraction and determine topological relationships. The additional information enables intelligent evaluation of CAD models for construction process planning and the automated equipment path planning required in computer-aided design/computer-aided construction (CAD/CAC) systems (Kunigahalli and Russell, 1995a; Kunigahalli et al., 1995; Requicha and Rossignac, 1992). A boundary-representation technique that stores topological relationships among geometric entities is most suitable for computer-aided generation of construction process plans. Primitive instancing, sweep representation, and CSG techniques are useful in developing user-friendly CAD software systems for design of civil-engineering structures. CAD systems that incorporate CSG or the primitive instancing technique during the interactive design process and that employ the boundary-representation technique for internal storage of design information are efficient for use in CAD/CAC systems (Kunigahalli and Russell, 1995b).

18.4.3 Solid Modeling of Reinforcing Elements

18.4.3.1 General

The shape of the boundary of a reinforcing element corresponds to a solid cylindrical primitive. A solid cylindrical primitive consists of three faces, three edges, and two vertices. A boundary-representation scheme must account for storage and manipulation of these topological entities. A boundary-representation scheme, the rectangle adjacency graph (RAG), supports solid modeling of reinforcing elements for various structural components such as beams, columns, and slabs. A brief description of the RAG modeling approach for reinforcement detail is described next. A more detailed description can be found in Kunigahalli (1997).

18.4.3.2 Description of RAG Scheme for Reinforcement Detail

18.4.3.2.1 Beam (or Column) Components

An RC beam or a column component consists of longitudinal bars to resist bending moment and stirrups or ties to resist shear force. The portion of a beam or column having the same configuration of longitudinal reinforcement is called a **region**. The geometric and topological information regarding reinforcement detail in a given region of a beam or column component is stored in a structure known as a **Beam_Column_Region**. The information regarding the boundary and reinforcement detail of a beam or column component and the connectivity of a beam or column component to its adjoining structural joints is stored in a structure known as the **Beam_Column_Component**.

The **Beam_Column_Component** structure contains a beam identification number, pointers to two adjacent structural joints, a pointer to a **Face_Table** structure that stores the boundary representation

(B-rep) of a beam or column component itself, and a pointer to a list of `Beam_Column_Region` structures. A parent pointer included in the `Beam_Column_Region` structure enables faster identification of the relative location of a region with respect to a complete RC-framed structure. `Long_Circular_List` and `Loop_List` store geometric and topological information pertaining to longitudinal reinforcement and stirrup or tie reinforcement, respectively.

The geometric and topological information regarding an individual reinforcing bar in a given region i is stored using an `Edge_Face` structure that contains a pointer to the parent region and an enumerated type to uniquely identify an individual longitudinal bar in a given region. Geometric and topological information pertaining to lap-spliced bars are stored using a separate structure known as the `Splicing_Rebar`. The `Edge_Face` structures of longitudinal bars in a given region i are stored in a circular list. A specification for the ordering of the circular list and labeling of longitudinal bars using the enumerated types has been provided to ensure an unambiguous representation.

There can be more than one loop of stirrup/ties to resist the shear force at a given cross-section of a beam or column component. The spacing of loops, and in some cases configurations of the loops of stirrups or tie bars themselves, may vary along the length of a given region. Geometric information pertaining to the vertices and faces is stored using floating point numbers. The information regarding the identified edge of a stirrup or tie reinforcing bar is stored using a pointer to an `Edge_Type` structure. The edge-to-edge and edge-to-contact-vertex topological relationships between a stirrup or tie bar and a longitudinal bar at the location of a standard hook can also be stored using a tailored structure designed specifically for storing hook information.

18.4.3.2.2 Slab Component

The RAG scheme supports solid modeling of reinforcement detail pertaining to a slab component, designed using one-way and two-way slab theories, that consists of longitudinal reinforcing bars to resist positive bending moment, negative bending moment, and torsion at the four corners. The reinforcement for positive bending moment and torsion are typically provided in two layers of bars—namely, upper and lower—that are placed along the two principal orthogonal directions x and y . There exists a boundary edge-to-edge contact between a given longitudinal bar and every other longitudinal bar placed in the other (orthogonal) direction. Negative bending moment reinforcement for a slab normally results in edge-to-edge contacts with longitudinal bars near the top faces of the beams enclosing the slab.

The geometric and topological information pertaining to a reinforcing bar in a slab component can be stored using an `Edge_Face_Slab` structure in the RAG scheme that stores the bar as an enumerated type. The enumerated bar type enables identification of appropriate topological relationships that must be stored. The direction of a given longitudinal bar is also stored using another enumerated type. As only two types of boundary edge-to-edge relationships occur in the case of slab-reinforcing elements, an array of only two elements that contain self-pointers is provided to maintain edge-to-edge topological relationships. The structures of longitudinal bars in a slab are arranged as lists ordered in the two principal directions x and y . Two such lists in orthogonal directions, which are confined within the boundary of a slab component, give rise to a rectangular grid structure. Thus, positive bending moment and torsional reinforcement in a slab component results in a total of five grid structures. Negative bending moment reinforcement for a slab component forms four lists, two in the x -direction and two in the y -direction, respectively.

