■ **Hepatic Artery Infusion.** Although hepatic chemotherapy infusion for metastatic colorectal cancer remains an area of investigation, findings to date do not suggest superiority compared to systemic chemotherapy. The rationale for hepatic artery infusion (HAI) is based on the principle that normal liver hepatocytes and early micrometastases obtain their primary blood supply from the portal vein. In contrast, tumors in the liver are thought to receive most of their blood supply via the hepatic artery.⁸⁹ Therefore drug administration via the hepatic artery should result in delivery of high concentrations of drug to the tumor cells with a much lower exposure to normal liver tissue. Also, for drugs that undergo a high first-pass extraction through the liver, systemic exposure and toxicity are minimized.

Because the liver is a common site of colorectal cancer metastasis, and the only site of metastatic involvement in up to one-third of patients, hepatic-directed therapies continue to be explored. Historically, floxuridine and fluorouracil have undergone the most study for hepatic artery infusion, particularly because of their high hepatic extraction rates, but newer active agents such as irinotecan and oxaliplatin have been studied as well. The observations seen with systemic therapy that continuous-infusion fluoropyrimidine provides greater response rates guide most strategies for HAI. Trials involving HAI have been conducted in patients with unresectable liver metastases and as adjuvant therapy following curative resection of isolated metastases.

The pharmacokinetic properties of floxuridine in particular provide for rapid systemic clearance and high liver drug extraction (94% to 99%).²⁸ Fluorouracil has a much lower extraction rate, but is also used frequently. Floxuridine is typically administered as a continuous 24-hour infusion at a dose of 0.1 to 0.3 mg/kg per day for a total of 14 days. This is in contrast to a comparable IV dose equal to 0.125 mg/kg per day. Heparin, in amounts up to 50,000 units per

50 mL of solution, is often added to the mixture in an attempt to decrease the incidence of arterial thromboses.

Regional HAI can be accomplished using a hepatic arterial port, a totally implantable pump, or a percutaneously placed catheter into the hepatic artery that is connected to an external pump. The volume of drug required to administer floxuridine can be contained within an implantable pump, whereas fluorouracil administration generally requires use of an external pump. Implanted infusion pumps are typically loaded with a 2-week volume of chemotherapy that is followed by an infusion of heparinized saline for 2 weeks.⁸⁹ Candidates are selected carefully based on documentation of hepatic-only disease, good performance status, and no significant comorbidities or liver anatomic variants.

Early trials of HAI revealed objective response rates ranging from 30% to 88%, many of which were observed in previously treated patients, as well as increased survival rates compared to historic controls. Because supportive care alone is no longer considered standard care for metastatic disease, when HAI was compared to systemic chemotherapy, most comparisons did not yield a survival benefit.⁸⁹ Furthermore, the majority of studies have allowed patients in the systemic therapy treatment groups to crossover to HAI upon tumor progression; therefore the impact of these treatments on survival is difficult to interpret.

In two randomized trials in which HAI floxuridine was compared to systemic fluorouracil plus leucovorin, and treatment crossover was not allowed, the European trial did not detect any treatment difference in progression-free or OS, whereas the CALGB trial showed improved time to hepatic progression (9.8 vs. 7.3 months) and median OS (22.7 vs. 19.8 months) with HAI.⁸⁹ However, both studies were affected by pump-related delays and complications, and the final analysis of the CALGB study has not been published.⁸⁹

Given the significant improvements with systemic chemotherapy for metastatic disease achieved with systemic chemotherapy over the past several years, attention has been directed to HAI with non-fluoropyrimidines, including irinotecan, oxaliplatin, and biologic

agents. Early studies have shown promising results, but whether this approach offers any advantage compared to systemic therapy will require significant further study. HAI has also been studied in alternating schedules with systemic fluoropyrimidines, but no survival advantages were observed.⁸⁹

The primary limitations of HAI include development and/or progression of extrahepatic disease and treatment toxicities. Common toxicities include hepatobiliary toxicity and peptic ulceration, which can be life-threatening. Systemic chemotherapy-related side effects, such as myelosuppression, stomatitis, nausea, vomiting, or diarrhea, are uncommon.⁸⁹ Inflammation or ulceration of the stomach or duodenum can occur from inadvertent drug exposure to these areas. Patients who complain of persistent abdominal pain, diarrhea, or melena should have their HAI withheld and undergo endoscopic evaluation. The degree of hepatobiliary toxicity ranges from an elevation in hepatic enzymes resulting in a chemical hepatitis, to biliary sclerosis. Elevation of liver function enzymes or increased serum bilirubin levels occurred in approximately 42% of patients in the randomized trials.⁸⁹ Progressive biliary sclerosis, usually associated with floxuridine, developed in 3% to 26% of patients in the randomized trials. Patients receiving HAI should have their liver enzymes and bilirubin monitored every 2 weeks during therapy, and guidelines are available for dose reductions or drug discontinuation.⁸⁹ Biliary sclerosis often resolves upon discontinuation of therapy within 2 to 4 weeks, although irreversible damage can occur. In an attempt to reduce inflammation and ischemia of bile ducts, dexamethasone is frequently added to HAI floxuridine, and appears to decrease the extent of liver function test abnormalities that occur in patients who experience hepatobiliary toxicity. Another approach is to alternate HAI floxuridine with hepatic arterial bolus fluorouracil, which does not cause hepatobiliary toxicity.

Gastritis and gastrointestinal or duodenal ulceration with risk of hemorrhage can also develop, which are reversible upon discontinuation of therapy. These effects are believed due to perfusion of chemotherapy into the stomach and duodenum via small vessels branching from the hepatic artery. These toxicities may be ameliorated by surgical ligation of the blood vessels supplying the stomach and

duodenum, or H₂-antagonist therapy. Cholecystitis, which occurs in approximately one-third of patients, can be avoided through removal of the gallbladder at the time of catheter placement.⁸⁹

Because of toxicities associated with HAI, most patients require some transient interruption of therapy, a decrease in dosage, or discontinuation of therapy. Furthermore, extrahepatic disease progression with HAI therapy alone remains a clinical problem. Although increased response rates and a trend toward improved survival have been reported, the costs and toxicities with this approach are significant. In a meta-analysis of actual costs (based on 1995 U.S. dollars) for HAI therapy, the average cost per patient was \$25,208 and \$29,562, for a patient in Palo Alto, California, and Paris, France, respectively.⁸⁹ In a comparison of costs with HAI floxuridine and systemic fluorouracil plus leucovorin, HAI was more cost effective than systemic chemotherapy. Therefore for the minority of patients who present with unresectable disease to the liver only, HAI may represent a reasonable therapeutic option, but it should not be considered standard therapy until the results of ongoing trials comparing HAI and systemic therapy, especially more effective regimens, become available.

SECOND-LINE THERAPY

Systemic chemotherapy represents the mainstay of therapy for patients whose disease progresses following initial treatment for metastatic disease. Figure 127–7 depicts an algorithm for treatment of refractory metastatic disease. Treatment options are based on type of and response to prior treatments, the site and extent of disease, and patient factors and treatment preferences.

Systemic Chemotherapy

Upon disease progression following standard initial therapy, appropriate treatment options may include oxaliplatin plus fluorouracil and leucovorin, irinotecan plus cetuximab, cetuximab, irinotecan, continuous-infusion fluorouracil, capecitabine plus irinotecan or

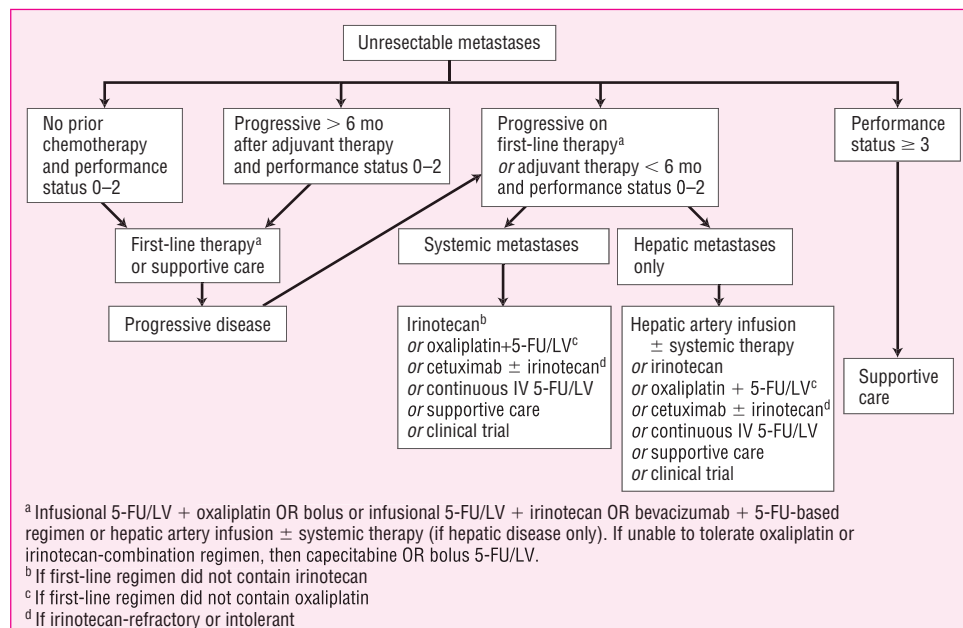

FIGURE 127–7. Algorithm for treatment of unresectable or refractory metastatic colorectal cancer.

oxaliplatin, capecitabine, intrahepatic therapy for selected patients, supportive care, or participation in a clinical trial. The choice of specific agents depends primarily on the type of prior therapy received. Since most patients will have received a combination of a pyrimidine with either irinotecan or oxaliplatin, second-line therapy with the alternate regimen should be considered; however, an optimal sequence for administration of both treatments has not been established.

■ **Irinotecan.** Two important trials have delineated an appropriate standard of care for patients who experience disease progression with fluorouracil therapy for metastatic colorectal cancer.^{97,99} The results of these trials demonstrate a survival benefit associated with irinotecan, which was approved by the FDA in 1996, as second-line therapy for recurrent or progressive disease following fluorouracil. In phase II studies of previously treated patients with metastatic colorectal cancer, objective response rates of 13% to 27% have been observed.^{97,99}

In a phase III trial of 189 patients with metastatic colorectal cancer that had progressed within 6 months of treatment with fluorouracil, irinotecan was compared to supportive care alone with regard to survival, quality of life, and other clinical variables.⁹⁷ Irinotecan was administered as 350 mg/m² IV every 3 weeks; the dose was reduced to 300 mg/m² for individuals who were 70 years of age or older, had a World Health Organization performance status of 2, or who had clinical risk factors for developing excessive treatment toxicity. Supportive care could include any symptomatic therapy with the exception of irinotecan or any other topoisomerase I inhibitor. With the exception of more patients with poor performance status being in the supportive care group, baseline patient characteristics were similar between groups. Median survival was 9.2 months with irinotecan, as compared to 6.5 months with supportive care alone. One-year survival was significantly greater with irinotecan (36.2% vs. 13.8%) and was not associated with significantly worse quality-of-life scores except for diarrhea. Clinical variables such as cognitive functioning, pain, dyspnea, and appetite loss were in favor of irinotecan therapy. The most common grade 3 or 4 side effects with irinotecan included leukopenia and neutropenia (22%), diarrhea (22%), nausea (14%), and vomiting (14%). Seventy-two percent of patients receiving irinotecan required hospital admission for adverse events, compared to 63% of supportive care patients. Thus irinotecan was associated with an improved survival and quality of life compared to supportive care alone, that appeared to balance treatment-related toxicities.

A comparison of irinotecan to continuous-infusion fluorouracil in a similar population of 267 patients allocated patients to irinotecan, 300 to 350 mg/m² IV every 3 weeks, or one of three continuous-infusion fluorouracil regimens: leucovorin 200 mg/m² IV over 2 hours followed by IV bolus fluorouracil (400 mg/m²) and 22-hour continuous-infusion fluorouracil (600 mg/m²), given the first 2 days of every 2-week period; fluorouracil 250 to 300 mg/m² as prolonged continuous IV infusion until disease progression; or fluorouracil 2600 to 3000 mg/m² per day IV over 24 hours, with or without leucovorin (20 to 500 mg/m² IV), given weekly for 6 weeks, with a 2-week rest period between cycles.⁹⁹ Median follow-up after 15 months revealed a longer 1-year survival (45% vs. 32%) and median survival (10.8 months vs. 8.5 months) with irinotecan, as compared to fluorouracil. Sixty-nine percent of patients receiving irinotecan experienced at least one grade 3 or 4 toxicity, as compared to 54% of patients receiving fluorouracil. The most common toxicities with irinotecan were diarrhea, neutropenia, pain, vomiting, and asthenia, whereas pain, asthenia, diarrhea, and dermatologic toxicities were most common with fluorouracil. There was no difference in hospitalization requirement for adverse effects between treatments.

Based on the results of these trials, irinotecan should be considered standard second-line therapy for patients who have failed prior treatment with fluorouracil-based regimens. Either dosage regimen (irinotecan 125 mg/m² IV weekly for 4 weeks followed by a 2-week rest period or 300 to 350 mg/m² IV every 3 weeks) is acceptable. For the every 3-week regimen, initial administration of irinotecan at the lower dose should be considered for patients who have received significant prior pelvic or abdominal irradiation. Protracted continuous-infusion fluorouracil could be considered for those individuals with disease that no longer responds to bolus IV fluorouracil plus leucovorin or irinotecan.

■ **Oxaliplatin.** For patients who received primary treatment with irinotecan and fluorouracil, oxaliplatin plus fluorouracil and leucovorin should be considered. Despite the low activity of oxaliplatin alone against fluorouracil-refractory disease, when oxaliplatin has been administered in a bimonthly regimen with high-dose leucovorin and continuous fluorouracil infusion, a 20.6% response rate with a median survival in excess of 10 months has been observed.¹¹⁸ The combination of oxaliplatin plus fluorouracil and leucovorin is also effective as salvage therapy after irinotecan plus fluorouracil and leucovorin triple therapy regimens that are standard for the initial treatment of metastatic colon cancer, with a response rate of about 20%.¹¹⁹ Whereas irinotecan can be used effectively as a single agent in colorectal cancer, it should be noted that oxaliplatin does not have substantial activity alone, and should only be given in combination with a fluoropyrimidine. Patients with progressive disease who have received irinotecan and oxaliplatin-containing regimens and desire further treatment may benefit from therapy with cetuximab.

◀ ■ **Biologic Therapy.** Cetuximab (IMC-C225, Erbitux) is a chimeric monoclonal antibody directed against an epidermal growth factor receptor (EGFR) that received FDA approval in 2004 for use in EGFR-expressing metastatic colorectal cancer. Cetuximab should be administered in combination with irinotecan, but can be used as a single agent in patients who cannot tolerate irinotecan-based chemotherapy.

In a phase II study, patients with EGFR-expressing metastatic colorectal cancer who had demonstrated clinical failure on an irinotecan-based regimen received open label cetuximab, 400 mg/m² IV as a loading dose, followed by weekly infusions of 250 mg/m² IV until disease progression.¹²⁰ Of 57 patients treated, 5 achieved a partial response, with a minor response or stable disease developing in 21 additional patients. The median survival was 6.4 months. The most common grade 3 or 4 adverse events were acne-like skin rash (18% grade 3) and adverse effects characterized as asthenia, lethargy, malaise, or fatigue (9% grade 3).

The combination of cetuximab plus irinotecan was also compared to cetuximab as a single agent in patients with EGFR-positive colorectal cancer that had progressed on irinotecan. Three hundred and twenty-nine patients were randomized in a 2:1 ratio to receive cetuximab plus continuation of the irinotecan or cetuximab alone.⁹⁸ The objective tumor response rates, 22.9% and 10.8% with cetuximab plus irinotecan and cetuximab alone, respectively, were very encouraging, and resulted in the endorsement of cetuximab by the FDA via accelerated approval. Median survival was 8.6 months for the combination and 6.9 months with monotherapy ($p = 0.48$). Time to disease progression was significantly longer with cetuximab plus irinotecan compared to cetuximab alone (4.1 vs. 1.5 months; hazard ratio 0.54), even among patients who also had oxaliplatin-refractory disease. The incidence of grade 3 or 4 adverse effects was as anticipated based on previous trials; asthenia and acne-like rash occurred most commonly

with cetuximab alone, and in addition to typical irinotecan-related side effects (e.g., nausea, vomiting, and diarrhea) with combination treatment. Interestingly, there was no association between tumor response and intensity of EGFR-positive staining. Because patients who experienced disease progression on monotherapy were allowed to crossover to combination treatment, any difference in OS between the two groups would be difficult to ascertain.

Whether cetuximab adds benefit to oxaliplatin-based regimens or as part of initial therapy for metastatic colorectal cancer will depend on findings from ongoing studies. At present, there are no data that demonstrate increased survival or improvement in disease-related symptoms with cetuximab, but studies are attempting to address these end points. Nevertheless, cetuximab should be considered in patients with irinotecan- and oxaliplatin-refractory colorectal cancer. Immunohistochemical evidence of EGFR-positive staining should be obtained prior to initiating therapy.

■ **Miscellaneous Salvage Chemotherapy.** Similar to initial treatment of metastatic colon cancer, capecitabine is being investigated as a replacement for infusional fluorouracil in salvage regimens in combination with irinotecan or oxaliplatin. Initial results from small trials suggest that this will be a safe and effective way to treat refractory disease.

Other agents used as salvage therapy include mitomycin C in combination with continuous-infusion fluorouracil, which produced a higher response rate (54% vs. 38%) and significantly longer median failure-free survival (7.9 months vs. 5.4 months) with no decrease in quality of life, as compared to fluorouracil alone.¹²¹ Thus these agents may act synergistically with fluorouracil, particularly when it is administered as a continuous IV infusion, and these combinations deserve further study. Synergistic clinical activity between raltitrexed and fluorouracil has also been observed. Pilot studies of higher doses of single-agent raltitrexed and different treatment schedules of raltitrexed plus fluorouracil demonstrate modest activity as second-line therapy.

One interesting subject of debate is whether treatment could be suspended once disease stabilization occurs and restarted upon disease progression. In a small number of patients who achieved a partial response or disease stabilization with fluorouracil plus leucovorin, chemotherapy was discontinued and then restarted upon disease progression.¹²² Reinstitution of therapy resulted in partial tumor response and disease stabilization in 18% and 53% of patients, respectively. While the efficacy of this approach requires confirmation from randomized trials, these preliminary data support the inclusion of fluorouracil in salvage treatment regimens with other agents. Finally, patients who fail standard treatment for metastatic colorectal cancer should be encouraged to participate in a clinical trial evaluating new treatment approaches for this incurable disease.

■ **Hepatic-Directed Therapies.** Patients with hepatic-predominant disease whose disease progresses with systemic therapy may be candidates for HAI, chemoembolization, cryotherapy, or radiofrequency ablation. Percutaneous ethanol injection can be performed but is considered relatively ineffective against colorectal hepatic metastases.¹²³ Response rates to HAI therapy in patients who are refractory to fluorouracil-based therapy may be as high as 33%.¹²⁴ Although HAI has not been compared to IV irinotecan as second-line therapy, tumor response rates from historical data are similar. Future applications of HAI may include hepatic-targeted therapy with antiangiogenic factors, small molecules designed to interfere with molecular targets, or attenuated genetically modified viruses.

The largest experience with hepatic arterial chemoembolization has been seen in patients with metastatic carcinoid tumors or primary hepatocellular carcinomas. Most recently, small trials have been expanded to include hepatic metastases caused by colorectal cancer. Hepatic arterial chemoembolization delivers high concentrations of cytotoxic agents directly to the tumor and results in the embolization or devascularization of the liver, which blocks perfusion of the tumor and eliminates its blood supply. This procedure involves the instillation of a mixture that incorporates chemotherapeutic agents, radioactive contrast dye, and/or an embolic agent directly into the hepatic artery. Agents and doses most commonly studied include doxorubicin (40 to 60 mg), mitomycin (10 to 20 mg), and cisplatin (100 to 150 mg), which are usually dissolved in approximately 10 to 15 mL of a radiographic contrast dye.¹²⁵ Addition of an embolic agent to the mixture, such as a gelatin sponge (Gelfoam), polyvinyl alcohol particles, bovine collagen, or iodized poppy seed oil (Lipiodol and Ethiodol), results in either a temporary or permanent occlusion of the hepatic artery. Although about 80% of patients in one trial experienced a response, the number of patients with colorectal cancer who have undergone this procedure thus far is relatively low. In addition, patients still experience eventual disease progression. However, preliminary results from small series suggest that the high tumor responses may be associated with a survival benefit, and randomized trials comparing systemic therapy to hepatic chemoembolization for unresectable disease are ongoing.

Cryosurgery involves placement of a cryoprobe into the tumor, either percutaneously or intraoperatively, and then lowering the probe temperature to -100°C .¹²³ This is repeated in cycles, resulting in the formation of an ice ball; the ice crystal formation causes tumor destruction. Cryosurgery may be used alone or in conjunction with other localized procedures, such as radiofrequency ablation, which is becoming increasingly used for colorectal liver metastases. The technique involves placement of a chilled perfusion electrode needle into the tumor with subsequent application of alternating electrical current through the electrode, resulting in thermal coagulative necrosis of the tumor.¹²³ Laser interstitial thermal therapy represents an alternate method for causing tumor coagulative necrosis using a laser. Radiofrequency ablation is also being evaluated in conjunction with HAI, in an effort to reduce local recurrence of metastatic tumors. Procedure-related complications may include bleeding, coagulopathy, liver abscess, biliary stricture, and pleural effusion.¹²³ While these approaches represent potential treatment strategies for patients with unresectable, yet limited hepatic-only metastases, additional experience is needed to determine long-term outcomes. Furthermore, extrahepatic sites of disease continue to be a problem even for those individuals in whom the liver tumors can be eradicated. Thus far none of these approaches has become established as standard care.

■ NEW STRATEGIES AND AGENTS IN DEVELOPMENT

At present, fluorouracil plus leucovorin, bevacizumab, irinotecan, and oxaliplatin are the most frequently used chemotherapeutic agents for cancer of the colon and rectum. New chemotherapy agents have been studied in an attempt to further improve antitumor efficacy and reduce treatment toxicities. Oral fluorinated pyrimidines and TS inhibitors, such as fluorouracil prodrugs and inhibitors of fluorouracil catabolism, can prolong in vivo fluorouracil exposure and enhance antitumor effects without the use of continuous IV infusions. However, treatment with traditional chemotherapy agents, which target rapidly-dividing cells, kills both malignant and nonmalignant cells, and new cancer therapies are needed to improve therapeutic

outcomes. In particular, targeted therapies aimed at the underlying cancer pathology are increasingly being developed and utilized in colorectal cancer treatment. A variety of agents targeted toward augmenting the host immune system response have undergone or are currently undergoing study for colorectal cancer, including monoclonal antibodies and tumor vaccines. Another potential strategy is regulating tumor growth through the inhibition of cell signal transduction processes, including farnesyl transferase inhibitors or targeting overexpressed growth factor receptors such as EGFR. Agents that can alter microenvironmental factors that support angiogenesis and tumor metastases may also be of benefit. Table 127–12 lists the mechanism of action, adverse effects, and phase of development for selected investigational agents for colorectal cancer.

In addition, observations that various tumor characteristics (e.g., TS expression), patient drug-metabolizing enzymes (e.g., DPD and plasma uracil: dihydrouracil ratio), and molecular markers (e.g., chromosome 18q allelic loss, microsatellite instability, and *p53* muta-

tion or loss) may predict prognosis and response to certain therapies that lead to opportunities to select optimal first-line therapies for individual patients. Patients who are deficient in DPD experience severe and potentially life-threatening toxicities with conventional doses of fluorouracil. However, determination of DPD activity is relatively time-consuming and the techniques are not amenable to routine clinical practice. As an alternative, plasma ratio determinations of uracil and dihydrouracil, which are more easily obtainable, appear to identify individuals with DPD deficiency and who are therefore at risk of developing significant toxicities.¹²⁶ Of factors predictive for tumor sensitivity to fluorouracil, TS expression has been most studied.²⁸ Results from *in vitro* studies demonstrate that pretreatment intratumoral TS levels are inversely correlated to tumor response to fluorouracil. Whether increased tumor TS expression reflects a biologically more aggressive tumor or is directly related to fluorouracil resistance is unknown. Studies are underway to use this and other information to identify rational therapeutic approaches for select patients.

PHARMACOECONOMIC CONSIDERATIONS

The estimated costs of treating colorectal cancer in the United States alone exceeds 6.5 billion dollars per year.¹²⁷ The total cost for managing a patient with cancer of the colon is estimated to be approximately \$45,000 to \$61,000. Costs for patients with rectal cancer are approximately 15% higher because of the added expense of radiation therapy. These cost estimates are higher than estimated lifetime attributable costs for treating other common tumors such as cancer of the breast, prostate, and lung.¹²⁷ In addition, medical care costs vary, depending on the stage of disease. Medicare claims data reveal greater costs are incurred during the initial phase of care as compared to the terminal stage of disease. For all stages of disease, initial care accounted for approximately one-half of the long-term cancer-related cost, but the terminal phase of treatment also represents a high proportion of treatment costs.³¹ Thus a long-term approach is needed to accurately estimate the cost of treating patients diagnosed with colorectal cancer. In addition, higher costs are noted for treating early-stage disease. The average total Medicare payments for treating stage II and IV colorectal cancer is \$68,000 and \$36,000, respectively.¹²⁸ This relates to higher continuing care costs for stage II patients such as adjuvant therapy and surveillance of patients not needed in patients with metastatic disease. The impact of changes in clinical practice on treatment costs, such as increased use of adjuvant therapy, changes in duration of hospital stay and outpatient delivery of health services, and incorporation of costly agents into standard treatment regimens, must also be continually considered.

An evaluation of the cost-effectiveness of adjuvant therapy for stage III colon cancer determined that 12 months of adjuvant therapy of fluorouracil plus levamisole resulted in 1.88 years of life-years gained for each treated patient, and a cost-effectiveness ratio of \$2094 per life-year saved.¹²⁹ However, a more accurate estimate of cost-effectiveness of current adjuvant therapy will need to evaluate 6-month courses of fluorouracil plus leucovorin and consider patients with both stage III and high-risk stage II disease.

The cost-effectiveness of therapeutic regimens in the metastatic setting has also been calculated. The combination of both infusional and bolus irinotecan plus fluorouracil and leucovorin have been compared to fluorouracil plus leucovorin alone.¹³⁰ Results have varied depending on second-line therapies evaluated and have ranged from approximately \$22,000 to \$50,000 per life-year gained. In one trial

the irinotecan group had an incremental cost of \$8341 per patient. The relationships between costs associated with newer drugs on treatment outcomes, especially agents such as bevacizumab and cetuximab, will need to be considered, especially as they have become incorporated into standard care therapies.

Although several investigations have evaluated cost-effectiveness of various screening procedures, published data regarding costs associated with colorectal cancer prevention are not currently available. In a recent cost-effectiveness analysis, assuming a 75% compliance rate with the screening procedure, the incremental cost effectiveness of combined sigmoidoscopy and fecal occult blood testing compared with colonoscopy performed twice-lifetime (at the ages of 50 and 60) was approximately \$330,000 and \$42,000 per life-year gained, respectively.¹³¹ The cost benefit for twice-lifetime colonoscopy remained when calculations were performed on compliance estimates ranging from 25% to 100%. In addition, a separate comparison of the cost-effectiveness of fecal occult blood testing, flexible sigmoidoscopy, and colonoscopy found colonoscopy to be the most cost-effective screening strategy when performed every 10 years. These evaluations are sensitive to the impact of uncertainty about actual compliance rates in different clinical practice settings, which must be considered in the interpretation of these data. Most accepted screening strategies, however, have cost-effectiveness ratios that are well below the accepted benchmark of \$50,000 per life-year saved.¹²⁷ Overall, when compared to other commonly accepted screening modalities, colon cancer screening is cost-effective. The incremental cost for screening is \$6600 per year of life saved, compared to breast cancer screening at \$22,000 per year of life gained.

EVALUATION OF THERAPEUTIC OUTCOMES

The goal of monitoring is to evaluate whether the patient is receiving any benefit from the management of the disease or to detect recurrence. Similarly, follow-up examinations help to determine whether preventive interventions or screening studies effectively reduce an individual's risk for developing colorectal cancer or presenting with an advanced stage of disease. During treatment for active disease, patients should undergo monitoring for measurable tumor response, progression, or new metastases; these tests may include chest CT scans

or x-rays, abdominal or pelvic CT scans or x-rays, depending on the site of disease being evaluated for response, and CEA measurements every 3 months if the CEA is or was previously elevated. In addition, a CBC should be obtained prior to each course of chemotherapy administration to ensure that hematologic indices are adequate. Baseline liver function tests and an assessment of renal function should be evaluated prior to and periodically during therapy. These tests and other selected serum chemistries should also be evaluated with the development of any new symptoms or significant change in disease status. Patients should be evaluated during every treatment visit for the presence of anticipated side effects, which generally include loose stools or diarrhea, nausea or vomiting, mouth sores, fatigue, and fever, as well as other side effects such as neuropathy and skin rash that are typically associated with oxaliplatin and cetuximab, respectively. Patients receiving bevacizumab should be evaluated for hypertension and proteinuria.

Symptoms of recurrence such as pain syndromes, changes in bowel habits, rectal or vaginal bleeding, pelvic masses, anorexia, and weight loss develop in fewer than 50% of patients. A greater percentage of recurrences are detected in asymptomatic patients because of increased serum CEA levels that lead to further examination. Although the value of CEA monitoring for asymptomatic disease recurrence is questioned by some because of the related expense and emotional stress associated with false-positive elevations, CEA monitoring plays an important role in postoperative follow-up studies for most individuals. A PET scan can be considered to identify localized sites of metastatic disease in situations in which a rising CEA level suggests metastatic disease, but CT scans and other imaging studies are negative.

Patients who undergo curative surgical resection, with or without adjuvant therapy, require close follow-up based on the premise that early detection and treatment of recurrence could still render them cured. In addition, early treatment for asymptomatic metastatic colorectal cancer appears superior to delayed therapy. Specific practice guidelines for postoperative surveillance examinations have been developed by the NCCN (Table 127–16). Colorectal cancer surveillance guidelines published by the American Society of Clinical Oncology recommend against routinely monitoring liver function tests, CBC, fecal occult blood testing, CT scans, annual chest x-rays, or pelvic imaging in asymptomatic patients.¹³²

Table 127-16 is not available in digital format.

Recent advances in the treatment for cancer of the colon and rectum now offer the potential to improve patient survival but for many patients, improved disease- and progression-free survival represent equally important therapeutic outcomes. Table 127–15 depicts the NCCN Practice Guidelines for chemotherapy for advanced or metastatic colorectal cancer. Although treatment approaches for metastatic colorectal cancer have been historically assessed by their ability to produce a measurable objective tumor response, which is generally believed necessary for any treatment to improve survival, the effects of therapies on survival are clinically more meaningful than their ability to induce a tumor response. However, with the availability of multiple active treatments for metastatic disease, and the likelihood that patients will receive more than one during the course of their treatment, improvements in OS with new therapies will be increasingly difficult to determine.

In the absence of the ability of a specific treatment to demonstrate improved survival, important outcome measures should include the effects of the treatment on patient symptoms, daily activities and performance status, and other quality-of-life indicators, as well as progression-free survival and time to treatment failure. Because metastatic colorectal cancer is incurable, a specific decision regarding an individual patient's care will ultimately be required; this should be based on a careful assessment of the balance between risks associated with treatment (or lack thereof) and benefits of treatment. Effort should also be made to ensure that the costs of screening, diagnostic tests, treatments, and procedures for colorectal cancer are consistent with their value in improving patient outcomes.

KEY CONCEPTS

- 1 Prostate cancer is the most frequent cancer in U.S. men. African-American ancestry, family history, and increased age are the primary risk factors for prostate cancer.
- 2 Prostate-specific antigen is a useful marker for detecting prostate cancer at early stages, predicting outcome for localized disease, defining disease-free status, and monitoring response to androgen-deprivation therapy or chemotherapy for advanced-stage disease.
- 3 The prognosis for prostate cancer patients depends on the histologic grade, the tumor size, and disease stage. More than 85% of patients with stage A₁ disease but less than 1% of those with stage D₂ can be cured.
- 4 Androgen ablation with a luteinizing hormone–releasing hormone (LH-RH) agonist plus an antiandrogen should be used prior to radiation therapy for patients with locally advanced prostate cancer to improve outcomes over radiation therapy alone.
- 5 Androgen ablation therapy, with either orchiectomy, an LH-RH agonist alone or an LH-RH agonist plus an antiandrogen (combined hormonal blockade), can be used to provide palliation for patients with advanced (stage D₂) prostate cancer. The effects of androgen deprivation seem most pronounced in patients with minimal disease at diagnosis.
- 6 Antiandrogen withdrawal, for patients having progressive disease while receiving combined hormonal blockade with an LH-RH agonist plus an antiandrogen, can provide additional symptomatic relief. Mutations in the androgen receptor have been documented that cause antiandrogen compounds to act like receptor agonists.
- 7 Chemotherapy, with docetaxel and prednisone, improve survival in patients with hormone-refractory prostate cancer. Patients with hormone-refractory prostate cancer should be considered for entry into clinical trials investigating new therapies for prostate cancer.

1 Prostate cancer is the most frequent cancer among American men and represents the second leading cause of cancer-related deaths in all males.¹ In the United States alone, it is estimated that 232,090 new cases of prostatic carcinoma will be diagnosed and more than 30,350 men will die from this disease in 2005.¹ Although prostate cancer incidence increased during the late 1980s and early 1990s owing to widespread prostate-specific antigen (PSA) screening, deaths from prostate cancer have been continuously declining since 1995.¹

Localized prostate cancer can be cured by surgery or radiation therapy, but advanced prostate cancer is not yet curable. Treatment for advanced prostate cancer can provide significant disease palliation for many patients for several years after diagnosis. The endocrine dependence of this tumor is well documented, and hormonal manipulation to decrease circulating androgens remains the basis for the treatment of advanced disease.

EPIDEMIOLOGY

1 Table 128–1 summarizes the possible factors associated with prostate cancer.^{2,3} The only widely accepted risk factors for prostate cancer are age, race-ethnicity, and family history of prostate cancer.³ The disease is rare under the age of 40, but the incidence sharply increases with each subsequent decade, most likely because

the individual has had a lifetime exposure to testosterone, a known growth signal for the prostate.³

RACE AND ETHNICITY

The incidence of clinical prostate cancer varies across geographic regions. Scandinavian countries and the United States report the highest incidence of prostate cancer, while the disease is relatively rare in Japan and other Asian countries.⁴ African-American men have the highest rate of prostate cancer in the world, and in the United States, prostate cancer mortality in African-Americans is more than twice that seen in Caucasian populations.¹ Hormonal, dietary, and genetic differences, as well as differences in access to health care may contribute to the altered susceptibility to prostate cancer in these populations.³ Testosterone, commonly implicated in the pathogenesis of prostate cancer, is 15% higher in African-American men compared with Caucasian males. Activity of 5- α -reductase, the enzyme that converts testosterone to its more active form, dihydrotestosterone (DHT), in the prostate, is decreased in Japanese men compared with African-Americans and Caucasians.³ In addition, genetic variations in the androgen receptor exist. Activation of the androgen receptor is inversely correlated with CAG repeat length. Shorter CAG repeat sequences have been found in African-Americans. Therefore the combination of increased testosterone and increased androgen receptor

TABLE 128–1. Risk Factors Associated with Prostate Cancer

| Factor | Possible Relationship |
|------------------------------|--|
| Probable risk factors | |
| Age | More than 70% of cases are diagnosed in men greater than 65 years old |
| Race | African-Americans have higher incidence and death rate |
| Genetic | Familial prostate cancer inherited in an autosomal dominant manner Mutations in <i>p53</i> , <i>Rb</i> , E-cadherin, α -catenin, androgen receptor, <i>KAI1</i> , microsatellite instability, loss of heterozygosity at 1, 2q, 12p, 15q, 16p, and 16q Candidate prostate cancer gene locus identified on chromosome 1 |
| Possible risk factors | |
| Environmental | Clinical carcinoma incidence varies worldwide Latent carcinoma similar between regions Nationalized males adopt intermediate incidence rates between that of the United States and their native country |
| Occupational | Increased risk associated with cadmium exposure |
| Diet | Increased risk associated with high-meat and high-fat diets Decreased intake of 1,25-dihydroxyvitamin D, vitamin E, lycopene, and β -carotene increases risk |
| Hormonal | Does not occur in eunuchs Low incidence in cirrhotic patients Up to 80% are hormonally dependent African-Americans have 15% increased testosterone Japanese have decreased 5- α -reductase activities Polymorphic expression of the androgen receptor |

Compiled from Carter et al,² Hsieh et al,³ and Ross et al.⁴

activation may account for the increased risk of prostate cancer for African-American men.³ The Asian diet generally is considered to be low in fat and high in fiber with a high concentration of phytoestrogens. Phytoestrogens, consisting of isoflavonoids, flavonoids, and lignans, are potential chemoprotectants.⁵ Combining the protection from a low-fat diet with decreased DHT activity may explain the decreased risk of prostate cancer found in Asian men. A positive family history for prostate cancer is associated with a two- to threefold risk elevation. Three other factors, the age of the man at risk, the age of the affected relative, and the number of relatives diagnosed with prostate cancer, modify the magnitude of the excess risk. In general, younger age (<65) of the man at risk, younger age of affected relatives, and increased number of relatives with prostate cancer increase the risk of prostate cancer beyond two- to threefold.³

FAMILY HISTORY

Carter and colleagues² have demonstrated that familial clustering of prostate cancer can be explained by Mendelian inheritance of a rare autosomal dominant allele, which accounts for 9% of all prostate cancer and 45% of disease reported in men under the age of 55.² Genome-wide scans have identified potential prostate cancer susceptibility loci on chromosomes 1, 2q, 12p, 15q, 16p, and 16q; however,

none of these susceptibility loci have demonstrated linkage to currently known candidate genes.⁶

An alternative explanation for the familial clustering may be polymorphisms in genes important for prostate cancer function and development.⁶ Candidate polymorphisms include a polymorphism in the androgen receptor, which has two different nucleotide repeat variants, the CAG or the GCC. The CAG repeat varies in repeat number from 11 to 31 repeats in healthy individuals, and the number of repeats is inversely proportional to the activity of the androgen receptor. Some studies have demonstrated that shorter CAG repeats are associated with increased prostate cancer risk. Another candidate polymorphism is SRD5A2, which is the gene that codes for 5- α -reductase, the enzyme that converts testosterone to the more active dihydrotestosterone. A variant in SRD5A2, the Ala49Thr, increases the activity and may increase prostate cancer risk.⁶

DIET

A number of epidemiologic studies support an association between high fat intake and risk of prostate cancer. A strong correlation between national per capita fat consumption and national prostate cancer mortality has been reported, and prospective case-control studies suggest that a high-fat diet doubles the risk of prostate cancer.

Other dietary factors implicated in prostate cancer include retinol, carotenoids, lycopene, and vitamin D consumption.^{6,7} Retinol, or vitamin A, intake, especially in men older than 70, is correlated with an increased risk of prostate cancer, whereas intake of its precursor, β -carotene, has a protective or neutral effect. Lycopene, obtained primarily from tomatoes, decreases the risk of prostate cancer in small cohort studies. The antioxidant vitamin E also may decrease the risk of prostate cancer. Men who developed prostate cancer in one cohort study had lower levels of 1,25(OH)₂-vitamin D than matched controls, although a prospective study did not support this.³ Clearly, dietary risk factors require further evaluation, but because fat and vitamins are modifiable risk factors, dietary intervention may be promising in prostate cancer prevention.

OTHER FACTORS

Benign prostatic hyperplasia (BPH) is one of the most common problems of elderly men, affecting more than 40% of men over the age of 70. BPH results in the urinary symptoms of hesitancy and frequency. Since prostate cancer affects a similar age group and often has similar presenting symptoms, the presence of BPH often complicates the diagnosis of prostate cancer, although it does not appear to increase the risk of developing prostate cancer.^{3,6}

Smoking has not been associated with an increased risk of prostate cancer, but smokers with prostate cancer have an increased mortality resulting from the disease when compared with nonsmokers with prostate cancer (relative risk 1.5 to 2).^{3,6} In addition, in a prospective cohort analysis, alcohol consumption was not associated with the development of prostate cancer.

ETIOLOGY

The growth and development of the prostate is under control of androgens and it is well known that men who undergo castration prior to puberty do not develop prostate cancer. The majority of risk factors for prostate cancer are factors that either increase or decrease testosterone exposure. Despite this, serum testosterone or DHT

levels obtained at diagnosis are not directly associated with prostate cancer risk, suggesting a multifactorial cause of prostate cancer.⁶

PATHOPHYSIOLOGY

MOLECULAR GENETICS

As described in the epidemiology section, a familial association in prostate cancer has been recognized and generally is accepted to be genetically determined, although the precise genetic mutation of polymorphism has not been identified. In addition, a number of genes are mutated in sporadic cases of prostate cancer, although the relative contribution and interrelationship of these genes are still unknown.

E-cadherin gene inactivation via hypermethylation has been reported frequently in prostate cancer.⁶ E-cadherin is a prognostic marker in prostate cancer, with aberrant E-cadherin expression associated with high-grade tumors and poor outcome in terms of disease progression and overall survival.⁶ P-cadherin expression is absent in most prostate cancers, but in prostate cancers where P-cadherin is expressed, PSA is characteristically absent. The cadherin-catenin pathway may be inactivated by gene mutations or hypermethylation, and is thought to be an early event in prostate carcinogenesis.

In cells with DNA damage, *p53* is thought to function by halting cell-cycle progression, resulting in cell death via apoptotic pathways. The loss of functional *p53* may result in replication of damaged DNA and subsequently unregulated cell growth. Point mutations in *p53* thought to be caused by environmental toxins have been identified in 42% of prostate carcinomas. Mutations were present in stages B to D, although not in latent prostate carcinomas studied.⁸ *Rb* mutations, also thought to be important in cell-cycle regulation, have been reported in prostate cancer patients.⁶ Abnormal *p53* and *Rb*, as measured by immunohistochemistry, may be independent predictors of survival. In one study,⁹ 15-year survival was 38% in patients with abnormal *p53* compared with 87% for those with normal *p53*. Aberrant *p53* also predicts radiation failure and is mutated in approximately 60% of metastatic bone marrow lesions.¹⁰

KAI1, or *Kang ai*, which is Chinese for anticancer, is an antimetastatic gene. The gene codes for a protein belonging to a family of leukocyte surface glycoproteins that function in cell-cell interactions and cell-extracellular matrix interactions and that is downregulated, without mutation, during the progression of prostate cancer.¹¹

As of the most recent update, there are 374 different reported mutations in the androgen receptor gene.¹² Mutations in the androgen receptor gene appear to occur more frequently in advanced and hormone-refractory prostate cancer.¹² Mutated androgen receptors may be activated not only by testicular androgens, but also by several androgens, steroids, and nonsteroidal antiandrogens, promoting subsequent prostate cancer growth. Androgen receptor mutations are speculated to explain the antiandrogen withdrawal syndrome.¹³

An additional hormonal mechanism may be mutation in 5- α -reductase, the enzyme responsible for converting testosterone to active DHT. In one series, mutations were identified in 57% of prostate cancer patients.¹⁴ While the function of the mutated enzyme has not been identified, it is hypothesized to be an activation, where increased amounts of DHT are formed. A significant number of latent prostatic carcinomas in Japanese men contain an inactivating mutation in the androgen receptor, whereas no such mutations were found in latent carcinomas of white American men.¹⁵ It appears that the stage in which an androgen receptor mutation occurs (latent versus metastatic), as well as the functional significance of the mutation, can alter the clinical course of prostate cancer. Additional genetic analysis

has identified mutations in *H-ras* in less than 4% of American prostate carcinomas and up to 25% of Japanese carcinomas. Mutations in late-stage clinical carcinoma were identified in *Ha-ras*; however, latent prostate carcinoma had mutations in *K-ras*, possibly indicating a protective mutation.³

Although the molecular characterization of prostate cancer is evolving, this area of study represents a major advance in our understanding of disease pathology and may represent future avenues for diagnosis, staging, and treatment of prostate cancer.

PATHOLOGY

The normal prostate is composed of acinar secretory cells arranged in a radial shape and surrounded by a foundation of supporting tissue. The size, shape, or presence of acini is almost always altered in the gland that has been invaded by prostatic carcinoma. Adenocarcinoma, the major pathologic cell type, accounts for more than 95% of prostate cancer cases.¹⁶ Much rarer tumor types include small cell neuroendocrine cancers, sarcomas, and transitional cell carcinomas.

Prostate cancer can be graded systematically according to the histologic appearance of the malignant cell and then grouped into well, moderately, or poorly differentiated grades.¹⁷ Gland architecture is examined and then rated on a scale of 1 (well differentiated) to 5 (poorly differentiated). Two different specimens are examined, and the score for each specimen is added. Groupings for total Gleason score are 2 to 4 for well-differentiated, 5 or 6 for moderately-differentiated, and 7 to 10 for poorly differentiated tumors. Poorly differentiated tumors grow rapidly (poor prognosis), while well differentiated tumors grow slowly (better prognosis).

Metastatic spread can occur by local extension, lymphatic drainage, or hematogenous dissemination.¹⁸ Lymph node metastases are more common in patients with large, undifferentiated tumors that invade the seminal vesicles. The pelvic and abdominal lymph node groups are the most common sites of lymph node involvement (Fig. 128–1). Skeletal metastases from hematogenous spread are the most common sites of distant spread. Typically, the bone lesions are osteoblastic or a combination of osteoblastic and osteolytic. The most common site of bone involvement is the lumbar spine. Other sites of bone involvement include the proximal femurs, pelvis, thoracic spine,

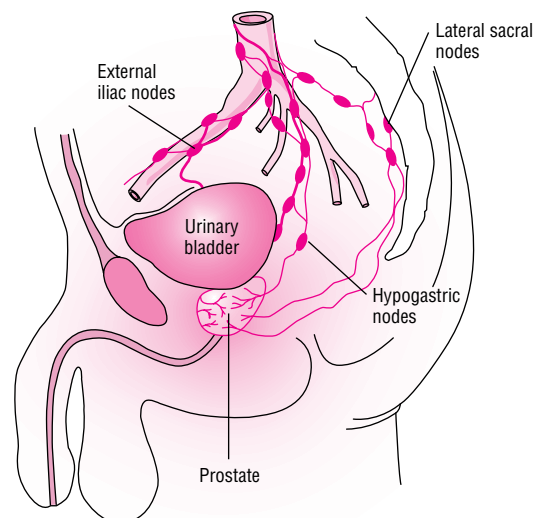

FIGURE 128–1. The prostate gland.

ribs, sternum, skull, and humerus. The lung, liver, brain, and adrenal glands are the most common sites of visceral involvement, although, these organs usually are not involved initially. About 25% to 35% of patients will have evidence of lymphangitic or nodular pulmonary infiltrates at autopsy. The prostate is a rare site for metastatic involvement from other solid tumors.

RATIONALE FOR HORMONAL MANAGEMENT

The prostate gland is a solid, rounded, heart-shaped organ positioned between the neck of the bladder and the urogenital diaphragm (see Fig. 128-1). The organ consists of single anterior, posterior, and median lobes and two lateral lobes. The posterior lobe is palpable by anterior rectal examination at 2 to 5 cm from the anal verge. Within the four morphologically defined areas of the prostate gland, 95% of the carcinomas arise from the glandular epithelium of the peripheral zone.¹⁸ In contrast, BPH arises from the central or periurethral regions of the prostate gland.

Normal growth and differentiation of the prostate depends on the presence of androgens, specifically DHT.¹⁹ The testes and the adrenal glands are the major sources of circulating androgens. Hormonal regulation of androgen synthesis is mediated through a series of biochemical interactions between the hypothalamus, pituitary, adrenal glands, and testes (Fig. 128-2). Luteinizing hormone-releasing hormone (LH-RH) released from the hypothalamus stimulates the release of luteinizing hormone (LH) and follicle-stimulating hormone (FSH) from the anterior pituitary gland. LH complexes with receptors on the Leydig cell testicular membrane and stimulates the production of testosterone and small amounts of estrogen. FSH acts on the Sertoli cells within the testes to promote the maturation of LH receptors and to produce an androgen-binding protein. Circulating testosterone and estradiol influence the synthesis of LH-RH, LH, and FSH by a negative feedback loop operating at the hypothalamic and pituitary level.²¹

^bInvestigational compounds or use.

LH, luteinizing hormone; LH-RH, luteinizing hormone-releasing hormone.

Prolactin, growth hormone, and estradiol appear to be important accessory regulators for prostatic tissue permeability, receptor binding, and testosterone synthesis.

Testosterone, the major androgenic hormone, accounts for 95% of the androgen concentration. The primary source of testosterone is the testes; however, 3% to 5% of the testosterone concentration is derived from direct adrenal cortical secretion of testosterone or C19 steroids such as androstenedione.^{18,19}

Only 2% of total plasma testosterone is present in the physiologically active unbound state. The remaining testosterone is reversibly bound to a steroid hormone-binding globulin. The unbound testosterone or androgen precursors penetrate the prostatic cell by passive diffusion and are converted to DHT by 5- α -reductase.^{18,19} DHT subsequently binds with a specific cytoplasmic receptor. This DHT-receptor complex is then transported to the nucleus of the cell, where transcription and ultimately translation of stored genetic material occur.^{18,19}

Huggins and Hodges²⁰ observed that both normal and malignant prostatic tissue contains a high level of acid phosphatase, suggesting that prostatic malignancy represents an overgrowth of prostate tissue. They then demonstrated that a decrease in serum acid phosphatase along with symptomatic relief occurred in patients with metastatic prostate cancer treated with either estrogens or orchiectomy therapies known to reduce circulating androgens.²⁰ Androgen ablation is used in the treatment and palliation of advanced prostate cancer because prostatic epithelium undergoes atrophy when the normal physiologic effect of androgens is reduced.⁸

Hormonal manipulations to ablate or reduce circulating androgens can occur through several mechanisms^{18,19} (Table 128-2). The organs responsible for androgen production can be removed surgically (orchiectomy, hypophysectomy, or adrenalectomy). Hormonal pathways that modulate prostatic growth can be interrupted at several steps (see Fig. 128-2). Interference with LH-RH or LH can reduce testosterone secretion by the testes (estrogens, LH-RH agonists, progestogens, and cyproterone acetate). Estrogen administration reduces androgens by directly inhibiting LH release, by acting directly on the prostate cell, or by decreasing free androgens by increasing steroid-binding globulin levels.^{18,19}

Isolation of the naturally occurring hypothalamic decapeptide hormone luteinizing hormone-releasing hormone or LH-RH has provided another group of effective agents for advanced prostate cancer treatment.²⁰ The physiologic response to LH-RH depends on both the dose and the mode of administration. Intermittent pulsed LH-RH

administration, which mimics the endogenous release pattern, causes sustained release of both LH and FSH, whereas high-dose or continuous intravenous administration of LH-RH inhibits gonadotropin release due to receptor downregulation.²¹ Structural modification of the naturally occurring LH-RH and innovative delivery have produced a series of LH-RH agonists that cause a similar downregulation of pituitary receptors and a decrease in testosterone production.²¹

Androgen synthesis can be inhibited in the testes or in the adrenal gland. Aminoglutethimide inhibits the desmolase-enzyme complex in the adrenal gland, thereby preventing the conversion of cholesterol to pregnenolone. Pregnenolone is the precursor substrate for all adrenal-derived steroids, including androgens, glucocorticoids, and mineralocorticoids.²² Ketoconazole, an imidazole antifungal agent, causes a dose-related reversible reduction in serum cortisol and testosterone concentration by inhibiting both adrenal and testicular steroidogenesis.^{22,23} As a secondary mechanism to its antiandrogen action, megestrol acetate inhibits the synthesis of androgens. This inhibition appears to occur at the adrenal level, but circulating levels of testosterone also are reduced, suggesting that inhibition at the testicular level also may occur.²²

Antiandrogens inhibit the formation of the DHT-receptor complex and thereby interfere with androgen-mediated action at the cellular level.²³ Megestrol acetate, a progestational agent, also is available and has antiandrogen actions.²² Finally, the conversion of testosterone to DHT may be inhibited by 5- α -reductase inhibitors.²⁴

CLINICAL PRESENTATION

Whereas prostatic carcinoma may be asymptomatic in patients with localized disease, most patients with signs and symptoms have advanced disease at presentation. In patients with locally invasive disease, the most common complaints arise from ureteral dysfunction or impingement. Patients complain of alterations in micturition manifested by urinary frequency, hesitancy, and dribbling.^{16,17,25} New onset impotence or less firm penile erections in an elderly male may indicate prostate cancer.

Most commonly, patients with advanced disease present with back pain and stiffness due to osseous metastases.²⁵ Eventually, spinal cord lesions may lead to cord compression if not treated properly.²⁵ Rarely, pathologic fractures can occur. Lower extremity edema can occur as a result of lymphatic obstruction. Anemia and weight loss are nonspecific signs of advanced disease.

CHEMOPREVENTION

Considerable interest in preventing prostate cancer exists and several large chemoprevention trials are sponsored and ongoing by the National Cancer Institute. The first large chemoprevention trial in prostate cancer, the Prostate Cancer Prevention Trial (PCPT), began in 1993 and randomized 18,881 men older than 55 years with a low risk of prostate cancer (PSA = 3 ng/mL) to receive 5 mg finasteride daily (a 5- α -reductase inhibitor) or placebo to determine if inhibition of DHT synthesis in the prostate for a prolonged period (7 years) would lead to a decreased incidence of prostate cancer.²⁴ Finasteride is currently used in the treatment of BPH.

The results of the PCPT were recently published, and confirmed the efficacy of finasteride in reducing the rate of acute urinary retention, the need for surgery for symptomatic BPH, and a reduced risk of progression of BPH. In addition, finasteride demonstrated a 24.8% reduction in prostate cancer prevalence during the 7-year period. Another way of looking at these results is the number needed to treat to prevent one prostate cancer. With a prostate cancer incidence of 6.3% in the finasteride and 8.7% in the placebo arm, the absolute reduction is 2.4%, giving a number needed to treat to prevent one cancer of 41. However, tumors in the treated group had a higher Gleason score, suggesting more aggressive disease compared to the placebo group for all men in whom prostate cancer developed during the study period, and it is too early to evaluate survival end points. So, while we now know that finasteride reduces the risk of prostate cancer development, whether it improves survival is still open to question.²⁴

CLINICAL CONTROVERSY

Prevention of prostate cancer with finasteride is controversial. In a recently completed trial comparing finasteride to placebo, those receiving finasteride had fewer prostate cancers, but those that developed were more aggressive. The effects of finasteride on survival are still unknown.

Therefore, the use of finasteride to prevent prostate cancer is currently under debate.²⁶ Because of its established benefit in treating BPH, the 20% to 30% of men over 50 with BPH may derive the additional benefit of prostate cancer prevention and should be offered treatment with finasteride. In the 70% to 80% of men without BPH, the benefits, side effects (primarily impotence), and risks of finasteride should be discussed prior to initiating therapy.

Selenium is a naturally occurring trace element that is an essential nutrient in the human diet. A large randomized clinical trial designed to examine skin cancer prevention first suggested that selenium has a beneficial effect in the prevention of prostate cancer.²⁷ The Alpha-Tocopherol Beta-Carotene Cancer Prevention Study conducted in Finland reported a 34% decrease in the incidence of prostate cancer in subjects receiving α -tocopherol (a form of vitamin E) compared with the placebo group. These results, in addition to previous data, prompted a second large-scale chemoprevention trial of prostate cancer. SELECT²⁸ is a phase III trial to determine whether selenium and/or vitamin E decreases the incidence of prostate cancer in healthy men. This trial, initiated by the National Cancer Institute in 2001 and with final results anticipated in 2013, is expected to shed more light on the role of these agents in the prevention of prostate cancer. Until results are available, supplementation with selenium or vitamin E for primary prevention of prostate cancer is not recommended.

SCREENING METHODS

Since prostate cancer is not curable in advanced stages, prevention efforts are under intensive evaluation. Early detection of potentially curable prostate cancers is the goal of prostate cancer screening. For cancer screening to be beneficial, it must reliably detect cancer at an early stage, when intervention would decrease mortality. Whether prostate cancer screening fits these criteria has generated considerable controversy.²⁹ Evidence from randomized clinical trials addressing whether screening reduces prostate cancer mortality may not be available for 10 to 15 years. In the interim, clinicians are faced with the dilemma of whether to screen or not to screen, as well as how best to treat early-stage prostate cancer.

DIGITAL RECTAL EXAMINATION

Digital rectal examination (DRE) has been recommended since the early 1900s for the detection of prostate cancer. The primary advantage of DRE is its specificity, reported at greater than 85%, for prostate cancer. Other advantages of DRE include low cost, safety, and ease of performance. However, DRE is relatively insensitive and is subject to interobserver variability. DRE as a single screening method has poor compliance and has had little effect on preventing metastatic prostate cancer in one large case-control study.³⁰

PROSTATE-SPECIFIC ANTIGEN

PSA is a prostate-specific glycoprotein produced only in the cytoplasm of benign and malignant prostate cells.³¹ PSA functions as a serine protease, which liquefies seminal fluid after ejaculation. In addition to its biologic activity, PSA also may enhance cellular growth by its ability to cleave insulin-like growth factor-binding proteins. Cleavage activates insulin-like growth factor (IGF), which can then bind to IGF receptors and stimulate growth in the prostate.³¹

Unlike acid phosphatase, PSA levels are not influenced by ambient conditions or subject to diurnal variation, but are influenced by sedentary conditions. Therefore it is recommended that all PSA measurements be made on sera collected from ambulatory patients. PSA levels not only rise with prostatic manipulation such as transrectal ultrasound (TRUS) and/or biopsy, but also remain above normal for several weeks thereafter. PSA has a serum half-life of 2 to 3 days.³¹

PSA is used widely for prostate cancer screening in the United States, with simplicity its major advantage and low specificity its primary limitation.³² PSA may be elevated in men with acute urinary retention, acute prostatitis, and prostatic ischemia or infarction, as well as BPH, a nearly universal condition in men at risk for prostate cancer. PSA elevations between 4.1 and 10 ng/mL cannot distinguish between BPH and prostate cancer, limiting the utility of PSA alone for the early detection of prostate cancer. Additionally, only 38% to 48% of men with clinically significant prostate cancer have a serum PSA outside the reference range.³¹

Neither DRE nor PSA is sensitive or specific enough to be used alone as a screening test.³¹ Although the relative predictability of DRE and PSA is similar, the tumors identified by each method are different. Catalona and associates³³ confirmed that the combination of a DRE plus PSA determination is a better method of detecting prostate cancer than DRE alone.

Efforts to increase PSA specificity include the use of free PSA measurements, age- and race-specific PSA levels, PSA density, and PSA velocity.^{31,32}

CURRENT SCREENING RECOMMENDATIONS

The common approach to prostate cancer screening today involves offering PSA measurements beginning at age 50 to all men of normal risk with a 10-year or greater life expectancy.

CLINICAL CONTROVERSY

Prostate cancer screening is controversial. Increased screening has led to an increased incidence of early-stage prostate cancer for which the most appropriate management is still unknown. Prostate cancer screening has not been shown to improve survival. However, the American Cancer Society currently recommends that digital rectal examination and PSA be offered annually to men beginning at age 50 years with at least a 10-year life expectancy, and to younger men (45 years old) who are considered to be at high risk for prostate cancer development (strong familial predisposition or African-American).

Despite this common practice, the benefits of prostate cancer screening are unproven. PSA measurements can identify small, subclinical prostate cancers, where no intervention may be required. Detecting prostate cancer in those not needing therapy not only increases the cost of care through unnecessary screening and work-ups, but also increases the toxicity of therapy, by subjecting some patients to unnecessary therapy.³⁴ Currently, the American College of Physicians recommends that rather than screening all men for prostate cancer as a matter of routine, physicians should describe the potential benefits and known risks of screening, diagnosis, and treatment, listen to the patient's concerns, and then decide on an individual's screening method. In a randomized, controlled trial of an educational videotape describing the advantages and disadvantages of prostate cancer screening, patients who viewed the videotape had an increase of 78% ($p = .001$) in prostate cancer knowledge and a decrease of 18.5% ($p = .009$) in requests for screening over control patients.³⁵ The American Cancer Society (ACS) currently recommends that DRE and PSA be offered annually to men beginning at age 50 years with at least a 10-year life expectancy and to younger men (45 years old) who are considered to be at high risk for prostate cancer development (strong familial predisposition or African-American). The ACS defines an abnormal PSA value to be above 4 ng/mL. If both tests are normal, no further diagnostic action is required; however, if either is abnormal, further work-up by TRUS is indicated.

Two ongoing national randomized trials will provide important data to help resolve the prostate cancer screening controversies. The first is the Prostate, Lung, Colon, and Ovarian Trial, which is designed to test the efficacy of prostate cancer screening in 74,000 men aged 60 to 74.³¹ The second is the Prostate Cancer Intervention Versus Observation Trial, which is a randomized study comparing radical prostatectomy with expectant management.³⁶ These trials, when complete, likely will provide key information regarding the costs and benefits of prostate cancer screening and the most appropriate early management.

DIAGNOSIS

Transperianal or transrectal prostate biopsy is necessary to confirm a prostate cancer diagnosis and to grade the tumor specimen. TRUS-guided biopsies of hypoechoic areas may help define extraprostatic extension.³⁷ For patients with visceral or lytic metastases, these lesions may be biopsied, because this presentation is common for one

TABLE 128–3. Diagnostic and Staging Work-Up for Prostate Cancer

of the variant histologies (small cell neuroendocrine) that requires a treatment strategy different from that for adenocarcinomas.³⁷

Table 128–3 summarizes the diagnostic staging work-up. When DRE is performed, prostatic carcinoma is classically characterized by a rock-hard nodule or mass in the gland, whereas the gland is smooth and rubbery in BPH.

STAGING

The information obtained from the diagnostic tests is used to stage the patient. There are two commonly recognized staging classification systems (Table 128–4). The formal international classification system (tumor, node, metastases; TNM), adopted by the International Union Against Cancer in 1974, was updated in 1992 in an effort to provide congruence with the classical American Urologic System (AUS) staging system for prostate cancer.³⁸ The AUS classification is the most commonly used staging system in the United States (see Table 128–4). Patients are assigned to stages A through D and corresponding subcategories based on size of the tumor (T), local or regional extension, presence of involved lymph node groups (N), and presence of metastases (M).³⁸ Some studies classify patients who have progressed after hormonal therapy as stage D₃.³⁸ Based on men diagnosed with prostate cancer at Walter Reed Army Medical Center from 1988 to 1998, including over 2042 prostate cancer diagnoses, localized prostate cancer (stage T₁ and T₂) was diagnosed more

TABLE 128–4. Staging and Classification Systems for Prostate Cancer

| AUS ^a Stage (A–D) | AJC-UICC ^b Classification (TNM) |
|--|--|
| A (occult, nonpalpable) A ₁ : Focal A ₂ : Diffuse | T _x N _x M _x (cannot be assessed) T ₀ N ₀ M ₀ (nonpalpable) T ₀ : Focal or diffuse |
| B (confined to prostate) B ₁ : Single nodule in one lobe, <1.5 cm B ₂ : Diffuse involvement of whole gland, >1.5 cm | T ₁ N ₀ M ₀ , T ₂ N ₀ M ₀ T ₁ (Clinically inapparent tumor not palpable or visible by imaging) T _{1a} : Tumor incidental histologic finding in 5% or less of tissue resected T _{1b} : Tumor incidental histologic finding in 5% or more of tissue resected T _{1c} : Tumor identified by needle biopsy (e.g., because of elevated PSA) T ₂ : (Tumor confined within the prostate ^c) T _{2a} : Tumor involves half of a lobe or less T _{2b} : Tumor involves more than half a lobe, but not both lobes T _{2c} : Tumor involves both lobes |
| C (localized to periprostatic area) C ₁ : No seminal vesicle involvement, <70 g C ₂ : Seminal vesicle involvement, >70 g | T ₃ N ₀ M ₀ , T ₄ N ₀ M ₀ T ₃ : (Tumor extends through the prostatic capsule ^d) T _{3a} : Unilateral extracapsular extension T _{3b} : Bilateral extracapsular extension T _{3c} : Tumor invades the seminal vesicle(s) T ₄ : (Tumor is fixed or invades adjacent structures other than the seminal vesicles) T _{4a} : Tumor invades any of bladder neck, external sphincter, or rectum T _{4b} : Tumor invades levator muscles and/or is fixed to the pelvic wall |
| D (metastatic disease) D ₁ : Pelvic lymph nodes or ureteral obstruction D ₂ : Bone, distant lymph node, organ, or soft tissue metastases | Any T, N _{1–4} , M ₀ , or N _{0–4} , M ₁ N ₁ : Metastasis in a single lymph node, 2 cm or less in greatest dimension N ₂ : Metastasis in single lymph node more than 2 cm but not more than 5 cm in greatest dimension; or multiple lymph node metastases, none more than 5 cm in greatest dimension N ₃ : Metastasis in lymph node more than 5 cm in greatest dimension M _{1a} : Nonregional lymph node(s) M _{1b} : Bone(s) M _{1c} : Other site(s) |

frequently (89% vs. 68%), and advanced disease (stages T₃, T₄, and D) was diagnosed less frequently (11% vs. 32%) when comparing the 1998 to the 1988 incidence rates.

PROGNOSIS

3 The prognosis for patients with prostate cancer depends on the histologic grade, the tumor size, and the local extent of the primary tumor.¹⁷ The most important prognostic criterion appears to be the histologic grade, because the degree of differentiation ultimately determines the stage of disease. Poorly differentiated tumors are highly associated with both regional lymph node involvement and distant metastases.¹⁷ Other prognostic factors that are being explored include DNA content, cell proliferative activity, epidermal growth

factor (EGF), transforming growth factor- α , EGF receptor, *erbB2* oncogene, *ras* oncogene, *RBI* tumor-suppressor gene, *p53* tumor-suppressor gene, and change in PSA.³⁹

During 1992 to 1999, 5-year overall survival rates were estimated at 98% for whites and 93% for African-Americans.¹ For this same period, the survival rates for localized or regional disease (100%), and distant disease (33%) in white males were about the same as the survival rates for localized or regional disease (100%), and distant disease (26%) in African-American males.¹ A 6.3% decline in age-adjusted mortality has been documented for the period 1991 to 1995.⁴⁰ Ten-year cancer-specific survival is estimated as 95% for stage A₁, 80% for stages A₂ to B₂, 60% for stage C, 40% for stage D₁, and 10% for stage D₂.⁴¹ It is estimated that more than 85% of patients with stage A₁ can be cured, whereas fewer than 1% of patients with stage D₂ will be cured.

TREATMENT: Prostate Cancer

DESIRED OUTCOME

The desired outcome in early-stage prostate cancer is to minimize morbidity and mortality due to prostate cancer.³⁷ Unfortunately, the most appropriate therapy of early-stage prostate cancer is unknown.

CLINICAL CONTROVERSY

Treatment of localized prostate cancer is controversial. While early-stage disease is curable by surgery or radiation therapy, both modalities have significant morbidity and mortality and watchful waiting is an option for some patients.

Early-stage disease may be treated with surgery, radiation, or watchful waiting. While surgery and radiation are curative, they are associated with significant morbidity and mortality. Since the overall goal is to minimize morbidity and mortality associated with the disease, watchful waiting is appropriate in selected individuals. Advanced prostate cancer (stage D) is not currently curable, and treatment should focus on providing symptom relief and maintaining quality of life.⁴²

GENERAL APPROACH TO TREATMENT

The initial treatment for prostate cancer depends primarily on the disease stage, the Gleason score, the presence of symptoms, and the life expectancy of the patient.^{16,37} Figure 128–3 shows the National Comprehensive Cancer Network (NCCN) consensus-based practice guidelines for initial prostate cancer management.³⁷ All the treatment options were considered “category 2A” by the panel of experts that developed these guidelines; this means that the recommendations were uncontested and generally accepted by all panel members, but the recommendations were based on lower level evidence, including clinical experience.

Prostate cancer is usually initially diagnosed by PSA and DRE and confirmed by a biopsy, where the Gleason score is assigned. Asymptomatic patients with a low risk of recurrence, those with a T₁ or T₂, with a Gleason score of 2 through 6, and a PSA of <10 ng/mL may be managed by observation, radiation, or a radical prostatectomy. As patients with asymptomatic early-stage disease generally have an

excellent 10-year survival, immediate morbidities of treatment must be balanced with the likelihood of dying from prostate cancer. In general, more aggressive treatments of early-stage prostate cancer are reserved for younger men, although patient preference is a major consideration in all treatment decisions. In a patient with a normal life expectancy of less than 10 years, observation and radiation therapy may be offered. In those with a normal life expectancy of 10 to 20 years, either observation, radiation (external beam or brachytherapy), or radical prostatectomy may be offered. Patients with a normal life expectancy of greater than 20 years are offered radiation therapy or a radical prostatectomy. Radical prostatectomy and radiation therapy generally are considered therapeutically equivalent for localized prostate cancer, although neither has been proved to be better than observation alone.^{37,42,43} A prospective, randomized trial comparing the two treatments showed a cause-specific survival of 81.2% in the surgery group and 84.6% ($p = .024$) in the radiation group. Patients in the surgery group also had an increased incidence of incontinence and a poorer quality of life, suggesting that radiation therapy may be preferred.⁴⁴ Complications from radical prostatectomy include blood loss, stricture formation, incontinence, lymphocele, fistula formation, anesthetic risk, and impotence. Nerve-sparing radical prostatectomy can be performed in many patients; 50% to 80% regain sexual potency within the first year.⁴⁵ Acute complications from radiation therapy include cystitis, proctitis, hematuria, urinary retention, penoscrotal edema, and impotence (30% incidence).¹⁶ Chronic complications include proctitis, diarrhea, cystitis, enteritis, impotence, urethral stricture, and incontinence.¹⁶ Since radiation and prostatectomy have significant and immediate mortality when compared with observation alone, many patients may elect to postpone therapy until symptoms develop.

Individuals with T_{2b} and T_{2c} disease or a Gleason score of 7 or a PSA ranging from 10 to 20 ng/mL are considered at intermediate risk for prostate cancer recurrence.³⁷ Individuals with less than a 10-year expected survival may be offered observation, radiation therapy, or radical prostatectomy, and those with a greater than 10-year life expectancy may be offered either radical prostatectomy or radiation therapy.

4 The treatment of patients at high risk of recurrence (stages T_{3a} to T_{3b}, a Gleason score ranging from 8 to 10, or a PSA value >20 ng/mL) depends on life expectancy.³⁷ In those with a life expectancy of 5 years or less, either observation or hormonal therapy are options. For patients with this stage of disease and a life expectancy of greater than 5 years, a combination of radiation therapy and

Figure 128-3 is not available in digital format.

hormonal therapy is recommended, although select individuals with a low tumor volume may receive a radical prostatectomy in place of radiation therapy. A study supporting the combination of radiation therapy and hormonal therapy randomized over 400 subjects to receive goserelin, 3.6 mg every 4 weeks; and flutamide, 250 mg three times a day for 2 months before radiation therapy and during radiation therapy, or radiation therapy alone.⁴⁶ After 8 years of follow-up, androgen ablation was associated with an improvement in local control (42% vs. 30%), reduction in the incidence of distant metastases (34% vs. 45%), disease-free survival (33% vs. 21%), biochemical disease-free survival (PSA <1.5; 24% vs. 10%), and cause-specific mortality (23% vs. 31%). The authors performed an additional subset analysis, showing that the beneficial effect of short-term androgen ablation is most pronounced in patients with Gleason scores of 2 to 6, for whom there was a highly significant improvement in all end points, including survival (70% vs. 52%). Most clinicians continue the androgen ablation for a total of 2 to 3 years.^{37,47}

Patients with T_{3c} and T₄ disease have a very high risk of recurrence and are not candidates for radical prostatectomy because of extensive local spread of disease.³⁷ Patients may be offered androgen ablation or a combination of radiation therapy and androgen ablation. Recent evidence suggests that androgen ablation should be instituted at diagnosis rather than waiting for symptomatic disease or progression to occur. In a randomized clinical trial enrolling 500 men with locally advanced prostate cancer who were randomized to either immediate initiation of androgen ablation with either orchiectomy or androgen ablation, or deferred hormonal therapy, individuals with immediate therapy had a median actuarial cause-specific survival duration of 7.5 years for immediate treatment and 5.8 years for deferred treatment.⁴⁸

5 The major initial treatment modality for advanced prostate cancer (stage D₂) is androgen-ablative pharmacotherapy using either orchiectomy or LH-RH agonists, either alone or combined with antiandrogens.³⁷ Estrogens were once widely used; however, the primary estrogen, diethylstilbestrol (DES), was withdrawn from the U.S. market in 1997 due to increased cardiovascular risk. Secondary hormonal manipulations, cytotoxic chemotherapy, or supportive care is used for the patient who progresses after initial therapy.²²

■ NONPHARMACOLOGIC THERAPY

■ ORCHIECTOMY

Bilateral orchiectomy, or removal of the testes, rapidly reduces circulating androgens to castrate levels (<50 ng/dL).¹⁶ However, many patients are not surgical candidates owing to their advanced age, and other patients find this procedure psychologically unacceptable.¹⁶ Orchiectomy is the preferred initial treatment in patients with impending spinal cord compression or ureteral obstruction.

■ PHARMACOLOGIC THERAPY

■ DRUG TREATMENTS OF FIRST CHOICE

■ LH-RH Agonists

Luteinizing hormone–releasing hormone (LH-RH) agonists are a reversible method of androgen ablation and are as effective as

orchiectomy in treating prostate cancer.⁴⁹ Currently available LH-RH agonists include leuprolide, leuprolide depot, leuprolide implant, and goserelin acetate implant.²⁰ Leuprolide acetate is administered once daily, whereas leuprolide depot and goserelin acetate implant can be administered either once monthly, once every 12 weeks, or once every 16 weeks (leuprolide depot, every 4 months). The leuprolide depot formulation contains leuprolide acetate in coated pellets. The dose is administered intramuscularly, and the coating dissolves at different rates to allow sustained leuprolide levels throughout the dosing interval. Goserelin acetate implant contains goserelin acetate dispersed in a plastic matrix of D,L-lactic and glycolic acid copolymer and is administered subcutaneously. Hydrolysis of the copolymer material provides continuous release of goserelin over the dosing period. A recently approved leuprolide implant is a mini-osmotic pump that delivers 120 mcg of leuprolide daily for 12 months. After 12 months the implant is removed, and a different implant can be placed.

Several randomized trials have demonstrated that leuprolide and goserelin are effective agents when used alone in patients with advanced prostate cancer.²¹ Response rates around 80% have been reported, with a lower incidence of adverse effects compared with estrogens.²¹ There are no direct comparative trials of the currently available LH-RH agonists or the dosage formulations, but a recent meta-analysis reported that there is no difference in efficacy or toxicity between leuprolide and goserelin. Therefore the choice between the two is usually made based on cost and patient and physician preference for a dosing schedule.

The most common adverse effects reported with LH-RH agonist therapy include a disease flare-up during the first week of therapy, hot flashes, erectile impotence, decreased libido, and injection-site reactions.²¹ The disease flare-up is thought to be caused by initial induction of LH and FSH by the LH-RH agonist, and manifests clinically as either increased bone pain or increased urinary symptoms.²¹ This flare reaction usually resolves after 2 weeks and has a similar onset and duration pattern for the depot LH-RH products.^{50,51}

LH-RH agonist monotherapy can be used as initial therapy, with similar response rates to orchiectomy and estrogen administration expected. There is a lower incidence of cardiovascular-related adverse effects associated with LH-RH therapy than with estrogen administration. Patients should be counseled to expect worsening symptoms during the first week of therapy, and caution should be exercised when initiating LH-RH agonist therapy in patients with widely metastatic disease involving the spinal cord or having the potential for ureteral obstruction because irreversible complications may occur.

■ Antiandrogens

Three antiandrogens, flutamide, bicalutamide,^{33,72} and nilutamide,³² are currently available (Table 128–5).

Antiandrogens have been used as monotherapy in previously untreated patients, but a recent meta-analysis determined that monotherapy with antiandrogens is less effective than LH-RH agonist therapy.⁵¹ Efficacy of the antiandrogens was similar. Flutamide has a response rate of 50% to 87%,²² bicalutamide has a response rate of 54% to 70%,^{52,53} and nilutamide has a response rate of approximately 40%.⁵⁴ Objective responses are manifested as decreased bone pain, decreased prostate size, decreased PSA, and/or improved performance status. However, for advanced prostate cancer, all currently available antiandrogens are indicated only in combination with androgen-ablation therapy; flutamide and bicalutamide are indicated in combination with an LH-RH agonist, and nilutamide is indicated in combination with orchiectomy.²²

TABLE 128–5. Antiandrogens

| Antiandrogen | Usual Dose | Adverse Effects |
|--------------|--|--|
| Flutamide | 750 mg/day | Gynecomastia Hot flashes Gastrointestinal disturbances (diarrhea) Liver function test abnormalities Breast tenderness Methemoglobinemia |
| Bicalutamide | 50 mg/day | Gynecomastia Hot flashes Gastrointestinal disturbances (diarrhea) Liver function test abnormalities Breast tenderness |
| Nilutamide | 300 mg/day for first month then 150 mg/day | Gynecomastia Hot flashes Gastrointestinal disturbances (nausea or constipation) Liver function test abnormalities Breast tenderness Visual disturbances (impaired dark adaptation) Alcohol intolerance Interstitial pneumonitis |

The most common antiandrogen-related adverse effects are listed in Table 128–5. In the only randomized comparison of bicalutamide plus an LH-RH agonist versus flutamide plus an LH-RH agonist, diarrhea was more common in flutamide-treated patients.^{55,56} Antiandrogens can reduce the symptoms from the flare phenomenon associated with LH-RH agonist therapy.

■ Combined Hormonal Blockade

Although up to 80% of patients with advanced prostate cancer will respond to initial hormonal manipulation, almost all patients will relapse within 2 to 4 years after initiating therapy.¹⁶ Two mechanisms have been proposed to explain this tumor resistance.⁵⁷ The tumor could be heterogeneously composed of cells that are hormone-dependent and hormone-independent, or the tumor could be stimulated by extratesticular androgens that are converted intracellularly to DHT. The rationale for combination hormonal therapy is to interfere with multiple hormonal pathways to completely eliminate androgen action. In clinical trials, combination hormonal therapy, sometimes also referred to as *maximal androgen deprivation* or total androgen blockade, has been used. The combination of LH-RH agonists or orchiectomy with antiandrogens is the most extensively studied combined androgen-deprivation approach.

Labrie and colleagues⁵⁸ reported an initial study combining an LH-RH agonist with flutamide and subsequently have provided follow-up for 363 patients. Response rates, the main end point of these studies, have been greater than 90% in previously untreated patients.⁵⁸ However, response rates of less than 35% have been observed with this combination in patients previously treated with initial hormonal manipulation.

These studies, although quite encouraging, have been criticized for lack of a concurrent control arm and for using response rather than survival as the final end point. For these reasons, the National

Cancer Institute (NCI) sponsored a randomized, placebo-controlled, double-blind multicenter trial comparing leuprolide with leuprolide plus 250 mg flutamide orally three times a day in newly diagnosed patients with stage D prostate cancer.⁵⁸

Both median progression-free survival (16.5 vs. 13.9 months) and median overall survival (35.6 vs. 28.3 months) were significantly longer in the 303 evaluable patients treated with leuprolide plus flutamide than in the 300 evaluable patients treated with leuprolide alone. The best response to combination therapy was observed in patients with minimal disease (no disease in ribs, long bones, or soft tissue other than lymph nodes) and a good performance status. An update of this trial has demonstrated that median survival was 61 months in the combination arm and 41 months in the leuprolide-alone arm in patients with minimal disease.⁵⁹ The addition of flutamide to leuprolide reduced the symptoms from the flare phenomenon associated with LH-RH agonist therapy. Patients in both groups experienced common adverse effects associated with LH-RH agonist treatment. Diarrhea was the only additional adverse effect attributable to flutamide administration. In a comparison of goserelin with goserelin and flutamide conducted in 589 patients with 10 years of follow-up, combined androgen blockade (CAB) showed no benefit over goserelin alone.⁶⁰

Several other studies comparing CAB with conventional medical or surgical castration have been performed.^{55,61–64} In studies with LH-RH agonists, the results have varied, with no consistent benefit demonstrated for CAB.

A recently completed NCI intergroup trial involving 1387 evaluable stage D₂ prostate cancer patients failed to show any significant survival benefits for the combination of orchiectomy plus flutamide over orchiectomy alone.⁶⁴ Like other studies of CAB, overall survival was longest in patients with minimal disease. Diarrhea, elevated liver function tests, and anemia were more common in those patients who received flutamide.

The most recent meta-analysis of 27 randomized trials in 8275 patients (4803 treated with flutamide, 1683 treated with nilutamide, and 1784 treated with cyproterone) comparing maximal androgen blockade with conventional medical or surgical castration showed a small survival benefit at 5 years for those treated with flutamide or nilutamide (27.6%) compared to those with castration alone (24.7%; $p = .0005$).⁶⁵

In one of the few combination androgen-deprivation studies comparing two different antiandrogens (bicalutamide vs. flutamide), the time to treatment failure (the main study end point), time to progression (as defined by appearance of new or worsening bone or extraskeletal lesions), and time to death were equivalent, suggesting that the two treatments are equally effective.⁶⁶

CLINICAL CONTROVERSY

The use of combined androgen blockade is controversial. Meta-analysis shows a small survival advantage when comparing combined androgen blockade to orchiectomy or LH-RH agonist alone. However, this modest benefit is achieved at significant financial cost and with additional toxicities.

Although some investigators now consider CAB to be the initial hormonal therapy of choice for newly diagnosed patients, the clinician is left to weigh the costs of combined therapy against potential benefits in light of conflicting results in the randomized trials²¹ and the modest benefit seen in the meta-analysis.⁶⁵ For those trials that did show an advantage for CAB, whether these effects are specific to the testosterone-deprivation method (orchiectomy vs. leuprolide vs. goserelin), the antiandrogen, the duration of therapy, or patient

selection is not clear. Until further carefully designed studies that use survival, time to progression, quality of life, patient preference, and cost as end points are conducted, it is appropriate to use either LH-RH agonist monotherapy or CAB as initial therapy for metastatic prostate cancer. CAB may be most beneficial for improving survival in patients with minimal disease and for preventing tumor flare, particularly in those with advanced metastatic disease. All other patients may be started on LH-RH monotherapy, and an antiandrogen may be added after several months if androgen ablation is incomplete.

There is still considerable debate concerning when to start hormonal-deprivation therapy in patients with advanced prostate cancer.⁶⁷ The original recommendation to start therapy when symptoms appeared was based on the Veterans Administration Cooperative Urologic Research Group (VACURG) trials, in which no overall survival difference was demonstrated in patients who either started DES initially or crossed over to active treatment when symptoms appeared; the excess mortality was attributed to estrogen administration.⁶⁸ Because LH-RH agonists and antiandrogens are considered suitable alternatives with less cardiovascular toxicity, it is not clear whether delaying therapy is justified. Reanalysis of the original VACURG data⁶⁹ and recent combined androgen-deprivation trials^{63,70} demonstrate a survival advantage for young, good-performance-status, minimal-disease patients treated initially with hormonal therapy, suggesting that early intervention before symptoms appear may be appropriate.⁶⁷ The issue of when best to start hormonal therapy is the subject of several clinical trials.⁶⁷

CLINICAL CONTROVERSY

Older data, using DES, showed that initiation of hormonal therapy at symptom onset yielded equivalent survival to starting hormonal therapy at initial diagnosis. With equivalent survival, decreased costs, and decreased toxicity from DES, the standard of practice was to delay initiation of hormonal therapy until symptoms developed. The favorable toxicity profile of LH-RH agonists led to the re-evaluation of the starting time for therapy; current research shows that younger men with a good performance status may benefit from initiation of hormonal therapy at diagnosis, rather than waiting for symptoms to develop.

Estrogens

DES was once a mainstay of prostate cancer therapy. While very effective in androgen ablation, DES-treated patients experienced increased cardiovascular mortality.⁶⁸ LH-RH agonists, with equivalent efficacy and decreased cardiovascular toxicity, supplanted DES as a mainstay of therapy. Recent evidence suggesting that parenteral estrogen reduces or negates the adverse cardiovascular effects of estrogen has renewed interest in estrogen androgen ablation. Hedlund and colleagues compared monthly intramuscular injections of polyestradiol phosphate with total androgen blockade by orchiectomy or CAB in 915 men, showing no difference in survival or cardiovascular mortality.⁵⁰ Other available estrogenic substances, such as ethinyl estradiol, conjugated estrogens, chlorotrianisene, and polyestradiol phosphate, cost more than DES and have not been studied as extensively.

DRUG TREATMENTS OF SECOND CHOICE

Secondary or salvage therapies for patients who progress after their initial therapy depend on what was used for initial management³⁷

Figure 128-4 is not available in digital format.

(Fig. 128-4). For patients initially diagnosed with localized prostate cancer, radiotherapy can be used in the case of failed radical prostatectomy. Alternatively, androgen ablation can be used in patients who progress after either radiation therapy or radical prostatectomy.

Secondary hormonal manipulations, such as adding an antiandrogen to a patient who incompletely suppresses testosterone secretion with an LH-RH agonist, or withdrawing antiandrogens in a patient receiving combination therapy, or using agents that inhibit androgen synthesis, can be attempted in patients initially treated with one hormonal modality. Supportive care, chemotherapy, or local radiotherapy can be used in patients who have failed all forms of

androgen-ablation manipulations because these patients are considered to have androgen-independent disease.

For patients who initially received an LH-RH agonist alone, castration testosterone levels should be documented. Patients with inadequate testosterone suppression (>20 ng/dL) can be treated by adding an antiandrogen or performing an orchiectomy. If castration testosterone levels have been achieved, the patient is considered to have androgen-independent disease, and palliative androgen-independent salvage therapy can be used.

6 If the patient initially received combined androgen blockade with an LH-RH agonist with an antiandrogen, then androgen

withdrawal is the first salvage manipulation. Objective and subjective responses have been noted following the discontinuation of flutamide,⁷¹ bicalutamide,⁷² or nilutamide⁷³ in patients receiving these agents as part of combined androgen ablation with an LH-RH agonist. Mutations in the androgen receptor have been demonstrated that allow antiandrogens such as flutamide, bicalutamide, and nilutamide (or their metabolites) to become agonists and activate the androgen receptor.⁷⁴ Patient responses to androgen withdrawal manifest as significant PSA reductions and improved clinical symptoms. Androgen withdrawal responses lasting 3 to 14 months have been noted in up to 35% of patients, and predicting response seems to be most closely related to longer androgen exposure times.¹³ Incomplete cross-resistance has been noted in some patients who received bicalutamide after they had progressed while receiving flutamide.⁵² Adding an agent that blocks adrenal androgen synthesis, such as aminoglutethimide, at the time that androgens are withdrawn may produce a better response than androgen withdrawal alone.⁷⁴ Because of the potential for response immediately after antiandrogen withdrawal, a sufficient observation and assessment period (usually 4 to 6 weeks) is usually required before a patient can be enrolled on a clinical trial evaluating a new agent or therapy for advanced prostate cancer.

Androgen synthesis inhibitors, such as aminoglutethimide or ketoconazole, can provide symptomatic relief for a short time in approximately 50% of patients with progressive disease despite previous androgen-ablation therapy.²² Adverse effects during aminoglutethimide therapy occur in approximately 50% of patients.²² Central nervous system effects that include lethargy, ataxia, and dizziness are the major adverse reactions. A generalized morbilliform, pruritic rash has been reported in up to 30% of patients treated. The rash is usually self-limiting and resolves within 5 to 8 days with continued therapy. Adverse effects from ketoconazole include gastrointestinal intolerance, transient rises in liver and renal function tests, and hypoadrenalism.

After all hormonal manipulations are exhausted, the patient is considered to have androgen-independent disease. At this point, palliative supportive therapy is appropriate.^{37,75} Palliation can be achieved by pain management, using radioisotopes such as strontium-89⁷⁶ or samarium-153 lexidronam⁷⁷ for bone-related pain, analgesics, corticosteroids, bisphosphonates,⁷⁸ or local radiotherapy.³⁷ Data are emerging that demonstrate that bisphosphonates such as pamidronate and zoledronic acid may prevent skeletal morbidity, such as pathologic fractures and spinal cord compression in men with hormone-refractory prostate cancer; however, other studies have shown no benefit. The early use of bisphosphonates has also been shown to prevent bone loss due to androgen deprivation therapy. The usual dose of pamidronate is 90 mg every month and the usual dose of zoledronic acid is 4 mg every 3 to 4 weeks. A trial of pamidronate or zoledronic acid can be initiated in prostate cancer patients with bone pain; if no benefit is observed, the drug may be discontinued.⁷⁹

On May 19, 2004, docetaxel was approved for the treatment of metastatic prostate cancer. The approval was based on the TAX327 study, a randomized, multicenter global clinical trial enrolling over 1000 men with metastatic, hormone-refractory prostate cancer.^{92,93} The study compared docetaxel 75 mg/m² every 3 weeks and prednisone 5 mg twice a day with docetaxel 35 mg/m² weekly five out of six weeks and prednisone 5 mg twice a day and mitoxantrone 75 ng/m² every 3 weeks and prednisone 5 mg twice a day. Docetaxel, in combination with prednisone, given every 3 weeks showed a survival advantage of approximately 2.5 months over the control group in the trial ($p = .009$). The most common adverse events reported were nausea, alopecia, and bone marrow suppression. In addition, fluid retention and peripheral neuropathy, known effects of docetaxel, were

also observed. Because this is the first chemotherapy regimen to show survival benefit in this setting, docetaxel and prednisone should be considered standard chemotherapy for hormone-refractory metastatic prostate cancer.

Androgen ablation is usually continued when chemotherapy is initiated.³⁷

Docetaxel and prednisone have recently been shown to improve survival in hormone-refractory metastatic prostate cancer and should be considered standard therapy. Single agents with modest activity in prostate cancer include cyclophosphamide, estramustine, 5-fluorouracil, methotrexate, dacarbazine, mitoxantrone, doxorubicin, paclitaxel, gemcitabine, vinorelbine, and cisplatin.⁸⁰ If disease stabilization is included as a favorable response, response rates up to 46% have been reported.⁸⁰ Several trials have evaluated the various combination regimens containing the most active single agents.^{80–82}

Both estramustine combined with vinblastine^{81,83} and mitoxantrone combined with prednisone are active combination regimens for refractory prostate cancer.⁸⁴ Although estramustine as a single agent^{81,89} produced similar response rates to other available chemotherapy agents, development of estramustine combinations (such as estramustine plus vinblastine or estramustine plus docetaxel) continued when its mechanism of action was discovered to involve microtubule proteins rather than alkylation.^{82,83}

Estramustine and vinblastine combinations have been evaluated in several trials.^{81,83} Response is manifested as objective tumor regression (partial response rate up to 50%), PSA declines, pain relief, and delay in bone scan progression. The toxicities of estramustine combined with vinblastine are nausea, gynecomastia, fatigue, and fluid retention. When vinblastine monotherapy was compared with estramustine plus vinblastine in a large phase III intergroup trial for men with metastatic androgen-independent prostate cancer, patients receiving the combination had improved time to progression and PSA improvement, although the difference in overall survival did not reach statistical significance.⁸⁶

Mitoxantrone plus prednisone is another combination regimen that can palliate hormone-refractory prostate cancer.⁸⁴ One hundred and sixty-one patients with hormone-refractory prostate cancer with pain were randomized to receive either 10 mg/day prednisone alone, or this same prednisone dose with mitoxantrone. The primary end point was a palliative (“clinical benefit”) response, as assessed by a pain scale and analgesic requirements. Quality of life was assessed with a series of linear analog health-assessment scales and the Prostate Cancer–Specific Quality of Life Instrument.

Palliative responses were noted in 29% of patients in the mitoxantrone plus prednisone group and 12% of patients in the prednisone-alone group. The duration of palliative response was greater and quality-of-life scores for pain, physical activity, constipation, and mood were better in patients who received mitoxantrone plus prednisone. Overall survival was the same in both groups. Patients treated with mitoxantrone plus prednisone experienced tolerable adverse effects, although five patients did develop some cardiac-related adverse effects. Mitoxantrone plus corticosteroids is approved by the FDA for hormone-refractory prostate cancer.

Other possible chemotherapeutic regimens suggested by the NCCN guidelines and clinical trials include ketoconazole plus doxorubicin, estramustine plus etoposide, or estramustine plus paclitaxel.³⁷

Although it would seem rational that prostate cancer is a heterogeneous disease composed of cells sensitive to hormonal therapy, chemotherapy, both therapies, or neither therapy, attempts to combine endocrine therapy and chemotherapy to produce an additive effect have not produced significant response rates. When orchiectomy

was compared with DES plus cyclophosphamide in a prospective, randomized trial in patients with stage D prostate cancer, the response rate, median survival, and time to progressive disease were similar between the two treatment groups.⁸⁷ Likewise, Osborne and colleagues⁸⁸ demonstrated a higher initial response rate for patients treated with hormonal therapy plus chemotherapy; however, overall median survival was similar. Furthermore, in a randomized trial involving 419 prostate cancer patients with bone metastases, subgroup analysis demonstrated that orchiectomy plus estramustine produced a longer time to progression compared with orchiectomy alone in patients less than 73 years old, although overall survival was similar.⁸⁷

Fluoxymesterone has been used in some trials designed to test androgen-priming strategies to get the cells to cycle more rapidly and therefore be more susceptible to the effects of cytotoxic chemotherapy. However, the response rates have been inconsistent and spinal cord compression has occurred in some patients, so it appears that the risks of androgen priming outweigh the benefits.⁸⁸

Cytotoxic chemotherapy for hormone-refractory prostate cancer may be offered to the patient as part of a clinical trial. To make the

results of a clinical trial applicable to the majority of hormone-refractory prostate cancer patients, the patient populations need to be clearly defined with regard to disease extent and hormone sensitivity.⁹⁰ Likewise, responses should be quantified by accepted disease-regression measures. If surrogate markers, such as PSA changes, are used, the response needs to be described in terms of the percentage decline, the number of times the decline is documented, and the period during which the decline is maintained.^{90,91} Quality-of-life end points are also appropriate outcome measures.

Many new drugs and new combinations are in development for prostate cancer management.⁷⁹ The first 38-patient trial of suramin demonstrated a 42-week median survival and significant PSA declines (greater than 75%).⁹⁴ Suramin also shows promise in combination with hydrocortisone. Other efforts include agents with novel anticancer targets and mechanisms (apoptosis inhibitors, growth factor inhibitors, and antimetastasis agents), targeted therapy (vaccines, monoclonal antibodies, or growth receptor antibodies), oncogene regulation (farnesyl transferase inhibitors), matrix metalloproteinase inhibitors, and gene therapy.²²

PHARMACOECONOMIC CONSIDERATIONS

The main economic concerns for prostate cancer focus on prostate cancer screening for asymptomatic men, initial therapy of clinically localized disease, surgical vs. medical castration, and the use of combined hormonal blockade as treatment for advanced disease. Unfortunately, there is generally insufficient clinical evidence to determine the most appropriate therapy, making economic modeling essentially meaningless.

Prostate cancer screening remains highly controversial because the survival benefits and the associated costs are not well defined.⁹⁵ Krahn and colleagues⁹⁶ determined that annual screening of all eligible men would cost 45 million Canadian dollars, or 0.15% of total health care expenditures. Available cost-utility studies estimate that the cost per crude or quality-adjusted life-year gained from prostate cancer screening ranges from \$3000 to \$729,000.⁹⁵⁻⁹⁸ Since the cost-effectiveness of prostate cancer screening cannot be determined until the benefits are documented, it is important to incorporate economic analysis into the large ongoing screening studies.

Treatment options for clinically localized prostate cancer include radiation therapy, surgery, or watchful waiting. There is currently no evidence to suggest which therapy is the most clinically effective, and treatment choice is often made by patient or physician preference. However, there are large economic differences in the therapies, with the cost of a radical prostatectomy \$12,000 more expensive than watchful waiting, and radiation therapy \$15,000 more expensive than watchful waiting.⁹⁹

Surgical castration (by removal of the testes) and medical castration with LH-RH agonists yield similar clinical results, although the majority of patients prefer medical castration. In two economic analysis comparisons, the primary cost of the surgical castration was hospital length of stay and medical castration drug costs. Both analyses found that in patients surviving 18 to 24 months, a surgical castration was more cost effective.¹⁰⁰

Table 128-6 lists the costs for the initial hormonal therapies for stage D₂ prostate cancer. Using a societal perspective and data from the original leuprolide plus flutamide versus leuprolide alone trial to calculate the incremental cost per life-year gained, Hillner and colleagues⁹⁷ concluded that CAB has an incremental cost-effectiveness of \$25,300 per life-year gained, which is within current

accepted benchmarks. The cost dropped to \$13,700 per life-year gained in patients with minimal disease.

In a follow-up study, this same group used physician focus group estimates to generate quality-of-life factors and incorporated these factors into an economic model.⁹⁸ The incremental cost per quality-adjusted life-year gained seemed reasonable when data from the original CAB were used: \$25,000 for patients with minimal disease and

TABLE 128-6. Comparative Costs of Hormonal Therapy for Advanced Prostate Cancer

| Drug | Dose | Average Wholesale Price per Month of Therapy |
|-----------------------------------|--|--|
| Leuprolide depot | 7.5 mg/mo | \$566.85 |
| Leuprolide depot | 22.5 mg/12 wk | \$1,700.63 |
| Leuprolide depot | 30 mg/16 wk | \$2,267.50 |
| Goserelin implant | 3.6 mg every 28 days | \$439.24 |
| Goserelin implant | 10.8 mg/12 wk | \$1,317.74 |
| Flutamide | 750 mg/day | \$315.70 |
| Bicalutamide | 50 mg/day | \$319.74 |
| Nilutamide | 300 mg/day for first mo then 150 mg/day | \$467.16 then \$233.58 |
| | | Average Wholesale Price per 3 Months of Therapy |
| Combined androgen blockade | | |
| Leuprolide depot 22.5 mg/12 wk | | |
| + flutamide | 750 mg/day | \$2,647.97 |
| + bicalutamide | 50 mg/day | \$2,659.85 |
| + nilutamide | 150 mg/day | \$2,401.37 |
| | | (\$2,634.95 1st month) |
| Goserelin depot 10.8 mg/12 wk | | |
| + flutamide | 750 mg/day | \$2,265.08 |
| + bicalutamide | 50 mg/day | \$2,270.96 |
| + nilutamide | 150 mg/day | \$2,018.48 |
| | | (\$2,252.06 1st month) |

Compiled from Drug Topics, Annual Pharmacists' Reference (Redbook). Oradell, NJ, Medical Economics, 1998.

\$18,000 for patients with severe disease. However, these incremental costs increased dramatically to \$53,700 for patients with minimal disease and \$41,000 for patients with severe disease when the same model was applied to survival data from a meta-analysis.

Because there is considerable debate about the value of using CAB for advanced prostate cancer, continued economic assessments of this therapy will be crucial to help policymakers and clinicians decide on the most appropriate therapy. It also will become very important to incorporate economic analyses into chemotherapy trials because these efforts move toward including clinical benefit response as a main end point.

EVALUATION OF THERAPEUTIC OUTCOMES

Monitoring of prostate cancer depends on the stage of the cancer.³⁷ When definitive, curative therapy is attempted, objective parameters to assess tumor response include assessment of the primary tumor size, evaluation of involved lymph nodes, and the response of tumor markers such as PSA to treatment. Following definitive therapy, the PSA level is checked every 6 months for the first 5 years, then annually. Local recurrence in the absence of a rising PSA may occur, so the DRE is also performed. In the metastatic setting, clinical benefit responses can be documented by evaluating performance status changes, weight changes, quality of life, and analgesic requirements, in addition to the PSA or DRE at 3-month intervals.

FUTURE DIRECTIONS

Prostate cancer occurs in older males and is curable when local disease is present. Efforts are underway to better define screening and early detection approaches and to determine how best to use PSA as a screening, diagnostic, and therapeutic monitoring test. Proper staging at initial patient presentation is essential because the therapy intensity will depend on the disease stage. Patients with localized prostate cancer can be managed effectively with surgery or radiation therapy. For patients with advanced disease, there are many treatment options. Androgen-ablative therapy is very effective for symptom palliation. Initial androgen-ablative measures include orchiectomy or an LH-RH agonist. CAB using an antiandrogen with either orchiectomy or an LH-RH agonist is used routinely despite equivocal studies and its cost. The effects of androgen ablation seem most pronounced in patients with minimal disease. Studies are still ongoing to define the best initial therapy, to determine when to start initial therapy, to identify which patient subpopulation might benefit best from a given treatment modality, and to identify which surrogate markers should be used to monitor disease activity.

Secondary therapies, including alternate hormonal therapies, antiandrogen withdrawal in a patient receiving CAB, chemotherapy, local radiotherapy, or supportive care can provide disease palliation. Continued efforts to develop new agents with novel mechanisms of action that prolong survival are ongoing. Further insight into the molecular basis for prostate cancer development may provide new therapeutic approaches.

LYMPHOMAS

Val R. Adams and Gary C. Yee

Learning Objectives and other resources can be found at www.pharmacotherapyonline.com.

KEY CONCEPTS

- 1 The goal of treatment of patients with Hodgkin's lymphoma is cure, regardless of disease spread or prognostic factors.
- 2 Most patients with early-stage Hodgkin's lymphoma should be treated with involved-field radiation and several cycles of combination chemotherapy.
- 3 Combination chemotherapy with doxorubicin (Adriamycin), bleomycin, vinblastine, and dacarbazine (ABVD) is the primary treatment for patients with advanced-stage Hodgkin's lymphoma. Patients who attain a complete response do not require consolidative radiation therapy, but patients who only achieve a partial response may benefit from involved-field radiation.
- 4 Many patients with Hodgkin's lymphoma will be refractory to initial therapy or will have a recurrence following a complete remission. Response to salvage therapy depends on the extent and site of recurrence, previous therapy, and duration of initial remission. High-dose chemotherapy and autologous hematopoietic stem cell transplantation should be considered in patients with refractory or relapsed disease.
- 5 The current classification system for non-Hodgkin's lymphoma is the Revised European-American Classification of Lymphoid Neoplasms and World Health Organization (REAL-WHO) classification system, which is based on the principle that a classification is a list of specific disease entities defined by a combination of morphology, immunophenotype, genetic features, and clinical features.
- 6 The Ann Arbor staging system correlates poorly with prognosis in non-Hodgkin's lymphoma. Several prognostic models have been developed to estimate prognosis in patients with non-Hodgkin's lymphoma. The International Prognostic Index (IPI) score is a well-established model for patients with aggressive non-Hodgkin's lymphomas. It is hoped that the Follicular Lymphoma International Prognostic Index (FLIPI) will become a useful model for patients with indolent lymphomas.
- 7 The clinical behavior and degree of aggressiveness can be used to categorize non-Hodgkin's lymphoma into indolent and aggressive lymphomas. Patients with an indolent lymphoma usually have a relatively long survival, with or without aggressive chemotherapy. Although these lymphomas respond to a wide range of therapeutic approaches, few if any of these patients are cured of their disease. In contrast, aggressive lymphomas are rapidly growing tumors and patients have a short survival if appropriate therapy is not initiated. Many patients with aggressive lymphomas respond to intensive chemotherapy and some are cured of their disease.
- 8 Patients with localized follicular lymphoma can be cured with radiation therapy alone. Advanced follicular lymphoma is not curable, and there are many treatment options, including watchful waiting, extended-field radiation therapy, single-agent alkylating agents, anthracycline-containing combination chemotherapy, purine analogues, interferon alfa, anti-CD20 monoclonal antibodies, and high-dose chemotherapy with hematopoietic stem cell rescue.
- 9 Patients with localized aggressive lymphomas can be cured with several cycles of cyclophosphamide, hydroxydaunomycin (doxorubicin), vincristine (Oncovin), and prednisone (CHOP) chemotherapy and involved-field irradiation. Patients with bulky stage II, stage III, or stage IV aggressive lymphomas can be cured of their disease with CHOP chemotherapy. The addition of rituximab to CHOP (R-CHOP) is used by many centers in place of CHOP.
- 10 Conventional-dose salvage therapy can induce responses in patients with aggressive lymphomas who relapse, but long-term survival and cure is uncommon. Some patients with aggressive lymphoma who relapse and respond to salvage therapy can be cured with high-dose chemotherapy and autologous hematopoietic stem cell transplantation.

Lymphomas are a heterogeneous group of malignancies that arise from malignant transformation of immune cells that reside predominantly in lymphoid tissues. They most commonly present as a solid tumor, but can sometimes present as circulating tumor cells in peripheral blood. The differing histology of lymphoma cells has

led to classification of Hodgkin's lymphoma (Reed-Sternberg cells) or non-Hodgkin's lymphoma (B- or T-cell lymphocyte markers). Non-Hodgkin's lymphomas (NHLs) are further classified into distinct clinical entities, which are defined by a combination of morphology, immunophenotype, genetic features, and clinical features.

Chemotherapy is the mainstay of treatment in patients with lymphoma, especially those with widespread disease. Overall cure rates are high for many subtypes of lymphomas, even when patients present with advanced disease.

HODGKIN'S LYMPHOMA

Thomas Hodgkin first described the mysterious disease of the lymph system that bears his name in 1932. Hodgkin's disease is a form of lymphoma, the cause of which is still unknown, and is fatal in more than 90% of patients untreated for 2 to 3 years. Studies have demonstrated the orderly spread of this disease. The prognosis for patients with Hodgkin's lymphoma is primarily determined by stage, presence or absence of systemic symptoms, presence of absence of a large mass, and the use of appropriate therapy. When appropriate therapy is given, more than 75% of all newly diagnosed Hodgkin's lymphoma patients will be cured. This extraordinary success has not been without cost. The treatment programs are intense, technically demanding, and associated with considerable acute toxicity and long-term complications. The long-term effects, particularly secondary malignancies, account for a higher cumulative mortality than Hodgkin's lymphoma 15 to 20 years after treatment. Long-term toxicities with standard chemotherapy regimens have been more fully documented in recent years and are shaping future therapies.¹⁻⁴

EPIDEMIOLOGY

It is estimated that nearly 7350 new cases of Hodgkin's lymphoma will be diagnosed in the United States in 2005, which represents less than 1% of all known cancers.⁵ It is expected that there will be 1410 deaths associated with Hodgkin's lymphoma during this same time. This disease occurs slightly more frequently in males than in females. Once thought to be only a disease of the young, it is now recognized that Hodgkin's lymphoma exhibits a bimodal distribution in industrialized countries. The first peak occurs between the ages of 15 and 40 (usually 25 to 30) and again in those older than 55.⁶ In recent years, the incidence has increased in younger patients and declined in those over 40, which may be due to more accurate diagnosis of lymphoid malignancies in this age group.⁷ The 5- and 10-year overall survival for all stages according to the SEER database is 82% and 76%, respectively.⁸ Death rates due to recurrent Hodgkin's lymphoma are less than those from other causes 15 years after treatment.⁹

ETIOLOGY

The etiology of Hodgkin's lymphoma is unknown. The cause of Hodgkin's lymphoma has been elusive for several reasons. Tissue taken from a Hodgkin's lymphoma mass reveals that only 1% to 2% of the cells are Reed-Sternberg cells (malignant), which has made it difficult to study.² Infection has been considered a potential cause of Hodgkin's lymphoma since the disease was first described. Viruses have emerged as the leading candidates for an infectious etiology. Studies have suggested an increased risk of Hodgkin's lymphoma in patients who have been infected with the Epstein-Barr virus (EBV). Reed-Sternberg cells (large, bilobate, multinuclear cells) are the malignant cells in Hodgkin's lymphoma, although they have also been found in mononucleosis patients. Consequently, the diagnosis of Hodgkin's lymphoma requires the presence of Reed-Sternberg cells and a history and physical examination consistent with the diagnosis of Hodgkin's lymphoma. Both serologic and molecular methods have linked EBV to Hodgkin's lymphoma, particularly in patients

over the age of 50 years.^{6,10} Homosexual men infected with human immunodeficiency virus (HIV) are also at a slightly increased risk of developing Hodgkin's lymphoma. Occasional geographic clusters of cases further support the linkage between Hodgkin's lymphoma and an infectious agent. Genetic factors also predispose people to Hodgkin's lymphoma. The risk of Hodgkin's lymphoma is increased slightly in individuals with certain human leukocyte antigen types and in people with ataxia telangiectasia. The strongest evidence suggesting that genes are important in the etiology of Hodgkin's lymphoma comes from identical twin studies, which show that the unaffected identical twin has about a 100-fold increase in risk. Other environmental risk factors have been linked with Hodgkin's lymphoma, but only appear to play a minor role.^{2,6,10,11}

PATHOPHYSIOLOGY

Hodgkin's lymphoma is a clonal malignant lymphoid disease of transformed lymphocytes. The malignant cell in Hodgkin's lymphoma is known as "Reed-Sternberg" after Dr. Carl Sternberg and Dr. Dorothy Reed who are credited with the first definitive microscopic description of Hodgkin's lymphoma in 1898 and 1902, respectively.² The origin of the Reed-Sternberg cell has eluded scientists because of the inability to isolate and analyze these cells to the necessary depth. A typical Hodgkin's lymphoma mass occurs in a lymph node and contains normal reactive and inflammatory cells, fibrosis, and a relatively small percentage (1% to 2%) of Reed-Sternberg cells. In recent years, new laboratory techniques have led to significant progress in identifying the origin of the Reed-Sternberg cell. Single-cell polymerase chain reaction (PCR) and DNA microarray analysis indicate that nearly all classic Hodgkin's lymphoma cases and all nodular lymphocyte-predominant Hodgkin's lymphomas have immunoglobulin gene rearrangements, which indicates a germinal center or postgerminal center B-cell origin (Table 129-1).^{10,11} Interestingly, nearly all Reed-Sternberg cells fail to express B-cell specific cell surface proteins (CD19, CD20, CD79 α). Current hypotheses about the transforming event and malignant process indicate that B-cell transcriptional processes are disrupted, which prevent B-cell surface marker expression and production of immunoglobulin mRNA. The normal cellular

consequence of failure to express immunoglobulin is apoptosis, but due to alterations in the normal apoptotic pathways, cell survival and proliferation are favored. Reed-Sternberg cells have been shown to overexpress nuclear factor- κ B, which is associated with cell proliferation and anti-apoptotic signals. Infections with viral and bacterial pathogens upregulate nuclear factor- κ B and consequently are hypothesized to be involved with the etiology of Hodgkin's lymphoma.^{10,11} This hypothesis is supported by the finding of EBV in many Hodgkin's lymphoma tumors, but it is important to note that not all tumors are associated with EBV.¹² As molecular techniques continue to improve, our understanding of the pathophysiology of Hodgkin's lymphoma will also improve.

The histopathologic classification of Hodgkin's lymphoma has undergone numerous changes over the last three decades. The current classification system used today is the WHO modification of the Revised European-American Classification of Lymphoid Neoplasms (Table 129–2).¹³ This classification divides Hodgkin's lymphoma into

two major groups: classical Hodgkin's lymphoma (cHL) and nodular lymphocyte-predominant Hodgkin's disease (NLPHD), which constitute approximately 95% and 5% of cases, respectively. Classical Hodgkin's lymphoma is further divided into four subtypes: nodular sclerosis, mixed cellularity, lymphocyte-depletion, and lymphocyte-rich. The subtypes in these classification systems are based on characteristics of the Reed-Sternberg cell, the surrounding cells, and connective tissue. Nodular sclerosis has features that make it distinct from the other three subtypes, which represent a continuum of background cellularity, with lymphocyte-predominance being the most cellular and lymphocyte-depletion being the least cellular. Nodular lymphocyte-predominant Hodgkin's lymphoma is separated because of its distinct immunophenotype: CD15⁻, CD20⁺, CD30⁻, and CD45⁺ (the opposite of classical Hodgkin's disease).¹¹ With the introduction of extensive staging, sophisticated megavolt radiotherapy, and effective combination chemotherapy, the true prognostic value of these subtypes is becoming less clear.