18.4.4 Computerized Engineering Model

Although solid modeling approaches try to capture the shape of a given design object, the focus still remains on the geometric and topological information pertaining to the design object. A true engineering model, however, must also account for project-specific information pertinent to the model, the semantic relationships between various components of the model, and context-specific information associated with a given engineering domain. This requirement gave birth to a whole new concept that utilizes the object-oriented paradigm to allow incorporation of domain-specific expertise into a CAD application (BSI, 1996).

18.4.4.1 Object-Oriented CAD Modeling

An engineering facility-delivery process involves various participants such as owners, architects, structural designers, and construction contractors. These participants often work on different hardware and operating systems. In large engineering organizations, it is not uncommon for different groups using different hardware and operating systems to work on a single engineering project. Successful implementation of computer-integrated construction (CIC) concepts requires that the CAD data originating in one environment must be usable in any other environment without translation. Further, to support CIC concepts, a CAD system must archive a model in such a way that it can be reactivated after years or decades—for operation and maintenance or renovation purposes—without depending on the hardware or operating systems used during the model-creation process. Such a capability would facilitate smooth progression of users to more cost-effective hardware and operating systems of the future. An object-oriented CAD system that supports CIC concepts must also be capable of handling large datasets. Further, information pertaining to objects (e.g., a beam) present in a project model must be in a consistent state at all times during a CAD session. This is achieved by making sure that the beam information is always accessed and modified by the schema that defined and created the beam object.

The horizontally fragmented nature of the architecture design/engineering/construction (A/E/C) industry requires simultaneous sharing of a given project model by many users for different purposes. For example, let us consider a single beam in a project model. A structural designer may need to modify model information such as the depth of a beam, diameter and spacing of stirrups, and diameter and number of longitudinal bars at the soffit. On the other hand, a rebar subcontractor needs only to query the number and diameter of longitudinal bars, diameter and spacing of stirrups, and grade of concrete and steel. Further, a formwork subcontractor would typically be interested in a query related to the surface area that results from the beam dimension. Apart from allowing tailored intelligent views for different project participants, an object-oriented CEM that supports CIC concepts must ensure that modifications to a project model are properly coordinated and the model is kept in a consistent state at all times during the facility-delivery process. A concrete engineering project typically involves collaboration between experts in several domains such as design, rebar detailing, formwork installation, rebar placement, and concrete placement. An object-oriented CEM must facilitate integration of the information created by each of the domains and allow easy and consistent access by users in other domains (e.g., HVAC, electrical, and mechanical systems). Hence, it should be possible for one schema to reference information defined and maintained by another schema within a given project model that includes schemas that support several disciplines such as architecture, structure, HVAC, construction, and operation and maintenance.

18.4.4.2 Example Object-Oriented CAD System

Objective MicroStation is an example system that addresses the requirements of an object-oriented CAD system and supports the concepts of computer-integrated construction. It includes a schema implementation language called *ProActiveM*, which is an object-oriented programming language that allows the engineering application developers to include domain-specific expertise by creating schemas tailored to model domain-specific information. A rebar design and detailing application, for instance, can focus on modeling domain-specific information such as spacing, hook location and type, grade of steel, and lap splicing.

18.4.4.3 Internet CAD

Downloading standard formwork components from a formwork vendor's website and attaching them to an existing CAD model to check if readily available formwork components fit the designed model geometry is not far from reality with the availability of an Internet CAD system such as *MicroStation*. Internet CAD supports an Internet programming environment that is simple, is active (i.e., works on all platforms), and possesses web-distribution functionality (Bentley, 1996). Java is an Internet programming language that was developed by Sun Microsystems. The Java programming language allowed inline sound and animation in a web page for the first time. Java is not just a Web browser with special features but is also a programming language for distributed application. Java allows adding new types of content and

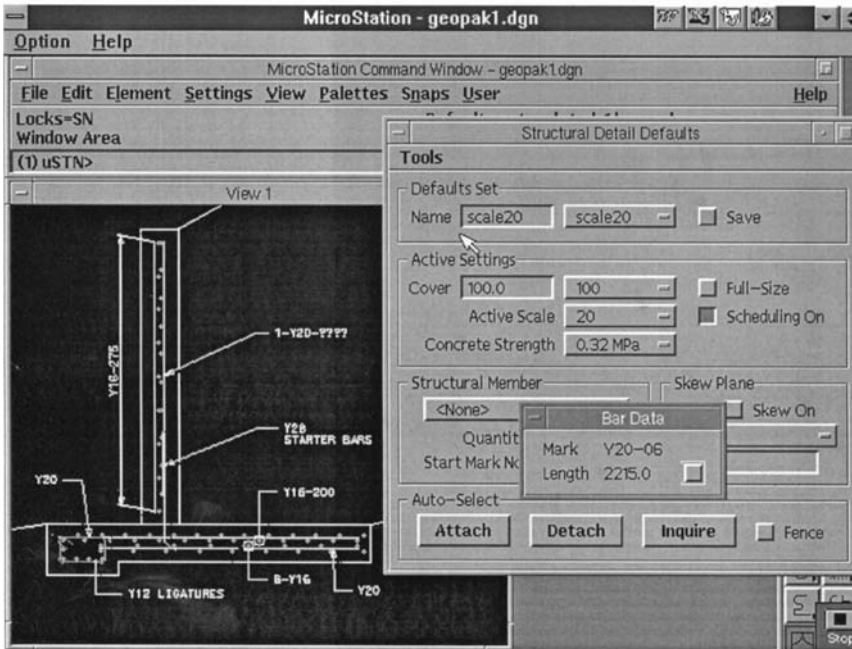

FIGURE 18.6 Geopak® rebar modeling.

the codes necessary to interact with that content; however, Java does not allow two aspects necessary for web-based manipulation of CAD models: maintaining active CAD models and automatic transaction management. ProActiveM, developed by Bentley Systems, Inc., includes all the functionalities of Java programming language and supports automatic transaction management and maintenance of active CAD models. By augmenting CAD systems, such as MicroStation, with an Internet programming language, such as ProActiveM, civil engineers can create **desktop sites** to work with active CAD models of a given project located at a remote **geographic site** (Bentley, 1996).

18.4.4.4 Example Rebar Modeling Systems

Geopak® rebar transforms the MicroStation CAD system into a rebar design and detailing system for reinforced concrete structures. Modeling of any regular or irregular reinforcement arrangements that include many configurations of rebar such as straight bars, stirrups, circular and spiral ties, and radial reinforcement is supported. Geopak provides the tight coupling of a given structural component with the rebar model used to reinforce the structural component. For example, a modification to the model that changes the overall dimension of a structural component will result in an automatic update in the arrangement, spacing, and clearance for the reinforcing steel bars. Automatic scheduling of bar lengths and bar quantities and monitoring of bar marks and shapes is supported for several national reinforced concrete design codes and specifications. Geopak exploits the graphical user interface (GUI) capabilities of MicroStation to provide a large range of specialized touch-click-and-drag editing functions to move, copy, or stretch an instance of a reinforcing-bar object. Figure 18.6 and Figure 18.7 show example screens from the Geopak rebar modeling system (Geopak, 1996). *ArtifexPlus* is a rebar and formwork planning software that specializes in complex compound units. Automatic prefabricated generation of completely reinforced structural modules such as staircases and foundations is supported. Reinforcement planning supports the import and export of reinforced areas, thereby enabling complete or partial reuse of reinforcement models for other projects. The mesh-reinforcement program supported by the reinforcement-planning package provides useful routines for laying single meshes or groups of meshes. Detailed

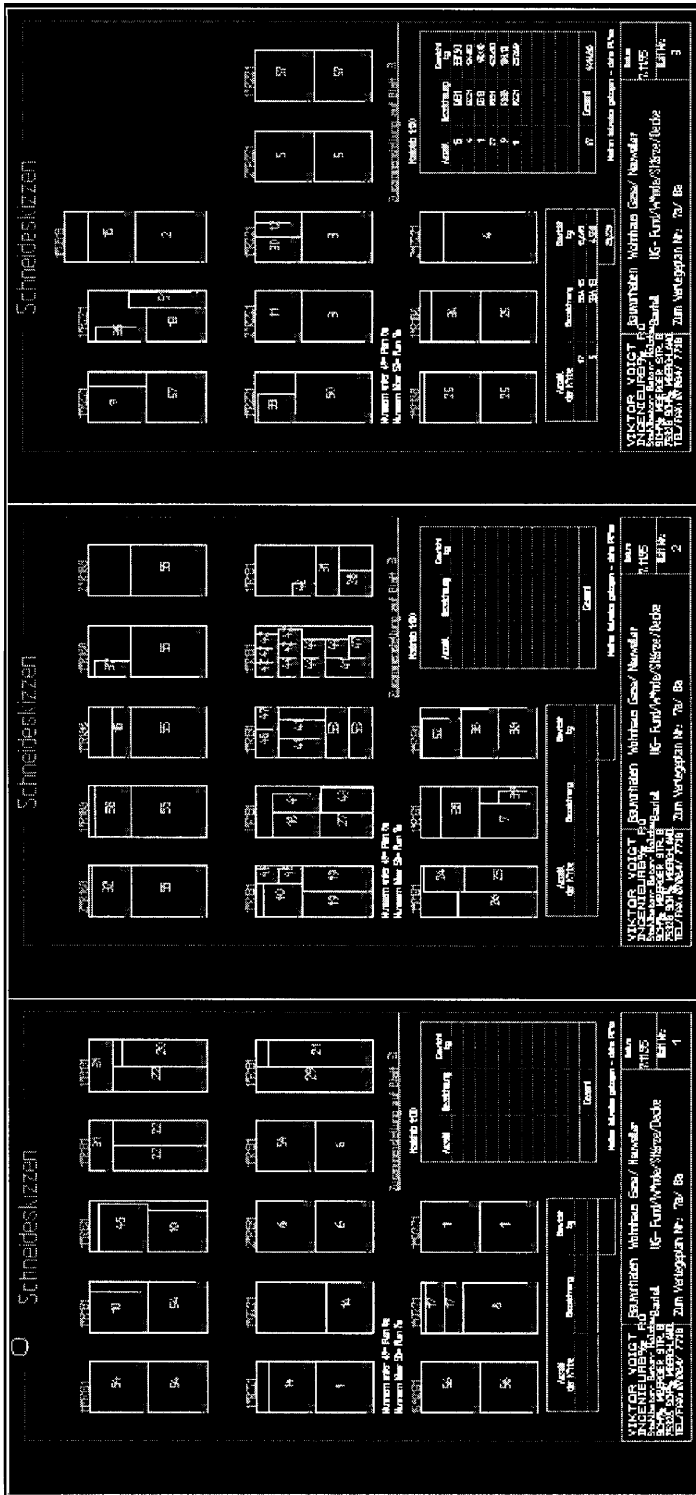

FIGURE 18.9 ArtifexPlus application, cross-sectional sketches.