TABLE 129–2. WHO Classification of Lymphoid Malignancies

| B Cell | T Cell | Hodgkin's Disease |
|---|---|--|
| Precursor B cell neoplasm Precursor B lymphoblastic leukemia/lymphoma (precursor B cell acute lymphoblastic leukemia) | Precursor T cell neoplasm Precursor T lymphoblastic lymphoma/leukemia (precursor T cell acute lymphoblastic leukemia) | Nodular lymphocyte-predominant Hodgkin's disease |
| Mature (peripheral) B cell neoplasms B cell chronic lymphocytic leukemia/small lymphocytic lymphoma | Mature (peripheral) T cell neoplasms T cell prolymphocytic leukemia | Classical Hodgkin's disease |
| B cell prolymphocytic leukemia | T cell granular lymphocytic leukemia | Nodular sclerosis Hodgkin's disease |
| Lymphoplasmacytic lymphoma | Aggressive NK cell leukemia | Lymphocyte-rich classical Hodgkin's disease |
| Splenic marginal zone B cell lymphoma (\pm villous lymphocytes) | Adult T cell lymphoma/leukemia (HTLV-1+) | Mixed-cellularity Hodgkin's disease |
| Hairy cell leukemia | Extranodal NK/T cell lymphoma, nasal type | Lymphocyte-depletion Hodgkin's disease |
| Plasma cell myeloma/plasmacytoma | Enteropathy-type T cell lymphoma | |
| Extranodal marginal zone B cell lymphoma of MALT type | Hepatosplenic $\gamma\delta$ T cell lymphoma | |
| Mantle cell lymphoma | Subcutaneous panniculitis-like T cell lymphoma | |
| Follicular lymphoma | Mycosis fungoides/Sézary syndrome | |
| Nodal marginal zone B cell lymphoma (\pm monocytoid B cells) | Anaplastic large cell lymphoma, primary cutaneous type | |
| Diffuse large B cell lymphoma | Peripheral T cell lymphoma, not otherwise specified (NOS) | |
| Burkitt's lymphoma/Burkitt cell leukemia | Angioimmunoblastic T cell lymphoma | |
| | Anaplastic large cell lymphoma, primary systemic type | |

Bold type represents those malignancies that occur in at least 1% of patients.

CLINICAL PRESENTATION

Most patients with lymphoma present with some form of adenopathy that waxes and wanes for an average of 5 months before diagnosis. A painless, rubbery lymph node is discovered in and is localized to the cervical region. Adenopathy of the inguinal and axillary regions may be present at diagnosis but is less common, while involvement of Waldeyer's ring and the epitrochlear nodes rarely occurs (Fig. 129-1). Other common sites of nodal involvement include the mediastinal, hilar, and retroperitoneal regions. Up to 40% of patients with Hodgkin's lymphoma may also present with constitutional symptoms (B symptoms) including fever, drenching night sweats, and unexplained weight loss (>10% in the 6 months preceding diagnosis). Pruritus is also commonly noted in patients with Hodgkin's lymphoma, but its presence does not appear to have significant prognostic value.^{2,6}

DIAGNOSIS, STAGING, AND PROGNOSTIC FACTORS

The diagnosis and pathologic classification of Hodgkin's lymphoma can only be made by review of a biopsy (preferably an excisional biopsy) of the enlarged node by an expert hematopathologist. Full evaluation of extent of disease, or staging, is necessary with Hodgkin's

lymphoma. Staging determines appropriate treatment of the disease and provides useful information regarding prognosis. In addition, specific knowledge of the involved sites can be used to determine response. Presence of advanced stage, extensive B symptoms, and massive mediastinal involvement implies a poorer prognosis for a given patient.²

The Ann Arbor staging classification, which was developed at the 1970 Ann Arbor conference, has proven to be a good workable scheme. At the Cotswolds meeting in 1989, the Ann Arbor classification was modified to account for new diagnostic techniques (e.g., computed tomography [CT] and magnetic resonance imaging [MRI]), and the understanding that prognosis is associated with the bulk of the disease and the number of involved nodal sites (Table 129-3).¹⁴ After careful staging, about one-half of patients have localized disease (stages I, II, and II_E) and the remainder has advanced disease (stages III or IV). About 10% to 15% present with metastatic disease (stage IV). It is important to note that Hodgkin's lymphoma appears to follow a predictable pattern of nodal spread that is not seen with the non-Hodgkin's lymphomas.

Diagnostic and staging procedures are based on recommendations made at the Ann Arbor and Cotswolds conferences and new scientific advances as outlined in the National Comprehensive Cancer Network (NCCN) guidelines.¹⁵ In addition to a careful physical exam and routine laboratory tests, chest x-ray and CT scans of the chest, abdomen, and pelvis are routinely performed. Bone marrow biopsy is recommended in patients with more advanced stage disease. Staging can be based on clinical or pathologic findings. Clinical stage (CS) is based on all noninvasive procedures (history, physical exam, laboratory tests, and radiologic findings), while pathologic stage (PS) is based on the biopsy findings of strategic sites (muscle,

TABLE 129-3. The Cotswolds Staging Classification of Hodgkin's Disease

bone, skin, spleen, and abdominal nodes) with an invasive procedure such as a laparoscopy or laparotomy. Those patients with extranodal disease (muscle, skin, bone, of Waldeyer’s ring) contiguous to involved nodes are classified with the subscript “E” in the Cotswolds staging system.¹⁴

Invasive staging procedures such as laparotomy and lymphangiogram are not usually performed during staging. These tests can detect occult disease in the abdomen, which would require systemic chemotherapy in addition to radiation for patients with early-stage supradiaphragmatic disease. Therefore these tests should only be considered for patients who will be treated with radiation alone if the results are negative. When the treatment plan includes systemic therapy, the use of these procedures does not impact treatment decisions or patient prognosis. Clinicians rarely order either procedure because the availability of lymphangiography is low and the complications of laparotomy are relatively high (about 5%).^{11,16,17}

Analyses of early studies led to the identification of prognostic factors that could predict poor treatment outcomes of Hodgkin’s lymphoma. Patient characteristics that have been determined as unfavorable prognostic factors include advanced stage, advanced age, male gender, presence of B symptoms, higher number of involved nodal regions, large mediastinal mass, extranodal disease, elevated erythrocyte sedimentation rate (ESR), presence of anemia, leukocytosis, lymphocytopenia, and low serum albumin.

Clinical trials performed by large cancer groups (e.g., European Organization for Research and Treatment of Cancer [EORTC] and German Hodgkin’s Lymphoma Study Group [GHLSG]) have used combinations of these prognostic factors to stratify patients into early-stage favorable, early-stage unfavorable (intermediate) disease, or advanced disease (Table 129–4). Canadian and United States cooperative groups use similar criteria. In the NCCN guidelines, bulky disease, elevated ESR, and number of involved nodal sides are de-

finied as unfavorable features.¹⁵ Although the exact criteria between groups or studies are not identical, stage, advanced age, bulky disease, and signs of systemic disease (B symptoms, elevated ESR, or extranodal disease) are of most prognostic significance.¹¹

Some of these factors can also be used to predict prognosis in patients with advanced disease. The International Prognostic Factors Project uses seven factors to generate an International Prognostic Score (IPS), which can be used to predict progression-free and overall survival (Table 129–5).¹⁸

TABLE 129–5. The International Prognostic Factors Project Score for Advanced Hodgkin’s Lymphoma

▶ TREATMENT: Hodgkin’s Disease

1 The current goal in the treatment of Hodgkin’s lymphoma is to maximize curability while minimizing short- and long-term treatment-related complications. According to the SEER database, the 5-year age-adjusted relative survival is greater than 80%.⁸ The development of effective therapies for all stages of Hodgkin’s lymphoma

remains one of the most remarkable achievements in modern cancer care. The introduction of modern linear accelerators providing radiation beams in the range of <10 megaelectron volts, effective combination chemotherapy regimens, and new methods of combining these two modalities, have all contributed to high cure rates.

In general, most patients with early-stage Hodgkin's lymphoma are treated with combination chemotherapy and radiation. Patients with advanced-stage disease are usually treated with combination chemotherapy alone, although those with bulky disease receive radiation therapy to the site of bulky disease. Patients who do not achieve a complete remission may benefit from consolidative radiation. For the 15% to 20% of patients with refractory or recurrent disease, salvage therapy consists of multiagent chemotherapy with or without high-dose chemotherapy and autologous hematopoietic stem cell transplantation (HSCT), which can be curative. The following sections will review treatment of early-stage favorable disease, early-stage unfavorable disease (intermediate), advanced-stage disease, and salvage therapy.

For Hodgkin's lymphoma, surgery is not usually part of the therapeutic treatment regardless of stage. It is, however, important for diagnosis (excisional biopsy), and on some occasions, placement of a central line.²

Radiation is commonly an integral part of the treatment plan. Select patients with early-stage disease can receive radiation as the only treatment modality, while others will receive chemotherapy and radiation. Although radiation is a local therapy, many patients with advanced (widespread) disease will also receive radiation therapy to residual or bulky disease sites after chemotherapy. The major concern with radiation therapy is its long-term effects, such as cardiovascular disease and secondary malignancies, which commonly occur in the lung, breast, gastrointestinal tract, and connective tissue.^{3,4} To avoid these toxicities, several studies have been completed and others are ongoing to maximize efficacy while minimizing the extent of radiation (radiation field) and the dose of radiation. The types of radiation fields used are shown in Fig. 129–2. Radiation to a single field that contains Hodgkin's lymphoma is called *involved-field radiation*; radiation to the involved field and a second uninvolved area is termed *extended-field radiation* or *subtotal nodal irradiation*; and radiation of all areas is called *total nodal irradiation*.^{1,6} Specific therapies discussing ra-

FIGURE 129–2. Radiation fields (shaded areas) commonly employed in Hodgkin's disease. diation dose and field are discussed below with the pharmacologic therapy.

TREATMENT OF EARLY-STAGE FAVORABLE DISEASE

RADIATION THERAPY ALONE

Patients with stage IA or IIA disease and favorable prognostic factors can be successfully treated with radiation alone. Until recently, extended-field radiation has been considered to be the treatment of choice for stage IA and IIA disease. This treatment produces disease-free survival rates ranging from 65% to 85% and overall survival rates ranging from 75% to 93%.^{2,6,11} If the decision is made to use radiation alone, extended-field radiation appears to be superior to involved-field radiation, based on a recent meta-analysis conducted by Specht and colleagues.¹⁹ Results of that analysis showed that more extensive radiation reduces the risk of treatment failure at 10 years (31% vs. 43%), but does not improve 10-year overall survival (77% vs. 77.1%). When the intent is to use radiation alone, pathologic (i.e., surgical) staging is recommended to assure that the patient has limited-stage disease. Surgical staging consists of laparotomy and splenectomy, which has been associated with a morbidity and mortality rate of approximately 5%, primarily postoperative infection and sepsis.^{2,6}

In an effort to avoid the long-term effects of extended-field radiation and risks of surgical staging, and improve treatment results, several studies have evaluated a combined modality approach that involves the use of short-duration chemotherapy and involved-field radiation.¹¹ Based on favorable results of these studies, most clinicians no longer treat patients with early-stage favorable disease with radiation alone.

CHEMOTHERAPY IN COMBINATION WITH RADIATION

2 Clinical trials comparing radiation alone to radiation plus chemotherapy have shown lower relapse rates in patients treated with combined modality therapy (radiation and chemotherapy), but no change in overall survival.^{11,20} Current studies focus on questions such as the optimal number of chemotherapy cycles and the volume of radiation that must be used to obtain optimal patient outcomes. In patients with advanced-stage disease, a minimum of six cycles are usually given. However, results of recent studies suggest that as few as two to four cycles of chemotherapy is adequate.¹¹ Different combination chemotherapy regimens have been used in these studies, and it is not clear that any one regimen is superior to another. Other studies showed that extended-field radiation did not improve progression-free or overall survival as compared with involved-field irradiation, when radiation was combined with several cycles of chemotherapy.¹¹

Based on these data, the current recommendation is to treat patients with early-stage favorable disease with two to four cycles of combination chemotherapy (i.e., ABVD; see below) and involved-field radiation.¹⁵ With this approach, 5-year progression-free and overall survival rates of >90% can be achieved.

TREATMENT OF EARLY-STAGE UNFAVORABLE DISEASE

Patients with early-stage disease who have certain features associated with a poor prognosis are defined as having unfavorable disease (see

Table 129–4). Because of the high relapse rate in patients with early-stage unfavorable disease treated with radiation alone, most clinicians currently favor combined modality therapy (combination chemotherapy and involved-field radiation) to reduce the relapse rate and avoid the toxicity associated with extended-field radiation and the mortality associated with surgical staging.^{2,11}

■ CHEMOTHERAPY IN COMBINATION WITH RADIATION

2 Although randomized trials show that combined modality therapy reduces the relapse rate in patients with early-stage unfavorable disease, questions concerning the appropriate radiation volume, most effective chemotherapy regimen, and number of chemotherapy cycles remain.¹¹ In one recent trial (GHSG HD8), patients with early-stage unfavorable Hodgkin's lymphoma treated with chemotherapy and involved-field radiation had similar outcomes as those treated with the same chemotherapy regimen and extended-field radiation.²¹

Several ongoing trials compare different chemotherapy regimens or number of chemotherapy cycles.¹¹ A combination of doxorubicin (Adriamycin), bleomycin, vinblastine, and dacarbazine (ABVD) has become the standard regimen used to treat patients with early-stage unfavorable disease because of its established effectiveness in patients with advanced-stage disease and its favorable toxicity (both acute and chronic) profile (Table 129–6).¹¹ The use of a less toxic regimen, epirubicin, bleomycin, vinblastine, and prednisone (EBVP), which is effective in early-stage favorable disease, was found to be inferior to MOPP/ABV in patients with unfavorable disease. Other regimens that have been found to be effective include CVPP (see below) in combination with mantle irradiation.² A relatively new regimen, Stanford V, has generated a great amount of interest because in patients with bulky early-stage disease and advanced-stage disease, it has produced a 5-year overall survival of 96% and freedom from progression rate of 89%.²² Finally, some trials are evaluating the number of chemotherapy cycles (4 vs. 6).

The current NCCN guidelines recommend four to six cycles of combination chemotherapy, followed by involved-field radiation (30 to 36 Gy).¹⁵ ABVD is the most common regimen used, but other regimens can be used as an alternative to ABVD.

■ TREATMENT OF ADVANCED-STAGE DISEASE

Advanced-stage disease consists of stage III and IV disease. In some studies, stage IIB with a large mediastinal mass or extranodal disease is also considered advanced-stage disease (see Table 129–4). It is almost always widespread, which precludes the use of radiation alone as a therapeutic modality. Intensive combination chemotherapy is the mainstay of treatment, although some patients will benefit from consolidative radiation following chemotherapy.

■ CHEMOTHERAPY

One of the initial combination chemotherapy regimens introduced in the early 1960s that was shown to produce cures in advanced Hodgkin's disease was the MOPP (mechlorethamine, vincristine [Oncovin], procarbazine, and prednisone) regimen (see Table 129–6).²³ MOPP chemotherapy has been a mainstay of treatment for patients with stage III and IV advanced Hodgkin's disease. According

to the 20-year follow-up of the National Cancer Institute (NCI) trial, MOPP has produced complete remissions (disappearance of all measurable disease) in 84% of patients and has a 10-year cure rate of 54%. Forty-six percent of the original patients are still alive at a median of 14 years posttreatment (19% died due to other illness).²⁴ This is in contrast to the results of single-agent therapy, in which remissions occur less rapidly and are not as durable. Patients should receive two cycles of therapy beyond that required to produce a complete response; a minimum of six cycles should be administered. Maintenance therapy has not been shown to increase survival and may contribute to the long-term complications seen with therapy. The delivery of full or nearly full doses of chemotherapy is extremely important (e.g., dose intensity). Dose reduction within the various studies is probably the single most important factor explaining the differences in response rates between institutions administering seemingly similar regimens.²⁵ Dosage reductions based on toxicity may be made, but significant reductions can alter response and survival.²⁴

Ever since MOPP therapy was created and the efficacy confirmed, researchers tried to modify the regimen in an attempt to improve efficacy and decrease toxicity.²⁵ Some MOPP variations include MVPP (vinblastine substituted for vincristine), CVPP (cyclophosphamide substituted for mechlorethamine), and ChlVPP (chlorambucil substituted for mechlorethamine, and vinblastine substituted for vincristine) were attractive alternatives to MOPP because they offered equal efficacy and differing or less severe toxicities. The various combination chemotherapy regimens appear to produce initial complete response rates in over 80% of the patients treated, and result in a 55% to 65% cure rate for advanced Hodgkin's lymphoma.

3 ■ **ABVD.** The development of ABVD (doxorubicin [Adriamycin], bleomycin, vinblastine, and dacarbazine) by Bonnadonna and colleagues at the Milan Cancer Institute about a decade later represents the next important step in the evolution of therapy for Hodgkin's lymphoma (see Table 129–6). ABVD was initially shown to be effective in MOPP failures and was later compared directly to MOPP in advanced disease, where it produced an 82% complete response rate, as compared with a 67% complete response rate with MOPP. Improved failure-free survival was demonstrated with ABVD, but no significant differences in 5-year overall survival were noted.²⁶ Since ABVD is less toxic and provided similar or better outcomes than MOPP, it gradually replaced MOPP as the standard regimen for advanced-stage Hodgkin's lymphoma.

■ **Alternating or Hybrid Regimens.** In the early 1980s, the Goldie-Coldman hypothesis proposed that chemotherapy resistance was related to spontaneous mutation rates and the development of resistant clones. To test that hypothesis, researchers designed several clinical trials to evaluate the efficacy of alternating non-cross-resistant drug combinations in patients with Hodgkin's lymphoma.²⁷

The initial approach investigators took was to alternate or combine the MOPP and ABVD regimens. When MOPP and ABVD (or ABV) are combined in a monthly cycle, it is referred to as a *hybrid* regimen. Besides a potential benefit in efficacy, a major potential benefit of alternating or hybrid regimens is decreased risk of long-term toxicities. In the alternating MOPP/ABVD regimen, the cumulative doses of procarbazine and mechlorethamine are reduced by 50% and the cumulative doxorubicin dose is reduced by 50%. In the hybrid regimen the cumulative doxorubicin dose is reduced by 33% and the cumulative bleomycin dose is reduced by 50%.

Several clinical trials have been performed to evaluate the efficacy of alternating or hybrid MOPP/ABVD regimens. The results of

TABLE 129–6. Combination Chemotherapy Regimens for Hodgkin’s Lymphoma

| Drug | Dosage (mg/m ²) | Route | Days |
|---------------------------------------|-----------------------------|-------|---|
| MOPP | | | |
| Mechlorethamine | 6 | IV | 1, 8 |
| Vincristine | 1.4 | IV | 1, 8 |
| Procarbazine | 100 | Oral | 1–14 |

these trials show that alternating and hybrid regimens are superior to MOPP but not to ABVD.^{4,11,26} Another approach was to administer sequential cycles of MOPP and ABVD (MOPP → ABVD). Results of an intergroup trial showed sequential MOPP and ABVD to be inferior to the MOPP/ABV hybrid regimen in terms of response and survival.²⁸ In another randomized comparison of the MOPP/ABV hybrid regimen and ABVD, the complete remission rate, failure-free survival,

and overall survival were similar between the two regimens.²⁹ However, that trial was closed prematurely because of an increased number of treatment-related deaths and secondary malignancies in the patients who received the MOPP/ABV hybrid regimen.

In summary, alternating, hybrid, or sequential MOPP/ABVD (or MOPP/ABV) regimens have not been shown to be more effective than ABVD. ABVD has the advantage of less acute toxicity, no sterility,

and a low risk of secondary acute myeloid leukemia/myelodysplastic syndrome. For these reasons, ABVD is the current standard for chemotherapy in advanced-stage Hodgkin's lymphoma.

■ **New Chemotherapy Regimens.** More recently, new regimens have been developed with increased dose-intensity or dose-density. Two relatively new regimens (BEACOPP and Stanford V) are variations of the above hybrid regimens that administer drugs with a shorter frequency or have escalated the dose of the most active agents. Since the majority of patients in the recent trials also received radiation therapy, results of these promising new trials are discussed in the next section.

■ **Summary.** In summary, the standard treatment of advanced-stage Hodgkin's lymphoma is six to eight cycles of ABVD chemotherapy. About 70% to 80% of patients will have a complete remission to ABVD chemotherapy, and about 60% to 70% will be cured of their disease. No further treatment is needed for patients attaining a complete remission. Patients achieving a partial remission should receive consolidative radiation to residual sites of disease (see below).

■ CHEMOTHERAPY IN COMBINATION WITH RADIATION

3 The role of low-dose consolidative radiation when added to chemotherapy for the treatment of advanced-stage Hodgkin's disease is controversial.^{11,30} The rationale for its use was based on the radiosensitivity of Hodgkin's lymphoma, a 20% to 40% relapse rate, and the tendency of Hodgkin's lymphoma to relapse at sites of initial involvement.³⁰ Many clinical trials were conducted to evaluate the benefit of additional radiation in patients who have a complete response to combination chemotherapy. The results of these studies were inconsistent, and a meta-analysis of 14 randomized trials showed a modest improvement in disease control at 10 years, but no difference in overall survival.³¹ In a recently published study, patients with advanced disease were randomized to receive either involved-field radiation after MOPP/ABV hybrid chemotherapy or no further therapy.³² Five-year event-free and overall survival were no different between patients who did not receive radiation and those who did (84% vs. 79% and 91% vs. 85%, respectively). However, in that study, patients who received radiation after a partial remission had 5-year event-free and overall survival that was similar to those in patients who achieved a complete remission to chemotherapy. These results suggest a role for consolidative radiation in patients who have a partial response after chemotherapy. Fewer secondary malignancies occurred in the group who did not receive radiation as compared to the radiation group (4% vs. 7.8%).

The Stanford V and BEACOPP regimens are relatively new regimens for advanced-stage Hodgkin's lymphoma (see Table 129-6). The Stanford V, a 7-drug regimen, was developed as a short-duration (12 weeks) regimen that maintained the dose-intensity of active agents, but reduced the cumulative doses of doxorubicin, bleomycin, and nitrogen mustard.³³ Developed by the German Hodgkin's Lymphoma Study Group, BEACOPP uses similar drugs as in the COPP/ABVD regimen (the same as MOPP/ABVD, with cyclophosphamide substituted for mechlorethamine), but rearranges the drugs in a shorter 3-week cycle.^{11,34} Several different versions of BEACOPP have been developed: standard-dose BEACOPP (BEACOPP baseline), higher-dose BEACOPP (BEACOPP escalated), and dose-dense BEACOPP (BEACOPP-14). Granulocyte colony-stimulating factor (G-CSF) support is required for the

BEACOPP escalated and BEACOPP-14 regimens. Most patients in these trials receiving these regimens have also received radiation therapy. Early studies with these regimens have reported 5-year overall survival rates of greater than 90%.^{11,22,34} Few randomized clinical trials have evaluated these newer regimens. An intergroup trial is currently testing Stanford V versus ABVD in patients with advanced-stage Hodgkin's lymphoma. The German Hodgkin's Lymphoma Study Group recently reported the results of a prospective randomized trial comparing COPP/ABVD, standard BEACOPP, and increased-dose BEACOPP.³⁵ Freedom from treatment failure at 5 years was 69%, 76%, and 87% for COPP/ABVD, standard-dose BEACOPP, and increased-dose BEACOPP, respectively ($p < 0.001$ for comparison of increased-dose BEACOPP with the COPP/ABVD group and with the BEACOPP group). Five-year overall survival was 83%, 88%, and 91%, for COPP/ABVD, standard-dose BEACOPP, and increased-dose BEACOPP, respectively ($p = 0.002$ for comparison of COPP/ABVD vs. increased-dose BEACOPP). Despite filgrastim support, 90% of patients in the increased-dose BEACOPP group had grade IV leukopenia, as compared to 19% in patients in the COPP/ABVD arm and 37% in the standard-dose BEACOPP arm. However, the higher rate of acute toxicity did not translate into a difference in acute treatment-related fatalities (<2% for all three regimens). The increased-dose BEACOPP was also associated with a higher rate of secondary acute leukemias. Longer follow-up of this trial will be required to determine whether the survival gain with increased-dose BEACOPP is maintained and outweighs the increased risk of long-term toxicities such as secondary malignancies. The current German study group study compares eight courses of BEACOPP escalated to six courses of BEACOPP escalated and eight courses of BEACOPP-14.

CLINICAL CONTROVERSY

Some clinicians believe that Stanford V or increased-dose BEACOPP is superior to ABVD in the treatment of patients with advanced-stage Hodgkin's lymphoma. Increased-dose BEACOPP has been shown to be superior to COPP/ABVD, which is similar to MOPP/ABVD. Other clinicians believe that ABVD is still the treatment of choice because increased-dose BEACOPP has not been tested directly against it. They also express concern over the short- and long-term toxicity with increased-dose BEACOPP. This controversy will be answered with currently ongoing randomized studies and longer follow-up of the increased-dose BEACOPP trial.

■ SALVAGE CHEMOTHERAPY

4 The goal of salvage therapy is cure regardless of the site(s) of recurrence or primary therapy. With the increasing use of chemotherapy with or without radiation, regardless of disease extent, the rate of primary refractory disease is decreasing. Patients who do not achieve a complete remission with the initial regimen are considered to have primary refractory disease. These patients have a poor prognosis when treated with salvage chemotherapy, and consequently are candidates for high-dose chemotherapy and HSCT.^{35,36}

Patients who relapse after an initial complete response can be treated with the same regimen, a different potentially non-cross-resistant regimen, radiation, or high-dose chemotherapy and autologous HSCT (often preceded by conventional-dose chemotherapy). The response to salvage therapy depends on the extent and site of recurrence, previous therapy, and duration of initial remission. Patients who relapse after radiation therapy alone have a good chance

of being cured with combination chemotherapy, although fewer patients are being treated with radiation alone. Other patient groups who have a favorable prognosis following salvage therapy include patients who experience a local recurrence in a nonirradiated location and those who relapse more than 1 year after completion of their initial chemotherapy. Patients who experience late relapses can be cured with retreatment with the same chemotherapy regimen, treatment with a different, potentially non-cross-resistant regimen, or high-dose chemotherapy and autologous HSCT. The NCI has reported on their long-term follow-up of MOPP-retreated patients. Patients with long initial remissions had a 45% disease-free survival rate at 10 years.³⁷

Patients who have an early relapse (less than 1 year after treatment) generally respond poorly to standard-dose salvage chemotherapy, with cure occurring in less than 20% of patients. High-dose chemotherapy and autologous HSCT is more effective, but also produces a higher risk of treatment-related mortality. The choice of salvage treatment should therefore consider the patient's tolerance for a particular set of chemotherapeutic agents and treatment approach (standard-dose chemotherapy vs. high-dose chemotherapy and autologous HSCT).

■ HEMATOPOIETIC STEM CELL TRANSPLANTATION

4 High-dose therapy should be considered in patients that relapse within 12 months of initial remission and those who are refractory to first-line chemotherapy.^{11,15,36} Although no one preparative regimen has been shown to be superior to another, most regimens do not include total body irradiation because of their potential pulmonary toxicity. Most patients are already at risk for pulmonary toxicity because they usually receive initial therapy containing one or more of the following: bleomycin, thoracic radiation, and nitrosoureas. High-dose chemotherapy with autologous HSCT produces long-term progression-free survival rates in patients with refractory and relapsed disease of 30% to 40% and 40% to 50%, respectively.^{11,36} More de-

tails describing high-dose chemotherapy and HSCT for refractory or relapse chemotherapy can be found in Chap. 134.

■ LONG-TERM COMPLICATIONS

A variety of acute and chronic toxicities may occur as a result of treatment for Hodgkin's lymphoma. Long-term complications of radiation therapy, chemotherapy, and combined modality therapy have become more evident as the curability and long-term survival of Hodgkin's lymphoma patients has improved.^{1,4} Gonadal dysfunction, secondary malignancies, and cardiac disease have become important considerations in the treatment of this malignancy. Almost all men and up to 50% of premenopausal women treated with six cycles of regimens containing alkylating agents will become sterile. This appears to be a dose-related phenomenon. For men, there does not appear to be a safe nonsterilizing dose of nitrogen mustard or chlorambucil, so if fertility is a major concern, ABVD may be the best alternative.^{1,2}

Now that 10-, 15-, and 20-year survival data are available, evaluation of secondary malignancies can be made. Recent reports show that after treatment for Hodgkin's lymphoma, the relative risk for secondary cancers is increased.^{1,2,4} Both solid tumors and hematologic malignancies (acute myelogenous leukemia/myelodysplastic syndrome and non-Hodgkin's lymphoma) have been observed. The increase in relative risk varies from about fourfold for solid tumors to over 100-fold for acute myelogenous leukemia. Radiation therapy is associated with the highest risk of developing a solid tumor (relative risk = 4.4).⁴ The overall risk of developing acute leukemia (usually occurring in the first 10 years) ranges from 2% to 6%, but may be significantly higher in certain subsets of patients.² The relative risk is highest in patients who are treated initially with chemotherapy, either alone or combined with radiation.⁴ Patients who receive MOPP or increased-dose BEACOPP therapy appear to have a higher risk of secondary acute leukemia as compared with ABVD; combined modality therapy further increases the risk of developing secondary leukemias.^{4,11}

NON-HODGKIN'S LYMPHOMA

The non-Hodgkin's lymphomas (NHL) are a heterogeneous group of lymphoproliferative disorders that affect people from early childhood to late adulthood. Advances in molecular biology techniques and our understanding of the human immune system have led to major progress in understanding the pathogenesis and treatment of the lymphomas. NHLs are classified into distinct clinical entities that are defined by a combination of morphology, immunophenotype, genetic features, and clinical features. These differences influence the natural history and approach and response to treatment. The use of extensive combination chemotherapeutic regimens has resulted in dramatic improvements in survival and cure in patients with a disease that once was considered incurable. The 5-year survival rate for patients with NHL has increased from 47% to 59% over the past 20 years.^{5,8} Further improvement in survival is anticipated with the continued expansion of our therapeutic armamentarium, including high-dose chemotherapy and biologic therapy.

EPIDEMIOLOGY AND ETIOLOGY

NHL is the fifth most common cause of newly diagnosed cancer in the United States and accounts for about 4% of all cancers. An estimated

56,390 new cases will be diagnosed in 2005, and it is estimated that 19,200 people will die from NHL during this same period.⁵ Although the average age of patients at the time of diagnosis is about 65 years, NHL can occur at any age.³⁸ The incidence rate generally increases with age, and is higher in men than in women and in whites than in blacks.⁸ The age-adjusted incidence rate of NHL has increased by more than 80% in the United States since the early 1970s, from about 11 cases per 100,000 in 1975 to more than 19 cases per 100,000 in the mid-1990s, with an average increase of about 3% to 4% per year.⁸ The incidence of NHL appears to have stabilized or even declined since reaching its peak in 1994, but it is not clear whether this observation is a long-term trend. The increase in the incidence of NHL over the past three decades is second only to melanoma, and has been referred to as an epidemic of NHL. Although the increased incidence has been particularly noted among the elderly and patients with the acquired immunodeficiency syndrome (AIDS), much of this increase cannot be explained by known risk factors.

The etiology of NHL is unknown, although several genetic diseases, environmental agents, and infectious agents have been associated with the development of NHL.^{38,39} An increased incidence of NHL is seen in many congenital and acquired immunodeficiency states, supporting the role of immune dysregulation in the etiology of NHL. Patients with congenital immunodeficiency disorders

(Wiskott-Aldrich syndrome, ataxia, or telangiectasia), acquired immunodeficiency disorders (AIDS, acquired hypogammaglobulinemia, or graft-versus-host disease), and chronic pharmacologic immunosuppression (solid organ transplantation) are predisposed to the development of NHL. Autoimmune diseases (Hashimoto's thyroiditis and Sjögren's syndrome) cause chronic inflammation in the mucosa-associated lymphoid tissue (MALT), which predisposes patients to subsequent lymphoid malignancies. Other autoimmune diseases such as systemic lupus erythematosus and rheumatoid arthritis have also been associated with the development of NHL, but the use of immunosuppressive agents in these diseases makes the pathologic cause less clear.

Certain infections have been associated with the development of lymphoma.^{38–40} EBV was discovered in cell lines from tumors of patients with African (endemic) Burkitt's lymphoma, and EBV DNA is associated with 95% of endemic Burkitt's lymphoma. However, EBV is associated with sporadic Burkitt's lymphoma in about 30% of cases. EBV is also associated with posttransplant lymphoproliferative disorders and some lymphomas in patients with AIDS or congenital immunodeficiencies. The human T-cell lymphotropic virus type 1 (HTLV-1) was the first human retrovirus associated with a malignancy. Infection with HTLV-1, especially in early childhood, is strongly associated with an aggressive form of T-cell lymphoma, known as adult T-cell leukemia/lymphoma (ATL). HTLV-1 is endemic in southern Japan, Africa, and the Caribbean. In endemic areas, more than 50% of all NHL cases are ATL. A third virus associated with NHL is human herpes virus 8. This virus was originally isolated from Kaposi's sarcoma lesions in AIDS patients. Finally, gastric infection with *Helicobacter pylori*, a gram-negative bacteria that leads to chronic gastritis, is associated with gastric MALT lymphomas.

A number of physical agents have also been associated with the development of NHL.^{38–40} Exposure to herbicides, particularly phenoxy herbicides, has been associated with the development of NHL. These observations may explain why workers in certain occupations, such as farmers, forestry workers, and agricultural workers, have been associated with a higher risk of NHL. Exposure to lawn care pesticides is also increasing in the general population. A higher risk of NHL has also been associated with exposure to other chemical solvents and dyes, exposure to radiation from nuclear explosions, and high intake of meats and dietary fats. Smoking or alcohol consumption has not been strongly associated with an increased risk of NHL.

GENETIC ABNORMALITIES

Chromosomal translocations have become a hallmark of many lymphoid malignancies.^{41,42} The presence of these specific translocations can be helpful in the diagnosis and classification of lymphoid malignancies. The mechanisms leading to the translocations are unknown, but they usually involve the antigen receptor loci. In contrast to most myeloid and some lymphoid leukemias, NHL usually places a structurally intact cellular protooncogene under the regulatory influence of the highly expressed immunoglobulin or T-cell receptor genes, leading to effects on cell growth, cellular differentiation, or apoptosis. The most common chromosomal translocations involve t(8;14), t(14;18), and t(11;14); each translocation involves the immunoglobulin heavy-chain gene locus on chromosome 14 at 14q32. The translocation t(8;14) that involves *c-MYC*, a well-characterized oncogene clearly associated with malignancy, is implicated in nearly all cases of Burkitt's lymphoma. The translocation t(14;18) that involves *BCL-2*, one of several putative B-cell lymphoma-associated oncogenes, is found in about 90% of follicular B-cell lymphomas. The translocation t(11;14) that involves *BCL-1*, is found in most patients

with mantle cell lymphoma. Another putative B-cell lymphoma-associated oncogene, *BCL-6*, is found in about a third of diffuse large B-cell lymphomas.

Although mutations in the *p53* tumor suppressor gene have been recognized in many human neoplasms, such mutations have not been consistently found in patients with lymphoma, which suggests that it may occur late in malignant evolution.

Detection of translocations, such as *BCL-2* in follicular lymphomas, can be used clinically to monitor for minimal residual disease. In patients with follicular lymphoma who received monoclonal antibody-purged autologous bone marrow transplantation, those whose bone marrow was negative by PCR for the *BCL-2* rearrangement after purging had significantly longer freedom from recurrence than those whose bone marrow remained PCR positive.⁴³

PATHOLOGY AND CLASSIFICATION

NHLs are neoplasms derived from the monoclonal proliferation of malignant B or T lymphocytes and their precursors. About 85% of NHLs in the United States are of B-cell origin. Proliferation of malignant cells results in the replacement of the normal cells and architecture of lymph nodes or bone marrow with a relatively uniform population of lymphoid cells. The classification of NHLs has evolved over the last five decades, as advances in immunology and genetics have allowed scientists to recognize a number of previously unrecognized subtypes of NHLs (Table 129–7).⁴⁴ The current classification schemes characterize the NHLs according to the cell of origin (B-cell vs. T-cell), clinical features, and morphologic features. Additional immunohistochemical markers, cytogenetic features, and genotypic characteristics may also be help to further classify NHL into subtypes.

MORPHOLOGY

The macroscopic and microscopic appearance of the involved tissue remains one of the most important factors in the diagnosis and classification of NHLs. In the 1950s, Rappaport and coworkers proposed a morphologic classification of malignant lymphomas based on two features: (1) that the malignant cell would disrupt the nodal architecture in a *nodular* or *diffuse* manner, and (2) that lymphomas of histiocytic origin existed. The Rappaport classification gained rapid acceptance in the United States because of its precision, simplicity, and prognostic significance. Application of the system divided NHLs into those with large (i.e., incorrectly called “histiocytes”) or small cells, with or without a nodular (i.e., follicular) growth pattern.

TABLE 129–7. Evolution in the Classification of Non-Hodgkin's Lymphomas

| Time | Classification System | Basis for Classification |
|-------------|-----------------------------------|----------------------------------|
| 1950s–1960s | Rappaport | Morphology |
| 1970s–1980s | Luke-Collins | Morphology and immunophenotype |
| 1970s–1980s | Kiel | Morphology and immunophenotype |
| 1980s–1990s | International Working Formulation | Morphology and clinical behavior |
| 1990s | REAL | Disease entities |
| 2001 | WHO | Disease entities |

REAL, Revised European-American Classification of Lymphoid Neoplasms developed by the International Lymphoma Study Group; WHO, World Health Organization.

IMMUNOLOGY

In the 1970s, it became apparent that NHLs were tumors of the immune system and were derived from B or T lymphocytes. The availability of techniques using antibodies to antigens on the surface of lymphoid cells (i.e., immunophenotyping) and cytochemical assays led to the following conclusions: (1) most NHLs were of B-cell origin; (2) all follicular or nodular lymphomas were of follicle center cell origin; and (3) most lymphomas previously classified as reticulum cell sarcoma or histiocytic lymphoma had the immunologic characteristics of transformed lymphocytes. Using this new information, a number of expert pathologists independently developed new classification schemes for NHL in the 1970s and 1980s.⁴⁴ The Kiel classification was based primarily on the work of Lennert and became widely used in Europe. In North America, the Luke-Collins classification scheme was used briefly, but was soon superseded by the International Working Formulation. Like the Rappaport classification, divisions within the International Working Formulation were based largely on cell size (large [“histiocytic”] versus small [lymphocytic]), cell shape (round vs. not round), and growth pattern (follicular [nodular] vs. diffuse). Both the Kiel and International Working Formulation classification schemes also considered the histologic grade of the tumor, but only the International Working Formulation considered actual survival curves of patients with the various subtypes of NHL. “Low-grade” indicated longer median survival (i.e., indolent) while “intermediate-grade” and “high-grade” indicated shorter median survival (i.e., aggressive). In the 1980s and early 1990s, the International Working Formulation became the most widely used classification scheme in North America, whereas the Kiel classification was widely used in Europe.⁴⁴ It was based on the premise that NHL was a single disease with a range of histologic grade and clinical aggressiveness.

NEW DISEASE ENTITIES

In the 1980s and early 1990s, rapid advances in immunology and genetics allowed scientists to recognize a number of previously unrecognized subtypes of NHLs. Cytogenetic and molecular genetic analyses identified the presence of many chromosomal translocations, oncogenes, and their gene products in patients with NHL (see the section on genetic abnormalities). In addition, diseases that would have been lumped together as “low grade” or “intermediate/high grade” in the International Working Formulation showed marked differences in survival, which prompted scientists to re-evaluate lymphoma classification schemes.

Information from these studies has allowed scientists to further classify B-cell lymphomas as malignant expansions of cells from either the germinal center, mantle zone, or marginal zone of normal lymph nodes (see Table 129–1).^{42,45} Germinal centers are complex structures that form in spleen and lymph nodes in response to antigenic challenge. In addition to B cells, germinal centers contain antigen-presenting cells and helper T cells that cooperate in mediating the B-cell changes that result in a more potent secondary immune response. Malignant transformation often occurs or is initiated in germinal center B cells. Follicular, Burkitt’s, and most large cell lymphomas are believed to be tumors of germinal center B cells. Three histologically distinct microenvironments have been described within the germinal center: a mantle zone surrounding interior dark and interior light zones. The mantle zone contains small resting B cells that have not been exposed to antigen (“naïve”). Tumors of cells from the mantle zone are usually clinically indolent and histologically low grade. Antigen-triggered activation of the densely packed

B cells of the dark zone causes cells to proliferate and causes genomic DNA to undergo somatic hypermutation. Surviving clones from within the dark zone then enter the light zone where proliferation slows and affinity selection occurs. During affinity selection, only cells with surface immunoglobulin receptors with high affinity for the antigen survive. Antigen-specific B cells generated in the germinal center reaction leave the follicle and reappear in the outer mantle zone, to form a marginal zone. Marginal zones are particularly prominent in mesenteric lymph nodes, Peyer’s patches, and the spleen. These post-germinal center B cells include memory B cells of the marginal zone and plasma cells. Marginal cell B-cell lymphomas tend to be indolent and may be either extranodal or nodal; extranodal marginal cell B-cell lymphomas are also referred to as MALT lymphomas.

T-cell lymphomas can be classified on the basis of antigen expression as either precursor (thymic) or mature (peripheral) in origin. These classifications clinically translate to precursor lymphoblastic lymphomas or to a heterogeneous group of peripheral T-cell lymphomas. Tumors of natural killer or natural killer-like T cells are uncommon.

The International Lymphoma Study Group, an informal group of 19 hematopathologists from the United States, Europe, and Asia, adopted a new approach to lymphoma classification in 1993. Since it represented a revision of current or prior European and American lymphoma classifications, it was called the REAL. The REAL classification system is based on the principle that a classification is a list of “real” disease entities, which are defined by a combination of morphology, immunophenotype, genetic features, and clinical features.^{46,47} The relative importance of each of these criteria for both definition and diagnosis differs among different diseases. Morphology is always important, and some diseases are primarily defined by morphology alone (e.g., follicular lymphoma), although immunophenotype can be helpful in difficult cases. Some diseases have a specific immunophenotype (e.g., mantle cell lymphoma or small lymphocytic lymphoma) that is virtually diagnostic of that disease. A specific genetic abnormality is important in some lymphomas—t(11;14) in mantle cell lymphoma, t(8;14) in Burkitt’s lymphoma, and t(14;18) in follicular lymphoma—while other lymphomas lack specific genetic abnormalities (e.g., MALT lymphoma and diffuse large B-cell lymphoma). Finally, other lymphoma classes take into account clinical features (e.g., extranodal vs. nodal presentation in marginal zone lymphoma and peripheral T-cell lymphoma). A recent retrospective study of the REAL classification confirmed the clinical relevance of this approach.⁴⁸

Since 1995, members of the European and American hematopathology societies have worked to develop a new WHO classification of hematologic malignancies. The final classification was published in 2001.¹³ The WHO classification uses an updated version of the REAL classification and expands the principles of the REAL classification to the classification of myeloid and histiocytic malignancies.

5 The REAL-WHO classification categorizes lymphoid malignancies into three major categories: B-cell lymphomas, T-cell (and putative natural killer cell) lymphomas, and Hodgkin’s lymphoma (see Table 129–2).^{46,47} Within the B-cell and T-cell neoplasm category, there are two major categories: “precursor” neoplasms, which correspond to the earliest stages of differentiation (lymphoblastic), and “peripheral” neoplasms, which correspond to the more differentiated B- and T-cell stages. The REAL-WHO classification uses the term “grade” to refer to histologic parameters such as cell and nuclear size, density of chromatin, and proliferation fraction, and the term “aggressiveness” to denote clinical behavior of a tumor. This

classification scheme includes both lymphomas and lymphoid leukemias, because there is no distinction between the solid and circulating forms of these diseases. The REAL-WHO classification includes several previously unrecognized types of lymphomas, including mantle cell lymphoma, monocytoid B-cell lymphoma, extranodal lymphoma of MALT, splenic marginal zone lymphoma, primary mediastinal large B-cell lymphoma, and a variety of T-cell lymphomas. New entities not specifically recognized in the International Working Formulation account for about 20% to 25% of the cases.

The REAL-WHO classification has broad clinical implications. The WHO Clinical Advisory Committee has agreed that clinical groupings of lymphoid neoplasms into prognostic categories are neither necessary nor desirable because such arbitrary groupings are of no practical value and may be misleading.⁴⁹ Treatment of a specific patient should be determined not by the broad prognostic group into which the patient's neoplasm falls, but by the specific type of neoplasm, with the addition of grade *within* the tumor type (if applicable), and clinical prognostic factors.

CLINICAL PRESENTATION

Patients with NHL present with a wide variety of symptoms, depending on the site of involvement and whether tumor involvement is nodal or extranodal.^{38,40} Sites of involvement and dissemination of the malignant cells can sometimes be predicted based on the cell of origin and the fact that the tumor frequently disseminates to areas where the normal counterparts of the lymphoma cells are located. For example, B-cell lymphomas involve areas of the lymphoid system normally populated by B-lymphocytes, such as lymph nodes, spleen, and bone marrow. T-cell lymphomas commonly disseminate to various extranodal sites such as the skin and lungs. In contrast to Hodgkin's lymphoma, the bone marrow is commonly involved in NHL.

In general, patients may have either localized or generalized adenopathy, with the involved nodes being painless, rubbery, and discrete, and usually located in the cervical and supraclavicular regions as in Hodgkin's disease. The liver or spleen may be enlarged in patients with generalized adenopathy. Patients with mesenteric or gastrointestinal involvement may present with signs and symptoms of nausea, vomiting, obstruction, abdominal pain, a palpable abdominal mass, or gastrointestinal bleeding. Patients with bone marrow involvement may have symptoms related to anemia, neutropenia, or thrombocytopenia. NHL has a greater tendency to involve the testes, epitrochlear nodes, and Waldeyer's ring than Hodgkin's lymphoma. The incidence of solitary brain lymphoma is increasing, especially in patients with AIDS. Infrequently, patients with NHL may present with acute renal failure from retroperitoneal adenopathy causing ureteral obstruction, or from metabolic abnormalities such as hyperuricemia with uric acid nephropathy.

In contrast to Hodgkin's lymphoma, only about 20% of patients with NHL have the constitutional symptoms of fever, night sweats, and weight loss of greater than 10%.

DIAGNOSIS, STAGING, AND PROGNOSTIC FACTORS

As with Hodgkin's lymphoma, the diagnosis of NHL must be established by pathologic review of tissue obtained by biopsy. The preferred procedure is an excisional biopsy, in which the entire involved lymph node is removed for review by an experienced hematopathologist. This procedure should be done carefully to prevent distortional artifact of the architecture, which could lead to an inaccurate diagnosis. Needle biopsy of the node can sometimes provide adequate tissue for

pathologic diagnosis, if an excisional biopsy cannot be performed. When adenopathy is not present, diagnosis may be established by biopsy of cutaneous lesions, bone marrow biopsy and aspiration in patients with unexplained myelosuppression, liver biopsy in patients with hepatomegaly or elevated liver function transaminases, or biopsy of involved extranodal organs, such as bone, Waldeyer's ring, lung, and testis.

After the diagnosis is established, further work-up is required to determine the extent of involvement.^{38,50} Clinical staging always begins with a thorough history and physical examination. Patients should be questioned about the presence or absence and extent of fever, night sweats, and weight loss. A detailed history of lymphadenopathy should also be obtained, including when and where the lymph nodes were first noted, and their rate of growth. A complete physical examination is performed to assess the extent of disease involvement, with special attention given to all nodal areas. All patients should have a complete blood count, serum chemistries including liver and renal profiles, a chest x-ray, and bone marrow aspiration and biopsy. The likelihood of bone marrow involvement varies among the different histologic types of lymphoma (Table 129–8). Lumbar puncture to evaluate the cerebrospinal fluid is recommended in patients who have histologic types of lymphoma that often spread to the central nervous system.

Imaging studies are usually important in the staging work-up.^{38,50} CT scanning can identify both nodal and extranodal sites of disease, and has largely replaced lymphangiography for the evaluation of retroperitoneal lymphadenopathy. The abdominal and pelvic CT scan can identify mesenteric and retrocrural node involvement. CT scans can also detect tumor involvement of organs, including the kidneys, ovary, spleen, and liver. MRI is of limited usefulness in the staging of NHL. Gallium scans are sometimes used as part of the staging work-up. Other tests, such as liver-spleen scan, bone scan, upper gastrointestinal series, and intravenous pyelogram, are sometimes useful in patients with organ symptomatology or serum chemistry abnormalities.

Staging laparotomy was widely used in the late 1960s and 1970s as part of the staging work-up in patients with lymphoma, but it is rarely used today because of technical improvements in imaging studies and the morbidity and potential mortality associated with the procedure.

The Ann Arbor staging classification developed for the clinical staging of Hodgkin's lymphoma is also used to stage patients with NHL (see Table 129–3). After completion of the staging work-up, most patients will be found to have advanced disease (stages III and IV). The frequency of localized disease at the time of diagnosis varies depending on the histologic type of lymphoma (see Table 129–8). Stage is a more important prognostic factor in Hodgkin's lymphoma than in NHL.

The Ann Arbor system emphasizes the distribution of nodal disease sites because Hodgkin's lymphoma usually spreads through contiguous lymph nodes and does not involve extranodal sites. But NHL is a disease with tremendous heterogeneity that does not spread through contiguous lymph nodes, and that often involves extranodal sites. As a result of these clinical differences between Hodgkin's lymphoma and NHL, there is poor correlation between Ann Arbor stage and prognosis.

6 This lack of accuracy with the Ann Arbor staging system in NHL has led to several international projects to develop prognostic models in the most common types of NHLs—diffuse large cell lymphomas and follicular lymphomas. The International Non-Hodgkin's Lymphoma Prognostic Factors Project was based on more than 2,000 patients with diffuse aggressive lymphomas treated with

TABLE 129–8. Patient Characteristics of the Common Histologic Types of Non-Hodgkin’s Lymphoma

| Histologic Type | % of Total | % Male | Median Age | % Stage I or II | % Marrow Positive | % IPI 0/1 | % IPI 4/5 |
|---|------------|--------|------------|-----------------|-------------------|-----------|-----------|

an anthracycline-containing combination chemotherapy regimen in the United States, Europe, and Canada.⁵¹ The Project identified five risk factors that correlated with low response to chemotherapy and poor survival: (1) age >60 years, (2) reduced performance status ≥ 2 , (3) abnormal serum lactate dehydrogenase (LDH) levels, (4) two or more extranodal sites of disease, and (5) advanced tumor stage (Ann Arbor stages III or IV; Table 129–9). In patients ≤ 60 years old, three risk factors correlated with low response to chemotherapy and poor survival: (1) reduced performance status, (2) abnormal serum LDH levels, and (3) Ann Arbor stage. It is unclear whether the effect of

serum LDH level is related to a tumor or a host event. LDH likely measures cellular catabolism (the enzyme is released from injured cells), or the product of tumor burden and proliferation. Because each of the factors has approximately the same impact (e.g., relative risk) on prognosis, the number of adverse risk factors is summed to provide the IPI score. Patients could therefore have a score of 0 to 5. Table 129–9 shows the correlation between the IPI score and complete response rate and 5-year survival. For patients ≤ 60 years old, a simplified IPI score can be developed based on Ann Arbor stage, serum LDH, and performance status.

TABLE 129–9. Risk Factors and Survival According to the International Non-Hodgkin’s Lymphoma Prognostic Factors Project

| All Patients | | Patients ≤ 60 Years of Age | |
|---------------------------------------|------------------------|---------------------------------|--------------------------|
| Age >60 years of age | | LDH > normal | |
| LDH > normal | | Performance status ≥ 2 | |
| Performance status ≥ 2 | | Ann Arbor stage III or IV | |

Adapted from Solal-Celigny et al.⁵²

Although the IPI is often used to predict prognosis in patients with other NHL subtypes, the IPI has several shortcomings when applied to patients with indolent lymphomas. Because only patients with diffuse aggressive lymphomas were used to develop the IPI system, some important prognostic factors may have been missed. Furthermore, the IPI system has limited discriminating power in follicular lymphoma because only about 10% of patients are categorized as high-risk in the IPI system. To address these concerns, several studies have attempted to develop a clinically useful prognostic model in patients with follicular lymphoma. However, none of these prognostic models has been validated or widely used. An international cooperative study was designed to develop a prognostic model similar to the IPI in patients with follicular lymphoma.

The results of that study, which was based on more than 4,000 patients with follicular lymphoma diagnosed between 1985 and 1992, was recently published.⁵² Five factors were identified that correlated with poor survival: (1) age >60 years, (2) advanced tumor stage (Ann Arbor stages III or IV), (3) low hemoglobin level (<12 g/dL), (4) five or more nodal sites of disease, and (5) abnormal serum LDH level. Analogous to the IPI, the number of adverse risk factors is summed to provide the FLIPI. Three prognostic groups were identified: low-risk (0 to 1 factors), intermediate-risk (2 factors), and high-risk (≥3 factors). The new system appeared to have higher discriminating power among groups as compared with the IPI system. Table 129–10 shows the correlation between the FLIPI score and overall survival.

▶ TREATMENT: Non-Hodgkin's Lymphoma

■ GENERAL TREATMENT PRINCIPLES

The primary goals in the treatment of NHL are to relieve symptoms, cure the patient of their disease whenever possible, and minimize the risk of serious toxicities. The treatment strategy depends on many factors including patient age, concomitant disease, disease type, stage of disease, site of disease, and patient preference.

Historically, both the clinical behavior and degree of aggressiveness are often used to describe NHLs. The term *favorable* is used to describe indolent lymphomas because of their relatively slow growing behavior. Indolent lymphomas make up about 25% to 40% of all NHLs. Patients with an indolent lymphoma usually have a relatively long survival, with or without aggressive chemotherapy. Although these lymphomas respond to a wide range of therapeutic approaches, there is no evidence of a survival plateau, which indicates that patients are rarely cured of their disease. In contrast, aggressive lymphomas are termed *unfavorable* because of their rapid growth rate and short survival (measured in weeks to months), if appropriate therapy is not initiated. Aggressive lymphomas make up about 60% to 75% of all NHLs. Although these unfavorable lymphomas are generally more aggressive than indolent lymphomas, many patients with aggressive lymphomas who respond to chemotherapy can experience prolonged disease-free survival and some are cured of their disease. Therefore the terminology for the NHLs represents a paradox, where “favorable” is bad and “unfavorable” is good in terms of the likelihood for cure.

Therapeutic approaches to NHL include radiation therapy, chemotherapy, and biologic agents. The role of radiation therapy in the treatment of NHL differs from its role in the treatment of Hodgkin's disease. Although the disease is responsive to radiation therapy, only a small percentage of patients with NHL present with truly localized disease that can be treated with local or regional radiation therapy. Radiation therapy is used more commonly in advanced disease, primarily as a palliative measure to control local bulky disease.

Effective chemotherapy for NHL ranges from single-agent therapy in indolent lymphomas to aggressive, complex combination chemotherapy regimens in aggressive lymphomas. The most active agents used in the treatment of NHL include the alkylating agents (e.g., cyclophosphamide and chlorambucil), bleomycin, doxorubicin, purine analogues, etoposide, methotrexate, vincristine, and corticosteroids (e.g., prednisone and dexamethasone).

B-cell lymphomas have served as a model for immunotherapy with monoclonal antibodies for more than 20 years, beginning with the successful use of custom-made monoclonal antibodies targeted against the idiotype present on the patient's cancer cells.⁵³ These encouraging results led to the development of monoclonal antibodies against a more “generic” target, a molecule on the surface of B cells that would be present on tumor cells.⁵⁴ One potential target, the CD20 molecule, was present only on cells in the B-lymphocyte lineage. It is expressed on the surface of both normal and malignant B-cells, but not on other normal tissues. Rituximab (Rituxan) is a chimeric monoclonal antibody directed at the CD20 molecule.⁵⁵ Since rituximab was approved in November 1997 to treat relapsed or refractory indolent or

follicular CD20⁺ lymphomas, it has become one of the most widely used therapies for NHL. More recently, two radiolabeled monoclonal antibodies (i.e., radioimmunoconjugates) targeted against the CD20 antigen have been approved. With the availability of monoclonal antibodies and radioimmunoconjugates for the therapy of lymphoma, most patients with NHL will receive one or more biologic agents during the course of their disease.

Objective response to therapy for NHL should be defined according to the International Workshop to Standardize Response Criteria for Non-Hodgkin's Lymphoma.⁵⁶ Appropriate therapy for NHL depends on the patient's age, histologic type, stage of disease, site of disease, and IPI or FLIPI score (or presence of adverse prognostic factors). In general, treatment of lymphoma can be divided into that of limited disease and that of advanced disease. The limited disease group includes those patients with localized disease (Ann Arbor stages I and II). The advanced disease group is defined as all Ann Arbor stage III or IV patients, and also frequently includes Ann Arbor stage II patients with poor prognostic features (see Tables 129–9 and 129–10).^{51,52}

The following section will discuss the clinical characteristics and therapy of the most common disease entities.

■ INDOLENT LYMPHOMAS

■ FOLLICULAR LYMPHOMAS

The combined group of follicular lymphomas makes up the second most common histologic type of NHL in the United States, comprising about 20% of all NHLs worldwide and up to 70% of indolent lymphomas reported in American and European clinical trials.^{48,57} These lymphomas are classified as *follicular small cleaved cell*, *follicular mixed cell*, and *follicular large cell lymphoma* in the Working Formulation.⁴⁶ In the study that led to the development of the International Working Formulation, patients with follicular small cleaved cell and mixed cell lymphomas had significantly better survival than did those with follicular large cell lymphoma.⁵⁸ Therefore, follicular small cleaved cell and mixed cell lymphomas were considered as low-grade lymphomas, whereas follicular large cell lymphomas were considered to be intermediate-grade lymphomas. However, it is difficult to divide cases of follicular lymphoma into distinct subtypes because there is a continuous gradation in the number of large cells (i.e., centroblasts), and there are no uniform criteria for assignment of follicular lymphoma into the various subtypes. As a result, there is major disagreement, even among expert hematopathologists, on the subtype in many cases. In the International NHL Classification Project, the percentage of agreement for the various grades of the follicular lymphomas was only 61% to 73%.⁴⁸

The WHO classification includes criteria for grading follicular lymphoma based on the number of centroblasts per high-power field (hpf): grade 1 (0 to 5 centroblasts/hpf), grade 2 (6 to 15 centroblasts/hpf), and grade 3 (> 15 centroblasts/hpf).¹³ The clinical behavior and treatment outcome of grades 1 and 2 follicular lymphoma are similar, and they are usually treated as indolent lymphomas. In contrast, grade 3 follicular lymphoma is synonymous with what is often referred to as follicular large cell lymphoma, and is usually treated as an aggressive lymphoma.

Follicular lymphomas tend to occur in older adults, with a slight female predominance (see Table 129–8). Most patients have advanced disease at diagnosis, but about 25% to 33% of patients have localized disease (clinical stage I or II) at diagnosis.⁴⁸ Extranodal disease, bulky disease, and B symptoms (constitutional symptoms) are

uncommon features at diagnosis. Most patients with follicular lymphoma have the chromosomal translocation t(14;18) at the time of diagnosis.

The clinical course is generally indolent, with median survivals of 8 to 10 years. Most patients have dramatic responses to initial therapy, and their disease course is characterized by multiple relapses, with responses to salvage therapy becoming progressively shorter after every relapse, eventually leading to death from disease-related causes.⁵⁹ The natural history of follicular lymphoma shows a pattern of constant relapses over time (i.e., no evidence of a survival plateau), which suggests that patients are not cured of their disease. But the natural history of follicular lymphoma can be unpredictable. Spontaneous regression of objective disease has been noted in as many as 20% to 30% of patients.⁵⁹ There is also a high conversion rate of follicular lymphoma to a more aggressive histology over time that steadily increases after diagnosis and reaches 40% to 70% at 8 to 10 years.⁵⁹ At autopsy, 95% of patients with follicular lymphoma have some evidence of diffuse large B-cell lymphoma. Patients with transformed indolent lymphoma should be treated in the same way as an aggressive lymphoma.

Certain subsets of patients with follicular lymphoma have a much better or worse prognosis. Some studies suggest that the natural history of follicular large cell lymphoma (i.e., grade 3 follicular lymphoma) is similar to that of other aggressive lymphomas, and that treatment with intensive combination chemotherapy regimens may result in long-term disease-free survival, including a possible plateau in the survival curve.^{57,60} The recent development of the FLIPI prognostic model should help clinicians to identify patients in different prognostic groups based on disease characteristics at the time of diagnosis.⁵² Patients who are predicted to have a poor prognosis (i.e., high-risk) could then be offered aggressive or experimental therapy, while those who are predicted to have a good prognosis (i.e., low-risk) would be treated with standard therapy, therefore avoiding unnecessary toxicity.

■ Therapy of Localized Disease (Stages I and II)

Radiation therapy is the standard treatment for early-stage follicular lymphoma. Involved-field, extended-field, and total nodal irradiation have been used. Carefully staged patients with either stage I or contiguous stage II disease treated with radiation therapy alone can achieve disease-free survival rates of 40% to 50% and overall survival rates of 60% to 70% at 10 years.⁵⁷ Late relapses are uncommon; only 10% of patients who reached 10 years without relapse subsequently experienced a recurrence.

Chemotherapy is not usually given in most patients with localized follicular lymphoma, but it may be helpful in some patients with high-risk stage II disease (e.g., multiple sites of involvement or bulky disease).⁶¹

8 About 40% to 50% of patients with clinical stage I or II follicular lymphoma are cured of their disease with radiation therapy alone.⁵⁷ Most centers use radiation at a dose of 30 to 40 Gy to either involved (i.e., local) or regional fields, which would consist of irradiation to the involved nodal region plus one additional uninvolved region on each side of the involved nodes. Extended-field irradiation is not usually used because of the absence of a survival benefit and possible increased risk of secondary malignancies. In addition, previous use of extended-field irradiation compromises the ability of that patient to receive subsequent chemotherapy. The 2004 NCCN guidelines state that locoregional radiation therapy, chemotherapy followed by radiation therapy, or extended-field radiation therapy are appropriate options for patients with early-stage follicular lymphoma.⁵⁰

■ Therapy of Advanced Disease (Stages III and IV)

8 The management of stage III and IV indolent lymphomas remains controversial, as standard therapeutic approaches have not been shown to be curative despite the high complete remission rates to initial therapy. Therapeutic options for these patients are diverse and include watchful waiting, radiation therapy, single-agent chemotherapy, combination chemotherapy, biologic therapy, and combined-modality therapy.^{38,57,62} Although complete remission can be achieved in 50% to 80% of patients with various treatments, the median time to relapse is usually only 18 to 36 months. About 20% of patients who have a complete response remain in remission for longer than 10 years. After relapse, patients are re-treated and again high remission rates can be achieved (see below). Unfortunately, the response rates and duration of response both decrease with each re-treatment.

Two different initial treatment approaches exist and are described as conservative or aggressive. Patients treated with the conservative approach receive no initial therapy followed by single-agent chemotherapy or radiation therapy when treatment is needed. Candidates for the conservative approach are usually older, asymptomatic, and have minimal tumor burden. Patients with symptoms, extensive extranodal involvement, bulky disease, or impaired end-organ function at the time of diagnosis are not candidates for conservative treatment. With the aggressive approach, patients usually receive rituximab, combination chemotherapy, or both, early in the disease course. There are no convincing data to indicate that immediate aggressive therapy significantly improves survival as compared with conservative therapy. More than 80% of patients with stage III or IV follicular lymphoma are alive at 5 years, and the median survival is about 7 to 8 years.

CLINICAL CONTROVERSY

The management of advanced indolent lymphomas is controversial because none of the therapeutic approaches have been shown to be curative despite the high complete remission rates to initial therapy. Therapeutic options for these patients are diverse and include watchful waiting, radiation therapy, single-agent chemotherapy, combination chemotherapy, biologic therapy, and combined modality therapy. Although more intensive therapies have a higher complete response rate, they have not been shown to increase overall survival as compared with more conservative approaches.

At the time of relapse, many treatment options are available.⁶³ At the time of relapse, the following factors must be considered: age, symptomatic status of the patient, tumor burden, rate of regrowth (based on previous assessment of active disease sites), presence or absence of characteristics suggesting transformation or biologic progression, prior therapy, degree and duration of response to prior therapy, availability of clinical trials, and patient preferences.

■ **No Initial Therapy.** Because there are no convincing data that standard treatment approaches have improved survival, some clinicians have adopted a “watch and wait” approach for asymptomatic patients in which therapy is delayed until the patient experiences systemic symptoms or disease progression such as rapidly progressive or bulky adenopathy, anemia, thrombocytopenia, or disease in threatening sites such as the orbit or spinal cord.⁵⁹ The median time until treatment is required is 3 to 5 years, and about 20% of patients do not require therapy for up to 10 years. The 10-year survival is 73%, which is not significantly different from patients who received therapy at the time of diagnosis. In a randomized study of asymptomatic patients

with indolent lymphomas (mostly follicular), patients who underwent watchful waiting had similar cause-specific and overall survival as compared with those who received immediate chlorambucil.⁶⁴ With a median length of follow-up of 16 years, about 17% of patients who were randomized to the watchful waiting group died of other causes without receiving chemotherapy and an additional 9% are alive and have not yet had chemotherapy. As described above, patients with follicular lymphoma who are followed without therapy sometimes have spontaneous regressions that can be complete, while the disease in other patients can convert to a more aggressive histology. If the watchful waiting approach is chosen, the patient should be evaluated at least every 2 months for the first year and quarterly thereafter, so that intervention can occur before serious problems occur.

■ **Radiation.** Follicular lymphoma is sensitive to radiation therapy, and total lymphoid irradiation or whole body irradiation has been used to treat patients with advanced follicular lymphoma. Although the results with total lymphoid irradiation have been excellent in selected patients with limited stage III follicular lymphoma,⁵⁷ extensive radiation therapy is rarely used for patients with advanced follicular lymphoma requiring systemic therapy because of concerns regarding prolonged myelosuppression and difficulties in administering future treatments. Total lymphoid irradiation has been given in combination with chemotherapy, but studies have failed to show a survival advantage for combined modality treatment.^{38,57} As a result, new high-dose chemotherapy regimens usually do not include the use of total lymphoid irradiation.

■ **Chemotherapy.** Oral alkylating agents, given either alone or in combination, have been the mainstay of treatment for follicular lymphoma. More intensive chemotherapy has not been shown to improve patient outcome. In a randomized trial of oral chlorambucil (0.1 to 0.2 mg/kg per day), oral cyclophosphamide (1.5 to 2.5 mg/kg per day), or CVP (cyclophosphamide, vincristine, and prednisone) in patients with indolent lymphoma, no significant difference in overall survival or freedom from relapse between the three groups was observed.⁵⁹ In a more recently published randomized trial of single-agent cyclophosphamide (100 mg/m² per day) versus CHOP-B (cyclophosphamide, doxorubicin, vincristine, prednisone, and bleomycin), no significant difference in overall time to failure or overall survival was observed at 10 years.⁶⁵ The dosage of single-agent chlorambucil or cyclophosphamide is usually adjusted to maintain a platelet count above 100,000/mm³ and a white blood cell count above 3,000/mm³. Although single-agent alkylating agents have a high initial complete remission rate, the time required to achieve a complete response is slow (median time is 9 to 12 months). Complete responses occur more rapidly with combination chemotherapy, particularly with doxorubicin-containing regimens. Many clinicians will therefore give CHOP (cyclophosphamide, doxorubicin, vincristine, and prednisone) or CHOP-like chemotherapy when a rapid response is necessary. Table 129–11 shows the CHOP regimen that is widely used in the

TABLE 129–11. CHOP Regimen

| Drug | Dose (mg/m ²) | Route | Treatment Days |
|----------------------|---------------------------|-------|----------------|
| Cyclophosphamide | 750 | IV | 1 |
| Doxorubicin | 50 | IV | 1 |
| Vincristine | 1.4 | IV | 1 |
| Prednisone | 100 | Oral | 1–5 |
| One cycle is 21 days | | | |

Note: Another name for doxorubicin is hydroxydaunomycin

treatment of NHL. In those who achieve a complete response, the duration of response is relatively short (about 2.5 years). There is no benefit of maintenance therapy. After the best response is achieved, many experts will discontinue therapy and observe.

Both single-agent alkylating agents and CVP are well tolerated by most patients. The advantages of oral chlorambucil are no hair loss, little or no nausea, and minimal myelosuppression. Because of its mild side-effect profile, oral chlorambucil is usually recommended for older patients who are minimally symptomatic or who have other comorbidities. There are some concerns with the risk of secondary acute leukemia in patients receiving continuous exposure to alkylating agents.

■ **Purine Analogues.** Several studies have reported encouraging results with two adenosine analogues, fludarabine phosphate and 2-chlorodeoxyadenosine (2-CdA; cladribine), in previously untreated and relapsed advanced follicular lymphoma. The mechanism of action for both drugs is not well understood, but both agents accumulate in lymphocytes and are resistant to adenosine deaminase. In patients with relapsed or refractory indolent lymphoma, single-agent fludarabine has an overall response rate of almost 50% and a complete response rate of 10% to 15%. Response rates are higher in previously untreated patients, with overall and complete response rates of 70% and almost 40%, respectively.⁶² The median time to progression is less than 6 months for relapsed disease and more than 12 months for previously untreated patients. Although the response rates to 2-CdA in previously untreated patients is similar to those with fludarabine, the duration of response appears to be shorter with 2-CdA. Combination regimens that include one of these purine analogues are also being investigated.⁶² Fludarabine and mitoxantrone (FN) and fludarabine, mitoxantrone, and dexamethasone (FND) are examples of fludarabine-containing regimens that have shown encouraging results in patients with indolent lymphoma.^{66,67}

Purine analogues usually do not cause nausea and vomiting or hair loss, but they are associated with cumulative and prolonged myelosuppression and profound immunosuppression, which increases the risk of opportunistic infections such as fungal infections, *Pneumocystis carinii* pneumonia, and viral infections.

■ **Interferon Alfa.** Single-agent interferon alfa (IFN- α) is active in the treatment of follicular lymphoma, with objective response rates of 30% to 50% in patients with relapsed disease.⁶⁸ About 10% of patients have a complete response to IFN- α . Several randomized controlled trials have evaluated the potential benefit of adding IFN- α to combination chemotherapy. Based on the results of one of these trials, IFN- α -2b (Intron A) was granted FDA approval as initial treatment for patients with clinically aggressive follicular lymphoma and a large tumor burden, in combination with an anthracycline-containing regimen. Its approval was based on the Groupe d'Etude des Lymphomes Folliculaires trial, which compared CHVP (cyclophosphamide, doxorubicin, teniposide, and prednisone) to CHVP and IFN- α -2b.⁶⁹ CHVP was given monthly for six cycles, then every 2 months for six more cycles, whereas IFN- α -2b was given at a dose of 5 million units three times a week for 18 months. Patients who received concurrent IFN- α -2b had a significantly higher response rate (85% vs. 69%), which translated into significant differences in median progression-free interval (2.9 years vs. 1.5 years) and overall survival (not reached versus 5.6 years).

At least ten randomized controlled trials in the United States and Europe have evaluated the role of IFN- α either during induction, as maintenance therapy, or in both settings. The results of these trials have been inconsistent.^{62,70} In a meta-analysis of more than 1,500

newly diagnosed patients from the various randomized trials, the efficacy of IFN- α depended on the intensity of the chemotherapy regimen and response to induction chemotherapy. The major conclusion of the meta-analysis was that IFN- α was probably beneficial in responsive patients (those who had a partial or complete response to induction chemotherapy) who were receiving more intensive chemotherapy (an anthracycline- or anthracene-containing regimen).

In the most recent randomized controlled trial, 571 patients with stage III or IV indolent NHLs (mostly follicular) were studied as part of a Southwest Oncology Group (SWOG) trial. Patients who responded to intensive chemotherapy that consisted of six to eight cycles of prednisone, methotrexate, doxorubicin, cyclophosphamide, and etoposide/mechlorethamine, vincristine, procarbazine, and prednisone (ProMACE/MOPP) or chemotherapy plus irradiation therapy were randomized to receive either consolidation IFN- α -2b (2 million units/m² given three times weekly SC) for 2 years or observation.⁷¹ With a median follow-up of more than 6 years, no difference in progression-free or overall survival was observed.

The reasons for the divergent results cannot be easily explained.⁷⁰ Based on these negative results, the significant cost and toxicities associated with this agent, and the recent availability of other treatment options, most clinicians no longer use IFN- α in patients with indolent lymphomas.

■ **Rituximab.** The approval of rituximab is arguably the most important recent development in the treatment of NHL. Its initial approval was based on an open-label multicenter study that enrolled 166 patients with relapsed or recurrent indolent lymphoma.⁷² Rituximab, given intravenously at a dose of 375 mg/m² weekly for 4 weeks, resulted in an overall response of 48% (complete response [CR]: 6%; partial response [PR]: 42%). Median time to progression for responders was 13.2 months and median duration of response was 11.6 months. Other studies of single-agent rituximab in patients with relapsed or refractory indolent NHL have reported overall response rates of 40% to 60% and complete response rates of 5% to 10%.^{55,73} Investigators have evaluated different dosages and dosage schedules of single-agent rituximab, including higher dosages (up to 2 g/m²), more frequent administration (three times per week), and more doses (weekly for 8 weeks). Although these alternative dosages or dosage schedules have been well tolerated (i.e., no dose-limiting toxicity was observed), they do not appear to increase the antitumor activity of rituximab.

Another advantage of rituximab is that it can be safely used as a retreatment option. About 40% of patients who relapsed after a response to rituximab have an objective response to re-treatment with rituximab.⁷⁴ Interestingly, patients who respond the second time usually have longer durations of remission than they did to the first course. Therefore, many clinicians will consider retreatment with rituximab for patients who have a sustained (i.e., more than 6 months) first remission and if their tumor has continued expression of CD20 antigen.

Based on the activity of rituximab in relapsed or refractory patients, it is increasingly being used as first-line therapy, either alone or in combination with chemotherapy.^{55,73} When given as a single agent to patients with previously untreated indolent NHL, the overall response rate is 60% to 70% and the complete response rate is 20% to 30%. It is interesting to note that many of these patients remain in molecular remission (i.e., PCR-negative) at 12 months.⁷⁵ In patients who respond to the standard rituximab regimen (375 mg/m² weekly for 4 weeks), some studies have evaluated the role of maintenance rituximab, given at a dose of 375 mg/m² weekly for 4 weeks every 6 months, in an attempt to improve the initial therapeutic response

and prolong duration of remission.⁷⁶ With continued maintenance therapy, the final response rate increased to 73%, with 37% complete responses. Median progression-free survival was 34 months. Based on these encouraging results, the role of maintenance rituximab is being investigated in a multicenter cooperative group randomized trial.

The rationale for the use of rituximab in combination with conventional agents is based on clinical activity of both agents/regimens, non-cross-resistant mechanisms of action, non-overlapping toxicities, and synergistic antitumor activity *in vitro*. Many clinical trials have evaluated the use of rituximab in combination with other chemotherapy agents.^{55,73} In a phase II trial of six courses of rituximab and CHOP chemotherapy (R-CHOP), the overall and complete response rate in 40 patients with previously untreated or relapsed indolent lymphoma was 95% and 55%, respectively.⁷⁷ More than 70% of patients are progression-free after 4 years of follow-up. In an updated analysis, median time to progression was reached at 82 months. Rituximab and CHOP chemotherapy can be combined in many different ways. In the R-CHOP regimen developed by Czuczman and associates,⁷⁷ two doses of rituximab are given before the start of CHOP therapy, two more doses are given in the middle of the six cycles of CHOP, and two additional doses are given at the end of CHOP therapy. No significant additional toxicity was observed in patients who received R-CHOP. Similar overall and complete response rates have been reported with clinical trials of rituximab combined with other chemotherapy regimens.^{55,73}

Most of the adverse effects of rituximab are infusion related, particularly after the first infusion, and consist of fever, chills, respiratory symptoms, fatigue, headache, pruritus, and angioedema.⁵⁵ Premedication with oral acetaminophen 650 mg and diphenhydramine 50 mg is usually given 30 minutes before rituximab infusion.

■ **Radioimmunotherapy.** The recent approval of the anti-CD20 radioimmunoconjugates ¹³¹I-tositumomab (Bexxar) and ⁹⁰Y-ibritumomab tiuxetan (Zevalin) has provided clinicians with a novel treatment option for patients with indolent NHLs.^{78,79} Both ¹³¹I-tositumomab and ⁹⁰Y-ibritumomab tiuxetan are mouse antibodies linked to a radioisotope, either iodine 131 (¹³¹I) or yttrium 90 (⁹⁰Y). Indolent lymphomas are known to be responsive to radiation therapy (i.e., radiosensitive), and the rationale of radioimmunotherapy is that the antibody will act as a “guided missile” to deliver its payload (i.e., radiation) to its target (i.e., lymphoma cells that express the CD20 antigen). The specificity of the monoclonal antibody allows delivery of the radiation selectively to the tumor (and adjacent normal tissues).

Radioimmunoconjugates have some advantages and disadvantages over unlabeled (“naked”) monoclonal antibodies such as rituximab. Tumor cell kill following rituximab depends on binding of the antibody to the tumor cell and the host immune system. Therefore tumor cells that do not express the target antigen are not accessible to the antibody, or are resistant to immune-mediated attacks and may escape treatment. Radioimmunoconjugates, because of their ability to deliver radiation over a distance from a source, can not only kill tumor cells that are in contact with the antibody, but also adjacent tumor cells which may not have been in contact with the antibody or may not express the target antigen. This effect is sometimes referred to as the relevant bystander or “crossfire” effect. However, one disadvantage of radioimmunotherapy is that it can also damage adjacent normal tissues, such as bone marrow cells.

Both ¹³¹I-tositumomab and ⁹⁰Y-ibritumomab tiuxetan have shown activity in relapsed and refractory patients with indolent or transformed lymphomas.^{78,79} In patients who respond to radioimmunotherapy, the duration of remission can be more than several

years. Based on these encouraging results, some clinicians are considering radioimmunotherapy earlier in the disease course, including patients with previously untreated disease. In a phase II study, patients with previously untreated follicular lymphoma were treated with six cycles of CHOP chemotherapy followed 4 to 8 weeks later by ¹³¹I-tositumomab.⁸⁰ The overall response rate to the entire treatment regimen was 90%, including 67% complete remissions, and the 2-year progression-free survival is estimated to be 81%. A current multicenter cooperative group study (SWOG S0016) randomizes patients with advanced indolent lymphomas to either CHOP or rituximab (given concurrently, based on the Czuczman regimen⁷⁷) or CHOP and ¹³¹I-tositumomab (given sequentially).

Radioimmunotherapy is generally well tolerated. The major acute toxicities with both radioimmunoconjugates are infusion-related reactions and myelosuppression. ¹³¹I-tositumomab can also cause thyroid dysfunction. The primary concern with radioimmunotherapy is the development of treatment-related myelodysplastic syndrome or acute myelogenous leukemia.⁸¹

The decision to use radioimmunotherapy must be made carefully because of the complexity, risks, and costs of the treatment regimen. Although oncologists usually select patients for therapy, the radioimmunotherapy regimen must be administered at a radiation oncology or nuclear medicine facility. Because of safety concerns related to delivery of radiation to bone marrow, candidates for radioimmunotherapy usually have limited bone marrow involvement and adequate absolute neutrophil and platelet counts.

■ **Hematopoietic Stem Cell Transplantation.** High-dose chemotherapy, followed by autologous or allogeneic HSCT, is another option for patients with relapsed follicular lymphoma.^{63,82,83} In patients who are transplanted at the time of initial treatment failure, 5-year event-free survival is about 40% to 50%. Although the rate of recurrence is lower after allogeneic HSCT as compared with autologous HSCT, that benefit is offset by increased treatment-related mortality after allogeneic HSCT.⁸³ The presence of a survival plateau after allogeneic HSCT suggests that some patients may be cured of their disease. In a recently published randomized trial, patients with relapsed follicular lymphoma who received autologous HSCT had significantly longer progression-free and overall survival than those who received additional courses of combination chemotherapy.⁸⁴

Based on these encouraging results, some studies have evaluated autologous HSCT as consolidation therapy after CHOP or CHOP-like chemotherapy in patients with poor-risk follicular lymphoma.⁸² Several large randomized trials are ongoing, and the results of these trials should further define the role of autologous HSCT as first-line therapy of follicular lymphoma.

Rituximab is being evaluated in the setting of autologous HSCT.^{73,85} It is given pretransplant as an *in vivo* purging agent prior to stem cell collection. In other studies, rituximab is given as post-transplant consolidation.

High-dose myeloablative transplants are usually reserved for younger patients without serious comorbidities, but nonmyeloablative allogeneic transplants may be an option for older patients who would not otherwise be eligible for autologous or allogeneic HSCT.

■ **Investigational Therapies.** As discussed above, the idiotype present on the patient’s tumor cells serves as a potential target for immunotherapy. This idiotype can be used to manufacture a patient-specific vaccine.⁵³ Vaccines would potentially produce both humoral and cellular immune responses, and would also be longer acting than passive immunotherapy. Several vaccines are being evaluated in clinical trials.³⁹

■ OTHER INDOLENT LYMPHOMAS

Marginal zone B-cell lymphomas, MALT (extranodal) and nodal types, are two of the new forms of NHL not previously recognized in the International Working Formulation.⁸⁶ Extranodal and nodal types of marginal zone B-cell lymphomas represent approximately 7.6% and 1.8% of new cases of NHLs.⁴⁸ Clinically, MALT lymphomas tend to be indolent. Most patients present with localized disease involving extranodal sites, which involves glandular epithelial tissues of various sites, such as the stomach, lungs, parotid gland, thyroid, and orbit (see Table 129–8). The stomach is the most frequent site and gastric MALT lymphomas are frequently associated with chronic gastritis and *Helicobacter pylori* infection. Because MALT lymphomas tend to remain localized for long periods, local treatment (surgery or local/regional radiation therapy) is effective and offers the opportunity for cure. Patients with gastric MALT lymphomas who are positive for *H. pylori* should be treated for their infection (e.g., antibiotics). Patients with disseminated MALT lymphoma should be treated with the same type of chemotherapy used in patients with follicular lymphoma.

■ AGGRESSIVE LYMPHOMAS

■ DIFFUSE LARGE B-CELL LYMPHOMA

Diffuse large B-cell lymphomas (DLBCLs) are the most common lymphoma in the International NHL Classification Project, accounting for about 30% of all NHLs.⁴⁸ Most DLBCLs are classified as *diffuse large cell cleaved, noncleaved, or immunoblastic* or *diffuse mixed cell* in the International Working Formulation.^{46,87} DLBCLs are characterized by the presence of large cells, which are similar in size to or larger than tissue macrophages and usually more than twice the size of normal lymphocytes. The median age at the time of diagnosis is in the seventh decade, but DLBCL can affect individuals of all ages, from children to the elderly. Patients often present with a rapidly enlarging symptomatic mass, with B symptoms in about one-third of the cases.^{38,88} About 30% to 40% of patients with DLBCL present with extranodal disease; common sites include the head and neck, gastrointestinal tract, skin, bone, testis, and CNS. DLBCL is the most common type of diffuse aggressive lymphoma, which share in common an aggressive clinical behavior that leads to death within weeks to months if the tumor is not treated. Diffuse aggressive lymphomas are also sensitive to many chemotherapeutic agents, and some patients treated with chemotherapy can be cured of their disease.

Several factors have been shown to correlate with response to chemotherapy and survival in patients with aggressive lymphoma. Since the IPI was originally developed based on patients with aggressive lymphoma, IPI score correlates with prognosis (see Table 129–9).⁵¹ Although IPI is a clinically useful tool to estimate prognosis, the factors used to calculate the IPI score probably represent clinical surrogates for the biologic heterogeneity among DLBCLs, and many researchers are interested in determining the prognostic importance of certain phenotypic and molecular characteristics of DLBCLs. For example, markers of apoptosis, cell-cycle regulation, cell lineage, and cell proliferation are being evaluated as potentially clinically useful prognostic factors. Gene expression profiling with biochips may also correlate with survival. Using gene expression profiling, investigators identified three molecularly distinct forms of DLBCL based on gene expression patterns indicative of different

stages of B-cell differentiation: germinal center B-cell-like, activated B-cell-like, and type 3.⁸⁹ The type 3 subgroup did not express either set of genes at a high level. The investigators used 17 genes to construct a model that correlated with overall survival after chemotherapy. In another study, investigators were able to develop a predictive model based on only six genes.⁹⁰ These results suggest that molecular classification of tumors on the basis of gene expression may allow identification of clinically significant subtypes of cancer.

Therapy of DLBCL is based on the Ann Arbor stage, IPI score, and other prognostic factors. About one-half of patients present with localized (stage I or II) disease. However, many patients present with large bulky masses (i.e., larger than 10 cm), and patients with bulky stage II disease are treated with the same approach as that used with those with advanced disease (stage III or IV).

■ Therapy of Localized Disease (Stages I and II)

Before 1980, radiation therapy was the primary treatment for patients with localized DLBCL. Five-year disease-free survival with radiation therapy alone was about 50% and 20% in patients with stage I and stage II disease, respectively.^{38,87,88} Randomized trials in the 1980s showed that radiation therapy followed by chemotherapy resulted in significantly longer disease-free and overall survival as compared with radiation therapy alone. Other studies reported excellent results with a short course of chemotherapy (three cycles) followed by involved-field radiotherapy or six to eight cycles of CHOP chemotherapy, with or without consolidation radiotherapy. With either of these approaches, 5-year progression-free survival was >90% for patients with stage I disease and about 70% for patients with stage II disease.^{38,87,88}

9 Since it was not clear which approach was more effective, the SWOG performed a randomized trial that compared three cycles of CHOP and involved-field radiotherapy or eight cycles of CHOP in patients with stage I and nonbulky stage II aggressive lymphoma.⁹¹ Patients treated with three cycles of CHOP plus radiotherapy had significantly better 5-year progression-free (77% vs. 64%) and overall (82% vs. 72%) survival than patients treated with CHOP alone. The incidence of life-threatening toxicity was higher in patients who received CHOP alone. Based on the results of this trial, the current standard for therapy of most patients with localized nonbulky aggressive lymphoma is three to four cycles of CHOP followed by locoregional radiation therapy (30 to 40 Gy).^{38,50,88} A stage-modified IPI score is sometimes used to identify patients with localized lymphoma who may have a poor prognosis. Patients with one or more of these poor prognostic factors (i.e., stage II, elevated LDH levels, age >60 years, or performance status ≥ 2) may benefit from more aggressive chemotherapy (six to eight cycles of CHOP) followed by locoregional radiation therapy. At some institutions, R-CHOP has replaced CHOP as standard therapy.

■ Therapy of Advanced Disease (Bulky Stage II and Stages III and IV)

It has been known since the late 1970s that intensive combination chemotherapy can cure some patients with disseminated DLBCL.^{38,40,88} Initial studies with COP (same as CVP) produced a plateau on the survival curve of just 10%, with a median survival of less than 1 year. Based on the activity of single-agent doxorubicin, McKelvey and colleagues developed the CHOP regimen (see Table

129–11).⁹² A few years later, a SWOG study showed that CHOP was more active than COP, and CHOP chemotherapy rapidly became the treatment of choice for patients with aggressive lymphomas.⁹³ Studies in larger numbers of patients showed that about 50% of patients had a complete remission to CHOP chemotherapy, and 50% to 75% of the patients who had a complete response (about one-third of all patients) experienced long-term disease-free survival and cure of their disease.

In an effort to improve these results, many investigators used several general approaches to develop second- and third-generation regimens in the 1980s and early 1990s.^{40,88} The first approach was to add a nonmyelotoxic drug, most often bleomycin, to the three-week cycle (e.g., CHOP-Bleo or BACOP). The second approach was to add nonmyelosuppressive agents *between* cycles of CHOP or BACOP. One example of this strategy was the M-BACOD (methotrexate, bleomycin, doxorubicin, cyclophosphamide, vincristine, and dexamethasone) regimen, in which high-dose methotrexate with leucovorin rescue was administered on day 10. M-BACOD was later modified to m-BACOD, which included the same drugs but had a lower methotrexate dosage. Another variation on this strategy was to give semicontinuous or weekly therapy; relatively small doses of myelosuppressive agents are administered, alternating over a 12-week period with nonmyelosuppressive agents. An example of this strategy is MACOP-B (methotrexate with leucovorin rescue, doxorubicin, cyclophosphamide, vincristine, prednisone, and bleomycin). The third approach was to give as many drugs as possible, as flexibly as possible (e.g., ProMACE/MOPP). ProMACE/MOPP was later modified to ProMACE/CytaBOM (prednisone, doxorubicin, cyclophosphamide, and etoposide, followed by cytarabine, bleomycin, vincristine, and methotrexate with leucovorin rescue). Results of phase II trials suggested that these second- and third-generation regimens were more active than CHOP, with slightly higher complete response rates and improved disease-free survival rates.^{38,40,88} However, they were also more difficult to administer, more toxic, and more expensive. Based on these results, oncologists generally adopted one of these second- or third-generation combination regimens as their standard regimen for patients with advanced aggressive lymphomas.

Many randomized studies have compared different combination regimens in patients with aggressive lymphoma.^{38,40,88} Although the results of these studies show that no one regimen is clearly superior to another, they show the superiority of anthracycline-containing regimens over those that do not contain an anthracycline. In the largest and most widely quoted study, the SWOG initiated a randomized trial in 1986 that compared CHOP to three of the most commonly used third-generation regimens (m-BACOD, ProMACE/CytaBOM, and MACOP-B) in nearly 900 patients with bulky stage II, stage III, or stage IV aggressive lymphoma. At the time of the initial publication (median follow-up = 35 months), no differences in disease-free and overall survival were observed between the four groups.⁹⁴ Furthermore, no significant differences in disease-free or overall survival were observed in any subgroup of patients. The risk of treatment-related mortality, however, was higher in patients receiving one of the third-generation regimens. Extended follow-up of that trial shows that about 35% of patients who participated in that trial are probably cured of their disease, regardless of the initial combination chemotherapy regimen.⁸⁷ Interestingly, the overall survival is about 10% higher than the disease-free survival, which probably reflects the effectiveness of salvage high-dose chemotherapy with autologous HSCT (see below).

Based on the lack of survival benefit with the newer combination chemotherapy regimens, the less complicated and less expensive CHOP regimen should be considered as the treatment of choice for most patients with DLBCL and other aggressive lymphomas.

Unfortunately, the major conclusion from these studies is not that all of these regimens are extremely effective, but that all of these regimens are equally bad. Less than 50% of patients with DLBCL are currently cured of their disease with combination chemotherapy, and most patients who relapse after an initial response do so in the first 2 years. New treatment approaches are clearly needed.

The IPI score should be calculated for every patient with DLBCL and incorporated into treatment decisions for individual patients (see Table 129–9). Patients with a low IPI score should be treated with conventional CHOP (or R-CHOP) therapy. But patients with a high-intermediate or high-risk IPI score should be identified as candidates for more aggressive treatments. These include addition of rituximab to CHOP, dose-intense or dose-dense chemotherapy with growth factor support, or high-dose chemotherapy with autologous HSCT.

Based on the encouraging results of R-CHOP in indolent lymphomas, several studies have evaluated this combination in aggressive lymphomas.⁵⁵ In a multicenter pilot study of 33 patients with previously untreated CD20⁺ aggressive NHL, the addition of rituximab to six cycles of CHOP chemotherapy produced a 94% objective response rate, with 61% of patients achieving a complete response.⁹⁵ Rituximab was given at a dosage of 375 mg/m² on day 1 of each cycle; cyclophosphamide, doxorubicin, and vincristine was given intravenously on day 3, and oral prednisone was given on days 3 to 7. In an updated analysis (62 months), progression-free and overall survival was 80% and 87%, respectively. In the 18 patients with an IPI score of ≥ 2 , the overall response rate was 89% and complete response rate was 56%. No significant additional toxicity was noted. Based on these encouraging results, including the results of the GELA study in elderly patients (see below), many institutions currently recommend R-CHOP in all patients with aggressive lymphoma.⁵⁰

Several studies have attempted to improve treatment results by increasing chemotherapy dose (i.e., dose-intensity), shortening the interval between chemotherapy cycles (i.e., dose-density), or both. Because of the increased risk of severe neutropenia, these approaches require growth factor support. Although results of these studies have not consistently shown improved survival, encouraging results from several recently published studies suggest that these approaches be evaluated in future randomized trials.^{96,97}

Another approach in high-risk patients is to give high-dose chemotherapy with autologous HSCT as intensive consolidation in high-risk patients with DLBCL who achieve a remission with standard chemotherapy.⁸⁷ Several randomized controlled trials have been conducted in patients with aggressive NHLs, and the results of these trials have been critically reviewed recently by two independent panels of experts.^{98,99} Based on a review of the available evidence, it was concluded that high-dose chemotherapy with autologous HSCT is effective in high-risk (i.e., high-intermediate/high-risk based on IPI score) patients who have a complete remission to conventional therapy (first complete remission in high-risk patients) and in untreated high-risk patients (high-dose sequential therapy in untreated high-risk patients).⁹⁹ There was inadequate evidence to make a treatment recommendation for the other possible clinical situations, such as in patients who do not respond to standard induction therapy (primary refractory disease) or in patients who have a partial remission to standard induction therapy (first partial remission after full-course induction therapy). Since those recommendations were published, another randomized study showed that high-dose chemotherapy with autologous HSCT improves event-free survival in patients with a lower IPI score (i.e., low, low-intermediate, or high-intermediate risk).¹⁰⁰

Unfortunately, the available evidence has led to a discussion of when high-dose chemotherapy with autologous HSCT should be

offered to high-risk patients with aggressive NHLs: early (i.e., when patients are in their first complete remission) or later (i.e., after patients have relapsed). To address this question, the various cooperative groups in the United States have agreed to conduct a randomized clinical trial of early versus delayed high-dose chemotherapy for patients with high-risk (high-intermediate or high-risk based on IPI score) DLBCL. In this trial, referred to as the North American High-Dose Therapy Trial, patients younger than 65 years old will receive five courses of CHOP chemotherapy. Patients who have a partial or complete response will then be randomized to receive either three more cycles of CHOP or one additional cycle of CHOP followed by high-dose chemotherapy with autologous HSCT. Patients on the standard CHOP treatment who relapse will then receive the same high-dose chemotherapy.

CLINICAL CONTROVERSY

Because of high relapse rate in patients who have a complete response to CHOP, some clinicians believe that high-dose chemotherapy with autologous HSCT should be given as consolidation therapy in high-risk patients with aggressive NHLs who have a complete remission to CHOP or R-CHOP chemotherapy. To address this question, the North American High-Dose Therapy Trial is a randomized clinical comparison of early versus delayed high-dose chemotherapy for patients with high-risk (high-intermediate or high-risk based on IPI score) diffuse large B-cell lymphoma. The results of this trial should determine when high-risk patients with aggressive lymphoma should receive high-dose chemotherapy with autologous HSCT.

9 In summary, all younger patients with bulky stage II, stage III, or stage IV disease should be treated with CHOP (or R-CHOP) or CHOP-like chemotherapy until a complete response is achieved (usually three to four cycles).⁵⁰ A rapid response to chemotherapy (i.e., a complete response achieved in the first three treatment cycles) is associated with a more durable remission compared with patients requiring longer treatment. Two or more cycles of chemotherapy should be given following attainment of a complete response (a total of six to eight cycles). The use of long-term maintenance therapy following a complete response has not been shown to improve survival. High-dose chemotherapy with autologous HSCT should be considered in high-risk patients who respond to standard chemotherapy. Patients should be enrolled in clinical trials of new treatment approaches whenever possible.

Therapy of Elderly Patients with Advanced Disease

More than one-half of patients with NHL are older than 60 years of age at diagnosis, and about one-third are over the age of 70 years. The International Non-Hodgkin's Lymphoma Prognostic Factors Project showed that patients older than 60 years of age had a significantly lower complete response rate and overall survival.⁵¹ The reasons for the poorer outcome in elderly patients are not clear. Older patients do not tolerate intensive chemotherapy as well as younger patients, and some studies have reported that older patients have a higher risk of treatment-related mortality. As a result, many clinicians treat elderly patients with reduced-dose or less-aggressive chemotherapy regimens. In general, these less intensive regimens have used anthracyclines with less cardiotoxicity than doxorubicin, have substituted

mitoxantrone for doxorubicin, or have used short-duration weekly therapy.^{38,88}

Over the past few years, several nonrandomized and randomized trials have evaluated different treatment approaches in older patients with aggressive NHL.^{38,88} The results of these studies suggest that carefully selected elderly patients with good performance status and without significant comorbidities may tolerate aggressive anthracycline-containing regimens as well as younger patients. These patients should be treated initially with full-dose CHOP or similar regimens; dosages can be reduced later if severe toxicity occurs. Hematopoietic growth factors may allow elderly patients to maintain dose intensity.

The combination of rituximab and CHOP (R-CHOP) has replaced CHOP as standard treatment for elderly patients with aggressive lymphoma, based on the results of the GELA study.¹⁰¹ In that study of 399 elderly patients with DLBCL, patients who were randomized to receive R-CHOP had a significantly higher complete response rate (76% vs. 63%) and longer event-free and overall survival as compared with those who received CHOP. In an updated analysis of that trial, significant differences in 4-year event-free survival (51% vs. 29%) and overall survival (59% vs. 47%) were observed between the two treatment groups. Further analysis of that study showed that the treatment benefit was primarily observed in patients with tumors that overexpressed *BCL-2* (*BCL-2*⁺).¹⁰² It is important to note that rituximab is given differently in the GELA study as compared with the Czuczman study in patients with indolent lymphomas. In the R-CHOP regimen developed by Czuczman and associates,⁷⁷ two doses of rituximab are given before the start of CHOP therapy; two more doses are given in the middle of the six cycles of CHOP; and two additional doses are given at the end of CHOP therapy. In the GELA study, rituximab is given on day 1 (the same day that cyclophosphamide, doxorubicin, and vincristine are administered) with each cycle of CHOP chemotherapy.

Salvage Therapy

Although many patients with aggressive NHL experience long-term survival and cure with intensive chemotherapy, nearly 50% of patients fail to achieve a complete remission, and of those patients who do achieve a complete remission, about 20% to 30% subsequently relapse. Therefore about 60% to 70% of all patients with aggressive NHL will require salvage therapy at some time during their disease course. Response to salvage therapy depends on the initial responsiveness of the tumor to chemotherapy. Patients who achieve an initial complete remission and then relapse generally have a better response to salvage therapy than those who are primarily or partially resistant to chemotherapy.

Many conventional-dose salvage chemotherapy regimens have been used in patients with relapsed or refractory NHL. Many patients who respond to salvage therapy (i.e., chemosensitive relapse) will then receive high-dose chemotherapy with autologous HSCT. In an effort to avoid cross-resistance, most salvage regimens incorporate drugs not used in the initial therapy. Some of the more commonly used salvage regimens include DHAP (dexamethasone, cytarabine, and cisplatin), ESHAP (etoposide, methylprednisolone, cytarabine, and cisplatin), and MINE (mesna, ifosfamide, mitoxantrone, and etoposide), and no one regimen appears to be clearly superior to any other regimen.^{38,40,88,103} Rituximab is sometimes added to these salvage regimens. With these salvage regimens, about 25% to 35% of patients achieve a complete response, with a median duration of remission of

1 to 2 years. Only about 5% to 10% of patients will have long-term disease-free survival.

ICE (ifosfamide, carboplatin, and etoposide) chemotherapy is a newer regimen that has been used in patients with refractory disease. Some clinicians believe that ICE is better tolerated than older cisplatin-based regimens, particularly in older patients. The combination of ICE and rituximab (RICE) is currently being evaluated as a salvage regimen, and early results are encouraging.¹⁰⁴ Rituximab is given before the first dose of ICE and then weekly during the regimen.

◀ To improve the cure rate, many studies have evaluated high-dose chemotherapy with autologous HSCT as intensive consolidation therapy in patients who respond to salvage therapy.^{98,99} In the PARMA study, 215 patients with relapsed aggressive NHL who had a response to DHAP salvage therapy were randomized to receive either high-dose chemotherapy or continued DHAP therapy.¹⁰⁵ Patients who received high-dose chemotherapy had significantly longer 5-year disease-free survival (46% vs. 12%) and overall survival (53% vs. 32%) than those treated with conventional salvage therapy. Further analysis of that study showed that patients who relapsed within 12 months of their initial diagnosis were less likely to benefit from high-dose chemotherapy than patients who relapsed after 12 months. Based on a review of the available evidence, including the PARMA study, it was concluded that high-dose chemotherapy with autologous HSCT is effective in patients who relapse for the first time and have responded to salvage therapy (first chemotherapy-sensitive relapse).^{98,99} Unfortunately, there was inadequate evidence to make a treatment recommendation for patients who relapse and have not responded to salvage therapy (chemotherapy-resistant relapse). Based on these studies, high-dose chemotherapy with autologous HSCT is considered to be the treatment of choice in younger patients with chemotherapy-sensitive relapse.^{38,50,88,106} High-dose chemotherapy with autologous HSCT is not recommended in patients with untested or chemotherapy-refractory relapse.

Rituximab is being evaluated in the setting of autologous HSCT.^{73,85} It is given pretransplant as an *in vivo* purging agent prior to stem cell collection. In one study of patients with aggressive lymphoma, two courses of rituximab (starting at day 42 and 6 months posttransplant) were given as posttransplant consolidation.⁸⁵

■ OTHER AGGRESSIVE LYMPHOMAS

Mantle cell lymphoma (MCL) is one of the new disease entities previously unrecognized by other classification systems.¹⁰⁷ This histologic type was found in 6% of cases in the International Non-Hodgkin's Lymphoma Classification Project.⁴⁸ The chromosomal translocation t(11;14) occurs in most cases of MCL. MCL usually occurs in older adults, particularly in men, and most patients have advanced disease at the time of diagnosis (see Table 129–8).¹⁰⁷ Extranodal involvement is found in about 90% of cases. The course of the disease is moderately aggressive; the median overall survival is about 3 years, with no evidence of a survival plateau.

Patients with disseminated MCL are usually treated with the same intensive combination chemotherapy regimens that are used in diffuse aggressive lymphomas. Overall response rates to these regimens is about 80%, with about one-half of patients achieving a complete response.¹⁰⁷ Median progression-free and overall survival was 20 and 36 months, respectively. In patients who respond to initial therapy, interferon alfa may have a role as maintenance or consolidation therapy. Despite the high response rates, MCL is not considered curable with standard chemotherapy. Therefore younger patients who

have an initial response to chemotherapy often undergo autologous or allogeneic HSCT as consolidation therapy.¹⁰⁸ Because MCL usually expresses CD20, rituximab, either alone or combined with CHOP, has been used with some success in patients with newly diagnosed and relapsed MCL.^{55,107} The NCCN Guidelines recommend that patients with advanced-stage MCL be treated initially with combination chemotherapy, either alone or combined with rituximab.⁵⁰

Primary mediastinal large B-cell lymphoma (PMBL) is a distinct clinicopathologic entity, accounting for about 7% of all DLBCLs and 2.4% of all NHLs in the International NHL Classification Project.⁴⁸ This type of lymphoma tends to occur in younger patients (median age at presentation is 30 years old) and has a female predominance (see Table 129–8).¹⁰⁹ Patients present with a locally invasive mediastinal mass originating in the thymus, with frequent airway compromise and superior vena cava syndrome. Although the disease course is similar to that of other aggressive lymphomas, the biologic features of PMBL clearly differentiate PMBL from other types of DLBCL.¹⁰⁹ Patients with PMBL should be treated similarly to other patients with localized DLBCL.

■ NON-HODGKIN'S LYMPHOMA IN AIDS

The risk of NHL for patients with AIDS is increased about 150- to 250-fold as compared to the general population.¹¹⁰ AIDS-related lymphoma arises as a consequence of long-term stimulation and proliferation of B lymphocytes from HIV and the reactivation of prior EBV infection due to HIV-induced immunosuppression.^{38,40,111} AIDS-related lymphoma usually occurs late in the course of HIV infection and is the cause of death in about 15% of HIV-infected individuals. Although HIV infects T cells, more than 95% of AIDS-related lymphomas are B-cell neoplasms. About 60% of AIDS-related lymphomas are classified as Burkitt's (30%) or diffuse large B-cell type (30%).¹¹¹

The clinical presentation is similar to that observed in other immunocompromised states. Most patients with AIDS-related lymphoma present with B (constitutional) symptoms and have advanced stage (III or IV) disease at the time of diagnosis.^{38,40,111} Involvement of extranodal sites is common. The clinical course of AIDS-related lymphoma is aggressive; median survival is about 6 months and 2-year survival is only 10% to 20%. Factors associated with decreased survival include age greater than 35 years, history of injection drug use, CD4 cell count <100/mm³, a history of AIDS prior to the diagnosis of lymphoma, stage III or IV disease, and elevated LDH levels.¹¹¹ The IPI has also been validated for use in patients with AIDS-related lymphoma.

The treatment of patients with AIDS-associated lymphomas is difficult because the immunocompromised state of these patients increases their risk of significant toxicity due to myelosuppressive therapy. Except for primary CNS lymphoma, AIDS-related lymphoma is never considered truly localized, and systemic chemotherapy is indicated. For patients with adequate immune function and without a history of an opportunistic infection, chemotherapy regimens similar to those used for aggressive lymphomas may be used.^{38,40,111} However, many patients with AIDS-related lymphoma are treated with less intensive regimens because of the increased risk of treatment-related toxicity. In the era of highly active antiretroviral therapy (HAART), however, some clinicians believe that standard doses of chemotherapy can be safely administered to patients who achieve a virologic response to HAART.

The results of treatment with standard chemotherapy regimens, including CHOP, BACOD, and CDE (cyclophosphamide, doxorubicin, and etoposide), have been disappointing. The complete response rate with combination chemotherapy is about 40% to 50%, with a median survival of about 8 months. Newer approaches such as the dose-adjusted EPOCH (etoposide, prednisone, vincristine,

cyclophosphamide, and doxorubicin) regimen developed at the National Cancer Institute appear promising.¹¹² At 53 months' median follow-up, disease-free and overall survival are 73% and 60%, respectively. Intrathecal chemotherapy should be administered to prevent CNS relapses. HAART and prophylactic antibiotics should be continued during chemotherapy.

EVALUATION OF THERAPEUTIC OUTCOMES

Hodgkin's and non-Hodgkin's lymphomas tend to respond well to radiation, chemotherapy, and biologic therapy. The goal of therapy for patients with Hodgkin's and aggressive non-Hodgkin's lymphoma is long-term survival and cure. The therapeutic goal in patients with indolent NHLs is less clear because of the indolent nature of the disease and the lack of convincing evidence showing that therapy prolongs survival. Therapeutic responses are evaluated based on physical exam, radiologic evidence, and other positive findings at baseline.⁵⁶ A complete response is defined as a normal physical exam, with normal lymph nodes and lymph node masses, and no evidence of disease in other sites. A classification of complete response "uncertain" is used when the patient has a normal physical exam and lymph nodes, shrinkage of >75% in lymph node masses, and a normal or indeterminate bone marrow biopsy. A partial response is defined as shrinkage of tumor in the lymph nodes or lymph node masses by $\geq 50\%$, or a completely normal exam except a positive bone marrow biopsy. Relapse or progression is defined as new nodes involved or an increase in nodal or spleen mass size.

Patients with Hodgkin's and aggressive non-Hodgkin's lymphoma are usually evaluated for response at the end of four cycles of therapy or at the end of treatment if less than four cycles of therapy are planned. If patients are treated with chemotherapy alone, two additional cycles of chemotherapy are given after the patient has achieved a complete remission. The rapidity of response to therapy in patients with indolent NHL depends on the choice of therapy. Responses occur slowly with therapy with oral alkylating agents, but occur much more rapidly with aggressive therapies such as combination chemotherapy with or without rituximab. If radiation alone is used, then a therapeutic evaluation should occur at the end of treatment.

CONCLUSIONS

Several decades ago, lymphomas were considered a fatal disease. Today most patients with Hodgkin's disease and many patients with aggressive NHLs can be cured with radiation therapy, chemotherapy, or a combination of radiation and chemotherapy. Our ability to achieve long-term survival and cure in these patients is the result of many factors, including development of accurate and reproducible classification systems; a more uniform approach to the staging of lymphoma; and advances in treatment strategies, especially the use of intensive combination chemotherapy. The routine use of hematopoietic growth factors allows oncologists to maintain dose intensity, which may be important for the treatment of aggressive lymphomas. The use of high-dose chemotherapy with autologous HSCT as intensive consolidation therapy for selected patients with aggressive NHL who respond to initial induction therapy, or as salvage therapy after relapse for patients with Hodgkin's lymphoma or aggressive NHL, has also contributed to increased cure rates.

New treatment approaches are needed, particularly for indolent NHLs. Although many new therapies have been developed recently

for indolent lymphomas, there is no convincing evidence that any of these therapies have changed the natural history of the disease. One of the most exciting new therapies is biologic therapy with anti-CD20 monoclonal antibodies. The recent approval of radiolabeled anti-CD20 antibodies (i.e., radioimmunoconjugates) provides another therapeutic option for these patients. As these new biologic therapies become available, it will be important to better understand how to use these agents, either alone or combined with standard chemotherapy. Although about one-third of patients with aggressive lymphomas can be cured of their disease, most patients will relapse and eventually die of their disease. More effective induction chemotherapy regimens are needed for newly diagnosed patients, and more active salvage therapy is needed for patients with relapsed aggressive NHL.

The goal for the future is to develop treatment modalities to achieve cure in a larger number of patients. But the acute and chronic toxicities associated with treatment must also be considered, particularly in elderly patients and those with significant comorbidities. Consideration of long-term toxicities is of particular concern to patients with Hodgkin's lymphoma because of the high cure rate.

Finally, it is hoped that a better understanding of the pathogenesis of NHL through continued research in molecular biology and immunology will lead to the development of specific therapies aimed at molecular targets. In addition, gene expression profiling may also allow researchers to identify new clinically important subtypes of NHL, and to identify subgroups of patients who respond poorly to standard therapy.

ABBREVIATIONS

ABVD: doxorubicin (Adriamycin), bleomycin, vinblastine, and dacarbazine
 AIDS: acquired immunodeficiency syndrome
 ATL: adult T-cell leukemia/lymphoma
 BACOP: bleomycin, cyclophosphamide, doxorubicin (hydroxydaunomycin), vincristine (Oncovin), and prednisone
 BEACOPP: bleomycin, etoposide, doxorubicin (Adriamycin), cyclophosphamide, vincristine (Oncovin), procarbazine, and prednisone
 2-CdA: cladribine
 CDE: cyclophosphamide, doxorubicin, and etoposide
 cHL: classical Hodgkin's lymphoma
 ChIVPP: chlorambucil, vincristine (Oncovin), procarbazine, and prednisone
 CHOP-B: cyclophosphamide, doxorubicin, vincristine, prednisone, and bleomycin
 CHOP: cyclophosphamide, doxorubicin (hydroxydaunomycin), vincristine (Oncovin), and prednisone
 CHVP: cyclophosphamide, doxorubicin (hydroxydaunomycin), teniposide, and prednisone
 COPP: cyclophosphamide, vincristine (Oncovin), procarbazine, and prednisone

CR: complete response
 CS: clinical stage
 CT: computed tomography
 CVP: cyclophosphamide, vincristine, and prednisone
 CVPP: cyclophosphamide, vincristine (Oncovin), procarbazine, and prednisone
 DHAP: dexamethasone, cytarabine, and cisplatin
 DLBCL: diffuse large B-cell lymphoma
 EBV: Epstein-Barr virus
 EBVP: epirubicin, bleomycin, vinblastine, and prednisone
 EORTC: European Organization for Research and Treatment of Cancer
 EPOCH: etoposide, prednisone, vincristine, cyclophosphamide, and doxorubicin
 ESHAP: etoposide, methylprednisolone, cytarabine, and cisplatin
 ESR: erythrocyte sedimentation rate
 FLIPI: Follicular Lymphoma International Prognostic Index
 FND: fludarabine, mitoxantrone, and dexamethasone
 FN: fludarabine and mitoxantrone
 G-CSF: granulocyte colony-stimulating factor
 GHLSG: German Hodgkin's Lymphoma Study Group
 HAART: highly active antiretroviral therapy
 HIV: human immunodeficiency virus
 HPF: high-power field
 HSCT: hematopoietic stem cell transplantation
 HTLV-1: human T-cell lymphotropic virus type 1
 ICE: ifosfamide, carboplatin, and etoposide
 IFN- α : interferon alfa
 IPI: International Prognostic Index
 IPS: International Prognostic Score
 LDH: lactate dehydrogenase
 MACOP-B: methotrexate with leucovorin rescue, doxorubicin, cyclophosphamide, vincristine, prednisone, and bleomycin
 MALT: mucosa-associated lymphoid tissue
 M-BACOD: methotrexate, bleomycin, doxorubicin (Adriamycin), cyclophosphamide, vincristine (Oncovin), and dexamethasone
 MCL: mantle cell lymphoma
 MINE: mesna, ifosfamide, mitoxantrone, and etoposide
 MOPP: mechlorethamine, vincristine (Oncovin), procarbazine, and prednisone
 MRI: magnetic resonance imaging
 MVPP: mechlorethamine, vinblastine, procarbazine, and prednisone
 NCCN: National Comprehensive Cancer Network
 NCI: National Cancer Institute
 NHL: non-Hodgkin's lymphoma
 NLPHD: nodular lymphocyte-predominant Hodgkin's disease
 PCR: polymerase chain reaction
 PMBL: primary mediastinal large B-cell lymphoma
 PR: partial response
 ProMACE/CytaBOM: prednisone, doxorubicin, cyclophosphamide, and etoposide, followed by cytarabine, bleomycin, vincristine, and methotrexate with leucovorin rescue
 ProMACE/MOPP: prednisone, methotrexate, doxorubicin, cyclophosphamide, and etoposide/mechlorethamine, vincristine, procarbazine, and prednisone
 PS: pathologic stage
 R-CHOP: rituximab, cyclophosphamide hydroxydaunomycin, vincristine (Oncovin), and prednisone
 REAL-WHO: Revised European-American Classification of Lymphoid Neoplasms and World Health Organization
 RICE: rituximab, ifosfamide, carboplatin, and etoposide
 SWOG: Southwest Oncology Group

OVARIAN CANCER

William C. Zamboni, Laura L. Jung, and Margaret E. Tonda

Learning Objectives and other resources can be found at www.pharmacotherapyonline.com.