FIGURE 18.10 Rebar cutting and bending machine: general view. (From Navon, R. et al., *Automat. Construct.*, 4(3), 239–253, 1995.)

representation of the single and double bars of meshes can be created easily, and the weight of all meshes is automatically determined and saved. ArtifexPlus supports creation of formwork drawings based on architectural drawings. Figure 18.8 and Figure 18.9 show example screens from an ArtifexPlus application (Computer Unterstützt, 1996).

18.4.4.5 Automated Manufacturing of Reinforcement Bars

Concrete construction shows a trend toward integrating the achievements of automated design and construction capabilities, at least in off-site production. One example of this trend is the development of an automated rebar manufacturing machine (Navon et al., 1995). This machine produces bars larger than 16 mm in diameter. The machine receives the raw steel bar in a discrete manner, automatically inputs the bars for processing, cuts and bends the bars, and disposes of the excess material. In addition, the machine deals with the temporary storage of the finished product (see Figure 18.10). The machine was designed and developed with the aid of the *ROBCAD* graphical simulation system. This made it possible to check, in a three-dimensional environment, the logic of the material flow, the production methodology, relative location of the subsystems, interference between parts of the machine and the product, and the productivity of the process. The developers of this machine claim a 30% higher productivity compared to traditional rebar-bending machines.

18.5 Conclusions and Future Activities

Research and development of core technologies for automated construction equipment continues to make remarkable progress; however, much remains to be accomplished to bring about the successful automation of today's concrete construction and related work tasks. Concerns for short-term profits, fierce competition among contractors, and lack of top management commitment to technological change are often cited as primary obstacles to the rapid introduction of automation and robotics technology among construction firms. To date, the primary motivation for the robotization of on-site work was to remove humans from safety and health hazards. Eventually, with shortages of skilled construction labor becoming more acute, the scope of tasks considered for automation will be enlarged to include the simple, high-volume, and repetitive tasks that could be effectively automated. More emphasis on the development of new construction systems will be put on the redesign of traditional work tasks to better match the limited capabilities of automation and robot technologies. Automation of design and planning of reinforced

concrete structures at A/E/C firms has become, to a large extent, a reality. The most recent developments in the automation of design–construction integration are taking advantage of the existence of the information superhighway, allowing company professionals to communicate and transfer data instantly not only within their own organization, but also to clients, subcontractors, and other parties that may be located worldwide. This trend, independent of on-site work automation, is likely to continue.

19.1 Introduction

Today's building construction projects are highly mechanized. With the growing industrialization of construction and the gradual shift to offsite prefabrication of structural and finishing elements that are then assembled (rather than produced) on site, production equipment is increasingly making room for *transportation* equipment. Thus, material handling and lifting equipment dominates construction sites as an essential resource, constituting a major part of the project's construction cost.

The typical concrete-construction building site will employ several or all of the following equipment types: (1) cranes, (2) material handlers, (3) concrete pumps, (4) hoists and lifts, and (5) forming systems. Concrete is commonly produced on-site only in the case of large projects requiring high concrete volumes or transportation distances that are too great for the supply of ready-mixed concrete. Earthmoving equipment is used for the initial, substructure phase of construction and often during final landscape development work but is hardly seen on the jobsite throughout construction of the structure itself (unless construction progress at various parts of the project is sequenced such that one part of the project is already above ground while another may still be under ground).

* Associate Professor of Construction Engineering and Management, Technion—Israel Institute of Technology, Haifa, Israel; specializes in construction equipment selection, operation, management, productivity, economics, and safety. Unless otherwise noted, all photographs in this chapter were taken by the author.

Of the above-listed equipment types, *cranes* are the most conspicuous machines on-site, not only because of their size but also because of the vital role they have in transporting materials and building components vertically and horizontally. When selecting equipment for the project, cranes are the centerpiece of the process, and decisions made on the selection and location of cranes commonly govern the selection of other equipment; therefore, cranes are discussed throughout this chapter in greater detail than other equipment types. The North American construction industry has traditionally been a *mobile-crane* culture (Shapira and Glascock, 1996); the number of mobile cranes in the United States is far greater than the number of *tower cranes*, which are the epitome of construction in Europe and the industrialized Far East. Tower cranes, however, have been increasing their presence in the United States since the early 2000s. Whereas mobile cranes are still by and large the backbone of the U.S. construction industry, the demand for tower cranes is on the rise. American contractors now favor tower cranes to a growing degree, and crane rental companies are responding to the demand by increasing the share of tower cranes in their fleets (Bishop, 2000; Shiffler, 2006b). High-rise construction has always been predominated by tower cranes, but now these machines are often seen on mid-rise and low-rise projects, as well, particularly for concrete construction of buildings, given the type of work and long service durations involved, as well as the all too often constricted sites that cannot accommodate mobile cranes.