KEY CONCEPTS

- 1 Patients with local disease have a 5-year survival rate greater than 90%, but most patients present with disseminated disease because symptoms are nonspecific and go unrecognized until late in the disease course. Patients with advanced disease have a 5-year survival rate of 10% to 30%.
- 2 Ovarian cancer usually occurs in postmenopausal women in the sixth decade of life; the risk of developing ovarian cancer is increased in women with a family history involving two or more first-degree relatives.
- 3 CA-125 is an antigen common to most nonmucinous epithelial ovarian carcinoma and is a useful marker for ovarian cancer; rising or falling CA-125 titers correlate with the disease extent.
- 4 Ovarian cancer management is based on the histologic type, pathologic grade, and disease stage at initial presentation. In general, the treatment of patients with ovarian cancer involves surgical debulking at the time of staging laparotomy and primary or adjuvant chemotherapy.
- 5 The beneficial effects of adjuvant chemotherapy in the treatment of local disease depend on the stage and disease subtype. Postoperative adjuvant chemotherapy is not required in stage IA or IB grade 1, whereas patients with stage IA or IB grade 2 or 3, and stage IC require adjuvant chemotherapy. All patients with stage II disease require adjuvant treatment. Paclitaxel plus carboplatin or cisplatin for three to six cycles is the current recommended adjuvant therapy for these patients.
- 6 Survival of patients with advanced ovarian cancer is a function of stage at initial diagnosis and the amount of residual disease after surgical debulking. Patients with stage III disease treated with optimal debulking (<2 cm of residual tumor) have a 4-year survival rate of 30%, while patients with stage III or IV disease who have undergone suboptimal debulking (>2 cm of residual disease) have less than a 10% long-term survival rate.
- 7 Current recommended treatment of advanced ovarian cancer (stage III or IV) is based on initial surgical debulking followed by paclitaxel plus carboplatin for six cycles.
- 8 Approximately 20% to 50% of patients without evidence of disease on second-look laparotomy will relapse. In addition, patients who were initially sensitive to chemotherapy and whose response lasted the longest have the greatest likelihood of achieving a response to retreatment with the initial treatment regimen or treatment with salvage therapy.
- 9 Patients with disease that was refractory to the initial platinum-containing chemotherapy or that recurs within 6 months after treatment (platinum-refractory) are unlikely to benefit from standard-dose platinum therapy. However, patients who relapse more than 6 months after the initial platinum-containing regimen (platinum-sensitive) have a response rate of 27% to 59% with a standard-dose second-line platinum regimen.
- 10 The NCCN guidelines recommend retreatment with either paclitaxel or platinum, or the combination of paclitaxel and a platinum compound if disease recurs more than 6 months after the initial treatment with paclitaxel in combination with a platinum analog. Treatment options for patients with refractory disease or disease recurrence within 6 months after treatment include topotecan, altretamine, oral etoposide, liposomal doxorubicin, gemcitabine, tamoxifen, referral for a clinical trial, or supportive care therapy.

Ovarian cancer is the fifth most common noncutaneous malignancy diagnosed in women.¹ Overall, it is the fifth leading cause of cancer-related death and the most common death from gynecologic malignancy.¹ The incidence of ovarian cancer is highest in the United States, Europe, and Israel, and lowest in Japan and developing countries.² In the United States alone, it is estimated that 22,220 new cases of ovarian cancer will be diagnosed, and 16,210 women will die from this disease in 2005.¹ Based on Surveillance, Epidemiology, and End Results data collected from 1995 to 2000, 5-year survival

for all stages is nearly 50%, although it dramatically increases to over 90% in patients with localized disease.¹

1 Unfortunately, most patients have disseminated disease at diagnosis because symptoms are nonspecific and may not be recognized until late in the disease course.⁴ Overall 5-year survival is slightly higher for white Americans (44%) as compared with African-Americans (38%). Survival for patients with localized disease is similar for white Americans and African-Americans (93%).¹ Surgery is an integral part of ovarian cancer management.³ Chemotherapy,

primarily the combination of a taxane plus a platinum analog, plays an important role for adjuvant therapy of localized and advanced disease.³

EPIDEMIOLOGY

2 Ovarian cancer usually occurs in postmenopausal white women during the sixth decade of life.² Only 5% to 10% of ovarian cancer is familial; the majority of ovarian cancer occurs sporadically. For women in the United States, the overall lifetime risk of developing ovarian cancer is 1.4% to 1.8%.² The most important risk factor appears to be family history of ovarian cancer. The lifetime risk for developing ovarian cancer markedly increases to 7% to 9% in women with a family history involving two or more first-degree relatives.² The risk for ovarian cancer is decreased to 0.6% in women who have had several pregnancies, especially in women who first became pregnant before age 25, and is increased to 3.4% in nulliparous women, suggesting that uninterrupted ovulation may be a contributing factor.² Prolonged oral contraceptive use or breast-feeding lowers the risk for developing ovarian cancer.² An increased risk has been associated with environmental exposure to asbestos or talc.²

GENETICS

Several hereditary ovarian cancer syndromes have been described, which include the development of breast and ovarian cancers or ovarian, endometrial, and nonpolyposis colon cancers.^{2,3,5} These syndromes tend to occur at an earlier age than the usual development for each of the individual malignancies and account for about 5% of the total ovarian cancer incidence.^{2,5} These syndromes may be linked to a number of genetic abnormalities that have been detected in patients with ovarian cancer.^{6–8} The most common genetic alterations include mutations in *BRCA1* and *BRCA2*, but may also involve *p21*, *Her-2/Neu*, *p53*, *OVAC1*, *OVAC2*, and *Rb* gene function, and loss of heterozygosity on chromosomes 6, 9, 13q, 17, 18q, 19p, and 22q.

BRCA1 and *BRCA2* are tumor suppressor genes thought to be involved in one or more pathways of DNA damage recognition and repair. The *BRCA1* gene is located on chromosome 17q12-21 and the *BRCA2* gene is located on chromosome 13q12-13. Current risk estimates for the development of ovarian cancer in women with mutations in *BRCA1* are 26% to 85% by 70 years of age, whereas mutations in *BRCA2* appear to confer a lesser risk of developing this disease with an estimated risk of <10% by 70 years of age.^{9,10} These estimates of ovarian cancer should be interpreted with caution, as they are limited by selection bias of the study populations for families with large numbers of breast and ovarian cancers.

Patients with *BRCA1*-associated ovarian cancer are usually significantly younger than patients with *BRCA2* mutations, with a mean age of 54 years.¹¹ *BRCA1*-linked ovarian cancers are typically of serous histology, moderate to high grade, and advanced stage at diagnosis.¹¹ Identification of *BRCA1* mutations in patients may confer some survival benefit. Rubin and colleagues reported higher rates of overall survival in patients with ovarian cancer with *BRCA1* mutations than their matched controls not known to have hereditary cancer (77 months vs. 29 months, respectively).⁸ In another study, patients with advanced-stage ovarian cancer with *BRCA1* mutations survived significantly longer than sporadic cases of ovarian cancer.¹¹ In this same study, patients with *BRCA1* or *BRCA2* mutations also had a significantly longer disease free interval (14 months vs. 7 months, respectively) compared to sporadic cases of ovarian cancer. Although it is unclear why *BRCA1* mutations may confer a survival advantage

in patients with ovarian cancer, one hypothesis suggests that these tumors may respond more favorably to chemotherapy. As *BRCA1* and *BRCA2* are thought to be involved in DNA damage or repair, their inactivation may result in an increased sensitivity of ovarian cancer cells to cytotoxic agents that act via induction of DNA damage.

Despite the progress made in understanding the genetic mechanisms and implications of ovarian cancer, much of this information is currently too premature to be clinically useful. Given current guidelines for the follow-up care of individuals at high genetic risk of ovarian cancer and the lack of clinically useful information, especially with *BRCA* mutations, additional clinical trials and research programs to further determine screening mechanisms for early detection, chemoprevention, and improved treatment are necessary.^{9,10}

PATHOLOGY

Ovarian carcinomas can be separated into three major entities: epithelial carcinomas, germ cell tumors, and stromal carcinomas. Most ovarian tumors (85% to 90%) are derived from the epithelial surface of the ovary.² The classification of common epithelial tumors has been developed by the World Health Organization and the International Federation of Gynecology and Obstetrics.^{12,20} The nomenclature takes into account cell type, location of the tumor, and the degree of the malignancy, ranging from benign tumors to tumors of low malignancy to invasive carcinomas. Low malignancy (“borderline malignancy”) epithelial tumors have a much better prognosis compared to invasive carcinomas and are characterized by epithelial papillae with atypical cell clusters, cellular stratification, nuclear atypia and increased mitotic activity. Malignant tumors are characterized by an infiltrative destructive growth pattern with malignant cells growing in a disorganized manner and dissection into stromal planes. Invasive epithelial carcinomas are characterized by histologic type and grade (degree of cellular differentiation).

The histologic types of common epithelial tumors include serous, mucinous, endometrioid and clear cell.^{3,13} Serous carcinoma is the most common type of epithelial ovarian cancer and accounts for more than 50% of cases. The peak age range is 45 to 65 years.¹³ Typical serous carcinomas display complex papillary and solid patterns and qualify as high-grade carcinomas. Endometrioid carcinomas are seen in women 40 to 50 years of age and comprise about 10% to 15% of ovarian carcinomas, of which about 6% are surface epithelial neoplasms.¹³ Endometrioid tumors are usually diagnosed as stage I disease and have a better prognosis than tumors with serous histology. Mucinous carcinomas occur in women between 40 and 70 years of age and account for about 12% of all ovarian cancers. The overall prognosis for mucinous carcinoma is better than for serous carcinoma because most patients present with stage I disease. Clear cell carcinoma comprises about 3% of ovarian epithelial neoplasms and about 8% to 10% of ovarian carcinomas in women, with a mean age of 57 years. Although clear cell carcinoma is the least common ovarian neoplasm, it is most commonly associated with paraneoplastic-related hypercalcemia.¹³

The true prognostic impact of histologic subtype and grade in patients with epithelial ovarian cancer remains to be determined. In early-stage ovarian cancer, clear cell histology is a poor prognostic factor, while mucinous and clear cell histologies are poor prognostic indicators in advanced-stage disease.^{14,15}

Germ cell tumors of the ovary are very uncommon, occurring in about 2% to 3% of all ovarian cancers in Western countries with an increased incidence in black and Asian women.²⁰ These tumors are highly curable and affect primarily young women, with a peak

age incidence in the early 20s. In contrast to epithelial tumors, approximately 60% to 70% of germ cell tumors are stage I at diagnosis. Serum markers (human β -chorionic gonadotropin [β -hCG] and α -fetoprotein [AFP]) are helpful in the diagnosis and management of these tumors.

Ovarian sex cord-stromal tumors account for about 5% of all ovarian cancers and tend to be diagnosed at stage I.²⁰ These tumors are associated with hormonal effects, such as precocious puberty, amenorrhea, and postmenopausal bleeding.

CLINICAL PRESENTATION

Patients with early ovarian cancer can present with nonspecific, vague abdominal symptoms such as nausea, discomfort, dyspepsia, flatulence, bloating, fullness, early satiety, and digestive disturbances.^{3,4} These symptoms can easily be confused with symptoms that happen normally throughout the menstrual cycle. Late symptoms can include pain, abdominal distention, ascites, and abdominal or pelvic masses.^{3,4} A palpable ovary in a postmenopausal woman should be promptly evaluated because functional cysts do not usually occur in this age group.¹⁶

CLINICAL PRESENTATION OF OVARIAN CANCER

GENERAL

The patient may not be in any acute distress and may complain of vague, nonspecific symptoms.

SYMPTOMS

The patient may complain of back pain, fatigue, bloating, constipation, abdominal pain, urinary urgency, nausea, or weight change.

SIGNS

Patients may have a palpable abdominal mass.
Patients may have lymphadenopathy.
Patients may have signs of ascites (abdominal distention, shifting, and dullness to percussion)

LABORATORY TESTS

CA-125 may be elevated.
Hepatic function abnormalities may suggest metastatic disease.
Abnormalities in renal function tests may suggest compression of the renal system by the tumor.

OTHER DIAGNOSTIC TESTS

Chest x-ray, cystoscopy, proctoscopy, MRI, and CT may indicate extent of disease and any possible metastases.

DIAGNOSIS

The diagnostic work-up for suspected ovarian cancer includes a careful physical examination including a thorough breast examination, a Pap smear, and a rectovaginal examination.^{16,17} A detailed family history should be taken, especially noting the rate and pattern of relatives with malignancies.

3 A complete blood count, chemistry profile (including liver and renal function tests), and a CA-125 assay should be performed. CA-125 is an antigen common to most nonmucinous epithelial ovarian

cancers and is detected in the laboratory with a monoclonal antibody directed at this antigen.^{18,19} CA-125 is a useful tumor marker because it is found in more than 80% of ovarian tumors and rising (or falling) titers correlate with disease extent.^{18,19} Normal CA-125 values are less than 35 units/mL.^{18,19}

Refractory disease is often associated with a CA-125 level that does not return to normal or that remains elevated after completion of chemotherapy.^{18,19} A new elevation in the CA-125 level may be the first sign of relapse.¹⁹

Other diagnostic tests should include a chest x-ray, an intravenous pyelogram, cystoscopy, proctoscopy, and a barium enema. Depending on clinical evaluation, computed tomography (CT), magnetic resonance imaging (MRI), or ultrasound may be indicated. An upper GI series is indicated in patients with gastrointestinal symptoms or with bowel obstruction.

The approach to diagnosing an adnexal mass discovered on pelvic examination depends on several factors, including the patient's reproductive age, adnexal mass size, menopausal status, and symptoms.²⁰ Exploratory laparotomy is indicated in premenarchal women, women with masses greater than 8 cm, women with masses that increase or persist through several menstrual cycles or that are fixed to peritoneal surfaces, women with bilateral masses, or women with intra-abdominal pain or ascites.²⁰

SCREENING

Ovarian cancer is an ideal malignancy for early screening efforts because more than 50% of cases are currently diagnosed with advanced disease.¹ However, for screening efforts to be successful, suitable sensitive, specific, cost-effective screening tests with an adequate positive predictive value must be available. Also, there must be a detectable preclinical phase, and the disease must be amenable to therapy.^{21–23} Three screening tests have been used to detect ovarian cancer: bimanual rectovaginal pelvic examination, CA-125 determination, and transvaginal sonography (TVS).²³ Bimanual rectovaginal pelvic examination is inadequate for screening purposes because it lacks useful sensitivity and specificity.^{21–23} CA-125 is elevated in only 50% of stage I cases and a significant number of women with benign ovarian disease have abnormal CA-125 values.^{21–23} TVS is not specific enough to use as the sole screening modality.

The following screening guidelines were developed at a National Institutes of Health consensus conference.²⁴

- All women should have a comprehensive family history taken that focuses on all the known ovarian cancer risk factors. Rectovaginal pelvic exam should be performed as part of ordinary medical care.
- For women without a family history of ovarian cancer or with a family history of ovarian cancer in one relative, routine screening with ultrasound or CA-125 is not recommended because current evidence does not support any benefit. Participation in ovarian cancer screening trials is appropriate.
- In women with a family history of ovarian cancer in two or more relatives, the risk for developing ovarian cancer is 7%. No conclusive data show that screening in these patients is beneficial. However, because this situation carries a 3% risk of having a hereditary ovarian cancer syndrome, these women should be counseled by a gynecologic oncologist or other qualified specialist regarding their individual risk.
- Women from families with hereditary ovarian cancer syndromes (i.e., Lynch II syndrome) have a 40% lifetime risk

TABLE 130–1. FIGO^a Staging for Epithelial Ovarian Cancer

| | |
|-------|--|
| I: | Confined to the ovaries |
| IA: | One ovary, no ascites, intact capsule |
| IB: | Both ovaries, no ascites, intact capsule |
| IC: | Ruptured capsule, capsular involvement, positive peritoneal washings, or malignant ascites |
| II: | Ovarian tumor with pelvic extension |
| IIA: | Extension to uterus or tubes |
| IIB: | Extension to other pelvic organs (bladder, rectum, or vagina) |
| IIC: | Pelvic extension, plus findings for stage IC |
| III: | Tumor involving the upper abdomen or lymph nodes |
| IIIA: | Microscopic seeding outside the true pelvis |
| IIIB: | Gross deposits ≤ 2 cm in diameter |
| IIIC: | Gross deposits > 2 cm in diameter or nodal involvement |
| IV: | Distant organ involvement, including or splenic liver parenchyma or pleural space |

^aInternational Federation of Gynecology and Obstetrics

of developing ovarian cancer. Although no data indicate that screening will reduce mortality, annual rectovaginal pelvic examination, CA-125 determinations, and TVS are recommended in these women until age 35 or when childbearing is complete. Prophylactic bilateral oophorectomy should then be considered to reduce the overall risk.

With regard to possible ovarian cancer development, current recommendations for follow-up care for individuals with *BRCA1* and/or possibly *BRCA2* mutations include genetic counseling and annual or semiannual transvaginal ultrasound with color flow Doppler and serum CA-125 beginning at age 25 to 35 years.¹⁷ There is not enough information to recommend for or against prophylactic oophorectomy or prophylactic use of oral contraceptives in *BRCA1* carriers. Participation in ongoing ovarian cancer screening trials should be encouraged.

STAGING

The stage of ovarian cancer depends on the extent of disease found at surgical exploration (Table 130–1). Epithelial ovarian cancer spreads by peritoneal surface shedding and lymphatic dissemination (Fig. 130–1).¹⁶ A careful and accurate surgical staging laparotomy is necessary to properly stage the patient; it is therefore recommended that a gynecologic-oncologic surgeon do this procedure to prevent understaging.^{25,26} Total abdominal hysterectomy, bilateral salpingo-oophorectomy, and partial omentectomy are performed.^{16,17} A care-

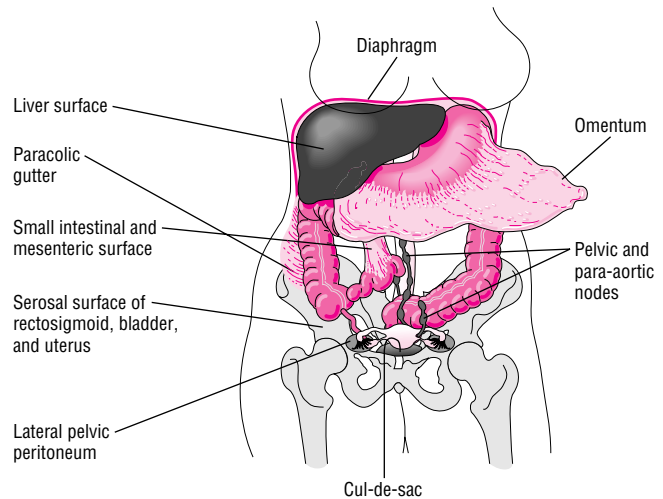

FIGURE 130–1. Staging laparotomy for ovarian cancer.

ful examination of all serosal surfaces is done and biopsies of any grossly involved areas are taken. Ovarian capsule rupture, if present, is noted. Ascites and peritoneal washings are collected. Integral to the initial surgical staging procedure, the surgeon attempts to debulk as much gross tumor as possible because the amount of residual disease in patients with stage III ovarian cancer correlates with survival.²⁰

PROGNOSIS

6 The prognosis for patients with epithelial ovarian cancer is related to disease stage, pathologic grade, and cell histology. Patients with well-differentiated stage IA or IB tumors have a 5-year survival rate of greater than 90% with no additional benefit derived from adjuvant therapy.^{17,24} With adjuvant therapy, patients with any poorly differentiated stage I, stage IC, or stage II disease have an 80% 5-year survival rate.^{17,27} Survival in patients with stage III disease is decreased compared to earlier stages, and is directly related to the size of residual tumors present after debulking surgery. Patients with implants less than 0.5 cm have a median survival of 40 months, those with implants 0.5 to 2 cm have a median survival of 18 months, and those with residual tumor greater than 2 cm have a median survival of 6 to 12 months.^{28,29} The 5-year survival rate for stage IV patients is only 5% to 10%.² Patients with borderline ovarian cancer have an excellent prognosis, with a 5-year survival rate of 93% and a 10-year survival rate of 91%.²

► TREATMENT: Ovarian Cancer

4 Ovarian cancer management is based on the histologic type, pathologic grade, and the stage of disease at initial presentation (Fig. 130–2). In general, the treatment of patients with ovarian cancer initially involves surgical debulking at the time of staging laparotomy followed by adjuvant chemotherapy.³⁰

However, the effect of debulking on outcome in patients with stage IV disease is unclear.³¹ Second-line therapy is recommended if residual disease is found after adjuvant chemotherapy. Although response rates are high, many patients with ovarian cancer still die from their disease, so it is important to diagnose patients earlier, and

it is appropriate to enroll patients with any disease stage into clinical trials.

■ TREATMENT BY STAGE

■ EARLY-STAGE DISEASE (STAGES I AND II)

Approximately one-third of ovarian cancer patients present with localized disease (stage I or II) at initial diagnosis.²⁴ In patients with

apparent early stage disease, comprehensive surgical staging is of utmost importance because approximately one-third of patients will have metastatic disease that is not apparent on gross total resection.³²

4 During laparotomy, the patient should undergo comprehensive staging, total abdominal hysterectomy, and bilateral salpingo-oophorectomy.³⁰ Women with stage IA, grade 1 ovarian tumors who wish to preserve ovarian and reproduction function can undergo a unilateral salpingo-oophorectomy without significant risk of decreased survival.^{30,33} The beneficial effects of adjuvant chemotherapy in localized disease depend on the stage and the disease subtype.

5 Postoperative adjuvant chemotherapy is not required in grade 1, stage IA or IB ovarian cancer, whereas patients with grade 2 or 3, stage IA or IB, and stage IC ovarian cancer benefit from adjuvant chemotherapy (see Fig. 130–2).^{16,24,30} All patients with stage II disease should receive adjuvant treatment.^{16,24,30} The role of adjuvant chemotherapy for patients with stage I disease is controversial. Recent data suggest that the outcome of patients with stage I disease who relapse following no adjuvant chemotherapy is similar to that of patients with stage III disease who relapse following chemotherapy.³⁴ For localized ovarian cancer (stage I or II), the recommended adjuvant regimen is paclitaxel plus cisplatin or carboplatin given for three to six cycles.³⁰

■ ADVANCED DISEASE (STAGES III AND IV)

7 The majority of women with ovarian cancer present with stage III or IV disease.³ The approach to the treatment of advanced ovarian cancer is initial surgical debulking followed by adjuvant/consolidative paclitaxel plus cisplatin or carboplatin for six cycles³⁰ (see Fig. 130–2). Overall survival is a function of the initial disease stage (stage III vs. IV) and the amount of residual disease left after surgical debulking.

■ PRIMARY CYTOREDUCTIVE SURGERY

4 The surgical removal of ovarian tumors should be as complete as possible to increase the likelihood of response to chemotherapy. The amount of residual disease after debulking is also a strong prognostic factor. Patients with stage III disease who have optimal debulking (<2 cm of residual tumor) have a 4-year survival rate of approximately 30%.² Patients with stage III or IV disease who have undergone suboptimal debulking (>2 cm of residual tumor) have less than a 10% chance of long-term survival.²⁸

■ PRIMARY ADJUVANT CHEMOTHERAPY

■ TREATMENT REGIMENS

Systemic chemotherapy following optimal surgical debulking is the cornerstone of first-line treatment of advanced epithelial ovarian cancer. Although there have been only modest improvements in long-term survival, there have been significant improvements in 5-year survival of patients with advanced ovarian cancer. Table 130–2 summarizes the chemotherapeutic regimens used as the initial treatment of newly diagnosed ovarian cancer.

The combination of cyclophosphamide and cisplatin or carboplatin was once the first-line adjuvant therapy of choice in women with advanced-stage ovarian cancer.^{29,35} However, paclitaxel alone, and in combination with platinum analogs, has shown significant

Figure 130-2 is not available in digital format.

activity in ovarian cancer.^{36–38} McGuire and colleagues reported that the combination of paclitaxel 135 mg/m² over 24 hours and cisplatin 75 mg/m² achieved better response rates and survival outcomes than cyclophosphamide 750 mg/m² and cisplatin 75 mg/m² in patients with newly diagnosed, suboptimally debulked, stage III and IV ovarian cancer.³⁹ Survival improved significantly in the paclitaxel arm, with an increase in median progression-free survival (18 months vs. 13 months) and an overall survival (38 months vs. 24 months). Neutropenia, alopecia, and peripheral neuropathy were more severe in the paclitaxel/cisplatin group. Similar results have been reported in a large European-Canadian Phase III randomized trial study.⁴⁰

Cisplatin and carboplatin have been used as single agents and in combination therapy in previously untreated ovarian cancer.⁴¹ Combination chemotherapy regimens containing cisplatin achieved higher response rates and overall survival than regimens without cisplatin in patients with stage III or IV ovarian cancer.¹⁷ A meta-analysis comparing treatment with platinum analogs, either as single agents or in combination regimens, reported a higher overall response rate and longer survival in the combination treatment group.

Single-agent carboplatin has been compared to platinum combination chemotherapy (paclitaxel plus carboplatin, or cyclophosphamide, doxorubicin, and cisplatin [CAP]) for first-line treatment of ovarian cancer in 2,074 patients with ovarian cancer, regardless of their stage at diagnosis.⁴² No difference was found in overall survival after 51 months of follow-up between paclitaxel plus carboplatin and single-agent carboplatin or CAP. A small increase (1.2 months) in progression-free survival was noted in favor of paclitaxel plus carboplatin in comparison to either carboplatin or CAP. However, this

TABLE 130–2. Initial Chemotherapeutic Regimens of Epithelial Ovarian Cancer

| Drug(s) | Dose(s) | Cycle Frequency |
|---|--|------------------|
| Cisplatin | 100 mg/m ² IV day 1 | Every 28 days |
| Carboplatin | 400–800 mg/m ² IV day 1 | Every 28–35 days |
| Cisplatin + cyclophosphamide | 50–100 mg/m ² IV day 1 500–1,000 mg/m ² IV day 1 | Every 21–28 days |
| Carboplatin + cyclophosphamide | 200–300 mg/m ² IV day 1 500–1,000 mg/m ² IV day 1 | Every 28 days |
| Cisplatin + doxorubicin + cyclophosphamide | 50–60 mg/m ² IV day 1 40–50 mg/m ² IV day 1 500–750 mg/m ² IV day 1 | Every 28 days |
| Paclitaxel + cisplatin | 135 mg/m ² IV (24-h infusion) day 1 75 mg/m ² IV day 1 | Every 21 days |
| Paclitaxel + carboplatin | 175 mg/m ² IV (3-h infusion) day 1 Dosed to AUC 5–7.5 IV day 1 | Every 21 days |
| Docetaxel + carboplatin | 75 mg/m ² IV day 1 Dosed to AUC 5 IV day 1 | Every 21 days |

AUC, area under the curve

increase in progression-free survival was associated with more alopecia, fever, and sensory neuropathy than single-agent carboplatin, and more sensory neuropathy than CAP.

Carboplatin has been used in place of cisplatin in combination therapy for patients with advanced ovarian cancer because of better tolerability, ease of administration, and apparent equivalent survival.^{43–47} Several prospective, randomized phase III trials comparing carboplatin plus paclitaxel versus cisplatin plus paclitaxel in patients with advanced ovarian cancer have been conducted.^{48–52} Results concluded that carboplatin plus paclitaxel is the preferred regimen because of equal efficacy and less toxicity. In the U.S. study (Gynecologic Oncology Group [GOG] 158), 840 previously untreated patients with optimally resected stage III disease (no residual tumor nodule > 1 cm) were randomized to carboplatin (area under the curve [AUC] = 7.5) plus paclitaxel 175 mg/m² over 3 hours, or cisplatin 75 mg/m² plus paclitaxel 135 mg/m² over 24 hours administered every 21 days for 6 cycles.^{48,49} The study was designed for equivalence with the primary end point being time to progression. Results demonstrated no difference in recurrence-free survival with median times of 19.4 months for the cisplatin arm versus 20.7 months for the carboplatin arm. More toxicity was observed in the cisplatin arm. The incidence of grade 4 leukopenia, grade 3 or 4 gastrointestinal toxicity, grade 1 to 4 fever, and grade 1 to 4 metabolic toxicity was higher for patients in the cisplatin arm, whereas patients in the carboplatin arm experienced more grade 3 or 4 thrombocytopenia and grade 1 or 2 pain. Neurotoxicity was similar between the two treatment arms, which may be related to the carboplatin dose (AUC = 7.5). These results suggest carboplatin plus paclitaxel is preferred over cisplatin plus paclitaxel because of equivalent efficacy, better tolerability, and ease of administration.

Docetaxel plus carboplatin may be emerging as the combination regimen of choice for first-line treatment of ovarian cancer. Preliminary results of the Scottish Randomized Trial in Ovarian Cancer (SCOTROC) Phase III trial comparing carboplatin (at an AUC of 5) in combination with docetaxel (75 mg/m² over 1 hour) or paclitaxel (175 mg/m² over 3 hours) administered every 21 days for 6 cycles as first-line chemotherapy for stages IC to IV epithelial ovarian cancer have been reported.⁵⁴ Although survival analyses are ongoing, the progression-free survival at 1 year, clinical response, and CA-125 responses were similar in the two treatment arms. The docetaxel-carboplatin regimen produced more myelotoxicity, edema, and hypersensitivity reactions than paclitaxel-carboplatin. However,

docetaxel-carboplatin was associated with significantly less neurotoxicity. The overall incidence of grade 3 and 4 toxicities was <10% in both arms. These preliminary results suggest that first-line treatment of ovarian cancer with docetaxel-carboplatin achieves similar response rates with significantly less neurotoxicity than treatment with paclitaxel-carboplatin.

The Progress in the Management of Gynecologic Cancer Conference recently published a consensus summary statement.⁵³ In that statement, carboplatin and paclitaxel (or carboplatin and docetaxel) was recommended as appropriate first-line chemotherapy for patients with advanced ovarian cancer. These recommendations are similar to those contained in the National Comprehensive Cancer Network (NCCN) guidelines. The 2005 NCCN guidelines list paclitaxel and carboplatin as the preferred regimen, although docetaxel and carboplatin is listed as an alternative regimen.

CLINICAL CONTROVERSY

Based on preliminary data of decreased neuropathy, some practitioners are treating patients newly diagnosed with ovarian cancer with docetaxel-carboplatin as first-line treatment. However, other practitioners are awaiting 5-year survival outcomes comparing paclitaxel-carboplatin to docetaxel-carboplatin to determine the preferred first-line treatment.

■ Dose Intensity

Dose intensity, or the amount of drug delivered over a specified time interval (expressed as mg/m² per week) may be an important factor in determining treatment outcomes with platinum-based regimens in patients with ovarian cancer.⁸⁴ However, a retrospective review of 45 randomized trials found no correlation between cisplatin dose and treatment outcome. A prospective randomized trial in patients with suboptimally debulked stage III (>1-cm residual masses) and any stage IV disease, randomized patients to receive cyclophosphamide 500 mg/m² IV plus either cisplatin 50 mg/m² IV or 100 mg/m² IV every 3 weeks.⁵⁵ Patients in the cisplatin 50 mg/m² group received eight cycles and patients in the cisplatin 100 mg/m² group received four cycles (same total cisplatin dose). Clinical and pathologic response rates, response duration, and survival were similar in both groups. Hematologic and gastrointestinal effects, febrile episodes,

septic events, and renal toxicities were significantly more common and severe in the patients receiving the higher cisplatin dose. Similarly, Kaye and colleagues reported no survival difference in patients receiving six cycles of cyclophosphamide plus cisplatin 100 mg/m² IV or 50 mg/m² IV.⁵⁶ Neurotoxicity persisted in more patients in the high-dose arm (10 of 31), as compared to the low-dose arm (1 of 24). Likewise, dose-intensity analyses with carboplatin have demonstrated equivocal results.^{57–59} Accumulating evidence seems to indicate that the dose-response curve for the platinum compounds levels off within the clinically useful dosage range.⁵⁷ However, it is not clear that providing higher cumulative platinum doses confers any survival advantage over the standard cisplatin 75 mg/m² IV dose.

■ Duration of Therapy

The duration of consolidative chemotherapy has been evaluated in several studies. In advanced ovarian cancer, the administration of five cycles of cyclophosphamide, cisplatin, and doxorubicin was equally effective and less toxic as compared to 10 cycles of chemotherapy.⁶⁰ Six to nine cycles of chemotherapy has become the standard approach and results in clinical response rates of approximately 60% to 70%, with 5-year survival rates of 10% to 20%. Because approximately 50% of patients with a confirmed pathologic response will ultimately relapse,¹⁶ chemotherapy may be extended for two or three cycles beyond best response.²¹

The NCCN guidelines recommend three to six cycles of treatment for lower stage tumors and at least six cycles of treatment for patients with stage III or IV disease.³⁰ However, results of a recent randomized study showed that 12 months of maintenance paclitaxel significantly prolongs the duration of progression-free survival in patients with advanced ovarian cancer who attain a complete response to initial platinum and paclitaxel-based chemotherapy.⁶¹

Many questions still need to be answered about initial therapy for advanced stages of ovarian cancer. Ongoing clinical trials are addressing whether some of the paclitaxel-containing regimens are better than current regimens for early-stage disease. There are also several comparative trials for advanced-stage ovarian cancer. These studies include determining the optimal paclitaxel dose, schedule, and treatment duration, and determining whether dose intensification aided by growth factor support will achieve higher response rates and improve survival. The results of the SCOTROC trial may result in the combination of docetaxel and carboplatin becoming first-line therapy in newly diagnosed ovarian cancer.⁵⁴ In addition, low-dose weekly carboplatin-paclitaxel, new triplet combinations of carboplatin-paclitaxel with agents such as gemcitabine or topotecan, and sequential doublets such as cisplatin-topotecan followed by cisplatin-paclitaxel, are also under investigation.^{61,62}

■ RECURRENT OR /REFRACTORY DISEASE

8 The choices for effective treatment of recurrent ovarian cancer are limited. In addition, approximately 20% to 50% of patients without evidence of residual disease on second-look laparotomy will relapse. Options include secondary cytoreductive surgery, salvage chemotherapy, hormonal therapy, radiotherapy, intraperitoneal chemotherapy, and high-dose chemotherapy with stem-cell support. Patients who respond to initial chemotherapy and whose response lasts the longest have the greatest likelihood of achieving a response to the same first-line regimen or to second-line treatment.⁶⁴ Also,

patients with recurrent or refractory disease after initial chemotherapy historically have a poor overall prognosis. Improved outcomes have been achieved in recurrent and refractory ovarian cancer with the use of high-dose chemotherapeutic agents such as cisplatin, carboplatin, and paclitaxel, and the use of combination regimens containing these agents. In addition, topotecan, pegylated liposomal doxorubicin, and gemcitabine have shown antitumor activity in patients with relapsed-refractory ovarian cancer.^{64–72} Table 130–3 summarizes some of the chemotherapeutic regimens used in the treatment of recurrent or refractory ovarian cancer.

■ SECONDARY CYTOREDUCTIVE SURGERY AND INTERVAL SURGICAL DEBULKING

Operative re-exploration (or secondary laparotomy) was once an integral part of the management of advanced ovarian carcinoma. However, the role of secondary cytoreduction (or interval debulking) after consolidative chemotherapy is currently unclear. Several conflicting studies exist with regard to the survival advantages of secondary cytoreduction. A nonrandomized GOG study evaluated 112 International Federation of Gynecology and Obstetrics (FIGO) stage I or II ovarian cancer patients who first underwent initial surgical staging and then underwent a restaging operation following adjuvant therapy. The study reported that only 5% of the patients who were asymptomatic prior to surgery had disease confirmed by second-look laparotomy, as compared to half of the patients who were symptomatic prior to second-look laparotomy.⁷³ In patients with optimal (no residual tumor nodule >1 cm) stage III disease, preliminary results indicate second-look surgery does not influence the recurrence-free survival in this patient population. These data suggest that second-look laparotomy may not be warranted in asymptomatic patients with early-stage disease. In addition, the National Cancer Institute (NCI) consensus conference recommends that second-look operations should be performed only when the results will change management or as part of a clinical trial.²⁴

Randomized trials of secondary surgical cytoreduction have reported conflicting results. In an older randomized trial, van der Burg and colleagues performed interval debulking surgery on 140 stage IIB to stage IV suboptimally debulked (>1 cm of residual disease) ovarian cancer patients after receiving three cycles of cisplatin plus cyclophosphamide.⁷⁴ Patients then received an additional three cycles of these same drugs after surgery. Patients randomized to the nonsurgical treatment arm received six cycles of chemotherapy. Interval debulking surgery significantly prolonged overall and progression-free survival and reduced the death risk by 33%. However, in a recently published study of 550 women with stage III or IV treated with maximal primary cytoreductive surgery and three cycles of paclitaxel and cisplatin, patients randomized to receive secondary cytoreductive surgery followed by three more cycles of chemotherapy had similar progression-free survival and overall survival as compared with those randomized to receive three more cycles of chemotherapy alone.⁷⁵

The overall effect of interval debulking is influenced by several factors including initial response to chemotherapy, the amount of residual disease before and after second-look surgery, and the presence of microscopic residual disease. The results of recent trials suggest that secondary surgical cytoreduction does not prolong survival in patients who are treated with maximal primary cytoreductive surgery followed by appropriate postoperative chemotherapy.

CLINICAL CONTROVERSY

Some clinicians believe secondary cytoreduction improves survival in patients with ovarian cancer, while others do not. Factors that will affect the results of interval debulking are initial response to chemotherapy, amount of residual disease before and after secondary cytoreduction, and the presence of microscopic disease.

SALVAGE CHEMOTHERAPY

The NCCN guidelines for salvage therapy for recurrent or refractory disease include several treatment options (Fig. 130–3).³⁰ A useful guideline when treating a patient with refractory or relapsed disease is to administer a salvage regimen for two courses and then to evaluate for response.⁶⁴ If no response is observed, then an alternative salvage regimen may be selected. For topotecan or liposomal doxorubicin, evidence suggests continuation of treatment for four cycles and then re-evaluation for response.

Patients with prior low-stage, low-grade disease who have disease recurrence and who have never received chemotherapy should be treated as if they are newly diagnosed advanced-stage patients, undergoing surgical debulking and adjuvant chemotherapy with the combination of paclitaxel and a platinum agent. The NCCN guidelines suggest that tamoxifen is an appropriate therapy in patients with stage I or II ovarian cancer with a rising CA-125 as their only manifestation of disease progression.^{30,76}

PLATINUM SENSITIVE VERSUS REFRACTORY DISEASE

10 The choice of retreatment with platinum-containing chemotherapy depends on the time frame in which the disease recurs.³ Patients with advanced ovarian cancer that experience disease recurrence following initial chemotherapy are divided into two therapeutic groups. Patients who do not respond to the initial platinum-containing chemotherapy or who have recurrence within 6 months after discon-

tinuing treatment are defined as *platinum-refractory*. These patients are unlikely to benefit from additional platinum or paclitaxel therapy and would be candidates for treatment with second-line salvage chemotherapy.³⁰ Patients who respond to the initial chemotherapy and relapse more than 6 months after discontinuation of chemotherapy are termed *platinum-sensitive*. These patients often benefit from secondary treatment with paclitaxel alone, a platinum agent alone, or paclitaxel in combination with a platinum analog.^{77–83} Patients who had a long disease-free interval with a locally recurrent tumor might benefit from a second cytoreductive surgery.

Carboplatin has been used in the treatment of platinum-refractory ovarian cancer. Kavanagh and colleagues treated 33 platinum-refractory ovarian cancer patients with disease progression after taxane salvage therapy with carboplatin 300 mg/m² every 28 days.⁸⁴ These investigators noted a 21% partial response rate, a 39% stabilization rate, and a median response duration greater than 7 months. However, all responding patients had a platinum-free interval of at least 12 months.

Paclitaxel has also shown significant activity in platinum-refractory ovarian cancer.^{37,85–90} At the approved dose of 175 mg/m² over 3 hours every 21 days, the response rate was 15% in patients with relapsed ovarian cancer.⁸⁵ Dose-intense paclitaxel regimens (250 mg/m² over 24 hours every 21 days plus filgrastim support) appear to produce higher objective response rates compared to conventional-dose regimens.^{86–88} Altering infusion schedules of paclitaxel has been explored to maximize the cytotoxic activity of paclitaxel against ovarian cancer cells.⁶³ Weekly infusions may increase the dose intensity of paclitaxel while minimizing bone marrow suppression and other toxicities associated with paclitaxel administration.^{63,89–90} Paclitaxel can be safely administered weekly at a dose of 80 mg/m² over 1 hour to heavily pretreated patients with advanced ovarian cancer, resulting in clinical response rates of approximately 30% in patients with relapsed ovarian cancer.^{89–90} Ongoing and future clinical trials will help define the role of weekly paclitaxel in the treatment of patients with advanced ovarian cancer.

Docetaxel offers an alternative taxane treatment in patients with platinum-refractory ovarian cancer.^{91–93} Preclinical studies show that docetaxel has more potent in vitro activity than does paclitaxel.⁹⁴ Docetaxel has produced overall response rates of 20% to 40% in patients with platinum-sensitive and platinum-refractory advanced

TABLE 130–3. Chemotherapeutic Regimens for Relapsed or Refractory Ovarian Cancer

| Drug(s) | Dose(s) | Cycle Frequency |
|---------------------------------|--|------------------|
| Gemcitabine | 800–1,200 mg/m ² IV days 1, 8, and 15 | Every 28 days |
| Docetaxel | 100 mg/m ² IV day 1 | Every 21 days |
| Pegylated-liposomal doxorubicin | 40–50 mg/m ² IV day 1 | Every 28 days |
| Paclitaxel | 80 mg/m ² IV (1-h infusion) day 1 | Every week |
| Paclitaxel | 135–250 ^a mg/m ² IV ^b day 1 | Every 21 days |
| Carboplatin | 400–800 mg/m ² IV day 1 | Every 28–35 days |
| Paclitaxel | 135 mg/m ² IV (3-h infusion) day 1 | Every 21 days |
| Cisplatin | 75 mg/m ² IV day 1 | |
| Topotecan | 1.5 mg/m ² IV once daily for 5 days | Every 21 days |
| Tamoxifen | 20 mg orally twice a day | Continuous |
| Etoposide | 50 mg/m ² orally once daily for 21 days | Every 28 days |
| Altretamine | 260 mg/m ² orally (total daily dose divided in four doses) for 14–21 days | Every 28 days |

^aFilgrastim used with 250 mg/m² dose.

^b3-hour or 24-hour infusion.

Figure 130-3 is not available in digital format.

ovarian cancer.^{91–93} The response rates ranged from 17% to 20% in patients who were platinum-refractory, defined as a treatment-free interval of 0 to 4 months.⁹² Neutropenia is the dose-limiting toxicity of docetaxel and fluid retention appears to be a cumulative toxicity, which can be managed with diuretics and steroids. Docetaxel is active in patients who have received prior platinum therapy, but it is important to assess the activity of docetaxel after paclitaxel failure, particularly because paclitaxel is considered a standard in front-line regimens. Further studies are also indicated to determine if docetaxel has a role as part of initial chemotherapy.

The combination of paclitaxel/platinum versus conventional platinum-based chemotherapy has been assessed in women with platinum-sensitive relapsed ovarian cancer.⁹⁵ A total of 802 patients were randomized between the two treatment groups and balanced for initial treatment with paclitaxel/platinum chemotherapy. Overall survival curves favored treatment with paclitaxel/platinum therapy with a hazard ratio of 0.82 ($p = 0.02$), corresponding to an absolute difference in 2-year survival of 7%. Progression-free survival curves also favored paclitaxel/platinum therapy, with a hazard ratio of 0.76 ($p = 0.0004$), corresponding to an absolute difference in 1-year progression-free survival of 10%.

CLINICAL CONTROVERSY

In patients with relapsed ovarian cancer that is platinum-sensitive, some clinicians believe patients should be immediately re-treated with a chemotherapy regimen including a platinum agent. Other clinicians believe the platinum-free interval for these patients should be extended by treating with a non-platinum regimen (i.e., topotecan) and reserving the platinum agent until the next relapse.

■ Regimens Not Containing Taxane or Platinum

As most patients will receive a taxane in combination with a platinum agent as initial therapy, there is a need for effective non-cross-resistant agents for use as second-line and salvage chemotherapy. In addition, the optimal chemotherapeutic agent or regimen in the treatment of platinum-refractory disease is currently unclear.

Topotecan, an analog of the plant alkaloid 20(S)-camptothecin, is active in patients with metastatic ovarian cancer and is non-cross-resistant with platinum-based chemotherapy.^{65,66,96,97} Preclinical studies suggest that protracted schedules of administration using low doses of topotecan achieve the greatest antitumor response.⁹⁹ Topotecan has demonstrated efficacy in phase II trials as second-line and salvage therapy in patients who have relapsed after, or progressed during, platinum-based therapy.^{65,66,96,97} A randomized phase III trial compared topotecan and paclitaxel in patients with advanced ovarian cancer who had failed one platinum-based regimen.⁶⁵ Patients were randomized to receive topotecan 1.5 mg/m² per day as a 30-minute infusion for 5 days repeated every 21 days or paclitaxel 175 mg/m² as a 3-hour infusion every 21 days. The overall response rate was 20.5% and 13.2% for the topotecan- and paclitaxel-treated groups, respectively. The median time to progression for topotecan-treated patients (32 weeks) was not significantly different than for paclitaxel-treated patients (20 weeks). Median survival was 61 weeks in the topotecan-treated group and 43 weeks in the paclitaxel-treated group. Topotecan was well tolerated with minimal nonhematologic toxicities.^{65,66,96,97}

Pegylated liposomal doxorubicin is an emerging option for patients with recurrent ovarian cancer.^{67–69} In an early phase II study, 35 patients with progressive disease after at least one platinum and paclitaxel-based regimen received pegylated liposomal doxorubicin 50 mg/m² every 3 weeks (with a dose reduction to 40 mg/m² in the event of grade 3 or 4 toxicities or a lengthening of the interval to 4 weeks);⁶⁷ the overall response rate was 25.7%. A large randomized phase III study was completed comparing pegylated liposomal doxorubicin 50 mg/m² every 4 weeks to topotecan 1.5 mg/m² per day for 5 days repeated every 21 days in patients who failed first-line platinum therapy.⁶⁹ A total of 474 patients were randomized, 239 to pegylated liposomal doxorubicin and 235 to topotecan. The overall confirmed response rate for the pegylated liposomal doxorubicin and topotecan groups were 20% and 17%, respectively. Overall survival tended to favor pegylated liposomal doxorubicin, with a median of 108 weeks versus 71.1 weeks for topotecan. Differences in toxicity were observed between the arms, with more hematologic toxicity occurring in the topotecan arm and more palmar-plantar erythrodysesthesia in the pegylated liposomal doxorubicin arm.

Gemcitabine, a novel pyrimidine antimetabolite, has achieved overall response rates of approximately 13% to 19% as a single agent

in patients with platinum-sensitive and platinum-refractory recurrent ovarian cancer.^{70–72} The main toxicities include myelosuppression, fatigue, myalgias, and skin rash. Gemcitabine is a promising agent in combination with other agents in previously untreated and treated patients with advanced ovarian cancer.⁹⁹ Because of the non-cross-resistant activity and in vivo synergy with platinum agents, the NCI is sponsoring clinical studies evaluating gemcitabine in doublet regimens in patients with refractory disease and with carboplatin/taxane regimens in previously untreated patients.^{100,101}

Other agents that have shown an overall response rate of 15% to 25% in patients with recurrent ovarian cancer include altretamine, etoposide, ifosfamide, 5-fluorouracil, tamoxifen, vinorelbine, gemcitabine, and oxaliplatin.^{76,102–107} Response rates tend to be higher in the platinum-sensitive subgroups. There are limited data in the scientific literature in well-defined refractory patient populations. Of these agents, altretamine, etoposide, and tamoxifen are available in oral formulations, allowing for easy administration. Altretamine is approved as single-agent therapy at doses of 260 mg/m² per day administered in four divided doses for 14 to 21 days given every 28 days.¹⁰³

Much progress has been made in the treatment of refractory and relapsed ovarian cancer. However, because most patients will receive paclitaxel and platinum combinations as first-line adjuvant therapy, there is still a need to develop non-cross-resistant agents that are active in patients who have progressed on, or relapsed after, this combination regimen. Management of advanced ovarian cancer that is refractory to first-line therapy is not well defined. Selection of salvage regimens is based on the mechanisms of action and toxicity profiles of the particular agents. Additionally, there are a variety of innovative treatment options that may have a role in the treatment of patients with advanced ovarian cancer, including antitumor vaccines, gene therapy, and angiogenesis inhibitors. Therapies directed at reversing *p53* gene-associated resistance are also being investigated.^{108,109} There is also evidence suggesting the growth and proliferation of ovarian tumors depends on neovascularization, or angiogenesis.¹¹⁰ Hence antiangiogenic agents may have a future role in the treatment of patients with advanced ovarian cancer.

■ RADIATION THERAPY

The use of radiation therapy in the treatment of ovarian cancer is controversial. The two forms of radiation therapy used in ovarian cancer are external beam whole-abdominal irradiation and intraperitoneal isotopes, such as ³²P. Radiation therapy has been used as adjuvant

therapy in patients with no residual disease and as consolidation therapy in patients with minimal residual disease.

Abdominal irradiation^{111,112} and intraperitoneal isotopes^{113,114} have not shown improvements in response and are associated with greater toxicity. Ovarian cancer patients treated with abdominopelvic radiation were analyzed for posttreatment complications.¹¹² The incidence of acute complications associated with treatment were vomiting (61%) and diarrhea (68%). Serious late complications included bowel obstruction in 4.2% of patients; 64% required surgical intervention. The incidence of bowel obstruction was significantly higher in the intraperitoneal ³²P-treated versus the cisplatin-treated groups (11% and 2%, respectively; *p* = 0.004).¹¹⁴ There is currently no study reporting the use of radiation therapy to be superior to chemotherapy for ovarian cancer in any treatment setting.

■ INTRAPERITONEAL CHEMOTHERAPY

Significant advances have occurred in understanding the advantages, limitations, and administration methods of intraperitoneal (IP) chemotherapy for ovarian cancer treatment.^{115–117} Following initial treatment of advanced ovarian cancer, many patients who achieve a complete clinical response will have persistent disease or will develop recurrent disease. Overall, the proportion of patients achieving long-term survival is small. Ovarian cancer is an ideal disease for IP chemotherapy because the bulk of the disease remains in the peritoneal cavity.^{115–117} The theoretical advantage of IP administration is to increase the dose intensity and total drug exposure directly to the tumor, while decreasing the systemic exposure and possible toxicity. With IP administration, cytotoxic agents are instilled directly into the peritoneal cavity in large volumes to allow these agents to reach all sites within the peritoneal cavity. Studies show potential value in IP administration for initial, consolidation, and salvage therapy. Data suggest that patients with small-volume tumors (<2 cm) are best suited for IP administration as initial therapy or as salvage therapy in relapsed disease. Therefore IP administration is a theoretically attractive approach, taking into account the biology of the disease, the anatomic characteristics of the peritoneal cavity, and the pharmacokinetic advantage of drugs administered intraperitoneally versus intravenously. Drugs that have been administered IP include cisplatin, carboplatin, cytarabine, etoposide, doxorubicin, mitoxantrone, paclitaxel, 5-fluorouracil, thiotepa, melphalan, methotrexate, and topotecan.^{115–123} Table 130–4 summarizes IP chemotherapeutic regimens.

TABLE 130–4. Intraperitoneal (IP) Chemotherapeutic Regimens for Ovarian Cancer

| Drug(s) | Dose(s) | Cycle Frequency |
|--|--|------------------|
| Topotecan | 3 mg/m ² (24-h infusion) day 1 | Every 21 days |
| Cisplatin | 50–100 mg/m ² IP day 1 | Every 21–28 days |
| Cisplatin Cyclophosphamide | 100 mg/m ² IP day 1 600 mg/m ² IV day 1 | Every 21 days |
| Etoposide Cisplatin Sodium thiosulfate | 200–350 mg/m ² IP day 1 100–200 mg/m ² IP day 1 12–16 mg/m ² IV day 1 | Every 28 days |
| Cisplatin Cytarabine | 100–150 mg/m ² IP day 1 600–1,200 mg/m ² IP day 1 | Every 28 days |
| Paclitaxel | 125 mg/m ² IP day 1 | Every 28 days |
| Mitoxantrone | 20–30 mg/m ² IP day 1 | Every 28 days |

Of particular interest are the agents that appear to be the most effective against ovarian cancer, which include the platinum analogs and paclitaxel. These agents appear to have a pharmacologic advantage when administered intraperitoneally. Peritoneal exposure of cisplatin or carboplatin after IP administration is approximately 10- to 20-fold greater than after systemic administration.¹²¹ The exposure of the peritoneal cavity to paclitaxel after IP administration is approximately 30 times higher than plasma exposure.^{122,123} Additionally, cytotoxic concentrations of paclitaxel may persist within the peritoneal cavity for 5 to 7 days after a single dose. Therefore weekly administration may result in continuous exposure of the peritoneal surface to the drug.¹¹⁵

■ FIRST-LINE INTRAPERITONEAL THERAPY

IP chemotherapy has been evaluated as treatment for newly diagnosed patients with advanced ovarian cancer. Multicenter, randomized trials using IP chemotherapy as first-line therapy have been conducted.^{124–126} In a phase III trial, women with previously untreated stage III ovarian carcinoma with residual tumors of <2 cm were randomized to receive cyclophosphamide 600 mg/m² in combination with IP cisplatin 100 mg/m² or IV cisplatin 100 mg/m².¹²⁴ Median survival was significantly longer in the IP cisplatin-treated group (49 months) as compared to the IV cisplatin-treated group (41 months). In addition, moderate to severe tinnitus, hearing loss, and neuromuscular toxicities were significantly more frequent in the IV cisplatin-treated group. These data suggest that IP cisplatin is more effective and less toxic than IV cisplatin. However, further studies are needed to confirm the advantage of IP cisplatin over IV cisplatin.

A phase III trial examined a total of 462 eligible patients with small (<1 cm in maximal diameter), residual, advanced ovarian cancer who were randomized to receive two courses of either carboplatin (AUC = 9) followed by IV paclitaxel 135 mg/m² over 24 hours and IP cisplatin 100 mg/m² every 21 days for six cycles, or IV paclitaxel 135 mg/m² over 24 hours and IV cisplatin 75 mg/m² every 21 days for six cycles.¹²⁶ Progression-free survival was superior in the IP arm versus the IV arm (median 27.9 months vs. 22.2 months, respectively). Overall survival was 63.2 months in the IP arm versus 52.2 months in the IV arm. Although a significant improvement in progression-free survival was observed, toxicity was much greater in the experimental arm. Results from this study provide future direction for clinical studies in patients with small-volume disease.³⁰

■ SALVAGE INTRAPERITONEAL THERAPY

Intraperitoneal therapy has also been evaluated as salvage therapy in patients with relapsed and refractory ovarian cancer in many phase I and II clinical trials.^{115–117} Intraperitoneal cisplatin and carboplatin have achieved documented complete responses in relapsed patients initially treated with systemic platinum-containing regimens.^{127,128} In the salvage setting, most of the IP experience has been with cisplatin, either alone or in combination. The primary toxicity associated with IP cisplatin was bone marrow suppression; neurotoxicity and nephrotoxicity have also been observed.¹¹⁷ At doses greater than 125 mg/m², the dose-limiting toxicity of paclitaxel IP is abdominal pain.¹²³

The impact of IP chemotherapy on survival in the salvage setting is limited because of the absence of randomized trials; however, there is some indirect evidence suggesting a positive influence.¹¹⁷ Several studies have evaluated factors that influence the response to IP therapy.^{115–117} A retrospective study evaluated the results of IP cisplatin with etoposide or cytarabine as salvage therapy.¹²⁷ Of patients

with microscopic disease at the time of IP therapy, 41% achieved a surgically-defined complete response, whereas only 29% of patients with macroscopic disease (largest residual tumor mass <0.5 cm in diameter) had a surgically-defined complete response. Patients whose largest residual tumor mass was greater than 1 cm had less than a 5% complete response rate. This is consistent with data showing a 1 to 2 cm depth of penetration of IP cisplatin into tumor or normal tissue.¹²⁹

An objective response rate of less than 10% is anticipated for IP cisplatin in patients who fail to demonstrate at least a partial response to initial systemic cisplatin.¹¹⁸ Thus IP cisplatin should not be used in cisplatin-refractory patients. In addition to platinum sensitivity and tumor size, extent of tumor spread must also be considered. IP therapy is most beneficial when the tumor is confined to the abdomen.^{115–117} IP therapy is unlikely to have an advantage in patients with bulky disease because drug penetration into larger tumor nodules is limited. Additionally, patients best suited for IP administration should have limited IP adhesions with free fluid distribution.

Complications from IP therapy may be related to catheter function, infection, or bowel problems.^{117,130} Mechanical obstruction to fluid inflow has been reported in approximately 5% of patients. Most commonly, this results from fibrin sheath formation around the catheter tip.¹³¹ In some cases, peritoneal adhesions obstruct fluid entry into the abdominal cavity, causing uneven distribution of the chemotherapeutic agent. Infectious complications, such as superficial cellulitis around the catheter entry site, deep tissue infections, and peritonitis, are the most prevalent IP-related complications and are reported in approximately 10% of patients.^{130,131} Bowel-related complications (approximately 3% incidence) include obstruction, ileus, and perforation. IP administration may also result in a false CA-125 elevation.¹³⁰

Currently, IP chemotherapy outcomes for ovarian cancer treatment have been very encouraging, but additional well-designed comparative trials are needed to define the role of IP versus systemic chemotherapy. The NCCN guidelines consider IP therapy an investigational approach to ovarian cancer management.³⁰

■ AUTOLOGOUS HEMATOPOIETIC STEM CELL TRANSPLANTATION

Ovarian cancer is initially very chemosensitive; however, drug resistance is a major issue. Increased drug exposure to chemotherapeutic agents is a likely way of overcoming resistance and of possibly increasing response rates and survival. The use of high-dose myeloablative chemotherapy followed by bone marrow or peripheral blood progenitor cell rescue has been used as salvage therapy in hematologic and solid tumor malignancies. The most common ablative regimens used in ovarian cancer contain platinum analogs (i.e., cisplatin or carboplatin), alkylating agents (i.e., melphalan, thiotepa, or cyclophosphamide), and/or etoposide.^{132–134}

Shpall and associates evaluated the use of IP cisplatin and high-dose systemic cyclophosphamide and thiotepa followed by autologous bone marrow support in advanced ovarian cancer.¹³² Of patients evaluated, 75% had pathologically documented partial response (i.e., >75% reduction in tumor mass). Legros and colleagues treated poor-prognosis ovarian cancer patients with either high-dose melphalan or high-dose carboplatin plus cyclophosphamide followed by autologous stem cell transplantation after receiving cisplatin induction therapy and second-look operations.¹³³ They reported an overall 60% 5-year survival rate and a 73% 5-year survival rate in patients with a pathologic complete response at second-look laparotomy. In patients with persistent or recurrent ovarian cancer treated with high-dose

chemotherapy plus autologous stem cell transplantation, tumor bulk and chemosensitivity to prior regimens were the most important prognostic factors.¹³⁴ The use of high-dose chemotherapy in the setting of ovarian cancer has been reviewed.^{135,136} The data demonstrate increased response rates with limited survival advantages.

Recently, Stiff and coworkers analyzed data from 421 women who were reported to the Autologous Blood and Marrow Transplant registry from 1989 to 1996.¹³⁷ This project was undertaken to assess the effectiveness of high-dose chemotherapy and autotransplantation. More than 80% of the patients analyzed had stage III or IV disease at diagnosis, and approximately 50% were in a clinically complete response before transplantation. Because of the limitations of this study, such as center-specific differences in selection of patients for transplant, varied timings of transplant, and varied high-dose chemotherapy regimens, the authors suggest data from this study can only be used to identify groups of patients that should or should not be studied further. The results indicate that patients with platinum-refractory disease have a 2.24 times higher mortality rate than do patients with platinum-sensitive disease. The probability of a 2-year survival after transplantation was 23% and 39% for patients with platinum-refractory and platinum-sensitive disease, respectively. The results from this study suggest better outcomes with autotransplantation than with conventional chemotherapy. However, there are inherent biases that must be considered because of the relatively small numbers of patients studied in this trial. Randomized trials are needed to fully understand the role of transplantation in patients with ovarian cancer.

A large, randomized phase III trial (GOG 164) comparing standard-dose chemotherapy to high-dose chemotherapy plus peripheral blood progenitor cell transplantation was recently closed in the United States because of slow accrual.¹³⁵ Currently, investigators in Europe are conducting randomized trials using high-dose chemotherapy and stem cell transplantation. Until the results from this and other ongoing trials are available, the role of bone marrow or peripheral blood progenitor cell transplantation in the initial and subsequent treatment of advanced refractory ovarian cancer is unclear and should be considered an investigational approach.

■ BORDERLINE OVARIAN CANCER

Borderline (low malignant potential) ovarian cancers account for approximately 15% of all epithelial ovarian cancers; the majority (75%) are stage I at the time of diagnosis.¹³⁸ These tumors must be recognized because their prognosis and treatment are clearly different from those of malignant invasive carcinomas. Trimble and Trimble reviewed 953 patients with a mean follow-up of 7 years and found a survival rate of 92% for advanced-stage tumors with the usual cause of death being benign disease complications (e.g., small-bowel obstruction) and therapy-related complications. Malignant transformation was rarely the cause of death. In one series, the 5-, 10-, 15-, and 20-year survival rates of patients with all stages of low malignant potential tumors were 97%, 95%, 92%, and 89%, respectively.¹³⁸

In patients with stage I or II disease, no additional chemotherapy or radiation treatment is indicated for a completely resected tumor of

low malignant potential.^{139,140} In the presence of bilateral ovarian cystic neoplasms or a single ovary involvement, partial oophorectomy or a unilateral salpingo-oophorectomy can be performed if childbearing potential is to be maintained. When childbearing is not a consideration, a total abdominal hysterectomy and bilateral salpingo-oophorectomy is appropriate therapy because most clinicians favor removing the remaining ovarian tissue, which is at risk for recurrence of a borderline tumor or rarely developing invasive carcinoma.

Patients with advanced disease should undergo a total hysterectomy, bilateral salpingo-oophorectomy, omentectomy, node sampling, and aggressive cytoreductive surgery. However, there is little evidence that adjuvant chemotherapy or radiotherapy improves outcome.^{138,140} There have been no controlled studies comparing postoperative treatment with no treatment.

■ NONEPITHELIAL OVARIAN CANCER

■ OVARIAN STROMAL TUMORS

Ovarian stromal tumors normally have an indolent natural history and rarely occur bilaterally. They are managed by unilateral salpingo-oophorectomy and usually do not require additional treatment.¹⁶ Stage II stromal tumors require more extensive surgery owing to the lack of effective adjuvant therapy. Because this tumor is relatively rare, the role of chemotherapy is unclear.

■ OVARIAN GERM-CELL TUMORS

Ovarian-derived germ-cell tumors are rare and may have a mixed histology. Thus treatment should be directed toward the most malignant component of the tumor. Surgery alone has not been very effective, producing 2-year survival rates of 13% to 16%.¹⁴¹ Combination chemotherapy has produced high cure rates and improved prognosis in patients with germ-cell tumors.

Endodermal sinus and dysgerminoma are two subtypes of germ-cell tumors. Endodermal sinus tumors are aggressive tumors that usually occur unilaterally. Without chemotherapy, most patients die from their disease; thus patients with all stages of disease should receive combination chemotherapy. The most common combination chemotherapeutic regimens used are vincristine, dactinomycin, and cyclophosphamide in combination, and cisplatin plus bleomycin in combination with vincristine or etoposide.¹⁴¹ Dysgerminoma tumors have a high cure rate and are highly sensitive to radiation therapy; however, the sterility associated with abdominal irradiation has resulted in systemic chemotherapy becoming first-line therapy. The treatment of choice for newly diagnosed disease is a platinum-containing regimen.¹⁴¹⁻¹⁴³ The combination of bleomycin, etoposide, and cisplatin (BEP) demonstrated a 97% remission rate at 10 to 54 months in 35 patients with germ-cell tumors.¹⁴⁴ Also, two GOG trials demonstrated that 89 of 93 patients with stages I, II, and III disease and completely resected tumors were disease-free after three BEP cycles.¹⁴²⁻¹⁴⁴ Patients with recurrent or refractory disease after cisplatin-based chemotherapy can be treated with radiation therapy.¹⁴¹

PHARMACOECONOMIC CONSIDERATIONS

The majority of economic analyses in ovarian cancer management have focused on the cost-effectiveness of paclitaxel combinations as

initial treatment regimens because the combination of paclitaxel and cisplatin has increased the median survival of newly diagnosed patients with advanced-stage disease compared to the combination of cisplatin and cyclophosphamide.³⁹ In the United States, incremental

costs per life-year gained \$19,820 (inpatient) and \$21,222 (outpatient),¹⁴⁶ and \$19,603^{146,147} have been calculated for patients treated with paclitaxel plus cisplatin compared to cyclophosphamide plus cisplatin. In comparison, the incremental costs per life-year gained of \$20,355¹⁴⁸ and \$32,213¹⁴⁹ have been reported for patients treated with paclitaxel plus cisplatin as compared to cyclophosphamide plus cisplatin in Canada. In addition, Messori and associates reported an \$18,200 cost per quality-adjusted life-year gained.^{146,147} The results of these studies suggest that the additional cost for the combination of paclitaxel and cisplatin compares favorably to costs for other medical interventions that are considered cost-effective. Cost considerations should be an important factor in the decision-making process of using a particular treatment strategy or deciding whether to pursue a new strategy in randomized trials.

EVALUATION OF THERAPEUTIC OUTCOMES

When applied mainly to clinical trials, complete response is defined as complete resolution of all disease and is further categorized either as a pathologic or a clinically complete response. A pathologic complete response is defined as no detectable disease on second-look laparotomy. A clinical complete response is defined as no detectable disease by radiologic imaging techniques. The National Institutes of Health consensus conference on ovarian cancer concluded that second-look laparotomy should be performed only in clinical trials.²⁴ Partial response is defined as a greater than 50% decrease in all measurable disease. Stable disease is defined as disease maintenance without progression. In addition, general definitions for response duration and survival apply to ovarian cancer. Disease-free survival is defined from the point of achieving a complete response to the time of disease recurrence. Recent studies have evaluated the percentage of CA-125 reduction as a surrogate marker for response.^{150,151}

Localized ovarian cancer is highly curable by surgery, and if appropriate, chemotherapy. The goals of therapy should be to maintain the patient's quality of life and to preserve reproductive capabilities, if desired. Newly diagnosed advanced ovarian cancer is highly responsive to surgical debulking and subsequent consolidative chemotherapy; however, cure rates are much lower than with localized disease. The goals of therapy in advanced ovarian carcinoma are to cure the disease, to extend disease-free survival, and to prolong overall survival. Patients with recurrent or refractory disease are generally not curable and have a poor long-term prognosis. Thus the primary direction of therapy may be symptom management, quality-of-life maintenance, and minimization of treatment-related toxicity.¹⁵¹

FUTURE DIRECTIONS

Although the number of women in the United States dying from ovarian cancer continues to increase, substantial treatment progress has been made. However, there are still several therapeutic questions that need to be asked and problems that need to be solved. New approaches to the treatment of advanced primary as well as recurrent and refractory ovarian cancer, such as agents to overcome resistance, should be studied. The optimum adjuvant and consolidation treatment modalities should be determined. The results of the ongoing ICON5 trial may provide information on the most appropriate two- and three-agent combinations, and altering the sequence of chemotherapy regimens in the treatment of newly diagnosed ovarian cancer. However, these studies were initiated prior to the results of the SCOTROC trial, and

thus none of the treatment arms contain docetaxel. The role of IP chemotherapy in all stages of disease is unclear, as is the most appropriate salvage therapy. Answering these therapeutic questions and solving these therapeutic problems may prolong the long-term survival in patients with local and advanced ovarian cancer.

ACUTE LEUKEMIAS

Helen L. Leather and Betsy Bickert

Learning Objectives and other resources can be found at www.pharmacotherapyonline.com.

KEY CONCEPTS

- 1 Acute leukemias are the most common malignancies in children and the leading cause of cancer-related death in patients younger than age 35 years.
- 2 Despite the World Health Organization classification system for myeloid neoplasms, the French-American-British classification remains the most widely used.
- 3 To establish a definitive diagnosis of acute leukemia the following diagnostic components are required: bone marrow biopsy and aspirate (with >20% blasts), cytogenetics, and immunophenotyping.
- 4 There are several well-known risk factors that correlate with prognosis for ALL. Poor prognostic factors include high WBC counts at presentation, very young or very old age at presentation, delayed remission induction and presence of cytogenetic abnormalities (e.g., Ph⁺ chromosome).
- 5 Therapy of both ALL and AML are based on specific risk factors such as age or WBC count at time of diagnosis in ALL. For both ALL and AML, cytogenetic abnormalities provide significant information regarding risk stratification and identify subgroups that may benefit from novel molecularly targeted therapies.
- 6 There are several well-known poor prognostic factors for adult AML, and they include older age (>60 years), organ impairment, certain FAB subtypes (FAB M0, M5, M6, M7), presence of extramedullary disease, and presence of cytogenetic abnormalities (i.e., -5, -7, complex karyotype).
- 7 For children with ALL, induction therapy includes vincristine, a corticosteroid, and asparaginase, with or without an anthracycline. For adults with ALL, vincristine, prednisone, and an anthracycline are given, and asparaginase is sometimes added.
- 8 Because the high risk of central nervous system relapse in ALL, all patients require prophylactic therapy to prevent CNS disease. The choice for therapy includes a combination of the following: cranial irradiation and single-agent intrathecal chemotherapy, triple-drug intrathecal chemotherapy, or high-dose systemic chemotherapy that crosses the blood-brain barrier.
- 9 Patients with ALL frequently relapse after consolidation due to residual disease. Long-term maintenance therapy for 2 to 3 years is essential, and eradicates residual leukemia cells and prolongs the duration of remission. Maintenance therapy consists of pulse doses of vincristine, oral methotrexate, and oral mercaptopurine.
- 10 Colony-stimulating factors can be safely and effectively used with myelosuppressive chemotherapy for acute leukemias. The benefits can include reduced incidence of serious infections, reduced hospital stays, and fewer treatment delays, but do not include prolonged disease-free survival.
- 11 Therapy of AML usually includes induction therapy with an anthracycline and cytarabine. Post-remission therapy is required in all patients and can include either consolidation chemotherapy with or without maintenance therapy, or hematopoietic stem cell transplantation.
- 12 Treatment of acute promyelocytic leukemia consists of induction therapy, followed by consolidation and maintenance therapy. Induction includes tretinoin and an anthracycline; consolidation therapy consists of two to three cycles of anthracycline-based therapy; maintenance consists of pulse doses of tretinoin, mercaptopurine, and methotrexate for 2 years.

The leukemias are heterogeneous hematologic malignancies characterized by unregulated proliferation of the blood-forming cells of the bone marrow. These immature proliferating leukemia cells (blasts) physically “crowd out” or inhibit normal cellular maturation in bone marrow, resulting in anemia, neutropenia, and thrombocytopenia. Leukemic blasts may also infiltrate a variety of tissues such as lymph nodes, skin, liver, spleen, kidney, testes, and the central nervous system.

The term *leukemia* was coined by Virchow to describe the “white blood” of some patients that he saw under the microscope in 1845.¹ Historically, leukemia has been classified as acute or chronic based on differences in cell of origin and cell line maturation, clinical presentation, rapidity of progression of the untreated disease, and response to therapy. Four major leukemias are recognized: acute lymphocytic (or lymphoblastic) leukemia (ALL), acute myeloid leukemia (AML), chronic lymphocytic leukemia (CLL), and chronic myeloid

leukemia (CML). Undifferentiated immature cells that proliferate autonomously characterize acute leukemias. Chronic leukemias also proliferate autonomously, but the cells are more differentiated and mature.¹ Untreated, the acute leukemias are rapidly progressive, resulting in death within 2 to 3 months.

EPIDEMIOLOGY

1 In 2005 it is estimated that 15,930 new cases of acute leukemias—11,960 cases of AML and 3970 cases of ALL—will be diagnosed in the United States, accounting for less than 2% of the total cancer incidence. The incidence has been relatively stable for two decades. An estimated 10,490 deaths per year, representing about 2% of all cancer deaths, are caused by acute leukemias. The acute leukemias are the leading cause of cancer-related deaths in persons younger than age 35, but an uncommon cause of cancer-related death after age 35 years.^{1,2} Among adults, acute and chronic leukemias occur at equal rates. More than 90% of the cases of acute and chronic leukemia occur in adults. There are approximately 4.0 cases of AML and 1.4 cases of ALL per 100,000 individuals.³ The median age at diagnosis of patients with AML is about 65 years, while the median age for ALL patients is about 10 years.^{1–3} The incidence of AML rises with age from 1.8 per 100,000 in individuals younger than age 65 years to 17.7 per 100,000 in those 65 years or older.³ Acute leukemia is slightly more common in males than in females. In the United States, acute leukemia is more common among whites than among African-Americans, American Indians, and Hispanic ethnicities.^{1,3}

Despite the low incidence rate, the acute leukemias are the most common malignancy in persons younger than 15 years of age, constituting about 30% of all childhood malignancies.³ In the United States, 9200 persons younger than 15 years of age are diagnosed with cancer each year; 2,200 of them have ALL.⁴ AML accounts for about 20% of all childhood leukemias, and the chronic leukemias account for less than 5%.³ Childhood ALL is 30% more common in males than females, peaks at 2 to 5 years of age, and is twice as likely to affect white children than African-American children.³ The incidence of childhood AML is highest in the Hispanic population and occurs throughout childhood without any peak age period. Acute leukemia during the first year of life (infant leukemia) is twice as likely to be ALL as AML.³

Chemotherapy has dramatically improved the outlook of patients with acute leukemia. Over 85% of children and young adults with acute leukemia achieve an initial complete remission (CR) of their disease. Overall, 65% to 85% of adults achieve an initial CR.^{1,4} For persons less than 20 years of age, the 5-year survival rate is 83% for ALL and 50% for AML.³ The prognosis of adult acute leukemia is generally worse than that of childhood leukemia, with only 30% to 40% of patients becoming long-term survivors.^{1,4}

ETIOLOGY

The exact cause of the acute leukemias is unknown. A multifactorial process involving genetics, environmental and socioeconomic factors, toxins, immunologic status, and viral exposures is likely. Table 131–1 summarizes the major factors that have been linked to acute leukemias. Infectious and genetic factors have the strongest associations to date.^{1,5} In pediatric ALL, a number of environmental factors have been investigated as possible causes: exposure to ionizing radiation, toxic chemicals, herbicides and pesticides; maternal use of

contraceptives, diethylstilbestrol, or cigarettes; parental exposure to drugs (amphetamines, diet pills, and mind-altering medications), diagnostic radiographs, alcohol consumption, or chemicals before and during pregnancy;⁶ and chemical contamination of groundwater. A few studies have reported a possible link between electromagnetic fields of high-voltage power lines and the development of leukemia, but a recently published study could not confirm this association. In most patients who develop leukemia, a causative agent cannot be identified.

Risk factors associated with childhood AML include Hispanic ethnicity, prior exposure to alkylating agents or epipodophyllotoxins, and in utero exposure to ionizing radiation.¹ Maternal alcohol consumption, parental and child pesticide exposure, and parental benzene exposure are also potential risk factors for childhood AML.

PATHOPHYSIOLOGY

A basic understanding of normal hematopoiesis is needed before one can understand the pathogenesis of leukemia. The reader is referred to Chap. 98 for a detailed discussion of hematopoiesis. Normal hematopoiesis consists of multiple well-orchestrated steps of cellular development. A pool of pluripotent stem cells undergoes differentiation, proliferation, and maturation, to form the mature blood cells seen in the peripheral circulation. These pluripotent stem cells initially differentiate to form two distinct stem cell pools. The myeloid stem cell gives rise to six types of blood cells (erythrocytes, platelets, monocytes, basophils, neutrophils, and eosinophils), while the lymphoid stem cell differentiates to form circulating B and T lymphocytes. Leukemia may develop at any stage and within any cell line.

Two features are common to both AML and ALL: first, both arise from a single leukemic cell that expands and acquires additional mutations, culminating in a monoclonal population of leukemia cells. Second, there is a failure to maintain a relative balance between proliferation and differentiation, so that the cells do not differentiate past a particular stage of hematopoiesis. Cells (lymphoblasts or myeloblasts) then proliferate uncontrollably. Proliferation, differentiation, and apoptosis are under genetic control, and leukemia can occur when the balance between these processes is altered. New anti-leukemia drug therapies are being developed that are specifically

targeted to the biologic processes involved in proliferation and differentiation.⁴

AML probably arises from a defect in the pluripotent stem cell or a more committed myeloid precursor, resulting in partial differentiation and proliferation of immature precursors of the myeloid blood-forming cells. In older patients, trilineage leukemic involvement is common, suggesting that the cell of origin is probably a stem or very early progenitor cell. In younger patients, a more differentiated progenitor becomes malignant, allowing maturation of some granulocytic and erythroid populations. These two forms of AML exhibit different patterns of resistance to chemotherapy, with resistance more evident in the older adults with AML. ALL is a disease characterized by proliferation of immature lymphoblasts. In this type of acute leukemia, the defect is probably at the level of the lymphopoietic stem cell or a very early lymphoid precursor.¹

Leukemic cells have growth and/or survival advantages over normal cells, leading to a “crowding out” phenomenon in the bone marrow. This growth advantage is not caused by more rapid proliferation as compared with normal cells. Some studies suggest that it is caused by factors produced by leukemic cells that either inhibit normal cellular proliferation and differentiation, or reduce apoptosis as compared with normal blood cells.

The types of genetic alterations that lead to leukemia have only recently become evident. The genetic defects may include (1) activation of a normally suppressed gene (protooncogene) to create an oncogene that produces a protein product that signals increased proliferation; (2) loss of signals for the blood cell to differentiate; (3) loss of tumor suppressor genes that control normal proliferation; and (4) loss of signals for apoptosis. Most normal cells are programmed to die eventually through apoptosis, but the appropriate programmed signal is often interrupted in cancer cells, leading to continued survival, replication, and drug resistance. Signal transduction, RNA transcription, cell-cycle control factors, cell differentiation, and programmed cell death may all be affected.

One example of a genetic defect leading to acute leukemia is abnormal activation of the *ras* gene.⁷ These genes produce G proteins (guanine nucleotide-binding proteins) that couple activation of outer cell membrane receptors to activation of signal transduction.

The abnormal activation of these signal transduction pathways can lead to increased cell proliferation. Point mutations in the *ras* gene lead to unregulated proliferation and differentiation. Defects in this gene are present in 25% to 44% of AML patients, and in 6% to 18% of ALL patients. Disruption of *ras* signaling also creates a useful target for therapeutic intervention. The investigational agents called farnesyl transferase inhibitors (such as tipifarnib [R115777, Zarnestra] or lonafarnib [Sarasar]) block an early part of the *ras* pathway, and are undergoing evaluation in various types of cancer, including leukemias.

LEUKEMIA CLASSIFICATION

2 The French-American-British (FAB) classification system identifies eight different subtypes of AML based on granulocytic differentiation and maturation (Table 131–2), and this system is used to determine prognosis and choice of therapy. However, it does not consider clinical characteristics, clonal cytogenetic abnormalities, immunophenotyping, or response to therapy. The World Health Organization (WHO) and the Society of Hematopathology have proposed a new classification system for myeloid neoplasms (Table 131–3).⁸ This new classification system incorporates not only morphologic findings, but genetic, immunophenotypic, biologic, and clinical features. It has long been known that certain cytogenetic abnormalities have prognostic significance, but did not always correlate well with the FAB classification system.⁹ In addition, this new classification attempts to formally incorporate the relationship between AML and myelodysplastic syndrome (MDS). A limitation of the WHO classification is that it does not account for some of the myeloid disorders of childhood. There are recommendations to expand the myelodysplastic/myeloproliferative disorders to include additional subclasses such as juvenile myelomonocytic leukemia and patients with Down’s syndrome.¹⁰

Lymphoid leukemias are not addressed in the current WHO classification system. Markers on the cell surface or membrane of the lymphoblast can be used to classify ALL (Table 131–4). ALL may also be described by cytogenetic abnormalities. Chromosome alterations include numerical (hyperdiploidy and hypodiploidy), and structural

abnormalities due to exchanges of genetic information within (inverting) or between (translocation) chromosomes.¹¹

CLINICAL PRESENTATION

3 Common signs and symptoms at presentation are described in the clinical presentation boxes. In addition to clinical presentation, laboratory and pathology evaluations are required for a definitive diagnosis of leukemia. The most important test is a bone marrow biopsy and aspirate, which is submitted to hematopathology for numerous evaluations. Cytochemical stains are helpful to determine if the acute leukemia is of myeloid or lymphoid lineage. Immunophe-

notyping involves the analysis of specific antigens, known as clusters of differentiation, often abbreviated “CD,” present on the surface of hematopoietic cells. While no leukemia-specific antigens have been identified, the pattern of cell surface antigen expression reliably distinguishes between lymphoid and myeloid leukemia.¹ Common immunophenotypic markers seen in AML and ALL are listed in Table 131–5. Cytogenetic analysis of the marrow to determine the presence of nonrandom numerical and structural chromosomal abnormalities in leukemic cells is also helpful for diagnosis, establishing prognosis, and evaluating response to therapy.⁹ Chromosome translocations can result in abnormal expression and/or function of cellular oncogenes. Unique translocations can identify specific subtypes of acute leukemia. For example, APL is characterized by a specific translocation between chromosomes 15 and 17: t(15;17). Recently, technically difficult cytogenetic analysis has been supplemented with fluorescent in situ hybridization (FISH) that allows for quick, sensitive analysis of samples that might be inadequate for karyotyping.^{13,14} FISH is a process in which specific genes in an intact cell are visualized with fluorescent-labeled probes. Molecular tests may be used to identify products of specific translocations, such as promyelocytic leukemia-retinoic acid receptor- α (PML-RAR α) in APL.

TABLE 131–5. Common Immunophenotypes in Acute Leukemia

| Leukemia | Common Immunophenotypes |

| Acute myeloid leukemia | CD13, CD15, CD33, CD14, CD64, and C-KIT |
| B-cell acute lymphoblastic leukemia | CD19, CD20, CD10, and CD22 |
| T-cell acute lymphoblastic leukemia | CD2, CD3, CD4, CD5, and CD7 |

PRESENTATION OF ACUTE MYELOID LEUKEMIA^{1,8,12}

GENERAL

Typically a 1- to 3-month history of vague symptoms such as tiredness, lack of exercise tolerance, chest pain, and “feeling unwell,” but in no obvious distress.

SYMPTOMS

The patient may report weight loss, malaise, fatigue, and palpitations and dyspnea on exertion. They may also present with fever, chills, and rigors suggestive of infection; bruising (excessive vaginal bleeding, epistaxis, ecchymoses, and petechiae); gum hypertrophy (AML M4 and AML M5 subtypes); bone pain; seizures, headache, and diplopia.

SIGNS

Temperature may be elevated due to low neutrophil count; petechiae

LABORATORY TESTS

Complete blood cell count (with differential). Anemia is usually present and is normochromic and normocytic (without a compensatory increase in reticulocytes). Thrombocytopenia (severe, less than 50,000/mm³ platelets) is present in approximately 50% of cases. Leukopenia/leukocytosis: approximately 20% of patients will present with an elevated white blood cell (WBC) count, 20% with a low WBC count, and the rest with normal counts. Even patients with elevated counts can be considered functionally neutropenic.

Uric acid is elevated in 50% of patients due to rapid cellular turnover (more common in patients presenting with elevated WBC counts).

Electrolytes: potassium and phosphate are usually elevated.

Coagulation: elevated prothrombin time, partial thromboplastin time, D-dimers; hypofibrinogenemia.

OTHER DIAGNOSTIC TESTS

Bone marrow biopsy and aspirate: send for morphologic examination, cytochemical staining, immunophenotyping, and cytogenetic (chromosome) analysis. At diagnosis the marrow is typically hypercellular, with normal erythropoiesis being replaced by leukemic blasts. To be diagnosed with AML, there needs to be more than 20% blasts.

For patients presenting with CNS signs, a diagnostic lumbar puncture should be performed. CNS involvement is common with AML M4 and M5 subtypes.

with fever, chills, and rigors suggestive of infection; bruising (excessive vaginal bleeding, epistaxis, ecchymoses, and petechiae); bone pain; seizures, headache, and diplopia.

SIGNS

Temperature may be elevated due to low neutrophil count; petechiae; splenomegaly, hepatomegaly, and lymphadenopathy.

LABORATORY TESTS

Complete blood cell count (with differential). Anemia is usually present and is normochromic and normocytic (without a compensatory increase in reticulocytes). Thrombocytopenia (severe, less than 50,000/mm³ platelets) is present in approximately 50% of cases. Leukopenia/leukocytosis: approximately 20% patients will present with an elevated white blood cell (WBC) count, 20% with a low WBC count, and the rest with normal counts. Even patients with elevated counts can be considered functionally neutropenic.

Uric acid is elevated in 50% of patients due to rapid cellular turnover (more common in patients presenting with elevated WBC counts).

Electrolytes: potassium and phosphate are usually elevated.

OTHER DIAGNOSTIC TESTS

Bone marrow biopsy and aspirate: send for morphologic examination, cytochemical staining, immunophenotyping, and cytogenetic (chromosome) analysis.

CNS involvement is common in all ALL patients, and is a common cause of relapse. All patients should have a screening lumbar puncture performed.

PROGNOSTIC FACTORS

Many clinical and laboratory features at diagnosis are associated with response to treatment, as measured by the CR rate, duration of remission, and long-term survival. Identification of these risk factors may allow the clinician to better understand the disease and to tailor treatment according to risk of disease recurrence. For example, if a patient has many clinical and laboratory features that are associated with a good response to chemotherapy (“good risk”), then the clinician may choose to give less intensive therapy to reduce the risk of long-term toxic effects. Conversely, if a patient is unlikely to respond well to therapy (“high risk” or “poor risk”), then the clinician may choose to give more intensive chemotherapy that might include hematopoietic stem cell transplantation (HSCT).

ACUTE LYMPHOBLASTIC LEUKEMIA

In both adults and children with ALL, recent studies have identified several risk factors that correlate with prognosis (Table 131–6). As most patients with ALL achieve a CR, these factors correlated with the risk of leukemic relapse rather than the risk of not achieving a CR.

4 Poor prognostic factors include high WBC count at presentation, very young or old age at presentation, delayed remission induction, and the presence of specific cytogenetic abnormalities.¹⁵

5 Several specific chromosomal translocations have been identified and are now being routinely used in risk assessment,

and subsequently to direct therapy (Table 131–7). Adult patients generally have a worse prognosis than children due to disease biology and treatment tolerance. Adults typically have more cytogenetic abnormalities, particularly the presence of the Philadelphia chromosome (Ph⁺) or t(9;22), which confer higher-risk disease. Other poor prognostic factors more common in adults include chemotherapy resistance, slower response to chemotherapy, high WBC at presentation, and a mediastinal mass or extramedullary involvement.

The National Cancer Institute developed an ALL risk stratification to create a standard for comparison in children¹⁵ (Table 131–8). Therapy is initially selected based on this classification, but may be modified based on the presence or absence of cytogenetic abnormalities, slow response to induction treatment, or CNS involvement. In the adult population with ALL, age <35 years, good performance status, time to CR <4 weeks, timely clearance of blasts, and presenting WBC count of <30,000/mm³ all qualify as “standard risk” factors.⁵

ACUTE MYELOID LEUKEMIA

5 6 Several prognostic factors have been identified for adults with AML. The most important patient factor is age, with younger patients more likely to achieve a CR than older patients (older than age 60).^{1,12} The lower CR rate in older patients appears to result from an increased frequency of fatal infectious and bleeding complications, as well as disease resistance to conventional chemotherapy.¹²

TABLE 131–8. National Cancer Institute Acute Lymphoblastic Leukemia Risk Stratification

| Risk Group | Age (Years) | White Blood Cells (cells/mm ³) | | Karyotype |

| Standard | 1 to <10 | <50,000 | – | No t(9;22) or t(4;11) |
| High | 1 to <10 | ≥50,000 | – | t(9;22) or t(4;11) |
| | <1 or ≥10 | Any | – | |
| | Any | Any | – | |

From Wells et al.¹⁶

The duration of remission is also shorter in older patients compared to younger patients. Other patient-specific prognostic factors include concurrent infection and any major organ impairment.¹² FAB morphologic subtype may be a factor, with types M0, M5, M6, and M7 having the worst outcome.^{1,12} Patients with extramedullary disease, CNS involvement, or underlying MDS have a worse prognosis.^{1,12} Certain cytogenetic abnormalities are also known to worsen the response rate and survival of patients with AML (see Table 131–7).^{1,9} In addition, patients who develop a “secondary” leukemia after treatment of another malignancy usually have a very poor response to antileukemic chemotherapy.¹

Prognostic factors associated with pediatric AML have been reported but few have been shown to consistently predict treatment outcome. Historically, poor prognostic factors include an initial WBC count greater than 100,000/mm³, FAB subtype M1 without Auer rods, certain chromosomal abnormalities (see Table 131–7), age <5 years, and having AML secondary to prior chemotherapy or radiation therapy. A recent report from the Children’s Cancer Group identified both poor and favorable prognostic factors. Poor prognostic factors at diagnosis included male gender, platelet count ≤20,000/mm³, hepatomegaly, MDS, FAB subtype M5, greater than 15% bone marrow blasts at day 14 of induction therapy, and trisomy 8.¹⁶ Abnormal chromosome 16 was associated with a higher rate of CR.¹⁶

TREATMENT GOALS

The short-term goal of treatment for acute leukemia is to rapidly achieve a complete clinical and hematologic remission. In the absence of a CR, a rapid and fatal outcome is inevitable. Complete remission is defined as the disappearance of all clinical and bone marrow evidence (normal cellularity >20% with <5% blasts) of leukemia, with restoration of normal hematopoiesis (neutrophils ≥1,500/mm³ and platelets >100,000/mm³). Partial remission is a significant response

TABLE 131–7. Risk Category According to Cytogenetic Abnormalities Present

| Disease | Risk Category | | |
|------------------------|---|--|---|
| | Good Risk | Intermediate Risk | High Risk |
| AML | t(8;21)(q22;q22); inv(16); t(15;17); t(9;11) trisomy 21 | Normal karyotype; trisomy 8; 11q23; del(7q); del(9q); trisomy 22 | Complex karyotype; –5; –7; del(5q); inv(3p) |
| Probability of relapse | ≤25% | 50% | >70% |

ALL, acute lymphoblastic leukemia; AML, acute myeloid leukemia. From Hasle et al¹⁰ and Thomas et al.¹⁹

to treatment, although evidence of residual disease in the bone marrow remains (5% to 25% blasts) and is considered a treatment failure requiring additional therapy. The definition of response for adult AML has recently been re-evaluated, and there is a proposal to change the definition of response to include not only CR, but also morphologic CR, CR with incomplete count recovery, cytogenetic CR, and molecular CR.^{17,18}

► TREATMENT: Acute Lymphoblastic Leukemia

Successful treatment of ALL was first developed in children. Current regimens induce CR in 97% to 99% of children with ALL.¹¹ Cure rates in children have risen from less than 5% with treatments used in the 1960s to approximately 80% by 1995.³ Although treatment results with adult ALL are worse than those with childhood ALL, recent use of aggressive chemotherapy in adult ALL has increased the CR rate to 60% to 85%. Long-term disease-free survival (DFS) in this population, however, remains low (between 30% and 40%) due to the higher proportion of adults presenting with poor-risk disease. CR rates and DFS vary according to a number of poor prognostic factors (see Tables 131-6 and 131-7), and certain types of ALL are associated with a very poor outcome. Ph⁺ ALL, characterized by the presence of the t(9;22) cytogenetic abnormality, has a dismal 5-year survival (10% adults; 25% children).¹⁹ Although this specific type of ALL is treated essentially like all other ALL patients, patients with Ph⁺ ALL can benefit from the addition of a targeted molecular therapy, as discussed later.

Therapy for ALL has historically been divided into three phases: (1) remission induction; (2) consolidation therapy; and (3) maintenance therapy (Fig. 131-1). Central nervous system (CNS) prophylaxis is a mandatory component of any ALL treatment regimen and is administered longitudinally during the induction and consolidation phases. Recently more complex regimens have been explored. All patients still receive induction therapy to yield a CR. Post-remission therapy is needed to treat microscopic disease and may include intensive inpatient therapy (consolidation or intensification therapy) followed by less aggressive outpatient therapy (maintenance or continuation). Tables 131-9 and 131-10 illustrate representative treatment regimens for adult and pediatric ALL.²⁰⁻²²

REMISSION INDUCTION

7 The goal of remission induction is to rapidly induce a complete clinical and hematologic remission. The CR rate is 97% to 99%

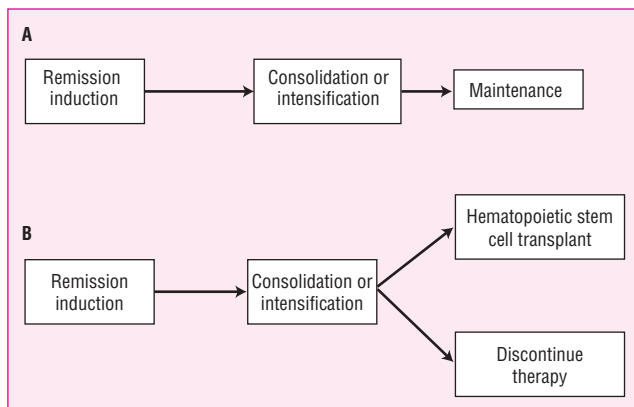

FIGURE 131-1. Treatment algorithm for (A) ALL and (B) AML.

After a CR is achieved, the goal is to maintain the patient in continuous CR. As discussed later, the occurrence of leukemic relapse in the bone marrow significantly reduces the likelihood of curing the disease. Most patients who will die from acute leukemia die within the first 6 years; the survival curve (percentage alive versus time) beyond the sixth year after therapy does not continue to decline as rapidly, and at this time patients can be considered “cured.”¹

in children treated with vincristine, dexamethasone or prednisone, and asparaginase or pegaspargase.¹ In children with high-risk ALL, daunorubicin is added to standard three-drug induction. Complete remission is achieved in 72% to 92% of adults with daunorubicin or doxorubicin, vincristine, and prednisone.^{1,5} Since most adults are considered high-risk, adults usually receive more intensive remission induction regimens. However, the value of adding more drugs to the basic three- or four-drug induction regimen is unclear. Equally unclear is the value of higher doses of the standard combination of drugs for remission induction. Some studies suggest that high-dose methotrexate and cytarabine alternating with fractionated cyclophosphamide plus vincristine, doxorubicin, and dexamethasone (hyper-CVAD) may improve response and survival in adults with ALL.^{23,24} However, this treatment may be associated with significant cerebellar toxicity.²⁵ Higher doses of cyclophosphamide may be indicated for patients with T-cell ALL.⁵

Some experts suggest that most treatment failures in childhood ALL result from inadequate initial reduction of the leukemic clone and the acquisition of drug resistance by residual lymphoblasts.²⁶ This is the basis upon which many trials have incorporated four-drug (or more) induction remission regimens and aggressive intensification or consolidation regimens in the management of higher-risk patients. Most treatment protocols add daunorubicin to induction for high-risk ALL, and some also add other agents, such as cyclophosphamide, methotrexate, cytarabine, and teniposide. The rate of clearance of blasts may be an important prognostic factor. Children with a slow rate of clearance of blasts from the bone marrow in the first 7 (high-risk) or 14 (standard-risk) days of therapy have an eventual outcome that is inferior to those with rapid clearance of blasts (see Table 131-8 for definitions of risk).²⁷ Additional therapy significantly improves outcome of children with a slow early response.²⁷ Historically, prednisone has been the primary glucocorticoid used in pediatric ALL regimens. Dexamethasone is now being used in some standard-risk protocols due to its longer duration of action and higher cerebrospinal fluid penetration compared to prednisone.²⁸ Dexamethasone, when used in place of prednisone during induction and maintenance, also improves event-free survival (EFS) and decreases the risk of CNS relapse.²⁸ However, dexamethasone increases side effects such as avascular necrosis, steroid myopathy, hyperglycemia, and infections.^{28,29}

Ph⁺ ALL is associated with poor long-term outcomes, although the availability of imatinib mesylate, a molecularly targeted therapy, has prompted much research into the effect of this new drug on long-term survival rates. While responses may be seen with imatinib mesylate as monotherapy, this approach does not produce durable remissions.³⁰ Clinical trials are now exploring the addition of this targeted therapy to conventional chemotherapy, with encouraging early results. The combination of hyper-CVAD and imatinib appears to produce better outcomes compared to historical control data with hyper-CVAD alone, but additional studies and long-term follow-up are needed to conclusively determine if this

| Prednisone 40 mg/m ² per day for 7 days on weeks 8 and 17 |
| Vincristine 1.5 mg/m ² per dose (max 2 mg) IV on the first day of weeks 8, 9, 17, and 18 |
| Methotrexate 200 mg/m ² per dose IV + 800 mg/m ² dose over 24 hours on day 1 of weeks 7, 10, 13, 16, 19, and 22 |
| Intrathecal methotrexate on weeks 5, 6, 9, 12, 15, and 18 |
| Late intensification (weeks 25–52) |
| Methotrexate 20 mg/m ² per dose IM weekly or 25 mg/m ² per dose orally every 6 hours for 4 doses every other week |
| Mercaptopurine 75 mg/m ² per dose orally at bedtime |
| Prednisone 40 mg/m ² per day orally for 7 days on weeks 25 and 41 |
| Vincristine 1.5 mg/m ² per dose (max 2 mg) IV on the first day of weeks 25, 26, 41, and 42 |
| Intrathecal methotrexate on day 1 of weeks 25, 33, 41, and 49 |
| Maintenance (12-week cycles) |
| Methotrexate 20 mg/m ² per dose orally at bedtime or IM weekly with dose escalation as tolerated |
| Mercaptopurine 75 mg/m ² per dose orally at bedtime on days 0–83 |
| Vincristine 1.5 mg/m ² per dose (max 2 mg) IV on days 0, 28, and 56 |
| Dexamethasone 6 mg/m ² per day orally on days 0–4, 28–32, and 56–60 |
| Intrathecal methotrexate on day 0 |

IM, intramuscularly; IV, intravenous.

strategy will become the new standard of care in this high-risk population.¹⁹

CENTRAL NERVOUS SYSTEM PROPHYLAXIS

8 CNS prophylaxis may overlap with or be incorporated into induction, consolidation, or maintenance. The rationale for CNS prophylaxis is based on two observations. First, many chemotherapeutic agents do not readily cross the blood-brain barrier. Second, results from early clinical trials of ALL showed that 50% to 75% of

patients with ALL and no CNS involvement at diagnosis experienced an extremely high rate of early isolated CNS relapse.⁵ These observations indicate that the CNS is a potential sanctuary for leukemic cells and that undetectable leukemic cells are present in the CNS in many patients at the time of diagnosis. Detectable CNS involvement at the time of diagnosis is relatively uncommon (<10%) in ALL.¹ Factors that are associated with an increased risk of CNS involvement at diagnosis in children include a high initial WBC count, T-cell phenotype, mature B-cell phenotype, age ≤ 1 year, thrombocytopenia, lymphadenopathy, and hepatomegaly or splenomegaly. In adults, risk factors for CNS disease include mature B-cell ALL phenotype and a high proportion of cells in the S phase (indicator of cellular turnover).⁵

The goal of CNS prophylaxis is to eradicate undetectable leukemic cells from the CNS. Leukemic meningitis is more easily prevented than treated. Once CNS relapse has occurred, patients are at increased risk of bone marrow relapse and death from refractory leukemia. Initial trials in childhood ALL in the 1960s established craniospinal irradiation as the standard for prevention of CNS relapse.¹¹ However, this approach was associated with long-term sequelae including neuropsychological deficits, precocious puberty, osteoporosis, thyroid dysfunction, an increased incidence of brain tumors, short stature, and obesity. Subsequent trials have demonstrated that irradiation may be replaced by frequent administration of intrathecal chemotherapy in most children with ALL.¹¹

The selection of a CNS prophylaxis regimen must consider efficacy, toxicity, and risk of CNS disease.

8 Intrathecal chemotherapy, cranial irradiation, and high-dose intravenous methotrexate or cytarabine can be used to treat or prevent CNS disease. These treatment approaches have reduced CNS relapses to less than 2% among children.^{1,11} Intrathecal therapy consists of methotrexate and cytarabine alone or in combination. When given together, hydrocortisone is commonly added to decrease the incidence of arachnoiditis. The doses of intrathecal chemotherapy used in pediatric ALL patients must be individualized based on age because of differences in the volume of cerebrospinal fluid at various ages. Due to the long-term sequelae associated with cranial or craniospinal irradiation, only children with CNS disease at diagnosis or who are in certain high-risk subsets receive this therapy in the United States.

■ CONSOLIDATION THERAPY

Consolidation (or intensification) therapy in ALL is started after a CR has been achieved, and refers to continued intensive chemotherapy in an attempt to eradicate clinically undetectable disease. Regimens usually incorporate either non-cross-resistant drugs that are different from the induction regimen, or more dose-intensive use of the same drugs.

Randomized trials show that consolidation therapy clearly improves patient outcome in children, but its benefit in adults is less clear.^{1,11} The relative benefit of individual components of treatment regimens is difficult to demonstrate because of the overall complexity of therapy in ALL. The adult regimens listed in Table 131-9 offer two different approaches to consolidation with similar results. Consolidation therapy in the German regimen is similar to the remission induction regimen, but substitutes dexamethasone for prednisone (due to its better CNS penetration to prevent leukemic meningitis), doxorubicin for daunorubicin, and thioguanine for mercaptopurine.³¹ Alternatively, the Cancer and Leukemia Group B (CALGB) trial uses a consolidation regimen far more complicated than the induction regimen. The latter includes different drugs and higher doses, at least for the cyclophosphamide dose.²¹ The outcomes from these distinctly different approaches are similar. The German investigators found a median survival duration of 27.5 months and an estimated 5-year survival rate of 39%.³¹ With a shorter follow-up time (median, 43 months), the CALGB study showed a median survival duration of 36 months and a 3-year survival rate of 39% for those 30 to 59 years old.²¹ The results of these studies suggest that a consolidation phase in adult ALL therapy is necessary, although specific questions remain about drug selection, duration of therapy, dosing, and timing of administration.

In children, the intensity of consolidation therapy is based on the child's risk classification and rate of cytoreduction during induction.

Patients who respond slowly to induction therapy are at higher risk of relapse if they are not treated on more aggressive regimens. Various consolidation regimens have been studied with similar results. Two examples of consolidation regimens are presented in Table 131-10. One strategy is to include one or two delayed intensification phases separated by low-intensity interim maintenance cycles to maintain remission and to decrease cumulative toxicity. This strategy yields a 6-year EFS of 76% for a single delayed intensification and 83% for two cycles in intermediate-risk patients.³² Current studies are testing similar regimens in standard-risk patients. The antimetabolite-based regimens may have a reduced risk of late toxicities, but the more intensive consolidation regimens appear to result in better survival for some patients, especially those with higher-risk disease.

Current studies are designed to continue the assessment of the intensity of consolidation needed for patients with different levels of risk and to determine whether methotrexate should be administered orally or intramuscularly due to compliance issues.

Children with Ph⁺ ALL or infants with t(4;11) mixed lineage leukemia (MLL), or children who only achieve a partial remission may be transplanted in first remission if a suitable donor is available.^{1,33} In adults, the indications for transplantation are less clear,¹ but if the patient is not too old, and an allogeneic matched-sibling donor is available, many treatment centers would recommend allogeneic hematopoietic stem cell transplantation (alloHSCT) in first remission. Autologous hematopoietic stem cell transplantation (autoHSCT) has not been demonstrated to be superior to chemotherapy. The International Bone Marrow Transplant Registry (IBMTR) reports 44% DFS for matched unrelated donor (MUD) transplants. Haploidentical and cord blood transplants are being investigated since many patients do not have matched sibling donors available.

■ MAINTENANCE THERAPY

9 Many adult ALL patients relapse shortly after completion of remission induction and consolidation therapy, presumably because of residual disease. Maintenance therapy allows long-term drug exposure to slowly dividing cells, allows the immune system time to eradicate leukemia cells, and promotes apoptosis (programmed cell death). The goal of maintenance therapy is therefore to further eradicate residual leukemic cells and prolong remission duration. Although maintenance therapy is clearly beneficial in childhood ALL, the possible benefit in adults has only recently been demonstrated. In some adult ALL trials that included induction and consolidation, but omitted maintenance, the DFS at 2 years was lower compared to trials that included maintenance.^{1,34,35}

Maintenance therapy usually consists of mercaptopurine and methotrexate, at doses that produce relatively little myelosuppression, with intermittent "pulses" of vincristine and a steroid. Table 131-9 lists the typical doses for these agents in this phase. In an effort to determine the long-term outcome of the duration and intensity of maintenance therapy, the Childhood ALL Collaborative Group published findings from a large meta-analysis involving 12,000 randomized children from 42 trials initiated prior to 1987.³⁸ The analysis revealed that longer maintenance, pulses of vincristine and prednisone, and the inclusion of one or two intensive reinduction courses significantly reduced the total number of deaths or relapse. However, only intensive reinduction improved survival.

The optimal duration of maintenance therapy in adults is unknown, but most treatment programs continue maintenance therapy for 24 to 36 months. Based on the results of studies that show a trend

toward an increase in late relapse (excluding isolated testicular relapse) among male children treated for 2 years versus 3 years, some centers treat female children for 2 years while males receive maintenance for 3 years. Decisions about maintenance therapy in adults are also based on the patient's subtype of ALL. Adults with common pre-B-cell ALL benefit from conventional maintenance therapy with methotrexate and mercaptopurine, while those with B-cell ALL or Ph⁺ ALL probably gain greater benefit from intensive induction and consolidation and little from maintenance.⁵

Interpatient variability in the pharmacokinetics of oral methotrexate and mercaptopurine may also be an important determinant of the effectiveness and toxicity of maintenance therapy. Patients who take their oral methotrexate and mercaptopurine on an evening versus a morning schedule appear to have a superior outcome.³⁶ To account for the interpatient variability, most pediatric protocols titrate the dose of either agent to maintain an absolute neutrophil count of 750 to 1,500/mm³. Some protocols circumvent bioavailability and poor compliance issues by administering methotrexate parenterally. The importance of these pharmacokinetic issues in adults is less well defined.

Genetic polymorphisms may affect drug metabolism, receptor expression, drug transportation, drug disposition, and pharmacologic response. These alterations may contribute to acute and chronic toxicity from ALL therapy as well as differences in treatment outcome. The most studied polymorphism involves thiopurine metabolism. Thiopurines are inactivated by S-methylation by cellular thiopurine methyltransferase (TPMT). About 10% of the population have intermediate TPMT activity due to heterozygous polymorphisms in the gene encoding for TPMT, and one in 300 has extremely low activity due to homozygous presence of this TPMT polymorphism.³⁷ Deficiency of TPMT activity results in excessive myelosuppression from mercaptopurine and thioguanine. Patients with low activity (homozygous mutant TPMT genotype) may require 85% to 90% dose reductions.³⁷ Prospective evaluation of TPMT status was complicated in the past, since many ALL patients receive transfusions prior to definitive diagnosis. TPMT status can now be determined directly by DNA-based testing, which may become a standard of care in the near future.

ACUTE LYMPHOBLASTIC LEUKEMIA IN INFANTS

ALL and AML in infants less than 1 year of age accounts for less than 5% of the reported acute leukemias in childhood, but they are associated with poor outcomes. EFS in infant ALL is 20% to 40%.³⁹ Sixty to seventy percent of infants with acute leukemia have a translocation that involves the MLL gene located at 11q23.³⁹ In infant ALL, the t(4;11) is most common and has been associated with an extremely poor outcome in the past, with only 10% to 20% EFS.³⁹ Other poor prognostic factors in infant ALL include age less than 6 months, a high WBC count, hepatosplenomegaly, and CNS disease. These factors are also closely associated with MLL translocations. Patients with infant ALL may have greater drug resistance to asparaginase and prednisone, but increased sensitivity to cytarabine.³⁹ Although the use of intensive regimens such as high-dose methotrexate and high-dose cytarabine have improved survival rates, unacceptably high mortality rates have also been observed with some regimens. Lack of pharmacokinetic data for chemotherapy in infants has contributed to toxicity from inappropriate dosing of doxorubicin and vincristine. To reduce neuropsychological complications, most protocols avoid cranial irradiation. The use of HSCT for infants with ALL remains controversial

due to a lack of donors, concerns over the long-term toxicity of total body irradiation, and excessive mortality in some series.

ACUTE LYMPHOBLASTIC LEUKEMIA IN THE ELDERLY

A considerable number of ALL cases occur in patients older than age 60 years, but no specific treatment recommendations can be made. The response to therapy and durability of response seem less than in younger adults or children. Older patients have a higher incidence of Ph⁺ ALL compared to younger patients, and a lower occurrence of T-cell ALL.^{5,19} Based on data demonstrating excellent responses in CML, the addition of imatinib to conventional chemotherapy in Ph⁺ ALL patients is an increasingly common approach.¹⁹ Whether this leads to any increase in EFS or overall survival (OS) remains to be seen. In general, older patients have a lower CR rate, and when achieved, the duration of remission is shorter than with younger patients.

TREATMENT OF RELAPSED ACUTE LYMPHOBLASTIC LEUKEMIA

The most common site for relapse is the bone marrow, although isolated relapses can occur in the CNS or testicles. Marrow relapse usually follows isolated CNS or testicular relapses. Therefore patients with isolated extramedullary relapses are treated with localized radiation (cranial or testicular) and aggressive systemic chemotherapy similar to that given to patients with a marrow relapse.¹

Patients who have completed treatment and who have stayed in remission for longer periods are more likely to be reinduced into remission again. Patients with more favorable risk factors initially, and those who received less intensive initial treatments, are more likely to respond well to reinduction/salvage regimens.³³ In general, long-term survival after relapse is very poor, and aggressive therapies are used.

Matched sibling alloHSCT is the treatment of choice for all childhood ALL in second remission (CR2). Children who relapse more than 36 months after completion of initial therapy have reasonable outcomes with chemotherapy alone.¹¹ For patients with shorter initial remissions or who relapse on therapy (including most adults), alloHSCT performed while in CR2 is associated with longer DFS than chemotherapy (40% vs. 17%).³³ Patients who undergo HSCT are less likely to relapse, but are more likely to experience treatment-related morbidity and mortality. Recently published studies suggest that relapsed pediatric patients may have better 5-year DFS after alloHSCT in CR2 as compared to chemotherapy alone, regardless of duration of remission, WBC count at diagnosis, or number of agents used in initial induction.⁴⁰

ROLE OF COLONY STIMULATING FACTORS IN ACUTE LYMPHOBLASTIC LEUKEMIA

◀ The use of granulocyte colony-stimulating factor (G-CSF) in children and adults administered during, after, or between courses has been shown to shorten the duration of neutropenia by 2 to 10 days.^{41–47} Standard-risk ALL therapy in children is not myelosuppressive and does not warrant the use of colony-stimulating factors (CSFs). It was initially thought that children with high-risk ALL may

benefit from a CSF if treatment delays could be avoided. However, a recent trial in high-risk patients demonstrated that while there was a decrease in the median time to neutrophil recovery, this did not translate into any benefit in terms of episodes of febrile neutropenia, positive blood cultures, or serious infections.⁴⁶ Length of hospital stay and time to complete induction therapy were not significantly altered.⁴⁶ Similarly, there was no difference between filgrastim and placebo in hospitalization rate for fever and neutropenia, incidence of severe infection, or EFS.⁴⁶ Patients did have shorter hospital stays (average, 4 days) and fewer documented infections. A trial of filgrastim in high-risk pediatric ALL patients may be warranted in patients with treatment delays due to neutropenia if the patient's quality of life is not impaired by daily subcutaneous injections.