Equipment offered and used for building construction has seen other changes in recent years. Most notable is the abundance of telescopic machines used for moving materials and workers about the jobsite. Modern *telehandlers* now replace the traditional forklifts. Coming with a variety of front-end attachments, these machines are gradually taking over other equipment as well, such as backhoe-loaders and small rough-terrain mobile cranes. Telescopic aerial work platforms and scissor-type lifts are often used on works for which conventional scaffolds commonly had to be erected. Sometimes a great number of these and other light, versatile, and mobile units may be seen on just one construction site.

This chapter focuses on equipment typically used for concrete construction on today's *building* sites. Forming systems, also undergoing significant modernization in recent years, are an integral component of today's on-site equipment for concrete building construction. Formwork design and forming systems in general are treated elsewhere in this book (see Chapter 7), but this chapter, in its last section, addresses mechanized form systems for building construction.

19.2 Equipment Selection

19.2.1 General

Selection of equipment (often termed *equipment planning*) for a construction project is one of the major functions and decision-making processes carried out by the construction company planning the construction of the project. This is due to the key role in the success of the project played by the selection of the appropriate equipment. Simple, "regular" projects, especially if similar to projects the company has previously built, may not pose a challenge in terms of equipment selection; however, when the project is no longer "regular," and definitely in the case of complex and large-scale projects, equipment selection also becomes very complex and challenging. This is due mainly to the following reasons, which should also serve as general guidelines for conducting the selection process:

- A great variety of makes and models is available for each type of equipment which, by itself, generates a great number of alternatives.
- For many equipment types, and particularly for cranes, selection also means the consideration of various location alternatives, within the overall site layout planning.
- For most equipment types, selection cannot be carried out separately for each type because they are interrelated (e.g., cranes, concrete pumps, and forming systems).
- The consideration of equipment alternatives is often interrelated with the consideration of construction methods (e.g., cast-in-place vs. precast concrete elements), thus the circle of options widens further.

FIGURE 19.1 Example site layout (Alternative 1).

- Constructing a building is a dynamic process that continues to change throughout the project life. Equally variable are the equipment requirements. With the high level of uncertainty typically inherent in construction projects, equipment planning is frequently reexamined and occasionally even revised during construction.
- Construction companies commonly build several projects concurrently, each requiring its own equipment planning, and individual equipment plans that look into utilizing equipment owned by the company must be in concert with each other.
- Feasible equipment alternatives are primarily evaluated and compared on the basis of costs; however, a great many qualitative and intangible factors that are difficult or impossible to quantize must be considered systematically to ensure the selection of a “good” alternative (Shapira and Goldenberg, 2005).

The following example demonstrates these issues (Goldenberg and Shapira, 2007).

19.2.2 Example

Figure 19.1 is a site layout drawing for the construction of a 42-floor, 470-ft-high residential and office tower sitting above a 60-ft-high podium of commercial space. The building is set in a confined site, located within a busy urban area and in proximity to congested thoroughways; the entire area is occasionally subject to strong winds. The structural frame of the building is cast-in-place concrete, but the contractor is free to convert the external walls of the tower into precast elements. Construction progress for the concrete work for the tower is scheduled at one floor per week, and overall construction time is set at 24 months.

19.2.2.1 Alternatives

As shown in Figure 19.1, major equipment for the project (Alternative 1) includes two tower cranes (C_1 and C_2) and a concrete pump with a placing boom (P). Not shown in the drawing is a self-climbing wall system for the forming of all tower walls (external and core walls). With placing of concrete for all tower elements carried out by the pump and climbing boom and with the crane-free operation of the automatic climbing form system, only one crane (C_1) satisfies all other required lifting services for the tower (mainly

rebar, slab forms, and various finish materials). This is a full-height (520 ft) external crane, whose mast is braced to the west façade of the tower. The second tower crane (C_2) is a much shorter (100-ft), freestanding crane that serves the lower structure (commercial floors); this crane is located inside the building in openings left in the floors. The stationary concrete pump is located outside the southeast corner of the building, in close proximity to a gate for the entrance of ready-mixed concrete trucks. The placing boom and concrete supply pipeline climb inside the elevator shaft. Other equipment on the site, not shown in the drawing, includes a passenger lift serving the tower, as well as a telehandler serving the lower structure (but also the entire site as a multipurpose utility machine).

Each one of these equipment types offers a great variety of options in terms of specific makes and models entailing various dimensions, capacities, and other important work parameters. Related to these factors are locations of the equipment. For example, if the tower crane serving the high-rise structure (C_1) were placed inside the building in a climbing configuration, a shorter jib would suffice to secure full coverage of the high-rise building, and only a small portion of the sections currently making up the external crane mast would be required. On the other hand, dismantling an internal climbing crane is a much more complicated and costlier operation than that for an external tower crane.

Decisions on each major equipment type affect the entire equipment array on site. For example, another lifting solution (Alternative 2) would be two full-height external tower cranes, one on each side of the high-rise building (east and west façades). Concrete placing can then be accomplished with the cranes, eliminating the need for a concrete pump. The costly automatic climbing wall-form system may also be relinquished, but at the likely cost of extended work hours due to crane time overload. The cranes will also have to provide partial lifting services to the lower structure, within their reach and lifting capacity limits; otherwise, lifting for the lower structure would be done by the telehandler. Concrete for the lower structure is to be placed in this alternative by a truck-mounted pump and placing boom. The pump can be stationed in various locations along the north and west façades.