In the adult ALL population, one trial has demonstrated an improved CR rate, but this has not been confirmed in other large randomized studies.⁴⁷ No trial has shown improved EFS or OS in either the pediatric or adult populations. Several studies reported a decrease in the incidence of febrile neutropenia,^{42,45} duration of hospitalization,^{41,43,47} and duration of antibiotic use.⁴²

Current American Society of Clinical Oncology (ASCO) guidelines recommend the initiation of CSFs after completion of the first

few days of chemotherapy of either the initial induction or first remission course.⁴⁸ The British Society of Hematology has more recently published their recommendations for the use of CSFs in patients with hematologic malignancies, and recommend their use following intensive phases of treatment to decrease the severity of neutropenia.⁴⁹

LATE EFFECTS OF ACUTE LYMPHOBLASTIC LEUKEMIA

Certain late effects associated with cranial or craniospinal irradiation and/or corticosteroids were discussed earlier. Some childhood ALL regimens that incorporate intensive use of topoisomerase II inhibitors (etoposide and teniposide) are associated with unacceptably high risks of development of secondary leukemia.¹¹ High cumulative doses of anthracyclines used in high-risk or relapsed patients can cause cardiomyopathy. Cranial irradiation has also been found to cause learning deficits, especially in patients less than 5 years of age at the time of treatment. Patients who received cranial radiation as children also have higher unemployment rates and lower marital rates among females two decades after diagnosis.⁵⁰

TREATMENT: Acute Myeloid Leukemia

AML accounts for most cases of acute leukemia in adults, and occurs with increasing frequency in elderly patients. It accounts for only 15% to 20% of the acute leukemias in children, but is responsible for 30% of leukemia-related mortality. With recent advances in chemotherapy and supportive care, 65% to 85% of all patients achieve CR and 20% to 40% become long-term survivors.^{1,4} Overall, the median duration of remission is 1 to 2 years.^{1,4} In patients older than age 60 years, the percentage of patients achieving a CR is lower (39% to 64%), and the median duration of remission is shorter than 1 year.⁵¹ In contrast to ALL, effective therapies used in AML cause severe and often prolonged myelosuppression, with the exception of tretinoin. As a result, patients with AML, particularly patients older than age 60 years, are at greater risk for treatment-related fatal infectious and bleeding complications.

The 5-year survival in children with AML has increased from 17% in 1976 to 50% in 2000.³ Children with Down's syndrome and AML receive less intense therapy and have EFS of 68% to 100%.⁵² Treatment of AML, unlike that of ALL, usually only consists of induction and intensive post-remission therapy (see Fig. 131-1). CNS prophylaxis is not routinely given in adult AML (with the exception of some M4 and M5 leukemias), but is generally administered to pediatric patients. Table 131-11 presents several representative induction regimens for treatment of adult AML.⁵³⁻⁵⁹

REMISSION INDUCTION

As with ALL, the goal of remission induction for AML is to rapidly induce a CR. Compared to ALL, however, fewer patients with AML achieve CR. Since the CR rate in AML is related to the intensity of the remission induction regimen, the drugs used in AML are given at doses that uniformly cause severe marrow hypoplasia (except tretinoin). One reason for the lower CR rate in AML as compared to ALL is the inability to give optimal doses of chemotherapy because of marrow toxicity. With continued improvement of supportive care for patients

undergoing chemotherapy, more intensive treatment regimens are being given in an effort to reduce the high rate of leukemic relapse and increase the proportion of long-term survivors. Most patients achieve a CR after one or two courses of chemotherapy. Patients who require additional chemotherapy to achieve a CR have been reported to have a poor prognosis, even if remission is ultimately achieved.¹

▶ The most active single agents in AML (non-M3) are the anthracycline antibiotics (daunorubicin, doxorubicin, and idarubicin), anthracenediones (mitoxantrone), and the antimetabolite cytarabine. The most common regimen ("7 + 3") combines daunorubicin administered as a short infusion of 45 to 60 mg/m² per day on days 1 to 3, along with cytarabine administered as a continuous 24-hour infusion of 100 mg/m² per day on days 1 to 7. The CR rate with the 7 + 3 regimen is 60% to 80% in younger adults. The remission rate decreases to 40% to 50% in patients older than age 60 years. OS rates with an anthracycline and cytarabine are 15% at 5 years.⁶⁰ Several trials have attempted to improve upon conventional 7 + 3 therapy, but have shown no improvement by (1) increasing cytarabine to 10 days, (2) shortening cytarabine to 5 days, (3) substituting doxorubicin for daunorubicin, (4) adding thioguanine, or (5) increasing cytarabine dosage to 200 mg/m² per day (given by continuous infusion).^{4,12}

Other clinical trials have evaluated idarubicin or mitoxantrone as alternatives to daunorubicin in combination with standard continuous infusion cytarabine.^{55,60-66} Preliminary data showed that idarubicin or mitoxantrone increased CR rates in adults younger than 60 years of age and increased survival durations.^{55,62,66} Conversely, other trials in older adults showed no difference in CR rates or survival, but did report an increased number of patients achieving a CR with only one course of idarubicin plus cytarabine as compared to daunorubicin plus cytarabine.⁶⁰ In a review of long-term follow-up results from randomized trials evaluating idarubicin versus daunorubicin, only one trial maintained a significant difference favoring idarubicin. The effect of anthracycline choice on the CR rates in the elderly was studied by the Eastern Cooperative Oncology Group (ECOG).⁶⁴ Elderly AML patients were randomized to standard doses of cytarabine combined with either daunorubicin (45 mg/m² for 3 days), idarubicin

TABLE 131–11. Representative Chemotherapy Regimens for Adult AML

| | |
|---|---|
| Induction therapy | |
| Yates/CALGB ⁵⁴ (“7 + 3”) | Daunorubicin 45 mg/m ² IV daily on days 1 to 3 Cytarabine 100 mg/m ² CIV daily on days 1 to 7 |
| Weirnik et al ⁵⁵ | Idarubicin 13 mg/m ² IV daily on days 1 to 3 Cytarabine 100 mg/m ² CIV daily on days 1 to 7 |
| Weick et al ⁵⁶ | Daunorubicin 45 mg/m ² IV daily on days 1 to 3 Cytarabine 2,000 mg/m ² IV every 12 h × 12 doses on days 1 to 6 |
| Mitus et al ⁵⁷ | Cytarabine 100 mg/m ² CIV daily on days 1 to 7 Daunorubicin 45 mg/m ² IV daily on days 1 to 3 Cytarabine 2,000 mg/m ² IV every 12 h × 6 doses on days 8 to 10 |
| Bishop/ALSG ⁵⁸ (“7 + 3 + 7”) | Cytarabine 100 mg/m ² CIV daily on days 1 to 7 Daunorubicin 50 mg/m ² IV daily on days 1 to 3 Etoposide 75 mg/m ² IV daily on days 1 to 7 |
| Bishop et al ⁵⁹ (“HIDAC + 3 + 7”) | Cytarabine 3,000 mg/m ² IV every 12 h on days 1, 3, 5, and 7 Daunorubicin 50 mg/m ² IV daily on days 1 to 3 Etoposide 75 mg/m ² IV daily on days 1 to 7 |
| Post-remission chemotherapy^a | |
| Mitus et al ⁵⁷ | <i>Cycles 1 and 3</i> Cytarabine 200 mg/m ² CIV daily on days 1 to 5 Daunorubicin 60 mg/m ² IV daily on days 1 and 2 <i>Cycle 2</i> Cytarabine 2,000 mg/m ² IV every 12 h × 6 doses on days 1 to 3 Etoposide 100 mg/m ² IV daily on days 4 and 5 |
| Mayer et al ⁵³ | Cytarabine 3,000 mg/m ² IV every 12 h on days 1, 3, and 5 (6 doses) × 1 to 4 cycles |

^aNumber of postremission chemotherapy cycles is dependent on patient characteristics and inclusion of hematopoietic stem cell transplantation in treatment plan.
CIV, continuous intravenous infusion.

(12 mg/m² for 3 days), or mitoxantrone (12 mg/m² for 3 days). No difference in DFS, OS, or toxicity was seen between the three induction regimens.⁶⁴

CLINICAL CONTROVERSY

Is there a superior anthracycline to use as part of the induction regimen for acute myeloid leukemia? Some clinicians believe that idarubicin is superior in attaining a complete remission following one cycle of induction compared to alternative anthracyclines or anthracenediones. Randomized trials in the elderly show similar remission rates with all anthracyclines and anthracenediones. Whether there is a difference in younger patients remains to be seen.

Thus the anthracycline of choice for a standard 7 + 3 regimen remains controversial, with many centers adopting idarubicin into the induction regimen in younger AML patients, and the choice in the elderly is based on individual clinician preference and institutional acquisition costs.

Other researchers have studied the impact of adding another agent, etoposide, to remission induction regimens for AML.⁵⁸ A comparison of standard 7 + 3 with or without etoposide on days 1 to 7 (“7 + 3 + 7”) in newly diagnosed AML patients aged 15 to 70 years demonstrated no difference in CR rates or OS. A subset analysis of patients less than 55 years of age demonstrated a doubling of the duration of remission and OS in the etoposide-containing arm. The 7 + 3 + 7 regimen was more toxic in patients older than 55 years of age. A small trial in relapsed or refractory adults younger than 70 years of age also reported an increased duration of remission in patients receiving etoposide combined with high-dose cytarabine, as compared to high-dose cytarabine alone, thus confirming the activity of etoposide in the treatment of AML.⁶⁷

Based on experimental tumor models that showed a steep dose-response curve for cytarabine, higher doses of cytarabine have also been evaluated as a means to enhance the outcome of remission induction therapy.⁶⁸ The addition of high-dose cytarabine on days 8 to 10 following conventional 7 + 3 therapy resulted in a CR rate of 89%, which is higher than that reported in the Southeastern Cancer Study Group or the CALGB trial (see Table 131–11).⁵⁷ In adults younger than 60 years of age, high-dose cytarabine (3,000 mg/m² every 12 hours on days 1, 3, 5, and 7) combined with daunorubicin and etoposide led to an improved duration of CR as compared with the same combination with standard-dose cytarabine, although the CR rate and OS were no different between the high-dose and standard-dose cytarabine groups.⁵⁹ The Southwest Oncology Group compared standard- and high-dose cytarabine (2,000 mg/m² every 12 hours for 12 doses), given in combination with daunorubicin.⁵⁶ High-dose cytarabine improved DFS, but did not significantly improve the CR rate or OS and was associated with more toxicity. A recent retrospective study conducted by the European Group for Blood and Marrow Transplantation showed that the cytarabine dose administered during induction and/or consolidation did not influence the outcome in patients who ultimately went on to receive allogeneic or autologous HSCT.⁶⁹ These data suggest that high doses of cytarabine during induction may not be needed in patients scheduled to receive a HSCT as post-remission therapy. In summary, the role of high-dose cytarabine during induction remains controversial. If used during induction, high-dose cytarabine is more appropriate in younger patients than in elderly patients because of poor tolerance by elderly patients.

The National Comprehensive Cancer Network (NCCN) has published guidelines for the treatment of AML.⁷⁰ The classic 7 + 3 regimen may be insufficient in adults younger than age 60 because the duration of remission is less than that reported in some studies that employed high-dose cytarabine in induction.⁷⁰ The NCCN committee recommends that adults younger than 60 years be treated with

more aggressive chemotherapy with high-dose cytarabine with an anthracycline or anthracenedione. In patients older than age 60 years with good performance status, the conventional 7 + 3 regimen should be used or the patient should be enrolled in available clinical trials. The approach in patients with an antecedent hematologic disorder differs, and younger patients should be offered available clinical trials or proceed to alloHSCT (provided a suitable donor is available). Older patients (>60 years) with an antecedent hematologic disorder are usually offered best supportive care because of the dismal outcomes associated with conventional chemotherapy. All adult patients who present with CNS symptoms, and all AML M4 and AML M5 patients who are not symptomatic, should have a diagnostic lumbar puncture, and if it is positive, should be treated for disease. Methotrexate 12 to 15 mg, with or without cytarabine, should be administered intrathecally twice a week until clearance of leukemic blasts from the CSF, and then monthly for approximately 6 months.

The most effective induction regimens for children have included an anthracycline plus cytarabine, and either thioguanine or etoposide, yielding a remission rate of 75% to 85%.⁷¹ Intensified therapy regimens, which include more antileukemic agents or compress the time in which the agents are delivered, have improved survival rates. In compressed or intensified treatment regimens, the second course of therapy is given 6 days after the first, without waiting for marrow recovery to occur. While there was an increased mortality rate associated with intensive versus standard timing in children with AML, the long-term EFS was significantly better in the intensive therapy group.⁷¹

Following induction therapy, patients should be evaluated for a response. A proportion of children will not enter into a CR, and will require additional chemotherapy called "reinduction." Typically a bone marrow biopsy is performed 7 to 10 days after the completion of chemotherapy (or day 14 from the start of chemotherapy), to document disease eradication. If there is persistent disease, a second course of therapy is administered. The second course may be identical to the initial induction regimen, or include high-dose cytarabine and asparaginase, or mitoxantrone and cytarabine. If the marrow is aplastic, a repeat marrow biopsy should be performed upon hematologic recovery to document a CR.

POST-REMISSION THERAPY

Although most adults with AML achieve a CR, the duration of remission is short (4 to 8 months) if no further treatment is given. Relapse is presumably a consequence of the presence of residual, but clinically undetectable, leukemic cells after remission induction therapy. The goal of intensive post-remission therapy is to eradicate these residual leukemic cells and to prevent the emergence of drug-resistant disease. The need for post-remission therapy is based on postmortem analysis and cell kinetic data suggesting that nearly 10^9 residual leukemic cells remain after effective remission induction therapy.¹² Strategies evaluated as post-remission therapy include (1) low-dose, prolonged maintenance therapy; (2) short-course intensive chemotherapy-alone regimens; and (3) high-dose chemotherapy with or without radiation therapy followed by allo- or autoHSCT.

CHEMOTHERAPY

11 In the treatment of AML, post-remission therapy is often referred to as consolidation or maintenance therapy. Results

of randomized trials in adults clearly show that post-remission therapy following remission induction therapy prolongs survival versus no therapy, although the exact duration of maintenance is controversial.^{72,73} Trials have shown that a shorter duration of maintenance therapy is as effective as a longer duration of maintenance therapy. Alternatively, one to four courses of intensive chemotherapy can be administered over 6 months. An ECOG trial demonstrated that one course of more intensive chemotherapy, termed "consolidation therapy," increased EFS as compared to lower-dose maintenance therapy administered for 2 years, although alternative strategies might again be needed for the elderly due to toxicity.⁷⁴

The intensity of post-remission therapy has been shown to be important. In a large CALGB trial, all patients received standard 7 + 3 induction, and once a CR was achieved, were randomized to receive one of three cytarabine-based consolidation regimens: 100 mg/m² per day or 400 mg/m² per day as a continuous 24-hour infusion, or 3,000 mg/m² every 12 hours on days 1, 3, and 5.⁵³ For adults younger than 60 years, the probability of remaining in CR after 4 years was significantly higher in patients who received high-dose cytarabine (25% vs. 29% vs. 44%, respectively).⁵³ Elderly patients had lower response rates in all arms and did not benefit from the administration of higher doses of cytarabine, probably because they were unable to tolerate the high-dose regimen. Dose-limiting neurotoxicity in the high-dose arm was greater in elderly patients.⁵³ Table 131-11 lists other approaches to intensive chemotherapy consolidation.

It is not clear whether the same agents (cytarabine and an anthracycline) given for remission induction should be used for post-remission therapy in higher doses, or whether different agents altogether should be given. If leukemic relapse is caused by a resistant cell line, then the use of different agents that are non-cross-resistant with drugs used in induction would appear to be beneficial.

High-dose cytarabine appears to be a key part of post-remission therapy, particularly if not used in induction therapy. However, many questions remain, such as the optimal dose (g/m²), number of doses per cycle, and number of cycles of high-dose cytarabine. The only generally accepted practice is that induction alone is insufficient and that some form of post-remission therapy prolongs survival. The NCCN guidelines recommend four cycles of high-dose cytarabine for adults younger than 60 years of age and with good cytogenetics.⁷⁰ If a patient is older than age 60 years, standard-dose cytarabine with or without anthracycline, a dose-reduced high-dose cytarabine regimen (1 to 1.5 g/m² per day for four to six doses), or enrollment in a clinical trial is recommended. Patients with poor-risk cytogenetics, underlying MDS, or secondary AML should be referred for either a matched sibling or MUD alloHSCT.⁷⁰

CLINICAL CONTROVERSY

What is the best dose of cytarabine to use for consolidation, how many doses and how many cycles should be administered? The optimal dose of high-dose cytarabine to administer, the number of doses per cycle, and the number of cycles to give remains unknown. What is known is that post-remission therapy is necessary to prevent relapse and that regimens containing high-dose cytarabine appear to be a key part of post-remission therapy.

Children with a matched sibling donor should proceed to alloHSCT once in remission. Children with no suitable stem cell donor should receive consolidation chemotherapy, with which survival results are similar to those seen with autoHSCT.⁷⁵

■ ALLOGENEIC HEMATOPOIETIC STEM CELL TRANSPLANTATION

AlloHSCT represents the most aggressive approach to post-remission therapy in the management of AML. Much controversy surrounds this treatment approach, specifically the appropriateness, timing, treatment design, and donor selection.

The antileukemic activity of alloHSCT is based on the administration of pretransplant high-dose chemotherapy (or chemoradiotherapy) and the development of a posttransplant immune-based antileukemic response. The immune-based response, referred to as a graft-versus-leukemia (GVL) effect, often accompanies the graft-versus-host disease (GVHD) reaction. The immune-based benefit of alloHSCT has been demonstrated through the observation of consistently lower relapse rates with alloHSCT as compared to autologous or syngeneic HSCT. This potential benefit of alloHSCT can be offset by the risk of posttransplant complications such as GVHD, veno-occlusive disease, graft failure, and infections.

AlloHSCT was first evaluated as a treatment modality for AML in refractory patients, but because of initial success in small numbers of patients, it has also been evaluated as intensive post-remission therapy in AML patients in first or subsequent remission. Nonrandomized trials of human leukocyte antigen (HLA)-identical sibling alloHSCT performed in AML patients in first CR report 5-year survival rates of 45% to 60% with relapse rates of 10% to 20%.^{76,77} Transplant-related mortality following sibling alloHSCT is 20% to 30% in most series. As clinicians have gained more experience in this intensive form of therapy and been provided with more effective immunosuppressive and antibiotic regimens, transplant-related mortality rates have decreased and survival rates have increased. Bone marrow registry data indicate that long-term survival rates in AML patients who receive a matched sibling alloHSCT while in first remission have increased from about 45% in the early 1980s to about 60% in the mid-1990s.^{1,4}

Table 131–12 presents the results of randomized comparisons of alloHSCT to autoHSCT or intensive consolidation chemotherapy alone.^{78–81} AlloHSCT from an HLA-matched sibling donor in AML patients in first CR results in long-term DFS in 43% to 55% of patients. Although the results vary, some of the studies show longer DFS and lower relapse rates with alloHSCT in AML in first CR as compared to chemotherapy-alone post-remission regimens.⁸²

AlloHSCT is still generally restricted to patients younger than 60 years of age, which limits the number of patients eligible for treatment of a disease that primarily affects older adults. One new

approach, termed nonmyeloablative stem cell transplant (NST), uses less toxic nonmyeloablative preparative regimens and is now being evaluated in AML patients, particularly older patients or those with comorbid illnesses that would limit their eligibility for conventional alloHSCT. NST is designed to provide enough immunosuppression in the preparative regimen to allow for engraftment of donor cells, and depends heavily on the development of a GVL effect as a means to treat and prevent relapse of AML. Initial results of NST in AML patients indicate that the procedure is well tolerated in a wide age range of patients, and that it is associated with low rates of regimen-related toxicity.^{83,84} Evaluations in larger numbers of patients are necessary to determine the comparative impact of NST on GVHD, DFS, and OS. Because only 30% of patients will have an HLA-matched sibling donor, alloHSCT is further restricted as a treatment alternative for AML patients. MUD transplantation using a phenotypically HLA-matched donor identified from bone marrow registries is considered as a treatment alternative for young adults and pediatric AML patients. This approach is associated with long-term DFS rates of 30% to 40%, which are slightly lower than in AML patients undergoing HLA-matched sibling alloHSCT because of a higher risk of treatment-related mortality with the procedure.^{85,86}

■ AUTOLOGOUS HEMATOPOIETIC STEM CELL TRANSPLANTATION

Compared to alloHSCT, autoHSCT has the advantage of a lower risk of posttransplant complications because of lack of immunosuppression and GVHD, and more broad applicability because of a lack of donor limitations and fewer age restrictions. While the preparative regimen still provides antileukemic activity, autoHSCT is associated with higher incidences of relapse because of a lack of a GVL effect and potential tumor contamination with autologous stem cells. DFS following autoHSCT for AML in first CR ranges from 40% to 60%, with treatment-related mortality of 5% to 15% and relapse rates of 30% to 50%.^{74,78–81,87–89} Long-term response rates decrease proportionally as autoHSCT is employed in second or subsequent CR.

Controversies in autoHSCT include the optimal timing of therapy, the amount of consolidation therapy needed, the dose of stem cells needed, and the impact of posttransplant therapy.⁸⁹ Table 131–12 compares autoHSCT versus other post-remission therapies; they are discussed below.

TABLE 131–12. Comparative Trials of Allogeneic HSCT (AlloHSCT) or Autologous HSCT (AutoHSCT) or Chemotherapy (Chemo) Alone as Post-Remission Therapy for AML in First Complete Remission

| | Disease-Free Survival at 4 Years (%) | | | Overall Survival at 4 Years (%) | | |
|---|--------------------------------------|------------------|--------|---------------------------------|----------|------------------|
| | AlloHSCT | AutoHSCT | Chemo | AlloHSCT | AutoHSCT | Chemo |
| Zittoun et al ⁷⁸ (EORTC-GIMEMA) | 55% ^a | 48% ^b | 30% | 59% | 56% | 46% |
| Harousseau et al ⁷⁹ (GOELAM) | 44% | 44% | 40% | 53% | 50% | 54% |

^c*p* = 0.02.

■ COMPARISONS OF POST-REMISSION THERAPY OPTIONS

Several randomized trials in AML patients in first CR have compared outcomes following alloHSCT, autoHSCT, and/or intensive consolidation chemotherapy (see Table 131–12).^{78–81} In most trials, eligible patients based on age and donor availability received an alloHSCT and the remaining patients were randomized between autoHSCT and chemotherapy alone. The EORTC-GIMEMA trial observed a DFS advantage and reduced relapse risk for alloHSCT or autoHSCT as compared to chemotherapy alone, but no differences in OS.⁷⁸ Survival rates were comparable because of a higher relapse rate in the chemotherapy group as compared to a higher treatment-related mortality rate in the alloHSCT group. This is the only trial that has demonstrated superior 4-year DFS with transplantation versus chemotherapy. Interestingly, the response rates in the conventional chemotherapy arm in this trial were lower than those reported in other studies, and this may account for the benefit. Several other trials have showed no difference in DFS or OS between autoHSCT, alloHSCT, and conventional chemotherapy.^{79–81} In aggregate, these trials show that either autoHSCT or alloHSCT can reduce the risk of relapse, although this has not translated into a survival benefit. One of the trial design issues that may explain this lack of survival benefit was the low percentage of patients who progressed to transplantation when randomized, thus diluting the effect of transplantation. The effect of stem cell source on DFS and OS is controversial. Several comparative trials of bone marrow versus peripheral blood have been completed, with only two demonstrating a survival advantage for recipients of peripheral blood.^{90,91}

5 Most transplant centers base their decision to transplant on cytogenetic risk category.⁴ Patients with poor-risk cytogenetics do poorly with conventional chemotherapy or autoHSCT (DFS <15%), and therefore alloHSCT is the treatment of choice in this population. Patients with good-risk cytogenetics should not proceed to transplant in first CR, as their outcomes with conventional chemotherapy remain very good, and alloHSCT should be reserved in case of relapse. The optimal treatment of choice in patients with intermediate-risk cytogenetics is not clear and is based on clinician preference. Many centers consider a relapse probability of 40% to 50% sufficiently high enough to warrant the risk of transplant-related mortality.

According to the NCCN guidelines, the decision to proceed to HSCT depends on cytogenetics.⁷⁰ If the patient has a good-risk cytogenetic profile and is younger than age 60 years, then high-dose cytarabine for four cycles or one cycle of high-dose cytarabine-based therapy followed by autoHSCT is preferred over alloHSCT. If the patient has a poor-risk cytogenetic profile and is younger than age 60 years, then alloHSCT transplant should be considered early after remission induction. Patients with intermediate-risk cytogenetics should be entered into a clinical trial, but if a clinical trial is not available, either a matched sibling alloHSCT or an autoHSCT should be considered. AutoHSCT can be used if a hematologic and cytogenetic remission is achieved. For patients older than age 60 years, the NCCN guidelines do not favor HSCT and recommend either enrollment into a clinical trial, or consideration of conventional high-dose cytarabine. In recent years clinicians increasingly consider autoHSCT as a treatment option, and for selected patients older than 60 years of age, NST is being used more frequently.^{83,84} For the AML patient who relapses early after induction therapy, if a sibling or matched related donor is available, then alloHSCT is the primary reinduction therapy because conventional chemotherapy offers little help. If the relapse occurs late, then HSCT can be used as post-remission consolidation after conventional induction therapy.⁷⁰

■ ACUTE MYELOID LEUKEMIA IN INFANTS

Infant AML is usually myelomonoblastic or monoblastic in morphology. Poor prognostic factors include t(1;22), high WBC count, and CNS disease. Neonates with Down's syndrome may develop transient clonal megakaryoblastic myeloproliferative syndrome that usually spontaneously resolves without treatment within a few months.⁵³ Infants with AML receive the same therapy as children of other ages, with the dosing per kilogram and not per squared meter.

■ ACUTE MYELOID LEUKEMIA IN THE ELDERLY

As the median age at diagnosis is in the range of 65 to 70 years, AML is a disease of the elderly. Unfortunately, long-term DFS is lower in older patients, ranging from 5% to 15%, as compared to 40% in younger patients.^{92,93} In patients older than age 55 years, a review of ECOG studies reported the median duration of survival to be 6 to 9 months, as compared to 11 months in patients younger than age 55 years. The actual response and survival rates may be even lower, as many elderly patients with AML are not included in clinical trials because of a lack of eligibility and poor performance status.⁵¹

Elderly patients with AML have a poor outcome as a result of the frequent presence of unfavorable prognostic factors, including poor-risk cytogenetic features, preceding myelodysplasia, and a higher incidence of inherent drug resistance.⁴ Greater than 70% of de novo AML patients older than age 55 years will express the multidrug resistance (MDR1) phenotype associated with chemotherapy resistance, including resistance to the leukemia-active anthracyclines and etoposide.⁹⁴ Older patients with AML may also have poor outcome because of the inability to withstand aggressive therapy as a result of poor organ function, poor performance status, or existing comorbidities. Although older patients with AML may be able to tolerate aggressive induction therapy, intensive post-remission therapy is often too toxic, thus increasing the likelihood of patient relapse.⁹⁵ Older AML patients have also been reported to have an impaired capacity to recover from intensive therapy as a consequence of leukemic involvement of earlier hematopoietic cells.⁵¹

The potential therapeutic strategies in elderly AML patients include (1) no chemotherapy (i.e., best supportive care or palliative care therapy), (2) attenuated chemotherapy, or (3) standard-dose chemotherapy.⁴ The palliative approach is most appropriate in patients with slowly progressive leukemia ("smoldering leukemia"). The difficulty lies in the ability to reliably identify these patients at diagnosis. While initially accepted in older patients, palliative care approaches in older patients with AML with moderate to good performance status and organ function are now considered inappropriate. An ECOG/CALGB study prospectively randomized patients to either a conventional chemotherapy arm or to an observation arm in which patients could receive modest doses of chemotherapy for symptom palliation. Survival was twice as long in the chemotherapy group. The quality of life of each group was similar, with each spending approximately 50% of the study time in the hospital.⁹⁶ Chemotherapy may prolong survival without significantly decreasing the quality of life for elderly patients. Thus chemotherapy is a viable treatment option for elderly patients, although the best chemotherapy regimen and overall treatment approach is controversial. One approach is to attenuate the dose of chemotherapy, preferably using oral agents where possible, or lower doses of intravenous agents. Agents used in this strategy

include oral etoposide, low-dose subcutaneous cytarabine, and other oral agents such as thioguanine and idarubicin (oral idarubicin is not currently commercially available in the U.S.). Complete remission rates of 32% to 35% have been reported with low-dose subcutaneous cytarabine.⁹⁷

Another approach is to use standard induction regimens that would be used in younger adults. With standard 7 + 3 induction therapy, the complete response rate in older AML patients ranges from 39% to 48%, compared with 65% to 73% in adults <60 years. Half of the remaining patients are likely to die during induction therapy from infection or other complications, and the other half often has refractory disease.⁹⁵ More elderly patients than younger patients will require two courses of induction therapy to achieve a remission. In an effort to improve response rates, some trials have attempted to determine the best anthracycline and the appropriate dose. Unlike younger patients, comparative data in elderly patients do not suggest any efficacy or toxicity advantages of idarubicin or mitoxantrone over daunorubicin for AML induction therapy.^{64,98} Results of early uncontrolled trials reported high morbidity and mortality rates during induction in elderly AML patients who received aggressive doses of daunorubicin (>45 mg/m² per day for 3 days). More recent trials, however, suggest that older AML patients can safely withstand higher doses of daunorubicin (60 to 90 mg/m² per day), which may be a result of enhancements in supportive care.^{96,99} Unlike younger patients, older patients with AML do not experience added benefit when etoposide is incorporated into an anthracycline and cytarabine-containing regimen, nor do they appear to benefit when etoposide is substituted for cytarabine in induction.^{58,100}

Post-remission strategies in elderly AML patients are less well defined.⁴ Even though high-dose cytarabine has become a standard component of post-remission therapy in younger patients, it has not been shown to be beneficial in the elderly. In the elderly, attenuated-dose cytarabine during induction decreases remission and survival rates while decreasing treatment-related mortality rates, which raises the concern that attenuated-dose cytarabine during post-remission therapy may cause similar outcome. In the CALGB trial comparing post-remission cytarabine doses, there was less benefit of higher doses of cytarabine (3,000 mg/m²) in patients older than age 60 years as compared to younger patients.⁵³ Serious toxicities, particularly neurotoxicity, were more frequent in the elderly, and these toxicities limited the ability to deliver the planned four courses of therapy. A recent ECOG review of lower doses of cytarabine (1,500 mg/m² for 6 to 12 doses) in older AML patients were well tolerated, with a treatment-related mortality rate of only 2% and median survival at 2 years of 30%.⁹⁹ Based on these data, some clinicians question the need for doses of cytarabine as high as 3,000 mg/m² and suggest that attenuated high-dose regimens (such as 1,500 mg/m²) may be sufficient and beneficial. The appropriate number of cycles of post-remission consolidation therapy is unknown and currently under investigation in a randomized ECOG trial.

While maintenance therapy is considered inferior to intensive consolidation chemotherapy in younger patients, its role in older patients with AML is still undefined. Some studies suggest that maintenance therapy following consolidation prolongs DFS but not OS as compared to no maintenance therapy.^{92,101} Since older patients may not be able to tolerate more aggressive post-remission strategies such as HSCT, maintenance therapy may play an important role in improving outcomes.

More novel approaches to post-remission therapy targeted at immune modulation have been evaluated in elderly patients with AML. Early results with interleukin-2 (IL-2) as a means to enhance immune-mediated prevention of relapse have been promising.¹⁰² The CALGB

is currently conducting a randomized trial in the elderly comparing 90 days of post-remission low-dose, subcutaneous IL-2 versus observation. FLT-3 ligand is another immunomodulatory cytokine that enhances recovery and activity of hematopoietic and dendritic cells and is currently under investigation as post-remission therapy in elderly AML patients.

NST is another therapeutic option in elderly patients with AML and MDS. Two small studies suggest this is a feasible option, with actuarial OS and EFS rates of 44% to 69% and 37% to 56%, respectively.^{83,84} The advantage of this approach is less intensive chemotherapy with less toxicity, and the immune system providing the ongoing antileukemia effect via GVHD/GVL mechanisms (see Chap. 134).

■ TREATMENT OF RELAPSED OR REFRACTORY ACUTE MYELOID LEUKEMIA

The most common cause of treatment failure in AML patients receiving chemotherapy alone or undergoing HSCT is relapse. In addition, a substantial number of patients, especially elderly patients, experience refractory disease as defined by the inability to achieve a CR after two courses of induction therapy. In most cases, the preferred method of treatment for relapse or refractory disease is HSCT. Prolonged DFS is observed in 30% to 40% of patients receiving allo- or autoHSCT in first relapse or second CR.^{103,104} Unfortunately, only a small percentage of relapsed or refractory adult patients will be eligible for HSCT, particularly alloHSCT, because of age and donor restrictions. The role of NST is being evaluated as previously discussed.

The timing of HSCT to treat relapse is controversial. Some studies suggest that outcome of HLA-matched, related alloHSCT performed at the time of early first relapse is comparable to that observed when the procedure is performed in second CR.¹⁰³ The difficulty in this approach is identifying a patient in “early relapse,” as often the patient will present in a florid relapse. While performing the alloHSCT in first relapse eliminates the need for and toxicity of salvage chemotherapy, the feasibility of this approach can be limited by the logistics required to prepare and to activate a donor. A comparison conducted by the IBMTR demonstrated the superiority of alloHSCT over chemotherapy for treatment of relapse occurring 1 to 2 years following induction.¹⁰⁵ Prolonged leukemia-free survival occurred in at least twofold more alloHSCT recipients as compared to patients receiving chemotherapy. In the treatment of refractory disease, alloHSCT is superior to autoHSCT in adults younger than age 55 years.^{106,107}

Patients who relapse following alloHSCT have a poor outcome, with a median survival of about 3 to 4 months.¹ In this scenario, treatment options depend on performance status, clinical condition, and the time since alloHSCT. Patients relapsing less than 100 days following alloHSCT are unlikely to respond to current strategies, and salvage attempts are often associated with a high treatment-related mortality. For patients relapsing more than 1 year after alloHSCT, second alloHSCT may be an alternative in selected young adults, but the likelihood of prolonged survival is generally less than 10% with a second transplant.¹ Other strategies being investigated for AML relapsing after alloHSCT include immune manipulation to stimulate a GVL effect through donor lymphocyte infusions, and premature discontinuation of cyclosporine and other immunosuppressants.

AutoHSCT is an option at the time of first relapse if cells have been previously collected and stored during first remission. If such

cells were not collected, then it is necessary to achieve a second CR in order to proceed to autoHSCT. Prolonged DFS of 30% and 20% are reported when autoHSCT is performed in second and third CR, respectively.¹⁰⁸ The advantages of autoHSCT are the lack of donor limitations and fewer age-based restrictions; the disadvantage is the need to achieve a CR, which requires exposure to more cytotoxic chemotherapy. If patients relapse following autoHSCT, alloHSCT from a related or unrelated donor is preferred in selected younger patients. NST or other investigational therapies can be considered for older patients who relapse after autoHSCT.

If patients with relapsed or refractory disease are not candidates for HSCT, until recently the primary mode of treatment was salvage chemotherapy. The ability to achieve a second CR with salvage chemotherapy is related to the duration of the first remission. About 50% to 60% of patients who relapse greater than 2 years after induction therapy will achieve a second CR, often with the same induction regimen.¹⁰⁹ If the patient relapses 1 to 2 years after induction therapy, the second CR rate decreases to 40%, and only 10% to 20% of patients who relapse within 6 to 12 months following induction are able to achieve a second CR with alternate salvage chemotherapy regimens. Long-term survival at 3 years ranges from zero in patients who relapse early to 20% to 25% in those who experience a prolonged duration of initial remission. Based on these data, a risk-adapted approach should be taken when considering treatment options. The most commonly used salvage regimens are high-dose cytarabine-based regimens with doses of 2,000 to 3,000 mg/m² every 12 hours for 8 to 12 doses. High-dose cytarabine schedules that use once-daily doses or alternate-day doses have also been used in an attempt to minimize toxicity.^{1,109} Cytarabine has been administered alone or in combination with various agents, including etoposide, fludarabine, topotecan, and an anthracycline, as treatment of relapsed or refractory AML. Response rates to such salvage regimens range from 30% to 50%, but are often short-lived. Patients who received high-dose cytarabine during induction may be less likely to benefit from such a regimen for treatment of relapse, and thus require alternate salvage strategies. Patients with a remission duration of greater than a year appear to benefit most from high-dose cytarabine regimens.¹⁰⁹

About 70% of relapsed or refractory AML express the MDR1 phenotype, which confers a high degree of chemotherapy resistance because of its encoding and overexpression of P-glycoprotein. P-glycoprotein is a membrane protein capable of removing certain antineoplastics from the intracellular to extracellular space. Antagonists of P-glycoprotein, such as cyclosporine or the cyclosporine analog valspodar (formerly PSC 833), have been investigated as a strategy to overcome resistance in these patients.^{110–113} In addition to inhibiting P-glycoprotein, cyclosporine may also affect the disposition of agents such as anthracyclines, and thus increase the exposure to cytotoxic agents. Valspodar is 10-fold more effective in inhibiting P-glycoprotein than cyclosporine and lacks cyclosporine's renal toxicity. Unfortunately, randomized trials in previously untreated or relapsed/refractory patients have shown no advantages and more regimen-related deaths in patients older than age 60 years receiving the MDR modulator.^{112,113} Other MDR inhibitors with limited interference with hepatic metabolism are currently under investigation.

Monoclonal antibodies have been the subject of recent investigations in the treatment of relapsed or refractory AML, and have the ability to deliver targeted therapy to the malignant cell. Gemtuzumab ozogamicin is an anti-CD33 antibody complexed to the antitumor antibiotic calicheamicin. Since CD33 is expressed in 90% of leukemic blasts, this anti-CD33-directed product provides targeted cell kill to

leukemic cells. Patients with AML in first untreated relapse treated with gemtuzumab (9 mg/m² for two doses separated by 14 days) attained a CR in 16% of patients, with a further 13% of patients having normalization of blood counts with the exception of persistent platelet counts <100,000/mm³.^{114,115} Toxicity can be problematic with gemtuzumab. Common adverse effects include infusion-related reactions (fever and chills), prolonged neutropenia and thrombocytopenia, and transient elevations in hepatic enzymes. A more serious adverse event associated with gemtuzumab therapy is veno-occlusive disease. It was initially thought that this only occurred in patients receiving gemtuzumab following HSCT, but has now been described in several patients who were never exposed to HSCT. Close monitoring of a patient's weight should occur, as well as monitoring of liver function tests, particularly bilirubin. Because gemtuzumab lacks specific dose-limiting organ toxicities, it is also being investigated in combination with other chemotherapy agents.¹¹⁶ Gemtuzumab therapy in pediatric patients has been limited by the incidence of veno-occlusive disease of the liver when given prior to HSCT. Other antibodies under investigation in salvage regimens and high-dose preparative regimens for AML include radiolabeled anti-CD45 agents and HuM195, a humanized mouse monoclonal antibody targeted against the CD33 antigen.

Numerous classes of new agents are being investigated as alternate treatment approaches for relapsed or refractory AML, including the ubiquitin-proteasome pathway inhibitors (bortezomib), new novel nucleoside analogues (troxacitabine),¹¹⁷ hypomethylating agents (decitabine and 5-azacytidine),¹¹⁸ histone deacetylase inhibitors (phenylbutyrate),¹¹⁹ and angiogenesis modulators (bevacizumab and thalidomide).¹²⁰ Arsenic trioxide, which is effective in the treatment of APL, is also under investigation for treatment of AML via its modulation of apoptotic and chromatin remodeling pathways.¹²¹ Imatinib mesylate, the tyrosine kinase inhibitor exhibiting efficacy in the treatment of CML, also inhibits AML cell lines and is currently undergoing clinical trials in AML.¹²²

In children with AML, the duration of first remission predicts remission rates following relapse. The BFM group reported that patients who relapse within 1.5 years of initial diagnosis have a 5-year survival of 10%, versus 40% for those who relapse later than 1.5 years after initial diagnosis.¹²³ In children with relapsed or refractory AML, a regimen of mitoxantrone 12 mg/m² per day for 4 days starting on the third day of treatment and cytarabine 1,000 mg/m² per dose every 12 hours for eight doses can achieve a second CR rate of 76% with only a 3% mortality rate.¹²⁴ However, the 2-year OS rate was only 24%. Patients were eligible to receive intensification with high-dose cytarabine and etoposide at the investigator's discretion, and this arm was closed due to a toxic death rate of 10%. Currently, most pediatric patients in second CR receive alloHSCT if a suitable donor is available.

■ LATE EFFECTS OF THERAPY FOR ACUTE MYELOID LEUKEMIA

Due to the intense therapy received by children with AML, they are at risk for a variety of long-term sequelae. A recent study reported that more than 50% of survivors have growth abnormalities.¹²⁵ Other findings include neurocognitive deficits, transfusion-associated hepatitis, endocrine disorders, cataracts, and cardiomyopathy (median cumulative anthracycline dose 335 mg/m²). The 20-year cumulative risk for a second malignancy is estimated to be 1.8%.

► TREATMENT: Acute Promyelocytic Leukemia

APL is a subclass of AML (FAB M3) that accounts for 10% of all cases, and is the most curable leukemia of all AML subtypes. Most patients are diagnosed between the age of 15 and 60 years. Five-year DFS rates of 70% to 80% are reported with APL.¹⁸ APL has historically been diagnosed by the distinctive cytoplasmic granules seen on light microscopy. There are two variants: hypergranular (most common), and microgranular. APL is clinically unique from the other subclasses because of the common occurrence of severe coagulopathy (characterized by disseminated intravascular coagulation) at diagnosis and during induction therapy. In APL, differentiation and maturation arrest are caused by alterations in the retinoic acid receptor because of the translocation of chromosomes 15 and 17. The discovery of t(15;17) now provides a cytogenetic marker of the disease and is a prognostic marker in favor of response to differentiation therapy with tretinoin (commonly referred to as all-trans retinoic acid).¹²⁶ This translocation leads to a fusion protein of the promyelocytic leukemia (PML) gene on chromosome 15 and the retinoic acid receptor- α (RAR α) on chromosome 17.¹²⁶

Historically, treatment of APL involved combination chemotherapy regimens used in the treatment of other subclasses of AML. Such standard regimens produced CR rates of 50% to 60%, but were associated with a high treatment-related mortality rate caused by hemorrhagic complications. The introduction of molecularly targeted therapy with tretinoin allows for high CR rates with a significant reduction in life-threatening bleeding complications.

■ INDUCTION THERAPY

Tretinoin, an oral vitamin A analog, is usually given orally in a dose of 45 mg/m² per day, as a single dose or divided into two doses, given after a meal. Tretinoin-based regimens achieve CR rates as high as 95% in APL patients within 1 to 3 months. Tretinoin does not cross the blood-brain barrier; therefore leukemic meningitis should be treated with conventional intrathecal chemotherapy.

While being devoid of myelosuppressive effects, tretinoin therapy is associated with headache, skin and mucous membrane reactions, bone pain, nausea, and the retinoic acid syndrome. When tretinoin is started, rapid onset of differentiation of promyelocytes occurs, which can lead to leukocytosis and/or retinoic acid syndrome. The retinoic acid syndrome (fever, respiratory distress, interstitial pulmonary infiltrates, pleural effusions, and weight gain) is now referred to as the APL differentiation syndrome or APL hyperleukocytosis syndrome, because it has been associated with other treatment modalities in the management of APL. Among tretinoin-treated patients, this syndrome has been fatal in 5% to 29% of cases. A combination of chemotherapy with tretinoin induction decreases the incidence of retinoic acid syndrome, and rapid initiation of dexamethasone 10 mg (0.2 mg/kg per dose in children) twice daily for 3 days upon development of symptoms decreases associated mortality.

A number of clinical trials have evaluated optimum treatment regimens for APL since the discovery of tretinoin.^{127–135} These trials have demonstrated that tretinoin induction therapy, followed by consolidation chemotherapy, produced similar CR rates but decreased relapse and increased EFS and OS as compared to chemotherapy alone for induction and consolidation.^{127,128} However, a significant proportion of patients receiving tretinoin in that study relapsed by 4 years,

and 25% of patients experienced the retinoic acid syndrome.¹²⁷ In an effort to extend the duration of remission and decrease tretinoin-associated toxicity, other trials have evaluated the outcome of sequential and concurrent administration of tretinoin with chemotherapy during induction therapy. The UK MRC trial compared concurrent administration of tretinoin with chemotherapy to sequential tretinoin during induction (given 5 days before anthracycline-based induction chemotherapy) with the hope of reducing coagulopathy-related complications.¹²⁹ Concurrent administration was superior in terms of CR rates, early death, and EFS and OS at 3 years. The French study demonstrated similar CR rates with concurrent or sequential tretinoin and standard induction chemotherapy, but noted a better DFS and EFS at 2 years in the concurrent administration group (suggesting a synergistic or additive effect for the combination).¹³⁰ Based on these data, the current recommendations for induction therapy for newly diagnosed APL patients include tretinoin 45 mg/m² per day until a CR is achieved, in addition to an anthracycline (either daunorubicin 50 to 60 mg/m² per dose for 3 days, or idarubicin 12 mg/m² per dose every other day for four doses).¹⁸ Similar CR rates are observed with daunorubicin or idarubicin. APL cells appear to be more sensitive to anthracyclines, perhaps due to decreased P-glycoprotein expression.

It is important to note that chemotherapy regimens used in combination with tretinoin differ from standard AML regimens, primarily due to the lack of a cytarabine backbone. Several studies have evaluated the role of cytarabine in induction regimens for APL. The addition of cytarabine has not improved the CR rate.¹³¹ At some centers, children routinely receive both cytarabine and an anthracycline (usually the previously discussed 7 + 3 regimen) in combination with tretinoin.

■ POST-REMISSION THERAPY

Consolidation chemotherapy must also be administered to patients with APL due to the high relapse rate. Consolidation therapy usually consists of an anthracycline-based regimen. Recent studies suggest that there is a limited role for high-dose cytarabine in consolidation phases.¹³² Current recommendations reserve high-dose cytarabine regimens for patients who remain polymerase chain reaction-positive after consolidation with an anthracycline-containing regimen.¹⁸

Unlike other subtypes of AML, the role of maintenance therapy is well defined in APL. Before the advent of tretinoin, nonrandomized trials supported a benefit of continuous low-dose methotrexate and mercaptopurine in prevention of relapse of APL.¹³³ Larger prospective trials have demonstrated decreased relapse rates in patients who received maintenance therapy (either tretinoin or combination chemotherapy),^{18,127,132} and some trials have demonstrated increased EFS and OS.¹³⁰ In a study that compared maintenance with tretinoin, tretinoin plus chemotherapy, and chemotherapy or observation, observation was associated with the highest relapse rate and tretinoin plus chemotherapy with the lowest relapse rate.¹³⁰ Current recommendations for maintenance therapy in adult APL patients includes tretinoin 45 mg/m² per day for 15 days every 3 months, in addition to mercaptopurine 100 mg/m² orally daily and methotrexate 10 mg/m² per week, for 2 years in all patients.¹⁸

RELAPSED ACUTE PROMYELOCYTIC LEUKEMIA

Relapsed APL can also be effectively treated with tretinoin therapy in a large number of cases. Patients relapsing after tretinoin-based therapy are able to achieve second CR with tretinoin-based reinduction.¹²⁷ For patients resistant to induction or reinduction with tretinoin-based regimens, alternative strategies include arsenic trioxide, and allo- or autoHSCT. Outcomes with autoHSCT depend on the disease status of the patient at the time of transplant. AutoHSCT in CR2 (versus first CR) is associated with a lower OS, leukemia-free survival, and increased treatment-related mortality. Based on the sensitive nature of patients to chemotherapy, autoHSCT in first CR is currently not warranted, but offers an excellent option for polymerase chain reaction PML-RAR α -negative patients in CR2. AlloHSCT should not be offered to patients in first CR, as the mortality associated with alloHSCT outweighs the risks of conventional chemotherapy. In CR2, it is an appropriate choice as consolidation after reinduction with either arsenic trioxide or tretinoin.¹³⁶

Arsenic trioxide has induced clinical remissions in relapsed APL through its induction of apoptosis and differentiation.^{137–139} The recommended dose is 0.15 mg/kg per day IV until bone marrow remission, not to exceed 60 doses, followed by consolidation beginning 3 to 6 weeks after completion of induction at the same dose for a total of 25 doses over a period up to 5 weeks. Arsenic trioxide therapy is associated with two specific toxicities. First, it has been shown to cause the APL hyperleukocytosis syndrome, similar to that seen with tretinoin. Management is similar: corticosteroids at first signs of pulmonary distress or a rapidly rising WBC count. The second toxicity is a prolongation of the QTc interval.¹⁴⁰ It is therefore important to obtain a baseline 12-lead electrocardiogram (ECG) prior to starting therapy with arsenic trioxide, and correct any electrolyte abnormalities including potassium, calcium, and magnesium. Other medications known to prolong the QTc interval should be discontinued, if possible, during arsenic trioxide therapy. The QTc interval should not exceed 500 msec at baseline, and if it increases to >500 msec during therapy, the patient should be re-evaluated. Do not reintroduce the arsenic trioxide until the QTc is <460 msec. Following induction of a second CR with arsenic trioxide in relapsed patients, post-remission therapy with combination arsenic trioxide and chemotherapy can result in molecular remissions and improved DFS, as compared to chemotherapy or arsenic trioxide alone following remission.¹³⁹ Additional investigations are underway to evaluate the role of arsenic trioxide in multidrug post-remission regimens. Other drugs that are undergoing evaluation for efficacy in APL include gemtuzumab ozogamicin and Am 80.

PATIENT MONITORING

Detection of residual PML-RAR α transcripts in the bone marrow at the end of consolidation therapy is strongly associated with subsequent hematologic relapse. Achievement of PML-RAR α -negative status is associated with a higher probability of cure. The use of this molecular technique allows the clinician to assess response to therapy and also detect relapse earlier, which might prevent the development of overt disease recurrence and is associated with improved outcome compared with delaying treatment until overt morphologic relapse.¹⁸ Most experts recommend that APL patients should be routinely evaluated for continuous remission status. Suggested follow-up includes polymerase chain reaction for PML-RAR α every 3 to 6 months for 2 years, and then every 6 months for 2 years.¹⁸

USE OF COLONY-STIMULATING FACTORS IN ACUTE MYELOID LEUKEMIA

In AML, colony-stimulating factors (CSFs) have been evaluated as a means to enhance chemotherapy cytotoxicity, shorten the duration of neutropenia, and reduce the incidence and severity of infection following induction and consolidation chemotherapy. Most studies showed limited benefit with the use of CSFs as “priming” agents administered during induction therapy in an effort to recruit leukemia cells into the cycle to enhance susceptibility to cell-cycle-specific chemotherapy agents, leading to increased cell kill. However, the positive results of a recently published study with filgrastim as a priming agent in AML patients has renewed interest in this principle.¹⁴¹ While the response rates between the groups were no different, those patients in CR after induction chemotherapy receiving filgrastim had higher DFS. There was no effect on OS. Subgroup analysis did show improved OS and DFS for patients with standard-risk AML receiving filgrastim. Use of CSFs during chemotherapy administration is discouraged outside the setting of a clinical trial.

CLINICAL CONTROVERSY

Colony-stimulating factors were investigated a decade ago as “priming agents” to recruit cells into the cycle, so theoretically there was a greater leukemia cell kill. Most studies were negative and showed no incremental increases in CR rates. Recent data suggesting that there is improved disease-free survival has renewed interest in this principle.

Both filgrastim and sargramostim are approved by the FDA to treat neutropenia after antileukemia therapy. The original package inserts listed myeloid malignancies as contraindications to the use of filgrastim or sargramostim. Myeloid blast cells have receptors for G-CSF and GM-CSF, and there was initial concern that the use of these factors would stimulate regrowth of the myeloid leukemia. Although subsequent studies have not shown this not to be true, many pediatric clinicians do not initiate filgrastim until an initial remission is achieved.

A number of randomized trials, primarily in elderly patients, consistently demonstrate reduction in neutropenia when filgrastim or sargramostim is administered following AML induction chemotherapy.^{64,142–150} While neutropenia can be reduced from 2 to 12 days depending on the trial, results vary in terms of improvements in infectious morbidity and mortality, resource utilization, and disease response rates (Table 131–13). Comparison of outcomes between trials is difficult because of differences in study design and patient populations. The use of CSFs in elderly AML patients has received particular attention because complications related to prolonged neutropenia, particularly infection, are one of the major causes of failure to achieve remission. In one large trial in elderly AML patients, administration of sargramostim following induction and consolidation therapy significantly reduced infection rates and increased OS.⁶⁴ But another randomized trial evaluating *Escherichia coli*-derived sargramostim during and after chemotherapy has shown a negative impact of CSF therapy by reporting an unexplained decreased CR rate in the sargramostim arm.¹⁴⁸

As a result of these trials, the ASCO *Guidelines for the Use of Hematopoietic Colony-Stimulating Factors* only recommends the use of CSFs after initial induction therapy if the benefits of decreased hospitalization outweigh the CSF cost.⁴⁸ Patients older than age 55 years appear to derive the greatest benefit, and use is appropriate in

TABLE 131–13. Colony-Stimulating Factors Following Induction Therapy for Acute Myeloid Leukemia

| Reference | Drug | Enhanced Neutrophil Recovery | Other Benefits Related to Colony-Stimulating Factor Therapy |
|--------------------------------|---------------------------------|------------------------------|---|
| Godwin et al ¹⁴² | Filgrastim | Yes | Fewer days of fever and antibiotics |
| Heil et al ¹⁴³ | Filgrastim | Yes | Decreased duration of hospitalization |
| Dombert et al ¹⁴⁴ | Filgrastim | Yes | Increased complete remission rate |
| Rowe et al ⁶⁴ | Filgrastim | Yes | Decreased incidence of infection and increased survival |
| Usuki et al ¹⁵⁰ | Filgrastim | Yes | None |
| Stone et al ¹⁴⁵ | Sargramostim (<i>E. coli</i>) | Yes | None |
| Witz et al ¹⁴⁶ | Sargramostim (<i>E. coli</i>) | Yes | Increased disease-free survival |
| Zittoun et al ¹⁴⁷ | Sargramostim (<i>E. coli</i>) | No | Decreased complete remission rate |
| Lowenberg et al ¹⁴⁸ | Sargramostim (<i>E. coli</i>) | Yes | None |

this population where more rapid marrow recovery might decrease the duration of hospitalization.⁴⁸ Routine use in younger patients remains controversial. More recently, the British Society of Hematology has published guidelines on the use of CSFs in hematologic malignancies, which are in agreement with the ASCO guidelines. Both groups note that following consolidation therapy, there is a more profound shortening of the duration of neutropenia and a reduction in the use of antibiotic therapy.⁴⁹ Further pharmacoeconomic data are required in this setting, but the body of evidence supports their use following consolidation therapy in adults. Other controversial issues surrounding CSF use in AML include which CSF to use, what dose, which day to start after chemotherapy, how long to continue, and should the marrow be examined for leukemia prior to starting a CSF. The use of growth factors can also interfere with the interpretation of the day 14 bone marrow examination.

SUPPORTIVE CARE

The most common and significant toxic effect of antileukemic agents is marrow suppression. With the exception of prednisone (and dexamethasone), tretinoin, asparaginase, and vincristine, antineoplastic agents used to treat acute leukemia cause myelosuppression. During AML remission induction and post-remission therapy, daily monitoring of the complete blood count and the absolute neutrophil count is necessary to determine when red cell and platelet transfusions are needed and when neutropenia is achieved. Less frequent monitoring than daily may be sufficient during ALL induction. Marrow hypoplasia from the myelosuppressive regimens usually reaches its lowest point (nadir) after 1 to 2 weeks of therapy and lasts for another 1 to 2 weeks. During this period of hypoplasia, infectious and bleeding complications are major causes of death in leukemic patients. As typical signs and symptoms of infection may be absent in the neutropenic host, frequent monitoring of vital signs (especially fever) and daily physical examination are important.¹⁵¹ Infection control strategies often include routine hand washing; dietary restrictions; reverse isolation and laminar-air flow rooms; fungal, *Pneumocystis*, and bacterial prophylaxis; and the empiric use of broad-spectrum antibiotics when fever occurs (see Chap. 120).¹⁵¹ The NCCN guidelines, in contrast to those of many institutions, do not recommend prophylactic antimicrobials or gut decontamination during induction or consolidation unless there is a documented recurrent problem at the institution.⁷⁰

In children, prophylactic antibiotics have not proven useful and have resulted in increased resistance. Pediatric ALL patients on standard induction regimens, which generally are minimally myelosuppressive, often have recovered blood counts earlier and do not require very aggressive measures. However, they do require close monitoring of vital signs and blood counts until their counts recover. Pediatric AML patients are usually admitted for at least 1 month during induction and again for consolidation. Regardless of therapy, children with AML have a 10% to 20% induction mortality rate due to infection and bleeding complications.⁵² The incidence of viridans streptococci has increased with the intensity of therapy and is most associated with high-dose cytarabine. These infections can lead to meningitis or delayed acute respiratory distress syndrome.

Pneumocystis carinii prophylaxis (usually trimethoprim-sulfamethoxazole) is begun in all adults and children with ALL by the end of induction and continues until 6 months after therapy is discontinued.

Acute leukemia patients, particularly those with an initial elevated WBC count, are at risk for tumor lysis syndrome. Preventive measures include allopurinol or rasburicase, and adequate hydration (with or without sodium bicarbonate) prior to and during chemotherapy to prevent the development of urate nephropathy from rapid destruction of white blood cells. In adults, 300 mg of allopurinol once daily, started 1 to 2 days prior to chemotherapy, is usually adequate. Children should receive 10 mg/kg per day of allopurinol in three divided doses. Rasburicase, a recombinant urate-oxidase enzyme produced by genetic modification of *Saccharomyces cerevisiae*, catalyzes the enzymatic oxidation of uric acid into the inactive soluble metabolite, allantoin. In children, rasburicase 0.15 to 0.2 mg/kg per day more rapidly reduces uric acid levels in patients with aggressive malignancies compared to allopurinol, and reduces the need for dialysis.^{152–154} There are limited data supporting the use of this product in adults, although existing data suggest similar efficacy to that of the pediatric population.¹⁵² Because of the expense, this product is usually limited to patients with ALL who have a high WBC count or bulky extramedullary disease, high-grade lymphoma, or patients with AML with a high presenting WBC. Most institutions also include an elevated uric acid as part of the criteria for use. Due to the rapid onset of action of rasburicase, many institutions also limit the use to a single dose and allow repeat doses when the criteria for use are met again. Rasburicase is contraindicated in patients with glucose-6-phosphate dehydrogenase deficiency.

Tumor lysis syndrome may lead not only to hyperuricemia, but also to hyperkalemia, hyperphosphatemia, and hypocalcemia.

Hematologic support consists primarily of platelet and packed red blood cell transfusions. Platelet transfusions are often given for peripheral counts below 5000 to 10,000/mm³ or clinical signs of bleeding. Transfusions of packed red cells may also be indicated for a hematocrit under 25%, profound fatigue, shortness of breath, tachycardia, or chest pain. APL can release procoagulants that can cause disseminated intravascular coagulation, necessitating close monitoring and

replacement of coagulation factors with cryoprecipitate. Because of the gastrointestinal toxic effects of chemotherapy, parenteral nutrition may be required. Patients are frequently receiving infusions of antibiotics, fluids, hyperalimentation, and blood products simultaneously. To provide the total support needed for these patients, a multiple-lumen central venous access device such as a Hickman catheter may be placed at the start of therapy.

EVALUATION OF THERAPEUTIC OUTCOMES

Appropriate development of a pharmaceutical care plan for the acute leukemia patient begins with establishing the diagnosis and prognosis for the patient. Long-term therapeutic goals for the patient may include long-term DFS, although palliative care is a possibility in some patients. The desired short-term outcome is the establishment of remission. The return of hematologic values to normal and a repeat bone marrow biopsy that demonstrates no evidence of disease serve as documentation that remission has been achieved. Monitoring guidelines for induction or consolidation are similar (Table 131–14). After the appropriate post-remission therapy has been completed, the patient may return monthly for 1 year and then every 3 months, to check hematologic values. If no evidence of disease exists after 5 years from the diagnosis and the patient has been in continuous CR, the patient is considered cured.

Intense monitoring of fevers, hematologic and chemistry laboratory values, microbiology reports, and the patient's physical condition are necessary to identify infection, risk of bleeds, and tumor lysis syndrome early. A coagulation-screening panel will identify patients with ongoing disseminated intravascular coagulation, a particular risk with APL.

During therapy, the pharmacist can be an important provider of patient education. Patients should receive information regarding acute and chronic toxicities of the chemotherapy being administered, as well as possible treatments for those toxicities. The pharmacist can also be an important resource for information regarding antibiotics, antiemetics, nutritional support, CSFs, and other supportive care issues.

Pharmacists need to be involved in checking drug doses and any dose modifications for organ dysfunction or prior toxicity. Pharmacists are often in the best position to recognize the potential for

TABLE 131–14. Acute Myeloid Leukemia Assessment and Monitoring

| Baseline Work-Up | Monitoring During Therapy | Post-Remission Monitoring |
|--|---|--|
| History and physical examination | Daily physical examination | Routine physical examination at clinic visit |
| CBC with differential, platelets | CBC with differential, platelets | CBC with differential, platelets |
| Serum chemistries (creatinine, bilirubin, AST, ALT to assess organ function) | Serum chemistries (including uric acid, K ⁺ , PO ₄ ³⁻ , Scr during tumor lysis syndrome risk period ^a) | Bone marrow biopsy and aspirate at set intervals to evaluate ongoing remission |
| Coagulation (PT, PTT, D-dimers, fibrinogen) | Coagulation (PT, PTT, D-dimers, fibrinogen [if APL]) | |
| Bone marrow biopsy and aspirate with cytogenetics | Bone marrow biopsy and aspirate 7–10 days after end of chemotherapy (with cytogenetics if initially abnormal) | |
| Immunophenotyping and cytochemistry | Temperature curve (initiate antibiotics when febrile) | |
| Human leukocyte antigen (HLA) typing | Lumbar puncture (with intrathecal chemotherapy) if initial lumbar puncture was positive for leukemia | |
| Cardiac work-up (MUGA or echocardiogram; ECG) | | |
| Intravascular access | | |
| Lumbar puncture (if symptomatic or AML M4 or M5) | | |
| Chest x-ray | | |
| Height and weight | | |

^aRisk for tumor lysis syndrome during induction therapy only.

ALT, alanine aminotransferase; APL, acute promyelocytic leukemia; AST, aspartate aminotransferase; CBC, complete blood cell count; ECG, electrocardiogram; MUGA, multiple gated acquisition (blood pool scan); PT, prothrombin time; PTT, partial thromboplastin time; Scr, serum creatinine.

medication errors and drug interaction and to help avoid them. Similarly, pharmacists are often able to identify the possibility that patient problems are secondary to drug treatments.

Numerous late sequelae from leukemia therapy have been recognized and should be included in the monitoring plan after therapy is completed. The long-term consequences of HSCT are discussed in Chap. 134.

ABBREVIATIONS

ALL: acute lymphocytic (or lymphoblastic) leukemia
 alloHSCT: allogeneic hematopoietic stem cell transplantation
 AML: acute myeloid leukemia
 APL: acute promyelocytic leukemia
 ASCO: American Society of Clinical Oncology
 autoHSCT: autologous hematopoietic stem cell transplantation
 CALGB: Cancer and Leukemia Group B
 CLL: chronic lymphocytic leukemia
 CML: chronic myeloid leukemia
 CR: complete remission
 CR2: second remission
 CSF: colony-stimulating factor
 DFS: disease-free survival
 ECG: electrocardiograph
 ECOG: Eastern Cooperative Oncology Group
 EFS: event-free survival
 FAB: French–American–British classification system
 FISH: fluorescent in situ hybridization
 G-CSF: granulocyte colony-stimulating factor
 GM-CSF: granulocyte macrophage-colony stimulating factor
 GVHD: graft-versus-host disease
 GVL: graft-versus-leukemia (effect)
 HLA: human leukocyte antigen
 HSCT: hematopoietic stem cell transplantation
 hyper-CVAD: high-dose methotrexate and cytarabine alternating with fractionated cyclophosphamide plus vincristine, doxorubicin, and dexamethasone
 IBMTR: International Bone Marrow Transplant Registry
 IL-2: interleukin-2
 MDS: myelodysplastic syndrome
 MLL: mixed lineage leukemia
 MUD: matched unrelated donor
 NCCN: National Comprehensive Cancer Network
 NST: nonmyeloablative stem cell transplant
 OS: overall survival
 Ph⁺: Philadelphia chromosome
 PML: promyelocytic leukemia (gene)
 RAR α : retinoic acid receptor- α
 TPMT: thiopurine methyltransferase
 WBC: white blood cell
 WHO: World Health Organization

CHRONIC LEUKEMIAS

Timothy R. McGuire and Steven Z. Pavletic

Learning Objectives and other resources can be found at www.pharmacotherapyonline.com.

KEY CONCEPTS

- 1 Chronic myelogenous leukemia (CML) patients who have a cytogenetic response have an improved survival.
- 2 Interferon alfa is generally not being used in newly diagnosed CML patients.
- 3 Imatinib has revolutionized the management of CML, and the majority of newly diagnosed patients will receive imatinib for at least a year, with patients who achieve a complete cytogenetic response continuing therapy indefinitely.
- 4 Allogeneic hematopoietic stem cell transplantation (HSCT) is the only modality currently available that is known to cure CML, and it is increasingly used in patients who have failed imatinib therapy.
- 5 The management of chronic lymphocytic leukemia (CLL) is highly variable and may include delaying therapy in asymptomatic older patients, well-tolerated single-agent chemotherapy in symptomatic older patients, and more aggressive therapy in younger patients.
- 6 Fludarabine is now being used as first-line therapy in younger patients, either alone or combined with cyclophosphamide or monoclonal antibodies (rituximab).
- 7 Alemtuzamab is generally used to produce a response in patients who have failed fludarabine therapy.
- 8 Nonmyeloablative HSCT may have an important role in CLL, with reports of high rates of complete remission, although it is not clear whether these patients are cured of their disease.

Chronic leukemia includes at least four disease types: chronic myelogenous leukemia (CML), chronic lymphocytic leukemia (CLL), prolymphocytic leukemia, and hairy cell leukemia. It differs from acute leukemia in that its clinical course is indolent. Most patients with chronic leukemia survive for several years after their initial diagnosis, even without treatment. Conversely, most patients with acute leukemia die of their disease within weeks to months after diagnosis if not treated. Because CML and CLL occur more frequently and represent approximately 40% of all cases of newly diagnosed leukemias occurring in the United States during 2005, this chapter focuses on these two cancers.¹

CHRONIC MYELOGENOUS LEUKEMIA

CML is one of a group of hematologic cancers known as myeloproliferative disorders and results from the malignant transformation of a pluripotent stem cell. This malignant transformation leads to the clonal proliferation and accumulation of both progenitor and mature myeloid cells.^{2,3} The clinical course of CML has three phases: it begins with an indolent chronic phase in which signs and symptoms can be controlled with well-tolerated low-intensity chemotherapy; next is a transition phase known as the accelerated phase, in which low-intensity chemotherapy no longer controls the white blood cell (WBC) count; and, finally, there is a terminal phase, also known as a blast crisis, which is similar to acute leukemia and leads to rapid clinical deterioration and death of the patient.

EPIDEMIOLOGY AND ETIOLOGY

It is estimated that approximately 4600 new cases of CML will be diagnosed in the United States in 2005, representing nearly 15% of all leukemias.¹ CML is predominantly a neoplasm of middle-aged adults, with a median age at diagnosis of approximately 50 years of age.³ Although ionizing radiation and heavy occupational exposure to benzene are known to be associated with CML, it is rare for a newly diagnosed patient to give a history of exposure to a known risk factor. There is a 20- to 25-fold increase in the incidence of all leukemias in atomic bomb survivors. The risk of leukemia is highest in those who were exposed at a young age, with more CML cases than acute lymphoblastic leukemia cases.⁴ CML can also occur after radiotherapy for ankylosing spondylitis, and it may be one of the secondary malignancies that can occur after cancer treatment with chemotherapy.⁵ There are no known oncogenic viruses associated with CML.

PATHOPHYSIOLOGY

MOLECULAR BIOLOGY

CML was first described in 1845, but the extensive research into the genetic and molecular aspects of the disease began with the discovery of the Philadelphia chromosome (Ph) in 1960 by Nowell and Hungerford. Research in the 1980s identified the molecular changes that occur as a result of the Ph. An oncogenic protein resulting from the Ph was identified and implicated in the pathophysiology of CML.⁶

FIGURE 132-1. Diagram of the chromosomal translocation that results in the Philadelphia chromosome. This abnormality is encountered in 90% to 95% of patients who have chronic myelogenous leukemia. (From Fishleder AK. *Oncogenes and cancer: clinical applications*. Cleve Clin J Med 1990;57:721–726.)

Ph was the first karyotypic abnormality specifically implicated in the pathogenesis of cancer; its discovery has resulted in extensive research into the molecular biology of CML.^{3,6} This chromosomal abnormality is characteristic of CML and is present in 90% to 95% of patients with a presumptive diagnosis of the disease. It can also occur in as many as 20% of adults and 5% of children with acute lymphoblastic leukemia, and in as many as 5% of adults and children with acute myelogenous leukemia.³

Ph, identified as a shortened long arm of chromosome 22, is found in granulocyte and erythrocyte progenitors, macrophages, megakaryocytes, and some lymphocytes.³ This anomaly is the consequence of breaks in chromosomes 9 and 22, resulting in a transposition that relocates the 3' end of *abl*, the Abelson protooncogene, from its normal site on chromosome 9 at band 34 to the 5' end of the breakpoint cluster region (*bcr*) on chromosome 22 at band 11.³ This reciprocal translocation is usually symbolized as t(9;22)(q34;q11) and results in the formation of the hybrid *bcr-abl* fusion gene (Fig. 132-1). Through this chromosomal translocation, the *abl* protooncogene is able to escape the normal genetic controls on its expression and is activated into a functional oncogene, directing the transcription of an 8.5-kilobase mRNA molecule that is translated into a 210-kilodalton protein. This protein, known as p210BCR-ABL, is unique and has higher tyrosine phosphokinase activity than the 145-kilodalton protein translated by the mRNA of the normal *abl* gene. The higher kinase activity of p210BCR-ABL is essential in the development of CML because the phosphorylation of tyrosine residues on growth factor receptors are believed to serve as an important intracellular signal in cell proliferation and programmed cell death. This stimulation of cell proliferation and inhibition of apoptosis leads to accumulation of the malignant clone. The p210BCR-ABL protein has also been shown to transform hematopoietic cells in vitro and to induce a CML-like myeloproliferative disorder in mice after infection of their bone marrow with a retrovirus that encodes the p210BCR-ABL.⁷

NATURAL HISTORY

It is generally accepted that CML begins with the malignant transformation of a single cell and therefore is considered a clonal disease. This alteration gives the transformed progenitor cell an inheritable selective growth advantage, leading to the proliferation of a neoplastic, monoclonal population of pluripotent stem cells.⁸ The Ph can be found in both myeloid and lymphoid cells, which suggests that the transformed cell of CML is a pluripotent stem cell.^{3,6} Granulocytosis, usually present in CML, results from the increased growth rate of the transformed clone and disruption of normal hematopoi-

etic cell maturation. Disrupted maturation leads to additional divisions by CML progenitor cells before reaching a nonproliferative stage; the resulting number of circulating granulocytes may be many times higher than normal. Later in the clinical course of CML, cytopenias may occur in association with fibrotic changes in the bone marrow.³

In the chronic phase, therapeutic intervention can effectively control the expansion of the CML clone and normalize the white blood cell count. As CML progresses, the malignant clone becomes more genetically unstable, and chromosomal abnormalities other than Ph may occur. Clinical evidence of the accelerated phase of CML begins to emerge as the patient's WBC count becomes increasingly difficult to manage. The rate of progression of CML is variable, and the blastic phase can sometimes erupt without any apparent accelerated phase. The relative mass of the chronic phase cell populations, genetic pretermination, and differences in either genetic stability or proliferative state of the leukemic cells are possible explanations for this variability in disease progression.^{3,6} The final stage of CML, known as the acute phase or blastic phase, is marked by the presence of rapidly proliferating blast cells that have lost their ability to differentiate into nonproliferating cells.^{3,6} The proliferative advantage of blast cells over normal hematopoietic cells is much greater than that of chronic phase leukemic cells. CML in blastic phase is relatively resistant to treatment. The poor response to chemotherapy is not exclusively a result of drug resistance; it also results from the high proliferative rate of blastic phase CML and the replacement of malignant cells eliminated by chemotherapy.^{3,8} The increased proliferative rate of blastic phase CML is the consequence of a number of factors, such as the high levels of cytokines produced by CML cells and loss of tumor suppressor genes such as *p53*.^{3,6} Several cytokines have been identified as potentially important in CML, including hematopoietic growth factors and vascular endothelial cell growth factor.^{6,9}

bcr-abl AS A THERAPEUTIC TARGET

The *bcr-abl* fusion gene produces a mutant tyrosine kinase that is involved in both the increased proliferation of the CML clone, and in the reduction in FAS-mediated apoptosis. The characterization of the adenosine triphosphate (ATP) binding site on the tyrosine kinase has led to a new class of inhibitors. The first of these inhibitors, imatinib mesylate (Gleevec), was approved in 2001 for patients in chronic phase who had failed interferon alfa (IFN- α), and in accelerated phase or blast crisis. It obtained additional FDA approval in 2002 for first-line treatment in newly diagnosed CML. The clinical results associated with imatinib have changed the way CML is treated, and will be discussed in more detail under the treatment section of this chapter.^{10,11}

CLINICAL PRESENTATION AND PROGNOSIS

The diagnosis of CML is usually made during the chronic phase following an abnormal complete blood cell count. The blood sample is occasionally obtained during a routine physical examination, but is usually obtained after the patient presents with symptoms such as weight loss, fatigue, malaise, night sweats, and fever. Splenomegaly and hepatomegaly are found in 30% to 40% of patients. Typical laboratory findings of the peripheral blood during the chronic phase include leukocytosis, thrombocytosis, basophilia, and low leukocyte alkaline phosphatase. In one series of newly diagnosed CML patients, the most common feature of the peripheral blood was a highly

elevated WBC count ($>100,000/\text{mm}^3$) occurring in about 70% of patients.^{3,12}

Important poor prognostic factors include older age, splenomegaly, high platelet count, and a high percentage of blasts at diagnosis. Although these factors have prognostic importance, they often fail to predict the risk for disease progression in an individual patient. Despite their limitations, these clinical features have been used to develop a widely used prognostic scoring system called the Sokal system. Using these disease and patient characteristics, clinicians can categorize patients into one of three risk groups: low-risk (median survival of about 6 years), intermediate-risk (median survival of about 4 years), and high-risk (median survival of about 2 years).³

Methylation of the *abl* gene and shortening of telomere length have been investigated for their ability to predict disease progression.^{13,14} The *abl* gene may have an inhibitory effect on the *bcr-abl* oncogene, and methylation of *abl* reverses that inhibitory effect, leading to progression to blast crisis.¹³ Telomere shortening has also been shown to reduce the time to the accelerated phase.¹⁴ While

neither methylation of *abl* or telomere shortening are standard clinical assays, these and other molecular markers may be used in the future to predict prognosis and guide therapy selection.

The accelerated phase is clinically the least distinct of the three phases of CML and may be difficult to recognize in some patients. Hematologic signs and symptoms reflect a progression in myeloproliferative acceleration and the approach of fatal blast crisis. Physical symptoms of acceleration include a resurgence of splenic enlargement, unexplained fever, and persistent bone pain. WBC counts and other signs and symptoms begin to be increasingly difficult to control with low-dose chemotherapy.

The clinical course of CML terminates in blastic phase, in which patients have peripheral blood and bone marrow findings very similar to those of acute leukemia. The blastic phase is of myeloid lineage in about two-thirds of patients and of lymphoid lineage in the other third of patients. Blastic phase is confirmed by the presence of greater than 30% blasts in the bone marrow or peripheral blood.³ The median survival for patients in blastic phase is 4 to 6 months, with most treatment options providing modest or no survival advantage.

▶ TREATMENT: Chronic Myelogenous Leukemia

◀ Cure of CML can be achieved only by eradication of the malignant clone (i.e., Ph-positive cells). Treatment response can be defined in several different ways, depending on the tests used to measure response (Fig. 132–2). *Hematologic* response is defined as the normalization of peripheral blood counts. Although hematologic response is the easiest type of response to measure, this type of response is not associated with changes in the percentage of cells positive for the Ph. *Cytogenetic* responses evaluate the percentage of cells positive for Ph, with *complete* cytogenetic remission defined as the elimination of Ph from bone marrow, and *major* cytogenetic response defined as fewer than 35% Ph-positive cells in the bone marrow. Patients who have a cytogenetic response have an improved survival compared to those who fail to achieve a response. Conventional cytotoxic chemotherapy can be used in chronic-phase CML to attain a hematologic remission. However, low-dose chemotherapy used in chronic phase does not produce cytogenetic responses and has little or no effect on median survival. Interferon, imatinib, and hematopoietic

stem cell transplantation (HSCT) can produce cytogenetic responses that are associated with longer median survivals. However, even complete cytogenetic response does not define cure.

More sensitive measures of residual disease are being used to identify the group of patients likely to be cured of their disease. *Molecular* remissions are determined by polymerase chain reaction (PCR), which is several logs more sensitive than methods used to measure cytogenetic remissions. Although bone marrow aspirates are the conventional method of determining cytogenetic response, the use of PCR in peripheral blood to measure *bcr* gene rearrangements is increasingly being used to monitor disease because of the ease of obtaining blood compared to bone marrow.¹⁵ To date, only allogeneic HSCT (alloHSCT) has been shown to consistently eliminate the Ph-positive malignant clone. Fig. 132–2 illustrates the residual disease that remains after various types of responses and the response rates obtained with the common therapies for CML. Table 132–1 shows the effect of various treatment modalities on survival in chronic-phase CML.¹⁶

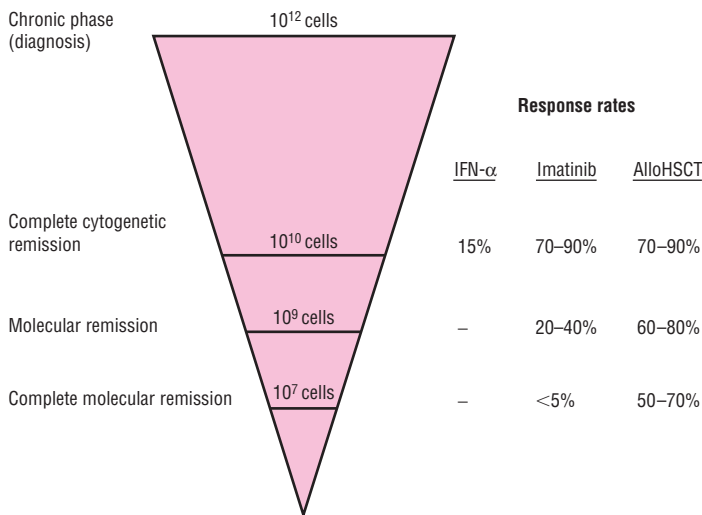

FIGURE 132–2. Response rates, based on different measures of response, obtained with the common therapies for CML.

TABLE 132–1. Effect of Therapy on Survival in Patients with Early Chronic-Phase Chronic Myelogenous Leukemia

| Therapy | 5-Year Survival (%) | Median Survival (Months) |
|----------------------------|---------------------|--------------------------|
| Busulfan | 30–40 | 40–50 |
| Hydroxyurea | 40–50 | 50–60 |
| IFN- α | 50–70 | 60–80 |
| IFN- α + cytarabine | 60–80 | NR |
| Allogeneic transplant | | |
| Matched sibling | 60–80 | NR |

CONVENTIONAL CHEMOTHERAPY

Busulfan (Myleran) and hydroxyurea (Hydrea) can be used to reduce white cell count shortly after diagnosis. These agents can be taken orally, are inexpensive, have reasonable side-effect profiles, and are able to rapidly normalize elevated WBC counts in chronic-phase CML. Although both agents produce predictable declines in WBC count and hematologic remissions in 70% to 80% of chronic-phase CML patients, busulfan and hydroxyurea have very little effect on Ph-positive cells in bone marrow.³ Based on results from a randomized study of nearly 500 CML patients by the German CML Study Group, which showed that hydroxyurea treatment provided a significant survival advantage over busulfan, hydroxyurea is the preferred conventional agent in newly diagnosed chronic-phase CML.¹⁷

Hydroxyurea inhibits the enzyme ribonucleotide reductase, leading to suppression of DNA synthesis, elimination of cells in the S phase of the cell cycle, and synchronization in the G₁ or pre-DNA synthesis phase.¹⁸ The drug is usually administered daily and can be initiated at 40 to 50 mg/kg per day in divided doses until the WBC count falls below 10,000/mm³. At that point, the dose can be decreased to a maintenance level of 20 mg/kg per day, but increasingly is tapered and stopped once imatinib therapy is started. Imatinib normalizes blood counts based on suppression of the malignant clone in the bone marrow, an effect not seen with hydroxyurea. Suppression of the malignant clone in the bone marrow is the desired therapeutic effect because of its impact on survival.¹⁹

INTERFERONS

Interferon was the first biologic therapy that showed important activity in cancer and was introduced into the market with a great deal of excitement. The interferons are a family of glycoproteins involved in many of the functional aspects of the hematopoietic system. Interferon alfa (IFN- α) and interferon beta (IFN- β) bind to the same cell-surface receptor on target cells, whereas interferon gamma (IFN- γ) binds to a separate receptor. Although all have been studied in the treatment of chronic-phase CML, IFN- α has been most extensively investigated in the management of CML and is FDA approved for this indication.³ Two recombinant forms of IFN- α are presently marketed: IFN- α_{2a} (Roferon A) and IFN- α_{2b} (Intron A). In addition, two polyethylene

glycol conjugated IFN products (PEG-IFN- α_{2b} and PEG-IFN- α_{2a}) are approved for the treatment of hepatitis C. Surprisingly, PEG-IFN- α_{2a} was found to be superior to conventional IFN- α in the treatment of hepatitis C, which gave hope that improved response might be seen in CML patients.²⁰ Unfortunately, a recent study reported that PEG-IFN- α_{2b} was not more effective and had a similar toxicity profile to the nonpegylated drug in CML patients.²¹

The exact mechanism of IFN- α activity in CML is unknown, but is complex with multiple effects on cellular function. Some of the proposed alterations include changes in gene transcription, substrate phosphorylation, antigen presentation, and apoptosis.^{6,22}

2 The past enthusiasm for the use of human IFN- α in the treatment of chronic-phase CML was based on the observation that 20% to 50% of patients achieve a cytogenetic response, which led to prolonged survival.^{3,23} Because of its unique activity in CML, imatinib has generally replaced IFN- α for initial treatment in patients who are not candidates for alloHSCT. However, there are patients who have already achieved cytogenetic response on IFN- α and continue to receive the drug as maintenance therapy, and depending on the physician, may not be switched to imatinib. In addition, IFN- α may have a role in those patients who do not tolerate or respond to imatinib. However, if current trends continue, IFN- α usage will continue to decline in CML.²⁴ The lack of enthusiasm for the use of IFN- α in the treatment of CML is related in part to its significant toxicity profile. IFN- α produces both short-term constitutional toxicities and potentially dose-limiting long-term toxicities. The most predictable early toxicity is a flu-like syndrome characterized by fever, chills, myalgias, headache, and anorexia. These dose-dependent effects may be a result of IFN- α -induced leukocytosis and release of cytokines. This acute flu-like syndrome can be ameliorated by starting IFN- α dosing at 50% of the final dose during the first week, giving the drug at bedtime, and coadministering acetaminophen or indomethacin with each IFN- α dose. Reduction of initial WBC counts to around 10,000/mm³ with hydroxyurea may also reduce these symptoms.³ Despite these methods of ameliorating toxicity, the flu-like syndrome is an important source of morbidity, occasionally requiring termination of therapy. Cardiovascular toxicities (tachycardia and hypotension) are seen in about 15% of patients in the first few weeks. Long-term adverse effects include weight loss, alopecia, neurologic effects (paresthesias, cognitive impairment, and depression), and immune-mediated complications (hemolysis, thrombocytopenia, nephrotic syndrome, systemic lupus erythematosus, and hypothyroidism), which can be dose limiting in about 5% to 20% of patients.³

IMATINIB

Imatinib (previously referred to as STI571) inhibits the p210 tyrosine kinase, leading to differentiation and apoptosis of the CML clone. Imatinib competitively binds to the ATP-binding site on the tyrosine kinase, which leads to inhibition of the phosphorylation of kinase substrates and inhibition of growth factor signals for the CML clone.

3 Imatinib demonstrated impressive activity in CML in early clinical trials and has changed the way CML is treated. Table 132–2 summarizes the clinical results of imatinib in CML patients in chronic phase, accelerated phase, and blast crisis. In the initial trials in chronic-phase CML and blast-crisis CML imatinib produced responses which are not usually seen in phase I studies.^{10,11} Fifty-four patients with chronic-phase CML who had failed IFN- α were studied. Of those who had received at least 300 mg daily of imatinib, nearly 100% of patients achieved complete hematologic remission and 30% had

CCR, complete cytogenetic response; MCR, major cytogenetic response. Adapted from Kantarjian et al,²⁴ O'Brien et al,²⁵ Talpaz et al,²⁸ Sawyers et al,²⁹ and Kantarjian et al.³⁰

a major cytogenetic remission. Hematologic responses were seen within 4 weeks, while major cytogenetic response occurred as early as 2 months and as late as 10 months after the start of treatment. A complete cytogenetic remission was obtained in seven patients (13%), and two of the seven patients had a molecular remission. The lack of a clear dose-limiting toxicity and the high response rates in these high-risk chronic-phase CML patients made imatinib unique among the various therapies for CML.¹⁰ Imatinib has also been studied in patients with myeloid blast-crisis CML, and about 55% of patients have a response to imatinib, including 10% of patients who achieve a complete hematologic response.¹¹ Imatinib was well tolerated in patients with blast-crisis CML, although a higher rate of grade 3 and 4 neutropenia was reported in patients with advanced disease.

A phase II study of imatinib in chronic-phase CML patients who had failed IFN- α confirmed the initial results reported in phase I studies. Patients were dosed at 400 mg/day because the phase I studies suggested a suboptimal response at 300 mg/day or less. Nearly all patients attained a complete hematologic remission and 60% achieved a major cytogenetic response. Perhaps most importantly, a complete cytogenetic remission was obtained in about 40% of patients treated with imatinib.²⁴

The most recently published study of imatinib was a phase III trial that compared IFN- α plus cytarabine to 400 mg daily of imatinib. This study, which is referred to as the International Randomized Study of Interferon versus STI571 (IRIS) trial, included over 1000 newly diagnosed CML patients. Patients who received imatinib had a significantly higher rate of complete hematologic remissions (95% vs. 55%), complete (74% vs. 8.5%), and major (85% vs. 22%) cytogenetic remissions, and a significantly lower percentage of patients who progressed to blast crisis in the imatinib group (96.7% vs. 91.5%).²⁵ The rate of response in the imatinib group was also more rapid, with most patients achieving complete hematologic responses in the first 6 weeks, and most complete cytogenetic responses occurring in the first 3 months of therapy. In a subsequent analysis of the IRIS data, Hughes and associates reported a higher molecular response in the imatinib-treated group (39%) compared to the IFN- α -treated group (2%) after 12 months of treatment.²⁶ In that study, molecular response was defined as a > 3-log decline in *bcr-abl* transcript expression. However, many experts believe that cure of CML requires a complete molecular remission, which requires at least an additional 2-log decline and loss of the *bcr-abl* signal (see Fig. 132–2). Complete molecular remissions occurred in only 3% of patients, which suggests that imatinib alone cannot cure most patients with CML. In addition to

superior activity, imatinib also was better tolerated, with less than 1% of patients intolerant to therapy, compared with about 25% in the IFN- α -treated group.

The role of molecular monitoring as a method to identify early relapse in imatinib-treated patients is unclear. Molecular monitoring would be helpful in patients on imatinib who have an initial molecular response, but who then have a gradual increase in the number of *bcr-abl* transcripts. If these patients were identified before they experienced a hematologic or cytogenetic relapse, clinicians could increase the imatinib dose or refer the patient for alloHSCT. However, the relationship between molecular and cytogenetic remission and the prognostic importance of molecular relapses are not clear. Therefore it is difficult at this time to integrate molecular relapse into clinical decision making.

In a recently published update of the IRIS trial, the complete cytogenetic remission rate in imatinib-treated patients is 79% at 24 months.²⁷ Nearly all patients in the IFN- α plus cytarabine group have crossed over to the imatinib arm due to better tolerability and higher activity.^{25,27} Because of this high cross-over rate to the imatinib arm, it may not be possible to determine the relative survival benefit of imatinib when compared to IFN- α .

Imatinib was rapidly approved based on phase II studies. Because of its rapid approval and relatively recent entry into the market, the best way to use this drug continues to evolve. Imatinib is often dosed at 600 mg per day in accelerated-phase CML and 800 mg per day in blast-crisis CML. This practice is based in part on data from the phase I study in CML blast-crisis patients in whom the majority of patients who obtained a bone marrow response received doses above 600 mg per day.¹¹ In subsequent phase II studies that compared 400 mg to 600 mg of imatinib in patients with accelerated-phase CML²⁸ and blast crisis CML,²⁹ there was either a trend or a statistically significant improvement in response rate in patients on the 600-mg dose.

CLINICAL CONTROVERSY

Nearly all chronic-phase CML patients receive a course of 400 mg per day of imatinib. Because the phase I trials suggested that response in accelerated-phase and blast-crisis CML was dose related, high-dose regimens of 800 mg per day are being evaluated in chronic-phase CML. Early results suggest a more rapid and extensive response can be achieved, but at the cost of more toxicity and financial burden. If there are high rates of complete molecular remission and these remissions are durable with 800 mg per day of imatinib, initial dosing regimens may be changed.

An area of controversy in patients in chronic-phase CML involves the optimal dosing regimen for imatinib. While 400 mg per day of imatinib is the recommended dose in chronic-phase CML, results of some studies suggest that the use of doses higher than 400 mg per day can produce more rapid and more extensive responses. About a third of patients who had not achieved a cytogenetic response after 1 year on 400 mg per day of imatinib achieved a major cytogenetic response when the imatinib dose was increased to 800 mg per day.¹⁹ In another study, Kantarjian and colleagues demonstrated in newly diagnosed patients the superior efficacy of 800 mg compared to 400 mg per day. Complete molecular responses after 18 months of therapy were uncommon at the 400-mg dose (7%), but occurred more commonly at 800 mg per day (28%).³⁰ However, higher imatinib doses are associated with greater toxicity, particularly grade 3 and 4 myelosuppression, and the cost of high-dose regimens may be prohibitive in some patients. Larger randomized studies that measure molecular

responses and evaluate durability of response are required to determine if the higher activity of high-dose regimens is worth the increased toxicity and cost.

While the phase I studies of imatinib in CML were unable to determine a maximum tolerated dose, most serious toxicities occur in patients receiving 750 mg or more per day. While grade 3 or 4 myelosuppression only occurs in 5% to 10% of patients with chronic-phase CML, it occurs in 50% to 60% of patients in accelerated phase or blast crisis.^{28,29} The myelosuppression often occurs during the first 2 to 4 weeks of starting the drug and is more common in patients with high blastic involvement of the bone marrow and in those with low hemoglobin counts.³¹ The neutropenia associated with imatinib seems to be associated with fewer infectious complications compared to neutropenia from cytotoxic chemotherapy, which may be related to the absence of the mucositis usually associated with cancer chemotherapy. The myelosuppression associated with imatinib is believed to be related to its therapeutic effect against the CML clone since similar rates of bone marrow suppression are not seen in patients receiving imatinib for gastrointestinal stromal tumors.³² Hematopoiesis in CML, particularly in accelerated phase and blast crisis, is so dependent on the CML clone that suppression of that clone can lead to myelosuppression.

Imatinib is also associated with some nonhematologic toxicities. Dose-related nausea and vomiting is the most common side effect and can be reduced by taking the drug with a meal. Edema and fluid retention are also dose related and most often manifests as periorbital edema. Rarely fluid retention can be severe, leading to pulmonary and cerebral edema. Risk factors for edema include female gender, age over 65, and a history of heart and kidney disease. About 20% to 40% of patients complain of musculoskeletal symptoms, which tend to occur during the first month of therapy and decline in severity over time. Drug rash can frequently occur but is usually mild. Severe rash, while uncommon, has been reported as an important cause for discontinuing therapy. Hepatotoxicity can occur, and the drug is usually stopped if liver function tests exceed five times normal. After the tests normalize, imatinib can be cautiously restarted at a reduced dose. The drug is then escalated upward to the prior dose if the liver function tests do not rise during 6 to 12 weeks of treatment at the reduced dose.¹⁹

Imatinib has several potentially clinically important drug interactions. Imatinib is metabolized by cytochrome P450 isoenzyme 3A4 (CYP3A4) and inducers of CYP3A4 metabolism may increase imatinib clearance. For example, a patient who was being treated with both imatinib and phenytoin had a suboptimal response and was found to have a 75% reduction in plasma imatinib concentrations as compared to patients not on phenytoin. The clinical significance of this interaction was confirmed by rapid disease response when phenytoin therapy was withdrawn.¹⁰ Imatinib may increase levels of other drugs metabolized by CYP3A4. For example, there have been reports of increased blood levels of cyclosporine and simvastatin in the presence of imatinib.¹⁹

HEMATOPOIETIC STEM CELL TRANSPLANTATION

4 Allogeneic hematopoietic stem cell transplantation (alloHSCT) is the only therapy proven to cure patients with CML, with many patients alive and disease-free more than 10 years after transplant.³ A recent study from the International Bone Marrow Transplant Registry (IBMTR) reported a 5-year survival rate of 69% in patients undergoing matched sibling alloHSCT within the first year of diagnosis.³³ As stated previously, patients who undergo matched-sibling alloHSCT

within the first year of diagnosis have a better 5-year survival rate than those who undergo alloHSCT beyond 1 year of their diagnosis (70% to 80% vs. 50% to 60%).^{33,34} The use of a targeted busulfan and cyclophosphamide preparative regimen may further improve survival following alloHSCT.³⁴ By adjusting busulfan doses based on plasma levels and eliminating total body irradiation, these investigators reported that the risk of leukemic relapse and transplant-related morbidity and mortality was reduced.

Unfortunately, fewer than 30% of patients eligible for alloHSCT will have a human leukocyte antigen (HLA)-matched sibling donor, and alternative donors must be considered. The most common alternative donor is an unrelated individual who is HLA matched. Results from several studies show that 50% to 70% of patients undergoing matched unrelated donor alloHSCT are alive at 3 to 5 years posttransplant.³³ The same predictors for good outcome in matched related alloHSCT, including undergoing transplantation within the first year after diagnosis and at a younger age at transplant, also apply to matched unrelated donor alloHSCT.^{35–37} AlloHSCT from matched unrelated donors may be more sensitive to delay than matched sibling transplants.³⁷ Results from these studies and a decision analysis suggest that patients who are candidates for a matched unrelated donor alloHSCT should be transplanted within the first year of diagnosis to optimize outcomes.³⁸

Because of the activity of imatinib, fewer transplants are being performed for CML. Data from the IBMTR showed that in 1998, over 600 transplants were performed for CML in 222 bone marrow transplant centers in North America. Transplants for CML accounted for 23% of the centers' total alloHSCT volume. In 2002, the same centers reported the number of transplants had declined to 268, accounting for only 9% of their alloHSCT volume.³⁹ As stated in the prior section, imatinib is likely to improve 5-year survival rates as compared to treatment with IFN- α .²⁵ However, neither IFN- α nor imatinib treatment is likely to cure patients, and no survival data exist comparing imatinib to alloHSCT.

CLINICAL CONTROVERSY

While the controversy of whether to use imatinib or alloHSCT as initial therapy is relevant to fewer than 30% of newly diagnosed CML patients, it is one of the major controversies in management of this disease. Current National Comprehensive Cancer Network (NCCN) guidelines demonstrate the imprecision of the decision-making process, suggesting that it is governed by the patient's preference. One reasonable approach is to evaluate hematologic remission at 3 months, and patients who have not had a complete remission and are eligible for transplant should have it offered. In patients receiving imatinib, cytogenetic responses should be evaluated every 3 months thereafter, and those who obtain a cytogenetic complete remission can be continued on imatinib, while those with incomplete cytogenetic responses at 9 to 12 months may consider transplantation. More sensitive measures of minimal residual disease (e.g., polymerase chain reaction) may allow further refinement of the decision making.

The controversy as to whether to use imatinib or alloHSCT is relevant only for those CML patients who are young enough to tolerate alloHSCT and who have a matched related or unrelated donor. With the median age of onset for CML being in the fifth or sixth decade of life and the high risk of mortality in patients over 50 years of age, at least half of CML patients will be excluded from alloHSCT based on age alone. Even when all the criteria are met (matched donor and

younger age), 100-day mortality after alloHSCT exceeds 10%. This risk of early mortality associated with alloHSCT may be too high in the imatinib era, when most patients have elimination of the Ph without significant toxicity. The NCCN CML guidelines recommend that the use of transplantation or imatinib therapy should be a patient's decision, made after careful discussion of the benefits and risks of each therapy.⁴⁰ The clinical decision is further complicated by the observation that there is a well recognized window when transplant is optimally performed. Patients who are transplanted beyond the first year after diagnosis because they were initially started on imatinib and later had an inadequate response, are less likely to be cured of their disease.

Some studies suggest that the use of certain drugs in the initial management of CML may also affect the outcome of alloHSCT. For example, busulfan and IFN- α may have negative effects on alloHSCT.³ Busulfan increases the risk of posttransplant complications and has been reported to reduce survival.³ The effect of previous IFN- α use is more controversial. The most recent study reported that if IFN- α was discontinued at least 90 days before transplantation, no effect on survival posttransplant was observed.⁴¹ The poorer outcomes in patients transplanted after busulfan therapy, and perhaps IFN- α therapy, is a cautionary experience that may have lessons for the use of imatinib in patients who are candidates for alloHSCT. Preliminary data suggest that patients previously treated with imatinib had significantly higher transplant-related mortality.⁴² The results of this study, while provocative, must be confirmed in studies with larger numbers of patients. The effect of imatinib on transplant outcome remains an important unanswered question and is part of the clinical uncertainty associated with initial therapy in CML.

Given that most patients treated with imatinib achieve cytogenetic complete remission and are likely to be alive at 5 years, strategies to improve transplant outcomes are critical if its role is to be other than a salvage therapy. One method is the infusion of donor lymphocytes as a form of adoptive immunotherapy to induce a graft-versus-leukemia (GVL) effect. In relapsed CML, donor lymphocytes have been shown to induce durable responses, and these responses strongly correlate with the development of graft-versus-host disease (GVHD).⁴³ In addition to development of acute GVHD, tumor burden also predicts likelihood of response to donor lymphocyte infusion in relapsed CML. There was a 100% response to donor lymphocytes

when treating molecular relapse, 75% response in cytogenetic relapse, and 35% if patients relapsed in accelerated phase or blast crisis. The dose, timing, and method of administration of donor lymphocytes may also impact effectiveness. In one study, there was a significantly lower incidence of GVHD with escalating doses of donor lymphocyte infusion rather than single-dose donor lymphocytes, while maintaining a similar 70% to 90% complete cytogenetic remission rate.⁴⁴ This study suggests that the administration of donor lymphocytes in fractionated doses rather than a single large dose after recovery from tissue damage caused by the preparative regimen may induce a GVL effect while minimizing GVHD. In another study, Guglielmi and associates reported that the administration of lower cell doses decreased the risk of acute GVHD without compromising antitumor responses.⁴⁵ The optimal method of administering donor lymphocytes remains unclear, but these data suggest it may be possible to partially separate the GVL effect from GVHD.

Imatinib has been used in patients who relapsed after alloHSCT. Cytogenetic response rates exceeded 50%, but at the expense of acute GVHD and myelosuppression.⁴⁶ While more work needs to be done on imatinib salvage therapy after alloHSCT, this high response rate is promising.

The importance of detecting the *bcr-abl* fusion gene product in CML patients after alloHSCT was studied in 346 patients and 634 collected blood samples. A positive polymerase chain reaction (PCR) 3 months or 36 months after transplant did not predict for relapse, but a positive PCR at 6 or 12 months after transplant was highly predictive.⁴⁷ With this tool, it may be possible to identify patients who are at high risk for clinical relapse and to treat them with donor lymphocyte infusion or imatinib in an attempt to suppress or eradicate residual disease.

It is too early to define the role of nonmyeloablative transplants in CML, but early results suggest equivalent efficacy to myeloablative transplants. While early transplant-related mortality is low following nonmyeloablative transplantation, transplant-related mortality is nearly 20% at 1 year.⁴⁸ However, in a recently published study of 24 CML patients receiving nonmyeloablative transplants, the estimated 5-year disease-free survival was 85% with low transplant-related mortality.⁴⁹ The excellent results reported in this study will need to be confirmed by larger studies from experienced centers.

CHRONIC LYMPHOCYTIC LEUKEMIA

CLL is a lymphoproliferative disorder characterized by progressive accumulation of functionally incompetent clonal B lymphocytes. CLL is a common form of leukemia in the United States, but is rare in Japan and China. It is estimated that about 9730 new cases of CLL will be diagnosed in the United States in 2005.¹ Occasional family clusters have been recognized, and first-degree relatives of patients with CLL are at three times the risk of developing a lymphoid malignancy as compared to the general population. CLL is a disease of the elderly, with a median age of onset in the sixth decade of life, although about 10% of CLL occurs in patients who are younger than 50 years of age. Etiologic factors have not been identified in CLL, and there are no data supporting either radiation or viral oncogenesis.³

CLINICAL PRESENTATION

The diagnosis of CLL is often made incidentally during a routine blood draw or after the patient complains of various constitutional

symptoms such as fever or fatigue. These symptoms result from reduction in normal hematopoiesis and the production of dysfunctional lymphocytes.³ Often an abnormal CBC is characterized by high numbers of mature-looking small lymphocytes. Lymphocytosis is nearly always present, and a bone marrow aspirate usually shows an infiltration of mature-appearing lymphocytes. The diagnosis is confirmed by analysis of the phenotypic characteristics of the peripheral blood lymphocytes. If there is a monoclonal B lymphocytosis, this is often sufficient to confirm the diagnosis. In about 60% of patients, there is lymphadenopathy, usually in the cervical, axillary, or inguinal areas. Intra-abdominal nodes may also be palpable, and about 50% of patients have spleen and liver enlargement. In addition to these relatively common presentations, lymphoid infiltrates can sometimes be detected at other anatomic sites, including skin, lung, gastrointestinal tract, and central nervous system.³

A number of laboratory abnormalities can be identified at the time of diagnosis. As stated above, lymphocytosis in the peripheral blood and lymphocytic infiltration of the bone marrow are usually seen at diagnosis. Anemia, thrombocytopenia, and neutropenia are frequently evident, either at the time of diagnosis or some time during

the course of the disease. The underlying reason for these cytopenias is not clear, but they most likely result from infiltration of the bone marrow by malignant lymphocytes. Other potential causes of cytopenias include autoimmune consumption of red blood cells and platelets and excessive T-suppressor cell or diminished T-helper cell function.³ Hypogammaglobulinemia is often present at diagnosis and develops in nearly all patients as the disease progresses. Unlike the Ph in CML, there is no single cytogenetic marker for CLL.

Although no single chromosomal rearrangement identifies CLL, more than 80% of patients with CLL have cytogenetic abnormalities. A number of the chromosomal rearrangements have been shown to correlate with prognosis.³

STAGING AND PROGNOSIS

There is a wide variability in survival times, with some patients dying within 3 years of diagnosis and others living two decades with CLL. The Rai staging system has helped to design appropriate management strategies for CLL. Prognosis depends on stage and tumor burden at diagnosis. The Rai staging system has been combined into a risk classification scheme: low-risk (stage 0), intermediate-risk (stages I and II), and high-risk (stages III and IV), with median survivals of greater than 10 years, 7 years, and 2 to 4 years, respectively.³ The other common staging system is the Binet System, which is more commonly used in Europe. Table 132–3 summarizes the Rai staging system.

Despite the prognostic importance of staging, the disease course varies within each stage so that one patient may have an indolent course with long survival time, whereas another patient may have

TABLE 132–3. Rai Staging System for Chronic Lymphocytic Leukemia

| Risk Class | Stage | Clinical Characteristics | % At Diagnosis | Median Survival (y) |
|--------------|--------|--|----------------|---------------------|
| Low | 0 | Lymphocytosis alone | 60 | >10 |
| Intermediate | I–II | Lymphocytosis and lymphadenopathy or spleen or liver enlargement | 20 | 6–8 |
| High | III–IV | Lymphocytosis and anemia or thrombocytopenia | 20 | 2–4 |

Adapted from Kantarjian et al.³

more aggressive disease and a relatively short survival time. Because staging systems, such as the Rai system, incompletely predict for subsets of patients who progress rapidly within each stage, numerous molecular markers are being investigated to identify patients who have poorer prognosis. One of the more promising markers is ZAP-70, an intracellular protein with tyrosine kinase activity. It is a surrogate measure for the unmutated variable region of the immunoglobulin heavy chain gene that is a strong predictor for rapid disease progression. Patients who have elevated ZAP-70 expression by flow cytometry have a poorer prognosis. The hope is that relatively easily measured molecular markers like ZAP-70 will allow the identification of patients who have poorer prognosis and may benefit from more aggressive treatment.⁵⁰

► TREATMENT: Chronic Lymphocytic Leukemia

Since currently available treatments have not been shown to cure CLL, the primary goal of therapy is to improve quality of life.³ Because molecular responses have been seen with newer therapies, it may be possible to cure CLL in a small subgroup of patients.⁵¹ Since few if any patients are cured, it is not surprising that management of CLL patients is highly variable. Some clinicians delay drug therapy after diagnosis to obtain several weeks of baseline information on signs and symptoms of the disease.³ The decision about whether drug therapy should be initiated after this baseline period is based on several parameters, including age of the patient, aggressiveness of the tumor, and symptoms. Treatment is often instituted for the following indications: signs and symptoms of progressive disease, worsening of blood dyscrasias, autoimmune complications, symptomatic splenomegaly, bulky lymph nodes, severe lymphocytosis ($>100,000$ to $200,000/\text{mm}^3$), and increased infectious complications.

Most stage 0 patients do not require treatment and are usually managed with close observation. In patients with stage I or II disease, management is controversial because the results of studies in this group of patients have not found a consistent survival benefit from drug therapy.³ The use of cytotoxic chemotherapy in early-stage CLL is usually reserved for patients who have disease characteristics consistent with a more aggressive course, such as short lymphocyte doubling times and diffuse lymphocytic infiltrates in the bone marrow biopsy. In stage III and IV disease, treatment is required, with the goal of achieving a partial or complete remission. Median survival times for patients who achieve some form of remission exceed 4 years, whereas those who do not achieve remission have a median survival of less than 2 years.³ Historically, drug therapy begins with

low-dose alkylating agents. Splenic radiation or splenectomy is often recommended in patients with stage III and IV disease to reduce symptoms and to improve autoimmune blood dyscrasias. The current treatment for patients requiring systemic therapy has shifted to fludarabine, unless the patient is elderly or has poor renal function.⁵¹

■ CYTOTOXIC CHEMOTHERAPY

The controversy surrounding CLL management with low-dose alkylating agents was evaluated in a meta-analysis.⁵² The results of that analysis showed that delayed treatment did not have an adverse effect on 10-year survival. If only deaths caused by CLL were considered, there was a statistically significant improvement in survival when treatment was deferred. Chlorambucil continues to be widely used in elderly patients as initial treatment for CLL, but its use is based on a small number of studies.^{3,53} The addition of prednisone to chlorambucil is likely to increase infectious risk with no advantage in the treatment of CLL. However, prednisone may have value in CLL-associated autoimmune blood dyscrasias.^{54,55}

Cyclophosphamide produces a similar response rate as chlorambucil (30% to 40%) and can be used in patients who have difficulty tolerating chlorambucil or in whom response is not optimal. Some patients refractory to chlorambucil will respond to cyclophosphamide. Cyclophosphamide is less commonly used because of its risk of hemorrhagic cystitis and bladder cancer with prolonged treatment.³

The purine nucleoside analogs fludarabine, 2-chlorodeoxyadenosine (cladribine), and 2-deoxycoformycin (pentostatin), have

an important role in the management of patients who have become resistant to chlorambucil, and as initial therapy for younger patients who can tolerate their immunosuppressive activity. Less data exist on the activity of pentostatin and cladribine in CLL than with fludarabine. There have been no randomized comparisons of the various purine nucleoside analogs, but the available data suggest that single-agent fludarabine and cladribine have similarly high activity in CLL.⁵⁶

Fludarabine was initially studied in 369 CLL patients who were refractory to chlorambucil. In that study, fludarabine produced an overall response rate of 47% and a complete response rate of 32%.⁵⁷ Sorensen and associates reported a similar overall response rate of 32% in patients with refractory CLL who were treated with fludarabine.⁵⁸ The most durable responses occurred in patients with lower-stage disease. Patients who received prior alkylating therapy and did not respond to the purine nucleosides had a poor survival. Based on these encouraging response rates in patients with refractory disease, fludarabine is now being used in chemotherapy-naïve patients, resulting in overall response rates of about 60% to 80%.⁵⁹ One randomized study has compared fludarabine to chlorambucil in chemotherapy-naïve patients, and the results of that study showed a higher complete remission rate with fludarabine (20% vs. 5%) as compared with chlorambucil.⁶⁰ However, the higher complete remission rate did not translate into a significant difference in overall survival, and patients treated with fludarabine had a higher rate of severe neutropenia and infection. The study allowed chlorambucil failures to cross-over to the fludarabine arm, which may have reduced the ability to show a survival advantage in patients treated with fludarabine. Based on the higher complete remission rate and improved time to disease progression, this study helped to establish fludarabine as a front-line therapy for CLL.

6 Based on the single-agent activity of fludarabine, many fludarabine-based combination regimens have been evaluated in patients with CLL. The activity of fludarabine is potentiated by alkylating agents and monoclonal antibodies. These combinations have recently been shown to have superior activity to single-agent therapy. Table 132-4 gives the response rates reported with purine nucleosides alone and in combination with other therapies. Fludarabine combined with alkylating agents have produced complete response rates higher than those achieved with fludarabine alone. The combination produced complete response rates between 30% and 50%, as compared to 10% to 20% for single-agent fludarabine.⁶¹⁻⁶⁴ Complete remission rates are higher in previously untreated patients. As indicated by the study comparing chlorambucil to fludarabine, high complete remission rates do not necessarily lead to improved survival. However, an exciting finding from one of these studies was that 17% of patients achieved a molecular remission.⁶³ While pentostatin as a single agent has not been as active as fludarabine, it has promising activity when combined with alkylating agents. A trial studying pentostatin and cyclophosphamide combinations in previously treated patients reported a 17% complete remission rate.⁶⁵

■ BIOLOGIC THERAPY

The most recent additions to therapy in CLL are the monoclonal antibodies directed against targets on lymphocytes.^{66,67} Rituximab targets the CD20 molecule which is expressed on B lymphocytes. Alemtuzumab was approved in May 2001 for the treatment of patients with CLL who had failed fludarabine therapy. Alemtuzumab targets

TABLE 132-4. Treatment for Newly Diagnosed (i.e., Untreated) and Previously Treated Chronic Lymphocytic Leukemia

| Treatment | Overall Response Rate | Complete Response Rate |
|--|-----------------------|------------------------|
| Chlorambucil | | |
| Untreated | 37% | 4% |
| Fludarabine alone | | |
| Untreated | 60–80% | 20–30% |
| Previously treated | 67% | 13% |

the CD52 molecule, which is expressed on nearly all lymphocytes. The CD20 molecule is less densely expressed in CLL cells compared to the B lymphocytes in indolent non-Hodgkin's lymphoma, the approved indication for rituximab. Concentrations of soluble CD20 are also higher in the plasma of CLL patients, which may neutralize the antibody's activity. When rituximab was used as the sole therapy in CLL, higher doses than those used in indolent non-Hodgkin's lymphoma had to be given to overcome these biologic features of CLL. Three recent studies of standard doses of rituximab demonstrated high complete response rates when combined with fludarabine-containing chemotherapy (30% to 70%).^{51,68,69}

Alemtuzumab has generally been used in CLL patients who are refractory to other available therapies. In this group of patients with refractory disease, the antibody produced an overall response rate of 30% to 40%, with a complete response rate of less than 10%. This level of response in refractory CLL is important, but is accompanied by a significant toxicity profile, including pancytopenia, infusion reactions, and opportunistic infections. An interesting finding with the combination of alemtuzumab and fludarabine is that patients resistant to each alone were sensitive to the combination.⁷⁰ This level of activity in refractory patients led to the evaluation of alemtuzumab earlier in therapy, alone or combined with purine nucleosides.^{51,56} Results with the antibody alone in newly diagnosed patients were similar to those with fludarabine alone. The combination of fludarabine and alemtuzumab may be too toxic, with high rates of cytomegalovirus (CMV) infection from the resultant severe immunosuppression.

7 While alemtuzumab alone may not improve results in newly diagnosed patients, it may be an important therapy for refractory patients. There are also interesting data that suggest that alemtuzumab can clear minimal residual disease after patients have been treated with chemotherapy. O'Brien and colleagues demonstrated that 38% of patients with residual disease after chemotherapy could achieve a molecular remission with alemtuzumab, and some of these remissions

appeared to be durable.⁷¹ The major complication in this study was infectious, with relatively high rates of CMV and Epstein-Barr virus infections. Because of the risk of CMV reactivation and *Pneumocystis* infections, prophylaxis with trimethoprim-sulfamethoxazole and fosciclovir or valaciclovir is recommended with the use of alemtuzumab.

HEMATOPOIETIC STEM CELL TRANSPLANTATION

There is a limited experience with the use of HSCT in CLL. Early mortality with autologous and allogeneic HSCT is approximately 10% and 40%, respectively. Those patients who achieve molecular remission as determined by PCR seem to have longer disease-free survival.⁷² While autologous transplantation has lower transplant-related mortality than allogeneic transplantation, relapse rates are high and it is generally not a preferred therapy in CLL. While cure is currently not considered achievable in CLL, alloHSCT is the most likely method of producing molecular complete remissions by initiating a GVL effect.^{73,74}

EVALUATION OF THERAPEUTIC OUTCOMES

The goal of disease monitoring in CML, which measures hematologic, cytogenetic, and molecular response, is to identify patients who have optimally responded to an initial course of imatinib. A suboptimal response to imatinib—defined by no hematologic response at 3 months or no complete cytogenetic response at 12 months—can be helpful in patients who are eligible for alloHSCT. In patients who obtain a hematologic or cytogenetic response to imatinib, but who later relapse during imatinib treatment should also be considered for transplantation. Alternatively, the dose of imatinib may be increased in an attempt to induce response. The role of molecular responses in making therapeutic decisions is not clear, but increased levels of *bcr-abl* transcripts in patients who have had a molecular response should be considered in the decision to increase imatinib dose, or in eligible patients, perform alloHSCT.

CLL is considered an indolent disease that is incurable and the goal of therapy should be to increase the duration and quality of life. Except in those patients who are younger and have aggressive disease, aggressive therapy should be avoided. The benefits of aggressive therapy should be carefully weighed against the risks and costs in older patients with indolent disease. A reasonable strategy for these patients is to administer single-agent well-tolerated chemotherapy or no therapy at all in patients without symptoms. Younger patients with aggressive disease should receive more active therapies, such as combinations of fludarabine plus chemotherapy, fludarabine plus monoclonal antibodies, or nonmyeloablative transplantation. If the decision is made to use these aggressive therapies and to accept the risk of potentially life-threatening toxicities, the goal of therapy should be to achieve a durable complete remission.

TREATMENT SUMMARY

Several experts and groups, such as the NCCN, have published guidelines for the treatment of patients with chronic leukemia. For the past several decades, alloHSCT has been the only curative therapy for CML. Cytogenetic responses have been obtained with IFN- α ,

CLINICAL CONTROVERSY

CLL is currently not considered a curable disease. However, a GVL effect has been demonstrated for CLL which may produce a long-term complete remission and perhaps cure. Because most CLL patients are elderly, full-intensity alloHSCT causes high transplant-related mortality and is generally not used in CLL. Nonmyeloablative HSCT may be an important treatment in CLL if it is not too toxic and if the GVL effect is sufficiently potent to destroy often bulky tumor as well as minimal residual disease.

8 AlloHSCT for CLL is an area of growing interest. Although this modality of treatment may hold promise of cure, the advanced age of most CLL patients and high treatment-related mortality limit the applicability of alloHSCT. Older patients who are not candidates for alloHSCT may be candidates for nonmyeloablative alloHSCT.³ A recent study reported a GVL effect in CLL patients treated with nonmyeloablative transplantation. This GVL effect may be potentiated by the treatment of patients with rituximab during the posttransplant course.⁷⁵

leading to an improved duration of survival. However, there are no convincing data to show that IFN- α can permanently eliminate the malignant CML clone, and its use is associated with many adverse effects. Imatinib has changed the management of CML. Most patients with chronic-phase CML receive imatinib as initial therapy at a dose of 400 mg per day, and attain a complete cytogenetic remission within the first year of therapy. It may be that imatinib can eliminate the malignant clone in a small subgroup of patients, particularly at higher doses, but longer follow-up will be required to determine the durability of these responses. NCCN guidelines indicate that patients who are candidates for alloHSCT and have a matched donor should receive alloHSCT if it is their preference. Based on recent trends in the number of transplants for CML, most clinicians and their patients prefer imatinib over alloHSCT. Patients who relapse after alloHSCT despite the development of acute GVHD should be placed on imatinib or possibly IFN- α . Patients undergoing alloHSCT who relapse or do not achieve remission and have not developed acute GVHD should be withdrawn from posttransplant immunosuppression to induce GVHD and GVL. If this is not successful, patients should receive donor lymphocyte infusion. Imatinib or IFN- α can be tried if donor lymphocyte infusion fails to produce a response.

Patients who are placed on imatinib at a dose of 400 mg per day as primary therapy and who do not achieve a hematologic remission 3 months after starting therapy may respond to an higher imatinib dose. Alternatively the patient should be evaluated for alloHSCT. Those patients on imatinib who achieve hematologic remission at 3 months should continue on imatinib, and cytogenetics should be evaluated every 3 to 6 months. Patients who have not achieved a complete cytogenetic remission at 1 year may respond to increased doses of imatinib or should be treated with alloHSCT if eligible. Patients in accelerated phase or blast crisis may respond to high doses of imatinib (600 to 800 mg/day), or in those with a matched related donor, alloHSCT can be offered. Unfortunately, responses in accelerated phase or blast crisis are usually not durable and patients usually die of their disease.

Because CLL is often an indolent disease that develops in older patients, an important goal is to optimize quality of life rather than to use aggressive, relatively toxic therapy. In younger patients,

fludarabine with or without an alkylating agent is often given with the goal of obtaining complete remissions. However, in the older patient the use of chlorambucil may still be preferred to decrease the infectious risk associated with fludarabine. In younger patients or patients with more aggressive CLL, a combination of fludarabine and an alkylating agent or monoclonal antibody or alloHSCT may offer long-term disease-free survival.

ABBREVIATIONS

alloHSCT: allogeneic hematopoietic stem cell transplantation
 ATP: adenosine triphosphate
 CLL: chronic lymphocytic leukemia
 CML: chronic myelogenous leukemia
 CMV: cytomegalovirus
 CYP 450: cytochrome P450 isoenzyme
 GVHD: graft-versus-host disease
 GVL: graft-versus-leukemia (effect)
 HLA: human leukocyte antigen
 HSCT: hematopoietic stem cell transplantation
 IBMTR: International Bone Marrow Transplant Registry
 IFN- α : interferon alfa
 IFN- α_{2a} : interferon alfa_{2a}
 IFN- α_{2b} : interferon alfa_{2b}
 IFN- β : interferon beta
 IFN- γ : interferon gamma
 IRIS: International Randomized Study of Interferon (versus STI571 trial)
 NCCN: National Comprehensive Cancer Network
 PCR: polymerase chain reaction
 PEG-IFN- α_{2a} : polyethylene glycol conjugated interferon alfa_{2a}
 PEG-IFN- α_{2b} : polyethylene glycol conjugated interferon alfa_{2b}
 Ph: Philadelphia chromosome
 WBC: white blood cell

MELANOMA

Rowena N. Schwartz

Learning Objectives and other resources can be found at www.pharmacotherapyonline.com.

KEY CONCEPTS

- 1 Cutaneous melanoma is becoming a common cancer, but it is a cancer that can be prevented and cured if detected early. Public education about screening and early detection is an effective strategy for controlling the increase in the incidence and the mortality associated with cutaneous melanoma.
- 2 Surgical resection of early-stage melanoma is associated with complete response and cure.
- 3 Patients with locally advanced disease should be evaluated for adjuvant therapy with interferon- α_{2b} or a clinical trial.
- 4 The toxicities associated with interferon- α_{2b} therapy are significant and require patient education, close patient monitoring, and appropriate dose delay and/or reduction.
- 5 Metastatic melanoma remains a clinical challenge. At this time, there is not a standard treatment approach for patients with metastatic disease. Dacarbazine is still considered one of the most active agents and can be used as a single agent; the use of combination chemotherapy has not been shown to be superior to single-agent therapy with dacarbazine.
- 6 High-dose aldesleukin (interleukin-2) is approved for the treatment of patients with metastatic melanoma. The toxicities with this regimen are high and close patient monitoring by an experienced health care team is essential during treatment. A small percentage of patients will experience a durable response.
- 7 A number of melanoma tumor vaccines have been evaluated in clinical trials in metastatic melanoma and in the adjuvant setting. The role of specific melanoma vaccines has not been defined at this time.

The incidence and mortality rate of cutaneous melanoma have increased during the past several decades in the United States and in most Caucasian populations throughout the world. It is estimated that about 59,580 new cases of melanoma will be diagnosed in the United States in 2005, although projections may represent an underestimation, as many superficial and in situ melanomas are still thought to be underreported.¹ The increase in incidence has most affected industrialized countries. In the last decade of the twentieth century, the increase in incidence was still apparent, but there appears to be a decline in the rate of increase in certain subgroups (e.g., women in the United States). Analysts believe the increase in cutaneous melanoma over time is due to a cohort effect; it appears that those individuals born before 1950 show increased risk, whereas those born after 1950 show a stable or declining rate.² Worldwide, the incidence of melanoma varies dramatically. The incidence is approximately 0.2 to 35 per 100,000 among females in New Zealand, and as high as 40.5 per 100,000 among males in Australia.

Mortality for melanoma is the highest of all the skin cancers. It is estimated that about 8,000 individuals will die of melanoma in 2005.¹ The mortality rate from melanoma appears to have stabilized and possibly declined in recent years in Australia, the United States, and Europe. The stabilization of mortality rates appears to be in part due to efforts at both primary and secondary prevention of melanoma.

ETIOLOGY AND EPIDEMIOLOGY

The etiology of melanoma, like most other malignancies, is not fully understood. A number of host factors and environmental factors have

been identified, and it is likely that these factors alone or in combination increase the occurrence of cutaneous melanomas. These factors are listed in Table 133–1.

Genetic factors have been strongly linked to the development of melanoma, but appear to account for a small percentage of the overall incidence.³ Familial atypical multiple mole syndrome (FAMMS) or hereditary dysplastic nevus syndrome (HDNS) is a hereditary disease characterized by a predisposition to develop dysplastic nevi and cutaneous melanoma. Approximately 8% to 10% of cases of melanoma are associated with family history or HDNS. The mode of inheritance is controversial and is believed to be polygenic. The p16^{INK4a} gene localized on the 9p21 locus is affected through germline mutations or deletions in approximately 50% of patients with familial melanoma. In individuals with dysplastic nevi and a family history of cutaneous melanoma, the cumulative lifetime incidence approaches 100%, whereas dysplastic nevi are thought to be precursors of 20% to 40% of sporadic melanoma.

Sunlight is one of the most important environmental factors in the pathogenesis of melanoma. Radiation in the ultraviolet B (UVB) range (280 to 320 nm) is thought to be a critical factor, although there is increasing concern that prolonged exposure to ultraviolet A (UVA) is also a risk factor for the development of melanoma. The use of UVB-blocking sunscreens may allow individuals to sustain more prolonged sun exposure without the ability to perceive erythema or pain, ultimately resulting in intense irradiation of the skin by UVA light.⁴

The incidence of melanoma has been associated with latitude and the intensity of solar exposure among susceptible populations. Skin characteristics are important in determining responses to

TABLE 133–1. Risk Factors for Melanoma*Host risk factors*

Adulthood (>15 years of age)
 History of cutaneous melanoma
 Dysplastic nevi
 Cutaneous melanoma in first-degree relative
 Immunodeficiency/immunosuppression
 High density of nevi
 High degree of freckling
 Sunburn easily/tan rarely
 Blonde or red hair
 Blue, green, or gray eyes
 Socioeconomic status (higher > lower)
 White (versus black) race

External risk factors

Intense intermittent sun exposures
 History of sunburn
 More than four painful sunburns before the age of 15
 Outdoor leisure

ultraviolet radiation. Whites with fair hair (red and blond), light-colored eyes (blue and green), and high degrees of freckling who have a tendency to burn and rarely tan with exposure to sunlight are especially at risk. Nonmelanoma skin cancers, such as squamous cell and basal cell cancer, have long been shown to be directly related to the total sun exposure, and it was thought that melanoma was similarly related to lifetime exposure to the sun. Epidemiologic research has not been able to demonstrate such a relationship between cumulative exposure to sunlight and the occurrence of cutaneous melanoma. Studies have demonstrated a lower risk for the development of melanoma in outdoor workers when compared to indoor workers.⁴ Intermittent overexposure to sunlight, blistering sunburns, and the time of life of exposure to the sun are now believed to be the more critical factors for development of cutaneous melanoma. Individuals who have a history of severe sunburns appear to have a higher risk of the development of melanoma than individuals who have had chronic sun exposure without a history of burning. The risk with sunlight and ultraviolet radiation seems to be greatest during childhood and adolescence. Intensive exposure to sunlight during infancy and early adolescence is more hazardous than exposure during adult life.

Immunocompromised patients are at increased risk for the development of cutaneous melanoma. Immunodeficiency includes those individuals with ataxia telangiectasia, chronic lymphocytic leukemia, Hodgkin's lymphoma, and immunosuppression following organ transplant. Acquired immunodeficiency syndrome also has been shown to increase the risk of developing cutaneous melanoma. Personal history of nonmelanoma or melanoma skin cancers is a risk factor for subsequent melanoma.

PATHOGENESIS

The pathogenesis of melanoma is not fully understood, but advances in the understanding of the immunology and molecular biology of melanoma provides a number of potential new avenues for the development of novel treatment strategies. Human melanocytes are dendritic pigmented cells that arise from the neural crest tissue during early fetal development and migrate by 4 to 6 weeks to a variety of sites within the body, such as the skin, uveal tract, meninges, and ectodermal mucosa. In the adult, most melanocytes are located at the epidermal-dermal junction of the skin and the choroid of the eye, but

can be found in a variety of other tissues such as the meninges and the alimentary and respiratory tract. Primary melanoma can therefore arise in any area of the body with melanocytes. The skin is the most frequent site of melanoma; cutaneous melanoma constitutes 90% of all melanoma. Primary melanoma can also arise in the eye (ocular melanoma) and less frequently in the meninges, respiratory tract, and gallbladder.

Normal melanocytes arise from melanoblasts and undergo a series of differentiation events before reaching a final end-cell differentiation state. Normal melanocytes can be arrested in their differentiation process at any given state of maturation without loss of their proliferation capacity. Melanocytes adhere to the basement membrane of the epidermis, and despite a resting state maintain a lifelong proliferation potential. Melanocytes synthesize melanin to protect various tissues such as the skin from ultraviolet radiation (UVR)–induced damage, and reach the keratinocytes in the upper layers of the epidermis via dendrites. Tyrosinase is an essential enzyme used within the melanosomes to synthesize melanin.

There is a malignant transformation of skin melanocytes from preexisting nevocellular nevi in the development of melanoma. A series of distinct steps are involved in the development and progression of melanoma from melanocytes. The pathologic components of the progression in human melanoma appear to involve a series of morphologic stages: (1) an acquired or congenital melanocytic nevus, (2) melanocytic nevus with architectural atypia, (3) histologically dysplastic nevus with cytologic atypia and architectural atypia, (4) primary melanoma in the radial growth phase in which limited growth and radial expansion of the nevi may occur without metastatic competence (nontumorigenic melanoma), (5) primary melanoma in the vertical growth phase with or without in-transit metastases in which there appears to be uncontrolled proliferation and increased angiogenesis, (6) regional lymph node metastatic melanoma (lymphatic), and (7) distant metastatic melanoma (hematogenous).⁵ Primary melanoma is characterized by radial growth and limited vertical thickness (less than 0.75 mm). Primary melanoma demonstrates little tendency to metastasize. Melanoma has a potential for metastasis formation with the onset of a vertical growth phase. Metastatic melanoma is seen with an increase in vertical thickness. Therefore the thickness of a primary melanoma is an important prognostic indicator, and is used in the staging classification of cutaneous melanoma. Individual melanomas can skip steps in this development. The progression from the melanocyte to the melanoma likely involves genetic aberrations.

Normal melanocytes require growth factors for proliferation, but melanoma cells are able to proliferate without growth factors.⁶ Melanoma cells secrete a variety of growth autocrine and paracrine factors that facilitate proliferation. Additionally, with progression, melanoma cells increase production of certain growth factors and cytokines. Basic fibroblast growth factors (bFGFs) are thought to be an important mediator of growth stimulation and cell survival and act as a motility factor for melanoma cells. Additionally, bFGFs upregulate serine proteinases and metalloproteinases. Melanoma cells are strong producers of chemoattractive proteins such as interleukin-8. Vascular endothelial growth factor can be triggered in the vertical growth phase. Most of these changes occur between the radial growth phase and vertical growth phase of primary melanoma, and metastatic cells often show highest productions of cytokines.

The types of products that have been isolated from melanoma include various growth factors, proteases, protease inhibitors, cell adhesion proteins, and host response modifiers. Melanoma cells express all major types of adhesion receptors including integrins and

cadherins, and the expression of these receptors increases as melanoma progresses.

The understanding of the biology of melanoma has provided potential targets for drug therapy. Understanding of hematopoietic and dendritic cell growth factors has led to the clinical investigation of granulocyte macrophage-colony stimulating factor in melanoma as an adjunct to vaccine therapy, and it has demonstrated promising results in pilot studies⁷ in the adjuvant treatment of melanoma. Identification of potential targets for therapy, such as bFGF, has led to the investigation of antisense oligonucleotides to block its role in modulating melanoma.

Immune factors appear to be involved in the progression of melanoma more often than in most other solid tumors. Spontaneous cancer regressions are rare, but are a well-documented phenomenon seen in melanoma. Focal regression in primary melanoma has also been reported. The regression of tumor appears to be associated with host immunity.

A number of different tumor antigens have been identified on melanoma cells by the use of monoclonal antibodies in both human and murine models. Melanoma-associated antigens (MAAs) have been identified in the cellular membrane and cytoplasm of melanoma cells. Ganglioside antigens have been of particular interest in the development of immunotherapy for melanoma. A large number of monoclonal antibodies to MAAs have been developed and are currently being used in clinical trials for the diagnosis and the therapy of melanoma.

The humoral and cellular responses of individuals with melanoma that express MAA have been described and provide the rationale for immunotherapy in the management of metastatic melanoma. Melanoma-directed antibodies have been isolated in the sera of patients with melanoma. The presence of antimelanoma antibodies in the sera of patients correlates with the clinical status of the patients, and the antibodies gradually disappear from the serum as the disease progresses. This phenomenon may be explained by the possible formation of anti-idiotypic antibody directed against the antimelanoma antibody, an increase in the circulation of soluble tumor antigens that saturate all the antibody combining sites, increased levels of immunosuppression, or absorption of the antibodies on the tumor mass.

In recent years, interest has focused on the role of cell-mediated immune response in melanoma. Specific cell-mediated responses may play a role in tumor regression, but the role of specific cells such as cytotoxic T lymphocytes (CTLs) is not fully understood. Tumor-infiltrating lymphocytes (TILs) have been shown *in vivo* and *in vitro* to possess antitumor reactivity. TILs contain a large number of mature tumor-specific lymphocytes and have been a target for manipulation in immunotherapeutic approaches for melanoma.

Specific genetic alterations have been demonstrated in the pathogenesis of melanoma.⁶ At least six genes with loci showing random deletions, rare translocations, and rare amplifications on chromosomes 1, 6, 7, 9, 10, and 11 have been identified in melanoma cells. Alterations in other genes located on other chromosomes may also contribute to the progression of melanoma. Alterations of chromosome 1 are seen in many forms of human cancer. The region of chromosome 1 that is involved in melanoma involves the tumor suppressor gene. The alterations seen in chromosome 6 potentially link melanoma and the major histocompatibility complex. The 9p21 locus is frequently affected in melanoma, and germline abnormalities are seen in approximately 50% of familial melanomas at this gene. In sporadic melanoma sporadic mutations are found in the *ras* gene; this mutation is seen more commonly in melanomas related to sun exposure. Genetic data suggest that familial melanoma is heterogenous

and likely due to several penetrant susceptibility genes acting alone or with multiple less-penetrant risk-factor modifier genes. *CDKN2A* and *DCK4* are highly penetrant susceptibility genes that have been identified. Variants of the *MC1R* (melanocortin-1 receptor) gene have also been associated with increased risk of melanoma. Additional deletions and mutations in *PEN/MMAC1* have been described in about 30% of cutaneous melanoma. The genetic influence to melanoma progression appears to involve a series of complex interactions. As these interactions are understood, the potential for gene therapy in melanoma expands.

HISTOLOGIC SUBTYPES OF MELANOMA

Cutaneous melanomas are categorized by growth patterns. The four histologic subtypes of cutaneous melanoma are distinctive in developmental phases and clinical features. The four major subtypes of cutaneous melanoma are superficial spreading melanoma, nodular melanoma, lentigo maligna melanoma, and acral lentiginous melanoma. There is no difference in the clinical outcome of the four subtypes if the comparison is controlled for depth of penetration. Any of the four subtypes of melanoma can occur as an amelanotic variant. Amelanotic melanomas appear to be devoid of clinically apparent pigmentation. Uveal melanoma is considered a separate disease from cutaneous melanoma.

Superficial spreading melanoma is the most common morphologic type of cutaneous melanoma and accounts for about 70% of all melanoma. The lesions usually arise from a preexisting nevus, known as a precursor lesion, and evolve slowly over 1 to 5 years. At some point, superficial spreading melanoma may progress to a more rapid growth phase. Early in lesion development the superficial spreading melanoma is flat, but as the lesion progresses, the surface becomes irregular and asymmetrical. The lesion enlarges when it enters into a rapid growth phase, and the edges appear notched or lacy. At times there are patches of regression within the lesion, signified by amelanotic areas. This subtype of melanoma is more common in women. The mean age of diagnosis of superficial spreading melanoma is 50 years, which is earlier than that noted for other subtypes. Superficial spreading melanoma usually occurs after puberty.

Nodular melanoma is the second most common growth pattern of melanoma and occurs in 15% to 30% of patients. Nodular melanoma is a pure vertical growth-phase disease. In nodular melanoma, a small expansive nodule in the papillary dermis invades the reticular dermis and subcutis. The radial growth phase is absent at all times. Nodular melanomas are more aggressive, and develop more rapidly than superficial spreading melanoma. Nodular melanomas are dark blue-black and often uniform in color with a shiny surface, although a small percentage of nodular melanomas are amelanotic and have a fleshy appearance. Nodular melanomas are raised and often symmetrical. They occur at any age, and are most common on the trunk, head, and neck. Nodular melanomas are more common in men.

Lentigo maligna melanoma represents a small percentage of melanomas and is unique from other histologic subtypes because it does not have the same propensity to metastasize. Lentigo maligna melanomas are generally large (>3 cm), flat, and tan-colored lesions with shades of brown and black. This subtype of melanoma occurs in an older age group, and is typically located on the chronically sun-exposed skin in older individuals. Lentigo maligna melanoma is uncommon before the age of 50, and may have been present for over 5 years. Lentigo maligna melanoma can be difficult to distinguish from solar lentigo.

Acral lentiginous melanoma presents as three distinct clinical subtypes: melanoma on the palms of the hands or soles of the feet, subungual melanoma, and mucosal melanoma. Most acral lentiginous melanomas are located on the soles of the feet and look like a large tan or brown stain. The lesions often have irregular convoluted borders. The initial macular component of palmar/plantar melanomas can be masked by the thickened stratum corneum at these sites. Many of these lesions look verrucous in appearance, making them difficult to distinguish from warts by the untrained eye. Suspicious lesions on the palms or soles of the feet should be evaluated. Acral lentiginous melanoma includes subungual melanoma, which arises in the nail matrix or nailbed. The most common presentation is a brown or black line in the great toe or the thumbnail. Mucosal melanoma is rare but can occur on any mucosal surface. Mucosal melanoma occurs most commonly in the oropharyngeal mucosa, followed by the anal/rectal mucosa, the genital mucosa, and the urinary mucosa. Unfortunately, mucosal melanoma often does not become clinically apparent until there is a large mass or the lesion bleeds. Acral lentiginous melanoma occurs in less than 10% of Caucasians with melanoma, but is the most common type of melanoma reported in blacks, Asians, and Hispanics.

Uveal melanoma is the most common primary intraocular malignancy seen in adults, but is an uncommon tumor. Unlike cutaneous melanoma, the frequency and mortality of uveal melanoma have remained steady. This melanoma arises from the pigmented epithelium of the choroid. Iris melanoma is a subset of uveal melanoma and tends to have a more benign course. The risk of metastasis varies with the histologic type and size of the tumor, as well as the location in the eye. Metastases occur most frequently in the liver, but have been documented in a variety of tissues.

CLINICAL PRESENTATION

The initial clinical presentation of melanoma is often a melanoma lesion. The lesion can be located anywhere on the body, but is most common on the lower extremities in women, and the back and trunk in men. The cardinal clinical feature of a cutaneous melanoma is a pigmented skin lesion that changes over a period of time. The clinical features used to describe or evaluate a questionable lesion are highlighted by the mnemonic “ABCD.” Unlike benign pigmented lesions, the shape of a melanoma lesion is often (A) *asymmetric*. Benign lesions tend to have regular margins, whereas melanoma lesions often have irregular (B) *borders*. The (C) *color* of melanoma lesions are often variegated, ranging in color from tan to blue-black, and at times the lesion is intermingled with colors of red, purple, and white. The size or (D) *diameter* of a melanoma lesion is frequently 6 mm or greater when identified, whereas benign lesions are usually smaller. Early melanoma lesions may be diagnosed at a smaller size. Another warning sign of a potential melanoma is a change in preexisting nevi. Some clinicians use the ABCDE mnemonic for melanoma, adding (E) for *evolution* of a mole. Changes such as a sudden or continuous enlargement of a lesion, an elevation of a lesion, or any change in the skin surrounding a nevus, including redness or swelling are important clinical signs. Uncommonly, the sensation of the lesion may become itchy or tender and painful. Friability of the lesion resulting in bleeding or oozing is also a danger sign. Perhaps the most important warning sign of danger is the evolution in any characteristic of a lesion.

The clinical appearance of a melanoma depends on the histologic subtype and the stage of development of the lesion. It is usually

possible to distinguish three variants of cutaneous melanoma including flat melanoma, nodular melanoma, and a flat melanoma with a nodular area. Flat melanoma usually corresponds to the histologic classification of superficial spreading melanoma.

The diagnosis of melanoma is complicated by a number of pigmented moles (melanocytic nevi) and nonmelanocytic lesions that resemble melanoma. Ordinary nevi, found on the skin of white adults, average between 10 and 40 lesions. These lesions are usually absent at birth and increase in number through adult life, and then gradually decline in number. They appear as tiny pinpoint macules and are usually uniform in color, but increase in size to a maximum of 4 to 6 mm. Nonmelanocytic pigmented lesions such as seborrheic keratoses, pigmented basal-cell carcinoma, and vascular lesions can also appear similar to a melanoma lesion.

➤ Improved survival rates for melanoma have been attributed to treatment of lesions identified at an earlier stage of development. Efforts to improve survival rates are concentrated on the diagnosis and treatment of the primary lesion. The cost-effectiveness of massive screening for all adults by a physician has never been demonstrated. A number of agencies, such as the American Academy of Dermatology and the American Cancer Society, have sponsored free annual screenings. Routine examination of the skin by physicians is recommended for individuals at high risk. The entire cutaneous surface should be examined including the scalp.

Self-examination of the skin places the responsibilities of identification on the individual. Identification of early melanoma allows the opportunity to treat the lesions when they are thin and curable. Educational pamphlets describing the method of self-examination (Table 133–2) for the public are available through the American Cancer Society, the American Academy of Dermatology, and the Skin Cancer Foundation. If a newly discovered pigmented lesion is identified or if a preexisting pigmented lesion changes, the individual should be evaluated by a physician immediately.

A biopsy is critical in establishing the diagnosis of melanoma. The subsequent pathologic interpretation of the biopsy will determine the appropriate therapy and prognosis. An excisional biopsy with a margin of normal-appearing skin is recommended for a suspicious lesion, and should include a portion of underlying subcutaneous fat for microstaging. Although a biopsy is recommended for large lesions where an excisional biopsy is impractical, an incisional biopsy can be performed, but should include a core of full thickness of skin and subcutaneous tissue. When excisional biopsies are not appropriate, as with the face or palmar surface of the hands, a full-thickness incisional or punch biopsy is preferred to a shave biopsy.

Evaluation of any individual with a suspected melanoma includes a complete history and total body skin examination. The focus of the patient history is to identify potential risk factors. Risk-related

TABLE 133–2. Self-Examination of Suspicious Moles

1. Examine your body front and back in the mirror, and then right and left sides with arms raised.
2. Bend the elbows and look carefully at the forearms and upper arms and palms.
3. Look at the backs of the legs and feet. Look specifically in the spaces between toes and at the soles of the feet.
4. Examine the back of the neck and scalp with the help of a hand-held mirror; part hair (or use a blow dryer) to lift hair and give you a closer look.
5. Check the back and buttocks with a hand-held mirror.

| IV | Reticular dermis and subcutaneous fat |

questions include an assessment of family history of melanoma, personal history of skin cancer and/or nevus excisions, sun exposure, and phototype. Total dermatologic examination is necessary to determine melanoma risk factors (e.g., mole pattern, mole type, or freckling) and for staging. For patients with melanomas of 1 mm or more in thickness, a baseline chest x-ray and liver chemistries are generally recommended despite the fact that they are relatively insensitive at detecting clinically occult distant disease. Lactate dehydrogenase should be evaluated, as it has been correlated with prognosis. Elevated serum lactate dehydrogenase was one of the most predictive independent factors of decreased survival in published studies, even after accounting for site and number of metastases.⁸ Any clinical indication of regional lymph node involvement should be confirmed with fine-needle aspiration or on biopsy of the enlarged lymph node. Additionally, any other signs or symptoms suggestive of metastatic disease should be completely evaluated.

There is a definite association between the size of a primary melanoma lesion and the likelihood of metastases. The prognostic factor originally used to determine survival was based on the cross-sectional profile of the primary tumor. The cross-sectional profile could be evaluated if the deepest invasive tumor cells lay above or below the sweat glands. This assessment was further clarified by Clark,⁹ who described the relationship of depth of invasion of the cancer cells to the standard anatomic landmarks of the skin (Table 133–3). Clark's classification is a practical approach for patients with more superficial tumors, because tumors classified as Clark levels I through III seldom metastasize. That classification system has been criticized because of problems associated with practical measurements. Melanoma lesions that occur in the presence of lymphoid infiltration, fibrosis, or even the cells of preexisting nevi are difficult to assess with classic reference landmarks.

Breslow¹⁰ replaced Clark's classification of reference landmarks with the use of thickness of the primary melanoma lesion. Tumor thickness is quantified to the nearest tenth of a millimeter with an ocular micrometer, measuring from the top of the granular layer of the overlying epidermis to the deepest contiguous invasive melanoma cell. The correlation between tumor thickness and probability of tumor metastases is strong, but does not include aspects such as tumor satellites, defined rather arbitrarily as skin involvement within 2 cm of the primary lesion, and vascular invasion. It was once thought that the presence of satellite nodule(s) had the same impact on prognosis as a high-risk primary lesion (tumor thickness >4 mm). It is now thought that patients with satellitosis have a worse prognosis than patients with thick primary lesions, and prognosis is more similar to that of patients with nodal metastases. There are a number of prognostic factors, in addition to tumor thickness and level of invasion, that are associated with the risk of developing metastatic disease.¹¹

The American Joint Committee on Cancer (AJCC) developed a staging system for melanoma that divides patients with localized melanoma into four stages according to microstaging criteria of

Breslow and Clark. In addition to consideration of the primary lesion, the AJCC staging system includes aspects of the tumor satellite, extent of lymph node involvement, and presence of metastatic disease. Recent analysis of several large databases worldwide has identified areas in which the AJCC staging system published in 1997 did not reflect the natural history of melanoma. Issues such as the appropriate cutoff values for primary tumor thickness, ulceration of the melanoma, and the satellite lesions of the primary tumor are important for determining the natural history of the disease in an individual, and should be considered when making decisions about therapy. The cutoff values initially proposed by Breslow for primary tumor thickness were initially used in the AJCC staging system, but it appears that cutoff depths of 1, 2, and 4 mm of thickness may better predict overall survival. Melanoma ulceration is associated with increased mitotic rate within a primary melanoma. The presence of ulceration of the primary lesion has been correlated with poorer survival for patients with very thin or thick lesions, but ulceration of the melanoma was not included in the 1997 AJCC staging system.

A revised staging system for cutaneous melanoma was approved by the AJCC.¹² Revisions of the new melanoma staging system include (1) melanoma thickness and ulceration for all tumors (except T₁ tumors); (2) the number of metastatic lymph nodes versus gross dimensions, and the delineation of clinically occult versus clinically apparent nodal metastases; (3) the site of distant metastases and the presence of elevated serum lactate dehydrogenase for metastatic disease; (4) upstaging of all patients with stage I, II, and III disease when a primary melanoma is ulcerated; and (5) a new convention for separating clinical and pathologic staging to include information obtained from intraoperative lymphatic mapping and sentinel node biopsy. Clinical staging includes microstaging of the primary melanoma and clinical and radiologic evaluation. It is used after the complete excision of the primary melanoma with clinical assessment for regional and distant metastasis. Pathologic staging includes the microstaging of the primary melanoma and pathologic information about the regional nodes after partial or complete lymphadenectomy. At this time it appears that patients with very limited disease (stage 0 or IA disease) do not require pathologic evaluation of lymph nodes (Tables 133–4 and 133–5). It is important to look closely at the staging system used in clinical trials to appropriately interpret the results.

As with other solid tumors, the presence of regional lymph node involvement is a powerful predictor of tumor burden and patient outcome. In the past, the primary method to determine nodal status was by surgical resection and analysis of the lymph nodes via a regional lymph node dissection. In recent years, preoperative lymphoscintigraphy and intraoperative sentinel node mapping have become more widely used methods to identify the first or sentinel lymph node in the direct pathway of lymph drainage from the primary cutaneous melanoma. The rationale for lymphatic mapping and subsequent sentinel node biopsy is based on the observation that regions of the skin have patterns of lymphatic drainage to specific lymph nodes in the regional lymphatic basin. The sentinel lymph node is believed to be the first node in the lymphatic basin into which the primary melanoma drains. Unlike other solid tumors, melanoma appears to progress in an orderly nodal distribution. The evaluation of sentinel nodes has been used for detection of micrometastases in breast cancer and is gaining popularity in melanoma. Sentinel lymph node biopsy provides an avenue to perform a more thorough examination of a single sentinel node than is possible when examining multiple lymph nodes with a lymph node dissection, and may be most useful in melanomas located in ambiguous drainage sites such as the head and neck areas.

TABLE 133–4. Melanoma TNM Classification

| T Classification | | | Thickness | Ulcerative Status | |
|------------------|--|-----------|-----------|--|----------------------------------|
| T ₁ | | ≤1 mm | | A: without ulceration and level II/III | B: with ulceration or level IV/V |
| T ₂ | | 1.01–2 mm | | A: without ulceration | B: with ulceration |
| T ₃ | | 2.01–4 mm | | A: without ulceration | B: with ulceration |
| T ₄ | | >4 mm | | A: without ulceration | B: with ulceration |

| N Classification | | No. of Metastatic Nodes | Nodal Metastatic Mass | |
|------------------|--|--|--|--------------------|
| N ₁ | | 1 node | A: micrometastasis | B: macrometastasis |
| N ₂ | | 2–3 nodes | A: micrometastasis | B: macrometastasis |
| N ₃ | | 4 or more metastatic lymph nodes, matted nodes, ulcerated melanoma, metastatic lymph nodes, or intransit metastatic or satellite lesions | C: in-transit metastases/satellite(s) without metastatic nodes | |

| M Classification | | Site | Serum Lactate Dehydrogenase |
|------------------|--|---|-----------------------------|
| M _{1a} | | Distant skin, subcutaneous, or nodal metastatic disease | Normal |
| M _{1b} | | Lung metastases | Normal |
| M _{1c} | | All other visceral metastases | Normal |
| | | Any distant metastasis | Elevated |

Micrometastases are diagnosed after sentinel or elective lymphadenectomy. Macrometastases are defined as clinically detectable lymph node metastases confirmed by therapeutic lymphadenectomy or when any lymph node metastasis exhibits extracapsular extension. *Barch.*¹²

Additionally, the detection of clinically undetectable disease in a lymph node basin that is not directly adjacent to the primary lesion may allow for the upstaging of patients who are initially believed to have node-negative disease. Currently, there is increasing interest in developing methods to improve the detection of occult micrometas-

tases in biopsied lymph nodes with more sensitive reverse transcriptase polymerase chain reaction assays to detect the presence of tyrosinase messenger RNA. This may be a method for broad clinical use to detect occult melanoma cells in the blood of patients with small clinical lesions.¹³

The stage of the melanoma at time of diagnosis is one of the primary indicators of natural history of the disease; other factors have been shown to influence survival of primary melanoma. Factors such as tumor growth phase, mitotic rate, density of TILs infiltrating the tumor tissue, anatomic site of the primary tumor, gender and age, have all been demonstrated to have an impact on survival (Table 133–6). In addition, a number of additional prognostic factors have been identified for patients with advanced disease. The number of metastatic sites, disease involvement of the gastrointestinal tract, liver, pleura, or lung, or a Eastern Cooperative Oncology Group (ECOG) performance status of ≥ 1 , male, and patients with prior immunotherapy have been associated with poor prognosis.

TABLE 133–6. Prognostic Factors for Cutaneous Melanoma

| | |
|---|--|
| <i>Tumor-related factors</i> | |
| Tumor thickness | |
| Level of tumor invasion | |
| Anatomic site of primary tumor (increased survival in tumors of extremities versus axial, neck, head, and trunk tumors) | |

| Angiogenesis | |
| Occurrence of microsatellites | |
| Area of tumor regression | |
| Presence of tumor-infiltrating lymphocytes (correlated with increased survival) | |
| <i>Patient-related factors</i> | |
| Age (decreased survival in patients >60 years of age) | |
| Gender (survival: female >male) | |

► TREATMENT: Melanoma

The treatment of a patient with cutaneous melanoma depends on the stage of the disease. Local disease is managed and often cured with surgical ablation. Regional disease is treated with surgical resection of the primary lesion, and depending on the risk of recurrence, possibly adjuvant therapy. The use of adjuvant therapy after surgical resection and the role of interferon- α as adjuvant therapy remain controversial. Treatment for disseminated melanoma remains a challenge. Although the literature provides numerous clinical trials of single-agent and combination chemotherapy, immunotherapy, and biotherapy regimens, there is not a single standard approach for management of the individual with metastatic melanoma.

■ SURGERY

2 Patients that present with a suspicious pigmented lesion should undergo a full thickness excisional biopsy, if possible. Sites in which excisional biopsy are inappropriate include the face, palm of the hand, sole of the foot, distal digit, and subungual lesions. A full thickness incisional or punch biopsy is preferred in these cases to provide microstaging and ultimately to determine therapy.

Cutaneous melanoma that is localized can often be cured with surgical excision. The extent of the excision margin is important in the prevention of local recurrence and ultimate survival. For melanoma in situ, excision of the lesion or biopsy site with 0.5 to 1 cm border of clinically normal skin and a layer of subcutaneous tissue is recommended at this time. Excision with a 1-cm margin of clinically normal skin and underlying subcutaneous tissue is recommended for invasive melanoma ≤ 1 mm thick.¹⁴ This recommendation is a significant reduction from the previous recommendation of a 5-cm margin. The appropriate margin of excision for melanomas between 1 and 2 mm in thickness is controversial. A recent study suggests there is a greater risk of locoregional recurrence when melanomas that are at least 2 mm thick are excised with a 1-cm margin rather than a 2-cm margin.¹⁵ Lesions that are 2 to 4 mm thick should be excised with a 2-cm margin. Primary tumors more than 4 mm thick require at least a 2-cm margin, but it is not clear if a larger margin is beneficial.¹⁶

Surgical management of lentigo maligna melanoma is problematic, as subclinical extension of atypical junctional melanocytic hyperplasia may extend beyond the visible margins; it is important to completely excise these lesions.

When isolated regional lymph nodes are detected via physical exam in the absence of distant disease, therapeutic lymphadenectomy is recommended. The extent of therapeutic lymph node dissection is often modified according to the anatomic area of the lymphadenopathy. The role of lymphadenectomy is not as established in situations in which the regional lymph nodes do not appear to be involved under clinical examination. Although a subgroup of patients with stage I melanoma will have microscopic metastatic disease in nonpalpable lymph nodes, prophylactic regional lymph node dissection has not been shown to prolong survival or decrease time to relapse in randomized clinical trials. Selective regional lymphadenectomy performed after scintigraphic and dye lymphographic identification of the affected sentinel draining lymph node(s) is becoming increasingly common. If the sentinel node is found to have micrometastatic melanoma, regional dissection of the involved nodal basin is performed. If lymphatic mapping with sentinel node biopsy is available, it should be considered in patients with melanomas that are over 1 mm thick or Clark level IV.

One of the most important aspects of the surgical management of cutaneous melanoma is the role of patient follow-up. Postsurgical follow-up of patients who have had a melanoma excised is essential to monitor for undetected metastatic disease and the development of a second primary cutaneous melanoma or second nonmelanoma primary malignancy. Scheduled screening in addition to routine surgical follow-up is required for any patient with a melanoma; the frequency and duration recommended depends on the stage of melanoma. The optimal duration of follow-up remains controversial. The majority of patients who are going to have recurrent disease will do so in the first 5 years following treatment, but late recurrences seen in patients over 10 years following surgery have been observed. The increased lifetime risk of developing a second primary melanoma supports lifetime dermatologic surveillance for all patients.

The role of curative surgery is limited to that of early-stage disease in cutaneous melanoma. The role of surgery beyond that of cure is less clear, although surgery may offer palliation for patients with isolated metastases. Resection of isolated lesions in the brain and the lungs may be appropriate in certain cases and should be evaluated based on individual patient criteria. Surgery can be an option in situations in which the lesion is accessible and when the lesion may cause problems if not removed. Melanoma in the gastrointestinal tract can lead to bowel obstruction, and appropriate resection or bypass may allow the patient significant relief of symptoms. Despite the lack of

controlled clinical trials, the impact on palliative surgery should be evaluated in the context of a patient's comfort and quality of life. Surgery may be an appropriate option if the perceived outcome is to provide patient comfort. On the other hand, surgery may constitute a significant physical challenge or financial burden to a patient with a limited life expectancy. The clinical scenarios involving surgical resection should be fully evaluated in terms of overall quality of life.

The risk of relapse and death after the resection of a local or regional cutaneous melanoma is the primary determinant for the use of adjuvant therapy after primary resection. Adjuvant trials have focused on patients at intermediate or high risk of recurrence.

■ IMMUNOTHERAPY

Melanoma is considered one of the most immunogenic solid tumors; it appears to interact with and respond to the immune system of the host in which it arises. Spontaneous regressions of melanoma suggest the importance of the immune system in disease modulation. Lymphoid infiltration into the primary melanoma also suggests that immunomodulation may impact the biology of melanoma. Early work with nonspecific immunomodulators, such as levamisole and bacille Calmette-Guérin, in melanoma demonstrated that tumor regression could occur with these therapies, although many of these regressions were limited and short-lived. Coupled with the fact that melanoma is one of the tumors most resistant to other standard systemic treatment modalities used for cancer (i.e., radiation and chemotherapy), immunotherapy offers an avenue of treatment if surgery fails or is not an option. Although the complete response (CR) rate seen in those patients with melanoma treated with biotherapy is low, the durability of the responses can be significant. This has led to increasing research in the optimization of biotherapeutic approaches for patients with metastatic melanoma and for the establishment of biotherapy in the adjuvant setting.

■ INTERFERON

The *interferons* consist of a group of antigenically and genetically distinct species and subspecies; the interferons have differing immunomodulatory activity and are directly cytostatic and cytotoxic. A number of studies have evaluated various doses and schedules of recombinant interferon for the treatment of metastatic melanoma, but no standard strategy is recommended. Response rates in metastatic melanoma range from 10% to 30%, and overall response rates are approximately 15% for interferon- α . Unfortunately the optimal dose, treatment schedule, and treatment combination/regimens have not been established for the management of metastatic melanoma.

In initial clinical trials with interferon therapy for patients with metastatic cutaneous melanoma, response rates were highest in those patients with minimal disease. Additionally, responses were seen in all sites of disease, but were most frequent in subcutaneous, lymph node, and pulmonary metastases. Success of interferon in a setting with minimal disease has encouraged investigators to evaluate the benefit of interferon in patients after curative surgical resection who were at high risk for recurrent disease (bulky disease or regional lymph node involvement). Early trials of short-term and/or low-dose regimens of interferon- α did not demonstrate a survival benefit in the adjuvant setting. In an attempt to optimize response in the adjuvant setting, a strategy was developed to administer maximum tolerated doses of interferon- α for 1 month, followed by prolonged therapy of

interferon- α at more tolerable doses for 48 weeks. The rationale for the induction phase was to provide peak levels of interferon sufficient to inhibit tumor growth and provide both antiangiogenesis and immunomodulatory effects while avoiding production of anti-interferon antibodies. A large, multicenter, cooperative group trial of interferon- α_{2b} versus observation was designed for patients with high-risk (stage IIB and III disease based on the 1997 AJCC staging criteria) melanoma following curative surgical resection. Interferon- α_{2b} was given intravenously as an induction therapy at maximum tolerated doses of 20 million international units/m² per dose 5 days per week for 4 weeks in an outpatient setting; treatment was continued for 48 weeks with subcutaneous interferon- α_{2b} 10 million international units/m² per dose three times per week at home. This therapy is now often referred to as high-dose interferon (HDI). Analysis of the 280 patients demonstrated a disease-free survival and an overall survival advantage with interferon- α treatment for patients with stage IIB and III disease following surgical resection.¹⁷ With longer follow-up, however, the difference in overall survival is no longer significant.¹⁸ The prolongation of overall survival was approximately 1 year, and the most significant reduction in melanoma recurrence was during the early treatment period. Subgroup analysis of this study indicated that patients with large primary tumors and node-negative disease (T₄N₀M₀) did not receive the same benefit from therapy, but the small number of patients in this group made it difficult to draw definite conclusions about the role of interferon treatment for adjuvant therapy in this subgroup. Whether the information from this trial should be extrapolated to patients with local recurrences, satellite lesions, or in-transit metastases is not known, and should be evaluated on an individual case basis.

Toxicities for the interferon therapy were common and severe in a majority of the patients at some point during therapy and necessitated dose reductions and/or delays during both the induction and maintenance phases of the study. Dose modifications were required for dose-limiting constitutional symptoms, hematologic toxicity, and hepatic toxicities, but 74% of the patients were able to complete the year of therapy in an outpatient setting.

The optimal dose of interferon in the adjuvant setting is not clear. A subsequent ECOG trial designed to evaluate the impact of lower doses of interferon (LDI; 3 million units per dose subcutaneous three times weekly) for 24 months compared to the high-dose regimen (HDI) described above versus observation did not demonstrate a survival advantage of HDI versus observation.¹⁹ At a median follow-up of 52 months, the 5-year estimated relapse-free survival for HDI was 44%, LDI 40%, and observation 35%. HDI was shown to be statistically superior for relapse-free survival, prolonging the median time to relapse by 10 months compared to observation and LDI. With longer follow-up, however, the difference in relapse-free survival is no longer significant.¹⁸ An overall survival benefit was not seen for HDI or LDI compared to observation, although the investigators speculated that this analysis of survival was affected by the number of patients in the observation arm that received interferon therapy after disease progression.¹⁹

The frequency and severity of toxicity seen with HDI in the adjuvant setting and the lack of overall survival benefit has raised several important questions: (1) Are the toxicities associated with HDI treatment worth the potential benefits for patients? (2) What are the mechanism(s) and best standard(s) of care for patients who experience interferon toxicity? (3) Is the regimen/schedule of interferon used in the initial positive trial (HDI) necessary to achieve the benefits seen in this study? Aggressive toxicity evaluation and individualized management is essential to help preserve quality of life in those individuals receiving interferon therapy.

4 One of the categories of toxicities seen with interferon- α therapy is actually a diverse group of side effects referred to as constitutional symptoms; this can include acute symptoms such as fever, chills, myalgia, and fatigue, and can encompass some of the more chronic toxicities such as fatigue, anorexia, and depression.²⁰ Acetaminophen may be used to prevent or minimize acute dose-related symptoms such as fever, myalgia, and chills. Opiates such as meperidine are often required when patients experience severe chills or rigors, most commonly during the initial month of the high-dose intravenous interferon- α induction phase. Nonsteroidal anti-inflammatory drugs (NSAIDs) have been used to manage interferon-related myalgia, but may have overlapping side effects with interferon, such as a decrease in renal blood flow and nausea. NSAIDs, like acetaminophen, may mask fevers that occur in those patients who experience neutropenia while on therapy. Fatigue is one of the most frequently observed dose-limiting toxicities seen with interferon therapy.²⁰ The mechanisms of interferon-induced fatigue are not fully understood at this time, and are often multifactorial in individual patients. Interferon-induced fatigue appears to be dose-related and may worsen with continued therapy. Pharmacologic (e.g., amantadine) and nonpharmacologic interventions (e.g., exercise, psychosocial techniques, distraction, energy management, and dietary modifications) are currently being evaluated to treat cancer-related fatigue and now interferon-related fatigue.^{20,21} Anorexia was reported in approximately 70% of patients receiving adjuvant interferon therapy for melanoma and is thought to be mediated through direct effects on hypothalamic neurons, modification of normal hypothalamic neurotransmitters/neuropeptides, or effects from stimulation of other cytokines.^{20,22} Depression is common and should be fully evaluated and treated based on patient-related symptoms.²⁰ Contributing factors such as interferon-induced hypothyroidism and/or concomitant interferon symptoms (e.g., nausea and fatigue) should be evaluated concurrently with depression symptoms to optimize treatment decisions. Taste alterations may contribute to anorexia. Investigational strategies for ameliorating interferon-induced anorexia include nutritional intervention, use of appetite stimulants such as megestrol acetate, and patient education. Glucocorticoids should not be used for appetite stimulation or as part of an antiemetic therapy, as they may adversely impact the immunomodulatory effects of the interferon. Other toxicities such as hematologic or hepatic toxicities require monitoring and appropriate dose modification.

Because of the associated toxicity and adverse effects seen with interferon- α therapy there has been worldwide concern about the usefulness of this intensive adjuvant therapy for melanoma despite the possible benefits in relapse-free and overall survival.²³ A subsequent report from the cooperative group study demonstrated a quality-of-life benefit with interferon therapy based on the quality-of-life-adjusted survival analysis.²⁴ This analysis calculates the quality-of-life-adjusted years gained as a result of interferon- α treatment or the clinical benefit of time without toxicities and without disease.

The role of interferon as adjuvant therapy is not clear at this time. The issue of patient side effects and cost needs to be carefully weighed against the disease-free survival benefit seen in those individuals with high risk of recurrence. As high-dose interferon remains the only therapy to demonstrate benefit in large comparative trials, it should be considered for patients with high-risk disease. According to the National Comprehensive Cancer Network (NCCN) Clinical Practice Guidelines for melanoma, interferon alfa is one of several options for select patients with high-risk disease.²⁵ Observation was also listed as an option. Individuals should be prescreened for potential problems associated with therapy; relative contraindications to high-dose interferon therapy include autoimmune diseases, immunosuppression,

decompensated liver disease, severe neuropsychiatric diseases, or life-threatening infection.²⁰ Efforts continue to better define the optimal treatment regimen for high-dose interferon versus other strategies in well designed clinical trials.

CLINICAL CONTROVERSY

There is significant controversy regarding the role of interferon- α as adjuvant therapy in high-risk patients after surgical resection of melanoma. Assessment of patient risk factors, availability of clinical trials, and cost of therapy should be evaluated prior to initiation of therapy.

The role of interferon in advanced disease is even more unclear, especially for those patients who have recurred after treatment with adjuvant interferon therapy. Interferon- α has been used as a single agent in patients with metastatic disease who have not received adjuvant therapy, and in combination with chemotherapy and/or other biotherapy for metastatic melanoma. The challenges of combination therapy are that many of the toxicities seen with interferon can be exacerbated by concomitant chemotherapy (e.g., nausea, vomiting, and neutropenia). In an attempt to limit systemic toxicity and to potentiate local benefits, the regional administration has been evaluated in a variety of settings. Intralesional and perilesional application of interferon has been shown to have some efficacy in small lesions and appears to be well tolerated.²⁶

INTERLEUKIN-2

Interleukin-2 (IL-2), a glycoprotein produced by activated lymphocytes, has been extensively studied in the management of metastatic melanoma. The precise mechanism of cytotoxicity of IL-2 is unknown; high concentrations of IL-2 have not been shown to have a direct antitumor effect on cancer cells in vitro. In vitro and in vivo, IL-2 stimulates the production and release of many secondary monocyte-derived and T-cell-derived cytokines, including IL-4, IL-5, IL-6, IL-8, tumor necrosis factor- α , granulocyte macrophage-colony stimulating factor, and interferon- γ , which may have direct or indirect antitumor activity. In addition, interleukin-2 appears to stimulate the cytotoxic activities of natural killer cells, monocytes, lymphokine-activated killer (LAK) cells, and cytotoxic T lymphocytes (CTLs). Although the clinical significance is not currently understood, preliminary studies have shown that several human melanoma cell lines express both α and β chains of the interleukin receptor that specifically bind to interleukin-2.

6 Based on preclinical studies that showed a dose-response relationship between recombinant IL-2 (aldesleukin) and tumor response, the initial clinical trials of aldesleukin in the treatment of patients with melanoma used relatively high doses of the drug as a single agent or in combination with LAK cells. The response rates seen in these trials ranged from 15% to 25%, and 2% to 5% of patients achieved complete responses, some of which were durable. Responses were seen at a number of metastatic sites such as lung, liver, bone, lymph nodes, and subcutaneous tissue. Based on the re-evaluation of early clinical trials,²⁷ recombinant IL-2 (aldesleukin) was approved by the FDA for treatment of metastatic melanoma. Overall, objective response rates were about 16%, but in some cases there were durable responses and responses seen in patients with large tumor burdens. The high aldesleukin doses used in the initial clinical trials and recommended in the labeling of the drug are associated with serious toxicities and may limit the practicality of therapy for individual patients and broad application in certain health care systems. At the

high doses (600,000 international units/kg per dose every 8 hours for 14 doses maximum) approved for treatment of metastatic melanoma, cytokine-induced capillary leak syndrome is a common problem and may be accompanied by hypotension, visceral edema, dyspnea, tachycardia, and arrhythmias. Increased permeability of capillary walls allows for a fluid shift from the intravascular space into tissue. As the patient becomes intravascularly dehydrated, hypotension may occur, resulting in reflex tachycardia and arrhythmias. In addition, the decrease in blood volume may result in decreased renal blood flow and urine output, manifesting as an increase in blood urea nitrogen, serum creatinine, edema, and weight gain, and a decrease in urine output (input greater than output). Visceral edema can result in pulmonary congestion, pleural effusions, and edema. The management of patients receiving high-dose aldesleukin requires careful monitoring and a staff trained in aspects of critical care such as hypotension management. Although some institutions manage patients receiving high-dose aldesleukin in an intensive care unit, most patients can be managed on a designated oncology unit. Additional side effects seen with aldesleukin include constitutional symptoms, pruritus and eosinophilia, bone marrow suppression including thrombocytopenia, an increase in liver function tests, and nausea.²⁸

CLINICAL CONTROVERSY

Although aldesleukin has been associated with long-term durable responses in a small subset of patients with metastatic melanoma, the toxicity profile, intensity of therapy, and cost has limited acceptance within the United States. Patients should be evaluated for treatment prior to initiation of therapy.

In an attempt to provide the benefit of aldesleukin therapy without the serious side effects, a number of studies have evaluated continuous-infusion aldesleukin therapy, and lower-dose aldesleukin alone or with chemotherapy and interferon therapy. Response rates have been promising, but survival has not been significantly affected. At this time, direct head-to-head comparisons of various dosing schedules and regimens are needed to determine the optimum approach to aldesleukin therapy in metastatic melanoma. The coadministration of LAK cells with aldesleukin does not appear to significantly improve clinical response. Although some studies have suggested improved response with coadministration of TILs with recombinant IL-2, the therapy is technically difficult and costly, and the overall clinical benefit has not been clearly demonstrated.

Histamine has been shown to inhibit the generation of reactive oxygen species by phagocytes and ultimately preserve natural killer cell and T-cell responsiveness to IL-2. Preclinical work led to a series of clinical trials evaluating the combination of aldesleukin and histamine dihydrochloride with the hope that the combination would increase the efficacy of aldesleukin in patients with metastatic melanoma. It was also hoped that lower doses of aldesleukin would allow for outpatient treatment for metastatic melanoma. In initial clinical trials, aldesleukin was administered subcutaneously with or without histamine dihydrochloride. A survival advantage was seen with the combination in a subset of patients, those patients with liver metastases.²⁹ Constitutional toxicities were common but less than those seen with high-dose aldesleukin; patients were able to maintain therapy at home. The addition of histamine dihydrochloride resulted in a significant toxicity secondary to the effects of the histamine, including vasodilation, cardiovascular effects, and injection-site reactions. Most toxicities were mild, except for headaches, and were managed symptomatically.³⁰

One of the greatest challenges in the management of patients with metastatic melanoma with immunotherapy is to determine for

an individual patient if the potential benefits of aldesleukin therapy outweigh the substantial risk. It is obvious from the reports of long-term responses (greater than 10 years) in some patients that the risk is certainly worth the benefit for those individuals. A number of parameters such as human leukocyte antigen (HLA) expression and pretreatment immunologic status have been evaluated as potential predictors to therapy. Unfortunately, at this time it is difficult to determine which individuals will respond to aldesleukin therapy, as no biologic or immunologic parameters have been found to correlate with response. The decision to treat an individual with high-dose aldesleukin should be based on an analysis of an individual patient's risk versus potential benefit. Patients with inadequate pulmonary function, cardiac function, renal insufficiency, active infection, or poor performance status are poor candidates for this therapy. Aldesleukin can be safely administered with a properly trained health care team, and is one of only two approved therapies for treatment of metastatic melanoma.

VACCINES

The rationale for vaccination as a therapeutic modality is based on the observation that tumor cells differ antigenically from normal cells, and the hope that vaccines might induce effective tumor-specific immune responses with fewer toxicities than conventional chemotherapy or other immunotherapies. Greater knowledge about tumor antigens and the mechanism of antigen presentation and immune response to antigens has led to the development of several vaccination strategies for the treatment of early and advanced melanoma. A number of these vaccine approaches are being evaluated in both metastatic disease and in the adjuvant setting (Table 133–7).^{31,32}

Active immunization is one of the well-characterized strategies for immunotherapy of melanoma. Current melanoma vaccines upregulate the antibody response of CTLs to specific tumor antigens. Melanoma antigens are either tumor-associated antigens (TAAs) or melanoma-associated antigens (MAAs). TAAs are common to melanoma cells and other tumor cells, while MAAs are usually proteins or glycoproteins found predominantly in melanomas and less commonly in normal melanocytes. The use of TAAs or MAAs for melanoma vaccines can be difficult, as the expression of antigens in melanoma cells is often heterogeneous and may change in response to the patient's immune response. Unfortunately, MAAs and TAAs also tend to be weakly immunogenic, although immunogenicity can be increased by physical alterations.

Melanoma vaccines range from complex antigen mixtures to purified antigens. Complex vaccines are polyvalent and can stimulate an immune response to a number of tumor antigens and are less

susceptible to antigenic modulation by the cancer cells. Single-antigen vaccines can be problematic if a single-resistant-antigen-negative tumor cell develops.

Melanoma vaccines can be prepared from a patient's own tumor (autologous preparations), and will therefore target antigens from that patient's melanoma cell. Autologous vaccines may involve modification of the tumor cells with a hapten to increase immunogenicity of the preparation. Allogeneic preparations do not require patient tissue to prepare the vaccine. Allogeneic preparations often include a number of cell lines to increase the content of immunogenic TAAs and MAAs.

Melanoma vaccines may also be prepared with tumor cell lysate. Lysate vaccines can be prepared from the whole cells or from the cellular elements most likely to contain the antigens important for the induction of protective immune responses. Material shed from the melanoma cells is believed to be rich in cell-surface antigens and has been used for preparation of a melanoma vaccine. Melacine is a lysate vaccine prepared from two human melanoma cell lines administered with an adjuvant immunostimulant monophosphoryl lipid A and purified mycobacterial cell-wall skeleton called DETOX.³³ Initial reports from uncontrolled clinical trials with Melacine have suggested a role in the treatment of patients with surgically resected and metastatic melanoma. It is thought that a subset of patients defined by HLA subtypes showed benefit, suggesting that this vaccine therapy may be a targeted approach for select patients. CancerVax is a polyvalent allogeneic whole-cell vaccine developed by Morton,³⁴ which is comprised of an irradiated live-cell preparation of three allogeneic melanoma cell lines selected for their high content of MAAs and TAAs. BCG is used as an adjuvant and the vaccine is administered intradermally. CancerVax is being evaluated for the postsurgical treatment of stage III melanoma and in stage IV disease after surgical resection.

An alternative approach to vaccine construction is to develop a vaccine from a single highly-specific antigen. Preparations currently in clinical trials include vaccines prepared from gangliosides, peptides such as MAGE or MART, and anti-idiotypic monoclonal antibodies. Gangliosides G_{M2}, G_{D2}, G_{M3}, G_{D3}, and O-acetyl-G_{D3} are present on the surface of many melanoma cells, but G_{M2} is the most consistently expressed and immunogenic antigen. One vaccine composed of the ganglioside G_{M2} coupled with keyhole limpet hemocyanine is being evaluated in the adjuvant setting. The vaccines from a single antigen have the advantage that they can be prepared in a reproducible manner on a large scale. The problem with this approach is that it is unclear if targeting a single antigen or peptide on a melanoma will be sufficient to kill the tumor cell. As with other approaches for targeted therapy, there is a concern that cancer cells will develop strategies to circumvent the targeted treatment approach.

■ OTHER APPROACHES

Dendritic cells are potent antigen-presenting cells for the initiation of antigen-specific immune responses. Dendritic cells express high levels of major histocompatibility complex class I and class II molecules, which are essential in antigen presentations. Activation of T cells and recruitment of non-antigen specific effectors, such as natural killer cells and macrophages, result in a broad immune response. One strategy to use dendritic cells for inducing antitumor immune responses has been done with peptide-pulsed dendritic cells. Antimelanoma CTLs can be generated from healthy donors and patients with melanoma with dendritic cells pulsed with melanoma-derived peptides. A number of clinical trials are evaluating dendritic cell-based immunotherapy.³⁵

Monoclonal antibodies have been used for the diagnosis and treatment of melanoma. Two strategies have been pursued: treatment

with a monoclonal antibody to activate the host immune system, and treatment with a conjugated monoclonal antibody (i.e., immunconjugate). Monoclonal antibodies have been conjugated to cytotoxic agents, radioisotopes, and toxins such as ricin A. Trials of monoclonal antibodies were initially limited secondary to the production of the monoclonal antibody. A problem seen in current studies is the induction of neutralizing antibodies to the murine monoclonal antibodies. Chimeric, humanized, or pure human monoclonal antibodies against MAAs could potentially avoid the development of human antimouse antibody. A vaccine which is composed of three monoclonal anti-idiotypic antibodies that include the internal image of several determinants of the MAA has been developed and looked at in clinical trials. One of the problems with this antibody is the inability to directly induce a cell-mediated antitumor effect; therefore adjuvants are now being used to increase the ability of the anti-idiotypic antibodies to induce a greater immune response.

Gene therapy of human melanoma is still in its infancy, but suggests several exciting approaches to the management of metastatic melanoma. Several strategies for gene therapy are currently under investigation for the treatment of melanoma. One approach to gene therapy for melanoma is the modification of melanoma cells with the insertion of one or more cytokine genes, and then administering these altered allogeneic or autologous cells as a vaccine. Cytokine gene transduction has been accomplished with a number of cytokines including aldesleukin (IL-2), tumor necrosis factor- α , IL-4, and interferon. It is hoped that the insertion of cytokine genes into melanoma cells will significantly increase the cells' immunogenicity.

Genes can also be transferred *in vitro* into TILs associated with melanoma in an attempt to potentiate the cytotoxicity of these cells. Rosenberg and colleagues were the first to attempt to transduce the gene coding for resistance to neomycin into human TILs. This approach has since been used to transfer the tumor necrosis factor gene into TILs.

Thalidomide and thalidomide analogs are also being evaluated in the management of melanoma. Thalidomide, given as either a single agent or in combination with chemotherapy or cytokines, is being evaluated in a variety of studies. Thalidomide analogs are also being evaluated to try and avoid toxicities associated with the parent compound. The thalidomide analogs are grouped into two classes; the selective cytokine inhibitory drugs and the immunomodulatory derivatives. Both classes appear to have antiangiogenic and anti-inflammatory properties, but the selective cytokine inhibitory drugs are phosphodiesterase inhibitors. Immunomodulatory derivatives also have effects on T-cell stimulation and inhibition of tumor necrosis factor- α . Several of these agents are being evaluated in clinical trials in metastatic melanoma.

■ CHEMOTHERAPY

A number of cytotoxic agents have demonstrated *in vitro* activity to melanoma; only a few drugs have consistently shown a response rate greater than 10% in patients with melanoma. Since chemotherapy has rarely cured a patient with melanoma, the primary goal of chemotherapy is palliation.³⁶ The results of clinical trials are generally expressed in terms of response rates. The response rate usually includes the fraction of patients who experience a partial response plus those who experience a complete response. Partial response criteria vary but may require a 50% reduction of the tumor for a minimum of 1 month. A complete response would require total regression of all metastases for at least 1 month and is uncommon (<5%). It is essential to realize that these response rates do not reflect survival,

and do not evaluate benefit to the patient. Response rates also do not represent the toxicities and the complications of therapy.

5 **Dacarbazine**, a cytotoxic drug thought to exert its antitumor effect through alkylation, is currently the most effective single agent for the treatment of melanoma. Dacarbazine remains the only FDA-approved chemotherapeutic agent for the treatment of metastatic melanoma in the United States. In prospective controlled clinical trials, response rates of 10% to 25% have been seen, with an average duration of response of 5 to 7 months. Complete responses are uncommon, with a dismal 2% of patients treated with single-agent dacarbazine sustaining long-term complete responses. There does not appear to be a survival benefit for dacarbazine relative to other treatments or supportive care. Early clinical trials demonstrate patients with skin, subcutaneous tissue, and lymph node involvement respond most frequently, whereas metastatic disease to the liver, bone, and central nervous system are often unresponsive. The optimum dose schedule of dacarbazine has never been determined; therefore single-dose regimens are often preferred for patient convenience. Common side effects of dacarbazine therapy include moderate myelosuppression, severe nausea and vomiting, and a flu-like syndrome after large doses. The nausea and vomiting can be prevented and managed with available antiemetics and is not a major complication. At this time, there is no known role of dacarbazine in the adjuvant setting.

Temozolomide is one of a series of imidazoletetrazine derivatives that was developed as a potential alternative to dacarbazine. Temozolomide is a prodrug of the active metabolite of dacarbazine. Dacarbazine requires hepatic transformation to its active intermediate, whereas at physiologic pH, temozolomide chemically degrades to the cytotoxic triazene monomethyl 5-triazeno imidazole carboxamide. Temozolomide is administered orally and appears to be less emetogenic than dacarbazine. Temozolomide appears to cross into the central nervous system, and therefore was initially thought to have benefit for patients with CNS metastases. In chemotherapy-naïve individuals with metastatic melanoma, response rates for temozolomide are similar to those seen with dacarbazine.

The **nitrosoureas** have also been shown to be active against melanoma. Nitrosoureas, such as carmustine and lomustine, have antitumor activity similar to dacarbazine, with reported response rates between 10% and 20%. Sites of responses are similar to those seen with dacarbazine. It was initially thought that there may be an added benefit to the use of the lipophilic nitrosoureas in a malignancy that can metastasize to the brain. Unfortunately, despite the ability of these agents to cross the blood-brain barrier, the commercially available nitrosoureas have not been shown to produce an increased response in melanoma in the central nervous system. Fotemustine, a nitrosourea available in Australia and some European countries, appears to cross the blood-brain barrier more rapidly than other nitrosoureas. Response rates of 30% have been reported in previously untreated patients, with response rates of 25% of patients who had cerebral metastases. Fotemustine is considered standard therapy in some countries.³⁷ The most common toxicity of the nitrosoureas is delayed myelosuppression, particularly thrombocytopenia. Leukopenia and thrombocytopenia may be seen as long as 3 to 5 weeks after drug administration, and may limit the inclusion of these agents to multidrug regimens.

Cisplatin and related compounds have also been evaluated in the management of metastatic melanoma. The effectiveness of platinum compounds as single agents is limited, with response rates reported to be less than 10%. The toxicities of cisplatin can be problematic, and include acute and delayed nausea and vomiting, renal toxicity, and neurotoxicity.

TABLE 133–8. Combination Chemotherapy Regimens for Metastatic Melanoma

| |
|---|
| Dartmouth regimen (CDBT): repeated every 3–4 weeks |
| Cisplatin 25 mg/m ² IV daily × 3 (days 1, 2, and 3) |
| Dacarbazine 220 mg/m ² IV daily × 3 (days 1, 2, and 3) |
| Carmustine 150 mg/m ² IV daily × 1 (day 1) |
| Tamoxifen 10 mg orally twice a day |
| CVD |
| Cisplatin 20 mg/m ² IV daily × 4 (days 2, 3, 4, 5) |
| Vinblastine 1.6 mg/m ² IV daily × 5 (days 1, 2, 3, 4, 5) |
| Dacarbazine 800 mg/m ² IV daily × 1 (day 1) |

Taxanes have demonstrated encouraging results in initial trials of metastatic melanoma but require further evaluation to warrant the toxicities commonly seen.

COMBINATION CHEMOTHERAPY

In an attempt to extend the efficacy seen with single agents, a variety of combination chemotherapy regimens (Table 133–8) have been evaluated in small and large clinical trials; response rates reported are as high as 30% to 50% in single-institution phase II trials in patients with metastatic melanoma. The combination of dacarbazine with other chemotherapy, most commonly cisplatin, has been able to increase the response rates reported with dacarbazine alone, but the survival benefit has been minimal. Again, responses were often limited to metastases in soft tissue, lymph nodes, and the lung—the sites most likely to respond to single-agent dacarbazine therapy. The concern with combination chemotherapy is increased toxicity, and any reports of an increase in response rates should be weighed against the effect of toxicities on overall quality of life. The initial reports with CVD regimen (cisplatin, vinblastine, and dacarbazine) were exciting; reported response rates were greater than 50% and were seen with acceptable toxicities. Comparisons of this regimen to dacarbazine alone have been conflicting. Initial studies indicated an increase in response rate, response duration, and survival benefit with the combination regimen. Subsequent reports showed no difference in response rates or survival.

The Dartmouth regimen is a combination chemotherapy regimen that includes carmustine, dacarbazine, cisplatin, and tamoxifen. Initial reports from uncontrolled phase II trials of this combination have demonstrated high response rates of 20% to 50%, but few patients achieve long-term survival. The benefit of tamoxifen to this regimen has been controversial, but a controlled clinical trial from the National Cancer Institute of Canada demonstrates no benefit in response or survival from tamoxifen in this combination.³⁸ Careful analysis of the initial studies demonstrates that the criteria used to measure response were not consistent with standards used in large multicenter studies. Phase III trials have shown no benefit for the Dartmouth regimen as compared to single-agent dacarbazine.^{39,40} Response rates were 15%, and median survival was about 7 months in both studies. Of concern, toxicities were higher with the combination study and included bone marrow suppression, nausea, vomiting, and fatigue.

ENDOCRINE THERAPY

The role of endocrine therapy in the management of melanoma has been debated over the last decade. Initial reports that described high-affinity cytoplasmic estrogen receptors in patients with metastatic

melanoma caused some experts to speculate about the possibility that antiestrogens or other hormonal manipulation may be beneficial to modulate the biology of melanoma. Additionally, estrogens have been shown to suppress T-lymphocyte activity and to suppress or stimulate the activities of B lymphocytes, macrophages, and natural killer cells, supporting a hypothesis that estrogens may influence the immunologic mechanisms that appear to be important in melanoma.

Tamoxifen was shown to have a response and survival benefit in a randomized trial when combined with dacarbazine in patients with metastatic melanoma; this benefit was most pronounced in women. Well designed prospective randomized studies demonstrate that tamoxifen does not significantly enhance the antitumor effect of dacarbazine alone or of the combination of dacarbazine with cisplatin and carmustine. As discussed previously, subsequent trials have not been able to confirm the initial reported benefit of the antiestrogen when combined with chemotherapy, and tamoxifen is no longer routinely included in chemotherapy regimens.

BIOCHEMOTHERAPY

Low overall response rates and toxicity have limited the routine use of chemotherapy alone or immunotherapy alone in the management of metastatic disease. Over the past decade, the strategy of a combination of chemotherapy and cytokines, aldesleukin and/or interferon, often termed *biochemotherapy*, has been a major focus of investigation in the management of metastatic melanoma and more recently in the adjuvant setting. The primary rationale is to combine two therapies with some biological activity to increase overall activity, and perhaps response rates. Additionally, some preclinical trials suggest potential synergistic interactions between cytokines and some chemotherapy agents. As with other treatment strategies in melanoma, the results from initial trials suggested a higher response rate with biochemotherapy than those seen with either chemotherapy or biotherapy alone. Although several studies have suggested an increase in response rate with the addition of interferon to chemotherapy, results of most studies show that the addition of interferon does not increase the antitumor effect of dacarbazine, but does increase toxicity and cost. Similarly, the combination of aldesleukin to chemotherapy has not been consistently shown to increase response or survival. The most encouraging results have been seen with combination chemotherapy and combination biotherapy, but the results of phase III studies have not demonstrated a

clear advantage of biochemotherapy as compared to chemotherapy alone.⁴¹ Results to date suggest response rates similar to or slightly better than those seen with dacarbazine alone, with increased toxicity. Toxicities can be severe, and are consistent with the individual agents in the regimen.

One of the problems seen in most studies of biochemotherapy is the relatively short duration of response. Recurrence rates among patients who do respond to therapy are as high as 50% within 18 to 24 months. Strategies such as subcutaneous low-dose interleukin-2 are being investigated in an effort to prolong overall survival and time to progression in the patients who do respond to treatment. The initial response rates, durable complete remission, and activity in those patients in which HDI therapy has failed has stimulated interest in evaluating biochemotherapy in the adjuvant setting for patients with high-risk node-positive patients as compared to HDI.

LIMB PERFUSION AND LIMB INFUSION

Isolated limb perfusion (ILP)^{42,43} is a surgical procedure of regional intravascular delivery of chemotherapy and/or biotherapy into an extremity with cutaneous melanoma. ILP is a method to escalate the dose of chemotherapeutic drugs in a specific region of the body while limiting the systemic toxicities of the agent. The majority of perfusions can be performed with drug exposures of less than 2%. The most significant side effect of ILP is regional toxicity; all of the skin, subcutaneous tissue, and tissue of the extremity receives the same dose and is subjected to the same perfusion conditions as the tumor located within the extremity. After regional perfusions, objective response rates have been reported to exceed 50% in treated limbs and overall response rates may be as high as 80%. The role of hyperthermia (39° to 40°C) with regional isolated perfusion is not clearly defined. Although most clinical trials have used melphalan, it is not known whether the combination of melphalan with other agents may improve results. Agents that have been combined with melphalan include actinomycin D, nitrogen mustard, thiotepa, and cisplatin. Recent work with the biologic response modifiers, such as tumor necrosis factor- α , have been encouraging. A simplified form of ILP, called isolated limb infusion (ILI), is a low-flow ILP performed under hypoxic conditions via small caliber arterial and venous catheters. It has been proposed that the hypoxia that develops during ILI may be beneficial with certain cytotoxic agents such as melphalan.

PREVENTION AND DETECTION

The results of early treatment emphasize the role for early detection and prevention. The American Academy of Dermatology recommends monthly self-examination of skin to serve as a mechanism of recognizing moles or marks on the skin that may be melanoma. Patients with a strong family history should have a clinical examination, and in some cases, screening photography to document size, shape, and location of moles.

Education and re-education about the importance of sun protection has the potential to help decrease the rising incidence of this disease. Historically, patients have been counseled that the risk of skin cancer can be limited by the use of sunscreens with a sun protection factor (SPF) of 15 or greater. It is important to include counseling about the appropriate use of sunscreens to optimize benefits from these products. One study noted that most consumers typically

apply less sunscreen than is needed to establish the SPF number on the bottle; the actual SPF received is 20% to 50% of that number.^{44,45} Sunscreens should be applied 15 to 30 minutes before going into the sun, and should be reapplied every 2 hours, after swimming, and after perspiring heavily.

Sunscreen lotions are more efficient in protecting against shorter ultraviolet wavelengths that lead to sunburns, than in protecting against the longer wavelengths in the UVA range which may lead to skin damage and skin cancers such as melanoma. It is not clear what the impact of the use of high potency sunscreens will have on the incidence of melanoma, as the lag time for melanoma is about two decades and the high potency sunscreens have only been popular for about 10 years.

It is important to educate the public that sunscreens should not be used to increase time in the sun. The slogan, “Slip! Slop! Slap!” (slip on a shirt, slop on the sunscreen, and slap on a hat), initially

TABLE 133–9. Sunscreens

| Physical Blockers (Reflectants) | Chemical Absorbers |
|---------------------------------|-------------------------|
| Zinc oxide | Ultraviolet B absorbers |
| Talc | Salicylates |
| Titanium dioxide | Chinnamates |
| Red petrolatum | Campho derivatives |
| | Aminobenzoates |
| | Ultraviolet A absorbers |
| | Benzophenone-6 |
| | Dibenzoylmethanes |

developed for public health campaigns in Australia, provides a more comprehensive approach to sun protection. Sun avoidance, especially during the peak hours of the sun intensity (10 AM to 4 PM), use of protective clothing and head coverings, and staying in the shade when outdoors are important education concepts for those individuals who are in the sun for prolonged periods of time and/or who are at high risk of burning (Table 133–9).⁴⁶

EVALUATION OF THERAPEUTIC OUTCOMES

The outcome of patients treated with melanoma depends on the stage of disease at presentation. The prognosis of patients with thin tumors (<1 mm in thickness) and localized disease is good, with long-term survival in more than 90% of patients. There is risk of regional nodal involvement with increasing tumor thickness, and therefore survival rates decrease in patients with nodal involvement. Long-term survival in patients with distant metastases is even lower. Therefore early diagnosis and appropriate treatment of early disease is essential. Patients with suspicious pigmented lesions should be evaluated and have the lesion excised whenever possible. Treatment is determined by patient factors and stage of disease.

There is no clear recommendation regarding appropriate follow-up of patients with melanoma. Clinical practice guidelines published by the NCCN provide some guidance for follow-up of patients with melanoma.²⁵ Intensive surveillance has the benefit of early detection of recurrent disease, which may lead to better options of surgical resection. Emphasis on evaluation of locoregional areas is important. For patients with in situ melanoma periodic skin examinations for life are recommended, although frequency is determined based on patient risk factors. For patients with stage IA disease, comprehensive history and physical examination is recommended every 3 to 12 months, again based on individual patient risk factors. Individuals with stage IB to III melanoma should have history and physical examination every 3 to 6 months for 3 years; then every 4 to 12 months for 2 years; and annually thereafter. Patients with stage IV disease who are disease-free after treatment should be followed as outlined for patients with stage III disease.

Local recurrence is associated with aggressive tumor biology and is frequently a manifestation of an aggressive primary tumor. If a local recurrence occurs after inadequate primary disease, the patient should undergo a work-up based on the lesion thickness of the original melanoma. Patients with nodal recurrence should be evaluated for lymph node metastases. Patients with systemic recurrence should be evaluated and treated in a fashion similar to those patients presenting with systemic disease.

ABBREVIATIONS

HEMATOPOIETIC STEM CELL TRANSPLANTATION

Janelle B. Perkins and Gary C. Yee

Learning Objectives and other resources can be found at www.pharmacotherapyonline.com.

KEY CONCEPTS

- 1 Hematopoietic stem cell transplantation (HSCT) is a process that involves intravenous infusion of hematopoietic stem cells from a donor into a recipient, following the administration of chemotherapy with or without radiation. The rationale is to increase tumor cell kill by increasing the dose of chemotherapy. Immune-mediated effects may also contribute to the tumor cell kill observed after allogeneic HSCT.
 - 2 Hematopoietic stem cells used for transplantation can come from the recipient (autologous) or from a related or unrelated donor (allogeneic). If the related donor is a twin, the transplant is referred to as a syngeneic transplant.
 - 3 Human leukocyte antigen (HLA) mismatching of allogeneic donor-recipient pairs at either class I or class II loci correlates with the risk of graft failure, graft-versus-host disease (GVHD), and survival. The ideal donor is one that is matched at HLA-A, -B, -C, and DRB1.
 - 4 Hematopoietic stem cells are found in the bone marrow, peripheral blood, and umbilical cord blood. Because of the rarity and similarity to other cells, hematopoietic stem cells are difficult to isolate and measure. These stem cells express the CD34 antigen, and the number of CD34⁺ cells has become a clinically useful measure of the number of hematopoietic stem cells.
 - 5 Due to clinical and economic advantages, peripheral blood has replaced bone marrow as the source of hematopoietic stem cells in the autologous HSCT setting. Peripheral blood stem cells are increasingly used in allogeneic HSCT.
 - 6 The purpose of the preparative (or conditioning) regimen in traditional myeloablative transplants is two-fold: (1) maximal tumor cell kill and (2) immunosuppression of the recipient to reduce the risk of graft rejection (allogeneic HSCT only).
 - 7 Posttransplant immunotherapy is based on the graft-versus-tumor (GVT) effect caused by certain subsets of T cells responsible for eradication of malignant cells. Posttransplant immunotherapy includes the use of donor lymphocyte infusions, immunomodulatory cytokines, monoclonal antibodies, or antitumor vaccines.
 - 8 Reduced intensity or nonmyeloablative transplants have been developed in order to reduce early posttransplant morbidity and mortality while maximizing the GVT effect of the allogeneic graft. The advantage to this approach is that many patients who would otherwise not be eligible for allogeneic HSCT can now be offered a potentially curative therapy.
 - 9 Transplant-related mortality associated with allogeneic HSCT ranges from 10% to 80% depending mostly on age, donor, and disease status. Major causes of death include infection, organ toxicity, and GVHD. The most common cause of death post-autologous HSCT is disease relapse; transplant-related mortality is usually less than 5%, depending on the conditioning regimen, age, and disease status.
 - 10 Treatment of acute GVHD is often unsuccessful and the resulting complications can be fatal. Patients undergoing allogeneic HSCT are given prophylactic immunosuppressive therapy which inhibits T-cell activation and/or proliferation. The most commonly used GVHD prophylaxis regimens are cyclosporine or tacrolimus and methotrexate.
 - 11 Treatment of chronic GVHD consists of prednisone alone, or alternate-day prednisone and either daily or alternate-day cyclosporine. Tacrolimus can be substituted for cyclosporine.
- 1 Hematopoietic stem cell transplantation (HSCT) is a process that involves intravenous infusion of hematopoietic stem cells from a compatible donor into a recipient, usually following administration of high-dose chemotherapy. Hematopoietic stem cells can be derived from the bone marrow, peripheral blood, or umbilical cord blood. The rationale for HSCT in the treatment of malignant disease is based on studies that show that most anticancer drugs have a steep dose-response relationship and that bone marrow suppression limits the chemotherapy dosage that can be safely administered. Although standard-dose chemotherapy can prolong survival in many cancer patients, most patients are not cured of their disease (Fig. 134-1). The infusion of hematopoietic stem cells allows oncologists to administer very high chemotherapy doses (as much as 10-fold higher). If tumor cells that are resistant to standard doses are sensitive to higher doses

FIGURE 134-1. Patients represented by the middle column are the best candidates for hematopoietic stem cell transplantation because this technique allows administration of chemotherapy or radiation in doses that would otherwise be intolerable due to severe myelosuppression.

of chemotherapy, then tumor cell kill will be greatly increased, and the likelihood of cure would be higher with HSCT. The chemotherapy dose cannot be escalated indefinitely, however, because of the risk of death caused by nonhematopoietic toxicity. The success and increasing use of nonmyeloablative transplants (NMT) shows that immune-mediated effects may also contribute to the tumor cell kill observed after allogeneic HSCT.

High-dose chemotherapy followed by HSCT has become an important treatment modality for a variety of malignant and non-malignant diseases. Approximately 45,000 transplants are performed worldwide each year, primarily for malignant diseases.¹ About 40% of these transplants are performed in North America. The number of transplants has declined in recent years because of declining use for breast cancer (autologous) and chronic myelogenous leukemia (allogeneic).

Historically the most common type of donor was a genetically nonidentical individual such as a histocompatible sibling (referred to as allogeneic HSCT [alloHSCT]). But the number of autologous transplants—in which the patient serves as his or her own donor—has increased dramatically, and the number of autologous transplants (autoHSCT) performed (about 30,000) currently exceeds the number of alloHSCTs (about 15,000) performed each year.¹ Although this chapter focuses on the application of HSCT in the treatment of malignant disease, it is important to note that many nonmalignant diseases—including aplastic anemia, thalassemia, sickle cell anemia, immunodeficiency disorders, and other genetic disorders—are potentially curable with alloHSCT. Transplantation is also being investigated as a treatment modality in patients with life-threatening autoimmune diseases such as rheumatoid arthritis, systemic and multiple sclerosis, and systemic lupus erythematosus.

This chapter summarizes the procedures involved in HSCT, and current issues in the field of HSCT, as well as the application of HSCT in the treatment of malignant diseases. More detailed information on HSCT can be found in recently published reviews and books.²⁻⁴ Information on HSCT can also be found on several Web sites (www.Bmtinfo.org, www.IBMTR.org, and www.Marrow.org).

DONORS AND HISTOCOMPATIBILITY TESTING

2 Different types of donors are used in HSCT. In *autologous* transplants, patients receive their own hematopoietic stem cells that were collected and stored before intensive cytotoxic therapy. In

syngeneic transplants, an identical twin serves as the donor. In *allogeneic* transplants, the donor is genetically not identical to the recipient, but shares some common tissue antigens. Immunologic compatibility is evaluated with studies of cell surface antigens encoded by genes of the major histocompatibility complex (MHC), which is located on the sixth chromosome and is referred to as the HLA (human leukocyte antigen) complex.⁵ The genes of the HLA system are clustered in three distinct regions designated as class I, class II, and class III. Class I and class II antigens function as major transplantation antigens, while products of class III genes play other important roles in the immune system. The major class I loci in humans are referred to as HLA-A, HLA-B, and HLA-C. There is one major class II locus (HLA-D); class II genes encode for the α and β polypeptide chains of the class II molecules. The designation of class II genes consists of three letters: the first (D) indicates the class, the second (M, O, P, Q, or R) the family, and the third (A or B) the chain (α and β , respectively). Class I and class II antigens differ in their tissue distribution, structure, and function. Class I antigens are expressed on virtually all nucleated cells and serve as the primary targets for cytotoxic T lymphocytes. In contrast, class II antigens are normally expressed only on macrophages, B lymphocytes, and activated T lymphocytes, and serve as the primary targets for helper T lymphocytes.

Historically, the most important HLA loci in alloHSCT were HLA-A, HLA-B, and HLA-D (or HLA-DR [D-related]). Typing for HLA-A, HLA-B, and HLA-DR has been traditionally performed by serologic typing with standard microcytotoxicity assays.⁶ HLA types determined by this method are reported as the loci (A, B, or DR), followed by a number (e.g., HLA-A2). Typing for the HLA-D region also can be performed with cellular typing methods, such as the mixed lymphocyte reaction (MLR) or mixed lymphocyte culture (MLC). A “positive” MLR or MLC indicates incompatibility somewhere in the HLA-D region. Individuals who have a low degree of reactivity in the MLR or MLC (expressed as a low percentage of relative response), and who meet other selection criteria, could serve as donors. However, HSCT centers no longer use this method alone to determine HLA-D compatibility because studies show that MLR or MLC reactivity does not correlate significantly with the risk of acute graft-versus-host disease (GVHD) or graft failure.

Serologic methods detect *antigen* mismatches because they are based on the formation of alloantibodies against specific HLA antigens. However, any given HLA antigen can be encoded by a family of HLA alleles that differ by only a few amino acids. Over 100 alleles at HLA-A, 200 at HLA-B, and 50 at HLA-C have been identified in different human populations. The HLA class II DRB and DPB loci are extremely polymorphic, with over 200 DR alleles and over 75 DP alleles. Different alleles encoding the same antigen can be distinguished only by high-resolution (i.e., DNA-based) typing techniques such as polymerase chain reaction (PCR)-based techniques. As discussed later, these *allele* mismatches may have an adverse effect on patient outcome.

3 HLA mismatching at either class I and II loci correlates with the risk of graft failure, GVHD, and survival.⁶ HLA *antigen* mismatches, particularly when they involve both class I and II antigens, are generally more important risk factors than *allele* mismatches. In an analysis of 1,876 patients who received matched unrelated donor (MUD) transplants under the auspices of the National Marrow Donor Program, high- or low-resolution mismatches at HLA-A, B, C, and DRB1 each had similar adverse effects on mortality.⁷ Only HLA-A mismatches were associated with an increased risk of GVHD. However, among patients who received transplants from “6 antigen matched” (HLA-A, B, and DRB1 matched) donors, the number of allele mismatches correlated with the risk of grades III through IV acute GVHD and survival. The observation concerning the prognostic

importance of HLA-C is particularly important, since this locus is omitted in most matching algorithms.

The most common donor for alloHSCT is an HLA-identical sibling. The odds that any one full sibling will match a patient are one in four. Only about 30% of Americans have an HLA-identical sibling. In an effort to offer alloHSCT to patients who lack an HLA-identical sibling donor, alternative donors are being used. Rarely, a parent can be HLA identical with his or her child. A relative can be a zero- (rare), one-, two-, or three-loci antigen mismatch (assuming testing for HLA-A, -B, and -DR antigens). It is estimated, however, that only an additional 10% of patients will have a closely HLA-matched related donor.

The most common type of alternative donor is an individual unrelated to the recipient who is fully or closely HLA matched. To facilitate identification of these donors, the National Marrow Donor Program (NMDP) was started in 1986 with initial funding from a U.S. Navy contract. To date, more than 5 million donors in the United States have been registered by the NMDP and the NMDP has facilitated more than 20,000 MUD transplants. About one-third of the alloHSCTs performed worldwide are from unrelated donors. The NMDP currently requires that the selected donor and recipient are matched at HLA-A, -B, and -DRB1; low/intermediate resolution typing is required at HLA-A and -B, while high-resolution typing is required at DRB1. Since each patient has two phenotypes for each locus (one from each parent), matching is analyzed at six antigens (or alleles). Therefore, a “completely” matched (i.e., “6 of 6 match”) unrelated donor is matched for HLA-A, -B, and -DR (or DRB1). A “closely” matched unrelated donor is usually incompatible at one HLA antigen. In addition to HLA-A, -B, and -DR (or DRB1), some NMDP transplant centers require additional testing for HLA-C (i.e., “8 of 8 match”). Based on the results of the recent study by Flomenberg and colleagues,⁷ the NMDP plans to require HLA-C typing and high-resolution typing for all MUD transplants in the near future.

The ideal unrelated donor is an allele-matched donor at HLA-A, -B, -C, and DRB1 (i.e., “8 of 8 match”). However, given the extreme polymorphism of the HLA system, most patients who undergo matched unrelated donor HSCT will not have an allele-matched donor. Furthermore, the cost of conducting a search for an allele-matched donor would be prohibitive in most patients, and prolongation of the search process would increase the risk of relapse in patients with high-risk hematologic malignancies. The following guidelines should be used in unrelated donor selection: (1) assume that HLA-A, -B, -C, and DRB1 are equally important; (2) avoid antigen mismatches, if possible; (3) accept one allele mismatch over one antigen mismatch; and (4) minimize the number of allele mismatches.⁸

The likelihood of any one unrelated individual being an antigen-level match ranges from 1 in 100 to 1 in 1,000,000, depending on the prevalence of the patient’s HLA type and ethnic background. With the current size of the NMDP registry, the matching likelihood is higher than 80% for Caucasians. Because most minorities are not as well represented in the program as whites, the likelihood of finding a donor for patients from certain ethnic groups is lower. Another limitation is the time needed to search for a potential donor. The average length of time from donor search to transplant is 3 to 4 months. Many patients with acute leukemia may relapse while waiting for completion of the search. Cost is also a concern, as the cost for donor search and marrow procurement ranges from \$25,000 to \$50,000. About two-thirds of MUD transplants are performed in patients with some form of leukemia, with chronic myelogenous leukemia (CML) being the most common diagnosis.

The clinical results of alloHSCT with alternative donors are encouraging. Although some patients who receive hematopoietic stem cells from an alternative donor are probably cured of their disease, the

risk of transplant-related mortality is high. In a study of nearly 3,000 patients with chronic myelogenous leukemia treated with alloHSCT, transplant-related mortality was significantly higher after alternative donor transplants than after HLA-identical sibling transplants.⁹ The difference in mortality was primarily related to a higher risk of graft failure and acute GVHD. Improved methods in HLA matching and supportive care have led to improved outcomes over the past few years.⁶ Results of a recent study showed that patients with chronic myelogenous leukemia who received matched (6 of 6) unrelated donor transplants while in the early chronic phase (i.e., within 1 year from diagnosis) had similar disease-free survival as those who received matched sibling transplants.⁹ When transplant was delayed beyond 1 to 2 years, however, outcome for the MUD transplants was worse than for those who received matched sibling transplants.

Allogeneic HSCT from a matched sibling or unrelated donor is not an option for some patients. In those cases, relatives who are partially HLA matched (i.e., mismatched) can serve as donors. About 10% of alloHSCTs are performed from related donors who are partially HLA matched. Although some patients who receive transplants from mismatched related donors experience long-term survival, the risks of graft failure and acute GVHD are higher than those for recipients of matched-sibling transplants.¹⁰

COLLECTION OF HEMATOPOIETIC STEM CELLS

Hematopoietic stem cells serve as “mother” cells for all blood cells including erythrocytes, leukocytes, and platelets (see Chap. 98).¹¹ Stem cells have varying degrees of “stemness”; true *pluripotent* stem cells are capable of replicating indefinitely and can give rise to stem and progenitor cells of *all* tissues. *Multipotent* stem cells, like the hematopoietic stem cell, have the capacity for self-renewal and can differentiate into more than one cell type in a particular tissue lineage. Because of their capacity for self-renewal, hematopoietic stem cells are capable of repopulating the marrow of the recipient.

4 Hematopoietic stem cells are rare cells, comprising less than 0.01% of all bone marrow cells. It is extremely difficult to isolate and measure stem cells quantitatively because of their rarity and their similarity in appearance to other cells. For these reasons, surrogate markers are used to measure the number of stem cells. Measurement of the number of cells expressing the CD34 antigen (CD34⁺ cells), as determined by flow cytometry, has become the standard method of measuring hematopoietic stem cell content.¹² CD34 is an antigen expressed on hematopoietic stem cells and other early progenitor cells.

Hematopoietic stem cells are found in the bone marrow, peripheral blood, and umbilical cord blood. Hematopoietic stem cells from the bone marrow are obtained by multiple aspirations from the anterior and posterior iliac crests while the donor is under general anesthesia. The procedure takes about an hour and yields 200 to 1,500 mL, depending on the size of the donor. The marrow is transferred into tissue culture medium containing preservative-free heparin. The pooled marrow is then passed through a series of stainless steel screens to break up aggregated particles, resulting essentially in a single-cell suspension. In alloHSCT, the marrow stem cells are given to the recipient within 12 to 24 hours after harvest. In autoHSCT, the marrow is frozen and stored until needed. After intravenous infusion, the marrow stem cells enter the systemic circulation and find their way to the bone marrow cavity, where they reseed and grow in the bone marrow microenvironment. Although the donor experiences local soreness for a few days, the procedure is usually well tolerated, with no delayed complications resulting from the marrow aspiration. The major risk of serving as a marrow donor is that of undergoing general anesthesia.

Hematopoietic stem cells in peripheral blood (peripheral blood progenitor cells [PBPCs] or stem cells [PBSCs]) are found in the mononuclear fraction of white blood cells (lymphocytes and monocytes) and are collected by a procedure called *leukapheresis* (or *apheresis*). In this outpatient procedure, about 9 to 14 liters of blood are processed over several hours during each daily leukapheresis session. Most of the blood cells are returned to the donor, and each leukapheresis yields approximately 200 mL of cells.

The number of hematopoietic stem cells that circulate in peripheral blood is normally too low for this approach to be technically feasible. Without mobilization techniques, at least six leukaphereses are usually required to collect a sufficient number of PBSCs. Several methods have been used clinically to mobilize hematopoietic stem cells from the bone marrow into peripheral blood.^{12–15} The first is to give chemotherapy, which can briefly increase the number of PBSCs as much as 100-fold. The second and most common method is to administer a recombinant hematopoietic growth factor such as granulocyte colony-stimulating factor (G-CSF; filgrastim) or granulocyte macrophage-colony stimulating factor (GM-CSF; sargramostim). Although both agents are FDA-approved for this indication, G-CSF is the most commonly used growth factor. Commonly used dosages are 5 to 16 mcg/kg per day for G-CSF and 250 mcg/m² per day for GM-CSF. The combination of chemotherapy followed by a hematopoietic growth factor increases the number of PBSCs to a greater extent than either method alone. This approach is more expensive and is associated with more adverse effects than a growth factor alone, but the number of leukaphereses is reduced, and the additional chemotherapy may further reduce the tumor burden before transplantation. With current mobilization techniques, most HSCT centers collect sufficient PBSCs with three or fewer leukaphereses. Figure 134–2 shows representative schemas for mobilization and collection of PBSCs.

Several studies show that the number of CD34⁺ cells infused correlates significantly with the rate of neutrophil and platelet recovery after high-dose chemotherapy.^{12–14} Rapid neutrophil recovery is usually observed in patients who receive at least 2 × 10⁶ CD34⁺ cells/kg (body weight of recipient). More rapid platelet recovery is observed when at least 5 × 10⁶ CD34⁺ cells/kg are transplanted as compared to lower cell doses. As a result, most transplant centers currently use 2 × 10⁶ CD34⁺ cells/kg as a minimum number to collect for autologous transplant, with 5 × 10⁶ CD34⁺ cells/kg as an optimal target. Some studies suggest that there are clinical and economic benefits associated with infusion of higher CD34⁺ cell doses.^{16,17} Although the difference in the *median* number of days to neutrophil or platelet recovery is usually no more than 1 to 2 days in patients who receive more than 5 × 10⁶ CD34⁺ cells/kg as compared to those who receive less than 5 × 10⁶ CD34⁺ cells/kg, fewer patients who receive more

than 5 × 10⁶ CD34⁺ cells/kg have delayed engraftment. This small effect may be important, because patients with delayed engraftment consume a disproportionate share of health care resources such as additional transfusions, hospital days, and drugs (e.g., antibiotics and growth factors).

The optimal regimen to mobilize PBSCs is not clear.^{13–15} Results of some randomized studies show that G-CSF alone provides higher yields of CD34⁺ cells as compared with GM-CSF alone.¹⁵ Higher doses of G-CSF or twice-daily administration of G-CSF may also mobilize more CD34⁺ cells. Many cytokines and other novel agents, given either alone or in combination with G-CSF, are being evaluated for use in mobilization regimens.^{14,15}

CLINICAL CONTROVERSY

Multiple regimens exist for mobilization of peripheral blood stem cells. Most centers use G-CSF alone, but some centers use a combination of G-CSF and GM-CSF. The optimal dose of the hematopoietic growth factor is not known. Some centers use chemotherapy in combination with G-CSF or GM-CSF, depending on their disease status. The choice of a secondary mobilization strategy is also controversial.

In some otherwise-eligible transplant candidates, an optimal number of CD34⁺ cells will not be obtained with standard mobilization methods. Risk factors associated with poor mobilization include the amount (greater than six cycles) and type of prior chemotherapy (alkylating agents) and prior radiation therapy.^{13–15} Older age is also associated with poor mobilization in some studies. Several strategies have been evaluated to overcome the obstacle of poor mobilization: remobilization with the same or higher doses of the same hematopoietic growth factor, a combination of hematopoietic growth factors, or a combination of chemotherapy and a hematopoietic growth factor. Bone marrow harvest is also an option, but is often of limited value.

5 The use of peripheral blood instead of bone marrow as a source of hematopoietic stem cells offers several advantages. The most clinically important advantage is that patients who receive mobilized PBSCs experience more rapid hematopoietic engraftment.^{18,19} Although engraftment of all lineages is more rapid when PBSCs are used, the most significant effect is observed with platelet recovery. Patients who receive mobilized PBSCs experience platelet recovery as much as 2 to 3 weeks earlier than those who receive bone marrow stem cells. Another advantage is that the donor does not experience the discomfort associated with marrow aspirations and is not exposed to the risk associated with general anesthesia. Also, PBSCs may be less likely to be contaminated with malignant cells compared with marrow stem cells. Finally, because PBSCs are collected from the mononuclear cell fraction, a fraction that also contains immunocompetent cells (e.g., natural killer cells and T lymphocytes), some investigators believe that infusion of PBSCs may represent a form of “adoptive immunotherapy.” In this model, natural killer cells and lymphocytes targeted against tumor cells help to kill residual tumor cells.

Although studies have not reported a significant difference in disease-free survival between patients who receive mobilized PBSCs and those who receive bone marrow, the use of mobilized PBSCs is associated with other clinical and economic benefits. Patients who receive mobilized PBSCs require fewer platelet transfusions and are usually discharged earlier from the hospital.^{18,19} In an economic analysis of a randomized controlled trial, Smith and colleagues reported that the total average cost of a PBSC transplant was \$13,521 lower than that of bone marrow transplant (BMT) (\$45,792 versus \$59,314).²⁰ At transplant centers with intensive clinic support, patients are able

FIGURE 134–2. Schema for collection of PBPCs after hematopoietic growth factor administration (*top*) or after chemotherapy and hematopoietic growth factor administration (*bottom*). Symbols with gray shading represent procedures done only if adequate numbers of CD34⁺ cells have not been collected.

to receive much of their posttransplant care as an outpatient, further reducing the cost of HSCT.²¹ As a result of these clinical and economic advantages, peripheral blood has replaced bone marrow as the source of stem cells in the autologous setting.

Peripheral blood is increasingly being used as a source of hematopoietic stem cells in alloHSCT.^{22,23} About 50% of the alloHSCTs performed currently come from PBSCs harvested from normal donors. This is despite early concerns that the increased numbers of T lymphocytes found in peripheral blood could increase the risk of GVHD. Concerns were also raised over the safety and ethics of administering G-CSF to normal individuals volunteering as donors. G-CSF is generally well-tolerated. Short-term effects are similar to those seen in cancer patients (e.g., bone pain, headache, fever, arthralgias, and malaise). Because the potential long-term effects related to G-CSF are unknown, careful follow-up of donors is recommended.

Randomized controlled trials show that patients who received allogeneic PBSC transplants from HLA-identical siblings experienced more rapid hematopoietic recovery and required fewer transfusions as compared to patients receiving BMT.^{22,23} The difference in the rate of engraftment may be related to the threefold higher numbers of CD34⁺ cells infused in recipients of PBSC transplants. Although most of these studies did not report an increased risk of acute GVHD or transplant-related mortality in patients receiving allogeneic PBSC transplants, a higher incidence of chronic GVHD was observed. In a meta-analysis of published reports, the risk of chronic GVHD was about 50% higher for patients who received allogeneic PBSC transplants as compared to those who received BMT.²⁴ Some studies have reported a correlation between the CD34⁺ cell dose and the risk of chronic GVHD, which suggests that the higher CD34⁺ cell dose may explain, in part, the increased risk of chronic GVHD.²⁵ Use of PBSCs from unrelated donors is also being investigated.²³ About 25% of the matched unrelated transplants coordinated by the NMDP use PBSCs.

In addition to bone marrow and peripheral blood, hematopoietic stem cells are also found in umbilical cord blood (UCB). UCB is an attractive source for several reasons. Because the stem cells are collected from placental blood, there is no risk to the mother or the baby. There is also very low risk of transmissible infectious diseases such as cytomegalovirus and Epstein-Barr virus. In addition, the cells are available immediately because the donor does not have to be located and harvested. Initially, UCB was obtained from siblings but now recipients of transplants from unrelated donors account for almost all patients who receive UCB transplants. It is estimated that more than 2,000 unrelated UCB transplants have been performed worldwide.²⁶

Results of uncontrolled studies show that recipients of UCB transplantation have a lower risk of GVHD but a higher risk of graft failure as compared with recipients of BMT.²⁶ Recipients of UCB transplantation usually receive a CD34⁺ cell dose more than 1 log lower than that given to recipients of BMT, and this difference in CD34⁺ cell dose may explain the delayed engraftment in recipients of UCB transplantation. In one study, the number of infused CD34⁺ cells correlated with the rate of engraftment, transplant-related mortality, and survival.²⁷ Although no randomized comparisons have been performed, a matched-pair analysis showed similar survival in children who underwent either unrelated UCB transplantation or BMT.²⁸

A major limitation to UCB transplants is the limited volume of blood collected, usually 60 to 150 mL. Although the relatively low numbers of hematopoietic cells may be adequate for hematopoietic engraftment in children and small adults, it may not be adequate for larger recipients. Efforts to expand the number of hematopoietic stem cells include culturing them *ex vivo* with combinations of hematopoietic growth factors, or “pooling” several units of UCB for one recipient. Preliminary results with unrelated UCB transplants in

adult recipients are encouraging,^{26,29} but more experience is needed with adult recipients before this procedure can be recommended as a standard procedure in that population.

UCB represents an alternative source of hematopoietic stem cells in children and some adults who do not have a HLA-matched sibling donor.^{26,29} As discussed above, UCB has some advantages over bone marrow stem cells. In addition, the time required to identify and obtain cells from an unrelated UCB donor is usually less than 1 month, which is significantly shorter than that required for an unrelated marrow donor. Therefore a UCB graft may be advantageous for patients who require an urgent transplant.

APPROACHES TO ERADICATE MALIGNANT CELLS

PRETRANSPLANT CHEMOTHERAPY OR CHEMORADIOTHERAPY

6 Nearly all patients who receive HSCT must be prepared (or “conditioned”) before infusion of hematopoietic stem cells.³⁰ In patients with malignant disease, the goal of the preparative or conditioning regimen is to kill as many malignant cells as possible. Preparative regimens usually include commonly used anticancer drugs given at very high doses—doses that would be associated with severe and life-threatening bone marrow suppression if hematopoietic stem cells were not infused. In patients undergoing alloHSCT, another purpose of the preparative regimen is to suppress the immune system of the recipient so that the graft is not rejected.

In some preparative regimens, the only drug given is cyclophosphamide, a drug with both immunosuppressive and cytotoxic effects. Because of the inadequate antitumor activity of cyclophosphamide in some types of cancers, other drugs are often added. Examples of drugs that often are included in preparative regimens are cytarabine (ara-C), busulfan, thiotepa, etoposide (VP-16), carboplatin, cisplatin, carmustine (BCNU), melphalan, and ifosfamide.³⁰

Total body irradiation (TBI) is also commonly used in pretransplant preparative regimens, particularly in patients with leukemia.³¹ In patients with malignant disease, the rationale is to eradicate malignant cells located in areas inaccessible to the systemic circulation, and thus to the cytotoxic agents. TBI also has significant immunosuppressive activity. Historically, the standard TBI regimen involved the administration of a midline tissue dose of about 1000 cGy (1 cGy = 1 rad), which is more than twice the lethal dose of radiation for a normal person. Many centers currently give fractionated (split over several days, once or twice a day) rather than single-dose TBI to patients with malignant disease. The rationale for this approach is an improved therapeutic ratio—destruction of more leukemic cells and marrow stem cells while sparing other normal tissues. The acute toxicities of TBI consist of fever, nausea, vomiting, diarrhea, mucositis, and tender swelling of the parotid gland. Long-term complications of TBI-containing regimens include cataract formation, growth retardation, carcinogenesis, permanent reproductive sterility, and secondary malignancies.

LEUKEMIA

Most patients with leukemia undergoing alloHSCT receive either cyclophosphamide and TBI (CyTBI) or busulfan and cyclophosphamide (BuCy). When given with TBI, cyclophosphamide is usually given first, as two 60-mg/kg per day doses, followed by TBI. TBI can be given as a single dose or fractionated over several days. One variation of that regimen is to give hyperfractionated TBI first, followed by

cyclophosphamide. In that regimen, which is primarily used in patients with acute lymphoblastic leukemia (ALL), 11 TBI doses of 120 cGy are given; doses are given three times a day on days -7 to -5 (day 0 is designated as the day of transplant), and twice a day on the last day (day -4). After TBI, two doses of cyclophosphamide are given intravenously once a day at a dosage of 60 mg/kg on days -3 and -2.

Because of the many acute and chronic toxicities of TBI, it would be advantageous to omit it from the preparative regimen. One widely used preparative regimen that does not include TBI is BuCy. In the original regimen (BuCy4), busulfan was given orally at a dosage of 1 mg/kg every 6 hours (4 mg/kg per day) for 16 doses on days -9 to -6, followed by four doses of cyclophosphamide, given intravenously once daily at a dosage of 50 mg/kg on days -5 to -2. In one widely used modification of that regimen (BuCy2), the total cyclophosphamide dosage is reduced from 200 (50 × 4) to 120 (60 × 2) mg/kg. Plasma busulfan concentrations are monitored at some centers because some studies suggest that systemic exposure may correlate with outcome,³² and the use of a targeted busulfan and cyclophosphamide preparative regimen may improve patient outcome.³³ An intravenous form of busulfan is also available commercially (Busulfex), which reduces some of the interpatient variability in systemic exposure.³⁴ The use of intravenous busulfan may also reduce the risk of hepatic veno-occlusive disease. The dose of IV busulfan approved for pretransplant conditioning regimens is 0.8 mg/kg every 6 hours for 4 days. Once-a-day dosing regimens have also been developed, which may facilitate outpatient administration of intravenous busulfan.

Several prospective randomized studies have compared CyTBI to BuCy in patients with acute or chronic myelogenous leukemia undergoing alloHSCT.³⁵⁻³⁷ The results of these studies show that BuCy has similar or greater antileukemic activity in patients with CML than CyTBI. But in patients with acute myelogenous leukemia (AML), some studies suggest that the CyTBI regimen was associated with slightly better disease-free survival rates than BuCy. However, none of the patients who were randomized to BuCy in these studies received busulfan doses adjusted on the basis of plasma concentrations. In children with ALL, a retrospective study showed higher survival in children who received CyTBI as a preparative regimen.³⁸ Long-term toxicities appear to be comparable between the two regimens.

Other drugs have been evaluated in addition to or instead of cyclophosphamide in the preparative regimen.^{30,37} Examples include cytarabine or etoposide in combination with TBI. There are no convincing data to indicate that any of these regimens are superior to CyTBI or BuCy. The same preparative regimens are usually given to patients undergoing autoHSCT for leukemia.