The interrelation between equipment selection and construction methods can be exemplified by the possible conversion of the tower's external walls from cast-in-place to precast concrete. Drawn from Alternative 1, the current case is likely to have the tower crane servicing the high-rise structure located inside the structure as an internal climbing crane. This way, the crane can handle the heavy precast elements along the circumference of the tower with a shorter jib; by moving the crane from the façade of the tower inside, the problem of installing precast wall panels at close proximity to the mast of the crane is also avoided. In this alternative, no forming of the external walls is required, and the use of the automatic climbing system is reduced to the core of the tower only.

Note that, in some cases, not only are equipment selection and construction methods interrelated such that the latter affect the former, but also *vice versa*. This brings into the picture the concept of *constructability*, where, among other things, equipment planning may begin as early as the design of the building. In such cases, the major equipment to be used on the project is taken into account in the course of design; alternatively, the initial design is revised. An example is the reorientation of a large set of wide-span precast concrete beams whose placement in the building according to the original orientation designed would not be possible with the crane already purchased for the project by the owner.

Alternatives 1 and 2 are merely two alternatives among several possible for this project. The *feasibility* of each alternative, in terms of satisfying all lifting and other logistics requirements, must be investigated and guaranteed before any cost comparison is conducted. The main parameters considered for each equipment type in the course of generating alternatives and investigating feasibility are mentioned separately for each equipment type in the subsequent sections of this chapter.

Cost estimates of each alternative examined will be affected by procurement patterns of the various machines. Procurement, in turn, essentially a matter of company policy (to own or rent equipment), is often dictated by the availability of existing company-owned equipment not engaged on any of the company's other projects. This could apply to whole machines or part of a machine; for example, even if the company owns the two tower cranes required for Alternative 2, it might still have to rent a portion of the mast sections for the two exceptionally high external cranes.

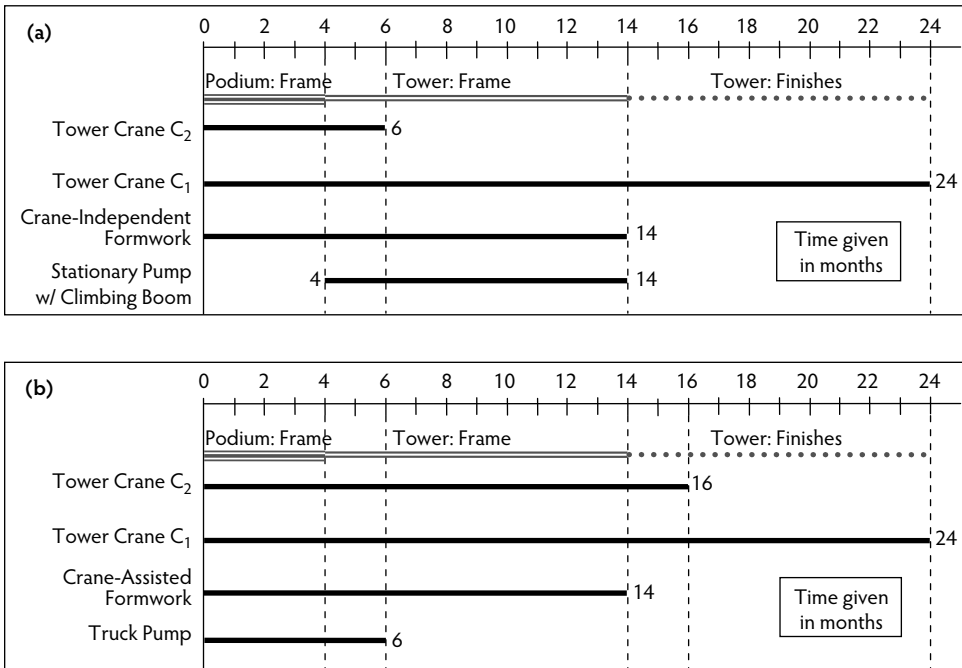

FIGURE 19.2 Example scheduling of equipment service: (a) Alternative 1; (b) Alternative 2.

Cost estimates must also take into account on-site service durations of each individual equipment unit, as derived from the schedule developed for each alternative. These schedules, in turn, must conform to the required construction progress and the overall construction time specified for the project. Figure 19.2 shows the schedules developed for major equipment in Alternatives 1 and 2.

19.2.2.2 Employment Times

Service durations of the various equipment units are closely associated with the planning of *daily crane employment*. Such planning is necessary to ensure the feasibility of each alternative. Table 19.1 is an example of crane employment times, as compared for the two equipment alternatives demonstrated in this section, focusing on the high-rise tower. Employment times are estimated on the basis of daily quantities of materials to be lifted and considering the predicted lift-cycle durations. Predicted lift-cycle durations should not be averaged but rather must correspond to the specific work conditions, as well as to the specific equipment reviewed. For example, the unit duration of 7.5 min per cu yd, as shown in Table 19.1 for concrete placement in slabs, corresponds to production rates of 8 cu yd per hr. Arithmetically, this could be achieved, for example, by the use of a 1.0-cu yd concrete bucket completing 8 cycles per hr (namely, 7.5 min per cycle), or by the use of a 2.0-cu yd bucket completing 4 cycles per hr (namely, a 15-min actual cycle time). Because bucket size virtually does not affect travel time, larger buckets would commonly be desirable, as they save crane time and entail overall higher productivity. (Note, though, that an increased concrete placing rate may require larger placing crews.) Here, however, enters another factor, which is the lifting capacity of the crane at the desired concrete placing location. A fully loaded 1.0-cu yd bucket weighs about 4800 lb (including self-weight); the respective weight of a 2.0-cu yd bucket is 9200 lb, or 4.6 tons. This is more than the maximum lifting capacity offered by many tower crane models at the jib end. For this reason, preparation of a crane employment table, such as Table 19.1, must relate, among other things, to the specific crane model and bucket size designated for the project.