LYMPHOMA

Based on experience in patients with leukemia, the initial regimen used in many patients with Hodgkin's and non-Hodgkin's lymphoma was CyTBI, particularly in alloHSCT. Most preparative regimens currently used in autoHSCT for lymphoma include an alkylating agent (either cyclophosphamide or melphalan), carmustine, and etoposide.^{30,39} TBI is usually not included in the conditioning regimen because many patients with lymphoma have received prior radiotherapy. One widely used regimen in autoHSCT is the CBV regimen, which consists of cyclophosphamide, carmustine (BCNU), and etoposide (VP-16). In that original regimen, cyclophosphamide was given at a dosage of 1.5 g/m² on days -6 to -3, carmustine was given at a dosage of 300 mg/m² on day -6, and etoposide was given at a

dosage of 100 mg/m² every 12 hours for six doses on days -6 to -4. Some centers have modified the original CBV regimen by changing the dosage of some of the drugs or adding or substituting other drugs including cytosine arabinoside, etoposide, melphalan, lomustine, and thioguanine. Other widely used nitrosourea-based regimens are BEAC (BCNU, etoposide, ara-C, and cyclophosphamide) and BEAM (BCNU, etoposide, ara-C, and melphalan). No one preparative regimen has been shown to be clearly superior to other regimens in the treatment of lymphoma.

Although TBI is usually not included in the conditioning regimen, some form of radiation therapy is often given, depending on the type, location, and extent of disease. Instead of TBI, some patients receive localized radiation in high doses to areas of residual or bulky disease. Many patients with Hodgkin's lymphoma have received thoracic radiation as primary therapy for their disease, so TBI is usually avoided in patients with Hodgkin's lymphoma. Conversely, most patients with indolent non-Hodgkin's lymphoma receive TBI as part of their preparative regimen because of the known sensitivity of these tumors to low doses of radiation.⁴⁰

One of the disadvantages of TBI is that it delivers as much radiation to normal organs as it does to tumor cells. The availability of anti-CD20 radiolabeled monoclonal antibodies offers the potential to deliver more radiation to tumor cells and less to normal organs. In these trials,¹³¹I-tositumomab was given, either alone or combined with high-dose cyclophosphamide and etoposide, with autoHSCT in patients with non-Hodgkin's lymphoma.^{41,42} With this approach, very high radiation doses could be delivered to sites of disease. Preliminary results with this approach are encouraging.⁴³

SOLID TUMORS

Most conditioning regimens in autoHSCT include at least one alkylating agent because of their steep dose-response curve and other favorable characteristics previously discussed.³⁰ Many regimens include more than one alkylating agent, based on preclinical studies that show that resistance to a specific alkylating agent does not impart cross-resistance to other alkylating agents. Other anticancer drugs that modulate the activity of alkylating agents in a synergistic manner, such as etoposide, are also attractive drugs to include in high-dose preparative regimens. The dose of nonalkylating agents with antitumor activity has also been escalated in patients with solid tumors based on tumor-specific activity. Examples include mitoxantrone, paclitaxel, and topotecan. It is not clear whether these regimens offer any clinical advantages over those that include only alkylating agents.

PURGING THE STEM CELL PRODUCT

One disadvantage of autoHSCT is that the stem cell product (graft) may be contaminated with malignant cells. Infusion of these malignant cells may contribute to tumor relapse. Many approaches have been developed to eliminate ("purge") the marrow of these tumor cells.⁴⁴ The most common approach is to add substances, such as chemicals or monoclonal antibodies, to the stem cell product while it is outside of the body (ex vivo) (Fig. 134-3). Because the substances are removed before infusion of the stem cells, nonhematopoietic tissues are not exposed to the substances and therefore are not damaged. However, these substances can remove or damage hematopoietic stem cells, which are essential for complete and rapid engraftment, and purging has been associated with a delay in marrow recovery. Ex vivo marrow purging is also performed in alloHSCT in an attempt to eliminate T lymphocytes believed to be responsible for acute GVHD (see

FIGURE 134-3. The use of ex vivo marrow purging to remove or destroy T cells (allogeneic only) or residual malignant cells (autologous only).

Fig. 134-3). Results with this approach are discussed below in the GVHD section.

One approach is to add one or more monoclonal antibodies that are directed against specific antigens present on the tumor cells, but which are absent on nearly all other cells.^{42,45} Although this approach is theoretically attractive, it is limited because not all cells from patients with the same type of cancer will express a specific antigen. Furthermore, for some types of cancers, it has been difficult to identify antigens distinct from those present on normal hematopoietic stem cells. To date, this strategy has been used most commonly in patients with lymphoid malignancies, either ALL or non-Hodgkin's lymphoma.

Another method of ex vivo purging is to add chemicals or drugs to kill the tumor cells.⁴⁶ The advantage of this technique is that it can be used for a broader range of tumor types. However, chemical purging is not completely selective for tumor cells, and it is therefore important to add the precise amount of chemical or drug that kills sufficient numbers of tumor cells while sparing the largest number of hematopoietic stem cells. The chemical that is most commonly used for purging is 4-hydroperoxycyclophosphamide (4-HC, or perfosfamide), a congener of cyclophosphamide. A stable compound, 4-HC enters cells and is rapidly reduced to 4-hydroxycyclophosphamide, which serves as the precursor to the reactive phosphoramidate mustard. The level of aldehyde dehydrogenase, the enzyme that inactivates 4-hydroxycyclophosphamide, appears to be highest in early hematopoietic progenitors and decreases as these cells differentiate. This observation may explain why 4-HC appears to have an acceptable therapeutic index. Other analogs of cyclophosphamide (e.g., mafosfamide) also are being investigated as chemical purging agents.

Another method to purge malignant cells is to identify, select, and concentrate hematopoietic stem cells, a process known as positive selection.⁴⁴ In this process, cells collected from marrow or peripheral blood are treated ex vivo with monoclonal antibodies against CD34. CD34⁺ cells are therefore separated from those that are CD34⁻, including most malignant cells. Although a randomized study showed that one of these techniques reduced the number of tumor cells by 1.6 to 6 (median 3.1) logs, no significant difference in disease-free or overall survival rate was observed.⁴⁷

Although ex vivo purging has been extensively studied, there is a lack of convincing evidence that it improves transplant outcomes.

Since these techniques can be cumbersome and add cost to the transplant procedure, their use should be restricted to clinical trials.

Rituximab has been used pretransplant for in vivo purging of the stem cell graft prior to autoHSCT in patients with non-Hodgkin's lymphoma.^{40,42} When used for in vivo purging, rituximab is usually given before each leukapheresis. Although the use of rituximab was effective in reducing the number of tumor cells in the stem cell graft, it is not clear whether this approach improves disease-free survival after autoHSCT.

POSTTRANSPLANT IMMUNOTHERAPY

The rationale for posttransplant immunotherapy is based on observations that certain subsets of T cells are responsible for the eradication of malignant cells. This is referred to as the graft-versus-leukemia (GVL) or graft-versus-tumor (GVT) effect. Evidence for GVL is based on retrospective studies that show that patients who developed graft-versus-host disease (GVHD) had a lower risk of leukemic relapse than those who did not develop GVHD.⁴⁸ But the overall survival rate was no different because of the increased non-relapse mortality associated with GVHD. Other anecdotal evidence supporting a T-cell mediated GVL effect was the increased risk of relapse found with T-cell-depleted transplants as compared to unmodified transplants, and the difference in relapse rates between recipients of syngeneic and HLA-identical sibling transplants.

DONOR LYMPHOCYTE INFUSIONS

Perhaps the most commonly used form of posttransplant immunotherapy is infusions of donor lymphocytes to treat disease relapse after alloHSCT.^{49,50} Lymphocytes are collected from the same donor who provided hematopoietic stem cells. Most of the experiences with donor lymphocyte (or leukocyte) infusion (DLI) have been for patients with CML. More than 80% of patients who are in cytogenetic or molecular relapse respond to DLI. The response rate is slightly lower in chronic phase relapse, whereas the response rates in more advanced phases are about 15% to 30%. Although the time to response is delayed (median of 3 to 4 months), patients often have a durable molecular remission to DLI.

Response rates to DLI in patients with other myeloid malignancies, such as AML and myelodysplasia, are generally lower (25% to 30%) than those seen in CML.^{49,51} This may be related to the rapid proliferation of acute leukemia versus the often prolonged time to response after DLI or to the lack of suitable target antigens on non-CML cells for recognition by donor cytotoxic T cells. Patients with AML are more likely to achieve a complete response to DLI post-HSCT if they have had a longer remission period after transplant and if they have had some GVHD after the DLI.^{49,52} Administration of induction chemotherapy prior to DLI may improve the antitumor activity of DLI in patients with AML, but this has not been tested in a randomized study. DLI has been shown to have limited benefit in patients with relapsed ALL after transplant.

DLI appears to be effective in patients with multiple myeloma who relapse after alloHSCT, with reported response rates of 40% to 50% in patients relapsing after transplant.^{49,51} Unfortunately, these responses tend to be transient and associated with the occurrence of GVHD. Anecdotal evidence suggests a graft-versus-lymphoma effect in patients with indolent non-Hodgkin's lymphoma and chronic lymphocytic leukemia (a disease entity that is closely related to the indolent non-Hodgkin's lymphomas).

The most serious complications of DLI are pancytopenia and GVHD. The cytopenias are generally transient and can be treated with hematopoietic growth factors. A small percentage of patients may have a more prolonged course of aplasia with associated risk of infection, bleeding, and anemia. Another infusion of donor stem cells may be beneficial in these patients. Acute GVHD (grade II or greater) occurs in 40% to 60% of those receiving DLI, and while the severity of GVHD has been correlated with GVL, complete responses have been seen in the absence of GVHD, suggesting that the effects can be separated. DLI is associated with 10% to 15% nonrelapse mortality at 1 year.

Because of the large potential of DLI as curative therapy for some patients with certain hematologic malignancies, investigators are evaluating strategies to separate the GVL effect from the GVH effect, thus making DLI more tolerable. Others are developing methods that would expand the efficacy of DLI to other malignancies. Some of these strategies include T-cell depletion from the stem cells followed by delayed T-cell add-back transplant for patients with evidence of residual disease around 3 months posttransplant; selective depletion

of CD8⁺ cells from the DLI; in vivo or in vitro T-cell activation with interleukin-2; or infusion of T cells that are selected to recognize tumor-specific antigens.^{49,51}

IMMUNOMODULATORY CYTOKINES

Another approach to induce a GVT effect in patients who relapse following HSCT is to administer a cytokine posttransplant with immunomodulatory activity, such as interleukin-2 (IL-2).^{48,53,54} Some beneficial effects have been observed with the use of IL-2 with respect to effects on natural killer cells and other important antitumor immune responses. Toxicities have been tolerable in most patients but can be serious and life-threatening. Studies are necessary to define the role of these cytokines in prolonging relapse-free survival after HSCT.

MONOCLONAL ANTIBODIES

Rituximab is being evaluated as adjuvant therapy in patients with non-Hodgkin's lymphoma treated with autoHSCT.^{42,55} The timing and number of doses of rituximab therapy varies. A recently published study by the Stanford program reported promising results with two 4-week courses starting at day 42 and 6 months posttransplant.⁵⁵ Neutropenia was observed in about 50% of the patients treated.

NONMYELOABLATIVE TRANSPLANTS

8 The newest approach to take advantage of the immunoreactivity between healthy donor T cells and host tumor cells is the use of nonmyeloablative transplants (NMT, "mini" transplants, or transplant "lite").⁵⁶⁻⁵⁹ The number of NMTs has risen from about 500 in 1999 to more than 1,500 in 2002; the number of NMTs in 2002 represents about one-third of the allogeneic transplants registered with the International Bone Marrow Transplant Registry.⁶⁰ The rationale for NMT is based on the assumption that most of the antitumor activity associated with alloHSCT is the result of the donor T-cell-mediated GVT effect, and not the result of the myeloablative doses of chemotherapy or radiation (Fig. 134-4). If this assumption is correct, the major role of the preparative regimen is to suppress the host immune system, thus allowing engraftment of donor hematopoietic stem cells and donor

FIGURE 134-4. Schema for nonmyeloablative transplantation for hematologic malignancy. Recipients (R) receive a nonmyeloablative preparative regimen and an allogeneic hematopoietic stem cell transplant. Initially, mixed chimerism is present with the coexistence of donor (D) cells and recipient-derived normal and leukemia/lymphoma (R_L) cells. Donor-derived T cells mediate a graft-versus-host hematopoietic effect that eradicates residual recipient-derived normal and malignant hematopoietic cells. Donor lymphocyte infusions may be administered to enhance graft-versus-tumor effects. (Adapted from Champlin R, Khouri I, Anderlini P, et al. Nonmyeloablative preparative regimens for allogeneic hematopoietic transplantation: biology and current indications. *Oncology* 2003;17:94-100.)

T-cell cytotoxicity. To test this model in a clinical setting, regimens have been developed that include lower doses of drugs than those used in conventional transplants or other anticancer drugs that are immunosuppressive. A major advantage of this “reduced-intensity” approach is that potentially curative transplants can be offered to patients who would not typically be considered for alloHSCT because of their unacceptably high risk of transplant-related complications (e.g., increased age or those with moderately compromised organ function).

A number of preparative regimens have been developed for use in NMT, and these regimens vary in their cytotoxic (and thus myelosuppressive) and immunosuppressive activity.^{56–59} Two general approaches have been used in the development of these regimens. The first consists of *reduced-intensity* regimens in which drugs with proven activity against the tumor are chosen. These regimens provide some immunosuppressive activity and are associated with some regimen-related toxicity. The second approach consists of *nonmyeloablative* regimens that have immunosuppressive conditioning regimens that are minimally myelosuppressive. Drugs that are often included in nonmyeloablative and reduced-intensity regimens include alkylating agents (busulfan, melphalan, or cyclophosphamide), purine analogs (fludarabine, pentostatin, or cladribine), and antithymocyte globulin. Low-dose (i.e., 200 cGy) TBI or alemtuzumab is included in some regimens.

DLIs are sometimes given posttransplant in NMT to convert mixed chimerism into full donor chimerism and to treat residual or progressive disease. Preliminary results show that DLI is effective and is associated with acceptable toxicity (mostly GVHD) in patients with early signs of disease persistence or progression after NMT.⁶¹ Prophylactic DLI is being investigated at some centers to eradicate residual disease and reduce the risk of relapse.

Numerous clinical trials have reported the results of NMT from HLA-matched related or unrelated donors in relatively small cohorts of patients.^{56–58} Follow-up is relatively short in most series. In the largest series, 253 patients received HLA-matched related NMT at one of several transplant centers that were part of an international consortium of transplant centers led by the Fred Hutchinson Cancer Research Center.^{58,62} All patients had a hematologic malignancy. The source of hematopoietic stem cells was G-CSF–mobilized PBSCs. Median age was 54 years; the oldest patient was 73 years old. Median follow-up was 13 months. The first cohort of 58 patients was conditioned with TBI alone (2 Gy); 17% of these patients experienced nonfatal graft rejection. Fludarabine was then added to the conditioning regimen in the remaining patients, and the incidence of graft rejection decreased dramatically. A combination of cyclosporine and mycophenolate mofetil was given as GVHD prophylaxis. Most patients did not need platelet transfusions, and only about two-thirds required red blood cell transfusions. The majority of the transplant was done entirely in the ambulatory care setting. Typical side effects such as mucositis, diarrhea, and organ toxicities were absent. While the risk of infection in the first 100 days appeared to be lower than that seen with myeloablative alloHSCT, the risk of late viral and fungal infections persisted.^{63,64} GVHD, although delayed compared to historical controls, was still a significant problem (discussed later).⁶⁵ Transplant-related mortality was only 5% at day 100. As compared with matched controls, patients who received NMT had significantly lower transplant-related mortality at day 100 and 1 year.⁶⁶ Follow-up is early, but remissions have been observed in virtually all disease categories, including molecular remissions. Disease remissions generally occurred slowly in 3 to 24 months, thus most likely making this form of therapy more beneficial in patients with chronic or indo-

lent malignancies or those that can be effectively debulked prior to transplant.

Under a similar protocol, the same consortium of transplant centers treated 89 patients with HLA-matched unrelated NMT.⁶⁷ Both peripheral blood and marrow was used as a source of hematopoietic stem cells. Durable engraftment was observed in 85% of patients who received G-CSF–mobilized PBSCs, but only in 56% of marrow recipients. Transplant-related mortality was 11% at day 100. Patients who received PBSCs had improved progression-free and overall survival as compared with marrow recipients.

Antitumor responses have been observed with NMT in patients with renal cell carcinoma, melanoma, breast cancer, and other solid tumors.^{59,68,69} In order to improve on the efficacy seen with NMT, some investigators are evaluating novel approaches to enhance allogeneic immune responses against tumor-associated antigens (if available) such as posttransplant vaccination.

NMTs are also being evaluated as salvage therapy in patients with a hematologic malignancy who do not respond to or have relapsed after autoHSCT,⁷⁰ and as intensive consolidation therapy in patients with multiple myeloma who are treated with autoHSCT.⁷¹

In summary, NMT from HLA-matched related or unrelated donors is a promising treatment modality for patients who are not candidates for myeloablative alloHSCT because of age or comorbidities. Myelosuppression is mild, and most patients do not develop severe neutropenia or thrombocytopenia. Because of the reduced intensity of the conditioning regimen, early transplant-related mortality is less than that seen with myeloablative alloHSCT. GVHD and infections, although occurring later after transplant, continue to be a significant cause of morbidity and mortality. Antitumor responses have been observed in hematologic malignancies and solid tumors.

TRANSPLANT-RELATED COMPLICATIONS

9 Although many patients with cancer who are treated with high-dose chemotherapy and autoHSCT or alloHSCT experience long-term survival and cure of their disease, this modality is associated with many serious and potentially life-threatening complications. In the early 1970s, early posttransplant mortality was extremely high, and most HSCT patients did not survive beyond 100 days. During those early years of alloHSCT, death was usually related to infection, GVHD, interstitial pneumonia, and leukemic relapse. Today, largely because of the availability of improved broad-spectrum antibiotics, immunosuppressive drugs, antiviral drugs, and hematopoietic growth factors, transplant-related mortality after alloHSCT with HLA-matched sibling donors has been reduced to less than 30% at most centers. Causes of death are usually related to transplant-related organ toxicity, GVHD, or immunosuppression. Until recently, alloHSCT was usually restricted to patients younger than 50 years old with an HLA-identical sibling donor. With advances in the prevention and treatment of transplant-related complications and the availability of NMT, alloHSCT is now being offered to patients older than 50 years of age. The risk of transplant-related mortality after high-dose chemotherapy with autoHSCT is less than 5% at many centers, depending on patient population and conditioning regimen. Mortality is lower with autologous transplants because of the lack of GVHD and associated complications of immunosuppression. Transplant-related mortality in autoHSCT is usually caused by regimen-related toxicity.

Table 134–1 lists the dose-limiting nonhematologic toxicity for several drugs that are commonly included in conditioning regimens.

TABLE 134–1. Dose-Limiting Nonhematologic Toxicities for Selected Chemotherapeutic Agents Included in Conditioning Regimens in Hematopoietic Stem Cell Transplantation

| Drug | Conventional Dose ^a (mg/m ²) | ABMT ^b Dose (mg/m ²) | Dose-Limiting Toxicity |
|------------------|---|---|------------------------------|
| Busulfan (oral) | 2 | 450 | Hepatic |
| Carboplatin | 400 | 2,000 | Hepatic, renal |
| Carmustine | 200 | 1,200 | Pulmonary, hepatic |
| Cisplatin | 100 | 200 | Renal, peripheral neuropathy |
| Cyclophosphamide | 1,000 | 7,500 | Cardiomyopathy |
| Etoposide | 300–600 | 2,400 | Mucositis |
| Ifosfamide | 5,000 | 18,000 | Renal |
| Melphalan | 40 | 225 | Mucositis |
| Thiotepa | 20–50 | 1125 | Mucositis, CNS |

^aDoses are approximate and are for drugs as single agents. When combinations are used, doses may need to be decreased.

^bABMT, autologous bone marrow transplantation.

Modified from Eder JP, Elias A, Shea TC, et al. A phase I–II study of cyclophosphamide, thiotepa, and carboplatin with autologous bone marrow transplantation in solid tumor patients. *J Clin Oncol* 1990;8:1242.

These toxicities may be uncommon or rare with the administration of conventional doses of a specific drug. Toxicities seen with conventional doses can be expected to be more frequent and/or severe when these agents are given in high doses (e.g., mucositis, enteritis, nausea, vomiting, hematuria, etc). Several unusual and severe manifestations of regimen-related toxicities are discussed in detail below.

HEPATIC VENO-OCCLUSIVE DISEASE

Hepatic veno-occlusive disease (VOD), also known as sinusoidal-obstructive syndrome, occurs as a result of chemotherapy-induced damage and obliteration of the small intrahepatic central venules leading to necrosis of hepatocytes, portal hypertension, and hepatic failure.⁷² Clinical signs of hepatic VOD include fluid retention leading to sudden weight gain and ascites, hepatomegaly (sometimes painful), and hyperbilirubinemia/jaundice usually occurring within the first 3 weeks after transplant. The incidence of hepatic VOD ranges from 5% to 20% in most series. Severe hepatic VOD is fatal in 50% to 75% of patients who develop it. Factors reported to increase the risk of hepatic VOD include the use of TBI-containing conditioning regimens and the presence of elevated liver function tests pretransplant. Pretransplant exposure to gemtuzumab ozogamicin (Mylotarg) has been implicated in the development of VOD.⁷³ The use of some drugs in the conditioning regimen, such as busulfan or carmustine, may also increase the risk of hepatic VOD. Busulfan concentrations have been correlated with the risk of hepatic VOD in some but not all studies.³² Based on these studies, some HSCT centers adjust busulfan doses based on plasma concentrations. The use of IV busulfan reduces the interpatient variation in systemic exposure associated with the oral formulation, and has been associated with a reduced risk of hepatic VOD.³⁴

Some studies suggest that prostaglandin E₁, unfractionated and low-molecular-weight heparin, or ursodiol may be partially effective in the prevention of hepatic VOD.⁷² Prophylactic defibrotide may also be effective.⁷⁴ Treatment is generally supportive. Recombinant tissue plasminogen activator has been given to patients with severe hepatic VOD because of the possible role of the coagulation cascade in the pathogenesis of VOD. Responses have been reported but patients also experienced a higher risk of bleeding.⁷² Defibrotide may also be beneficial in the treatment of VOD.⁷⁵

PULMONARY COMPLICATIONS

Pulmonary complications following HSCT can be categorized as infectious and noninfectious (infectious complications are discussed in Chap. 120). Noninfectious complications are described as early (first 100 days posttransplant) and late (>100 days posttransplant). Patients receiving high-dose BCNU are also at risk for pulmonary fibrosis as a result of direct pulmonary tissue damage caused by this agent. Early complications include diffuse alveolar hemorrhage, engraftment syndrome, and idiopathic interstitial pneumonitis.⁷⁶ Diffuse alveolar hemorrhage (DAH) is characterized by dyspnea, hypoxia, dry cough, and fever. Chest x-ray usually shows diffuse infiltrates in an alveolar pattern. DAH is diagnosed by examination of bronchoalveolar lavage fluid, which reveals progressively bloodier fluid with each instilled aliquot, and by negative findings on microbiologic analysis. Although it can be life-threatening or fatal, prompt treatment with high doses of corticosteroids is sometimes beneficial.

Fever, erythrodermatous skin rash, and noncardiogenic pulmonary edema can occur during neutrophil recovery after HSCT. Because these clinical manifestations usually occur immediately before or at the time of neutrophil engraftment, this clinical entity has been referred to as “engraftment syndrome.”⁷⁷ The incidence of engraftment syndrome is not known because of the lack of uniform diagnostic criteria, although some series report that about 10% of patients who receive autoHSCT develop this syndrome. Engraftment syndrome can progress to life-threatening respiratory failure with or without multiple organ failure. Corticosteroids are effective in some patients.

Idiopathic interstitial pneumonitis (IIP; also called idiopathic pneumonia syndrome) is defined as widespread alveolar injury in the absence of active lower respiratory tract infection following HSCT. Patients with idiopathic interstitial pneumonitis are clinically indistinguishable from those with interstitial pneumonitis related to infection. IIP is postulated to have a multifactorial etiology including toxic effects of myeloablative conditioning, immunologic cell-mediated injury, inflammatory cytokine-induced lung damage, and occult pulmonary infections. The risk is similar in recipients of autoHSCT or alloHSCT, but appears to be higher in patients who are conditioned with a TBI-containing regimen or who have acute GVHD. Mortality has been reported to be as high as 70% and treatment consists of supportive care only. The incidence of IIP may be

lower after nonmyeloablative as compared to conventional preparative regimens.⁷⁸

Late pulmonary complications cover a wide spectrum of disorders and include both obstructive and restrictive lung diseases. Included in these disorders are bronchiolitis obliterans with or without organizing pneumonia, diffuse alveolar damage, and lymphocytic interstitial pneumonia.^{76,79,80} Therapy consists of steroids, which are about 50% effective; patients with mild-to-moderate airflow impairment appear to have the best response. Mortality from these disorders is about 40%.

GRAFT FAILURE

Initial engraftment after high-dose chemotherapy conditioning regimens usually occurs in the first 2 to 4 weeks posttransplant. Engraftment is evidenced by rising peripheral blood counts and the presence of hematopoietic precursor cells in the marrow. In alloHSCT, the presence of donor cells is confirmed with cytogenetic markers (i.e., chimerism). In most patients, engraftment is sustained with complete recovery of hematopoiesis.

Graft failure can occur after autologous, syngeneic, and allogeneic HSCT. It can be a result of an immunologic reaction between donor and host, infusion of insufficient numbers of hematopoietic stem cells, a viral infection, recurrence of primary hematologic malignancy, drug reaction (e.g., ganciclovir), or the development of a secondary myelodysplasia. Two syndromes have been observed: early graft failure occurs when the rate of hematopoietic recovery is delayed (primary graft failure or delayed engraftment), whereas late graft failure is characterized by a decline in the peripheral blood counts after initial engraftment (secondary graft failure). With widespread use of PBSCs and posttransplant growth factors, primary graft failure is rare after autologous and HLA-matched related alloHSCT. When graft failure occurs after alloHSCT and is characterized by the regrowth of immunocompetent host cells and a simultaneous loss of donor cells, it is referred to as graft rejection. Graft rejection occurs rarely after HLA-matched related alloHSCT. An increased risk of graft rejection has been observed in recipients of hematopoietic stem cells from HLA-mismatched related or unrelated donors, recipients of T-cell-depleted marrow, and patients with severe aplastic anemia.^{6,9,10,81}

The long-term prognosis in patients with graft failure is poor. Despite supportive care, death may result from infection or bleeding. In some patients with an HLA-identical sibling donor, a second infusion of stem cells can be attempted. The most effective therapy for graft failure is G-CSF or GM-CSF. The 2000 American Society of Clinical Oncology guidelines recommend that patients with graft failure after HSCT be treated with GM-CSF 250 mcg/m² per day for 14 days followed by a 7-day break. Up to three such courses with dose escalation to 500 mcg/m² per day in the last course is advised.⁸²

Hematopoietic growth factors are usually given posttransplant to accelerate engraftment, although some clinicians believe that posttransplant G-CSF or GM-CSF use is unnecessary due to the already rapid engraftment seen after mobilized PBSC transplants.⁸³ The usual dosage of GM-CSF is 250 mcg/m² per day. Many different dosages and schedules of G-CSF have been used after autoHSCT. Originally, G-CSF was given at a dose of 5 to 10 mcg/kg per day beginning on the day of or the day after infusion of stem cells and continued until neutrophil recovery to greater than an arbitrary number of neutrophils (500 to 1,000/mm³). In one study of three different G-CSF dosages (5, 10, and 16 mcg/kg per day), there was no significant difference in the rate of hematopoietic recovery between the different dosages.⁸⁴ In another study, delayed initiation of G-CSF at a dosage of 5 mcg/kg per

day until day 5 posttransplant did not impair hematopoietic recovery after autologous PBSC transplantation.⁸⁵ Pegfilgrastim is currently being studied in the transplant setting.

Hematopoietic growth factors also accelerate the rate of hematopoietic recovery in patients undergoing alloHSCT. Although laboratory studies show that growth factors can modify T-cell and dendritic cell function, a meta-analysis of 18 studies, including 9 prospective randomized trials, showed no increased risk of acute GVHD when G-CSF or GM-CSF was used after alloHSCT.⁸⁶ However, a recently published retrospective study of patients with acute leukemia showed that G-CSF use after allogeneic BMT was significantly associated with an increased risk of acute GVHD and death.⁸⁷ It is interesting to note that no detrimental effects of G-CSF were noted in patients receiving allogeneic PBSC transplants.

None of the commercially available hematopoietic growth factors has a significant effect on platelet recovery. Results of studies with investigational platelet growth factors given posttransplant, such as thrombopoietin and interleukin-11, have been disappointing.⁸³ Platelet transfusions remain the standard of care in patients with thrombocytopenia below a given threshold (e.g., 10,000/mm³) or who are having significant bleeding.

Anemia may also be problematic in the posttransplant setting, especially in patients receiving allogeneic transplants. The etiology is unclear and most likely multifactorial. Erythropoietin administration may be useful in reducing the need for red blood cell transfusions and may be given in regimens similar to those given for malignancy-associated anemia.⁸³

GRAFT-VERSUS-HOST DISEASE

GVHD is caused by immunocompetent donor T cells reacting against antigens presented by antigen-presenting cells. In that setting, donor T cells recognize histocompatibility antigens of the host as genetically foreign, become activated, proliferate, and attack recipient tissue, thereby producing the clinical syndrome of GVHD.⁸⁸

Two different clinical GVHD syndromes have been recognized, depending on the time of onset and clinical presentation.⁸⁹ While there is considerable overlap, acute GVHD occurs early, while chronic GVHD occurs late in the posttransplant course; acute GVHD is usually limited to the gastrointestinal tract, skin, and liver, while signs and symptoms of chronic GVHD resemble an autoimmune disorder and can affect many organ systems

Acute Graft-Versus-Host Disease

Acute GVHD usually becomes clinically evident during the first 100 days posttransplant and is characterized by selective epithelial damage of target organs by donor T cells.^{89,90} The onset of acute GVHD is often delayed past day 100 following NMT.⁶⁵ The pathophysiology of acute GVHD has been described as a three-step process. In step 1, the high-dose preparative regimen leads to damage and activation of host tissues and the secretion of inflammatory cytokines such as interleukin-1 and tumor necrosis factor- α . In step 2, donor T cells are activated, and secretion of other cytokines by activated T cells results in the recruitment of other cell types (e.g., macrophages and natural killer cells) that also contribute to the pathology associated with GVHD. The third and final step is characterized by the generation of multiple cytotoxic effectors that contribute to target tissue injury. The term "cytokine storm" is sometimes used to describe the critical role of inflammatory cytokines in this process.

Based on this three-step model, three general approaches can be used to prevent GVHD in humans. The first is to reduce host tissue

FIGURE 134-5. Clinical grading of acute GVHD. The left panel summarizes the grading by organ system; the right panel shows the overall clinical grade. With grade I, only the skin can be involved. With more extensive involvement of the skin or involvement of liver and intestinal tract and impairment of the clinical performance status, either alone or in any combination, the severity grade advances from II to IV.

damage with the use of reduced intensity or nonmyeloablative conditioning regimens. The second and most widely used approach is to modulate donor T cells by reducing T-cell numbers (T-cell depletion), inhibiting T-cell activation (most immunosuppressive agents), or inhibiting T-cell proliferation (antiproliferative agents). The third approach is to block inflammatory stimulation and effectors (e.g., tumor necrosis factor- α inhibitors).

The principal target organs for acute GVHD are the skin, liver, and gastrointestinal tract. Acute GVHD is classified into four grades, depending on the number of organs involved and the degree of involvement of each organ (Fig. 134-5). Grade I disease involves only the skin, while grades II through IV involve the skin and either the liver or gastrointestinal tract or both. The initial sign of acute GVHD is usually a generalized maculopapular rash that involves the face, ears, palms, soles, and upper trunk. The skin rash can spread to the rest of the body. Acute GVHD usually progresses to involve other organs. Gastrointestinal GVHD is manifested as diarrhea, but may progress to abdominal pain/cramping and ileus. GVHD of the upper intestinal tract has also been described presenting as nausea, vomiting, anorexia, and dyspepsia. The diagnosis of gastrointestinal GVHD must be made by mucosal biopsy. Hepatic GVHD is usually asymptomatic, consisting of hyperbilirubinemia and increases in serum aminotransferase and alkaline phosphatase levels. The diagnosis is usually made by biopsy, although many patients are not biopsied.

The overall incidence of moderate to severe (grades II to IV) GVHD ranges from 10% to more than 80% after alloHSCT. Mortality directly attributable to acute GVHD or its treatment occurs in 10% to 20% of patients. The incidence of GVHD is related to the degree of histocompatibility, number of T cells in the graft, donor and recipient age, and prophylactic regimen. In patients receiving PBSC grafts, CD34⁺ cell dose and type of prophylactic regimen are also risk factors. The risk of acute GVHD is lower in recipients of NMT and UCB transplants as compared with myeloablative allogeneic transplants,^{26,65} and is slightly higher in recipients of allogeneic PBSC transplants as compared with allogeneic BMT.²⁴ The most severe acute GVHD is observed in alloHSCT with non-HLA-identical related or unrelated donors. In these settings, the incidence of grades II to IV acute GVHD exceeds 50%, despite aggressive GVHD prophylaxis. The risk of acute GVHD is lower in

patients with a certain interleukin-10 genotype.⁹¹ Interleukin-10 secreted by antigen-presenting cells promotes the development of immunologic tolerance and suppresses the production of inflammatory cytokines.

Multiorgan acute GVHD and the drugs given to prevent or treat it are associated with delayed immunologic recovery and increased susceptibility to infections. Infection is often the primary cause of death in patients with GVHD. Patients with GVHD on immunosuppressive therapy should receive prophylactic antiviral, antibacterial, and antifungal therapy.

10 Because treatment of established acute GVHD is often unsatisfactory, aggressive preventive measures are usually taken. The most common strategy used to prevent acute GVHD is to block the activation of T cells by administration of immunosuppressive agents.^{89,90} Several immunosuppressive agents have been used, including methotrexate, cyclosporine, tacrolimus, mycophenolate mofetil, antithymocyte globulin, corticosteroids, and monoclonal antibodies directed at T cells. The pharmacology of these drugs is reviewed elsewhere.⁹² Most GVHD prophylaxis regimens combine two or more immunosuppressive agents that affect different stages of T-cell activation. Another strategy is to remove or deplete most T cells from donor bone marrow *ex vivo* prior to transplant by physical separation (i.e., lectin agglutination) or by treatment with monoclonal antibodies directed at T cells (see Fig. 134-3).⁸¹

In alloHSCT with HLA-identical sibling donors, the combination of cyclosporine and either methotrexate or corticosteroids reduces the incidence of grades II to IV acute GVHD to 25% to 40%. Intravenous cyclosporine is usually started around day 0 at an initial dosage of 3 to 5 mg/kg per day, given in two divided doses. Dosages are adjusted based on trough cyclosporine concentrations. Patients are converted to oral cyclosporine when they can tolerate oral medications. Cyclosporine is given at full doses until about day 50 and in the absence of GVHD, is then gradually tapered and discontinued by day 180. Methotrexate is given intravenously on days 1, 3, 6, and 11 posttransplant. The methotrexate dosage is 10 mg/m², except for the first dose given on day 1 (15 mg/m²). Some protocols omit the day 11 dose because of its myelosuppressive effects. When cyclosporine is given in combination with corticosteroids, methylprednisolone is usually started during the first 2 weeks

posttransplant, given at full dosages for several weeks, and gradually tapered in the absence of GVHD. Although the efficacy of cyclosporine-methotrexate and cyclosporine-corticosteroids appears to be similar, the use of methotrexate may increase the risk of early graft failure, while corticosteroid administration has been associated with a higher incidence of infections. It is not clear whether three-drug regimens are more effective than two-drug regimens. In one prospective randomized study, the addition of methylprednisolone did not further increase the efficacy of the cyclosporine-methotrexate regimen.⁹³ Unexpectedly, patients who received the three-drug combination had a higher incidence of acute and chronic GVHD and infection than did those given cyclosporine and methotrexate.⁹⁴ In contrast, two other prospective randomized studies showed a benefit for the three-drug regimen versus a two-drug regimen.^{95,96} It is not completely clear why the trials reached different conclusions, but the different schedules of methylprednisolone may have had some influence on the results. In the first trial, methylprednisolone was given from days 0 to 35 posttransplant. In contrast, methylprednisolone was not started in the other trials until after day 7 posttransplant. Some investigators speculate that early administration of methylprednisolone may have interfered with the antiproliferative effects of methotrexate on T cells.⁹³

Tacrolimus, given either alone or combined with methotrexate or methylprednisolone, has also been studied as GVHD prophylaxis after alloHSCT.⁸⁹ Two large multicenter randomized trials compared cyclosporine and methotrexate with tacrolimus and methotrexate. One study was done in patients undergoing HLA-identical sibling alloHSCT,⁹⁷ while the other study was done in patients undergoing matched unrelated alloHSCT.⁹⁸ Both studies found the tacrolimus combination to be significantly superior to the cyclosporine combination in preventing grades II to IV acute GVHD. The incidence of renal impairment was higher in patients receiving tacrolimus, and more tacrolimus-treated patients in the HLA-sibling transplantation trial required hemodialysis. The incidence of hypertension was significantly higher in cyclosporine-treated patients in the HLA-matched sibling alloHSCT trial. No difference in the overall or relapse-free survival rate was reported in the two trials, although in the subgroup of patients with advanced disease in the HLA-sibling alloHSCT trial, cyclosporine-treated patients had significantly better overall and disease-free survival rates at 2 years as compared to those patients who received tacrolimus. The authors also explained that lowering the target blood levels to less than 20 ng/mL might reduce the renal toxicity of tacrolimus. Based on the results of these two studies, some transplant centers currently use tacrolimus and methotrexate as first-line acute GVHD prophylaxis.

Acute GVHD prophylaxis regimens used in NMT are usually similar to those used in myeloablative alloHSCT. Some centers, however, have developed novel prophylactic regimens specifically for patients undergoing NMT. An example of such a regimen is cyclosporine and mycophenolate mofetil,^{58,62} which was developed based on preclinical studies.⁹⁹

The role of ex vivo T-cell depletion from donor grafts is controversial (see Fig. 134–3).⁸¹ Although the use of T-cell-depleted marrow can reduce the incidence and severity of acute GVHD, it is associated with an increased risk of graft failure, delayed immune reconstitution, leukemic relapse, cytomegalovirus reactivation, and Epstein-Barr virus–related lymphoproliferative disorders. As a result, this approach does not improve the survival rate in recipients of HLA-identical sibling donor marrow. These observations suggest that important cell populations are being eliminated in the depletion process. Various approaches are being investigated to selectively remove the T cells responsible for GVHD while leaving those cells that

mediate engraftment, antileukemic effect, and suppression of Epstein-Barr virus–transformed lymphocytes. Another approach is to infuse the T cells originally depleted from the graft later in the posttransplant period to prevent leukemic relapse.¹⁰⁰ Because of the higher risk of GVHD in alloHSCT with HLA-mismatched or matched unrelated donors, T-cell depletion is sometimes included as part of the GVHD prophylaxis regimen in that setting.

With HLA-mismatched or matched unrelated donors, the risk of moderate-to-severe (grades II to IV) acute GVHD is 50% or higher with conventional two-drug prophylaxis. Several approaches are used to reduce the risk of acute GVHD in this high-risk group of patients: three-drug GVHD prophylaxis, pretransplant administration of antithymocyte globulin, or ex vivo T-cell depletion of donor bone marrow (see Fig. 134–3). Encouraging results have been reported with the addition of novel immunosuppressive agents such as sirolimus to two-drug prophylaxis regimens.¹⁰¹ The addition of rabbit antithymocyte globulin to the pretransplant conditioning regimen reduced the risk of acute GVHD, but increased the risk of lethal infections.¹⁰² Uncontrolled studies suggest that ex vivo T-cell depletion significantly reduces the risk of early graft failure and acute GVHD, with apparent preservation of the GVL effect.⁸¹

If a patient develops grade II to IV acute GVHD, prophylactic agents are continued and high-dose corticosteroids, given as intravenously administered methylprednisolone, are started. The usual dosage is 2 mg/kg per day, given in two divided doses. The initial dosage is as high as 10 mg/kg per day in some protocols, although there is no convincing evidence that higher dosages are more effective. About 20% to 40% of patients with established acute GVHD respond to high-dose corticosteroids. If the patient responds, the corticosteroid dose is tapered gradually over several weeks, depending on response. In patients who experience a flare in their GVHD during the taper phase, therapy consists of increasing the steroid dose. GVHD-associated mortality is strongly correlated to response to initial treatment, and ranges from about 25% in patients who had a complete response to about 80% in those patients who had no response or progressive disease.

Several randomized trials have evaluated other agents combined with methylprednisolone.⁸⁹ In particular, the addition of anti-T-cell antibodies such as antithymocyte globulin or monoclonal antibodies to methylprednisolone has not been shown to improve patient outcome. Administration of enteric beclomethasone dipropionate capsules to systemic methylprednisolone is more effective than systemic methylprednisolone alone in the treatment of gastrointestinal acute GVHD.¹⁰³

In patients who fail initial treatment with corticosteroids, salvage therapy with antithymocyte globulin, mycophenolate mofetil, thalidomide, sirolimus, or pentostatin has been given with some success.⁸⁹ In addition, a variety of humanized monoclonal antibodies or fusion proteins are being evaluated in the treatment of steroid-refractory acute GVHD: denileukin difitox (Ontak), daclizumab (Zenapax), infliximab (Remicade), and etanercept (Enbrel).^{104–106}

Chronic Graft-Versus-Host Disease

Chronic GVHD usually occurs after day 100 and is the major determinant of late transplant-related morbidity and mortality.^{89,90,107–109} The pathophysiology of chronic GVHD is poorly understood. Chronic GVHD is often considered an autoimmune disease because of its similarity to other autoimmune disorders.

The incidence of chronic GVHD in patients who survive more than 150 days ranges from 20% to 70%.^{89,107} The risk of chronic GVHD increases with increasing donor and recipient age, and is higher in patients who receive transplants from HLA-nonidentical

related or unrelated donors, patients who receive PBSC transplants, and patients who receive DLI. A meta-analysis reported that the risk of chronic GVHD is increased by about 50% in patients who receive allogeneic PBSC transplants as compared with BMT.²⁴ The risk of chronic GVHD is lower after UCB transplantation.²⁶ The incidence of chronic GVHD is increasing because of increasing use of alternative donors, PBSCs as the graft source, DLI for treatment of recurrence, and older recipient age. Previous acute GVHD increases the risk of chronic GVHD, but about 20% to 30% of patients who receive HLA-matched alloHSCT develop chronic GVHD with no history of acute GVHD (de novo). Unlike acute GVHD, prophylactic immunosuppression does not appear to reduce the incidence or severity of the chronic form of the disease.

The clinical manifestations of chronic GVHD can involve virtually all major organ systems.^{89,107,109} The diagnosis of chronic GVHD requires at least one manifestation that is characteristic of chronic GVHD: lichenoid oral or vaginal findings, ocular sicca, skin dyspigmentation, scleroderma, bronchiolitis obliterans, and esophageal web formation.¹⁰⁷ The most common sites of involvement are the skin, mouth, liver, and eye. Since signs and symptoms are sometimes not noticeable for several months, many centers require their alloHSCT patients to undergo screening studies to detect early clinical chronic GVHD.

The most commonly used staging system is the limited/extensive classification proposed by the Seattle HSCT program.^{89,107,109} In that system, chronic GVHD is classified as limited or extensive, depending on pathologic findings and the extent of systemic involvement. Limited chronic GVHD indicates localized skin involvement, mild hepatic dysfunction, or both. Most patients have extensive disease, with involvement of the skin, liver, eyes, mouth, esophagus, or other organs. Extensive disease is associated with a worse prognosis. The clinicopathologic findings of chronic GVHD are similar to those observed in various autoimmune diseases, with a marked increase in collagen deposition in the target organs. Several investigators have proposed improved staging systems based on larger numbers of patients and survival.¹¹⁰

If no functional impairment is present, patients with limited disease are not treated with systemic therapy. A variety of topical preparations may be used in patients with skin-only disease, such as clobetasol, tacrolimus, and pimecrolimus. Many patients with extensive chronic GVHD, if left untreated, will die of infections or become disabled. The long-term survival rate is worse in certain subgroups of patients, such as patients with extensive skin involvement, thrombocytopenia, progressive onset of chronic GVHD, and those who fail to respond to immunosuppressive therapy.

11 Initial treatment in patients with standard-risk chronic GVHD consists of prednisone (1 mg/kg per day) alone or alternate-day therapy with prednisone and cyclosporine (10 to 12 mg/kg per day in two divided doses).^{90,107–109} Although many clinicians prefer alternate-day prednisone and cyclosporine, a recently published randomized trial showed no differences in response or survival between the two regimens in standard-risk patients.¹¹¹ Tacrolimus is substituted for cyclosporine at some centers. Patients with high-risk disease should be treated with alternate-day therapy with prednisone and cyclosporine or tacrolimus. The calcineurin inhibitor is given daily rather than on alternate days at some centers. Treatment is continued until signs and symptoms of the disease have resolved, usually over a period of several months. As chronic GVHD improves, immunosuppressive therapy is gradually tapered and finally discontinued provided there is no flare of GVHD. About 60% of standard-risk patients and 40% of high-risk patients treated for chronic GVHD

have all of their immunosuppressive therapy successfully discontinued. Patients who fail initial therapy have a very poor prognosis and several therapies have been investigated with varying degrees of success: thalidomide, ultraviolet A irradiation after oral treatment with β -methoxypsoralen, extracorporeal photophoresis, tacrolimus, sirolimus, pentostatin, mycophenolate mofetil, hydroxychloroquine, and others.^{89,107,109}

CLINICAL CONTROVERSY

The choice of initial treatment of chronic GVHD is controversial. Many clinicians will treat standard- and high-risk patients with alternate-day prednisone and either daily or alternate-day cyclosporine. However, a randomized trial showed no differences in response or survival between prednisone alone and alternate-day prednisone and cyclosporine in standard-risk patients. Other clinicians will substitute tacrolimus for cyclosporine. Several randomized trials are in progress, and the results of these trials should help to determine the optimal initial therapy for chronic GVHD.

Infection is the primary cause of death in patients with chronic GVHD, and antimicrobial prophylaxis is an important component of the care of patients being treated for chronic GVHD. Patients should receive oral trimethoprim-sulfamethoxazole, penicillin, and acyclovir to prevent those infections commonly seen in immunocompromised patients.^{89,107,108} Some centers will also administer intravenous immunoglobulin to patients with low serum immunoglobulin G levels.

INFECTION

Patients undergoing high-dose chemotherapy with autoHSCT or alloHSCT are severely immunocompromised and therefore at high risk for bacterial, fungal, and viral infection. Management of these infections is discussed in detail in Chap. 120. Comprehensive guidelines for monitoring, prophylaxis, and treatment of infections in HSCT recipients are available at <http://www.cdc.gov/mmwr/preview/mmwrhtml/rr4910a1.htm>.

LATE COMPLICATIONS

With the success of HSCT, the number of long-term survivors has grown. Many survivors experience delayed complications of transplantation, especially those receiving alloHSCT, and primary care physicians will care for them.¹¹² Major late complications include restrictive and obstructive pulmonary disease; bone and joint disease; cataract formation; endocrine dysfunction, including sterility; impaired growth and development; infections; cardiovascular disease; and cirrhosis as a result of chronic hepatitis C infection and secondary malignancies.^{113,114}

Physical recovery tends to occur earlier than psychological or work recovery.¹¹⁵ Full recovery usually takes several years, and about two-thirds of patients do not have major limitations by 5 years.

CONCLUSIONS

Over the last few decades, HSCT has evolved from an idea into a well-established therapy used to treat thousands of patients with

serious malignant and nonmalignant hematologic diseases. Transplantation is also being investigated as a treatment modality in patients with certain solid tumors or life-threatening autoimmune diseases. Because myelosuppression is the dose-limiting toxicity for many anticancer agents, HSCT allows the administration of higher and potentially more effective doses of chemotherapy. In patients who receive alloHSCT, cells in the graft can mediate a GVT effect.

Although HSCT is a potentially curative therapy, this modality is associated with many serious and potentially life-threatening complications. With improved supportive care and management of infection, transplant-related mortality after alloHSCT with HLA-matched sibling donors has been reduced over the last few years. Causes of death are usually related to transplant-related organ toxicity, GVHD, or immunosuppression. Until recently, alloHSCT was usually restricted to patients younger than 50 years old with an HLA-identical sibling donor. With the availability of NMT, alloHSCT is now being offered to patients who would not otherwise be candidates for alloHSCT because of age or comorbidities. The risk of transplant-related mortality after autoHSCT is very low, and is primarily related to regimen-related toxicity. Many long-term survivors of HSCT will experience delayed complications.

ABBREVIATIONS

ALL: acute lymphoblastic leukemia
 alloHSCT: allogeneic hematopoietic stem cell transplantation
 AML: acute myelogenous leukemia
 autoHSCT: autogenous hematopoietic stem cell transplantation
 BEAC: BCNU, etoposide, ara-C, and cyclophosphamide
 BEAM: BCNU, etoposide, ara-C, and melphalan
 BMT: bone marrow transplant
 BuCy: busulfan and cyclophosphamide
 CBV: cyclophosphamide, carmustine (BCNU), and etoposide (VP-16)
 CML: chronic myelogenous leukemia
 CyTBI: cyclophosphamide and total body irradiation
 DAH: diffuse alveolar hemorrhage
 DLI: donor lymphocyte infusion
 G-CSF: granulocyte colony-stimulating factor
 GM-CSF: granulocyte macrophage-colony stimulating factor
 GVHD: graft-versus-host disease
 GVL: graft-versus-leukemia (effect)
 GVT: graft-versus-tumor (effect)
 4-HC: 4-hydroperoxycyclophosphamide
 HLA: human leukocyte antigen
 HSCT: hematopoietic stem cell transplantation
 IIP: idiopathic interstitial pneumonitis
 IL-2: interleukin-2
 MHC: major histocompatibility complex
 MLC: mixed lymphocyte culture
 MLR: mixed lymphocyte reaction
 MUD: matched unrelated donor
 NMDP: National Marrow Donor Program
 NMT: nonmyeloablative transplant
 PBPC: peripheral blood progenitor cell
 PBSC: peripheral blood stem cell
 PCR: polymerase chain reaction
 TBI: total body irradiation
 UCB: umbilical cord blood
 VOD: (hepatic) veno-occlusive disease

ASSESSMENT OF NUTRITION STATUS AND
NUTRITION REQUIREMENTS*Katherine Hammond Chessman and Vanessa J. Kumpf*

Learning Objectives and other resources can be found at www.pharmacotherapyonline.com.

KEY CONCEPTS

- 1 Classification of nutrition status is often desired as a means to identify those who are nutritionally at risk or malnourished.
- 2 Nutrition screening programs should identify those at risk for poor nutrition-related outcomes due to either over- or undernutrition.
- 3 Nutrition assessment is the first step in formulating a patient-specific nutrition care plan for a patient who is found to be nutritionally at risk or malnourished.
- 4 A nutrition-focused medical and dietary history and a nutrition-focused physical examination are key components of nutrition assessment and will reveal risk factors for and the likelihood of malnutrition and nutrient deficiencies.
- 5 Appropriate anthropometric measurements are essential in a complete nutrition assessment and should be evaluated based on published standards.
- 6 Biochemical (laboratory) tests are also essential for nutrition assessment, but must be interpreted in the context of the physical findings, medical history, and clinical status of the patient, as well as specific test limitations.
- 7 Nutrient deficiencies involving micronutrients (e.g., vitamins or trace elements) or macronutrients (e.g., fat, protein, or carbohydrate) are possible, and a comprehensive nutrition assessment will identify the presence of these.
- 8 When determining patient-specific nutrition requirements, goals should be established based on the patient's clinical condition and the need for maintenance or repletion in adults, as well as for continued growth and development in children.
- 9 Drug-nutrient interactions can affect a patient's nutrition status as well as the response to or adverse effects seen with drug therapy and must be considered when evaluating a patient's nutrition care plan.
- 10 An initial nutrition assessment and determination of nutrition requirements only defines an empirical starting point for a nutrition care plan. Close monitoring is required so that timely adjustments to the nutrition care plan can be made based on patient-specific responses to ensure appropriate nutrition-related outcomes.

Nutrition care is a vital component of quality patient care. This chapter reviews the current tools most commonly used for nutrition screening and accurate, relevant, and cost-effective nutrition assessment. Determination of patient-specific micro- and macronutrient requirements and potential drug-nutrient interactions are also discussed.

CLASSIFICATION OF NUTRITION DISEASE

1 Undernutrition usually results from starvation (inadequate nutrient intake) or altered metabolism (inappropriate use of ingested nutrients). Pure starvation occurs when inadequate amounts of appropriate nutrients are available to support tissue repair or synthesis, and changes can be reversed by adequate feeding.¹ An alteration in nutrient metabolism exists when the cell has altered substrate demands

or use such as cachexia associated with inflammatory or neoplastic conditions. In such situations, enhancing nutritional intake may not be sufficient to meet the increased demand.¹ Regardless of the cause, undernutrition results in changes in subcellular, cellular, and/or organ function that expose the individual to increased risks of morbidity and mortality (see Chap. 136). In general, deficiency states can be categorized as those involving protein and calories or those involving single nutrients such as individual vitamins or trace elements. Depletion of individual nutrients leads to symptoms related to that nutrient's function. Protein-calorie malnutrition may be classified as marasmus, kwashiorkor, or mixed marasmus/kwashiorkor.

Marasmus is a chronic condition resulting from a prolonged deficiency in total intake and/or nutrient utilization. Somatic protein (skeletal muscle) and adipose tissue (subcutaneous fat) wasting occurs, but visceral protein production (e.g., albumin and transferrin) is

preserved. Weight loss usually exceeds 10% of usual weight. When severe, cell-mediated immunity, measured by delayed cutaneous hypersensitivity (DCH), and muscle function are impaired. Patients with wasting diseases such as cancer commonly have marasmus and a prototypical starved, wasted appearance.

Kwashiorkor develops when there is adequate calorie but a relatively inadequate protein intake. These patients generally are well nourished but are extremely catabolic, usually secondary to trauma, infection, or burns. There is depletion of visceral (and to some degree somatic) protein pools with relative adipose tissue preservation, and hypoalbuminemia and edema are commonly seen. In the setting of severe metabolic stress and protein deprivation, *kwashiorkor* may develop rapidly and may result in impaired immune function.

Mixed marasmus/kwashiorkor is a form of severe protein-calorie malnutrition that develops in chronically ill, starved patients during periods of hypermetabolic stress. There is reduced visceral protein synthesis superimposed on wasting of somatic protein and energy (adipose tissue) stores. Immunocompetence is lowered, increasing the incidence of infection, and wound healing is compromised.

Obesity (overnutrition) is a major health care concern in the United States. Between 2000 and 2001, the prevalence of obesity in American adults (defined as a body mass index [BMI] of 30 kg/m² or greater) increased from 19.8% to 20.9%.² Additionally, approximately 15% of children and adolescents (ages 6 to 19 years) are obese (BMI at or above the 95th percentile for age³ on the gender appropriate BMI-for-age growth chart published by the Centers for Disease Control National Center for Health Statistics [NCHS]).⁴ Many more children are considered to be at-risk for obesity (BMI at or above the 85th percentile for age). Nutrition assessment allows identification of obese individuals or those at risk of becoming obese, and the numerous consequences of overnutrition, including type II diabetes mellitus, cardiovascular disease, and stroke (see Chap. 140).

NUTRITION SCREENING

Because a thorough nutrition assessment on every patient is not practical (or warranted), nutrition screening provides a systematic way of identifying individuals at risk for malnutrition. Risk factors for undernutrition include any disease state, complicating condition, treatment, or socioeconomic condition that may result in a decreased nutrient intake, altered metabolism, and/or malabsorption. Nutrition screening can be done in the home by the patient or home health care professional, in long-term care facilities, in ambulatory care clinics, or in the hospital. Various rating and classification systems have been proposed to assess nutrition risk and guide subsequent interventions.^{5–7} Checklists are used in many clinical settings to quantify a person's food and alcohol consumption habits; ability to buy, prepare, and eat food; weight history; diagnoses; or medical/surgical procedures. Depending on the specific criteria evaluated, three to four risk factors may put a person at risk for malnutrition. Pediatric screening programs most often evaluate growth parameters against the NCHS growth charts⁴ and medical conditions known to increase nutrition risk.⁸ Hospital screening programs must also identify patients receiving specialized nutrition support, or enteral or parenteral nutrition prior to admission.

The Joint Commission on Accreditation of Healthcare Organizations hospital standards state: “Based on the results of the nutrition screen and, when appropriate, nutrition assessment and re-assessment, the nutrition treatment plan is implemented for all patients determined to be at nutrition risk.”⁹ For inpatients, a nutrition screening process should occur within an institution-designated

period of time (usually 24 to 72 hours after admission). In the hospital setting, patients initially determined to be “not at risk” should be re-evaluated every 7 to 14 days to detect deterioration in nutrition status secondary to changes in food intake or clinical condition. By identifying at-risk individuals, nutrition screening can be a cost-effective way to help decrease complications and length of hospital stay.¹⁰ Nutrition screening should also occur frequently in the outpatient setting, especially in young children and the elderly, to ensure that potential nutritional issues are addressed before they become significant problems.

NUTRITION ASSESSMENT

A comprehensive nutrition assessment is the first step in formulating a patient-specific nutrition care plan. Nutrition assessment has four major goals: (1) identification of the presence or risk of developing malnutrition, including disorders resulting from micro- or macronutrient deficiencies (undernutrition), obesity (overnutrition), or impaired metabolism, (2) determination of risk of malnutrition-associated complications, (3) establishment of estimated nutrition needs, and (4) establishment of baseline parameters against which to measure nutrition therapy outcomes.

A comprehensive nutrition assessment should include a nutrition-focused medical and dietary history, a physical examination including anthropometric measurements and laboratory measurements, and provides a basis for determining the patient's nutrition requirements and the optimal type and timing of nutrition intervention.

CLINICAL EVALUATION

Clinical evaluation with a nutrition-focused medical and dietary history and physical examination remains the oldest, simplest, and most widely used method of evaluating nutrition status. Clinical evaluation of nutrition status correlates well with objective evaluations (e.g., laboratory parameters and anthropometric measurements). The medical and dietary history components of the clinical evaluation will provide information about factors that predispose to malnutrition (e.g., prematurity, chronic diseases, gastrointestinal [GI] malfunction, and alcohol abuse). The clinician should direct the interview to elicit any history of weight loss, anorexia, vomiting, diarrhea, and decreased or unusual food intake (Table 135–1).

The nutrition-focused physical examination consists of an assessment of lean body mass (LBM) and the physical findings of vitamin deficiency, trace element deficiency, and essential fatty acid deficiency. The assessment should characterize the presence and degree of muscle wasting, edema, loss of subcutaneous fat, dermatitis, glossitis, cheilosis, and/or jaundice¹¹ (Table 135–2).

In the 1970s, an initial, comprehensive nutritional assessment required up to 3 days to complete and cost several thousand dollars. In the 1980s, the subjective global assessment (SGA), a streamlined, simplified, reproducible, cost-effective approach to nutrition assessment that took only 20 minutes to complete was introduced and is used extensively today. Five aspects of the medical and dietary history are used in the SGA: weight changes in the previous 6 months, dietary intake changes, GI symptoms, functional capacity, and disease states. Weight loss of less than 5% of usual body weight is considered a “small” loss, 5% to 10% loss is a “potentially significant loss,” and more than a 10% loss is a “definitely significant loss.” Dietary intake should be characterized as either normal or abnormal, and the length of time and degree of abnormal intake should be noted. The presence of GI symptoms (e.g., anorexia, nausea, vomiting, or diarrhea) on a daily basis for longer than 2 weeks is significant. Functional

capacity assesses the patient’s energy level and whether the patient is active or bedridden. Finally, disease states present are assessed as to their impact on metabolic demands (i.e., no stress, low, moderate, or high stress). Four physical examination findings are rated as normal, mild, moderate, or severe: loss of subcutaneous fat (triceps and chest), muscle wasting (quadriceps and deltoids), edema (ankle and sacral), and ascites. The clinician then ranks the patient’s nutritional status as adequately nourished, moderately malnourished, or severely malnourished.

ANTHROPOMETRIC MEASUREMENTS

Anthropometric measurements, gross measurements of body cell mass, are used to evaluate LBM and fat stores. The most common measurements are stature (height or length, depending on age), weight, head circumference (for children younger than 3 years of age), and measurements of limb size, such as skinfold thickness, midarm muscle circumference (MAMC), wrist circumference, and waist circumference. Bioelectrical impedance analysis (BIA) is also an anthropometric assessment tool. These parameters are used to compare an individual with normative standards for a population and as repeated measurements in an individual to monitor response to a nutrition care plan. In adults, nutrition-related changes in anthropometric measurements occur slowly; several weeks or more are usually required before detectable changes are noted. In infants and young children, however, changes may occur more quickly. Acute changes in anthropometric measurements, specifically weight and skinfold thickness, usually reflect changes in hydration status, and this must be considered when interpreting these parameters, particularly in hospitalized patients.

WEIGHT, STATURE, AND HEAD CIRCUMFERENCE

Body weight is a nonspecific measure of body cell mass, representing skeletal mass, body fat, and the energy-using component referred to as LBM. Change in weight over time, particularly in the absence of edema, ascites, and voluntary losses, is an important indicator of altered LBM. Interpretation of any actual body weight (ABW) measurement should take into consideration ideal weight-for-height, also referred to as ideal body weight (IBW) or LBM, usual body weight (UBW), fluid status, and age (Table 135–3). Dehydration will result in

TABLE 135–3. Evaluation of Actual Body Weight

| Actual body weight (ABW) compared to ideal body weight (IBW) | |
|--|-----------------------|
| <i>Undernutrition</i> | |
| ABW <69% IBW | Severe malnutrition |
| ABW 70–79% IBW | Moderate malnutrition |
| ABW 80–90% IBW | Mild malnutrition |
| <i>Normal</i> | |
| ABW 90–120% IBW | Normal |
| <i>Overnutrition</i> | |
| ABW >120% IBW | Overweight |
| ABW ≥150% IBW | Obese |
| ABW ≥200% IBW | Morbidly obese |
| Actual body weight (ABW) compared to usual body weight (UBW) | |
| ABW 85–95% UBW | Mild malnutrition |
| ABW 75–84% UBW | Moderate malnutrition |
| ABW <74% UBW | Severe malnutrition |

From McClave et al.¹¹

TABLE 135-4. Ideal Body Weight Calculation and Assessment**Equations**

Males: IBW (kg) = 50 kg + [2.3 × (inches over 5 feet)]

Females: IBW (kg) = 45.5 kg + [2.3 × (inches over 5 feet)]

Children (1–18 years): IBW (kg) = [(height in cm)² × 1.65]/1000

Adjusted body weight for obesity = [(ABW – IBW) × 0.25] + IBW

Examples

| | |
|---------------------------------------|--|
| Male, weight 165 lb, height 6'2" | IBW = 50 kg + (2.3 × 14) = 82.2 kg ABW (75 kg) = 91% IBW Interpretation: normal |
| Female, weight 198 lb, height 5'6" | IBW = 45.5 kg + (2.3 × 6) = 59.3 kg ABW = 152% IBW Interpretation: obese |
| Child, weight 28.6 lb, height 3'2" | IBW = [(96.5) ² × 1.65]/1,000 = 15.4 kg ABW = 84% IBW Interpretation: mild malnutrition |

decreased ABW but not a loss in LBM. Once the patient is rehydrated, rechecking the weight is important to establish the baseline weight to use for nutrition evaluation. The presence of edema or ascites increases total body water (TBW), thus increasing ABW. Weights of patients with severe edema and ascites should not be used for nutrition assessment without taking the extra water weight into consideration. Subtle changes in fluid status that may affect ABW can be detected by monitoring the patient's daily fluid intake and output.

The IBW provides one population reference standard against which the ABW can be compared to detect both over- and undernutrition states. The IBW for a given height is the weight that correlates with maximum longevity. Numerous reference tables have been generated based on various population statistics. In clinical practice, mathematical equations based on gender and heights are used commonly to estimate IBW. Equations for adults (age 18 years and older) and children and examples of their use are given in Table 135-4.

Alternatively, IBW in children can be determined by identifying the weight that corresponds to the same growth percentile as the child's measured stature (length or height) on the appropriate NCHS growth chart.⁴ For obese patients, an adjusted IBW should be used for nutrition-related calculations (see Table 135-4).

Change in weight over time can be calculated as the percentage of UBW, where percent change = (ABW/UBW) × 100 (see Table 135-3). Use of the UBW as a reference point provides a more accurate reflection of clinically and nutritionally significant weight changes. Determining a patient's UBW, however, depends on patient or family recall, which may be inaccurate. The use of UBW avoids the problems of normative tables, and it documents comparative changes in body weight. The change in weight also should be interpreted relative to time. In adults, unintentional weight loss of more than 10% in less than 6 months has been correlated with a poor clinical outcome.

The best indicator of adequate nutrition in a child is appropriate growth. At each medical encounter, weight, stature, and head circumference should be plotted on the appropriate NCHS gender- and age-based growth curve.⁴ These charts were developed in 1977 from a large population of healthy, primarily Caucasian children and revised recently to better reflect the ethnic mix of the United States' population. Special growth charts are available for assessment of short- and long-term growth of premature infants¹² and children with Down syndrome.¹³ For premature infants with corrected postnatal age of 40 weeks or more, the NCHS growth charts can be used; however, weight-for-age and length-for-age should be plotted according to corrected postnatal age until 2 years and 3.5 years of age, respectively.

Recommended intervals between measurements are weight, 7 days; length, 4 weeks; height, 8 weeks; and head circumference, 7 days in infants and 4 weeks in children up to 3 years of age.¹⁴

TABLE 135-5. Expected Growth Velocities in Children

| Age | Weight (g/day) | Height (cm/month) |
|---------|----------------|-------------------|
| 0–3 mo | 24–35 | 2.8–3.4 |
| 3–6 mo | 15–21 | 1.7–2.4 |
| 6–12 mo | 10–13 | 1.3–1.6 |
| 1–3 y | 5–9 | 0.6–1 |
| 4–6 y | 5–6 | 0.5–0.6 |
| 7–10 y | 7–11 | 0.4–0.5 |

Example of growth assessment:
Age: 2 months; weight: 3.9 kg; weight at 1 month of age, 3.1 kg;
days since last wt: 30
Growth velocity = [(3.9 kg – 3.1 kg) × 1,000 g/kg]/30 days =
26.7 g/day
Interpretation: normal growth

From Centers for Disease Control.⁴

Growth velocity can be used to assess growth at intervals too close to plot accurately on a growth chart (Table 135-5). In newborns, average weight gain is 10 to 20 g/kg per day (20 to 30 g/day in term infants and 10 to 25 g/day in preterm infants).¹⁵ Weight gain declines considerably after 2 to 3 months of age. Head growth (measured by head circumference), which is usually 0.5 cm/week during the first year of life, can be compromised during periods of critical illness or malnutrition. Sustained head growth, especially at a rate above expected, during these periods suggests hydrocephalus.

Growth failure or failure-to-thrive is defined as weight-for-age or weight-for-height (or length) below the 5th percentile or a falloff of two or more major percentiles (major percentiles are defined as 95th, 90th, 75th, 50th, 25th, 10th, and 5th). Weight-for-height evaluation is age-independent and helps differentiate the stunted child (chronic malnutrition) from the wasted child (acute malnutrition). Short stature, which is associated with many chronic diseases, is a manifestation of chronic undernutrition. Short stature in the absence of malnutrition suggests an endocrinopathy such as growth hormone deficiency, but may also be a normal variant.

BODY MASS INDEX

BMI, defined as body weight in kilograms divided by the square of the height in meters (kg/m²), is another way to assess appropriateness of weight-for-height. BMI is more highly correlated with body fat than any other indicator using height and weight. It can be used to categorize both obesity and undernutrition in adults and children. Various tables listing BMI stratified by height and weight are available for quick reference.¹⁶ A BMI greater than 25 kg/m² is considered overweight, 30 kg/m² or higher is obese, and a BMI less than 18.5 kg/m² is indicative of malnutrition. Suggested interpretation of BMI values is shown in Table 135-6.^{17,18}

Although guidelines for BMI have not yet been universally accepted, in general, healthy weights are those associated with a reduction in disease risk. BMI values over 25 kg/m² are considered to be a risk factor for premature death and disability as a consequence of overweight and obesity (see Chap. 140). These health risks increase as the BMI increases. While BMI correlates strongly with total body fat, individual variation, especially in very muscular persons, may lead to erroneous classification of either obesity or malnutrition when BMI alone is used to assess nutrition status. As with other nutrition assessment parameters, BMI should be interpreted based on individual characteristics including gender and frame size. A major advantage of the revised NCHS growth charts for children was the addition of charts for assessment of BMI based on age and gender. It is hoped that

TABLE 135–6. Interpretation of Body Mass Index (BMI) Values

| BMI (kg/m ²) | Nutrition Status |
|--|---|
| Adults | |
| <16 | Severe malnutrition |
| 16–17 | Moderate malnutrition |
| 17–18.5 | Mild malnutrition |
| 19–25 | Healthy (19–34 years of age) |
| 21–27 | Healthy (over 35 years of age) |
| 25–30 | Overweight (19–34 years of age) |
| 27.5–30 | Overweight (over 35 years of age) |
| 30–40 | Moderate obesity |
| >40 | Severe or morbid obesity |
| Children | |
| BMI-for-age <5th percentile | Underweight |
| BMI-for-age 5th–85th percentile | Healthy |
| BMI-for-age >85th percentile | At risk for overweight |
| BMI-for-age ≥95th percentile | Overweight |
| Example of BMI calculation and assessment | |
| Male, 40 y, wt 180 lb, ht 5'10" | $BMI = 81.1 / (1.78)^2 = 25.8 \text{ kg/m}^2$ Interpretation: healthy |
| Female, 25 y; wt 185 lb, ht 5'5" | $BMI = 84.1 / (1.65)^2 = 30.9 \text{ kg/m}^2$ Interpretation: moderately obese |

From Meisler et al.¹⁷ and Himes et al.¹⁸

such charts will heighten parental and health care provider awareness of those children whose BMI and family history put them at risk for adult obesity and its associated risks.

CLINICAL CONTROVERSY

Historically, IBW has been used to evaluate an individual's nutrition status, specifically 1.5 times IBW has been designated as overweight. However, IBW is predicated on height, body frame size, and muscle mass. The use of IBW may lead to misclassification of nutrition status in some individuals. Body mass index is felt to be a better indicator of the level of adiposity in individuals and is becoming the standard for defining obesity. However, the BMI must also be interpreted carefully. While it is a convenient way to standardize over the normal range of height and weight seen in adults, it does not eliminate the need to consider gender and frame size.

SKINFOLD THICKNESS AND MIDARM MUSCLE CIRCUMFERENCE

Skinfold thickness measurement provides an estimate of subcutaneous fat, whereas MAMC estimates skeletal muscle mass. These simple, noninvasive anthropometric measurements are not used commonly in clinical practice, but are appropriate for both population analysis and individual long-term monitoring. Triceps skinfold thickness (TSF) is the most commonly used skinfold measurement, although reference standards also exist for subscapular and iliac sites. Over 50% of the body's fat is subcutaneous, and changes in subcutaneous fat usually reflect changes in total body fat. Careful technique in the use of pressure-regulated calipers is essential for reproducibility and reliability in measuring TSF. MAMC is a calculated value based on the measurement of the midarm circumference and TSF.

Individual anthropometric measurements should be interpreted cautiously because standards do not account for individual variations in bone size, large muscle mass, hydration status, or skin compressibil-

ity; reference standards do not account for obesity, ethnicity, illness, and increased age; and technique is critical and interobserver error may be as high as 30%. Furthermore, in adults these parameters are slow to change, often requiring weeks before significant alterations from baseline can be detected.

WAIST CIRCUMFERENCE

Waist circumference (WC) is used to assess abdominal fat content. Excess abdominal fat that is out of proportion to total body fat is considered an independent predictor of risk for obesity-related complications. Waist circumference is determined by measuring the distance around the smallest area below the rib cage and the top of the iliac crest. Interpretation varies with age. Men are considered at risk if the waist circumference is greater than 40 inches; women are at risk if the waist circumference is greater than 35 inches. These standards do not apply if the patient is less than 5 feet tall or has a BMI of 35 kg/m² or greater.

WAIST TO HIP RATIO

The waist:hip ratio has also been associated with undesirable health consequences. For most people, extra weight around the waist confers more of a health risk than extra weight around the hips and thighs. The waist:hip ratio is determined by dividing the waist circumference by the hip circumference. The hip circumference is determined by measuring the distance around the largest extension of the buttocks. For both men and women, a waist:hip ratio of 1 or greater is considered a risk factor for adverse health consequences. A ratio of less than 1 in men or 0.8 or less in women is considered "safe."

BIOELECTRICAL IMPEDANCE

Bioelectrical impedance (BIA) is a simple, noninvasive, and relatively inexpensive technique used to measure LBM.^{19–21} The procedure is based on the fact that lean tissue has a higher electrical conductivity (less resistance) than fat, which is a poor current conductor because of its greater fluid and electrolyte content. By placing electrodes on the wrist and ankle and applying a very small electric current, impedance (resistance) to flow can be measured. Assessment of LBM, TBW, and water's distribution into compartments can be determined with BIA. Increased TBW decreases impedance; therefore, it is important to evaluate fluid status along with BIA measurements. Other potential limitations of BIA include variability with electrolyte imbalance, interference by large fat masses (obesity), and the lack of reference standards that reflect variations in individual body sizes and clinical conditions. While BIA equations have high validity when used in the population in which they were developed (mostly young, healthy adults), BIA equations are subject to errors that cannot be determined a priori unless they are validated in the specific population in which they are applied.^{22–24}

BIOCHEMICAL ASSESSMENT OF LEAN BODY MASS

6 LBM includes skeletal muscle, somatic protein, and functional proteins such as circulating proteins and the visceral proteins. Biochemically, LBM can be assessed by measuring the serum visceral proteins, albumin (ALB), transferrin (TFN), and prealbumin (thyroxine-binding prealbumin or transthyretin). Other serum proteins, such as retinol-binding protein, fibronectin (an opsonic protein), and somatomedin-C (insulin-like growth factor-1), that have a very short half-life (less than 12 to 24 hours), have been suggested as

TABLE 135–7. Visceral Proteins Used for Assessment of Lean Body Mass

| Serum Protein | Biosynthetic Site | Half-life (days) | Function | Factors Resulting in Increased Values | Factors Resulting in Decreased Values |
|----------------------------|-------------------|------------------|--|--|--|
| Albumin | Hepatocyte | 18–20 | Maintains plasma oncotic pressure; transports small molecules | Dehydration, anabolic steroids, insulin, infection | Overhydration, edema, renal insufficiency, nephrotic syndrome, poor dietary intake, impaired digestion, burns, congestive heart failure, cirrhosis, thyroid/adrenal/pituitary hormones, trauma, sepsis |
| Transferrin | Hepatocyte | 8 | Binds Fe in plasma; transports Fe to bone | Fe deficiency, pregnancy, hypoxia, chronic blood loss, estrogens | Chronic infection, cirrhosis, burns, enteropathies, nephrotic syndrome, cortisone, testosterone |
| Prealbumin (transthyretin) | Hepatocyte | 1–2 | Binds T ₃ and to a lesser extent T ₄ ; carrier for retinol-binding protein | Renal dysfunction | Cirrhosis, hepatitis, stress, surgery, inflammation, hyperthyroidism, cystic fibrosis, renal dysfunction, zinc deficiency |

Fe, iron; T₄, thyroxine; T₃, triiodothyronine.
 From Spiekerman²⁷ and Erstad et al.²⁸

indicators of nutrition status.²⁵ However, the clinical availability of these alternative tests is limited, and their relevance to nutrition status and the outcome of patients is debatable. Creatinine-height index has historically been used to assess LBM, but is seldom used today due to multiple concerns with its validity and a lack of evidence to support its usefulness in assessing muscle mass.²⁶

VISCERAL PROTEINS

Measuring serum concentrations of the transport proteins synthesized by the liver can assess the visceral protein compartment. It is assumed that a low serum protein concentration in states of undernutrition reflects the hepatic protein synthetic mass, and therefore indirectly the functional protein mass of other organs such as heart, lung, kidney, and intestines. The visceral proteins with the greatest relevance for nutrition assessment are serum ALB, TFN, and prealbumin. Many factors other than nutrition may affect the serum concentration of these proteins, including age, abnormal renal (nephrotic syndrome) or GI tract (protein-losing enteropathy) losses, hydration status (dehydration results in hemoconcentration, overhydration in hemodilution), hepatic function (because this is the primary synthesis site), and metabolic stress (sepsis, trauma, surgery, and/or infection). Therefore visceral protein concentrations must be interpreted relative to the individual's overall clinical status (Table 135–7).^{27–30}

ALB was one of the first identified biochemical markers of malnutrition and has long been used in population studies. ALB is a relatively insensitive index of early protein malnutrition because there is a large amount normally found in the body (4 to 5 g/kg of body weight), it is highly distributed in the extravascular compartment (60%), and it has a long half-life (18 to 20 days).²⁸ However, chronic protein deficiency in the setting of adequate nonprotein calorie intake leads to marked hypoalbuminemia because of a net ALB loss from the intravascular and extravascular compartments (kwashiorkor). Serum ALB concentrations also are affected by moderate-to-severe calorie deficiency; hepatic, renal, and GI disease; and infection, trauma, stress, and burns. In many cases, interpretation of serum ALB concentrations relative to nutrition status is difficult; however, a positive correlation between decreased serum ALB concentrations and poor clinical outcome has been demonstrated in a variety of settings. Additionally, serum ALB concentrations of 2.5 g/dL or less can be expected to exacerbate ascites and peripheral, pulmonary, and GI mucosal edema due to decreased colloid oncotic pressure.

TFN is a glycoprotein that binds and transports ferric iron to the liver and reticuloendothelial system for storage. As a surrogate marker of nutrition status, it is more likely to decrease in response to protein depletion before serum ALB concentrations decrease because it has a shorter biologic half-life (8 days), and there is less of it in the body (less than 100 mg/kg of body weight).²⁷ Serum TFN concentrations may be determined by direct measurement or can be estimated indirectly from measurement of total iron-binding capacity (TIBC), where $TFN = (TIBC \times 0.8) - 43$. Critical illness, hydration status, and iron stores affect the serum TFN concentration. In iron deficiency, hepatic TFN synthesis is increased, resulting in increased serum TFN concentrations unrelated to protein status.

Prealbumin is the transport protein for thyroxine and a carrier for retinol-binding protein. The body's content of prealbumin is low (10 mg/kg of body weight), and it has a very short biologic half-life (1 to 2 days).²⁷ Prealbumin may be reduced in as few as 3 days after calorie and protein intake is significantly decreased, or when hypercatabolism or severe metabolic stress (trauma or burns) is present. Because of its short half-life, it is most useful in monitoring the short-term, acute effects of nutrition support.²⁸ As with ALB and TFN, serum prealbumin concentrations are depressed in those with liver disease due to decreased hepatic synthesis. Increased serum prealbumin concentrations have been noted in patients with renal disease due to impaired renal excretion.

These serum visceral proteins are of greatest value in assessing uncomplicated semistarvation and recovery. During severe acute stress (trauma, burns, or sepsis), these proteins are relatively poor markers of nutrition status because their synthesis is downregulated as the liver increases the production of acute-phase reactants such as C-reactive protein, α_1 -acid glycoprotein, and α_1 -antitrypsin.

IMMUNE FUNCTION TESTS

The frequency of impaired immunocompetence and increased incidence of infection in malnourished patients suggests that certain immune function tests can be used as nutrition status markers. Nutrition affects immune status either directly, affecting primarily the lymphoid system, or indirectly by affecting cellular metabolism or organ systems that are involved with immune system regulation. Immune function tests used in nutrition assessment are the total lymphocyte count (TLC) and DCH reactions. Both tests are simple, readily available, and inexpensive. TLC reflects the number of

circulating T and B lymphocytes. Tissues that generate T cells are very sensitive to malnutrition and undergo involution resulting in decreased T cell production²⁹ and eventually lymphopenia. TLC is calculated from a complete blood count with differential: $TLC = (\% \text{ lymphocytes} \times \text{total number of white blood cells})$. Values of less than 1500 cells/mm³ and 900 cells/mm³ have been associated with moderate and severe nutrition depletion, respectively.¹¹

DCH is commonly assessed using antigens to which the patient has been previously sensitized. The recall antigens used most frequently in nutrition assessment are mumps, *Candida albicans*, streptokinase-streptodornase, *Trichophyton*, coccidioidin, and purified protein derivative. Anergy is associated with severe malnutrition, and immune response may be restored with nutrition repletion. Other more sophisticated immune function tests have been used to evaluate nutrition status in research settings, including lymphocyte surface antigens (CD4 and CD8 counts, CD4:CD8 ratio), T-lymphocyte responsiveness, and serum interleukin concentrations. Many non-nutrition-related factors may affect immune function indicators. Non-nutrition factors that affect TLC include infection (e.g., human immunodeficiency virus/acquired immunodeficiency syndrome [HIV/AIDS], pertussis, viruses, and tuberculosis), immunosuppressive drugs (e.g., corticosteroids, cyclosporine, chemotherapy, and antilymphocyte globulin), and the presence of leukemia and lymphoma. DCH can be affected by a number of factors, including fever, viral illness, recent live virus vaccination, critical illness, irradiation, immunosuppressive drugs, diabetes mellitus, HIV/AIDS, cancer, and surgery. This lack of specificity currently limits the usefulness of these tests as nutrition status markers. There may be a role for these tests in monitoring response when a nutrition regimen includes immunotherapy.³⁰ Nutrients such as arginine, omega-3 fatty acids, and nucleic acids given in pharmacologic doses have been shown to improve immune function.^{31–33} Monitoring the efficacy of a nutrition care plan that includes these potentially immunomodulating nutrients may need to include immune function assessment with these or other immune function indicators.

SPECIFIC NUTRIENT DEFICIENCIES

7 A comprehensive nutrition assessment must include an evaluation of possible trace element, vitamin, and essential fatty acid deficiencies. Because of their key role in metabolic processes (as coenzymes and cofactors), a deficiency of any of these nutrients may result in altered metabolism and cell dysfunction, and may interfere with metabolic processes necessary for nutritional repletion. The evaluation of single-nutrient-deficiency states includes an accurate history to identify symptoms and risk factors that may indicate deficiency or predispose the patient to developing a deficiency state. A focused physical examination for signs of deficiencies and biochemical assessment to confirm a suspected diagnosis also should be done. Ideally, biochemical assessment would be based on the nutrient's function (e.g., metalloenzyme activity) rather than simply measuring the nutrient's serum concentration. Unfortunately, few practical methods to assess micronutrient function are available currently, and most assays measure serum concentrations of the individual nutrient.

TRACE ELEMENTS

Deficiency states have been described for the essential trace elements zinc, copper, manganese, selenium, chromium, iodine, fluoride, molybdenum, and iron. Each element is involved in a variety

of biologic functions and is necessary for normal metabolism, serving as a coenzyme and/or playing a role in hormonal metabolism or erythropoiesis. Other essential trace elements for which deficiency states have not been recognized include tin, nickel, vanadium, cobalt, gallium, aluminum, arsenic, boron, bromine, cadmium, germanium, and silicon. Toxicities can occur with excess intake of some trace elements. With the current public interest in alternative and complementary medicine, care should be taken to ask patients about their use of nutrition supplements and to assess for signs and symptoms of toxicities (overdose) as well as deficiencies (Table 135–8).

Zinc is a component of many enzymes and proteins and is involved in the regulation of gene expression. Zinc deficiency is characterized by several signs and symptoms, including a moist eczematous dermatitis most apparent in the nasolabial folds and around orifices (see Table 135–8).^{34–36} Zinc deficiency occurs most frequently with abnormal GI losses, such as in Crohn's disease, malabsorptive states (e.g., short bowel syndrome), and extensive ostomy or fistula losses, or from prolonged inadequate intake, such as with zinc-free or inadequately zinc-supplemented parenteral nutrition. Zinc deficiency can be documented by the presence of low plasma zinc concentrations. However, plasma zinc concentration decreases in acute stress states such as trauma, surgery, burns, or sepsis and will generally remain depressed until the stress resolves. Also, because zinc is a normal contaminant of most blood collection tubes, special zinc-free collection tubes must be used for plasma assays. Hair zinc analysis by atomic absorption spectroscopy or neutron activation analysis may be a good indicator of zinc status in children.³⁷ Lymphocyte 5'-nucleotidase activity and leukocyte zinc content are better indicators of zinc status, but these assays are not widely available.

Copper is a component of enzymes involved in iron metabolism. Copper deficiency may present as hypochromic, microcytic anemia as well as leukopenia, neutropenia, skeletal demineralization, and hypercholesterolemia (see Table 135–8).^{34,38} In severe cases, such as in Menkes' syndrome, copper deficiency is further manifested as hypothermia, hair and skin depigmentation, progressive mental deterioration, and growth retardation. Factors predisposing to copper deficiency include malabsorption states, protein-losing enteropathy, nephrotic syndrome, and copper-free parenteral nutrition.^{33,34,38,39} Excess copper ingested or inadequate elimination on a chronic basis can result in liver cirrhosis (e.g., Wilson's disease). Copper deficiency is assessed most frequently on the basis of plasma copper or ceruloplasmin concentrations. As with zinc, serum copper concentrations may not accurately reflect total body copper status because serum concentrations may be altered by a variety of conditions and may remain normal even when hepatic stores are deficient (see Table 135–8). Copper function may be assessed by measuring activity of the cuproenzymes, erythrocyte superoxide dismutase activity, or cytochrome-C oxidase in platelets or leukocytes. Enzyme activity is decreased significantly in copper deficiency.^{36,38} However, measurement of enzyme activity is method- and technique-sensitive and not available routinely.

Chromium is an important cofactor, along with insulin, in the maintenance of normal blood glucose concentrations. Chromium deficiency is characterized by glucose intolerance and impaired protein utilization. Patients with chromium deficiency also may have increased free fatty acid concentrations and a low respiratory quotient (RQ) (see Table 135–8). Chromium deficiency has only been identified in patients receiving long-term parenteral nutrition that provided inadequate chromium intake.^{35,36,40,41} Plasma chromium concentrations do not accurately reflect total body chromium status, presumably because the biologically active form of chromium is an organic substance known as the *glucose tolerance factor*. Chromium toxicity

| Trace Element | Signs of Deficiency | Signs of Toxicity | Factors Associated with Altered Plasma Concentrations |
|---------------|--|--|---|
| Chromium | Glucose intolerance, peripheral neuropathy, increased free fatty acid levels, low RQ, weight loss, increased LDL, glucosuria, impaired protein utilization | Industrial exposure: skin/nasal septal lesions, allergic dermatitis, increased incidence of lung cancer | Decreased: long-term inadequate intake Increased: renal failure |
| Copper | Neutropenia, leukopenia, hypochromic anemia, osteoporosis, hair and skin depigmentation, dermatitis, anorexia, diarrhea, mental deterioration, hypercholesterolemia | Wilson's disease: liver cirrhosis, diarrhea, vomiting, metallic taste | Decreased: high iron or vitamin C intake, corticosteroid use Increased: infection, rheumatoid arthritis, pregnancy, oral contraceptives, decreased biliary excretion |
| Iodine | Hypothyroid goiter, neuromuscular impairment, deaf-mutism, increased embryonic and postnatal mortality, cognitive impairment, impaired fertility, cretinism (severe cases) | Thyrotoxicosis: nodular goiter, weight loss, tachycardia, muscle weakness, warm skin | Decreased: long-term inadequate intake |
| Iron | Microcytic, hypochromic anemia, fatigue, weakness, pallor, glossitis, headache, dysphagia, fingernail changes, gastric atrophy, paresthesias | Liver cirrhosis, cardiomyopathy, pancreatic damage, skin pigmentation | Increased: blood transfusion Decreased: blood loss |
| Manganese | Nausea, vomiting, dermatitis, hair color changes, hypocholesterolemia, growth retardation, defective carbohydrate and protein metabolism | Parkinsonian-like symptoms, hyperirritability, hallucinations, libido disturbances, ataxia | Increased: decreased biliary excretion high iron or vitamin C intake |
| Molybdenum | Tachycardia, tachypnea, altered mental status, visual changes, headache, nausea, vomiting | Gout-like syndrome, increased urinary copper | Varies with assay used High iron or vitamin C intake |
| Selenium | Muscle weakness and pain, cardiomyopathy | Nausea, vomiting, hair and nail loss, tooth decay, skin lesions, irritability, fatigue, peripheral neuropathy | Decreased: malignancy, liver failure, pregnancy Increased: reticuloendothelial neoplasia |
| Zinc | Dermatitis, hypogeusia, alopecia, diarrhea, apathy, depression, growth retardation, impaired wound healing, immunosuppression | Acute: gastric distress, nausea, dizziness, death with large intravenous doses Chronic: immunosuppression, decreased HDL, copper deficiency | Decreased: infection, hypoalbuminemia, corticosteroids, pregnancy, burns, stress, inflammation Increased: tissue injury, hemolysis, contaminated collection tube |

HDL, high-density-lipoprotein cholesterol; LDL, low-density-lipoprotein cholesterol; RQ, respiratory quotient.

is not a common clinical concern and has been reported only with contaminated drinking water or industrial exposure.

Manganese is important in the function of many enzymes, including arginase (amino acid metabolism), pyruvate carboxylase (carbohydrate metabolism), and superoxide dismutase (cholesterol metabolism; antioxidant), and in bone formation. Manganese deficiency has only been reported in association with the ingestion of chemically defined manganese-deficient oral diets.^{34–36} Symptoms associated with manganese deficiency include nausea, vomiting, dermatitis, hair color changes, hypocholesterolemia, and growth retardation (see Table 135–8). Manganese toxicity is more concerning and has been described in several patients receiving long-term parenteral nutrition.^{42–44}

Manganese appears to accumulate in brain tissue, especially in the setting of chronic cholestasis and short bowel syndrome. Clinical toxicity is evidenced primarily by extrapyramidal symptoms mimicking Parkinson's disease. Serum manganese concentrations do not correlate well with the clinical presentation, but magnetic resonance imaging (MRI) of the basal ganglia may show hyperintensity areas, especially in the globus pallidus. In most reported cases, discontinuation of manganese in the parenteral nutrition solution resulted in resolution of neurologic symptoms in 6 months with partial or total normalization of the MRI after 1 to 2 years. Other methods of evaluating man-

gane status include measuring the manganese content of mononuclear blood cells⁴⁵ and the activity of manganese superoxide dismutase, a mitochondrial antioxidant enzyme.⁴⁶ While these methods are good indicators of manganese status, they are not widely available.

Selenium, as selenocysteine, is incorporated into glutathione peroxidase (antioxidant), iodothyronine deiodinase (thyroid hormone regulation), and selenoprotein P (vitamin C metabolism). Prematurity, acute illness, chronic GI losses, and long-term selenium-free parenteral nutrition are associated with low serum selenium concentrations and decreased glutathione peroxidase activity.^{36,47–49} The clinical significance of reduced serum selenium concentrations is unclear. Selenium deficiency has been described in patients receiving long-term selenium-free parenteral nutrition. Muscle pain and weakness are the most frequently observed signs and symptoms (see Table 135–8), but severe biochemical deficiency is not always accompanied by these symptoms.⁵⁰ Fatal cardiomyopathy has been reported in several cases.

Selenium toxicity may occur when patients receive doses exceeding 200 mcg/kg per day for prolonged periods.⁵¹ Selenium status may be assessed by measuring plasma selenium concentrations, which will reflect recent selenium intake. Decreased concentrations may indicate selenium deficiency, but reductions also have been observed in patients with malignancies, liver failure, and pregnancy. Assays that

measure the activity of the selenium-containing enzyme glutathione peroxidase in erythrocytes or the plasma concentration of selenoprotein P may be more sensitive measurements of selenium status because they reflect chronic ingestion, but neither is widely available.⁵⁰

Molybdenum is a cofactor for enzymes involved in catabolism of sulfur amino acids, purines, and pyrimidines (i.e., xanthine, aldehyde, and sulfite oxidases). Molybdenum deficiency is rare. One case of molybdenum deficiency has been reported in a patient receiving long-term home parenteral nutrition who presented with symptoms that included tachycardia, tachypnea, headache, night blindness, nausea, vomiting, central scotomas, lethargy, disorientation, and ultimately coma (see Table 135–8). Symptoms were reversed when molybdenum was added to the parenteral nutrition solution. Factors predisposing to molybdenum deficiency appear to be low birthweight,⁵² excessive loss via the GI tract, such as with short bowel syndrome, and long-term inadequate intake, such as with molybdenum-free parenteral nutrition. Biochemical abnormalities expected in molybdenum deficiency include very low serum and urine uric acid concentrations (low xanthine oxidase activity) and low urine inorganic sulfate concentrations (low sulfate oxidase activity).⁵³

Deficiency of iodine, a component of thyroid hormones, may result in goiter formation (see Chap. 73). However, not everyone with an iodine-deficient diet will develop a goiter. Thyroxine (T₄) and triiodothyronine (T₃) can be used to assess iodine status (see Table 135–8). Intravenous iodine supplements typically are not necessary except during long-term parenteral nutrition with minimal enteral intake. Iodine needs generally are met by cutaneous absorption of iodine from germicides (e.g., povidone-iodine) used in catheter care or consumption of iodized salt.^{54,55} Use of povidone-iodine will likely decrease with the increased use of chlorhexidine for catheter care, and the need for iodine supplementation must be individualized. Iodine excess is rarely a clinical concern when thyroid function is normal.

Iron is an important component of hemoglobin, myoglobin, and cytochrome enzymes; therefore, it is important in oxygen transport, muscle iron storage, and cellular energy production. Patients with iron deficiency anemia generally present with fatigue, weakness, and pallor, but they also may have other symptoms^{36,56} (see Chap. 99). Inadequate iron intake, malabsorption, and blood loss are the principal causes of iron deficiency anemia. Iron toxicity (overload) with possible organ damage can occur when chronic iron intake exceeds requirements. Iron deficiency is confirmed by assessment of body iron stores, as reflected indirectly by measurement of hemoglobin, serum iron, TIBC, and serum ferritin, or directly by marrow staining and liver biopsy.⁵⁶ Although the direct methods are the most accurate, they are invasive, and indirect measurements are used more commonly. However, indirect parameters may be altered by chronic illness independent of iron stores; thus concomitant illness must be considered in their interpretation.

VITAMINS

A thorough nutrition-focused history and physical examination is the most valuable means of screening patients for vitamin deficiency or toxicity (Table 135–9). It is uncommon to see a single vitamin deficiency; usually multiple vitamin deficiencies occur with general malnutrition. Single vitamin deficiencies do occur, however. Thiamine deficiency may result in lactic acidosis and encephalopathy,⁵⁷ whereas pernicious anemia due to vitamin B₁₂ deficiency has been reported with increasing frequency, especially in the elderly. Recently, the incidence of vitamin D deficiency has increased in children. Laboratory assessment may be useful to confirm the clinical suspicion of a deficiency state. The first indication of a deficiency is usually a fall in circulating serum concentrations of the vitamin or its coenzyme.

Subsequently, there is a decrease in urinary excretion of the vitamin, which in turn is followed by diminished tissue concentrations of the vitamin. The most common measurements of vitamin status are assays of circulating amounts in plasma or serum. Assays of biochemical or metabolic function of the vitamin are more likely to reflect body stores than are serum concentrations. Most of these functional assays use erythrocyte or leukocyte extracts to determine apoenzyme activity, which is dependent on the vitamin coenzyme (see Table 135–9).

ESSENTIAL FATTY ACIDS

The body can synthesize most fatty acids except for linoleic acid (an omega-6 fatty acid) and linolenic acid (an omega-3 fatty acid). Therefore intake of approximately 2% to 4% of total calories as these fatty acids is essential to prevent deficiency. Essential fatty acid deficiency is rare in adults and children but can occur with prolonged use of lipid-free parenteral nutrition, with severe fat malabsorption, with very-low-fat enteral feeding formulations, or with severe malnutrition, especially in stressed patients.⁵⁸ In critically ill adults and older children with increased metabolic demands, essential fatty acid deficiency has been reported to occur within 1 week of starting lipid-free parenteral nutrition.^{58,59} Newborns, especially those born prematurely, have limited fat stores; therefore, they may develop essential fatty acid deficiency more rapidly than adults. Biochemical essential fatty acid deficiency has been noted within 72 hours after birth in preterm infants receiving fat-free intravenous solutions.⁶⁰ Symptoms of essential fatty acid deficiency include dermatitis (dry, cracked, scaly skin), alopecia, impaired wound healing, growth failure, thrombocytopenia, and anemia.

Linoleic acid normally is converted to arachidonic acid (a tetraene fatty acid). If linoleic acid is unavailable, oleic acid will be substituted, which results in production of eicosatrienoic acid (a triene fatty acid) as the metabolic end product. Therefore essential fatty acid deficiency can be detected on the basis of decreased tetraene production and increased triene production. Normally, the ratio of trienes to tetraenes is less than 0.4; when this ratio becomes greater than 0.4, the diagnosis of essential fatty acid deficiency is established. Analysis of plasma fatty acids, however, is expensive and not widely available.

CARNITINE

Carnitine is a quaternary amine required for transport of long-chain fatty acids into the mitochondria for β -oxidation and energy production. Carnitine also binds acyl residues and helps in their elimination (detoxification), thereby decreasing the number conjugated with coenzyme A and increasing the ratio of free to acetylated coenzyme A. Carnitine is available from a wide variety of dietary sources (especially meats) and can be synthesized by the liver and kidneys from lysine and methionine. Hepatic synthesis is decreased in premature infants, and low plasma carnitine concentrations and/or overt carnitine deficiency have been documented in premature infants receiving parenteral nutrition or carnitine-free diets, as well as in those with inborn errors of metabolism.^{61–64} Other predisposing factors for carnitine deficiency include chronic kidney or liver disease, vitamin C deficiency, chronic use of valproic acid and zidovudine, and a vegetarian diet.^{63–65}

The clinical presentation of carnitine deficiency includes generalized skeletal muscle weakness, fatty liver, and fasting hypoglycemia. Carnitine status can be assessed by measurement of plasma, urine, or red blood cell total and free carnitine concentrations. Plasma and urine carnitine concentrations are most helpful in primary carnitine deficiency (an inborn error of metabolism). Plasma concentrations constitute less than 1% of the total body carnitine.^{64,65}

TABLE 135–9. Assessment of Vitamin Status

| Vitamin | Signs of Deficiency | Laboratory Assay | Comments |
|-------------------------------|--|----------------------------------|---|
| Water-soluble vitamins | | | |
| Thiamine (B ₁) | Paresthesias, nystagmus, impaired memory, lactic acidosis, congestive heart failure, Wernicke-Korsakoff syndrome | Red blood transketolase activity | Increased need with hemodialysis, peritoneal dialysis, malabsorption |
| Riboflavin (B ₂) | Mucositis, dermatitis, cheilosis, photophobia, corneal vascularization, lacrimation, decreased vision, impaired wound healing, normocytic anemia | Urinary riboflavin | |
| Pantothenic acid | Fatigue, malaise, headache, insomnia, vomiting, abdominal cramps | Serum pantothenic acid | |
| Niacin | Pellagra: dermatitis, dementia, glossitis, diarrhea, memory loss, headaches | Urinary niacin metabolites | Flushing and GI distress can be seen with supplements; increased need with hemo- and peritoneal dialysis, malabsorption |
| Pyridoxine (B ₆) | Dermatitis, neuritis, convulsions, microcytic anemia | Plasma B ₆ | Sensory neuropathy (high supplement intake) |
| Folic acid | Megaloblastic anemia, diarrhea, glossitis | Serum folate | Decreased with increased cellular/tissue turnover (pregnancy, malignancy, hemolytic anemia); masks neurologic complications of vitamin B ₁₂ deficiency; decreases risks of neural tube defects |
| Cobalamin (B ₁₂) | Pernicious anemia, glossitis, spinal cord degeneration, peripheral neuropathy | Serum B ₁₂ | Decreased absorption in the elderly, distal ileal resection, loss of gastric intrinsic factor |
| Biotin | Dermatitis depression, lassitude, somnolence | Urinary biotin | |
| Ascorbic acid (C) | Enlargement and keratosis of hair follicles, impaired wound healing, anemia, lethargy, depression, bleeding, ecchymosis | Plasma ascorbic acid | GI disturbances, kidney stones, excess iron absorption with excess intake; smokers need 35 mg/day more than nonsmokers |
| Fat-soluble vitamins | | | |
| A | Dermatitis, night blindness, keratomalacia, xerophthalmia | Serum vitamin A | Teratogenic effects, liver toxicity with excessive intake; alcohol intake, liver disease, hyperlipidemia, and severe protein malnutrition increase susceptibility to adverse effects of high intake; β -carotene supplements recommended only for those at risk of deficiency (fat malabsorption) |
| D | Rickets, osteomalacia, muscle weakness | Plasma 25-hydroxy vitamin D | Elevated intake causes hypercalcemia; decreased in uremia, vitamin D at ages >60 y may be decreased in winter, fat malabsorption |
| E | Hemolysis | Serum vitamin E | Excess intake: hemorrhagic toxicity; anticoagulant effect should be monitored carefully if taking supplements |
| K | Bleeding | Prothrombin time | Anticoagulant therapy can be affected by supplements or diet |

Acylcarnitine concentrations are more helpful in secondary causes of carnitine deficiency. When only total and free concentrations are available, the free is subtracted from the total to give the acylcarnitine concentration.

MUSCLE FUNCTION TESTS

A relatively new approach to nutrition assessment is to evaluate muscle function as an end-organ response. Hand-grip strength (forearm muscle dynamometry), respiratory muscle strength, and muscle re-

sponse to electrical stimulation have been used.⁶⁶ Hand-grip strength has been shown to correlate with patient outcome. Forearm muscle dynamometry is a relatively simple, noninvasive, and inexpensive procedure. Ulnar nerve stimulation causes measurable muscle contraction. In the setting of malnutrition, increased fatigue and a slowed muscle relaxation rate have been noted; these indices return to normal after refeeding. Both these parameters have the advantage of being indicators of tissue function rather than composition. Their utility in clinical practice is currently hampered by a lack of appropriate reference standards and limited data confirming their sensitivity and specificity as nutrition assessment tools.

OTHER NUTRITION ASSESSMENT TOOLS

Various methods to determine body composition have been used in the research setting. These methods generally are complex, require expensive technology, and at present are limited to research centers. One of the most promising for clinical practice is dual-energy x-ray absorptiometry (DEXA). This procedure is now available in many hospitals and clinics for measuring bone density. DEXA also can be used to quantify the mineral, fat, and LBM compartments. Ultrasound and infrared interactance can be used to measure subcutaneous fat. The latter uses an inexpensive and portable device, but these measurements have not been used extensively for nutrition assessment. MRI and computed tomography can measure subcutaneous, intra-abdominal, and regional fat distribution. Neutron activation is a means of measuring body nitrogen, calcium, sodium, chloride, and phosphorus. These measurements can then be used to calculate total body fat, bone, and protein. Isotope dilution methods determine TBW and underweight weighing determines density. In addition, these methods can be used to estimate LBM and body fat. Furthermore, LBM also can be estimated using total body electrical conductivity and by measuring the naturally occurring isotope ^{40}K .

ASSESSMENT OF NUTRIENT REQUIREMENTS

8 Nutrition requirements depend on an individual's clinical condition and the need for continued maintenance of adequate nutrition, or whether starvation or ongoing metabolic stress dictate a need for repletion. For obese patients, usual nutrition requirements may be altered due to the need for weight loss. In children, there is the added consideration of sustaining or re-establishing normal growth and development. Organ function (e.g., intestine, kidney, liver, and pancreas) may affect nutrient utilization.

Nutrient requirements vary with age, gender, size, disease state, clinical condition, nutrition status, and physical activity level. An estimate of nutrient requirements therefore must be made using guidelines interpreted in the context of these patient-specific factors. The recommended dietary allowances (RDAs) initially were intended to provide information to be used to prevent nutritional deficiencies in a healthy population of individuals,⁶⁷ but have often been used inappropriately to evaluate the diets of individuals. In the early 1990s, the Food and Nutrition Board began the task of revising the RDAs, and created a new family of nutrition reference values, the dietary reference intakes (DRIs) and seven nutrient groups.⁶⁸

The four categories of the new DRIs are estimated average requirements (EARs), recommended dietary allowances (RDAs), adequate intakes (AIs), and tolerable upper intake level (UL). EARs can be used for planning recommended nutrient intake for groups, as they are defined as the amount of the nutrient that meets the needs of 50% of persons in a given group. The RDA is designated as nutrient intake that meets the needs of almost all persons in the designated group. The RDA is approximately two standard deviations above the EAR for nutrients for which the requirement is well defined, and 1.2 times the EAR for nutrients for which there is more variability. AIs are defined as the average intake of a designated group that appears to sustain a particular nutrition state, growth, or other functional indication of health. This category is reserved for nutrients for which no EAR or RDA has been determined. Finally the UL is the maximum nutrient intake that is unlikely to pose adverse effects in almost all persons in a designated group. DRIs have been established for six of the seven established nutrient groups: (1) calcium, phosphorus, mag-

nesium, vitamin D, and fluoride;⁶⁹ (2) folate and other B vitamins;⁷⁰ (3) antioxidants (e.g., selenium and vitamins C and E);⁷¹ (4) trace elements;⁷² (5) macronutrients (e.g., protein, fat, carbohydrates, and fiber);⁷³ and (6) electrolytes and water.⁷⁴ Recommendations for group 7, which includes other food components (e.g., phytoestrogens), are still in development.

ENERGY REQUIREMENTS

The DRIs for macronutrients⁷³ recommend that adults consume 45% to 65% of their total calories from carbohydrates, 20% to 35% from fat, and 10% to 35% from protein. The recommendations for children are similar, except that infants and younger children need a higher proportion of fat (approximately 40% to 50% of total calories) in their diets. An RDA for total carbohydrates for adults and children of 130 g/day was set with the most recent revisions.⁷³

CLINICAL CONTROVERSY

Clinicians have debated whether calorie requirements should be expressed in terms of total or nonprotein calories. Those that use nonprotein calories base the decision on the theory that protein should be used for synthesis, not energy production. Those that correctly use total calories know that in the presence of adequate calorie intake, protein is not necessarily prioritized solely for anabolism. Also, standard equations such as the HBEs used to estimate energy needs were derived from measurement of energy expenditure and thus estimate total calories. In fact, while daily protein intake is used primarily for synthesis, protein is constantly being metabolized to energy. Approximately 15% of the total caloric expenditure comes from the breakdown of protein and other nitrogen-containing molecules. Additionally, calorie goals should be consistent among enteral, parenteral, and oral routes, necessitating the use of total calories.

There are numerous published methods for determining an individual's total energy or calorie (kcal) requirement. The most commonly used methods to determine energy requirements use calories per kilogram of body weight (kcal/kg), equations that estimate energy expenditure, or indirect calorimetry. The simplest method to assess energy requirements is to use population estimates of calories required per kilogram of body weight. This method assumes standard values for the energy requirements associated with various disease states or clinical conditions, as well as the additional requirements for repletion of a malnourished individual. It does not take into consideration age- or gender-related differences in energy needs. Daily adult requirements determined by this method, using actual body weight or adjusted body weight in kilograms, generally are accepted to be:

Healthy, normal nutrition status: 20 to 25 kcal/kg per day
 Malnourished or mildly metabolically stressed: 25 to 30 kcal/kg per day
 Critically ill, hypermetabolic: 30 to 35 kcal/kg per day
 Major burn injury (>50% total body surface area): 35 to 40 kcal/kg per day

Suggested calorie intakes for maintenance and normal growth of healthy infants and children are shown in Table 135-10.⁷³ For children, these maintenance energy requirements are approximately 150% of basal metabolic rate (BMR) with the additional calories

TABLE 135–10. Dietary Reference Intakes for Energy and Protein in Healthy Children

| Age (Reference age/wt) | Estimated Energy Requirement (kcal/day) | | Protein RDA (g/kg/day) |
|------------------------------------|--|--------|---------------------------|
| | Male | Female | |
| 0–6 mo (3 mo/6 kg) | 570 | 520 | 1.52 ^a |
| 7–12 mo (9 mo/9 kg) | 743 | 676 | 1.5 |
| 1–2 yr (24 mo/12 kg) | 1046 | 992 | |
| 1–3 yr (24 mo/12 kg) | | | 1.1 |
| 3–8 yr (6 y/20 kg) | 1742 | 1642 | |
| 4–8 yr (6 y/20 kg) | | | 0.95 |
| 9–13 yr (11 y/M: 36 kg; F: 37 kg) | 2279 | 2071 | 0.95 |
| 14–18 yr (16 y/M: 61 kg; F: 54 kg) | 3152 | 2368 | 0.85 |

F, female; M, male; RDA, recommended dietary allowance.

^aAdequate intake.

needed to support activity and growth. Caloric requirements increase with fever, sepsis, major surgery, trauma, burns, and long-term growth failure, and in the presence of chronic conditions such as bronchopulmonary dysplasia, congenital heart disease, and cystic fibrosis. Caloric needs may decrease with obesity and neurologic disability (e.g., cerebral palsy). Clinical judgment and close monitoring are essential to ensure that the desired nutrition therapy outcomes are attained.

Various equations are used to estimate energy needs (Table 135–11). The Harris-Benedict equations, which were first published in 1919, remain one of the most popular means used to assess energy requirements in adults. They have the advantage of taking into consideration the patient's age, height, weight, gender, and clinical condition. The HBEs were derived from oxygen consumption

TABLE 135–11. Equations to Estimate Basal Energy Expenditure in Adults and Children**Harris-Benedict (kcal/day):**

Males: $BEE = 66 + [(13.7W(kg)) + [5H(cm)] - (6.8A)]$

Females: $BEE = 655 + [(9.6W(kg)) + [1.8H(cm)] - (4.7A)]$

Modified Harris-Benedict (kcal/day) for adults >60 years of age:

Males: $BEE = [(8.8W(kg)) + [1128H(m)] - 1071]$

Females: $BEE = [(9.2W(kg)) + [637H(m)] - 302]$

Caldwell-Kennedy (kcal/day) for children <3 years of age:

$BEE = 22 + (31W) + [1.2H(cm)]$

Schofield (MJ/day) (to convert to kcal/day multiply by 239.2):

3–10 years of age

Males: $BMR = (0.08W) + [0.55H(m)] + 1.74$

Females: $BMR = (0.07W) + [0.68H(m)] + 1.55$

10–18 years of age

Males: $BMR = (0.07W) + [0.57H(m)] + 2.16$

Females: $BMR = (0.04W) + [1.95H(m)] + 0.84$

FAO/WHO/UNU (kcal/day):

3–10 years of age

Males: $BMR = 22.7W + 495$

Females: $BMR = 22.5W + 499$

10–18 years of age

Males: $BMR = 17.5W + 651$

Females: $BMR = 12.2W + 746$

A, age in years; BEE, basal energy expenditure; BMR, basal metabolic rate; FAO/WHO/UNU, Food and Agriculture Organization/World Health Organization/United Nations University; H, height in centimeters (cm) or meters (m), as indicated; MJ, megajoules; W, weight in kilograms.

TABLE 135–12. Stress Factors for Use in Children and Adults

| Condition | Factor |
|---|-----------|
| No stress | |
| Confined to bed | 1.2 |
| Out of bed: normal activity | 1.3 |
| Mild stress | |
| Postoperative recovery: uncomplicated surgery | 1 |
| Trauma: mild (e.g., long bone fracture) | 1.2 |
| Moderate stress | |
| Sepsis (moderate) | 1.3 |
| Trauma: central nervous system (sedated) | 1.3 |
| Trauma: moderate to severe | 1.5 |
| Severe stress | |
| Sepsis (severe) | 1.6 |
| Trauma: central nervous system (severe) | Up to 2.0 |
| Burns (proportionate to burned area) | Up to 2.0 |

measurements made on normally nourished individuals who were in a fasting and resting state. While these equations are commonly referred to as the basal energy expenditure (BEE) equations, they actually estimate resting energy expenditure (REE). This is the amount of energy expended by an awake individual to perform only basal functions such as breathing, circulating blood, and fasting metabolic processes. The original HBEs along with modifications for adults over age 60 years are shown in Table 135–11.