TABLE 19.1 Example Daily Crane Employment Requirement

Material/Element	Unit	Quantity	Lift Cycle Duration per Unit (min)	Total Duration, Cranes Only (min)	
				Alternative 1	Alternative 2
Concrete for slabs	cu yd	80	7.5	Concrete pump	600
Concrete for walls and columns	cu yd	50	9.6	Concrete pump	480
Reinforcement steel	ton	5	24	120	120
Slab forms	Complete work	1	100	100	100
Core forms	Complete work	1	100	Automatic climbing system	100
External wall forms	Complete work	1	100	Automatic climbing system	100
Finish materials (estimated)				100	100
			Total	320	1600
			15% idling time	48	240
			Total time	368	1840
			Required work shifts of cranes (10-hr, 600-min shifts)	One day shift	Three shifts: two parallel day shifts, one night shift

Another factor—in addition to bucket size and crane lifting capacity—that must be taken into account when actual *cycle times* are estimated is vertical travel distances. The values entered in Table 19.1 correspond to a building height of about 450 ft—namely, the top floors of the tower structure in Figure 19.1. Vertical travel times take up a major portion of the overall cycle time in such lifting heights, depending on the specific *hoisting* speed of the crane model. (Note that, to increase speed, hoisting motors may usually be replaced by more powerful ones, for any given crane model, whether new or used.) Thus, if a crane employment table were to be prepared for a low-rise building, then travel times would be almost ignored, as they virtually play no role in lifting heights of up to 60 ft. In these cases, crane cycle times are governed mostly by loading and unloading (or rigging and unrigging) times and by the fine maneuvering time required for the lifting hook of the crane to approach the exact loading/unloading point (Rosenfeld and Shapira, 1998). It can be concluded, then, that for the lower floors of the tower structure, lift-cycle durations are likely to be much shorter, resulting in shorter overall crane employment times.

According to the total-time results given in Table 19.1, the one crane serving the high-rise tower in Alternative 1 is underemployed. Note that 15% idling time was added to the computed service durations. In Alternative 2, on the other hand, the two cranes serving the tower are overloaded; therefore, one of them has to continue its work into a full night shift.

Preparing the crane employment table, which essentially takes into account other major equipment as well, is necessary to ensure feasibility, to obtain overall service durations of the equipment on-site, and to serve as the basis for the cost estimates of the various equipment alternatives. The study of employment times required for the project often involves refinement of more general decisions made when equipment alternatives were generated and checked for feasibility. Finally, calculation of work time exposes tradeoffs between type and quantity of equipment, overall size of labor crews, and workday duration, as exhibited by the various equipment alternatives.

19.2.2.3 Cost Estimates

Table 19.2 is an example of cost estimates worked out for major equipment in Alternatives 1 and 2. Costs were estimated based on total service durations of the cranes, pump, and wall-forming system, as shown in Figure 19.2. The extended work hours and night shifts revealed by the crane employment analysis shown in Table 19.1 for Alternative 2 incur higher wages for equipment operators and other labor crews.

TABLE 19.2 Example Cost Estimates of Equipment Alternatives

Equipment	Cost Factor	Cost Estimate (\$)	
		Alternative 1	Alternative 2
Tower crane (C ₁)	Capital cost (of owned equipment) or rental	377,000	310,000
	Maintenance	78,000	74,000
	Insurance, taxes, license	54,000	52,000
	Transportation, erecting, dismantling	44,000	44,000
	Ties, climbing device	102,000	102,000
	Operator wages	160,000	160,000
	Operating (energy)	24,000	24,000
	Climbing	6000	6000
Tower crane (C ₂)	Capital cost (of owned equipment) or rental	(-)	278,000
	Maintenance	14,000	49,000
	Insurance, taxes, license	8000	35,000
	Transportation, erecting, dismantling	33,000	44,000
	Ties, climbing device	(-)	53,000
	Operator wages	40,000	213,000
	Operating (energy)	4000	32,000
	Climbing	(-)	6000
Concrete pump	Capital cost (of owned equipment) or rental	96,000	51,000
	Maintenance	31,000	(-)
	Insurance, taxes, license	11,000	(-)
	Transportation, erecting, dismantling	(-)	(-)
	Operator wages	51,000	(-)
	Operating (energy)	9000	(-)
	Climbing	38,000	(-)
	Telescopic material handler	(-)	28,000
Forming systems	Capital cost (of owned equipment) or rental	682,000	(-)
	Maintenance	46,000	9000
	Insurance, taxes, license	38,000	(-)
	Transportation, erecting, dismantling	(Marginal)	(Marginal)
	Operating (energy)	(Marginal)	(-)
	Labor wages for vertical elements	498,000	1,692,000
Total cost for alternative		2,444,000	3,262,000