Because these equations approximate REE, their results must be modified by a factor that is most representative of the individual's clinical condition. For example, an individual who is confined to bed may require a calorie intake that is 20% above the REE, whereas a person who is suffering from a severe burn injury may require a 150% to 200% increase over the calculated REE. The metabolic response to stress in children appears to be similar to that seen in critically ill adults, and the "stress factors" used in adults shown in Table 135–12 can be used in children once the REE has been determined using one of the equations shown in Table 135–11.^{75,76} Controversy exists over the accuracy and reliability of predicting energy expenditure based on these equations because clinical judgments will vary with each clinician.^{77–79} Additionally, in validation studies in healthy subjects, these equations have been shown to overestimate REE by 5% to 15%.⁷⁹ It is also important to note that ABW (up to a BMI of 57 kg/m² in men and 40 kg/m² in women), not IBW, was used to generate the original data with these equations.⁷⁹

The most accurate clinical tool for determining energy requirements is to measure them using indirect calorimetry, also referred to as metabolic gas monitoring.⁸⁰ Indirect calorimetry methodology is based on the fact that when substrates (carbohydrates, fat, and protein) are oxidized, oxygen (O₂) is consumed and carbon dioxide (CO₂) is produced in varying amounts depending on the substrate being oxidized. Indirect calorimetry is a noninvasive procedure in which oxygen consumption (VO₂, mL/min) and carbon dioxide production (VCO₂, mL/min) are measured. Using the abbreviated Weir equation, REE (kcal/day) can be calculated as $(3.9VO_2 + 1.1VCO_2) \times 1.44$.⁸⁰

This measured energy expenditure represents the actual energy expended by the patient during the time period during which the measurements were taken. It is often extrapolated to a 24-hour period to approximate daily energy requirements. REE measurement reflects alterations in energy requirements due to disease or clinical condition, but does not include energy required for nutritional repletion of a malnourished individual or growth in a child. The energy intake required for these functions can be calculated as follows depending

on nutrition goals: maintenance, 1 to 1.3 \times REE; repletion or growth, 1.3 to 1.5 \times REE; and depletion, less than 1 \times REE.

The data obtained from indirect calorimetry also can be used to determine an RQ which reflects substrate oxidation, characterizes substrate use, and is calculated as V_{CO_2}/V_{O_2} . RQ values for nutrient substrates are fat, 0.7; carbohydrate, 1; protein, 0.8; and mixed substrate (fat, carbohydrate, and protein), 0.85. An RQ value of greater than 1 represents either lipogenesis or hyperventilation; an RQ value of less than 0.7 may indicate a ketogenic diet, fat gluconeogenesis, or ethanol oxidation. Values outside the 0.67 to 1.3 range should raise doubts as to the test's validity. Clinically the RQ is used to determine if a patient is being overfed, which is indicated by an RQ value greater than 1.

CLINICAL CONTROVERSY

The Harris-Benedict equations (HBEs) have been validated in many settings; however, depending on the "stress" factor chosen, may overestimate true needs in some populations. In patients with pulmonary artery catheters, energy needs can be determined using the Fick method assuming a respiratory quotient of 0.85, and using cardiac output and measurement of saturation of arterial and mixed venous blood. Indirect calorimetry can also be used to measure energy expenditure in an individual. All of these methods have advantages and disadvantages. Energy expenditure is not a fixed value that never changes. In critically ill patients particularly, energy expenditure can vary significantly from one period of time to the next, depending on other interventions (e.g., paralyzation, sedation, or analgesia), and the patient's clinical condition (e.g., sepsis, burns, or trauma). No one method has been shown to be superior to another. Estimates of energy needs derived from any of these techniques should be viewed as empiric estimates. The patient's response to these intakes should be carefully monitored.

There are limitations to the use of indirect calorimetry.^{79,80} Not all institutions have metabolic carts available or personnel trained to use them. Calibration errors are common, and indirect calorimetry overestimates REE for patients with hyperventilation, metabolic acidosis, overfeeding, and air leaks anywhere in the system. Underestimates of REE are likely with hypoventilation, metabolic alkalosis, underfeeding, and gluconeogenesis. Mechanically ventilated patients are technically easier to study because the indirect calorimeter circuit can be plugged into the ventilator circuit. The patient must be at complete rest for 1 hour, must not receive bolus feedings either by feeding tube or orally for 4 hours, should have no changes in substrate delivery for 12 hours, must be on a fraction of inspired oxygen of less than 0.6, and the positive end-expiratory pressure must be less than 5 cm H₂O to ensure a steady-state reading. Unfortunately, most of the patients in whom indirect calorimetry would be desirable will not meet these requirements.

PROTEIN

Daily protein requirements are based on age, nutrition status, disease state, and clinical condition. The RDA for protein for children is shown in Table 135-10, and for individuals over 18 years of age the RDA is 0.8 g/kg per day, which is much less than most people typically consume.⁷³ In adults older than 60 years of age, protein needs are increased to 1 g/kg per day to help reduce the loss of LBM that occurs with aging, and up to 1.5 to 2 g/kg per day may be needed in states of metabolic stress such as infection, trauma, and surgery,

to prevent loss of LBM.^{73,81} Protein requirements are also higher in pregnant and lactating women (1.1 g/kg per day).⁷³ In general, protein intake should be approximately 10% to 35% of total calories in the normal diet.

Protein metabolism depends on both kidney and liver function; therefore, protein requirements will be altered with decreased kidney or liver function (see Chap. 139). Critical illness (e.g., sepsis, burns, or trauma) will result in a hypercatabolic state in which there is increased protein synthesis and degradation. Consequently, protein requirements will be increased to 1.5 to 2 g/kg per day. In burn patients, protein requirements may be as high as 2.5 to 3 g/kg per day. Liver failure typically results in the need for protein restriction (0.5 g/kg per day) except if a hypercatabolic state is also present, in which case the requirement may be increased to 1.5 g/kg per day. Protein needs in renal failure are variable and affected by the various renal replacement therapies available. The application of these guidelines requires both clinical judgment and frequent monitoring of renal and liver function, serum chemistries, clinical condition, and nutrition outcomes (see Chap. 139).

Nitrogen is found only in protein and at a relatively constant ratio of 1 g nitrogen per 6.25 g protein. This ratio may vary somewhat for enteral and parenteral feeding formulations, depending on the biologic value of the protein source. Adequacy of protein intake can be assessed clinically by measuring urinary nitrogen excretion and comparing it with nitrogen intake—a nitrogen balance study. Nitrogen balance indirectly reflects an individual's protein use or protein catabolic rate, which increases in states associated with hypercatabolism.⁸² As the stress level increases, the concomitant increase in protein catabolism results in an increase in urinary nitrogen excretion.⁸³ Usually the amount of urea nitrogen is measured in a 24-hour urine urea collection (24-h UUN). In healthy individuals, the quantity of UUN accounts for 80% to 90% of the total urine nitrogen (TUN) excreted. Nitrogen output (g/day) can be approximated as 24-h UUN + 4, where 4 is a factor representing usual skin, fecal, and respiratory nitrogen losses.⁸⁴ Alternatively, if available, TUN can be measured and may be more accurate, but it is generally more expensive.⁸⁸ If TUN is used, then the best estimate of nitrogen output is $TUN \times 1.05$.⁸⁴ In patients with renal failure, in which case neither measured UUN nor TUN represents nitrogen generation, protein turnover can be approximated with equations based on urea kinetics that estimate the rate of urea production.²⁶

FAT

The AI for men and women for fat is 1.6 and 1.1 g of α -linolenic acid daily, respectively, and for linoleic acid is 17 g/day for adult men and 12 g/day for adult women. Overall, fat should represent no more than 20% to 35% of total calories with the recommendation that saturated fatty acids, *trans* fatty acids, and dietary cholesterol intake be kept as low as possible while consuming a nutritionally adequate diet.⁷³ As mentioned previously, fat intake in children less than 2 years of age is critical for proper central nervous system growth and development; therefore, no fat restriction (e.g., skim milk) should be imposed until after the age of 2 years.

FIBER

Maintenance of normal bowel habits, lower blood pressure, and lower cholesterol serum concentrations have been attributed to adequate dietary fiber intake. Some evidence, although inconclusive, also suggests that fiber has a role in the prevention of colon cancer and

promotion of weight control. Men and women 50 years of age and younger should ingest 38 g/day and 25 g/day, respectively, of total fiber. For men and women over the age of 50, the recommended intakes are 30 g/day and 21 g/day, respectively.⁷³ For children less than 16 years of age, the “age + 5” rule is often used. The recommended daily intake of fiber is calculated by adding 5 g to the child’s age in years. For example, a 6-year-old child should ingest 11 g/day of dietary fiber.

FLUID

The daily fluid requirement for adults depends on many factors but is generally 30 to 35 mL/kg. It also can be estimated as 1 mL/kcal ingested or as 1500 mL/m² per 24 hours. Fluid requirements per kilogram are higher for children and even higher for preterm infants due to their higher percentage of TBW and BEE. Additionally, premature neonates have increased fluid requirements due to greater insensible losses and the kidney’s inefficiency in concentrating urine. The Holliday-Segar method is a commonly employed, quick, and simple method for estimating minimum daily fluid needs of children that also can be applied to adults. Children who weigh less than 10 kg should receive at least 100 mL/kg per day. An additional 50 mL/kg per day should be provided for each kilogram of body weight between 11 and 20 kg, and 20 mL/kg per day for each kilogram above 20 kg. Thus maintenance fluid needs for a child weighing 8 kg would be 800 mL/day, whereas 1350 mL/day would be the projected need for a 17-kg child.

Factors that alter fluid needs for both adults and children are shown in Table 135–13. When determining daily fluid intake for an individual, all sources of fluid intake must be taken into consideration (e.g., fluid vehicles for intravenous medications and intravenous or feeding tube flushes). Monitoring of urine output and specific gravity as well as serum electrolytes and weight changes is used to assess fluid status. A urine output of at least 1 mL/kg per hour (in children) and approximately 50 mL/h (in adults) is considered adequate to ensure tissue perfusion. Urine output should be higher if large fluid volumes or high renal solute loads (e.g., parenteral nutrition or concentrated enteral feeding formulations) are being administered. Urine specific gravity depends on the kidney’s concentrating and diluting capabilities. Concomitant diuretic therapy due to increased solute excretion will limit the usefulness of urine specific gravity as an index of fluid status.

TABLE 135–13. Factors that Alter Fluid Requirements

| Increased Requirements | Decreased Requirements |
|--|---|
| Fever | Fluid overload |
| Radiant warmers | Cardiac failure |
| Diuretics | Decreased urinary output |
| Vomiting | Heat shields |
| Nasogastric suction | Relatively high humidity |
| Ostomy/fistula drainage | Humidified air via endotracheal tube |
| Diarrhea | Renal failure |
| Glycosuria | Hypoalbuminemia with starvation |
| Phototherapy | Syndrome of inappropriate secretion of antidiuretic hormone (SIADH) |
| Increased ambient temperatures | |
| Hyperventilation | |
| Prematurity | |
| Excessive sweating | |
| Increased metabolism (e.g., hyperthyroidism) | |
| Diabetes insipidus | |

MICRONUTRIENTS

Requirements for micronutrients (e.g., electrolytes, trace elements, and vitamins) vary with age, gender, and the route by which the nutrient is ingested (Table 135–14).^{69–72,74,85,86} The variability between oral and parenteral requirements is due to bioavailability considerations. Micronutrients poorly absorbed via the GI tract usually will be required in greater doses enterally than parenterally. However, many water-soluble micronutrients are excreted more rapidly via the kidneys when administered intravenously. In these situations, the intravenous dose will be greater than the oral dose. Other factors that affect micronutrient requirements include GI losses through diarrhea, vomiting, or high-output fistula; wound healing; and hypermetabolism/catabolism. Cutaneous micronutrient losses (e.g., zinc, copper, and selenium) also may be significant after major burn injury.^{87,88} Sodium, potassium, magnesium, and phosphorus are particularly dependent on renal function, and in the setting of renal failure, intake will likely need to be restricted. Calcium needs, on the other hand, may be increased in these patients. Patients who are severely malnourished will have increased electrolyte requirements during early refeeding owing to preexisting deficiencies and/or rapid intracellular uptake with anabolism. Failure to provide adequate electrolytes during refeeding has resulted in death from the refeeding syndrome.⁸⁹

DRUG-NUTRIENT INTERACTIONS

9 Drug-induced nutrient deficiency, poor therapeutic response, enhanced drug toxicity, and failure to achieve desired nutrition outcomes can occur if either nutrition support or drug therapy is stopped due to adverse effects.^{90–94} Patient outcomes may be enhanced when an effective screening method to identify significant drug-nutrient interactions is coupled with a patient counseling program.⁹ An important part of the screening process is to recognize risk factors that influence drug-nutrient interactions. The potential for drug-nutrient interactions is greatest in pediatric and elderly individuals, those with poor nutrition status (obesity and marasmus), and those receiving multiple drug therapies.

Mineral and electrolyte serum concentrations may change due to drug therapy. For example, with diuretics, urine sodium, potassium, and magnesium wasting may occur, causing a reduction in their respective serum concentrations (see Chaps. 49 and 50). Serum electrolyte concentrations also may increase as a direct result of the drug’s mechanism (e.g., potassium-sparing diuretics) or due to the drug’s salt form. Corticosteroids and cyclosporine are known to cause hyperglycemia, whereas other drugs are prescribed to pharmacologically lower blood glucose concentrations, e.g., insulin and oral hypoglycemics (see Chap. 72).

Vitamin status also may be affected by drugs (Table 135–15). For example, sulfasalazine therapy has been noted to cause a decrease in folic acid, isoniazid therapy causes pyridoxine deficiency, and furosemide therapy may result in decreased thiamin concentrations. Furthermore, some drug therapy outcomes may be affected by vitamin intake. The ingestion of megadoses of folic acid may decrease methotrexate’s therapeutic effect, whereas changes in an individual’s usual vitamin K intake may cause variability in warfarin’s anticoagulation effects.

Drug delivery vehicles also may contain nutrients. Most intravenous therapies (maintenance intravenous fluids, drugs, and electrolyte replacements) are delivered using either dextrose (e.g., dextrose 5% in water) or sodium (e.g., 0.9% normal saline) in the admixture. Lipid emulsion (10%) is used as the vehicle for the anesthetic

^aAdapted from Food and Nutrition Board,⁶⁷ Food and Nutrition Information Center,⁶⁸ Food and Nutrition Board,⁶⁹ Food and Nutrition Board,⁷⁰ Food and Nutrition Board,⁷¹ Jefferson,⁹⁰ Fuhr,⁹¹ and Kirk.⁹² Data represent either the RDA or the AI for each nutrient where established.

^bAs needed to maintain acid-base balance.

^cNewborns and low-birth-weight or very-low-birth-weight infants or with concomitant disease (e.g., necrotizing enterocolitis) may have higher requirements. Intake in nonhealthy children must be individualized.

^dNo RDA or AI has been established.

^eAn additional 20 mcg of chromium per day is recommended in patients with intestinal losses.

^fMay accumulate in cholestasis.

^gLong-term parenteral nutrition only; no topicals containing iodide or table salt are used.

^hAn additional 12.2 mg zinc/L of small bowel fluid lost and 17.1 mg zinc/kg of stool or ileostomy output is recommended; add an additional 2 mg zinc per day for acute catabolic stress.

ⁱHigher doses (15 mcg) recommended in those over 70 years of age.

AI, adequate intakes; NE, niacin equivalents; PN, parenteral nutrition; RDA, recommended dietary allowances; RE, retinal equivalents; TE, tocopherol equivalent.

agent propofol and may contribute a large amount of calories when continuous propofol infusions are used. In these instances, nutrition support regimens must be adjusted to accommodate the calories and other nutrients delivered through other therapies.

PRACTICAL GUIDELINES FOR NUTRITION ASSESSMENT

10 The value of any given marker used for nutrition assessment is only as great as its ability to accurately identify the patient with malnutrition and to correlate with malnutrition-associated com-

plications. Most of the currently available markers of nutrition status were first used in epidemiologic studies to define large populations suffering from malnutrition caused by famine. The response of the various nutritional status markers to nutrition therapy and the correlation between improvement in these markers and decreased morbidity and mortality further support their validity. However, when applied to an individual, most of these markers lack specificity and sensitivity, which makes the development of a clinically useful, cost-effective approach to individual patient nutrition assessment challenging.

The importance of the nutrition-focused history and physical examination in both nutrition screening and nutrition assessment cannot be overemphasized. The least amount of objective data that can further

TABLE 135–15. Drug Effects on Vitamin Status

| Drug | Effect |
|------------------------------------|--|
| Antacids | Thiamin deficiency |
| Antibiotics | Vitamin K deficiency |
| Anticonvulsants | Vitamin D and folic acid malabsorption |
| Antineoplastics | Folic acid antagonism and malabsorption |
| Antipsychotics | Decreased riboflavin |
| Cathartics | Increased requirements for vitamins D, C, and B ₆ |
| Cholestyramine | Vitamins A, D, E, and K, β -carotene malabsorption |
| Colestipol | Vitamins A, D, E, and K, β -carotene malabsorption |
| Corticosteroids | Decreased vitamins A, D, and C |
| Diuretics (loop) | Thiamin deficiency |
| Histamine ₂ antagonists | Vitamin B ₁₂ deficiency |
| Isoniazid | Vitamin B ₆ deficiency |
| Mineral oil | Vitamins A, D, E, and K malabsorption |
| Orlistat | Vitamins A, D, E, and K malabsorption |
| Pentamidine | Folic acid deficiency |
| Proton pump inhibitors | Vitamin B ₁₂ deficiency |

substantiate the clinical impression and provide a baseline for subsequent monitoring are those markers which show the best correlation with outcome: weight and serum albumin concentration. The cost-effectiveness of the addition of further biochemical parameters is yet to be determined. The assessment of other anthropometric measures is most useful in the setting of anticipated long-term nutrition support in which these measurements will serve as a longitudinal marker of an individual's response to the nutrition care plan.

Initially, nutrition requirements are determined on the basis of assumptions made about the patient's clinical condition and the nutrition needs associated with repletion or growth, if needed. Once a nutrition intervention has been initiated, periodic reassessment of nutrition status is critical to determine the accuracy of the initial estimate of nutrition requirements. Also, nutrition requirements are dynamic in the setting of acute or critical illness—as the patient's clinical status changes, so will protein and energy requirements, further emphasizing the need for continued reassessment.

Better markers of nutrition status and methods for determining patient-specific nutrition requirements are needed to allow further refinement of estimates of individual nutrition needs. Functional tests and simple, noninvasive tests for body composition analysis hold promise for the future. However, until better methods of assessment become available clinically and are demonstrated to be cost-effective, the currently available battery of tests will continue to be the mainstay of nutrition assessment.

Information in this chapter can be used to establish empiric goals for nutrition care. However, as with other forms of therapy, continuous monitoring and reassessment are required to determine if these goals are appropriate for an individual patient.

ABBREVIATIONS

ABW: actual body weight
 AI: adequate intake
 AIDS: acquired immunodeficiency syndrome
 ALB: albumin
 BEE: basal energy expenditure
 BIA: bioelectrical impedance analysis

BMI: body mass index
 BMR: basal metabolic rate
 DCH: delayed cutaneous hypersensitivity
 DEXA: dual-energy x-ray absorptiometry
 DRI: dietary reference intake
 EAR: estimated average requirement
 HBE: Harris-Benedict equation
 HIV: human immunodeficiency virus
 IBW: ideal body weight
 LBM: lean body mass
 MAMC: midarm muscle circumference
 NCHS: National Center for Health Statistics
 RDA: recommended dietary allowance
 REE: resting energy expenditure
 RQ: respiratory quotient
 SGA: subjective global assessment
 T₃: triiodothyronine
 T₄: thyroxine
 TBW: total body water
 TFN: transferrin
 TIBC: total iron-binding capacity
 TLC: total lymphocyte count
 TSF: triceps skinfold thickness
 TUN: total urine nitrogen
 UBW: usual body weight
 UL: tolerable upper intake level
 UUN: urine urea nitrogen
 VCO₂: carbon dioxide production
 VO₂: oxygen consumption

PREVALENCE AND SIGNIFICANCE OF MALNUTRITION

Gordon Sacks and Pamela D. Reiter

Learning Objectives and other resources can be found at www.pharmacotherapyonline.com.

KEY CONCEPTS

- 1 Weight loss is a hallmark sign of malnutrition in the cancer patient and correlates with decreased survival for some cancer types.
- 2 Nutritional problems in human immunodeficiency virus/acquired immunodeficiency syndrome (HIV/AIDS) patients have shifted from complications of severe wasting to metabolic changes associated with subcutaneous fat atrophy, visceral fat accumulation, hypertriglyceridemia, and insulin resistance.
- 3 Immune function, growth, and survival can be improved in HIV-positive children with aggressive nutritional and antiviral therapy.
- 4 Enteral nutrition (EN) decreases septic complications when compared with parenteral nutrition (PN) in severely injured trauma patients.
- 5 EN and PN promote remission in the majority of patients with acute Crohn's disease.
- 6 Adults with less than 60 cm remaining of small bowel after massive surgery will require PN for months to years.
- 7 EN supplemented with immune-enhancing nutrients lowers metabolic and infectious complications in adult surgical patients.
- 8 Catch-up growth can be achieved more rapidly in infants with bronchopulmonary dysplasia if they receive a diet higher in protein, calcium, phosphorus, and zinc.
- 9 Optimizing nutritional status of pediatric solid organ transplant patients pre- and post-transplantation can improve outcomes and reduce morbidity.
- 10 Malnutrition is associated with increased utilization of health care resources and nutritional interventions can contribute to cost savings by lowering length of hospital stay and morbidity associated with malnutrition.

The term *malnutrition* has been used to characterize a broad range of altered nutritional states. *Overnutrition* is the term used to describe excess nutrient intake, whereas *undernutrition* is used to describe insufficient intake or substrate use. Both nutritional states can contribute to the poor outcome of many disease states. Unless specifically stated, this chapter will use the nomenclature of malnutrition as synonymous with undernutrition (refer to Chap. 140 for a discussion on overnutrition/obesity). In children, malnutrition can be defined by a variety of criteria. Stages (e.g., Waterlow stages) have been developed to define the severity of protein-energy malnutrition. Anthropometric evaluations, using established age-based growth curves, can define acute and chronic malnutrition using either Z scores or height and weight percentiles. In general, malnutrition in children is defined as growth that is below the fifth percentile for age or less than 90% to 95% of the median value for age. In this chapter, the prevalence of malnutrition as defined by a variety of nutrition assessment parameters is documented, and the significant impact of abnormalities in these nutrition assessment parameters on the morbidity and mortality of selected disease states is presented. Interventional strategies for the prevention and management of malnutrition and the economic consequences of malnutrition are also presented.

PREVALENCE

Although malnutrition occurs throughout the world, it is most prevalent in underdeveloped countries, where food supply, ignorance, poverty, overcrowding, and poor sanitation are contributing factors. The most susceptible individuals in developed and underdeveloped countries are infants (especially premature infants), pregnant or lactating women, and the elderly. Factors that contribute to malnutrition in developed countries include poor maternal nutrition before and during pregnancy, misconceptions about the use of certain foods, fad diets, maternal illiteracy, household poverty, and alcohol or drug abuse. The relationship between malnutrition and breast-feeding is time-dependent. While the benefit of breast-feeding during the first 6 months of life in reducing mortality and improving growth is well known, prolonged breast-feeding (beyond 6 months to 1 year) has been associated with a higher risk of malnutrition. However, this latter association may be due to lower use of complementary foods within poor households, rather than breast-feeding per se.¹

Malnutrition is associated most commonly with exacerbations of chronic disease and acute illness and thus is prevalent in the hospital setting. Recognition of the scope of the problem coincides with the

systematic application of nutrition assessment techniques to hospitalized individuals in the last two decades. The prevalence of previously unrecognized malnutrition is 40% to 55% among adult patients from varying socioeconomic backgrounds hospitalized in a variety of institutions.² The prevalence of malnutrition has declined and there has been a heightened awareness of nutritional disease and better in-hospital nutrition management since the mid-1970s.³ Worldwide, nearly 200 million children are moderately to severely underweight, and 70 million are severely malnourished.⁴ Over one-half of global childhood deaths under 5 years of age can be attributed directly or indirectly to malnutrition.⁵ Chronic malnutrition in children less than 2 years of age is an independent predictor of poor cognitive development lasting up to 11 years of age.⁶ Severe malnutrition is both a medical and social disorder and successful management requires attention to both of these factors. Fortunately, the global trend indicates a modest but consistent decline in malnutrition-associated mortality in children less than 5 years of age.⁷

Because children have both limited body stores and high metabolic demands, they are at particular risk for developing malnutrition, especially during illness. While the majority of undernourished children are from underdeveloped countries, malnutrition is also seen in the United States and other industrial countries. In 1974, a publicly funded health and nutrition program known as the Pediatric Nutrition Surveillance System was established to generate data on the prevalence of malnutrition in children generally younger than 5 years of age. The most recent report published in 1998 revealed a reduction in the incidence of malnutrition.⁸ The prevalence of shortness (height for age) in children younger than 24 months of age has declined from 10.5% in 1989 to 9.7% today, a value still more than twice the expected value. In older children (aged 2 to 5 years), the prevalence of shortness in 1989 of 7.5% was only slightly higher than expected and the prevalence has now fallen to 5.7%. Recent values for thinness, or weight for height, have also declined since 1989 and are currently at 3.1% in infants less than 24 months old and 1.9% in children aged 2 to 5 years old. These values are lower than the expected value of 5% and indicate that the prevalence of acute malnutrition in this population is low. Anemia, hematologic evidence of poor nutrition status, and/or iron deficiency was very high between 1980 and 1985 (20% to 30%), but has declined to 18.4% in those less than 24 months of age and 16.9% in those between 2 and 5 years of age.⁸ Admittedly, the

nutritional health of children in the United States has changed over the past decade. The focus on malnutrition has now been shifted to the prevention and treatment of childhood obesity, which has reached epidemic proportions (see Chap. 140).

Children with chronic disease and those in periods of rapid growth have the highest prevalence of malnutrition. Hendricks and colleagues described the change in prevalence of protein-energy malnutrition in hospitalized children over a 15-year period.⁹ Overall prevalence was high, but significant reductions were detected in acute malnutrition (weight for height <90% of median) from 33.6% to 24.5%, and chronic malnutrition (weight for height <95% of median) from 46.8% in 1976 to 27.3% in the 1990s.

EFFECT ON ORGAN AND CELLULAR FUNCTION

The outcome of malnutrition is an inappropriate reduction in lean body mass resulting in alterations in the structure and/or function (Table 136–1) of essentially every organ. The clinical significance of the effect will depend on the specific anatomic structure or system and on the degree of malnutrition. For example, with mild malnutrition, loss of skeletal muscle mass may be apparent as weakness or a decreased level of physical activity. However, alterations in cardiac function usually are not apparent until severe malnutrition is present. Until recently, the effect of early malnutrition (fetal and neonatal) on organ and cellular function was only recognized in terms of short-term growth and development outcomes. Now we realize that “fetal programming” or “metabolic imprinting” is linked to adult health. Specifically, maternal body composition and dietary balance during pregnancy can influence the risk of adult-onset cardiac disease, type II diabetes, and obesity.^{7,10,11}

There is also a well-established biochemical and clinical relationship between malnutrition and immune function. Alterations in the immune system (Table 136–2) represent an end-organ or functional response to malnutrition and may reflect a decline in lean body mass as well as a deficiency in specific nutrients such as zinc.¹² Clinically, this is manifested as an increased incidence of infection.

Malnourished patients have an increased likelihood of developing wound infections from altered immunity. Although wound healing

TABLE 136–1. End-Organ Responses in Malnutrition

| Organ | Anatomic Responses | Physiologic Responses |
|-------------------------|--|--|
| Heart | Four-chamber dilation; atrophic degeneration with necrosis and fibrosis; myofibrillar disruption | QT prolongation, low voltage, bradycardia; decreased cardiac output, stroke volume, and contractility; preload intolerance; diminished responsiveness to drugs |
| Lung | Emphysematous changes; pulmonary infarcts; reduced bacterial clearance; muscle atrophy | Pneumonia; decreases in functional residual capacity, vital capacity, and maximum breathing capacity; depressed hypoxic/hypercarbic drives |
| Hematologic | Failure of stem-cell production; decreased PMN chemotaxis; decreased lymphocyte count with reduced helper T and increased suppressor T and killer cells; decreased blastogenesis to phytohemagglutinin | Anemia; anergy; decreased granuloma formation; impaired response to chemotherapy; increased infection rate |
| Renal system | Epithelial swelling; atrophy; mild cortical calcification; depressed erythropoietin synthesis | Reduced glomerular filtration rate and inability to handle sodium loads; polyuria; metabolic acidosis |
| Gastrointestinal system | Disproportionate mass loss; hypoplastic and atrophic changes; decrease in total mucosal height | Depressed enzymatic activity; shortened transit time; impaired motility; propensity for bacterial overgrowth; maldigestion and malabsorption |
| Liver | Mass loss; periportal fat accumulation | Decreased visceral protein synthesis; depressed microsomal activity; eventual hepatic insufficiency |

PMN, polymorphonuclear leukocyte.

TABLE 136–2. Immune Response Mechanisms in Malnutrition

| Parameter | Observation in Malnutrition |
|--------------------------------------|-----------------------------|
| Cell-mediated immune response | |
| Delayed cutaneous hypersensitivity | Decreased |
| Lymphocyte transformation | Decreased |
| Polymorphonuclear leukocyte response | |
| Phagocytosis | Normal or decreased |
| Metabolism | Decreased |
| Bactericidal capacity | Decreased |
| Chemotaxis | Decreased |
| Total lymphocyte count | Decreased |
| T cells | |
| CD4 ⁺ | Decreased |
| CD8 ⁺ | Decreased |
| Helper:suppressor ratio | Decreased |
| Humoral response | |
| Complement activity (CH50) | Decreased |
| Secretory Immunoglobulin A | Decreased |
| Serum complement | Decreased or normal |
| Serum immunoglobulins | Normal |
| Serum opsonization | Normal |

occurs at the expense of other tissues, in the setting of protein-energy malnutrition, the rate at which wounds heal and the tensile strength of the wound are decreased.⁹ Deficiency of arginine, copper, vitamin C, vitamin A, or zinc also may contribute to decreased wound healing (Table 136–3). Supplemental vitamin A can promote wound healing in animal models in the presence of deficiency,¹³ and arginine has improved markers of wound healing (i.e., protein and hydroxyproline in the wound bed) in elderly healthy human volunteers.¹⁴ Other nutrients, when ingested in excessive amounts, may impair wound healing. For example, excess vitamin E antagonizes the promotion of wound healing by vitamin A, and excess zinc will displace copper and interfere with lysyl oxidase (the enzyme necessary for collagen cross-link formation).¹³

DISEASE-SPECIFIC CONSEQUENCES

Malnutrition seldom exists as an isolated disease state, but rather is usually found in patients with other pre-existing illnesses. Often

TABLE 136–3. Nutritional Disorders and Wound Healing

| Nutritional Disorder | Effect on Wound Healing |
|-----------------------------|--|
| Arginine deficiency | Altered collagen formation |
| Copper deficiency | Impaired lysyl oxidase activity |
| Protein-energy malnutrition | Decreased wound strength because of reduced hydroxyproline content of wound; decreased rate of wound healing; increased incidence of wound infection |
| Vitamin C deficiency | Decreased fibroblast maturation with failure of collagen synthesis; decreased angiogenesis |
| Vitamin A deficiency | Decreased collagen accumulation; formation of abnormal collagen |
| Zinc deficiency | Impaired DNA and protein synthesis; impaired mitosis and cell proliferation |

the primary disease or complications of the disease predispose an individual to the development of malnutrition. The primary factors that enhance the likelihood of developing malnutrition include decreased dietary intake (e.g., due to nausea, vomiting, or anorexia), malabsorption (e.g., due to short bowel syndrome, severe diarrhea, or high-output fistula), and altered metabolism (hypermetabolic and catabolic states due to sepsis, trauma, cancer, or AIDS). Malnutrition is also associated with major organ failure: renal, hepatic, cardiac, and pulmonary failure and multisystem organ failure (see Chap. 139).

CANCER

1 Patients with cancer have many factors that contribute to the likelihood of developing malnutrition (Table 136–4). The frequency is highest (>80%) in patients with gastric and pancreatic tumors, and lowest in patients with hematologic malignancies.¹⁵ Weight loss, a sign of malnutrition, occurs in 30% to 80% of adult cancer patients. A significant relationship between weight loss and reduced survival has been demonstrated for some (lung, prostate, and colon cancer), but not all tumor types.¹⁵ The degree of reduction in median survival is statistically significant for some cancers and ranges from 49% to 79%.

Malnutrition in children with cancer is common, and the prevalence is highest in those with Ewing’s sarcoma (67%) and neuroblastoma (47%), and lowest in those with acute leukemias (6%) and non-Hodgkin’s lymphomas (10% to 15%). While undernutrition has historically been an independent prognostic factor in the long-term outcome of children with certain cancers, not all researchers agree and it remains an area worthy of continued research.^{16–18} Furthermore, due to advancements in cancer treatment strategies, the importance of nutritional status may diminish. The stage of disease progression and chemotherapy-related complications also has been associated with an increased prevalence.¹⁹ Theoretically, early recognition and management of malnutrition in cancer patients may minimize the nutritional consequences, improve tumor response, reduce side effects of therapy, and improve survival. Cancer patients treated with bone marrow transplantation have shown improved tumor response and clinical outcome with parenteral nutrition (PN) compared with control groups not receiving PN.²⁰

Improved nutrition status enhances survival and improves treatment tolerance in many but not all children.^{19,21} Malnutrition in cancer patients due to simple starvation, characterized by normal metabolism but inadequate nutrient intake or malabsorption, appears to be responsive to nutrition intervention.²² However, malnutrition due to cancer cachexia, characterized by altered nutrient use despite adequate supply, does not.^{23,24}

CLINICAL CONTROVERSY

The intent of EN and PN should be to prevent or reverse protein-calorie malnutrition, and treatment of malnutrition due to cancer cachexia is controversial. Some clinicians believe nutrition support is warranted in terminally ill children if an improved quality of life can be attained.

AIDS

2 Generalized wasting and malnutrition were common characteristics of HIV/AIDS during the early years of this epidemic. The etiology and risk factors of AIDS-associated malnutrition are multifactorial (Table 136–5).^{25–28} In many patients, weight loss and wasting were often the earliest symptoms along with opportunistic infection. The malnutrition was often progressive and led to death in

TABLE 136–4. Risk Factors for Malnutrition in Cancer Patients

| Risk Factor | Nutrition Consequence |
|--|--|
| Primary disease Tumor type | Weight loss, anorexia, altered taste, altered metabolism |
| Complicating conditions Malabsorption | Impaired absorption of all or selected nutrients, diarrhea |
| Bowel obstruction | Nausea and vomiting, inability to ingest nutrients orally or by enteral nutrition |
| Infection | Increased energy expenditure and protein requirements, altered metabolism, anorexia, malabsorption |
| Psychological response | Anorexia, food aversion |
| Treatments Chemotherapy | Taste and appetite alterations, nausea and vomiting, mucositis, esophagitis, diarrhea, constipation |
| Surgery Radical resection of oropharyngeal region | Problems with chewing and swallowing |
| Esophageal reconstruction | Gastric stasis and hypochlorhydria secondary to vagotomy; diarrhea and steatorrhea |
| Gastrectomy | Dumping syndrome, malabsorption, lack of intrinsic factor, hypoglycemia |
| Intestinal resection | Malabsorption, renal oxalate stones, metabolic acidosis, diarrhea |
| Pancreatectomy | Malabsorption, diabetes mellitus |
| Radiation Head and neck | Stomatitis, dysgeusia, xerostomia |
| Abdomen and pelvis | Bowel obstruction, fistulae, radiation enteritis (diarrhea, protein-losing enteropathy, malabsorption) |

some patients.^{29,30} Poor nutrition status as indicated by weight loss and decreased serum prealbumin concentrations has been shown to be a predictor of survival in adult AIDS patients.^{31,32} Furthermore, simultaneous micronutrient deficiencies such as vitamin A, vitamin B₁₂, zinc, and selenium have been significantly associated with HIV-related mortality, independent of CD4 counts <200 and changes in CD4 over time. When the individual effect of these micronutrient deficiencies was further delineated, selenium deficiency was the only independent predictor of HIV-related prognosis.³² Recently, nutritional problems have shifted from the characteristic lethal wasting associated with opportunistic infections to a syndrome of subcutaneous fat atrophy, visceral fat accumulation, hypertriglyceridemia, and insulin resistance.³³ The etiology is unclear but may be related to new protease inhibitor therapy.³⁴ The implications of these metabolic and body compositional changes on outcome and development of comorbidities (i.e., atherosclerosis) are unclear at this time.

3 Most HIV-positive children will experience nutritional deficits and growth abnormalities.²⁶ Infants with perinatal-acquired AIDS have normal birthweights, but show signs of growth delay as early as 4 months.³⁵ Failure to thrive has been reported in up to 33% of HIV-infected children.²⁷ Impaired linear growth also appears to correlate with periods of rapid viral replication and lower CD4 T-lymphocyte counts during the first 18 months of life.^{36,37} There is a

direct relationship between these growth abnormalities and morbidity and mortality.³⁸ Fortunately, immune function, growth velocity, and survival can be improved markedly if aggressive nutritional therapy and antiviral therapy are initiated.^{26,28,39}

The response to nutrition intervention in adults with AIDS has been variable. Supplemental dietary intake of selected micronutrients has been shown to have an impact on mortality in HIV-1 seropositive homosexual/bisexual men. High intakes of B-group vitamins (B₁, B₆, and niacin) and β -carotene were associated with improved survival, whereas an increased intake of zinc was associated with worse survival.⁴⁰ In a retrospective review of home PN in 22 AIDS patients with weight loss greater than 10% of usual body weight, 15 patients gained weight, 6 stabilized, and 2 continued to lose weight.⁴¹ Lean body mass repletion in AIDS patients with weight loss and inadequate food intake has been reported when enteral nutrition was the sole source of nutrient intake.⁴² Kotler and associates compared the effects of PN and an oral semi-elemental diet on body weight, body composition, survival, quality of life, and medical costs in AIDS outpatients with malabsorption syndromes.⁴³ At the end of 3 months, the PN group gained more weight and significantly more fat, but body cell mass measurements and survival did not differ between the groups. However, the group receiving an oral diet scored significantly better on a physical functioning subscale of quality of life. The

TABLE 136–5. Risk Factors for Malnutrition in AIDS

| Risk Factor | Nutrition Consequence |
|---|--|
| General factors: decreased oral intake, malabsorption | Anorexia, poor diet, esophageal/oral lesions, emotional stress, HIV wasting syndrome, diarrhea, enteropathy, medication side effects |
| Opportunistic infections: bacterial (MAI, TB); viral (CMV, herpes); fungal (<i>Candida albicans</i> , cryptococcus); protozoal (<i>Pneumocystis carinii</i> , microsporidia, <i>Isospora belli</i> , cryptosporidia, <i>Giardia lamblia</i>) | Fever, hypermetabolism, anorexia, malabsorption |
| Malignancies: Kaposi's sarcoma, lymphoma | Anorexia, hypermetabolism, medication side effects |
| Medications: antibiotics, anticancer chemotherapy, antidepressants | Nausea, vomiting, diarrhea, anorexia, mucositis |
| Neuropsychiatric disorders: dementia, depression, anxiety, encephalopathy | Poor oral intake, anorexia, poor diet |
| Socioeconomic factors: IV drug abuse, low income | Poor oral intake, anorexia, poor diet |

CMV, cytomegalovirus, MAI, *Mycobacterium avium-intercellulare*; TB, tuberculosis.

most dramatic differences were in medical costs, with a fourfold cost increase in patients receiving PN versus oral diet therapy.⁴³

With earlier diagnosis and initiation of treatment for HIV-positive status prior to the onset of AIDS, the prevalence of malnutrition may decline. New treatment modalities for AIDS are also being developed that may affect the prevalence of malnutrition and the response to nutrition intervention in this patient population (see Chap. 123). For example, 12 weeks of recombinant human growth hormone treatment was evaluated in 178 HIV-infected patients with unintentional weight loss of $\geq 10\%$. In this double-blind, placebo-controlled, multicenter trial, growth hormone administration resulted in a mean increase of 3 kg of lean body mass with a decrease of about 1.7 kg of body fat. These changes in body composition were accompanied by an improvement in functional performance, reflected by treadmill work output.⁴⁴ However, concerns regarding the development of hyperglycemia and diabetes associated with long-term use of growth hormone have tempered its utilization. Other agents including thalidomide,⁴⁵ testosterone,⁴⁶ and nandrolone decanoate⁴⁷ have also shown promise in reversing cachexia associated with AIDS.

CRITICAL ILLNESS, TRAUMA, AND BURN INJURY

One of the characteristics of critical illness is hypermetabolism. Trauma, burn injury, and sepsis are all catalysts for the release of mediators that initiate and regulate the hypermetabolic response. The metabolic consequences of this response include altered carbohydrate metabolism, increased protein synthesis and degradation, and increased lipid oxidation, which ultimately result in loss of protein and lean body mass.⁴⁸ In a previously well-nourished individual, critical illness can result in the onset of kwashiorkor-like malnutrition within 5 to 7 days. In a previously malnourished individual, critical illness can precipitate severe mixed marasmus-kwashiorkor in 3 to 5 days. In a prospective study of 129 patients admitted to the intensive care unit (ICU), 43% were malnourished.⁴⁹ The malnourished patients had an increased length of stay in the ICU (a mean of 27 vs. 19 days) and a statistically significantly increased incidence of complications (55% vs. 40%) compared with well-nourished patients with a similar severity of illness.

4 The goal of nutrition support in critically ill patients is to prevent the development or worsening of malnutrition. Patient outcomes related to tissue repair and organ function may be improved through nutrition support in these patients.⁴⁸ Enteral nutrition (EN) initiated within 24 to 48 hours of injury may attenuate the hypermetabolic response.⁵⁰ Enteral nutrition also has been shown to result in fewer septic complications when compared with PN.⁵¹ Two recent meta-analyses suggest that critically ill patients may derive the greatest benefit when enterally fed an immune-enhanced formula that contains pharmacologic doses of immune-modulating nutrients such as arginine, glutamine, nucleic acids, and omega-3 fatty acids.^{52,53}

INFLAMMATORY BOWEL DISEASE

Malnutrition has been reported in 20% to 45% of patients with inflammatory bowel disease (IBD). Malabsorption, increased gastrointestinal losses, or poor oral intake are the predominant causes.⁵⁴ Decreased food intake may be due to pain, anorexia, or altered taste; malabsorption may be due to mucosal abnormalities, bacterial overgrowth, or diminished absorptive surface area after surgical resection of diseased bowel, and hypermetabolism may be a consequence of fever and infection.⁵⁵ Various nutrient abnormalities, such as anemia

and vitamin and trace mineral deficiencies, have been observed in IBD patients.⁵⁴ Growth failure occurs in 15% to 40% of prepubertal patients and is characterized by retarded skeletal maturation (which may be irreversible) and delayed development of secondary sex characteristics.⁵⁶ The nutrition consequences of ulcerative colitis tend to be less severe than those of Crohn's disease. Approximately 25% to 50% of patients with ulcerative colitis are hypoalbuminemic, and 2% to 20% experience growth failure.

5 Nutrition management of IBD may be achieved with enteral nutrition and/or PN.⁵⁷ Enteral is the preferred route except in patients with a high-output fistula or obstruction or if enteral feeding exacerbates pain. EN or PN is likely to facilitate remission in 60% to 80% of patients with acute Crohn's disease. However, the course of ulcerative colitis is not influenced by the use of nutrition support, although nutrition status may be maintained in an acute exacerbation.

CHRONIC INTESTINAL PSEUDO-OBSTRUCTION

Pseudo-obstruction, a hypomotility or dysmotility disorder of the gastrointestinal tract that is thought to be a neuromuscular disorder of the smooth muscle and/or its innervation, often presents with the symptoms of bowel obstruction. Prolonged dysmotility can result in malnutrition as well as growth failure in children.⁵⁸ Primary factors contributing to a risk of malnutrition are anorexia, nausea, vomiting, and obstruction, which may recur over years. Approximately 15% to 30% of patients with pseudo-obstruction require nutrition support with either PN or EN.⁵⁸

SHORT BOWEL SYNDROME

Short bowel syndrome (SBS) is the result of the surgical resection of a large portion of the intestinal tract. The degree of nutrition impairment depends on the amount and location of excised bowel. Malabsorption is present to some extent immediately following surgery and may be permanent.⁵⁹ Bowel adaptation will occur over time (6 to 12 months), but may not result in restoration of the full absorptive capacity of the intestine. Intestinal adaptation occurs more frequently in children than in adults.⁶⁰ The minimal intestinal length required to achieve complete bowel adaptation in infants and children has been reported to vary from 10 cm to 57 cm.^{61,62} Premature infants may have the best adaptive response to SBS owing to normal rapid intestinal growth during late gestation when the jejunum, ileum, and colon more than double in length.⁶³

6 Adults who have 600 to 700 cm of ileum remaining after surgical resection (i.e., 100 to 200 cm of ileum resected) will require vitamin B₁₂, calcium, and magnesium supplementation. Massive resection of the small bowel leaving less than 60 cm in adults and less than 10 cm in children will result in severe malabsorption of all nutrients and these patients will require total or supplemental PN for months or years postoperatively.^{60,64,65} Removal of the colon with the retention of <50 cm of jejunum and ileum may require that patients remain on PN for life.⁶⁴ One long-term study of 124 adults with non-malignant SBS maintained on PN demonstrated that the presence of terminal ileum in continuity with the colon enhanced the probability of weaning from PN and survival.⁶⁶ In the absence of nutrition support, malnutrition is inevitable and can be life-threatening. For those children with extensive bowel loss or life-threatening complications from prolonged PN, innovative surgical procedures including bowel lengthening and transplantation can improve the gut's adaptive process and reduce the need for PN.^{60,67,68}

SURGICAL PATIENTS

Malnourished patients tend to have a greater risk of postoperative morbidity and mortality than well-nourished patients. Several nutrition assessment parameters predict morbidity and mortality in surgical patients. In a classic study by Mullen and colleagues, the value of 16 nutritional and immunologic variables was examined and serum concentrations, of albumin and transferrin, as well as delayed cutaneous hypersensitivity reactions were found to be the most reliable predictors of outcome.⁶⁹ These factors have been confirmed by several authors to correlate with morbidity and mortality.^{70,71} A retrospective study by Kudsk and colleagues⁷² extended these findings by showing that operative site, in addition to the preoperative albumin concentration, was an independent risk factor in predicting clinical outcome: patients who underwent a colectomy and gastrectomy tolerated greater degrees of hypoalbuminemia than those patients who underwent esophagectomy or pancreatectomy. The complication rate was higher and resource utilization increased in patients who underwent pancreatic or esophageal surgery with serum albumin concentrations less than 3.25 g/dL. The Subjective Global Assessment (SGA), developed by Detsky and colleagues, is a clinical method that can aid in the recognition of undernutrition by evaluating a patient's nutritional status based on features of the medical history and physical examination.⁷³ In prospective studies, SGA has been shown to be very successful in predicting complications in surgical patients. One study demonstrated SGA to be a better predictor of postoperative infectious complications than serum albumin, serum transferrin, delayed hypersensitivity skin testing, anthropometry, creatinine-height index, and the prognostic nutritional index (PNI).⁷³ No studies have evaluated the effect of nutrition support on the PNI and the subsequent patient outcome. However, the use of preoperative PN in patients with malnutrition, particularly when associated with a low serum albumin concentration, has been demonstrated to reduce the incidence of major postoperative complications in several patient populations.⁷⁴ Parenteral nutrition administered solely after surgery was actually associated with an increased incidence of complications in approximately 10% of patients. Conflicting data were found in the multi-institutional VA Cooperative Study.⁷⁵ This prospective, randomized clinical trial in 395 malnourished patients evaluated the impact of perioperative PN on mortality and the rate of postoperative complications at 30 and 90 days. Differences in mortality at 30 and 90 days were not statistically significant, and there was no significant reduction in complication rate. The types of complications in the two groups were different. The PN group had a higher incidence of infectious complications and a lower incidence of noninfectious complications. The incidence of noninfectious complications was higher in those with the greatest degree of malnutrition (determined by calculation of a nutrition risk index using serum albumin concentration and weight). In the PN group, the highest incidence of infectious complications was in the borderline or mildly malnourished patients. The investigators concluded that perioperative PN did not result in an improved postoperative course except in patients who were severely malnourished preoperatively. In patients who were mildly to moderately malnourished, the incidence of infectious complications associated with the use of PN outweighed the benefits. As with critically ill patients, enteral feeding with immune-enhanced formulas in surgical patients appears to promote the best nutrition and clinical outcome with fewer metabolic and infectious complications.⁷⁶

PEDIATRIC DISEASES

Regardless of the disease process, pediatric patients in general are at greater risk for nutrition disorders and develop the most severe con-

TABLE 136–6. Management Principles of Severe Pediatric Malnutrition

1. Recognize the physiologic effects of reductive adaptation. Every organ system has adapted to starvation and cannot tolerate aggressive reintroduction of nutrition.
2. Treat or prevent hypoglycemia, hypothermia, and dehydration (days 1–3). Initiate small, frequent feedings (every 2–3 hours) and provide only enough calories to meet basic metabolic demands.
3. Avoid a high-protein diet (days 1–3) secondary to liver incompetence.
4. Correct electrolyte imbalance (day 1 through week 6).
5. Assume the child has an infection and empirically treat with antibiotics (days 1–7).
6. Avoid cardiac failure secondary to aggressive rehydration. Parenteral rehydration should be avoided at all costs and only used if the child is in shock. Avoid diuretics during the first 1–5 days even if edema is evident.
7. Advance enteral feeding to recover lost weight and provide for “catch-up growth” (day 7 through week 26).
8. Correct micronutrient deficiencies with vitamins and minerals (without iron on days 1–7 and with iron on day 7 through week 6).
9. Correct emotional and social disorders.

sequences more frequently (Table 136–6). Nutrition deficiency in the young affects existing organs and cells, may impair normal development, and may result in permanent, irreversible damage. Pharmacologic and technologic advances in neonatal medicine have improved the survival of extremely premature infants (<750 g). However, the prevalence of neonatal diseases such as bronchopulmonary dysplasia and necrotizing enterocolitis also has increased, which may further complicate the infant's nutrition status (see Table 136–6).

BRONCHOPULMONARY DYSPLASIA

Bronchopulmonary dysplasia (BPD) or chronic lung disease is a clinical, pathologic, and radiographic disease of the newborn resulting from prolonged exposure to positive-pressure ventilation and elevated oxygen concentrations. Risk factors for developing BPD include extent of prematurity, nutrition status, and immunologic status. Characteristics of BPD include pulmonary edema and tissue destruction with subsequent repair, fibrosis, and inflammation. These infants also have an elevated metabolic rate and growth failure.

CLINICAL CONTROVERSY

Supplemental vitamin A is used in some neonatal treatment centers to reduce the risk of BPD and sepsis in preterm infants. However, concern over the risk of vitamin A toxicity (i.e., posthemorrhagic hydrocephalus or liver disease) and sequelae from repeated intramuscular injections of vitamin A prevent its widespread use.

Growth failure and altered body composition are common in infants with BPD when compared with their peers without BPD.^{77,78} The persistence of this altered body composition can last into the first years of life.⁷⁸ Estimates of growth failure after hospital discharge range between 30% and 67%.⁷⁹ The origin of growth failure is multifactorial and has been associated with elevations in both resting and total energy expenditure, use of corticosteroids, intrauterine growth retardation, and feeding problems.^{80,81} Given that pulmonary edema is common, fluid restriction is often necessary. This restriction further impedes provision of adequate calories and may contribute to

poor growth.⁸⁰ Optimal oxygen therapy during the first year of life in infants with BPD can result in growth patterns similar to those seen in infants without BPD.⁸² Growth failure during the first 2 years of life, early childhood, and beyond has been reported, but it appears that prematurity and sociodemographic factors rather than BPD per se are most predictive of future growth.^{83,84} Catch-up growth can be attained faster when infants are fed higher intakes of protein, calcium, phosphorus, and zinc.⁸⁵ Vitamin A deficiency has been associated with BPD, but supplementation of vitamin A in all BPD patients is not universally endorsed. Benefits of vitamin A supplementation (i.e., a trend toward reduction in ventilatory support) must be considered with risks of repeated intramuscular injections.

NECROTIZING ENTEROCOLITIS

Necrotizing enterocolitis (NEC) is a complex disorder characterized by intestinal mucosal injury secondary to ischemia, bacterial overgrowth, and/or the presence of nutrients within the gut lumen. NEC typically occurs in the first 1 to 3 weeks of life and in premature infants (<38 weeks' gestational age) with inadequate immune function and an immature intestinal epithelial barrier.⁸⁶ Rapid advancement of EN has been linked to the development of NEC. The severe inflammation of the intestinal tract caused by mucosal injury results in malabsorption of nutrients. Total bowel rest is the treatment of choice; hence PN is required to prevent malnutrition. If NEC results in bowel perforation, necrosis, or stricture, surgery is required to resect the injured portion of the bowel. SBS may be a consequence if more than 70% of the bowel is resected, and long-term home PN will then be required. Additionally, infants with advanced disease who require surgery are at increased risk of growth failure. Fortunately, advances in surgical techniques have increased the survival rate of NEC over the past decade to between 60% and 80%, depending on the gestational age at the time of diagnosis.⁸⁷ If significant intestinal resection can be avoided, growth and nutrient absorption in these children may be normal.⁶¹

CYSTIC FIBROSIS

The predominant clinical findings of cystic fibrosis (CF) are related to altered pulmonary function and pancreatic exocrine function. Historically, growth retardation and failure to thrive have been classic features of CF. According to the National Cystic Fibrosis Patient Registry data, malnutrition (height for age or weight for age <5th percentile) was very prevalent in infants (47%), adolescents (34%), and children with newly diagnosed CF (44%).⁸⁸ Over the past decade, the nutritional status of children with CF has improved, largely due to the association of nutritional intervention with disease progression and clinical outcome. A recent longitudinal study confirmed that nutrition and lung function are codependent variables in CF.⁸⁹ Other factors that contribute to the nutrition disorders associated with CF include an increased energy expenditure, malabsorption, anorexia, gastroesophageal reflux, pharmacotherapy, glucosuria, and inadequate pulmonary toilet.^{90,91} Increased energy requirements in CF patients are the result of the increased amount of work required to breathe and an elevated resting energy expenditure (REE) during pulmonary exacerbations. Recent data suggest that children with only mild to moderate lung disease may be spared from this rise in REE during an acute exacerbation.⁹² It is also theorized that the genetic defect that causes CF affects metabolism, causing an increase in energy requirements. The physical pounding on the back of the patient while in a partially inverted position (i.e., pulmonary toilet) is designed to

loosen the thickened bronchial secretions that impair breathing. It may be performed numerous times throughout the day and may result in an increase in energy expenditure. It also interferes with the feeding schedule, which needs to be designed to ensure that the stomach is empty or nearly empty before the pulmonary toilet process begins, to prevent pulmonary aspiration of stomach contents.

As life expectancy of patients with CF increases, the recognition of CF-associated diseases has also increased. CF-related diabetes mellitus is now a well-recognized problem and further complicates the nutritional management of those individuals.⁹³ Altered pancreatic function is common and over 90% of CF patients need pancreatic enzyme supplementation. Insufficiency of pancreatic enzyme secretion into the intestine reduces the absorption of fat and fat-soluble vitamins. Consequently, more than two-thirds of the CF centers in North America use a hydrolyzed (semi-elemental) enteral formula with low fat content for infants with CF. However, the nutrition benefits of this expensive hydrolyzed formula over a conventional cow's milk formula have been challenged. Several investigations do not support the use of a hydrolyzed formula as part of routine nutrition care.^{94,95} Nutritional management typically focuses on the use of oral pancreatic enzymes (e.g., Viokase and Pancrease), supplemental fat-soluble vitamins, and a high-protein, high-calorie diet.⁸⁸ If nutrition status cannot be maintained with these measures, supplemental EN or PN may be indicated.

SOLID-ORGAN FAILURE IN CHILDHOOD

Malnutrition with growth impairment is a well-recognized complication of renal, hepatic, and cardiac failure in children. Evidence suggests that these factors increase the risk of morbidity and mortality. Mechanisms responsible for malnutrition include reduced energy intake, increased resting energy rates, and increased total energy expenditure.^{96–99} Early clinical onset of organ failure can have profound effects on growth and development, especially in children with end-stage liver disease, in whom the liver is not able to perform intermediary metabolism. Among children diagnosed with hereditary renal disorders, 50% had marked growth retardation (mean age at observation = 10 years).⁹⁹ Prevalence of malnutrition in hospitalized children with cardiac disease varies with age and type of cardiac lesion. Seventy-nine percent of infants with heart disease had evidence of acute malnutrition, compared with less than 30% in all other age groups. The prevalence of chronic malnutrition was common in all age groups. An inverse relationship to age was observed with 82%, 84%, 61%, 58%, and 38% of infants, toddlers, preschool children, school-age children, and adolescents, respectively, being malnourished.¹⁰⁰ Children with complex cardiac disease or left-to-right intracardiac shunts had the highest prevalence of both acute and chronic malnutrition (38% to 80%). Catch-up growth in children with chronic renal failure, complex congenital heart lesions, and advanced cirrhosis can be attained with aggressive feeding regimens, including tube feedings.^{97,101} Optimizing nutritional status during the pre- and post-transplant phase can improve outcomes and reduce morbidity.^{102,103} After liver transplantation, catch-up growth can occur, but final height remains 0.5 to 1 standard deviation below normal.¹⁰⁴

MANAGEMENT

The increased awareness of the prevalence and significance of untreated protein-calorie malnutrition has provided a strong incentive for a more rigorous evaluation of abnormalities of nutrition status and prompt initiation of nutrition support for malnourished patients.

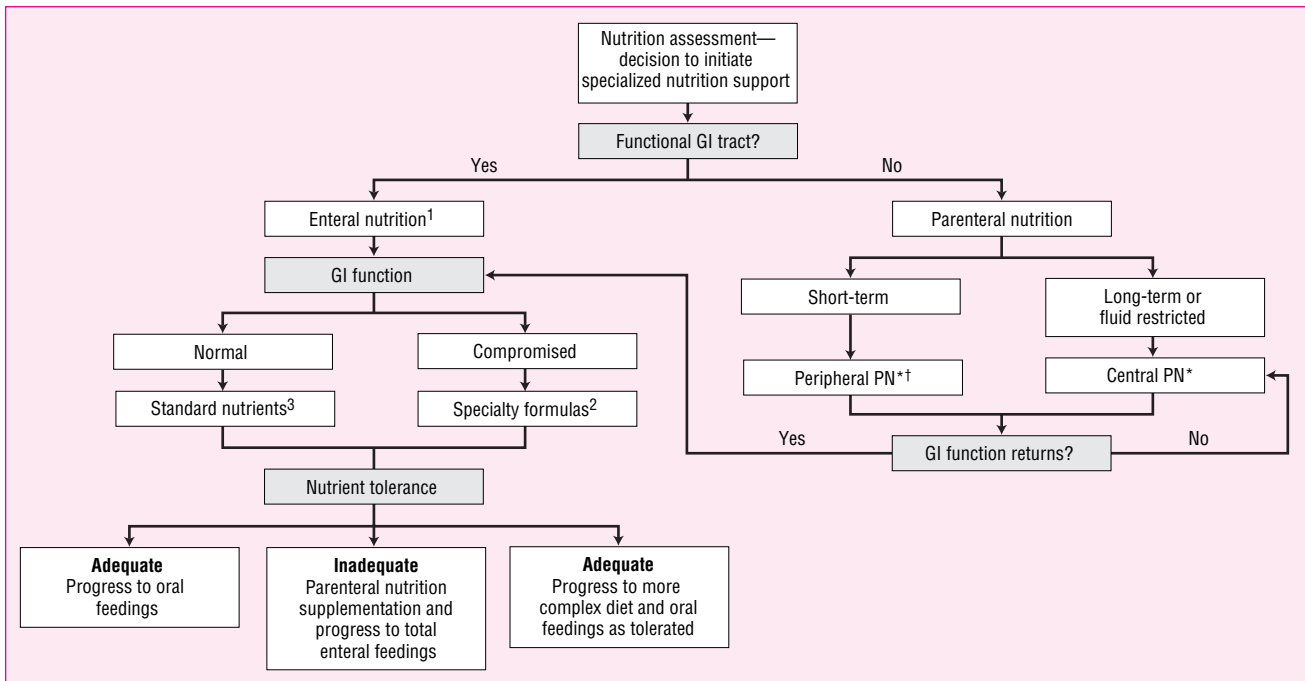

FIGURE 136–1. Routes to deliver nutrition support to adults: Clinical decision algorithm. *Formulation of enteral and parenteral solution should be made considering organ function (e.g., cardiac, renal, respiratory, or hepatic). †In selected patients, peripheral parenteral nutrition may be considered to provide partial or total nutrition support for up to 2 weeks in patients who cannot ingest or absorb oral or enteral-tube-delivered nutrients, or when central vein parenteral nutrition is not feasible. ¹Short-term: nasogastric, nasojejunal. Long-term: gastrostomy, jejunostomy. Feeding may be more appropriate distal to the pylorus if the patient has an increased risk of aspiration. ²Formulas should be tailored to patient GI tolerance and include elemental, low/high fat content, lactose-free, fiber-rich, and modular formulas. ³Polymeric, complete formulas are appropriate.

If nutrition assessment (see Chap. 135) reveals no malnutrition, then the patient should be counseled on appropriate maintenance goals for nutrition intake. If mild to moderate malnutrition is present, an anabolic feeding regimen should be initiated using oral supplements. If anorexia is a major contributing factor, enteral tube feeding may be indicated. Intact nutrients can be administered enterally when normal bowel function is present, but a specially designed formula that has a modified fat content, is lactose-free, contains fiber, and/or is calorie or protein enriched may be indicated if intestinal function is compromised (see Chap. 138). If malabsorption is a major contributing factor, tube feeding using a disease-specific formula, or alternatively, supplemental or total PN may be indicated. In the presence of severe malnutrition, an anabolic feeding regimen should be initiated either enterally or parenterally depending on intestinal function and malabsorption¹⁰⁵ (Fig. 136–1). Data from international studies show the median mortality rate secondary to severe malnutrition in children under 5 years of age is 25%. Since some institutions have reported a rate less than 5%, the treatment strategy that is employed appears to be critical. Therefore the World Health Organization has published guidelines for the management of severe malnutrition in children (see www.who.int/nut/managem.pdf).

When bowel obstruction or SBS is present, PN is indicated. Equivocal data exist whether EN is absolutely contraindicated in hypoperfusion of the gut. The most recent recommendations advocate holding enteral nutrition when patients have; sustained hypotension (<70 mm Hg), a need for increasing doses of pressor agents to maintain the mean arterial pressure \geq 70 mm Hg, increasing ventilatory support requirements, or worsening signs of GI intolerance to the enteral nutrition (i.e., sudden abdominal distention, abrupt increases in

nasogastric output, and sudden abdominal pain).¹⁰⁶ The anticipated duration of the need for parenteral support will dictate whether one uses the peripheral or central venous route of administration (see Chap. 137). Routine re-evaluation of the response to nutrition therapy and attainment of nutrition goals should be incorporated into the overall patient care plan.

PHARMACOECONOMIC CONSIDERATIONS

Malnourished patients have increased complications during their hospital course and an increased length of stay (LOS), and thereby incur increased health care costs.^{3,107} Low serum albumin concentrations must also be interpreted in the context of the surgical site (esophagus vs. colon), since this has been shown to affect the complication rate, thereby influencing hospital and ICU LOS.⁷² As disproportionate consumers of health care resources, malnourished patients rank among the top 10%.¹⁰⁸

Although the evidence is strong that malnutrition is associated with increased health care costs, it has been more difficult to establish the cost-benefit or cost savings of nutrition intervention. Based on assumptions derived from the literature, Twomey and Patching¹⁰⁹ concluded that preoperative PN could be cost-saving in patients undergoing surgery for gastrointestinal cancer. A similar conclusion applied to a broader patient population is supported by a model that examines the financial implications of malnutrition and nutrition therapy.¹⁰⁸ This model takes into consideration the increased costs associated with an increased LOS, and morbidity and mortality caused by malnutrition,

as well as the costs of identifying patients at risk for malnutrition, providing nutrition support, and managing the complications associated with the nutrition support. Tucker and Miguel confirmed the association between poor nutritional status and prolonged length of hospital stay, and also determined that when nutrition intervention occurred (oral, enteral, or parenteral nutrition), the average LOS was decreased by 2.1 days.¹⁰⁷

Trauma patients are at an unusually high risk for developing malnutrition due to the hypermetabolic and hypercatabolic state associated with underlying injury. Although several clinical trials have compared the efficacy of EN versus PN, little data are available regarding the cost-effectiveness of these two routes of administration. Trice and colleagues¹¹⁰ assessed the economic impact of the delivery of EN versus PN to trauma patients. Their evaluation of the data from nine prospective, randomized clinical trials revealed that postoperative PN was associated with an almost fourfold increased risk of infectious complications and 15-fold greater risk of catheter sepsis compared with EN. Estimated total costs thus were four- to 12.5-fold greater in patients receiving PN versus EN. Thus the decision to prescribe PN over EN should be evaluated carefully when considering nutrition support in trauma patients.

Economic savings also have been achieved when specialized nutrition support teams are involved with the provision of EN.¹¹¹ A benefit of \$4.20 was realized for every \$1 invested in nutrition support team management. Furthermore, management by the nutrition support team resulted in reductions in mortality rate, length of hospital stay, readmission rates, and complications, compared with management by a nonteam group. Thus intervention by specially trained health care practitioners, including pharmacists, can lower operating costs associated with nutrition intervention without compromising the quality of patient care.

EVALUATION OF THERAPEUTIC OUTCOMES

Although the cost-benefit analysis of nutrition intervention is weak, the issue that seems clear is that malnutrition is associated with significant morbidity and mortality in numerous disease states and clinical settings. Furthermore, it is likely that improved patient outcomes can be achieved by a systematic approach to identify the presence of risk factors for malnutrition, quantitate the degree of malnutrition, and initiate nutrition management.¹¹² The clinician's responsibilities in the management of nutrition disease include the following:

1. Assist in identifying patients at risk for malnutrition and/or candidates for nutrition intervention.
2. Assist in the design of patient-specific nutrition-support regimens.
3. Evaluate and manage all drug-nutrient interactions.
4. Evaluate laboratory data, especially parameters used to determine safety and efficacy of nutrition support.

ABBREVIATIONS

AIDS: acquired immunodeficiency syndrome
 BPD: bronchopulmonary dysplasia
 CF: cystic fibrosis
 CLD: chronic lung disease
 EN: enteral nutrition
 HIV: human immunodeficiency virus
 IBD: inflammatory bowel disease

LOS: length of stay
 NEC: necrotizing enterocolitis
 PNI: prognostic nutritional index
 PN: parenteral nutrition
 REE: resting energy expenditure
 SBS: short bowel syndrome

PARENTERAL NUTRITION

Todd W. Mattox and Pamela D. Reiter

Learning Objectives and other resources can be found at www.pharmacotherapyonline.com.

KEY CONCEPTS

- 1 Four steps to developing a successful nutrition plan include definition of nutrition goals, determination of nutrition requirements, determination of appropriate route of delivery of nutrients, and subsequent monitoring of the nutrition regimen to evaluate suitability of the regimen as a patient's clinical condition changes and to minimize or treat complications early.
- 2 The appropriate route of nutrition support depends on the functional condition of the patient's gastrointestinal (GI) tract, risk of aspiration, expected duration of nutrition therapy, and clinical condition.
- 3 Identifying the patient who is most likely to benefit from PN therapy includes consideration of the patient's age, nutrition status, expected duration of GI dysfunction, and potential risks of initiating therapy.
- 4 Parenteral nutrition (PN) solutions may be appropriately formulated for administration by peripheral or central venous access.
- 5 PN solutions may be infused continuously or intermittently.
- 6 Biochemical and clinical measurements considered necessary for effective monitoring of patients receiving PN include serum chemistries, vital signs, weight, total daily fluid intake and losses, and nutritional intake.
- 7 Non-catheter-related complications of PN therapy are minimized with application of age-appropriate nutrient dosing guidelines, frequent monitoring, and rational adjustments to the PN regimen when metabolic abnormalities occur.
- 8 Expenses associated with PN therapy may be minimized by using PN in appropriate patients, appropriate use of laboratory measurements associated with PN therapy, maximizing efficient purchasing practices for PN solutions and compounding supplies, streamlining compounding procedures, and minimizing PN waste.

Maintenance of adequate nutrition status during illness has been recognized for over 50 years as an integral part of the medical treatment plan for patients who are unable to use normal physiologic means of nourishment. Successful techniques for providing intravenous nutrition support were introduced to clinical practice in the early 1960s.¹ Metabolic complications associated with fluid overload and electrolyte imbalances stimulated the investigation of central venous access. The use of larger vessels permitted infusion of concentrated formulas, which decreased the fluid volume required and avoided the phlebitis that commonly occurred when hypertonic infusions were given peripherally.

By the late 1960s, Rhoads and Dudrick had documented continued growth and improvement in nutritional markers in humans with the use of central intravenous nutrition.¹ By the early 1970s, intravenous nutrition was used to sustain growth and development in premature infants.²

Further clinical experience and research fostered development of protocols that promoted better patient care and resulted in a decline in complications associated with parenteral nutrition (PN) therapy.³ The scope of practice for nutrition support clinicians has broadened as a result of increasing knowledge regarding the metabolic consequences associated with acute injury and chronic disease states. The pharmacist's role in providing safe and effective nutrition-support care requires knowledge of the principles of patient selection, initial therapy design, preparation and dispensing of the nutritional formu-

lations, and outcome monitoring (Table 137-1).⁴⁻⁷ However, the role of other health care professionals may be similar because of the evolving interdisciplinary approach to providing parenteral and enteral nutrition.⁶⁻¹¹ This chapter reviews indications for PN, components of PN formulations, routes of intravenous administration, practical aspects of regimen design, solution admixture, outcome monitoring, and management of complications for both adult and pediatric (neonates, infants, and children) patients.

DESIRED OUTCOMES

- 1 The overall objective of nutrition support therapy is to promote positive clinical outcomes of an illness or improve a patient's quality of life. Four fundamental steps are key to providing optimal care for patients who require nutrition support. They are definition of nutrition goals, determination of nutrient requirements for achievement of the nutrition goals, delivery of the required nutrients, and subsequent assessment of the nutrition regimen.⁶⁻⁸

A patient's nutrition goals can be established after a thorough nutritional assessment (see Chap. 135). Nutrient requirements and an appropriate route for delivery of the required nutrients can then be determined (see Chaps. 136 and 138). Goals of nutrition support include correction of the patient's caloric and nitrogen imbalances, fluid

From Holcombe et al.⁴

or electrolyte abnormalities, and any known vitamin or trace element abnormalities, without causing or worsening other metabolic complications. Specific caloric goals include (1) adequate energy intake to promote normal growth and development in neonates, infants, and children, (2) energy equilibrium and preservation of fat calorie stores in well-nourished adults, and (3) positive energy balance in malnourished patients with depleted endogenous fat stores. Obese patients with excess endogenous fat stores (>120% of ideal body weight) may require less caloric support than nonobese patients with the same clinical condition.¹² Specific nitrogen goals are positive nitrogen balance or nitrogen equilibrium and improvement in the serum concentration of visceral protein markers such as transferrin or prealbumin.

2 The gastrointestinal (GI) tract is the optimal route for providing nutrients unless obstruction, severe pancreatitis, or other GI complications are present¹³ (see Fig. 136–1). Other considerations that may have an impact on determination of an appropriate route for nutrition support include expected duration of nutrition therapy and risk of aspiration. Patients who have nonfunctional GI tracts or are otherwise not candidates for enteral nutrition (EN) may benefit from PN. Use of the intravenous route for nutrition support is also commonly referred to as total parenteral nutrition (TPN) or hyperalimentation. Routine monitoring is necessary to ensure that the nutrition regimen is suitable for a given patient as his or her clinical condition changes and to minimize or treat complications early.

INDICATIONS FOR NUTRITION SUPPORT

The association between malnutrition and development of complications and mortality has been well documented in adult and pediatric patients.^{14–16} Although improvement in nutrition status as defined by various clinical nutrition markers has been reported in patients who received PN, the impact on clinical outcome has been difficult to demonstrate in many adult populations. Several investigations have reported a positive effect of PN on complications and mortality, whereas others have failed to demonstrate any difference.^{14,15,17} Early studies have been criticized for defects in study design such as small sample sizes, inappropriate randomization, and inconsistent baseline nutrition status among the study group, which hindered demonstration of the effectiveness of PN therapy. The impact of PN on clinical outcome has been more successfully demonstrated in critically ill infants and children, particularly those with acquired or congenital GI tract anomalies.² Consensus guidelines for use of PN in adults and pediatric patients are based on clinical experience and investigations in specific patient populations^{17–19} (Table 137–2). Unfortunately, conflicting data have resulted in a lack of consistency in published guidelines from different sources, which complicates identification of the patient who is most likely to benefit from PN. However, these published reports may serve as resources for development of institution-specific standards.

3 The decision to initiate PN is based on the assessment that the patient cannot meet his or her nutritional requirements with use of the GI tract. This assessment must include an evaluation of the patient's nutrition status, clinical status, age, and potential risks of initiating therapy, such as infection and other metabolic abnormalities. The appropriate length of time to wait prior to starting PN therapy has not been well defined.¹³

CLINICAL CONTROVERSY

The most appropriate time to initiate PN in adults differs between various consensus reports because few data specifically address this issue. Hence some recommendations are evidence-based from findings extrapolated from clinical investigations of adult patients receiving PN or enteral nutrition, while others are based on meta-analysis review of PN use in adults.

However, adult PN therapy is not an emergent intervention and should not be initiated until the patient is hemodynamically stable.¹³ In general, adults who are not candidates for EN should be considered candidates for PN after 7 to 14 days of suboptimal nutritional intake.¹³ Guidelines for use in infants and children are primarily influenced by age. The younger the patient, the sooner PN should be considered.

CLINICAL CONTROVERSY

Although clinical data suggest that critically ill neonates will benefit from aggressive PN within the first 24 hours of life, some clinicians withhold PN therapy for 2 to 3 days after birth because of concerns for development of adverse effects associated with protein intolerance, such as hyperammonemia, azotemia, and metabolic acidosis.

However, the most appropriate time to initiate therapy is controversial. Early PN within the first 24 hours of life has been recommended.^{19–21} Protein loss in extremely low-birth-weight infants can be twofold higher than in term infants, and frequently results in a negative nitrogen balance that cannot be corrected by

TABLE 137–2. Indications for Parenteral Nutrition (PN)

1. Inability to absorb nutrients via the gastrointestinal tract because of one or more of the following:
 - a. Massive small bowel resection.

Adults: Usually patients with <100 cm of small bowel distal to the ligament of Treitz without a colon, or <50 cm of small bowel without an intact colon.

Pediatrics: PN should be initiated in all patients who undergo resection of any part of the small bowel significant enough to result in restriction of enteral intake.
 - b. Intractable vomiting when adequate enteral intake is not expected for 7–14 days.
 - c. *Severe diarrhea:*

Intractable diarrhea of infancy: infants younger than 3 months who have persistent diarrhea for more than 2 weeks with three or more stool cultures negative for enteropathogens, who have failed a trial of enteral nutrition support.
 - d. *Inflammatory bowel disease (Crohn’s disease or ulcerative colitis):*

PN may benefit patients with acute exacerbations of ulcerative colitis when surgery is being considered and when preservation of lean body mass and functional capacity with enteral nutrition is impossible. PN is indicated for children with Crohn’s disease who have near-complete bowel obstruction, high-output fistulae, gastrointestinal bleeding, and progressive surgical resection resulting in short bowel syndrome.
 - e. *Bowel obstruction:*

Pseudo-obstruction: PN is indicated in patients with prolonged dysmotility of the gastrointestinal tract distal to the pylorus, or in patients who cannot grow and gain weight with enteral nutrition alone.
 - f. *Gastrointestinal fistulae:* PN is indicated in patients in whom enteral intake must be restricted longer than 7 days.
2. *Cancer:* Antineoplastic therapy, radiation therapy, or hematopoietic stem cell transplantation.
 - a. PN may benefit some severely malnourished cancer patients or those in whom gastrointestinal or other toxicities are anticipated to preclude adequate oral nutritional intake for a prolonged period of time.
 - b. PN is not routinely indicated for well-nourished or mildly malnourished patients undergoing surgery, chemotherapy, or radiation treatment, and in whom adequate oral intake is anticipated.
 - c. PN is unlikely to benefit patients with advanced cancer whose malignancy is documented as unresponsive to chemotherapy or radiation therapy. However, its use in carefully selected patients with good performance status, an estimated life expectancy >40–60 days, with strong social and financial support who have also failed trials of less invasive medical therapies may be appropriate.
3. *Pancreatitis:* It can be used in patients with moderate to severe pancreatitis when adequate enteral intake is not expected for 5–7 days. PN should be used when enteral feeding exacerbates abdominal pain, ascites, or fistula output in patients with pancreatitis and limited oral intake.
4. *Critical care:*
 - a. PN should be used in those patients in whom enteral nutrition is contraindicated or is unlikely to provide adequate nutritional requirements within 5–10 days (e.g., major surgery, trauma, sepsis, traumatic brain injury, or cerebrovascular accident).
 - b. Organ failure (liver, renal, or respiratory): PN should be used in patients with moderate to severe catabolism, with or without malnutrition, when enteral feeding is contraindicated.
 - c. Burns: PN should be used in those patients in whom enteral nutrition is contraindicated or is unlikely to provide adequate nutritional requirements within 4–5 days.
5. *Perioperative PN:*
 - a. Preoperative: For malnutrition when the gastrointestinal tract is not functional and surgery is not expected for at least 7 days.
 - b. Postoperative: PN should be used in patients in whom enteral nutrition is contraindicated or is unlikely to provide adequate nutritional requirements within 7–10 days.
6. *Hyperemesis gravidarum:* When enteral tube feeding is not tolerated.
7. *Eating disorders:* PN should be considered for patients with anorexia nervosa and severe malnutrition who require nonvolitional feeding, but who cannot tolerate enteral support for physical or emotional reasons.
8. *Low-birth-weight (premature) infants:* PN is indicated within the first day of life in selected low-birth-weight infants such as those diagnosed with necrotizing enterocolitis or bronchopulmonary dysplasia, before enteral nutrition is initiated and as a supplement while enteral nutrition is being advanced.
9. *Inborn errors of metabolism:* PN use may be necessary in children who are unable to tolerate certain specialized formulas enterally because of disease-induced nausea and vomiting and poor palatability of the formulas.

From ASPEN Board of Directors.^{13,18,19,110}

glucose as a sole nutrient. Additionally, decreased hyperglycemic events, improved growth, and other positive metabolic outcomes have been demonstrated with early aggressive PN in neonates.²² However, many clinicians hesitate to initiate early PN due to concern of adverse effects associated with protein intolerance. Withholding PN for 2 to 3 days after birth, coupled with a slow advancement of substrate, only appears to contribute to the acute semistarvation and growth failure seen in many neonates.^{21,23,24} Term infants who have failed EN support or have a dysfunctional GI tract will benefit from initiation of PN after 2 to 3 days of suboptimal nutritional intake.^{19,20} Well-nourished children who are not candidates for EN should be considered candidates for PN after 5 to 7 days of suboptimal nutritional intake.^{20,25} Children with preexisting malnutrition likely will require earlier

intervention. Guidelines for older children are similar to those in adults.

COMPONENTS OF PARENTERAL NUTRITION

PN solutions should provide the optimal combination of macronutrients and micronutrients to meet the specific nutritional requirements of the patient. Macronutrients include water, protein, dextrose, and intravenous lipid emulsion. Micronutrients include vitamins, trace elements, and electrolytes. Both macronutrients and micronutrients are necessary for maintenance of normal metabolism. In general, macronutrients are used for energy (dextrose and fat) and as structural

substrates (protein and fats). Micronutrients are required to support a variety of metabolic activities necessary for cellular homeostasis such as enzymatic reactions, fluid balance, and regulation of electrophysiologic processes. These components usually require individualized adjustments as the patient's clinical condition dictates changes in metabolic stress, organ function, fluid and electrolyte balance, and acid-base status.

AMINO ACIDS

Protein in PN solutions is provided in the form of crystalline amino acids (CAAs), which are used primarily for protein synthesis. When oxidized for energy, 1 g of protein yields 4 calories. However, including the caloric contribution from protein when calculating calories provided by the PN regimen is controversial.²⁶

CLINICAL CONTROVERSY

While sufficient energy substrate should be provided to allow use of amino acids for protein synthesis rather than as an energy source, oxidation of amino acids for energy has been demonstrated in critically ill patients and is thought to occur because of metabolic derangements seen during severe metabolic stress. Hence some practice settings may differ in expressing calories provided by a PN regimen as total calories (protein, carbohydrate, and fat calories) or nonprotein calories (carbohydrate and fat calories).

Commercially available CAA solutions may be categorized as standard amino acid solutions or modified amino acid solutions. Standard CAA solutions are designed for use in patients with "normal" organ function and nutritional requirements (Table 137–3). Although standard CAA solutions differ in the proportion of specific amino acids, they contain a balanced profile of essential, semiessential, and nonessential L-amino acids. Despite these differences, similar effects on markers of protein use have been reported.²⁷ These products also differ in protein concentration, total nitrogen, and electrolyte content. Because the nitrogen concentration of dietary protein is approximately 16%, 6.25 (100 g protein/16 g nitrogen) is commonly accepted as the conversion figure for calculating the amount of nitrogen provided by CAA protein. Differences in nitrogen content per gram of amino acids among CAA products may affect calculation of nitrogen amounts infused when determining nitrogen balance.^{27,28} The clinical significance of these differences in calculations of nitrogen balance for routine clinical use is not known.²⁸

Electrolyte composition of standard CAA solutions varies from small, obligatory amounts, to the provision of maintenance requirements of most electrolytes for an adult. The contribution of electrolytes from CAA solutions must be considered when determining a patient's individual requirements. The availability of CAA in several different concentrations facilitates compounding of patient-specific PN regimens. Highly concentrated products (15% to 20%) are attractive for use in critically ill patients who typically require fluid restriction but have large protein needs. Modified amino acid solutions are designed for use in patients who have altered protein requirements such as those with hepatic encephalopathy, renal failure, and metabolic stress or trauma, as well as neonates and pediatric patients (see Table 137–3). These solutions tend to be more expensive than standard CAA solutions. The rationale for and clinical efficacy of modified amino acids in disease-specific PN regimens is controversial (see Chap. 139).

Several commercially available CAA solutions are designed to provide conditionally essential amino acids (CEAAs). CEAAs are considered nonessential during health because they are produced from other amino acids. However, under certain physiologic conditions such as prematurity or sepsis, these amino acids cannot be synthesized in sufficient quantities.²⁷ CAA solutions specifically designed for use in neonates and pediatric patients contain increased amounts of taurine, aspartic acid, and glutamic acid. Other CEAAs, such as cysteine, carnitine, and glutamine, are not available in commercial CAA solutions in pharmacologic amounts because they are relatively unstable or poorly soluble.²⁷

PN solutions therefore may need to be modified by clinicians to provide supplemental amounts of CEAAs. Cysteine is a CEEA in preterm and term infants that may be added to PN solutions at the time of compounding. An additional benefit of including cysteine is that it enhances calcium and phosphate solubility in PN solutions by decreasing the solution's pH.²⁹ Carnitine is a quarternary amine required for transport of free fatty acids into the mitochondria for beta-oxidation and energy production.³⁰ Newborns are at risk for carnitine deficiency because of their immature synthetic and conservation mechanisms. Decreased plasma carnitine concentrations are associated with impaired lipid metabolism in patients receiving intravenous lipid emulsion (IVLE).³¹

Supplemental carnitine may be added to the PN solution at the time of compounding. However, routine addition to neonatal PN regimens is controversial because the effect of supplemental carnitine on clinical outcomes such as weight gain and lipid utilization is not clear.³¹

CLINICAL CONTROVERSY

Little evidence of sustained positive outcomes after carnitine supplementation exists. However, decreased plasma carnitine concentrations have been reported in neonates within 2 weeks of inadequate enteral intakes of carnitine-containing infant formula. Thus intravenous carnitine supplementation is generally reserved for patients receiving sole PN support for more than 2 weeks.

Glutamine is the most abundant free amino acid in the body and is an important intermediate for many metabolic processes. Glutamine is reported to have an important role in maintaining intestinal integrity, immune function, and protein synthesis during conditions of metabolic stress.^{27,32} Investigations in humans and animals have reported positive effects on nutritional markers such as nitrogen balance, whereas others have reported significant improvement in other outcome markers such as decreased length of hospitalization, incidence of infections, and GI toxicities associated with chemotherapy or radiation.³³ However, the best adult candidate for response to glutamine therapy has not been clearly identified.³³ The clinical utility of glutamine in neonates is less clear.³⁴ The clinical use of glutamine is further complicated because there is no commercially available intravenous glutamine formulation. Currently available CAA solutions do not contain glutamine because of poor solubility and instability. Use of intravenous glutamine requires special manufacturing techniques not readily available in many institutional pharmacies.³⁵ Additional controlled trials are warranted to clearly justify risks and costs associated with extemporaneous compounding before routine use of intravenous glutamine can be recommended.^{33,35} Dipeptide amino acids are a potential parenteral source for CEAAs that may provide a solution to the instability and solubility limitations. Dipeptides are synthesized by combining

TABLE 137–3. Macronutrient Components of Parenteral Nutrition Solutions

| Nutritional Substrate | Intravenous Source | Commercial Product (Manufacturer) | | Comments | | |
|---|---|--|--|---|-----------------|---------------------|

AAA, aromatic amino acids (includes phenylalanine and tyrosine); BCAA, branched-chain amino acids (leucine, isoleucine, and valine); EAA, essential amino acids (leucine, isoleucine, valine, phenylalanine, tryptophan, methionine, threonine, and lysine); LCT, long-chain triglycerides; MCT, medium-chain triglyceride.

^aUsed as a supplement to a standard amino acid solution to increase BCAA content.

^bUsed as a supplement to crystalline amino acid solutions.

two amino acids with a peptide bond. The resulting protein is more soluble and stable than the individual amino acids.²⁷ Intravenous dipeptide formulations would be advantageous clinically because they incorporate higher concentrations of some specific amino acids, as well as some low-solubility, low-stability amino acids that are omitted or present in small quantities in current CAA solu-

tions. In addition, use of dipeptides would allow formulation of CAA solutions with a higher nitrogen content. Further studies are needed to assess long-term safety and optimal combinations of amino acids in different disease states. Examples of commercially available CAA products and some investigational amino acids are listed in Table 137–3.

DEXTROSE

The primary energy source in PN solutions is carbohydrate, usually in the form of dextrose monohydrate. This nutritional substrate is available in a variety of concentrations ranging from 5% to 70%. When oxidized, each gram of hydrated dextrose provides 3.4 kcal. Dextrose is oxidized at a maximum rate of 4 to 7 mg/kg per minute in adults receiving intravenous dextrose infusions.³⁶ Premature infants have a higher rate of glucose oxidation because of their relatively large body proportion of metabolically active organs. Although the fetal nutrient delivery rate is approximately 5 to 6 mg/kg per minute, maximum glucose oxidation rates of 12 to 14 mg/kg per minute have been reported in very-low-birth-weight neonates and term infants.^{19,22,37} However, an investigation of critically ill children from 1 to 11 years old reported glucose oxidation rates similar to those observed in adults.³⁸ The appropriate dose of intravenous dextrose depends on the patient's age and clinical condition. If the dextrose infusion rate exceeds the glucose oxidation rate, metabolically expensive pathways such as glycogen repletion and lipid synthesis will be favored, resulting in increased energy expenditure, increased oxygen consumption, and increased carbon dioxide production. Excessive dextrose infusion rates also may contribute to the development of hyperglycemia, excess carbon dioxide production, and increased biochemical markers for liver function associated with fatty infiltration of the liver.^{38,39} Although infusion rates of up to 11 to 12 mg/kg per minute have been recommended for young children, the recommended dose of dextrose for routine clinical care rarely exceeds 5 mg/kg per minute in older critically ill children and adults.^{25,35,36,38}

Insulin is essential to transport dextrose into many cells such as skeletal muscle for oxidation to yield energy. Because many clinical conditions associated with impaired insulin secretion or activity may complicate provision of PN, non-insulin-dependent sources of carbohydrate have been investigated (see Table 137-3). Of these nutrients, only glycerol is available commercially for clinical use in humans as a carbohydrate source for PN. Glycerol is a sugar alcohol that provides 4.3 kcal/g and is available as a 3% solution in combination with 3% amino acids and supplemental electrolytes (ProcalAmine, B. Braun). This product is nearly isotonic, so it may be infused peripherally. A major disadvantage of this formula is the dilute concentrations of amino acids and carbohydrate. Most adult patients require up to 3 to 4 L/day of ProcalAmine solution together with lipid emulsion as a caloric source to provide minimum energy requirements.⁴⁰ Intravenous glycerol use in catabolic adults is safe and effective, but similar data are not available for infants and children.⁴¹

LIPID EMULSION

IVLE is used as a concentrated source of calories and essential fatty acids. Commercially available IVLE products differ in source of triglycerides (soybean oil or a combination of soybean oil and safflower oil), fatty acid content, and commercially available concentrations (10%, 20%, and 30%; see Table 137-3). These products also contain egg phospholipids as an emulsifying agent and glycerol to make the emulsion isotonic. Although the caloric contribution of fat is 9 kcal/g, the caloric content of IVLE is 1.1 kcal/mL for 10% emulsion, 2 kcal/mL for 20% emulsion, and 3 kcal/mL for 30% emulsion because of the caloric contribution of the egg phospholipid and glycerol.⁴² The sources of triglyceride in IVLEs differ in fatty acid composition. Soybean oil emulsions contain approximately 50% to 55% linoleic acid and 4% to 9% linolenic acid, whereas IVLEs that contain safflower oil are made of approximately 66% linoleic acid and 4% linolenic acid.⁴² Linolenic acid, an omega-3 fatty acid,

and linoleic acid, an omega-6 fatty acid, are both polyunsaturated long-chain triglycerides (LCTs).⁴³ IVLE products also differ in phospholipid and triglyceride concentrations. Higher-concentrated IVLEs (20% and 30%) have a lower phospholipid:triglyceride ratio compared with 10% IVLE.⁴⁴ Because higher amounts of circulating phospholipids have been associated with impaired triglyceride clearance in neonates and infants, 20% IVLE is the preferred product for this population.^{20,25,35,39,44,45}

Both types of IVLEs are effective in the treatment or prevention of essential fatty acid deficiency (EFAD). EFAD is the result of a biochemical deficiency of linoleic acid and arachidonic acid, which are considered essential in humans.⁴⁶ Although linolenic acid may be essential, all commercially available IVLEs contain soybean oil as a predominant source of linolenic acid. These fatty acids are important for a variety of functions such as cellular integrity, platelet function, postnatal brain development, and wound healing.^{25,46} Normally, linoleic acid is converted to the tetraene arachidonic acid. When linoleic acid is not present in sufficient amounts, oleic acid is converted to the triene 5,8,11-eicosatrienoic acid, a fatty acid of lesser physiologic integrity, and EFAD occurs. EFAD may be prevented by providing 2% to 5% of total calories as linoleic acid. This may be achieved in most adult patients by giving approximately 100 g IVLE weekly.⁴⁷ Neonates and infants require a minimum of 0.5 to 1 g/kg daily.^{20,25,39}

Plasma clearance of IVLE is directly related to gestational age of infants and appears to be influenced by the rate of infusion and the patient's clinical status.^{25,44,45} The risk of developing hypertriglyceridemia lessens with longer infusion times.^{35,39,45} Rapid IVLE infusions in neonates have been reported to contribute to pulmonary dysfunction such as decreased oxygenation.³⁹ Adverse pulmonary effects are thought to be caused by polyunsaturated fatty acid (PUFA)-driven prostaglandin production, which results in altered vascular tone. However, the association between IVFE and pulmonary dysfunction is not clear.³⁹ In addition, data in animals and humans also suggest that rapid infusion of long-chain fatty acid formulations may have a negative impact on immunocompetence by saturating the reticuloendothelial system.^{43,45}

As a caloric source, use of IVLE may facilitate provision of adequate calories and minimize complications of nutrition therapy such as hyperglycemia, hepatotoxicity, or increased production of carbon dioxide.⁴³ Although the frequency of acute adverse effects is reported to be less than 1% with current formulations, patients receiving their first dose of IVLE should be monitored for dyspnea, chest tightness, palpitations, and chills. Headache, nausea, and fever also have been reported and may be associated with a rapid infusion rate. In general, the use of IVLE is contraindicated in patients with an impaired ability to clear lipid emulsion, such as patients with pathologic hyperlipidemia and hypertriglyceridemia associated with pancreatitis.⁴⁵ Finally, patients with a reported egg allergy should be evaluated carefully for the nature and severity of the reaction before deciding to initiate a lipid-based PN regimen.

Commercially available 10% and 20% IVLE products may be administered either by the central or peripheral route. They may be added directly to the PN solution as a total nutrient admixture (TNA) or 3-in-1 system (lipids, protein, glucose, and additives), or they may be piggybacked with the CAA-dextrose solution.⁴³ The more concentrated 30% IVLE is only approved for use in the preparation of TNA and is not intended for direct intravenous administration.

The negative effects of LCTs on immune function have stimulated a search for new sources of lipids.^{43,48} Medium-chain triglycerides (MCTs) may offer several advantages, especially for critically ill patients. MCTs are hydrolyzed and cleared more rapidly than

LCTs, and they do not accumulate in the liver. In addition, MCTs do not require carnitine for entrance into mitochondria for oxidation. However, MCTs are not a source of essential fatty acids. Subsequent studies of intravenous MCT-LCT mixtures in a number of patients have demonstrated safety and efficacy comparable with standard LCT emulsions.^{43,48} Several MCT-LCT products are available in Europe, although no intravenous MCT formulations are currently available commercially in the United States. Other intravenous lipid formulations currently being investigated contain omega-3 PUFAs.⁴³ Current IVLEs contain omega-6 PUFAs as linoleic acid and omega-3 PUFAs as linolenic acid. Omega-3 PUFAs are metabolized to cytokine mediators, which may be less inflammatory and immunosuppressive than those derived from omega-6 PUFAs. The effect of IVLE administration on immune function, as well as patient morbidity and mortality, is not clear.^{39,49,50} However, investigations of enteral solutions with a higher concentration of omega-3 PUFAs have reported decreased infections and improvement in *in vitro* immunologic indices in critically ill patients.⁵¹ Although IVLE products remain the most common source of parenteral lipids, a number of drugs have been introduced that contain lipid as either a vehicle for delivery or as a portion of the drug molecular formulation. Propofol, an intravenous anesthetic, is delivered in a soybean oil-in-water emulsion that is essentially the same as Intralipid 10%. This agent is used commonly for continuous sedation of ventilated patients and should be considered a potentially significant source of calories that may require adjustment of a patient's nutrition regimen.⁵² The antifungal amphotericin B is available in several lipid-containing combinations such as liposomal and lipid complex formulations. The caloric contribution from these products when used in standard doses generally is small and is not relevant clinically.

VITAMINS

Vitamins are necessary for the maintenance of normal metabolism and cellular function. Fat-soluble vitamins (i.e., A, D, E, and K) are stored extensively in the body's fat tissue, whereas water-soluble vitamins are stored in limited amounts by the body. Maintenance guidelines for daily parenteral vitamin supplements have been established by the Nutrition Advisory Group of the American Medical Association (NAG-AMA) for adults, children, and infants.⁵³ The NAG-AMA identified 13 essential vitamins that include four fat-soluble vitamins and nine water-soluble vitamins. These guidelines are based on the recommended daily allowances (RDAs), which are designed to meet requirements of healthy people. Vitamin requirements for preterm infants and patients with metabolic stress or specific organ failures are controversial.^{39,54–56} Revised NAG-AMA recommendations for parenteral vitamin requirements in infants and children reflect data reported in pediatric patients who received currently available formulations.⁵⁶ In general, the revised recommendations focused on changes for preterm infants requiring PN.

Several adult and pediatric parenteral multiple-vitamin products formulated to comply with the NAG-AMA guidelines are available commercially. Currently there are two commercially available parenteral vitamin products designed for use in pediatric patients. These parenteral multiple-vitamin formulations provide 13 essential vitamins, including vitamin K. MVI-Pediatric (Mayne Pharma) and Infuvite Pediatric (Baxter) are formulated to meet the revised NAG-AMA guidelines for infants weighing less than 1 kg to children up to 11 years old. However, there are no commercially available intravenous multivitamin products designed to specifically meet the unique requirements of premature infants, including higher vitamin A and lower

vitamin B₁, B₂, B₆, and B₁₂ doses relative to recommendations for term infants and older children.

In the past, parenteral multiple-vitamin formulations for adults contained only 12 essential vitamins. Vitamin K was not included to minimize the risk of a drug-nutrient interaction in patients receiving anticoagulants, which antagonize vitamin K. However, in 2000, the Food and Drug Administration (FDA) mandated reformulation of adult parenteral multiple-vitamin products to include 150 mcg vitamin K in addition to higher doses of vitamins B₁, B₆, and C.⁵⁷ The NAG-AMA recommendation for vitamin K in adults is 2 to 4 mg weekly. However, other practitioners have recommended larger doses of 5 to 10 mg weekly. An investigation of patients receiving long-term IVLE-containing PN at home suggests that supplemental vitamin K may not be necessary to maintain normal prothrombin times and plasma vitamin K concentrations.⁵⁸ Vegetable oils such as soybean and safflower oils used in IVLEs are a natural source of phylloquinone (vitamin K₁). However, the vitamin K concentration depends on the type and concentration of vegetable oil in the IVLE.^{57–59} Mean concentrations of 13.2 and 26.5 mcg/100 mL were reported for 10% and 20% Liposyn II (Abbott), which contains both soybean and safflower oil.⁵⁹ Mean concentrations of 30.9 and 67.5 mcg/100 mL were reported for 10% and 20% Intralipid (Kabivitrüm), which contains only soybean oil. The bioavailability of vitamin K₁ from IVLEs is not known. Although hospitalized patients who received no additional vitamin K supplementation during short-term PN that included a low-vitamin K-containing IVLE experienced minimal effects on International Normalized Ratio, supplemental vitamin K may be given intramuscularly or subcutaneously or added to the PN solution if needed.^{57,60} However, the role of supplemental vitamin K when using a vitamin K-containing multiple-vitamin product is not clear.

Vitamin requirements may be altered in malnutrition and other specific disease states or with certain drug therapies. Individual and combination products are available to provide additional or tailored supplementation, which may be necessary to prevent development of vitamin toxicities or deficiencies caused by altered metabolism or drug therapy.

TRACE ELEMENTS

Trace elements are minerals that are required in very small amounts for a variety of biochemical and physiologic functions. Many trace elements are an important part of metalloenzymes and also function as cofactors in a variety of regulatory metabolic pathways.^{54,56} Although 17 trace elements have demonstrated biologic importance, clear deficiency syndromes in humans have been described only for iron, iodine, cobalt (as vitamin B₁₂), zinc, and copper.^{56,61,62} The NAG-AMA recognized zinc, copper, and chromium as being essential for intravenous supplementation in patients receiving PN.⁶³ While a clear deficiency syndrome for manganese has not been reported in humans, the NAG-AMA considered manganese essential based on case reports of patients receiving PN with metabolic complications that corrected after manganese supplementation.⁶³ Reports of syndromes associated with selenium and molybdenum deficiency suggest that they also may be essential.^{56,61,62} Recommendations for trace elements in pediatric patients receiving PN have been revised as well.⁵⁶

Intravenous trace elements are available as single-mineral solutions and as multiple-mineral combinations with or without electrolytes. Most products provide the daily requirements for the trace minerals considered essential by the NAG-AMA (zinc, copper, chromium, and manganese), whereas some also include iodide,

TABLE 137–4. Fluid, Electrolyte, and Acid–Base Abnormalities

| Problem | Possible Causes | Intervention |
|---------------------|--|---|
| Hypovolemia | Gastrointestinal fluid losses, osmotic diuresis | Increase fluid intake |
| Hypervolemia | Renal failure, cardiac failure, excess fluid intake | Decrease fluid intake, diuretics |
| Hyponatremia | Gastrointestinal losses, fluid overload, diuretics | Varies with cause |
| Hypnatremia | Dehydration, net relative sodium excess | Increase fluid intake, decrease sodium intake |
| Hypokalemia | Gastrointestinal losses, diuretics, anabolism | Increase potassium intake |
| Hyperkalemia | Renal failure, potassium-sparing drug therapy, metabolic acidosis | Decrease potassium intake, correct metabolic acidosis |
| Hypophosphatemia | Phosphate-binding antacids, anabolism, phosphate-free dialysate | Discontinue phosphate binders, increase phosphorus intake |
| Hyperphosphatemia | Renal failure | Decrease phosphorus intake |
| Hypomagnesemia | Diarrhea, malabsorption, anabolism; magnesium-wasting drug therapy | Increase magnesium intake |
| Hypermagnesemia | Renal failure | Decrease magnesium intake |
| Hypocalcemia | Hypoalbuminemia, chronic renal failure | Calculate estimated serum calcium concentration corrected for hypoalbuminemia, or monitor serum ionized calcium concentrations to verify hypocalcemia, increase calcium intake if necessary |
| Hypercalcemia | Dehydration, malignancy | Decrease calcium intake, increase fluid intake |
| Metabolic acidosis | Diarrhea, high-output fistulae, renal failure | Treat underlying causes, increase acetate and decrease Cl in PN solution |
| Metabolic alkalosis | Gastric losses | Treat underlying cause, increase Cl and decrease acetate in PN solution |

Adapted with permission from Teasley-Strausburg et al.⁹¹

molybdenum, or selenium. Combination products are available for pediatric patients that provide manganese, copper, chromium, zinc, and selenium.

Requirements for trace elements also change depending on the clinical condition of the patient. For example, higher doses of supplemental zinc likely are necessary in patients with high-output ostomies or diarrhea because the predominant route of excretion for zinc is via the GI tract. Manganese and copper are excreted through the biliary tract, whereas chromium, molybdenum, and selenium are excreted renally. Hence these trace elements should be restricted or withheld from PN solutions in patients with cholestatic liver disease and renal failure, respectively.

ELECTROLYTES

Electrolytes such as sodium, potassium, calcium, magnesium, phosphorus, chloride, and acetate are necessary components of PN for the maintenance of numerous cellular functions including acid-base balance and cellular growth. Electrolytes may be given to maintain normal serum concentrations or to correct deficits. Patients who have “normal” organ function and relatively normal serum concentrations of any electrolyte should receive normal maintenance doses of electrolytes on initiation of PN and daily thereafter (see Chap. 135). Requirements for specific electrolytes will vary according to the patient’s age, disease state, organ function (see Chap. 139), previous and current drug therapy, nutrition status, and extrarenal losses (Table 137–4). Electrolytes are available commercially as single- and multiple-nutrient solutions. Multiple-electrolyte solutions are useful in stable patients with normal organ function who are receiving PN. Concentrated multiple-electrolyte solutions designed for addition to PN solutions generally contain only sodium, potassium, calcium, and magnesium. Phosphorus must be added as a separate additive. Further information regarding metabolism and requirements of vitamins, trace elements, and electrolytes is given elsewhere.³⁵

DESIGNING A PARENTERAL NUTRITION REGIMEN

4 Several factors including venous access, fluid status of the patient, and macronutrient and micronutrient requirements are important considerations when designing the PN regimen for an individual patient. A patient’s venous access and fluid status will determine how concentrated the PN solution may be compounded and hence will have an impact on the amount of nutrient that may be provided. PN solutions may be administered by central or peripheral venous access. The clinical condition of the patient will determine which route is most appropriate (Fig. 137–1).

ROUTES OF PARENTERAL NUTRITION ADMINISTRATION

PERIPHERAL ROUTE

Because of physical limitations of peripheral veins, peripheral parenteral nutrition (PPN) regimens usually are dilute solutions of amino acids, dextrose, and micronutrients. Although early PPN studies supported the use of amino acids alone as protein-sparing therapy, subsequent investigations have challenged this theory.^{17,64} The rationale for protein-sparing PPN was based on the theory that the provision of dextrose in the setting of altered metabolism or stress would promote further increases in serum insulin concentrations and thereby hinder the use of endogenous fat stores and promote nitrogen catabolism. Protein-sparing PPN is used for patients with marginal nutrition status and inadequate oral intake who are not candidates for central catheter placement, and when the expected length of PN therapy is less than 1 week. However, investigations of adults receiving postoperative PN suggest that some patients who meet criteria for protein-sparing PPN may not benefit from PN support.¹⁷

The addition of IVLEs to PPN is referred to as the lipid system. The lipid system is designed for use in mild to moderately stressed

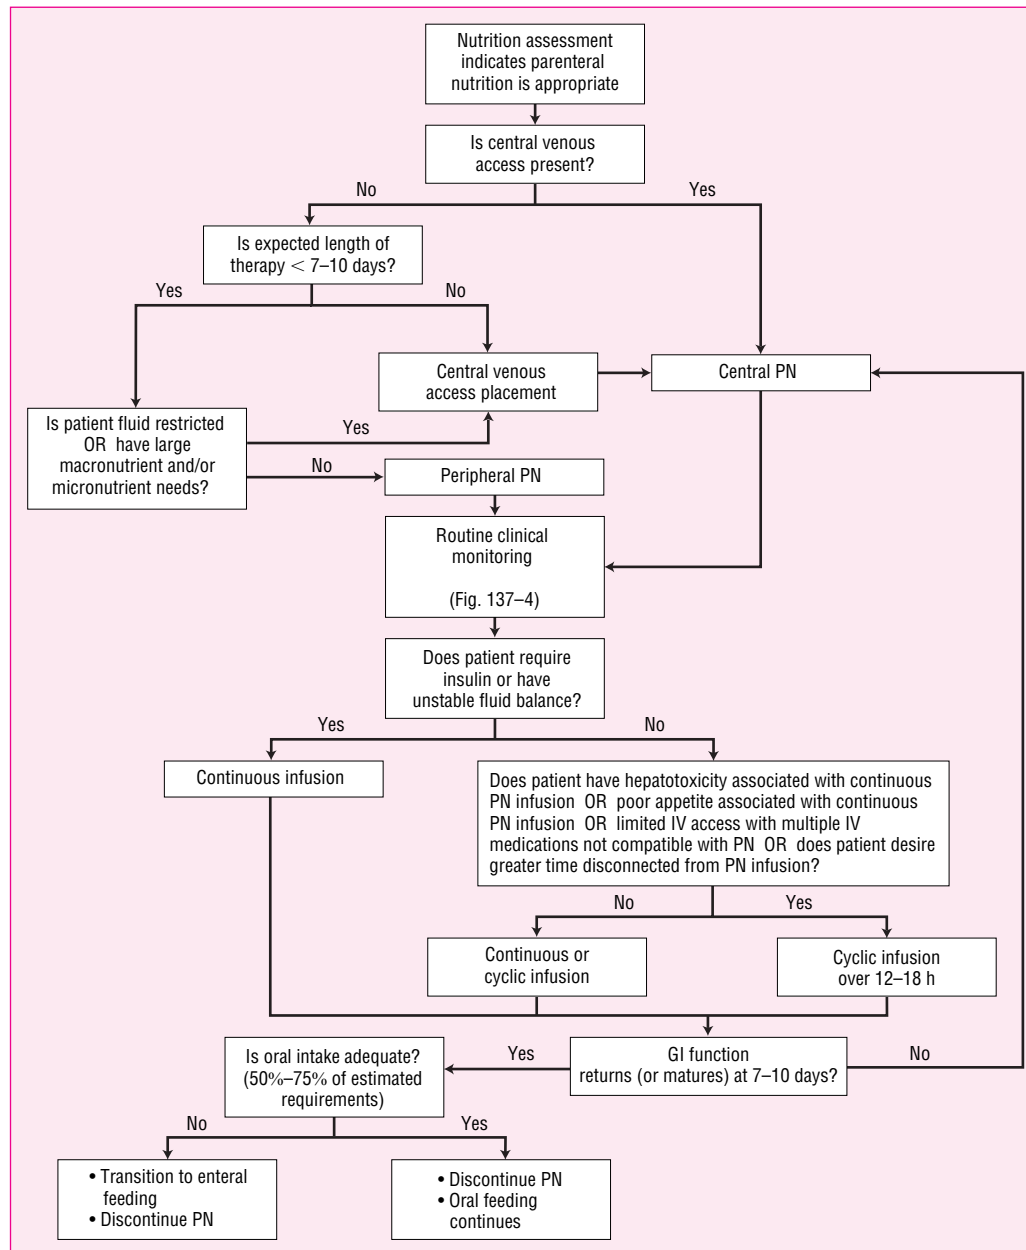

FIGURE 137-1. The route of PN and the infusion type depend on the patient's clinical status and the expected length of therapy.

patients in whom central access is unavailable or undesirable and function of the GI tract is expected to return within 7 to 10 days. The addition of IVLE increases caloric support to levels more consistent with PN regimens administered centrally. Advantages of PPN include a lower risk of infectious, metabolic, and technical complications that may occur with central vein catheterization. However, several other factors may complicate use of PPN in many patient populations. Patients who have received multiple courses of chemotherapy, malnourished patients, premature infants, elderly patients, and others with an illness of long duration who have already been subjected to multiple venous accesses for administration of fluids and medications are likely to have limited peripheral venous access. Use of PPN is also limited by relatively poor tolerance of peripheral veins to hypertonic solutions. Thrombophlebitis is a commonly reported complication in patients

receiving PPN. Although the risk of developing phlebitis is greater with solution osmolarities greater than 600 to 900 mOsm/L, peripherally administered total nutrient admixtures with much higher osmolarities have been associated with low infusion-site complications in some centers.^{64,65} Efforts to minimize development of phlebitis and/or infiltration sequelae in patients receiving PPN include addition of IVLEs to the regimen as a possible venous lumen protectant, subtherapeutic doses of heparin (0.5 to 1 unit/mL) to prevent thrombus formation, and/or small doses of hydrocortisone (5 mg/L) to minimize inflammation of the access site.⁶⁵ The osmolarity of a PN solution may be estimated by using the guidelines for osmolarities of selected PN components in Table 137-5. Because lower-osmolarity solutions are relatively dilute, much larger volumes of solution generally are required to meet nutritional requirements. Finally, patients with large

TABLE 137–5. Osmolarities of Selected Parenteral Nutrients

| Nutrient | Osmolarity |
|--|--------------|
| Amino acid | 100 mOsm/% |
| Dextrose | 50 mOsm/% |
| Lipid emulsion | 1.7 mOsm/% |
| Sodium (acetate, chloride, phosphate) | 2 mOsm/mEq |
| Potassium (acetate, chloride, phosphate) | 2 mOsm/mEq |
| Magnesium sulfate | 1 mOsm/mEq |
| Calcium gluconate | 1.4 mOsm/mEq |

nutrition requirements who receive PPN likely will require the use of IVLEs as a caloric source, so these patients also should be evaluated for lipid tolerance.

In summary, PPN is a relatively safe and simple method of nutritional support when patients are selected appropriately. Candidates for PPN include patients who do not have large nutritional requirements, are not fluid restricted, and are expected to regain function of the GI tract within 7 to 10 days.^{64,65}

CENTRAL ROUTE

Central parenteral nutrition (CPN) solutions are highly concentrated hypertonic solutions that must be administered through a large central vein. Unlike peripheral veins, central veins have a higher blood flow, which quickly dilutes the hypertonic solutions. There are multiple sites for obtaining central venous access in adult and pediatric patients. The choice of site depends on a number of factors, including the age and anatomy of the patient. Central venous catheters most commonly are inserted percutaneously into the subclavian vein and advanced so that the tip is at the superior vena cava. If this approach is not possible, the internal jugular vein may be used. Radiographic verification of correct placement is necessary prior to infusion of the CPN solution. Catheterization may be performed either in the operating suite or in the patient's hospital room. Strict adherence to established protocols and catheter placement by an experienced clinician lessen the risk of complications (Table 137–6).⁶⁶

TABLE 137–6. Complications of Central Venous Catheters

| Complication | Description |
|------------------------|---|
| Arterial injury | Puncture of subclavian or carotid artery during catheter insertion |
| Pneumothorax | Perforation of the pleura or lung during insertion, which results in air collection in the pleural space |
| Air embolism | Introduction of air into the catheter, which subsequently enters the venous circulation |
| Catheter embolism | A portion of the catheter fragments and enters the venous circulation |
| Venous thrombosis | Formation of thrombosis inside the lumen of the catheter and/or inside the vessel around the catheter, which may result in catheter or vessel occlusion |
| Chylothorax | Injury to the thoracic duct during catheter insertion |
| Brachial plexus injury | Injury to the nerve during catheter insertion, or injury secondary to catheter malposition or extravasation of a hypertonic solution |

Data from Grant.⁶⁶

Central venous catheters vary in composition, lumen size, number of injection ports, and other special features that affect ease or convenience of care and maintenance. They may be placed for short- or long-term access. Frequently, short-term central venous access is obtained in critically ill neonates via a catheter placed in the umbilical vein.²⁰ Other sites for central venous access in infants and older children are similar to those in adults.^{20,25,66} When therapy is expected to last longer than 4 weeks, the catheter usually is tunneled subcutaneously before entering the central vessel, secured initially with retaining sutures, and anchored in place with a felt cuff that promotes the growth of subcutaneous fibrotic tissue around the catheter. The injection port may remain external or be concealed entirely beneath the skin. Implanted central venous catheters have a larger port or reservoir that is surgically placed beneath the skin surface and anchored in the muscle of the chest wall.