Direct costs of all equipment include capital costs (in case of owning) or rental costs, maintenance, insurance and licensing of owned equipment, deployment (transportation to the site and erection) and dismantling, climbing operations of cranes and placing booms (including work required to close openings left in slabs), operating costs (energy), and operator wages where applicable (always for owned equipment and, depending on the contracting base, “bare rental” or “all-included,” for rented equipment). For tower cranes, costs entailed by the specific crane configuration should be added (e.g., bracing to the structure and climbing mechanism for high cranes). Earthworks and foundations for the cranes, where applicable, are included in erection costs. There are *time-dependent* cost items (e.g., capital cost or rental), *production-dependent* cost items (e.g., operating costs), and *fixed* cost items (e.g., deployment). The values for all these, as shown in Table 19.2, are computed using the basics of engineering economics and common assumptions with respect to useful life, interest rate, maintenance rates, residual (resale) value of owned equipment, etc. These computations are beyond the scope of the current chapter; the interested reader should refer to Peurifoy et al. (2006) or any other similar book addressing the economics of construction equipment.

Indirect equipment costs in this example, with respect to major equipment, include auxiliary equipment (e.g., a telehandler for the low structure in Alternative 1) and labor wages in formwork. Note how the latter may constitute the largest single cost item (Alternative 2). Passenger lifts serve the high-rise tower equally in the two alternatives and are not included in Table 19.2. It should be noted that cost estimation

is much more than merely technical calculations; critical, big-picture decisions, on the one hand, and a great many fine details, on the other hand, are equally embedded in the process and mirrored in its results.

With respect to specific project and company data that are behind the numbers appearing in Table 19.2, the following should be noted as examples of parameters affecting cost estimation of equipment alternatives, in addition to those mentioned above:

- *General*—Capital costs and rentals reflect a specific given situation, in which part of the equipment is owned by the company and part is rented. Additionally, part of the owned equipment may have already exceeded its nominal useful life (and therefore no longer incurs capital costs). Note that “equipment” in this respect is not necessarily the complete machine as configured for the specific project; for example, the company may own a tower crane but not enough mast sections. Similarly, it may have to rent a climbing device for its owned crane. This is a rather common situation with equipment (such as mobile and tower cranes) that is modular in terms of its use and therefore also in terms of its manufacturing and procurement; manufacturers and dealers of such equipment cater this way to the great variety of different and changing requirements. On the other hand, other types of equipment (mainly when viewed by the company as being more of specialized equipment, given the company’s line of project types) are commonly procured in the complete configuration required for a particular use. An example could be a climbing concrete placing boom system, which would include the climbing mast, climbing gear, the placing boom, and all other accessories.
- *Climbing the cranes*—For the external cranes (C_1 in Alternative 1, C_1 and C_2 in Alternative 2), the cost of climbing depends only on the number of climbing steps, as no completion works are entailed in the floors (as would be with an internal crane). The number of climbing steps depends on the freestanding height of the crane, as specified by the manufacturer, and on the height to which the crane was erected initially. The higher these two are, the fewer the climbing steps required. If any of these cranes were in an internal-climbing configuration, a much higher overall climbing cost would result, due to (1) higher cost of each climbing step, (2) greater number of climbing steps, and (3) completion works in the floors. The cost for climbing the concrete placing boom in Alternative 1, an operation similar to that of climbing an internal crane, reflects these differences. The short crane installed inside the lower commercial structure (C_2 in Alternative 1) is initially erected to its full-required height, which does not change during construction. Hence, climbing costs in this case are incurred only by completion works of the lower structure’s floors, and these are marginal.
- *Location of concrete placing boom*—As shown in Figure 19.1, and also mentioned above, the placing boom transporting concrete from the stationary pump is located inside the elevator shaft. Elevator shafts, as well as stairwells, are commonly part of the structural core of the building. As such, they are a natural choice for the location of climbing booms and cranes, in terms of transferring loads imposed by the equipment. Indeed, when such equipment is located elsewhere inside the building, it usually requires temporary vertical shoring of the floors and sometimes additional bracing of the permanent structure being constructed. However, from the viewpoint of the construction process and progress, there are at least two disadvantages to locating climbing equipment in the elevator shaft: (1) it delays the installation of the building’s permanent elevators; and (2) it may interfere with, and therefore limit the choice of, forming systems for the walls of the core. As a compromise, the boom can climb elsewhere in the core, rather than in the elevator shaft. Stairwells should likewise be left free so as not to interfere with the installation of the stairs, as these serve workers moving between the floors during construction.
- *Ties and climbing device*—The device used to climb an external crane, whether it is a freestanding crane or a crane braced to the building, is modular equipment, often referred to as a *climbing cage*. A company owning several tower cranes may be able to climb them using a smaller number of climbing cages (owned or rented), depending on compatibility (due to make and model and to the cross-section of the mast). This is a desired situation, given the high price of these devices.

The ties and climbing device costs appearing in Table 19.2 reflect a similar situation, where one climbing cage can climb both external cranes in Alternative 2. Hence, the procurement cost of the cage in Alternative 2 was taken into account only once (C_1). The corresponding cost for the second crane (C_2) is essentially that of the ties to the building, with a small addition for moving the cage between the two cranes (as mentioned above, the number of climbing steps in this case is small). No climbing device costs appear in Table 19.2 for the concrete placing boom, as these were computed within the concrete pump's rental costs.