CPN is used predominantly for patients who require PN for periods of greater than 7 to 10 days during hospitalization or indefinitely at home. These patients may have large nutrient requirements, poor peripheral venous access, and/or fluctuating fluid requirements such as metabolically stressed patients with extensive surgery, trauma, sepsis, multiple organ failure, or malignancy. Disadvantages of CPN include risks of catheter insertion, routine use of the catheter, and care of the access site. Relative to peripheral venous access, central venous catheter access is associated with a greater potential for infection. In addition, the risk of more serious catheter-induced trauma and related sequelae and other serious technical or mechanical problems is greater than with peripheral access.

ORDERING THE PARENTERAL NUTRITION REGIMEN

Once the route of delivery has been chosen, components of the PN regimen are decided based on the patient's nutritional assessment. Some health care systems may require the entire PN formula to be written in individual components and additives. More commonly, the ordering process has been simplified by the use of order forms designed specifically for PN. These standardized order forms promote education of practitioners by providing brief guidelines for initiating PN and foster cost-efficient nutrition support by minimizing errors in ordering, compounding, and administration.^{67,68} Standardized order forms also may include options for ordering certain related procedures, laboratory tests, protocols for patient management, or consultations with other medical services related to the patient's nutrition support. Standardized forms and protocols should be reviewed and updated periodically to reflect changes in the practices and patient population of a practice setting and also advances in technology that may affect provision of nutrition support.

ADULT PARENTERAL NUTRITION SOLUTIONS

In general, there are two formats for ordering adult PN. The standard formula approach offers a variety of base formulas (CAA-dextrose combination) with a fixed nonprotein-calorie:nitrogen ratio (NPC:N). This format usually includes different formulas designed for mild to moderately stressed patients, renal failure patients, fluid-restricted patients, and liver failure patients. Because the NPC:N is fixed, the amount of nutrient delivered depends solely on the infusion rate. Other institutions may compound individualized formulas. This approach permits compounding of patient-specific solutions. Compounding of the PN solution is limited only by the concentrations of stock solutions and stability concerns. The amount of nutrient delivered depends on the daily volume of the PN solution infused and the nutrient

concentrations in the PN solution. The total daily amount of PN solution may be prepared in multiple bags, or more cost-effectively in a single container.³⁵

Traditionally, adult PN solutions have been ordered by expressing the final concentrations of each component in the solution. For example, CAA and dextrose are ordered commonly in final percentage, electrolytes in milliequivalents per liter, and other additives in amount (milliliters or units) per day. This inconsistency may promote confusion and misinterpretation of PN solution contents that may result in harm, especially when patients are transferred between health system environments. To ensure that PN labels in all health system environments clearly and accurately reflect the PN solution contents, guidelines for standardized adult PN labeling have been recommended.³⁵ In addition to including a variety of other information on the label such as dosing weight and route of administration, the guidelines suggest expressing PN ingredients in amounts per total volume, which minimizes the need for pharmaceutical calculations to determine the nutrient value of the admixture. Computer software for calculating PN solutions is widely available, and several programs have adapted the recommended labeling guidelines. However, because some institutions may continue to follow traditional ordering practices, the steps for pharmaceutical calculations of a PN base solution will be reviewed briefly (Fig. 137–2).

There are several guidelines or clinical rules of thumb that may help the pharmacist calculate a PN regimen after a patient's nutritional requirements have been decided. For example, adult patients receiving only PN therapy may need larger volumes of fluid to provide maintenance requirements and replace extrarenal losses. However, patients requiring other intravenous drug therapy may receive adequate fluid in their intravenous maintenance solution (e.g., 0.45% NaCl in 5% dextrose) and/or piggybacked medications. Depending on individual institutional practices, maximally concentrating the PN solution and using an inexpensive maintenance fluid to manage hydration may provide a cost-effective regimen that requires fewer adjustments. Another guideline that may be helpful in designing a PN regimen in which the CAA-dextrose base is infused separately from the IVLEs is to allow a volume of approximately 100 to 150 mL/L of base solution for electrolytes and other additives. PN regimens for patients who require very small amounts of additives, such as patients with renal failure, may be further concentrated.

PEDIATRIC PARENTERAL NUTRITION SOLUTIONS

Pediatric PN solutions are typically ordered using an individualized approach because clinical practice guidelines often recommend nutrient intakes based on the patient's weight. For that reason, many institutions use a PN order form that expresses daily nutrient amount based on kilogram weight. For example, protein and fat are ordered as grams per kilogram per day, dextrose as milligrams per kilogram per minute, and electrolytes as milliequivalents per kilogram per day. However, some institutions may order macronutrients by expressing the final concentration of each component in the solution. Current safe practice guidelines suggest that the pediatric PN label identify components as an "amount per day" with a secondary expression of components as "amount per kilogram per day."³⁵ Auxiliary labels may be needed when the format between PN ordering and PN labeling is different. Clinician awareness of institution-specific labeling practices is imperative to minimize the risk of misinterpreting orders and potentially causing patient harm. Calculations for determining a pediatric PN solution are reviewed to clarify fundamental concepts for ordering pediatric PN solutions (Fig. 137–3). Additional features of the pediatric PN label should include the dosing weight, adminis-

tration date and time, expiration date, infusion rate, and duration of infusion. Because infants and children generally receive daily maintenance fluid from the PN regimen, supplemental intravenous solutions are rarely needed. Pediatric PN may be provided as a 2-in-1 or TNA formulation. However, the TNA system is not recommended for use when compounding neonatal PN due to instability of lipid particles with higher calcium and phosphorus content.³⁵ The labeling guidelines for IVLE in children are similar to those in adults.

ADMINISTRATION TECHNIQUES

PN solutions should be administered with an infusion pump to ensure consistent and controlled delivery of the solution. The intravenous administration line may include an in-line filter at a point prior to connection to the catheter. A 0.22-micron filter is recommended for use with CAA-dextrose solutions to remove particulate matter, air, and any microorganisms that may be present in the solution from prior manipulations of the admixture or the administration line. Because the average size of IVLE particles is approximately 0.5 micron, IVLEs administered separately from the CAA-dextrose solution must be piggybacked into the PN line at a site beyond the in-line filter.³⁵ Routine use of in-line filters (>0.22 micron) with TNA solutions is controversial.^{69,70} However, the FDA recommends use of a 1.2-micron filter, which may be effective in preventing catheter occlusion due to precipitates or lipid aggregates.³⁵ This filter size is also reported to remove *Candida albicans*.

INITIATING AND ADVANCING THE PARENTERAL NUTRITION INFUSION

ADULT PARENTERAL NUTRITION

The patient's nutrition status, current clinical status, history of glucose tolerance, and concentration of dextrose in the formula will dictate the infusion rate at which the adult PN solution should be initiated. Many institutions begin infusion of the goal PN slowly and increase the rate gradually over 12 to 24 hours to the desired rate. The infusion rate is likewise reduced in a stepwise fashion when the decision to end PN therapy is made. This approach should prevent development of hyperglycemia and rebound hypoglycemia, respectively. However, many patients should tolerate initiation of PN at the goal infusion rate. Stable patients with normal organ function and stable baseline serum glucose concentrations have demonstrated minimal effect on serum glucose concentrations when abruptly initiating or discontinuing PN therapy.^{71–73} Tapered initiation and cessation has been recommended for patients receiving intermittent subcutaneous regular insulin, patients with severe renal or hepatic disease, patients with other disease states that may increase the risk for development of hypoglycemia, such as severe diabetes or pancreatic malignancy, and patients who are receiving concurrent drug therapy that may predispose to development of hypoglycemia or mask the cardiovascular symptoms of hypoglycemia (β -blockers).⁷¹ Others have recommended routinely tapering the PN rate for all patients by decreasing the rate by 50% for 1 hour prior to discontinuation.⁷²

Although the IVLE dose should not exceed 2.5 g/kg per day or 60% of total daily calories, lower doses of 1 g/kg per day not to exceed 30% of calories have been recommended to minimize negative effects associated with long-chain fatty acids.³⁵ Manufacturer's information recommends IVLE infusion over 4 to 8 hours for adults. However, infusion over 16 to 24 hours appears to be the best clinical strategy

Patient Case: A 53-year-old patient's estimated nutritional requirements have been assessed at approximately 95–105 g protein/day and 1800–2100 total kcal/day. The patient has a central venous access and reports no history of hyperlipidemia or allergy to eggs. The patient is not fluid restricted. The PN solution will be compounded as an individualized regimen utilizing a single-bag, 24-h infusion of a crystalline amino acid (CAA)/dextrose combination with intravenous lipid emulsion (IVLE) piggy-backed into the PN infusion line. The stock solutions used to compound this regimen are 10% CAA and 70% dextrose

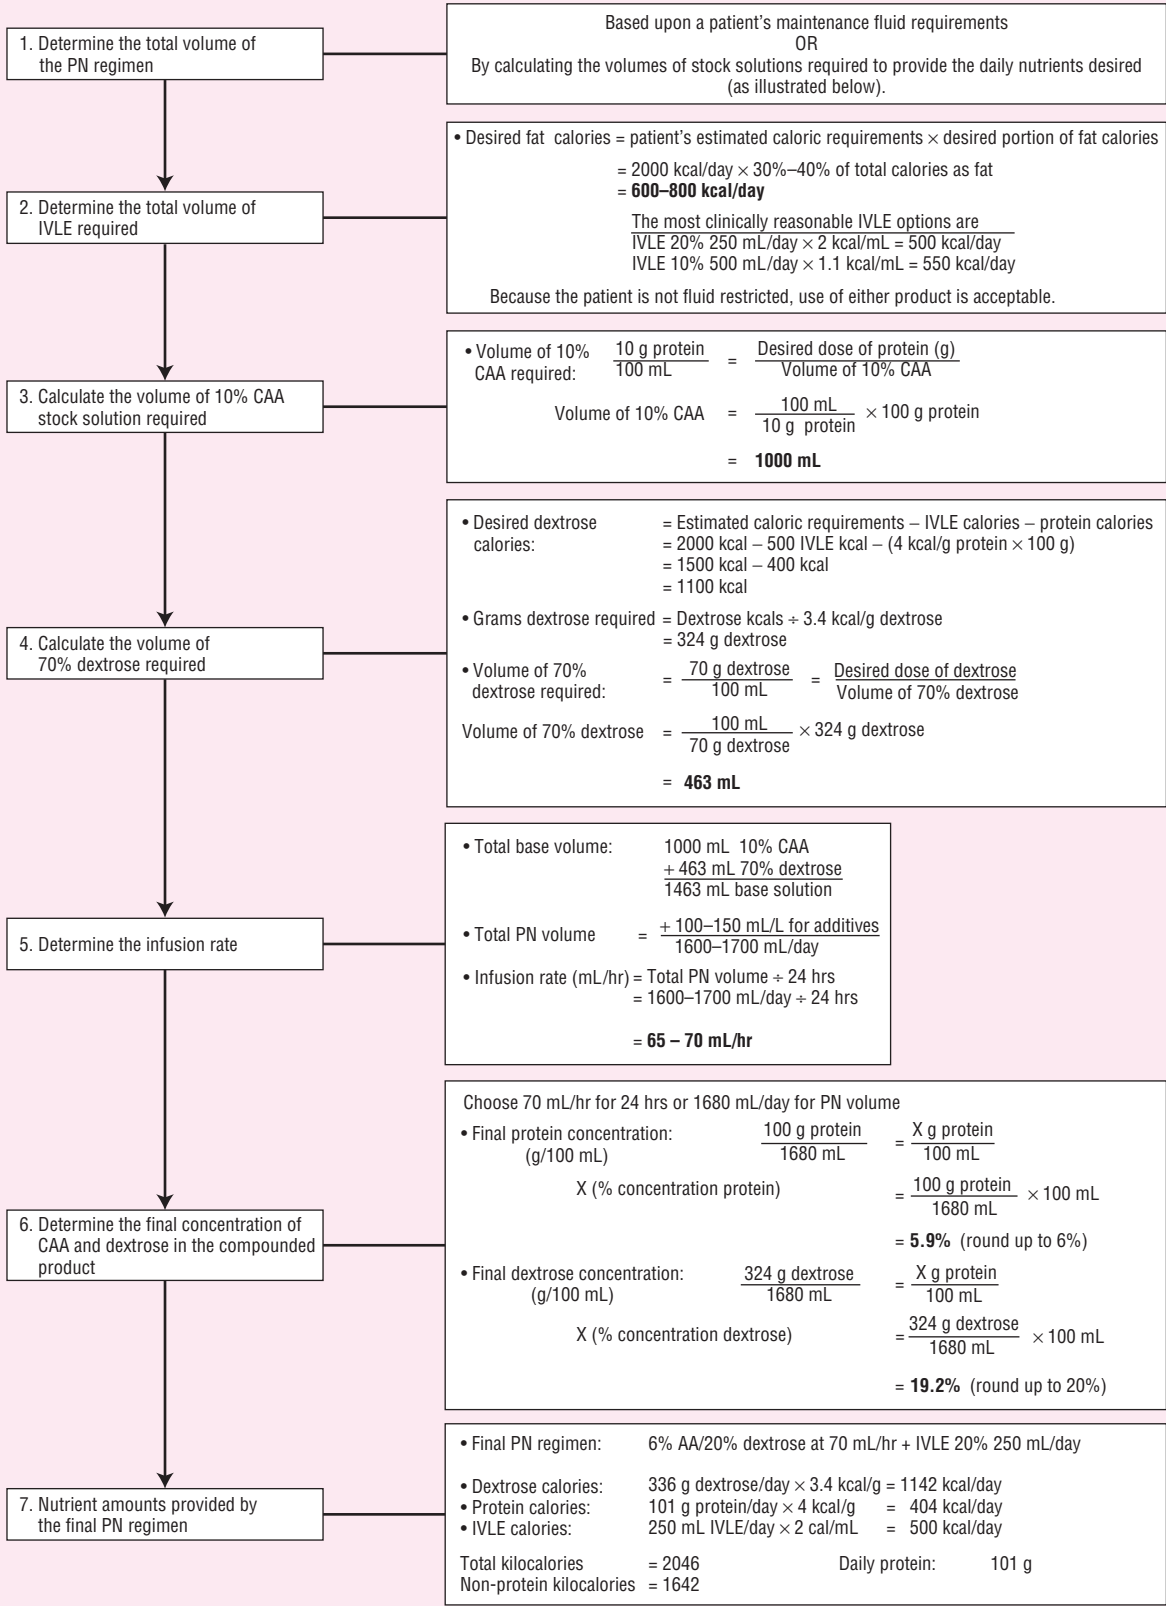

FIGURE 137–2. Calculation of a compounding plan for an adult PN regimen.

Patient Case: A 28-week gestational age infant's (weight 1.3 kg) estimated nutritional requirements have been assessed at 3.5 g/kg/day of protein, 3.5 g/kg/day of intravenous lipid emulsion (IVLE), and 120 non-protein kcal/kg/day. The infant has central venous access and has no history of hyperlipidemia or allergy to eggs. The PN solution will be compounded as an individualized regimen utilizing a single-bag, 24-h infusion of a crystalline amino acid (CAA)/dextrose combination with IVLE piggy-backed into the PN infusion line. The stock solutions used to compound this regimen are 10% CAA and 70% dextrose.

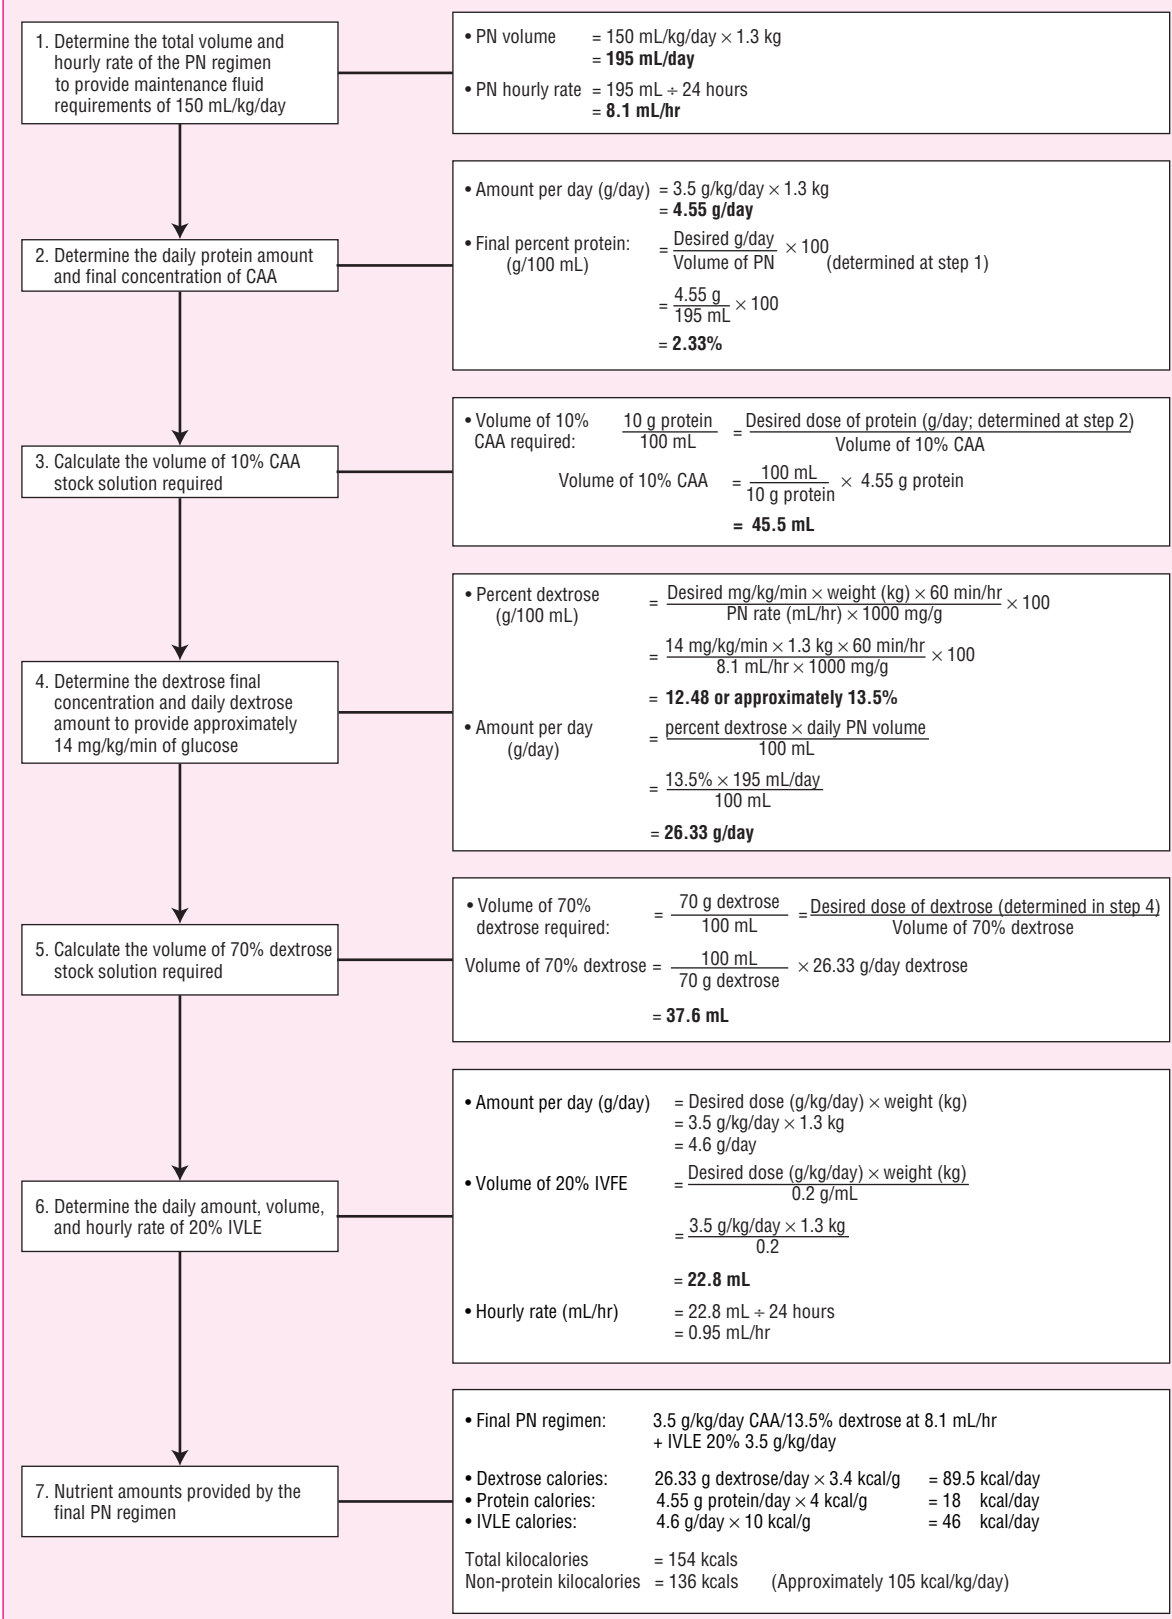

FIGURE 137-3. Calculation of a compounding plan for a pediatric PN regimen.

to promote IVLE clearance and minimize risk of negative effects on pulmonary and immune function.^{44,45}

The manufacturer's guidelines recommend initiating IVLE in adults with a test dose of 0.5 to 1 mL/min for the first 15 to 30 minutes because of the potential for an immediate hypersensitivity reaction. In most patients, this is probably not necessary because of the relatively low incidence and benign nature of acute adverse reactions. In addition, infusion over 20 to 24 hours eliminates the need for a test dose because the infusion rate is less than the test-dose rate recommended by the manufacturer. Appropriate electrolytes should be provided to patients with normal organ function based on standard nutrient ranges.³⁵ Adjustments may be necessary depending on the patient's clinical condition. Adults and children older than 11 years of age should receive daily amounts of trace elements and an adult vitamin formulation.

PEDIATRIC PARENTERAL NUTRITION

Pediatric PN solutions are typically initiated with a volume calculated to provide a patient's daily maintenance fluid requirements on the first day of therapy. Individual substrates are then advanced daily as tolerated with a goal PN regimen generally achieved by day 3 of therapy. As mentioned previously, PN should be initiated with the goal protein dose.^{19–21} The initial dextrose dose for older infants and children is based on previous glucose tolerance history. Although specific institution practices may vary, one approach is to start with (final concentration) 10% dextrose and advance the concentration in 5% increments daily as tolerated to a goal not to exceed 5 to 7 mg/kg per minute. Initial dextrose doses for premature infants should approximate fetal nutrient delivery rates of 5 to 6 mg/kg per minute. Frequently this mathematically translates into a final concentration range of 5% to 10% dextrose. The dextrose concentration for the neonatal PN should be advanced daily by 1% to 2.5% or by 2- to 4-mg/kg-per-minute increments to a goal that does not exceed 12 to 14 mg/kg per minute. Neonates tolerate a higher glucose infusion rate because of the relatively large proportion of metabolically active organs and low hepatic production of glucose. Initiation of IVLE is usually started at 0.5 g/kg per day in neonates and 0.5 to 1 g/kg per day in older children and increased daily by 0.5 to 1 g/kg per day to a maximum of 3 to 4 g/kg per day.^{19,20,38} The IVLE dose should not exceed 60% of total daily calories for neonates and 30% of total calories for children. More conservative doses are warranted for jaundiced neonates because fatty acids released during hydrolysis can displace bilirubin from albumin-binding sites and thereby increase the risk of kernicterus.^{16,38,39} The manufacturer's guidelines recommends initiating IVLE at 0.05 to 0.1 mL/min for 10 to 15 minutes in pediatric patients because of the potential for an immediate hypersensitivity reaction. In general, the best clinical strategy for minimizing the risk of adverse effects associated with rapid IVLE administration, minimizing the risk of negative effects on pulmonary and immune function, and promoting IVLE clearance is to infuse IVLE over 20 to 24 hours or 0.15 g/kg per hour.^{44,45} This slow infusion also eliminates the need for a test dose because the infusion rate is less than the test-dose rate recommended by the manufacturer.

Electrolytes should be added on the first day of therapy according to age-appropriate nutrient ranges.^{19,35} Adjustments may be necessary depending on the patient's clinical condition.

Intravenous vitamins and trace elements should be initiated on the first day of therapy and continued as a daily component of the PN solution. Children under age 11 should receive a vitamin product formulated for pediatric patients. Two multivitamin dosing schemas have been suggested for infants and children.³⁵ One method recommends 2 mL/kg per day for infants weighing less than 2.5 kg and 5 mL

per day for infants and children weighing more than 2.5 kg. The other suggests 30% of a vial (1.5 mL/day) for infants weighing less than 1 kg, 65% of a vial (3.25 mL/day) for infants weighing 1 to 3 kg, and 100% of the vial (5 mL/day) for children weighing more than 3 kg (up to 11 years of age). Adult intravenous vitamin formulations should not be used in infants because of potential neurotoxicity from accumulation of polysorbate and propylene glycol preservatives. Pediatric trace element formulations are dosed based on the child's weight. The usual recommended intake is 0.3 mL/kg for children weighing less than 3 kg and 0.2 mL/kg (maximum 5 mL/day) for children weighing more than 3 kg. Children weighing more than 25 kg should receive an adult trace element formulation. Pediatric patients receiving PN commonly transition from PN support to enteral nutrition by gradually decreasing the PN infusion rate while increasing the enteral intake. This transition may take days to weeks. However, abrupt discontinuation of PN therapy is not recommended for neonates and infants because of immature counterregulatory mechanisms and the risk for developing rebound hypoglycemia.¹⁹ Reducing the PN rate for 1 to 2 hours prior to stopping the infusion has been recommended.¹⁹ Blood glucose concentrations should be checked within 15 to 60 minutes after the PN infusion ends.

CONTINUOUS VERSUS INTERMITTENT INFUSIONS

5 PN solutions may be infused continuously or intermittently (see Fig. 137–1). Continuous infusions are attractive for use in patients with unstable fluid balance or glucose control. Cyclic PN is the infusion of PN over a period of time less than 24 hours, usually for 12 to 18 hours each day.⁷² Cyclic PN is useful in hospitalized patients with limited venous access in whom administration of multiple other medications requires interruption of the PN infusion. Cyclic PN also may prevent or treat hepatotoxicities associated with continuous PN therapy. In addition, cyclic PN allows patients receiving PN at home the ability to resume a relatively normal lifestyle.⁷² Recommendations for administration of cyclic PN are similar to those for continuous PN. Various protocols have been reported that suggest incremental increases to the maximum infusion rate for a desired period of time followed by a gradual taper to discontinue the solution.^{19,71,72} However, metabolically stable adults and older children (more than age 2 years) receiving lipid-based PN regimens are likely candidates for abrupt initiation and discontinuation of the cyclic PN regimen.^{19,71,73} Cyclic PN may not be well tolerated by patients with severe glucose intolerance or diabetes, or by those patients with unstable fluid balance.

EVALUATION OF OUTCOMES

Thorough and consistent monitoring of patients receiving PN is necessary to ensure that the desired nutritional outcomes are achieved and to prevent the occurrence of adverse effects or complications. Routine evaluation should include the assessment of the patient's clinical condition with a focus on nutritional and metabolic effects of the PN regimen. Serial documentation of a patient's response to a particular regimen is a helpful guide for determining appropriate adjustments in fluid, electrolyte, and nutrient therapies.

6 A number of biochemical and clinical measurements are necessary for effective monitoring of patients receiving PN. Important clinical laboratory measurements include serum concentrations of electrolytes, hematologic indices, and biochemical markers for renal function, liver function, and nutrition status. Other important clinical measurements include vital signs, weight, total fluid intake and losses, and nutritional intakes. Weekly height/length and head

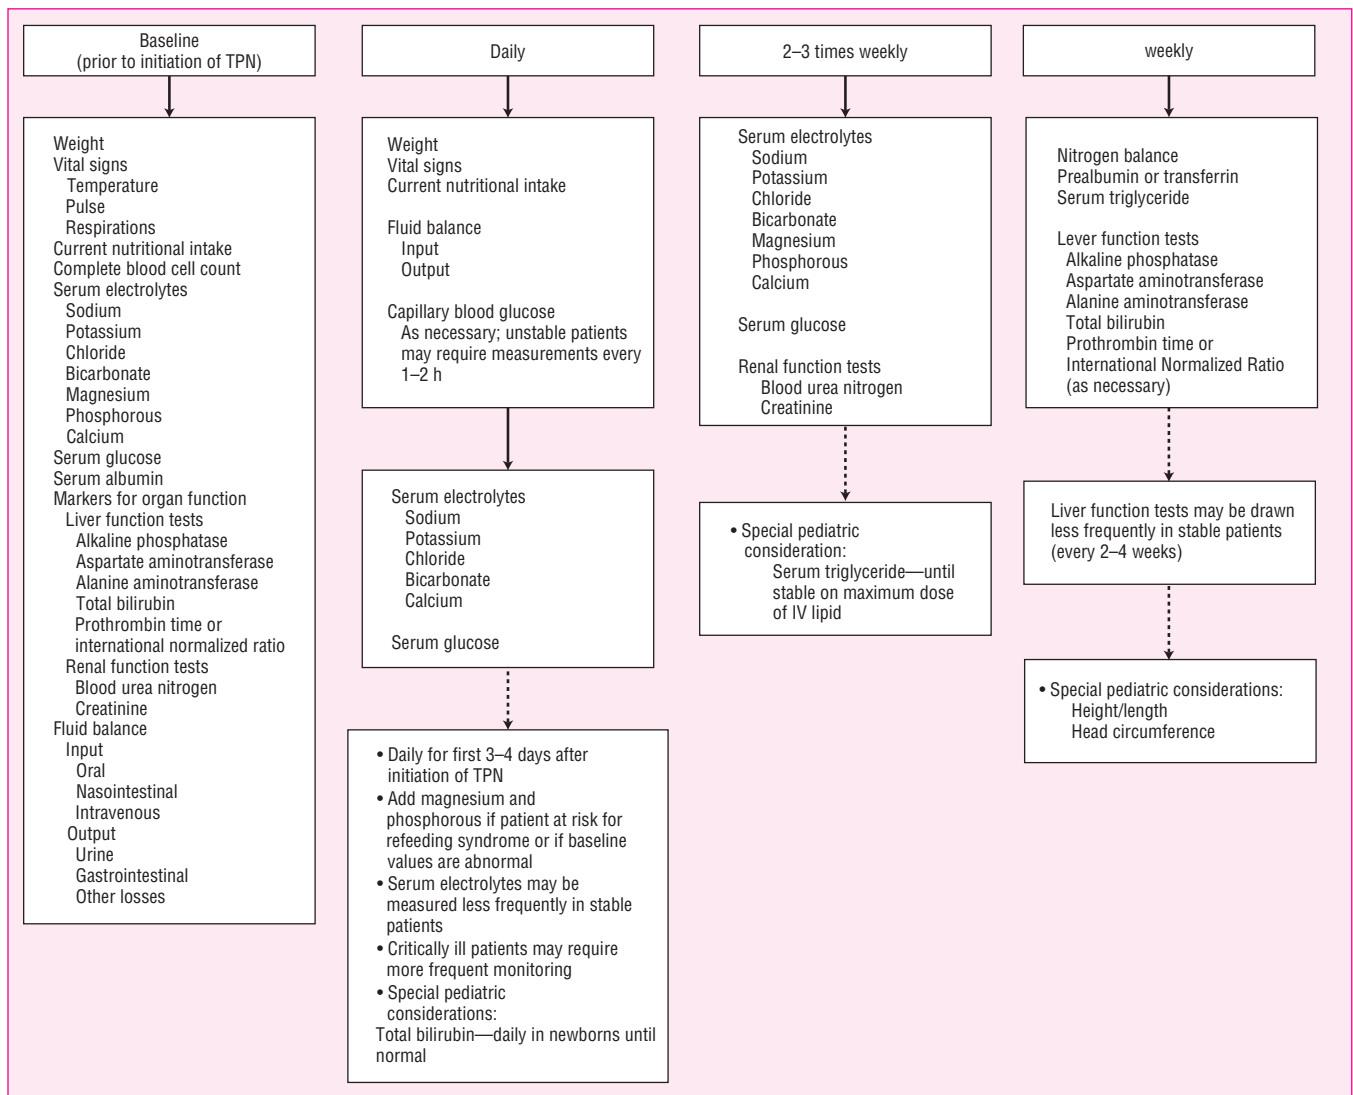

FIGURE 137-4. Monitoring strategy for patients receiving parenteral nutrition.

circumference measurements are helpful for monitoring nutritional changes in neonates. The frequency of clinical laboratory measurements usually depends on the stability of a patient's clinical condition and age. For example, frequency of blood laboratory measurements in neonates and infants tends to be more conservative due to their smaller circulating blood volumes, and in some cases, lack of central vascular access. Monitoring parameters considered important for patients receiving PN and the suggested frequency of measurement for each are outlined in Fig. 137-4. Appropriate assessment and evaluation of patient data can identify impending complications that may be avoided or treated early. Monitoring protocols should be developed and tailored for the patient population, medical practices, and resources of individual practice settings.

COMPOUNDING, STORAGE, AND INFECTION CONTROL

Several considerations are necessary when preparing and storing PN solutions. In general, the type of solution being prepared will dictate methods of compounding, storage, and infusion. Currently, the two most commonly used types of PN solutions are the CAA-dextrose

combination with or without IVLEs piggybacked into the PN line, and TNAs. Use of TNA solutions offers several potential advantages, including reduced inventory (infusion pumps, tubing, and other related supplies), decreased time for compounding and administration, a potential decrease in manipulations of the infusion line (which should correspond with a decreased risk of catheter contamination), and ease of delivery and storage for patients receiving home PN.⁷⁴ Potential disadvantages include increased risk of infections, and stability and compatibility concerns. For example, the stability of TNA solutions may be less predictable compared with that of CAA-dextrose solutions, which make their use less desirable in specific patient populations such as neonates and infants.³⁵ In addition, the opaque solution that results after the addition of IVLEs makes detection of particulate matter difficult, and TNA solutions cannot be filtered with a bacteria-retentive 0.22-micron filter.³⁵ Methods for compounding PN solutions vary based on a health care system's patient population and medical practices and the number of PN solutions that need to be prepared. PN base solutions may be prepared by using gravity-driven transfer of CAA stock solutions to partially filled bags of concentrated dextrose stock solutions.^{35,75} Other practice settings may use commercially prepared CAA-dextrose products that are separated within a single bag and then mixed prior to use.³⁵ Advances in compounding technology

have facilitated use of automated compounders for preparing PN solutions. Automated compounders are computer-based systems that perform the calculations necessary to determine volumes of nutrient stock solutions for PN solutions. In addition, most automated compounding systems include software that communicates the determined calculations directly to a transfer pump device that delivers fluid from the source container to the final container by either a volumetric or gravimetric fluid pumping system.⁷⁵ Advantages associated with automated compounders include reduction in personnel time and compounding materials and improved accuracy of compounding. Disadvantages include the potential for equipment failure and power outages.

Assurance of solution sterility during compounding, storage, and administration is necessary to reduce the risk of infection and related complications.^{76,77} Several studies have demonstrated that because of their acidic pH and hypertonicity, CAA-dextrose PN solutions are poor media for bacterial growth.⁷⁷ However, *Pseudomonas aeruginosa*, *Escherichia coli*, and fungi such as *Candida albicans* have been noted to grow in CAA-dextrose solutions.⁷⁷ In general, TNA solutions appear to support growth of bacteria less than IVLEs, but more than CAA-dextrose solutions. However, investigations of TNAs hung for up to 24 hours have demonstrated that the risk of contamination was no greater than that reported with CAA-dextrose solutions.^{43,69}

Because IVLEs also support growth of gram-positive and gram-negative bacteria as well as fungi, the Centers for Disease Control and Prevention recommend that IVLE infusions not exceed 12 hours, unless volume considerations require more time, in which case IVLE infusions should be completed within 24 hours.⁶⁹ Administration sets for IVLE and TNA solutions should be changed every 24 hours. Other clinical investigations of IVLE solutions infused for up to 24 hours in patients receiving PN demonstrated no correlation between risk of infection and length of hang time, so many institutions allow expiration times of up to 24 hours.^{78,79}

Frequently IVLE doses for neonates are considerably smaller volumes than are commercially available. For some patients the volumes may be as low as 2 mL/day. To facilitate safe and accurate infusion of these small volumes, some institutions aseptically repackage IVLE into plastic syringes for syringe pump infusion. The effect of this repackaging process on the risk of infection has not been studied in large well-designed trials. In addition, conflicting guidelines for use of other IVLE-containing medications such as propofol further confound application of Centers for Disease Control guidelines because these recommendations do not address the use of repackaged IVLE preparations.^{69,80}

CLINICAL CONTROVERSY

The best delivery method for IVLE (manufacturer's bottle vs. repackaged syringe) and suggested interval of tubing change continue to be debated.

However, recent standards from the United States Pharmacopeia (USP) indicate administration of extemporaneously compounded lipid-based emulsions should be completed within 12 hours.⁷⁶

The USP Chapter 797 details the procedures and requirements for compounding all sterile preparations including PN formulations.⁷⁶ These standards will apply to all health care settings in which sterile preparations are compounded and will be used by boards of pharmacy, the FDA, and accreditation organizations such as the Joint Commission on Accreditation of Healthcare Organizations. Compounded sterile preparations (CSP) are defined by risk level (high, medium, low) based on the probability of microbial, chemical, or physical contami-

nation. PN solutions are classified as a medium-risk CSP. In general, PN solutions should be prepared using aseptic technique under a properly maintained laminar flow hood.^{69,76} The hood should be situated such that the contaminant potential of normal work traffic and air currents is minimized. Personnel must be trained adequately and must practice strict aseptic technique. Supervision by a pharmacist experienced in compounding intravenous solutions and knowledgeable about stability, compatibility, and storage of PN solutions is also necessary. Quality assurance procedures should be developed to maintain safe and accurate admixture preparation. The potential risk of sepsis associated with PN solution contamination can be decreased greatly when pharmacy-based admixture programs follow specific guidelines developed to ensure proper compounding of PN solutions.⁷⁶

STABILITY AND COMPATIBILITY

Comprehensive sources of current information about compatibility and stability of PN solutions are *Trissel's Handbook on Injectable Drugs*, which is published every 2 years with supplements during alternating years, and the *King Guide to Parenteral Admixtures*, which is updated quarterly.^{81,82} In many cases, the exact answer to a compatibility question may not be readily available, and a review of the primary literature may be necessary. When information is not available, clinical judgment and experience must be used carefully to resolve the situation.

CAA-dextrose solutions generally are stable for 1 to 2 months if refrigerated at 4°C and protected from light.⁸³ However, TNA formulations are complex mixtures that are inherently unstable. Several factors affect stability of TNA solutions, including pH, electrolyte charges, temperature, and time after compounding.⁸³

Because of differences in pH among various CAA products and differences in phospholipid content among IVLE products, specific manufacturers should be consulted for compatibility and stability information prior to routine mixing of components. One approach to compounding TNA formulations manually is to add electrolytes (except phosphorus) and trace elements to the dextrose solution, and add phosphate salts to the CAA solution. Finally, the amino acid solution should be added to the IVLEs prior to or simultaneously with the dextrose solution. However, mixing components in this specific order and time sequence may not be possible with the use of automated compounders. The compounder's manufacturer should be consulted for the optimal mixing sequence to ensure safe compounding of TNA solutions.

The precipitation of calcium and phosphorus is a common interaction that is potentially life-threatening.^{35,83} Factors that enhance the risk of precipitate formation include high concentrations of calcium and phosphorus salts, use of the chloride salt of calcium, decreased amino acid and dextrose concentrations, increased solution temperature, increased solution pH, use of an improper sequence when mixing calcium and phosphorus salts, and the presence of other additives including IVLEs.^{35,82,83} Electrolyte stability in TNA solutions is difficult to assess because of poor visualization of a precipitate should one occur. PN solutions for neonates and infants tend to have a higher content of calcium and phosphorus as well as other divalent cations that limit the use of TNA formulations. Because of the relatively limited amount of published stability information, the use of a 2-in-1 formulation with separate administration of IVLEs is recommended for neonates and infants.³⁵ In general, alternative methods of delivering electrolytes or other medications should be pursued in any clinical situation in which compatibility information involving a TNA solution is lacking. Because the addition of bicarbonate to acidic PN solutions may result in the formation of carbon dioxide gas

and insoluble calcium and magnesium carbonates, the use of sodium bicarbonate in PN solutions is not recommended.³⁵ Use of a bicarbonate precursor salt such as acetate usually is preferred.

Vitamins may be affected adversely by changes in solution pH, presence of other additives, storage time, solution temperature, and exposure to light.⁸³ Because of variable stabilities of individual vitamins, intravenous vitamin solutions should be added to the PN solution as near to the time of administration as is clinically feasible, and should not be in the PN solution longer than 24 hours.

Increased peroxide concentrations have been reported in dextrose-amino acid solutions after addition of intravenous multivitamins and/or exposure to air or light.^{84,85} Increased peroxide production also has been reported in IVLEs after exposure to light.⁸⁶ Peroxide formation in dextrose-amino acid solutions depends on the concentration of intravenous multivitamins, amino acids, and dextrose, and the presence of IVLEs.⁸⁴ Peroxide production in IVLEs also depends on the intensity of light and is enhanced with phototherapy light in neonates.⁸⁶ Multiple *in vitro* experiments have reported negative effects of peroxides and associated metabolites on organ and immune function.^{39,84–87} However, the clinical effects of PN containing peroxides are not clear.³⁹ Neonatal and infant PN regimens usually deliver a higher daily peroxide load when compared with those for adults.⁸⁴ To minimize the risk of negative metabolic effects from peroxide infusion, the use of light-protective PN bags and infusion tubing for neonatal and infant IVLE and PN solutions has been recommended.^{84,85}

Many patients receiving PN at home or in a hospital also receive other intravenous medications. The compatibility of these medications and other intravenous solutions is an important concern in delivering safe and effective drug and nutritional therapy. Intravenous medications are infused most often as a separate admixture piggybacked in the PN line. However, some medications may be added directly to the PN solution and administered at the same rate as the PN infusion. Because of the potential for ineffective drug therapy or other complications associated with physiochemical incompatibility and stability of the PN solution, specific criteria should be considered before one adds a medication directly to the PN solution.⁸⁸ The dosage regimen should be stable for each 24-hour period and should have pharmacokinetic properties appropriate for continuous infusion. There should be documented chemical and physical compatibility of the medication with PN mixture components and other medications that may be piggybacked concomitantly into the PN line. Finally, the PN regimen should be infused continuously over 24 hours. Advantages of using PN admixtures as drug vehicles include consolidation of dosage units, improved pharmacotherapy for certain drugs, conservation of fluid in volume-restricted patients, fewer venous catheter violations, and decreased compounding and administration times.⁸⁸ However, a major disadvantage to the use of PN solutions as drug-delivery vehicles is the lack of compatibility and stability data in the PN solutions that are used commonly in clinical practice. Medications frequently added to PN solutions include albumin, regular insulin, and histamine₂-antagonists.^{81,82,88}

COMPLICATIONS OF PARENTERAL NUTRITION

PN can be a safe and effective therapy when appropriate patients have been selected and the course of therapy is monitored and adjusted correctly. However, PN support is a complex therapy that is associated with numerous complications. These complications may be divided into four categories: mechanical or technical, infectious, metabolic, and nutritional.

MECHANICAL OR TECHNICAL COMPLICATIONS

Mechanical or technical complications include malfunctions in the system used for intravenous delivery of the solution. Examples of such malfunctions include infusion pump failure, problems with administration sets or tubing, and problems with the catheter. Catheter-related complications are potentially life-threatening.

Pneumothorax, catheter misdirection or migration into the wrong vein or improperly-positioned within the cardiac chambers, arterial puncture, bleeding, and hematoma formation may occur during surgical placement of the catheter. Many of these complications, in addition to venous thrombosis and air embolism, may occur after insertion as well. Catheters occasionally occlude or break during use. If these problems cannot be rectified easily, the catheter may need to be surgically replaced.⁶⁶

INFECTIOUS COMPLICATIONS

Infectious complications can be a major hazard in patients receiving CPN. Often these patients are predisposed to infection as a result of compromised immunity and/or concomitant infection. Frequent use of broad-spectrum antibiotic therapy and malnutrition are also predisposing factors for development of infection. Infection rarely develops secondary to solution contamination.^{69,77} However, strict adherence to specific protocols for preparation of PN solutions should minimize this occurrence.^{76,77} A more common source of systemic infection is catheter-related infection. Catheter-related bloodstream infection is defined as the presence of bacterial or fungal growth from the catheter tip and peripheral blood cultures. Catheter infection or a colonized catheter is defined as microbial growth from the catheter tip or from a blood culture drawn from the catheter with no growth of the same organism in the peripheral blood culture.⁶⁹ Patients with catheter-related infections may exhibit signs of sepsis syndrome such as fever, chills, mental status changes, hypotension, or glucose intolerance. These infections occur when the catheter becomes colonized by direct microbial invasion of the skin at the insertion site or at the infusion site of the catheter. For example, colonization may occur after multiple manipulations of the line used for PN administration, which can occur when the PN line is used to administer other medications. Other examples include failure of in-line bacterial filters, poor placement technique, and poor care of the insertion site.⁶⁹

When no other source of infection is apparent in symptomatic patients, the catheter should be evaluated as the potential source. Blood cultures are drawn from a peripheral site and from the central catheter. In many institutions the suspected catheter is removed, the tip is cultured quantitatively, and a new central catheter is inserted. If bacterial or fungal growth of the same organism occurs from the catheter tip and the peripheral blood culture, the exchanged catheter is removed, and another is placed in a different anatomic site. If bacterial or fungal growth occurs from the catheter tip or from a blood culture drawn from the catheter with no growth of the same organism in the peripheral culture, the catheter may be removed and replaced with another in the same anatomic location. However, because the clinical value of frequent central catheter replacement in patients with sepsis secondary to catheter-related infection is controversial, other treatment protocols have been suggested.⁸⁹

METABOLIC AND NUTRITIONAL COMPLICATIONS

Metabolic complications associated with PN therapy are numerous, and if left untreated, may be potentially fatal. Common metabolic abnormalities related to substrate intolerance and fluid,

TABLE 137–7. Substrate Intolerance in Parenteral Nutrition

| Complication | Possible Causes | Intervention |
|---|---|---|
| Hyperglycemia | Stress, infection, corticosteroids, pancreatitis, diabetes mellitus, peritoneal dialysis, excessive dextrose administration | Decrease dextrose load by decreasing infusion rate or dextrose concentration (may substitute fat calories); administer insulin |
| Hypoglycemia | Abrupt withdrawal of dextrose, insulin overdose | Increase dextrose intake; decrease exogenous insulin; taper infusion rate prior to discontinuing PN |
| Excess of carbon dioxide production | Excess dextrose intake | Decrease dextrose intake; balance calories from fat and dextrose |
| Hypertriglyceridemia | Stress, familial hyperlipidemia, pancreatitis; excess IVLE dose; rapid IVLE infusion rate | Decrease IVLE dose; decrease rate of IVLE infusion; discontinue IVLE if indicated |
| Abnormal liver function tests (elevated AST, alkaline phosphatase, and bilirubin) | Stress, infection, cancer, excess carbohydrate intake, excess caloric intake, essential fatty acid deficiency | Decrease dextrose load (substitute fat); decrease total calories; provide essential fatty acids; cycle PN infusion; transition to enteral nutrition regimen |

AST, aspartate aminotransferase (SGOT); IVLE, intravenous lipid emulsion.

electrolyte, and acid-base disorders are presented in Table 137–4 and Table 137–7 along with predisposing factors and general strategies for intervention. The etiology, mechanisms, and implications of individual metabolic abnormalities are multifactorial and have been summarized in multiple reviews.^{20,25,35,39,45,47,52,72,90–92}

PN-associated hepatic dysfunction, as evidenced by elevations in serum liver function measurements such as total bilirubin, aspartate aminotransferase, alanine aminotransferase, and alkaline phosphatase is well documented.^{92–94} No single etiology has been identified, although several risk factors have been reported. Risk factors for children include degree of prematurity, sepsis, hypoxia, lack of enteral nutrition, small bowel bacterial overgrowth, GI conditions requiring surgical intervention, duration of PN therapy, and long-term administration of excessive calories.^{25,39,93–95} PN-associated hepatic dysfunction in infants is characterized clinically by a serum direct bilirubin concentration greater than 2 mg/dL.⁹⁵ Taurine deficiency has been proposed as an etiology of cholestasis in preterm infants and neonates.^{25,95} Taurine is a CCAA not present in standard CAA solutions that is important in neonatal and infant bile metabolism. However, the effectiveness of PN regimens with CAA solutions containing supplemental taurine is unclear.^{25,94,95} Risk factors for PN-associated hepatic dysfunction in adults include preexisting liver diseases, sepsis, preexisting malnutrition, large extent of bowel resection, duration of PN therapy, lack of enteral intake, and long-term administration of excessive calories.^{92–94} PN-associated hepatic dysfunction in adults typically presents as steatosis and steatohepatitis on biopsy.^{93,94} Clinically, PN-associated hepatic dysfunction is characterized by mild elevations in serum liver enzymes, usually less than three times the upper limit of normal, with peak enzyme levels usually occurring between 1 and 4 weeks after initiating PN.^{93,94} In many cases, the liver abnormalities improve or resolve with manipulation of substrate intake or discontinuation of PN therapy. However, death from PN-associated liver failure in adults and pediatric patients receiving long-term home PN has been reported.⁹²

Hypertriglyceridemia, defined as serum triglyceride concentrations of 400 to 500 mg/dL in adults and 150 to 200 mg/dL in preterm infants, neonates, and older pediatric patients, may occur in patients receiving IVLE-based PN. Risk factors include preexisting liver or pancreatic dysfunction, sepsis, multiple organ failure, degree of prematurity, rate of IVLE infusion, and dose.^{37,44,45}

IVLE-associated hypertriglyceridemia generally is thought to be due to defective lipid clearance.⁴⁴ Premature infants and neonates have relatively slower lipid clearance compared with adults because of immature metabolic pathways, including decreased lipoprotein lipase activity.^{37,44,45} Reducing the infusion rate or IVLE dose or withholding IVLE therapy should be considered when patients present with hypertriglyceridemia or lipemic serum.^{44,45} Use of low-dose heparin to stimulate lipoprotein lipase activity has been suggested as a potential therapeutic intervention to treat IVLE-associated hypertriglyceridemia.^{44,45} The role of carnitine for treatment of IVLE-associated hypertriglyceridemia is not clear.^{44,45}

The refeeding syndrome (RS) is a nutritional complication reported in severely malnourished patients with significant weight loss who receive PN.^{39,96} RS is associated primarily with hypophosphatemia, although hypokalemia, hypomagnesemia, and life-threatening cardiac dysfunction have been reported as well. The mechanism of the electrolyte abnormalities appears to be related to acute provision of macronutrient substrates that promote anabolism in an environment of depleted total body stores of phosphorus, potassium, and magnesium. Cardiac dysfunction is thought to occur because of an acute volume expansion that increases cardiac demand. Recommendations for initiating PN in adults at risk for RS include providing less than 50% of the calculated nonprotein caloric requirements initially. The dextrose dose should be initiated at approximately 150 to 200 g/day. Calories should be advanced over 3 to 4 days to the desired goal. Because the metabolic abnormalities described with RS appear to be related primarily to acute provision of large amounts of dextrose, the goal protein dose may be provided with the initial PN infusion.⁹⁶ Pediatric PN regimens are usually advanced over several days as a general practice for all patients. However, additional recommendations for minimizing the risk of refeeding syndrome in pediatric patients includes provision of additional phosphorus and potassium above standard nutrient requirements at the time PN is initiated.³⁹

Other nutritional complications of PN therapy may develop over a prolonged course of therapy (weeks to months) as a result of inappropriate intake of a particular nutrient. Certain conditions, such as metabolic stress in a previously malnourished patient, may elicit symptoms of deficiency much earlier if a nutrient is not appropriately provided. For example, lactic acidosis and other life-threatening complications associated with severe thiamine deficiency have been

reported in patients who received PN solutions without multivitamin supplementation.⁹⁷ At least maintenance doses of vitamins, trace elements, and essential fatty acids should be provided to all patients with normal age-related organ function receiving PN.

Patients receiving PN regimens without IVLEs for extended periods (weeks to months) are at risk for development of EFAD. Clinical signs of EFAD include hair loss, desquamative dermatitis, thrombocytopenia, and malabsorption and diarrhea resulting from changes in intestinal mucosa.^{46,47} EFAD also may be diagnosed by evaluating plasma fatty acid profiles. A triene:tetraene ratio more than 0.4 is biochemical evidence for EFAD. These manifestations may occur 1 to 3 weeks after initiation of fat-free PN in adults and within 72 hours in premature infants.³⁷

Metabolic bone disease is a complication usually reported in adults and children receiving long-term home PN.^{92,98} This disorder in adults is characterized by osteomalacia with or without osteoporosis that may present without associated clinical, radiologic, or biochemical abnormalities. The diagnosis may not be made in premature infants until after the development of bone fractures or overt rickets. The etiology is poorly understood and likely multifactorial. Treatment options include pharmacologic intervention, calcium and vitamin D supplementation, and exercise. Others have recommended removal of vitamin D from the PN in patients with low serum parathyroid hormone and 1,25-hydroxyvitamin D concentrations.⁹²

Clinical symptoms of trace element deficiencies, although rare, have been reported in patients receiving PN. More commonly, decreased serum trace element concentrations have been reported in a variety of patient populations. However, the clinical significance of decreased concentrations of many trace elements is not known because serum concentrations often do not correlate with total body stores.^{61,62} Clinical signs and symptoms of trace element deficiencies have been reviewed elsewhere.⁶¹

Occasionally, patients may develop nutrient-induced toxicities, most commonly as a result of the accumulation of fat-soluble vitamins or trace elements due to either excessive intake or decreased excretion. Certain disease states (e.g., severe renal or hepatic failure) may necessitate reduction in vitamin and trace element intake.

Many trace elements are present in PN components as contaminants.^{53,99,100} The content varies among components and manufacturers. Some investigations of patients with normal organ function receiving PN have reported concern with elevated serum concentrations of particular trace elements such as chromium and manganese.^{61,99,100} Aluminum is a common contaminant of many sterile intravenous solutions including those used for compounding PN. Calcium and phosphorus solutions are among those components with higher levels of aluminum contamination.^{101,102} Aluminum accumulation may occur during long-term PN therapy, especially in patients with renal insufficiency, and is associated with abnormal neurologic and hematologic function and metabolic bone disease in adults and premature infants.^{98,101–104} Preterm infants are at higher risk of aluminum toxicities because they receive larger doses (micrograms per kilogram) from PN solutions than adults.^{98,101–104} Preterm infants are also more likely to retain aluminum because of immature renal function. Although the maximum safe level of intravenous aluminum intake is not known, the FDA has defined parenteral doses of 4 to 5 mcg/kg per day as amounts associated with central nervous system and bone toxicity in patients with impaired renal function, including premature neonates.^{102,103} Even lesser amounts may result in tissue accumulation but no documented toxicity.

Recent data suggest that the aluminum content of sterile solutions used for compounding PN has declined due to awareness of toxicity

and improvements in industrial PN component preparation.¹⁰⁴ However, in 2004 the FDA implemented a restriction of aluminum content in large-volume PN stock solutions to a maximum of 25 mcg/L and require a statement of aluminum content on the label of small-volume PN solutions beginning in 2004.¹⁰³

HOME PARENTERAL NUTRITION

Advances in technology for the delivery of intravenous solutions have allowed medically stable patients who require extended PN therapy to be maintained indefinitely on intravenous nutrition. An increasing concern for cost containment of health care services has fostered use of sophisticated infusion devices to provide PN at home. Numerous programs are now available outside the traditional health care setting to support patients with various long-term or permanent medical conditions. Standards have been developed to promote safe and effective care.⁷ Home PN services may be coordinated and administered through a hospital, by a commercially operated corporation, or through a joint venture between the two.

Many factors are considered in selecting candidates for home PN therapy. Significant benefit must be expected from placing a patient into the program. Additionally, the patient and his or her caregiver must be willing to complete training successfully and assume numerous other responsibilities that are important for managing a new daily routine in the home. Other logistics such as funding, procurement of solutions and supplies, and clinical management and follow-up must be evaluated, resolved, and implemented for each patient in order to achieve the desired outcomes.^{92,105}

Patients with Crohn's disease, ischemic bowel disease, severe GI motility disorders, extensive intestinal obstruction, and congenital bowel dysfunction have been maintained successfully with home PN.¹⁰⁵

In the past, patients or their caregivers may have been trained to mix PN solutions in the home. Today patients commonly receive premixed PN solutions from the hospital or a commercial vendor. Intravenous vitamins or other additives may be added daily by the patient or caregiver, depending on the arrangement with the PN provider. The solution generally is administered through the night by infusion pump over 10 to 12 hours.⁷² A cycled regimen allows the patient time away from the pump during daylight hours and provides many patients with the freedom to have a reasonably normal daily routine. Clinical management and follow-up are performed periodically according to the needs of the patient and the protocol of the care provider. A coordinated effort among several health care professionals, including physicians, pharmacists, nurses, social workers, and the patient and his or her caregiver, as well as the suppliers, is paramount to providing safe and effective management. Home PN affords some patients the potential for an ambulatory lifestyle while maintaining an intravenous feeding regimen that was previously only available in the hospital setting. For others, home PN may contribute to a better quality of life in the comfort of their home.

PHARMACOECONOMIC CONSIDERATIONS

8 Because numerous variables have an impact on the provision of PN support and the response to therapy, determining the true cost of PN is difficult.^{106–108} In general, PN is an expensive intervention, and cost likely varies depending on the underlying indication for treatment and whether PN is provided at home or in an acute care

TABLE 137–8. Costs Associated with Parenteral Nutrition (PN) Therapy

| Type of Cost | Description |
|--|---|
| Direct | |
| • PN solution Components Preparation | Dextrose, AA, IVLE, other additives Dependent on system used for compounding: solution transfer sets, bags, syringes, technician time, pharmacist time |
| Administration | Administration sets, solution filter, pump, nursing time |
| • Catheter placement and site management | Venous access device <i>Central catheter:</i> site of procedure (bedside vs. operating room), radiographic confirmation of placement, supplies used for site care <i>Peripheral line:</i> nursing time, supplies used for site care |
| • Monitoring | Routine laboratory and clinical measurements, changes in therapy to prevent complications or toxicities, nutrition support clinician time |
| • Complications | <i>Mechanical:</i> treatment of specific complication <i>Infectious:</i> cost of antibiotic therapy or venous access replacement <i>Metabolic:</i> increased clinical and laboratory measurements, possible waste of PN solution |
| Indirect | |
| • Morbidity | Quality-of-life expenses such as cost of patient discomfort, time lost from work or other activities as a result of PN therapy |
| • Mortality | Cost of premature death based, for example, on expected future wages |

AA, amino acids; IVLE, intravenous lipid emulsion.

setting.^{92,106–108} Expenses associated with PN therapy may be categorized as direct and indirect costs (Table 137–8).^{108,109} Direct costs may be further categorized as fixed or variable costs. Fixed costs do not depend on the volume of patients receiving therapy. For example, an automatic compounder and the tubing sets required to transfer volumes of stock solutions to the administration bag would be considered fixed costs in many practice settings. These costs per patient tend to be highest in low-volume environments. Variable costs such as PN administration bags depend directly on the number of patients receiving PN. Other direct costs include ancillary services required by patients receiving PN and costs related to the management of nutritionally associated complications.

Benefits and other clinical effects of PN (i.e., length of stay and frequency of complications) in specific patient populations have been evaluated.^{17,18,110} Few investigations have reported an economic assessment of the therapy. However, economic data from many of these reports would not necessarily reflect current costs. Indeed, the direct cost of PN solution components generally has declined over the past decade. Attempting to measure the cost or cost savings associated with reported benefits of PN therapy and other clinical effects based on results of controlled clinical trials is difficult.^{106,107} Clinical outcomes measurements and hence economic outcomes are influenced by multiple factors, including experimental design, sample size, and specific health system practices. Several investigations used for determining costs and benefits of PN therapy have been criticized for such biases.^{14,108}

While the results of economic analyses of PN remain controversial, similarities among several reports provide a basis for methods of limiting the costs of PN therapy. These include the following:

1. Use of PN only for appropriate patients as described by institution-specific criteria based on current consensus statements.¹¹¹ The costs and complications associated with EN have been demonstrated to be less than those associated with PN.^{112,113}
2. Frequent evaluation of the need for routine laboratory measurements used for monitoring PN therapy. In

general, the level of laboratory monitoring should decrease as a patient's clinical condition stabilizes (see Fig. 137–4).

3. Minimize the cost of PN by using efficient purchasing practices for PN solutions and compounding supplies through contract purchasing, streamlined compounding procedures, standardized administration times and 24-hour hang times to reduce waste, single-bag PN solutions, and optimized monitoring plans.

CONCLUSIONS

Appropriate patient selection, assessment, and monitoring are key to successful nutritional therapy and prevention of unnecessary complications or harm to the patient. Standardized order forms and monitoring protocols are useful tools to ensure appropriate administration and monitoring of PN therapy. Because pharmacists have been actively involved in the provision of PN at many levels, including direct patient care, education, and research, nutrition support has been recognized as a pharmacy practice specialty.¹¹⁴ In addition, as the interdisciplinary approach to specialized nutrition support has evolved, standards of practice have been defined for pharmacists as well as other health care professionals who provide nutrition support care.^{5,9–11} The future of PN therapy and the role of the nutrition-support clinician will be affected primarily by new insights from clinical research and economic challenges in the health care environment.

ABBREVIATIONS

CAA: crystalline amino acid
CEAA: conditionally essential amino acid
CPN: central parenteral nutrition
CSP: compounded sterile preparations
EFAD: essential fatty acid deficiency

EN: enteral nutrition
 IVLE: intravenous lipid emulsion
 LCT: long-chain triglyceride
 MCT: medium-chain triglyceride
 NAG-AMA: Nutrition Advisory Group of the American Medical Association
 NPC:N: nonprotein-calorie:nitrogen ratio
 PN: parenteral nutrition
 PPN: peripheral parenteral nutrition
 PUFA: polyunsaturated fatty acid
 RDA: recommended daily allowance
 RS: refeeding syndrome
 TNA: total nutrient admixture
 TPN: total parenteral nutrition

ENTERAL NUTRITION

Vanessa J. Kumpf and Katherine Hammond Chessman

Learning Objectives and other resources can be found at www.pharmacotherapyonline.com.

KEY CONCEPTS

- 1 The gastrointestinal (GI) tract defends the host from toxins and antigens by both immunologic and nonimmunologic mechanisms, collectively referred to as the gut barrier function. Whenever possible, enteral nutrition (EN) is preferred over parenteral nutrition (PN) because it is as effective, may reduce metabolic and infectious complications, and is less expensive.
- 2 Candidates for EN are those who cannot or will not eat, those who exhibit a sufficiently functioning GI tract to allow adequate nutrient absorption, and in whom enteral access can be safely obtained.
- 3 The most common route for both short-term and long-term EN access is directly into the stomach. The method of delivery may be either continuously via an infusion pump, intermittently via a pump or gravity drip, or bolus administration.
- 4 Patients unable to tolerate feeding directly into the stomach due to impaired gastric motility or for those at high risk of aspiration, feeding tube tip placement into the duodenum or jejunum may be indicated. When feeding into the small bowel, the continuous method of delivery via an infusion pump is required in order to enhance tolerance.
- 5 Selection of the enteral feeding formulation depends on nutritional requirements, the patient's primary disease state and related complications, and nutrient digestibility and absorption. A standard polymeric formulation will meet the needs of the majority of adult patients and children older than 10 years of age.
- 6 Measurement of gastric residual volumes can be used to monitor GI tolerance in patients receiving gastric feeding. Although not always reliable, excessive residual volumes may be associated with nausea, abdominal distention, and increased risk for aspiration.
- 7 Management of diarrhea in patients receiving EN should focus on identification and correction of the most likely cause(s). Tube feeding-related causes include too rapid delivery or advancement of formula, intolerance to the formula composition, and occasionally formula contamination.
- 8 Prior to administering medications through a feeding tube, the feeding tube tip location should be verified (stomach or small bowel) and the most suitable dosage form selected. Medications that should not be crushed and administered through a tube include enteric-coated or sustained-release capsules or tablets and sublingual or buccal tablets.
- 9 The coadministration of medications with EN can result in alterations in bioavailability and/or changes in the desired pharmacologic effects of several medications, including phenytoin, warfarin, selected antibiotics, antacids, and omeprazole.

Enteral nutrition (EN) is defined as the delivery of nutrients by tube or by mouth into the GI tract. This chapter focuses on nutrient delivery through a feeding tube rather than the oral ingestion of food. The terms EN and tube feeding are thus used interchangeably in this context. The goal of EN is to provide calories, macronutrients, and micronutrients to patients unable to achieve these requirements from an oral diet. Over the past 20 to 30 years, EN has replaced parenteral nutrition (PN) as the preferred method of specialized nutrition support in many patients at risk of malnutrition. Improvements in enteral access techniques and feeding formulations, and the recognition of methods to prevent and manage complications have resulted in an increased use of EN across all health care settings.

In this chapter, the principles and practices related to the successful use of EN support are described. Digestive and absorptive physiology is reviewed and the beneficial effects of EN are presented. The indications for EN, and descriptions of various enteral access and administration methods are also summarized. Characteristics of

commercially available enteral feeding formulations are presented, as well as initiation and monitoring guidelines to prevent and manage complications. Clinical therapeutic controversies are highlighted and discussed. In addition, issues of drug compatibility, drug-nutrient interactions, and drug administration via enteral feeding tubes are discussed. Finally, the effectiveness and pharmacoeconomics of EN in enhancing nutrition and disease outcome goals are reviewed.

GASTROINTESTINAL TRACT PHYSIOLOGY

DIGESTION AND ABSORPTION

Digestion and absorption are GI processes that generate the body's usable fuels.^{1–3} Digestion consists of the stepwise conversion of a complex chemical and physical nutrient into a molecular form which is absorbable by the intestinal mucosa. Absorption from the GI tract

TABLE 138–1. Gastrointestinal Enzymes and Hormones

| Enzyme/Hormone | Site of Secretion | Main Actions |
|-------------------------------------|---------------------------|--|
| Amylase | Salivary glands, pancreas | Converts carbohydrates, starch, and glycogen to simple disaccharides |
| Cholecystokinin (CCK) | Duodenum, jejunum | Stimulates pancreatic enzyme secretion and gallbladder contraction |
| Chymotrypsinogen | Pancreas | Breaks down proteins into proteases and peptides |
| Enteroglucagon | Duodenum, small intestine | Inhibits pancreatic enzyme secretion and bowel motility |
| Gastric inhibitory peptide (GIP) | Small intestine | Decreases gastric motility and stimulates insulin secretion |
| Gastrin | Stomach, duodenum | Stimulates gastric acid secretion and mucosal growth |
| Glucagon | Pancreas | Stimulates hepatic glycogenolysis and inhibits motility |
| Lipase | Pancreas | Hydrolyzes short-chain and medium-chain triglycerides, involved in fat absorption |
| Pancreatic polypeptide | Pancreas | Inhibits gallbladder contraction and pancreatic and biliary secretion |
| Pepsinogen | Stomach | Converts large proteins into polypeptides |
| Secretin | Small intestine | Stimulates hepatic and pancreatic water and bicarbonate |
| Trypsinogen | Pancreas | Breaks down proteins into proteases and peptides |
| Vasoactive inhibitory peptide (VIP) | Small intestine, pancreas | Vasodilator; stimulates water and bicarbonate secretion, release of insulin and glucagon, and production of small intestinal juice |

is a multistep process that includes the transfer of a nutrient across the intestinal cell membrane. The nutrient ultimately reaches the systemic circulation through the portal venous or splanchnic lymphatic systems, provided the GI or biliary tract does not excrete it. Ingested nutrients are primarily large polymers that cannot be absorbed by the intestinal cell membrane unless they are transformed into an absorbable molecular form. In addition, a coordinated interplay of GI motility and neurohormonal secretion is required to facilitate adequate digestion and absorption.

Nutrient digestion involves the complex coordination of multiple mechanical, enzymatic, and physicochemical processes.^{1–3} Mechanical dissolution of food occurs by chewing, mixing, and grinding of the stomach contents. Food stimulates the secretion of numerous neurohormones and enzymes from the salivary glands, stomach, liver and biliary system, pancreas, and intestines (Table 138–1). As food passes along the gut lumen, these neurohormones modulate GI motility and the secretions from subsequent organs of the digestive system. Nutrient digestion occurs within the gut lumen and is a specific function of the intestinal cell membrane, which is comprised of finger-like pro-

jections called the villi. Each individual villus is made up of epithelial cells called enterocytes. The enterocyte surface contains special luminal projections called microvilli, which provide an increased surface area that is referred to as the brush border membrane.

Digestion and absorption of carbohydrate, fat, and protein within the small intestine is illustrated in Fig. 138–1. Carbohydrates are presented to the small intestine as either a digestible or nondigestible form. Polysaccharides (starches) and oligosaccharides (sucrose and lactose) undergo enzymatic digestion within the small intestine to produce simple sugars. The simple sugars are absorbed via active and passive transport mechanisms and are eventually released into the portal vein. Polysaccharides such as cellulose complexes and other fiber components pass undigested to the colon, where they are digested by bacteria and enzymes to short-chain fatty acids (SCFAs).⁴ Absorption of SCFAs by the colon stimulates sodium and water reabsorption, serves as an energy source, and provides nourishment to the colonic mucosa cells.

Fat is presented to the small intestine as long-chain triglycerides (LCTs).⁵ Its digestion requires pancreatic enzyme release and

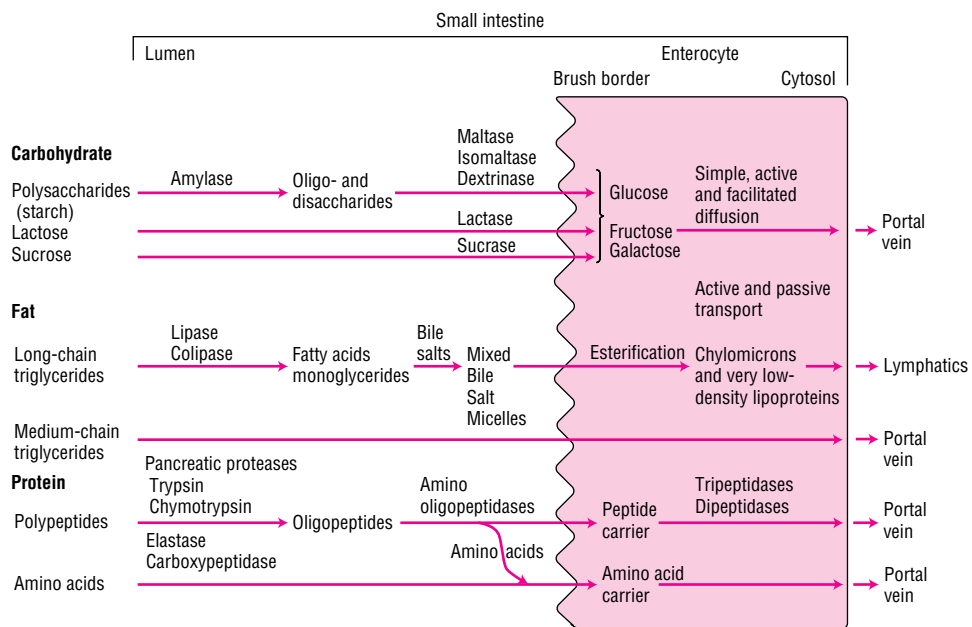

FIGURE 138–1. Schematic representation of carbohydrate, fat, and protein digestion.

formation of mixed bile salt micelles, which then facilitate absorption across the intestinal enterocyte. Within the enterocyte, triglycerides are re-esterified and packaged into chylomicrons for release into the lymphatic system. Medium-chain triglycerides (MCTs) can be absorbed intact by the mucosal membrane and are acted on by intracellular lipase within the enterocyte to release free fatty acids which pass directly into the portal vein.

Protein is presented to the small intestine primarily as large polypeptides and to a small extent as free amino acids due to the denaturation of protein within the stomach. Luminal polypeptide digestion generates oligopeptides, which are further hydrolyzed to dipeptides and tripeptides. Absorption of peptides occurs via a peptide transport system while free amino acids are carried via specific amino acid transport systems. The carriers for the peptides have proven to be very efficient, whereas absorption of free amino acids appears to be more limited and less efficient.³ Understanding the mechanisms of digestive and absorptive physiology can greatly enhance the rational use of EN support during conditions of normal or altered GI anatomy and/or function. Several circumstances may alter the efficacy of nutrient digestion and absorption (Table 138–2). For example, the functional immaturity of the neonatal gut may lead to clinical problems associated with inadequate digestion and absorption of EN. These factors, as they relate to successful EN practice, are discussed in detail throughout this chapter.

GUT HOST DEFENSE MECHANISMS

1 Besides digesting and absorbing nutrients to maintain nutritional health, the GI tract is actively involved in defending the host from toxins and antigens by means of nonimmunologic and immunologic mechanisms (Table 138–3).⁶ These gut host defense mechanisms are

TABLE 138–3. Gut Host Defense Mechanisms

| Bile salts | |
| Salivary secretions | |
| Indigenous microflora | |
| Limits microbial proliferation | |
| Microbial antagonism | |

also collectively referred to as the gut barrier function. The gut barrier acts to prevent the spread of intraluminal bacteria and endotoxin to systemic organs and tissues. Hydrochloric acid secreted by the stomach kills the majority of the bacteria ingested with food. Under normal circumstances, a mucus gel layer coats the intestinal epithelium and thereby alters the adherence of bacteria to the cells of the GI tract and provides a favorable environment for anaerobic bacteria. Anaerobic bacteria, which normally colonize the mucus layer, aid in preventing tissue colonization by potential pathogens. Small bowel peristalsis further prevents bacterial stasis and overgrowth. The gut barrier function is also maintained by the intestinal immune system, known as the gut-associated lymphoid tissue (GALT). This GALT regulates the local immune response to antigens within the GI tract. Specific immunoglobulins are secreted to kill remaining organisms and neutralize any toxins they produce. The hepatic Kupffer cells help to maintain gut barrier function by clearing the portal blood of gut-derived bacteria and endotoxins. The integrity of gut barrier function may be affected by numerous pathogenic insults such as physiologic stress and ischemia, and a variety of drugs, including chemotherapeutic agents. The nutritional aspects that influence the maintenance of the gut barrier will be addressed later in this chapter.

INDICATIONS FOR ENTERAL NUTRITION

2 The decision to initiate EN is based on a variety of factors as outlined in Fig. 136–1 in Chap. 136. Suitable candidates are those who cannot or will not eat a sufficient amount to meet nutritional requirements, those who exhibit a sufficient functioning GI tract to allow the absorption of nutrients, and those in whom a method of enteral access can be safely obtained.^{7,8} Enteral nutrition may be indicated in a variety of conditions or disease states (Table 138–4). For example, patients who have certain neurologic disorders, such as following a cerebrovascular accident, and have difficulty swallowing

TABLE 138–4. Potential Indications for Enteral Nutrition

| | |
|-------------------------------|---|
| Neoplastic disease | Gastrointestinal disease |
| Chemotherapy | Inflammatory bowel disease |
| Radiation therapy | Short bowel syndrome |
| Upper gastrointestinal tumors | Esophageal motility disorder |
| Cancer cachexia | Pancreatitis |
| Organ failure | Fistulas |
| Hepatic | Gastroesophageal reflux disease |
| Renal | Esophageal atresia |
| Cardiac cachexia | Neurologic impairment |
| Pulmonary | Comatose state |
| Bronchopulmonary dysplasia | Cerebrovascular accident |
| Congenital heart disease | Demyelinating disease |
| Hypermetabolic states | Severe depression |
| Closed head injury | Failure to thrive |

| Trauma | Other indications |
| Postoperative major surgery | Acquired immune deficiency syndrome |
| Sepsis | Anorexia nervosa |
| | Complications during pregnancy |
| | Geriatric patients with multiple chronic diseases |
| | Organ transplantation |
| | Inborn errors of metabolism |
| | Cystic fibrosis |
| | Extreme prematurity |

often require EN. Patients unable to eat due to conditions such as facial or jaw injuries, lesions of the oral cavity or esophagus, esophageal stricture, or head and neck cancer may be candidates for EN delivered distal to the affected site. Extreme prematurity necessitates tube feeding because the suck-swallow mechanism has not yet developed sufficiently to allow safe oral intake.

Critically ill patients who are endotracheally intubated for mechanical ventilation represent a large percentage of patients requiring EN. Many of these patients may have reduced gastric motility and emptying caused by sepsis, postoperative anesthetic agents, opioid analgesics, and underlying pathology such as diabetic gastroparesis. However, successful EN can often be achieved by bypassing the stomach and placing the tip of the feeding tube beyond the pylorus into the duodenum, or preferably into the jejunum.

The use of EN during acute pancreatitis has increased. Concerns that feeding may exacerbate the disease process by stimulating exocrine pancreatic secretion historically led to the widespread use of PN and bowel rest in these patients. However, EN is well tolerated in patients with pancreatitis if the GI tract is otherwise functioning normally.⁹ The degree of pancreatic stimulation depends on the location of the tip of the feeding tube and the composition of the feeding formulation. The more distally the feeding is delivered, the less pancreatic stimulation occurs. Jejunal feeding is associated with fewer complications than PN in patients with acute pancreatitis and has not been shown to exacerbate the disease. When patients with pancreatitis require specialized nutrition support, EN should be attempted prior to initiating PN.⁷

The only absolute contraindications for EN are mechanical obstruction⁸ and necrotizing enterocolitis.¹⁰ However, conditions such as severe diarrhea, protracted vomiting, enteric fistulae, severe GI hemorrhage, and intestinal dysmotility may result in significant challenges to the successful use of EN.

BENEFITS OF ENTERAL NUTRITION

The importance of maintaining nutrient delivery through the GI tract in patients without contraindication to its use is well supported. The possible reasons for the apparent beneficial effects of EN when compared to PN will be discussed. Another factor contributing to the beneficial effects of EN, specifically in the critically ill patient, is related to when it is initiated. Initiating EN within 24 to 48 hours of admission to an intensive care unit may be beneficial.

ENTERAL VERSUS PARENTERAL NUTRITION

A considerable body of laboratory and clinical evidence supports the importance and potential advantages of using EN when compared to PN. Clinical studies comparing EN to PN in the critically ill or injured patient often demonstrate improved outcomes from EN in terms of decreased infectious complications.^{11–13} The precise mechanism that accounts for the apparent beneficial effects is not clear. One suggested explanation for the decrease in infectious complications is that EN prevents bacterial translocation.

Bacterial translocation is the migration of bacteria, fungi, or endotoxins from the GI tract through the mucosal barrier. Without intraluminal fuels, it has been proposed that the integrity and function of the GI tract may deteriorate, and under stress, allow for the translocation of microbes or endotoxins.¹⁴ It is further proposed that endotoxin release can activate inflammatory pathways and thereby contribute to the development of multisystem organ failure. Provision of enteral nutrients appears to help maintain intestinal mucosal structure and

function.¹⁵ It has been suggested that this will prevent translocation of gut bacteria to the portal or lymphatic circulation. However, this theory is primarily limited to data supporting the occurrence of bacterial translocation in the animal model and human studies are not available. There is no direct evidence to suggest that EN prevents or modifies bacterial translocation in humans; only indirect evidence exists.^{14,16,17} Enteral nutrition appears to play some type of role in maintaining gut mucosal growth and development to preserve gut barrier function, but the mechanism remains unclear.

Critical reviews of available randomized controlled trials comparing EN to PN in the critically ill adult patient with an intact GI tract suggest a significant reduction in infectious complications associated with EN.^{7,13} Decreased infectious complications have been documented in patients with abdominal trauma, burns, or severe head injury given EN compared to PN. The use of EN has been recommended over PN as the preferred route of feeding in the critically ill patient requiring specialized nutrition support.^{7,13}

Enteral nutrition is more physiologic than PN in terms of nutrient utilization and is therefore generally associated with fewer metabolic complications. A metabolic advantage of enteral feeding compared with the parenteral route is improved glucose tolerance and lower insulin requirements to maintain normoglycemia.¹⁸ It has been proposed that better blood glucose control occurs during enteral administration because the insulin released is absorbed with the glucose via the portal vein and is handled by the liver. The enteral route is also as effective as the parenteral route in maintaining or promoting repletion of nutritional indices among several patient populations.¹⁹ An additional physiologic benefit of enteral feeding is that it stimulates bile flow through the biliary tract and hence reduces the development of gallbladder sludge and stone formation, which has been associated with long-term PN and bowel rest.²⁰ Also, EN avoids the potential infectious and technical complications associated with the placement and use of a central venous access device typically required for PN. Finally, EN is less costly than PN when all factors are considered.

EARLY VERSUS DELAYED INITIATION

The optimal timing of initiation of EN is a controversial issue. It has been suggested that initiating EN early in the course of illness may attenuate the stress response and improve feeding tolerance. Clinical studies demonstrating a decrease in infectious complications with the use of EN compared to PN in the critically ill patient initiated feeding within 24 to 48 hours of hospital admission.^{21,22} It appears that the benefits of decreased infectious complications are not apparent when the initiation of EN is delayed. A review of available studies comparing early versus delayed EN in critically ill patients showed a trend toward a reduction in infectious complications with early EN.¹³ In addition, a trend toward reduction in mortality associated with early EN was noted.

In critically ill patients who are hemodynamically unstable, early EN may result in gut ischemia due to poor gut blood flow and increased oxygen demand. It is therefore recommended to delay initiation of EN until the patient is fluid resuscitated and has an adequate perfusion pressure. Once this goal is obtained, often within 6 hours of hospitalization, the initiation of low rates of EN is considered appropriate as long as close clinical monitoring for GI intolerance is maintained.^{23,24} Therefore, early EN (within 24 to 48 hours after hospital admission) has been recommended in critically ill patients.¹³

Early initiation of EN does not apply to the mild to moderately stressed patient who is otherwise well nourished. It is reasonable to delay the initiation of EN in these patients until oral intake is inadequate for 7 to 14 days or expected to be inadequate over a 7- to 14-day period.⁷

TABLE 138–5. Options and Considerations in the Selection of Enteral Access

| Access | Indications | Tube Placement Options | Advantages | Disadvantages |
|-----------------------------|--|--|--|--|
| Nasogastric or orogastric | Short-term Intact gag reflex Normal gastric emptying | Manually at bedside | Ease of placement Allows for all methods of administration Inexpensive Multiple commercially available tubes and sizes | Potential tube displacement Potential increased aspiration risk |
| Nasoduodenal or nasojejunal | Short-term Impaired gastric motility or emptying High risk of GER or aspiration | Manually at bedside Fluoroscopically Endoscopically | Potential reduced aspiration risk Allows for early postinjury or postoperative feeding Multiple commercially available tubes and sizes | Manual transpyloric passage requires greater skill Potential tube displacement or clogging Bolus or intermittent feeding not tolerated |
| Gastrostomy | Long-term Normal gastric emptying | Surgically Endoscopically Radiologically Laparoscopically | Allows for all methods of administration Large-bore tubes less likely to clog Multiple commercially available tubes and sizes Low-profile buttons available | Attendant risks associated with each type of procedure Potential increased aspiration risk Requires stoma site care |
| Jejunostomy | Long-term Impaired gastric motility or gastric emptying High risk of GER or aspiration | Surgically Endoscopically Radiologically Laparoscopically | Allows for early postinjury or postoperative feeding Potential reduced aspiration risk Multiple commercially available tubes and sizes | Attendant risks associated with each type of procedure Bolus or intermittent feeding not tolerated Requires stoma site care |

GER, gastroesophageal reflux.

ENTERAL ACCESS

Recent advances in enteral access techniques have contributed to the expanded use of EN for conditions in which PN had previously been used. In particular, improved methods of achieving jejunal access for feeding have allowed for the use of EN during the early postoperative and postinjury period when gastric motility is typically delayed. As outlined in Table 138–5, various factors influence the selection of access site, including anticipated duration of use (short-term or long-term) and whether to feed into the stomach or small bowel. A review

of the various enteral access options is important because it influences the overall success of achieving nutrient goals by the enteral route. Illustrations of enteral access options are shown in Fig. 138–2.

SHORT-TERM ACCESS

3 Short-term enteral access is generally easier, less invasive, and less costly than long-term access.²⁵ The most frequently used routes for short-term enteral access are those accessed by inserting a tube through the nose and passing the tip into the stomach

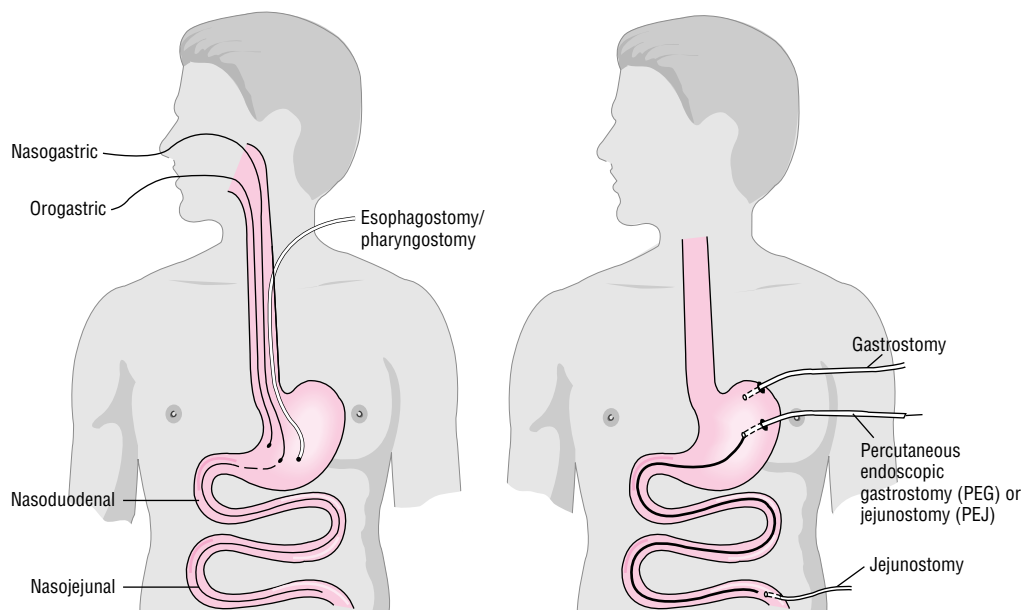

FIGURE 138–2. Access sites for tube feeding.

(nasogastric; NG), duodenum (nasoduodenal; ND), or jejunum (nasojejunal; NJ). In general, these tubes are used in the hospitalized patient when the anticipated tube feeding duration is less than 4 to 6 weeks. The orogastric (OG) route is generally reserved for patients in whom the nasopharyngeal area is inaccessible or in young infants who are obligate nasal breathers. These routes do not require surgical intervention and therefore are the least invasive. The feeding tube is frequently held in place only by a piece of tape on the nose or face, and therefore can be inadvertently pulled out relatively easily.

Nasogastric tubes vary in diameter size and stiffness. The large-bore (≥ 14 French [F]) rigid NG tubes are used primarily to decompress the stomach, but can also be used for feeding. There is a low incidence of clogging with these tubes, and they provide a reliable way to measure gastric residual volumes. The major disadvantage associated with the use of these tubes is patient discomfort. Small-bore nasal tubes designed solely for feeding are available in varying lengths (16 to 60 inches) and diameter sizes (5 to 12F) to accommodate both pediatric (including neonates) and adult patients. The tip of the tube can be placed into the stomach, duodenum, or jejunum. These tubes consist of a lightweight, pliable silicone or polyurethane material that is comfortable to the patient. A disadvantage of the small-bore tubes is that they may become occluded, often due to improper medication or tube flushing technique. Another disadvantage to the use of these tubes is that they do not allow a reliable way to monitor gastric residual volumes, as they will collapse when aspiration of gastric contents is attempted. Therefore when the monitoring of gastric residual volumes is important, such as in a critically ill patient, a large-bore NG tube is preferred.

4 In general, the stomach is the least expensive and the least labor-intensive access site to use for enteral feeding; however, feeding into the stomach is not always tolerated. Patients with impaired gastric motility may be predisposed to aspiration and pneumonia when feedings are delivered into the stomach. Many critically ill, injured, and postoperative patients exhibit delayed gastric emptying, limiting their ability to tolerate gastric feeding. In addition, patients with diabetic gastroparesis or patients with severe gastroesophageal reflux disease or intractable vomiting are at a higher risk for aspiration of gastric contents resulting in pneumonia. In these patients, placing the tip of the tube into the duodenum or jejunum (also referred to as transpyloric placement) may be required to enable successful enteral feeding. However, studies have yet to prove definitively that transpyloric tube feedings actually do decrease the risk of aspiration and pneumonia, but are limited by small sample size. One meta-analysis of studies comparing gastric to transpyloric feeding in critically ill patients demonstrated no difference in the incidence of pneumonia,²⁶ while another critical review of the same patient population suggested that small bowel feedings were associated with a reduction in gastroesophageal regurgitation and a lower rate of ventilator-associated pneumonia.²⁷ Therefore, the true difference in aspiration and pneumonia risk between gastric and small bowel feeding remains unclear. However, the transpyloric route may be beneficial in patients who do not tolerate gastric feeding. Its use may enable the successful use of EN in patients who would have otherwise failed and required PN.

The NG, OG, ND, and NJ tubes can be placed at the patient's bedside by trained medical personnel. However, greater skill is required to place the feeding tube beyond the pylorus at the bedside. Several techniques have been described in the literature to help facilitate bedside placement. The tip of the small-bore feeding tube can be inserted into the stomach and allowed to spontaneously pass into the duodenum. Tubes have been modified with various tip shapes, weights, and a stylet (wire placed in the tube to stiffen it) to facilitate transpyloric insertion. Many facilities do not allow the use of the stylet at the bedside, however, due to the risk of inadvertent tube place-

ment into the lung. Prokinetic agents, such as metoclopramide and erythromycin, have been given prior to insertion to increase GI motility and facilitate spontaneous passage of the tube from the stomach into the small intestine.^{28,29} Variable success rates have been reported with these techniques and is likely largely dependent on clinician experience. Alternatively, a variety of endoscopic and fluoroscopic techniques have been described to insert transpyloric tubes.²⁵ Radiographic confirmation of NG or transpyloric feeding tubes placed by bedside techniques should be obtained prior to use to verify appropriate tip placement.⁷

LONG-TERM ACCESS

Feeding tubes used for short-term enteral access are usually not optimal for long-term use due to patient discomfort, long-term complications, and mechanical failures that develop over time. Long-term access should generally be considered when EN is anticipated for longer than 4 to 6 weeks. Many techniques can be used to establish long-term enteral access, including laparotomy, laparoscopy, endoscopy, and fluoroscopy. The ability to perform the various techniques will be somewhat dependent on the expertise and facilities available within each institution. Long-term enteral access options include esophagostomy, pharyngostomy, gastrostomy, and jejunostomy.

Pharyngostomies and esophagostomies are invasive because the tube is located in the neck and passes through the skin into the esophagus or the pharynx. Historically, they have been used in patients with head and neck malignancies or patients with impaired swallowing due to neuromuscular disorders. However, better long-term enteral access techniques have replaced the need for the pharyngostomy and esophagotomy routes. They are rarely performed today due to the high complication rate and extreme difficulty associated with their care.³⁰

A gastrostomy is the most common type of long-term enteral access. It eliminates the nasal irritation and discomfort associated with an NG, OG, ND, or NJ feeding tube and inadvertent removal is unlikely. In addition, since feeding gastrostomies utilize large-bore tubes, clogging is typically not a problem. Multiple techniques for insertion of a gastrostomy tube have been described, including surgical laparotomy, endoscopy, radiography, and laparoscopy. Surgical placement of a gastrostomy tube can be done at the time of a laparotomy for an unrelated problem, or it can be performed for the sole purpose of inserting the tube. Advantages of the open surgical gastrostomy compared to other gastrostomy techniques include a high success rate, avoidance of perforation and laceration of other intra-abdominal organs, and secure fixation of the stomach to the abdominal wall (decreasing the risk of intraperitoneal leakage). Disadvantages include the inherent risks associated with an invasive surgical procedure and general anesthesia, increased pain, a longer recovery time, and higher cost than other gastrostomy techniques.

The percutaneous endoscopic gastrostomy (PEG) is the most common long-term enteral access. It is minimally invasive and can be performed safely and cost-effectively in an endoscopy suite or at the bedside using conscious sedation and local anesthesia. Small children, however, will usually require general anesthesia for the procedure. Numerous commercially available kits are available for PEG placement in both children and adults and vary in size (12 to 28F; 1 to 4.5 cm shaft lengths), material used, internal and external bolsters, and insertion techniques. Advantages of the PEG compared with open surgical gastrostomy include decreased cost, avoidance of general anesthesia, quicker recovery, and the ability to be performed as an outpatient procedure. The disadvantage is the inability to visualize intra-abdominal pathology or anatomy that could lead to laceration or perforation of other organs. Also, early dislodgment of the PEG

can lead to intra-abdominal leakage and peritonitis if the tract has not matured, because the only thing holding the stomach to the abdominal wall is the internal bolster. A review combining the results of 95 studies evaluating the use of the PEG procedure showed a 96.5% success rate and 0.7% procedure-related mortality rate.³⁰ However, the 30-day mortality rate was 10.5% and significantly higher than the open surgical gastrostomy, indicating that the procedure is being performed in patients who have existing severe comorbid conditions. The ethical implications regarding determination of appropriate candidates for PEG placement has been a topic of considerable interest in the literature.^{30–32} The PEG tube is often placed inappropriately based on unrealistic and inaccurate expectations of what EN can accomplish in patients unable to eat. Patients with an unclear prognosis should be carefully selected and may benefit from a 60-day trial of small-bore NG feedings prior to PEG placement.³³

Newer techniques for gastrostomy placement may be considered if the stomach cannot be accessed via endoscopy, including the percutaneous radiologic gastrostomy and laparoscopic gastrostomy.^{30,34,35} The percutaneous radiologic gastrostomy (PRG) technique has been described using fluoroscopy, ultrasound, or computed tomography scan. These procedures are performed by interventional radiologists and involve distending the stomach and percutaneously cannulating the stomach with a needle to allow gastrostomy insertion. Placement requires a radiologist skilled in the procedure and use of local anesthesia with or without conscious sedation. The tubes used are usually smaller than a PEG (9 to 14F), so they may become more easily occluded. The laparoscopic gastrostomy is performed in the operating room, usually under general anesthesia. It provides another option to the open surgical gastrostomy if a PEG or PRG is not possible due to altered anatomy or other complications.

Once the gastrostomy tract has matured, a low-profile skin-level gastrostomy device may be placed for patient convenience and comfort. This device, a “gastric button,” consists of a short silicone self-retaining conduit with either a mushroom tip or a balloon at the internal end and a one-way valve and small flange at the external end. It offers the convenience of avoiding having a tube end protruding when not in use, so it tends to be preferred in children or ambulatory adults who are receiving intermittent feedings. The exit site of all gastrostomies requires general stoma care to prevent inflammation and infection. When a gastrostomy tube is no longer needed, it can be easily removed. In adults, a common practice is to cut off the tube at skin level and allow retained components to pass through the GI tract. This technique has been associated with serious complications in children, including esophageal perforation and death, and therefore is not recommended in children.^{36–38} Gastrostomy removal by traction or endoscopy (if there is an internal bolster) is associated with few complications. The gastrocutaneous fistula closes spontaneously in more than 70% of patients. If leaking continues, most cases will respond to use of histamine₂-antagonist therapy and silver nitrate cautery. Surgical closure is required in up to 23% of cases.³⁵ In general, the longer the tube is in place, the more likely it is that the fistulous tract will require surgical closure. Patients whose tubes are in place for less than 11 months are more likely to have spontaneous closure than those whose tubes are in for longer than 11 months.³⁶

In patients at high risk of gastroesophageal reflux disease and aspiration who require long-term enteral access, a jejunostomy may be the most appropriate option.³⁹ Jejunostomies may also be indicated in patients unable to tolerate gastric feeding due to impaired gastric motility or delayed gastric emptying. These tubes can be inserted surgically, endoscopically, radiologically, or laparoscopically. The most appropriate technique depends on the skill, expertise, and facilities available. A surgical jejunostomy may be preferred if the patient requires a laparotomy or laparoscopy for other reasons. Endoscopic

placement of a jejunostomy can be done by various methods. Typically, a small-bore jejunal extension tube (6, 8, or 10F) is inserted through a PEG and advanced through the pylorus into the duodenum or jejunum. This procedure has been referred to as percutaneous endoscopic jejunostomy (PEJ), but this is misleading. The PEJ designation implies a direct opening from the skin into the jejunum. The more appropriate name is percutaneous endoscopic gastrojejunostomy or PEG with a jejunal extension tube. In addition, laparoscopically and radiologically placed jejunostomies are described in the literature.³⁹ Because jejunostomies are smaller-bore tubes, occlusion occurs more commonly than with gastrostomy tubes.

ADMINISTRATION METHODS

Enteral nutrition may be administered by continuous, cyclic, bolus, or intermittent methods and may be accomplished by bolus, gravity, or infusion pump–controlled techniques. The method of delivery depends on the location of the tip of the feeding tube, the clinical condition and intestinal function of the patient, the environment in which the patient resides, and the patient’s tolerance to the tube feeding.

CONTINUOUS

Continuous tube feeding is characterized by the administration of an enteral feeding formulation via a delivery system generally 24 hours per day, allowing for occasional interruption of the feeding for medication administration, procedures, and other treatments. In the hospitalized patient, the continuous administration of tube feeding is the method most commonly used for initiation, and is generally the preferred method in critically ill patients.⁴⁰ When initiating feeding into the stomach, the continuous method of delivery is considered less likely to result in abdominal distention, vomiting, and diarrhea than the intermittent bolus method. Once tolerance is established, a conversion to intermittent bolus administration may be warranted. When feeding into the small intestine, the continuous method is recommended to enhance tolerance. The rapid delivery of feeding into the small intestine, especially hyperosmotic formulations, may contribute to abdominal distention, cramps, hyperperistalsis, and diarrhea. Therefore conversion to intermittent bolus administration is not recommended when feeding into the duodenum or jejunum. Continuous feeding may also be preferred in patients who have limited absorptive capacity due to rapid GI transit or severely impaired digestion. Slow continuous administration in such patients allows greater time for digestion and absorption of nutrients as they pass through the intestine.

The delivery system for a continuous infusion generally includes a feeding reservoir or bag attached to an extension set that is connected to an infusion pump. The delivery system is then attached to the patient’s enteral access tube. Continuous infusion may increase nursing time because routine checks of the enteral infusion are needed, but this disadvantage may be negated by the potential for improved tolerance. For adults, infusion rates generally range from 50 to 125 mL/h, although higher infusion rates have been reported without complications. In children, initial infusion rates of 1 to 2 mL/kg per hour or 20 to 25 mL/kg per day with similar rate advancements every 4 to 8 hours or more depending on patient characteristics to the goal rate needed to meet caloric needs usually are tolerated well. The primary disadvantage to this method of administration is the cost and inconvenience associated with the pump and administration sets. In the home care setting, ambulatory enteral pumps are available to free the patient from the infusion pole and allow greater mobility.

CYCLIC

It may be warranted to infuse EN by way of a continuous infusion over a fixed time period rather than over the entire day. A patient who is not eating well during the day because of complaints of fullness and lack of appetite may benefit from a trial of stopping the enteral feeding during the day and infusing only at night. In addition, the infusion of EN only at night will free the patient from the pump during the day and allow for greater mobility. This may be particularly useful for the home patient or patient requiring rehabilitation. Since a pump controls the rate of infusion, this method of administration may be used in patients with either gastric or small bowel access.

BOLUS

The bolus administration of EN is most commonly used in the long-term setting in patients who have a gastrostomy. The administration technique involves the rapid delivery of the enteral feeding formulation, usually over 5 to 10 minutes. Essentially the only equipment needed is a syringe to instill the feeding solution into the tube. Depending on the patient's nutritional requirements, a volume of 240 to 500 mL is generally given per feeding and repeated 4 to 6 times/day. From a convenience standpoint, it is generally preferable to dose the bolus volume in increments of the feeding formulation can size (usually 240 mL). The volume in children is usually 20 to 25 mL/kg per feeding until adult volumes are reached. For convenience and by convention, feedings in children are often dosed based on increments of one-half to 1 ounce. Although many patients tolerate the rapid administration of the feeding into the stomach, the bolus technique may result in cramping, nausea, vomiting, aspiration, and diarrhea. Its use should be avoided in patients with delayed gastric emptying or patients at high risk of aspiration. Its use is also not recommended in patients with duodenal or jejunal access because the rapid delivery of a feeding formulation into the small intestine is generally not tolerated.

INTERMITTENT

The intermittent technique is similar to the bolus technique except that the prescribed volume of feeding is administered over a longer

time period, generally 20 to 60 minutes. Like bolus feeding, its use should be limited to patients with gastric enteral access. The desired volume of feeding formulation is emptied into a reservoir bag or container and infused by an infusion pump or gravity drip using a roller clamp. Compared to the bolus technique, more equipment is required for intermittent administration. However, if a patient is experiencing intolerance to bolus administration, a switch to the slower infusion period may be warranted. Both bolus and intermittent administration are more consistent physiologically with normal eating patterns than the continuous method. One study in infants demonstrated that normal gallbladder emptying did not occur with continuous infusion feedings, but was normal in those infants receiving bolus feedings.⁴¹ This has implications in patients receiving both EN and long-term PN, especially children, and the development of cholestatic liver disease.

ENTERAL FEEDING FORMULATION SELECTION

Historically, enteral formulas were created to provide essential nutrients. Over the years, enhancements have been made to meet specific patient needs and improve tolerance. For example, enteral formulas have been modified in nutrient composition by changing the content of the amino acids (such as glutamine and arginine), changing the omega-3 polyunsaturated fatty acid content, and adding ribonucleic acid to promote a favorable physiologic effect that improves disease outcome. These specific nutrients have been called nutraceuticals or pharmaconutrients due to the intent of their use to modify the disease process and improve clinical outcome. Currently, enteral feeding formulations are categorized by the Food and Drug Administration (FDA) as medical foods. They are considered components of supportive care and are simply regulated to ensure sanitary manufacture. Unfortunately, they are not subject to rules governing health claims, and the issue of using medical foods for therapeutic intent is an unrecognized area by the FDA.^{42,43}

The macronutrient content of enteral formulas (namely, protein, carbohydrate, and fat) varies in nutrient complexity (Table 138–6). Nutrient complexity refers to the amount of hydrolysis and digestion

TABLE 138–6. Enteral Formula Nutrient Complexity

| Nutrient | Polymeric or Intact | Partially Hydrolyzed or Elemental |
|--------------|---------------------------------|-----------------------------------|
| Carbohydrate | Starches | Oligosaccharides |
| | Fruit, vegetable, cereal solids | Maltodextrins |
| | Glucose polymers | Disaccharides |
| | Corn syrup solids | Maltose, sucrose, lactose |
| | Polysaccharides | Monosaccharides |
| | | Glucose |
| | | Galactose |
| Fat | Long-chain triglycerides | Medium-chain triglycerides |
| | Polyunsaturated fatty acids | Coconut oil |
| | Corn oil | Palm kernel oil |
| | Safflower oil | Free fatty acids |
| | Soybean oil | Linoleic |
| | Butterfat | |
| | Menhaden oil | |
| | Fish oils | |
| Protein | Whole | Oligopeptides |
| | Egg, milk, wheat, whey | Dipeptides |
| | Isolates | Tripeptides |
| | Caseinate salts | L-Amino acids |
| | Lactalbumin | |

a substrate source requires prior to intestinal absorption. Polymeric or intact substrates are of similar molecular form as the food we eat. Enteral formulas that contain partially hydrolyzed or elemental substrates are characterized as elemental, or defined-formula diets. The caloric contribution of each of the macronutrients is as follows: carbohydrates, 4 kcal/g; protein, 4 kcal/g; and fat, 9 kcal/g. Micronutrients, including electrolytes, vitamins, trace elements, and water, do not contribute to caloric content.

PROTEIN COMPOSITION

Important factors concerning the protein within enteral formulas are the quantity, quality, and molecular form of protein. The essential amino acid content of the protein source determines the quality of the protein, and most commercially available enteral feeding formulations contain proteins of high quality. The molecular form of the protein source in enteral formulas will determine the amount of digestion that is required for absorption within the small bowel. Polymeric or intact protein sources require digestion to smaller peptides and free amino acids before they are absorbed from the GI tract. Therefore enteral formulation protein sources such as meat, milk, eggs, and caseinates require digestion by hydrochloric acid, specific protein enzymes, and pancreatic enzymes. Enteral formulations may also contain protein sources that are partially hydrolyzed as peptides or L-amino acids. As the molecular form of protein is reduced in size, the osmotic load within the enteral formula is increased. Many commercially available enteral feeding formulations contain combinations of intact and partially hydrolyzed protein sources.

CONDITIONALLY ESSENTIAL AMINO ACIDS

Glutamine and arginine are normally considered nonessential amino acids. However, during periods of high physiologic stress, glutamine and arginine may become deficient and therefore have been characterized as conditionally essential. They are usually absent or present in only low amounts in enteral feeding formulations. Therefore certain enteral formulations targeted for the critically ill have been supplemented with glutamine and/or arginine.

Glutamine serves as a key fuel for rapidly dividing cells, including enterocytes, endothelial cells, lymphocytes, and fibroblasts. The primary site of glutamine production is skeletal muscle. During critical illness, the catabolism of skeletal muscle provides an increased supply of glutamine, but this may not be enough to meet the high rate of glutamine use by cells of the immune system and other cells involved in recovery and repair. Glutamine depletion may result, particularly during prolonged periods of metabolic stress. However, it is unclear whether the supplementation of glutamine to enteral formulations plays a role in preserving normal intestinal morphology and function or preserving immune function.^{44,45} Questions still remain about whether glutamine may enhance the growth of some tumors in that it may act as a tumor stimulator. Further research and investigation are required to determine the potential benefits and harm associated with glutamine-enriched enteral feeding formulations.

Like glutamine, arginine is an amino acid that may not be synthesized in sufficient quantity during states of trauma or stress. Supplementing the diet with arginine in healthy volunteers results in stimulation of T-cell blastogenesis. In animals, supplemental arginine has been shown to decrease protein catabolism, enhance nitrogen retention following injury, and also accelerate wound healing. While arginine supplementation has been shown to improve survival in various

animal models and improve a number of in vitro measures of immune function in humans, prospective trials evaluating the effect of arginine on clinical outcomes in humans are lacking.⁴⁶ Arginine is added to selected enteral formulations in the range of 4.5 to 14 g/L.

CARBOHYDRATE COMPOSITION

The carbohydrate component of enteral feeding formulations usually provides the major source of nonprotein calories. Polymeric or intact enteral formulations contain starches and numerous types of glucose polymers, which require digestion to the monosaccharide moieties prior to intestinal absorption (see Fig. 138–1). As the hydrolysis of carbohydrate increases within an enteral formulation, the osmolality of the formulation increases. Elemental carbohydrates such as glucose and galactose contribute significantly to the osmolality of enteral formulations, which may contribute to feeding intolerance. Therefore polymeric entities, rather than elemental sugars, are preferred in enteral formulas. Glucose polymers provide a useful carbohydrate source that is tolerated by most individuals (see Table 138–6). The polymers are large chains that provide minimal osmotic load, yet are absorbed easily in the intestine. The one shortcoming of glucose polymers and oligosaccharides is that they are not as sweet as simple glucose and thus may decrease the palatability of orally consumed products. Finally, almost all commercially available enteral feeding formulations used in adults are lactose-free because some ethnic populations are lactase deficient and disaccharidase production within the gut lumen is reduced during illness or bowel rest. Infant formulas are available with or without lactose.

FAT AND FATTY ACID COMPOSITION

Fat is an important constituent in the diet because it provides a concentrated calorie source and serves as a carrier for fat-soluble vitamins. Sufficient linoleic acid is required to prevent essential fatty acid deficiency and should approximate 1% to 3% of total daily calories. The most common sources of fat in enteral feeding formulations are vegetable oils (soy or corn) rich in polyunsaturated fatty acids. The concentration of fat varies between less than 2% to 45% of total calories. High fat content of the diet has been associated with delayed gastric emptying. Enteral feeding formulations can also contain fat in the form of medium-chain triglycerides (MCTs), derived from palm kernel or coconut oils. Because MCTs do not contain linoleic acid, most enteral formulations that contain MCTs will also contain a source of LCTs to provide essential fatty acids. Potential advantages of MCTs compared to LCTs are that they are more water soluble, they undergo rapid hydrolysis, they require little to no pancreatic lipase or bile salt for absorption, and they do not require carnitine for transport into the mitochondria where they are converted to energy. They also do not require chylomicron formation for small bowel enterocyte absorption.

The source of long-chain fat within some enteral formulations has been modified from omega-6 to omega-3 fatty acids in an effort to modulate the inflammatory response to metabolic stress.^{46,47} The omega-6 fatty acids serve as precursors to certain cytokines that have been shown to be potent inflammatory mediators and also to decrease cell-mediated immune response. The omega-6 fatty acids are high in linoleic acid and are derived from vegetable oil, whereas the omega-3 fatty acids, derived from coldwater fish oils, are high in linolenic acid. It has been proposed that if the dietary proportion of omega-3 fatty acids is increased and omega-6 fatty acids is decreased, less inflammation and immunosuppression may occur during metabolic stress.

Docosahexaenoic acid (DHA) and arachidonic acid (ARA) are two fatty acids abundant in human milk, but until recently, were not contained in commercial infant formulas. While the role of ARA supplementation is unclear, DHA is known to be important in both brain and eye development. In some studies, DHA and ARA supplementation has been shown to provide benefits to a child's visual function and/or cognitive and behavioral development.^{48–51} Other studies have shown no difference with DHA and ARA supplementation.⁵² The FDA has classified the plant-based fatty acid blends of DHA and ARA (DHASCO, ARASCO; Martek Biosciences Corporation) as generally recognized as safe in infant formulas.

FIBER CONTENT

Fiber, in the form of soy polysaccharides, has been added to several enteral feeding formulations intended for use in both children and adults in amounts ranging from 5.9 g to 24 g of dietary fiber per liter. Infant formulas do not contain fiber, with the exception of one formula intended for use in infants with diarrhea (Similac Isomil DF, Ross Products Division, Abbott Laboratories). Fiber supplementation is common in clinical practice, primarily because fiber-free enteral formulations have been implicated as a contributing factor to both diarrhea and constipation. Ingested fiber undergoes bacterial degradation within the colon to produce short-chain fatty acids (SCFAs). Potential benefits of fiber are the trophic effects on the colonic mucosa as well as promotion of sodium and water absorption within the colon.⁴ It may help regulate bowel function in both normal individuals and those with altered colonic motility conditions. In addition, the resulting SCFAs are an excellent energy source. Although beneficial effects of fiber supplementation have not been clearly proven in clinical studies, there is experimental evidence that fiber may play an integral role in normal human nutrition and risk is generally minimal.⁵³ Fiber supplementation may be beneficial when long-term EN is required or in patients who experience diarrhea or constipation while receiving a fiber-free enteral formulation. In intensive care units, however, drugs and metabolic stress seem to be more powerful determinants of bowel function than the presence or absence of fiber.

OSMOLALITY AND RENAL SOLUTE LOAD

The osmolality and the renal solute load can affect tolerance to enteral feeding formulations. The osmolality of a given enteral formulation is a function of the size and quantity of ionic and molecular particles, primarily related to the protein, carbohydrate, electrolyte, and mineral content within a given volume. The unit of measure of osmolality is milliosmoles per kilogram (mOsm/kg). Iso-osmolar is considered approximately 300 mOsm/kg. Enteral formulations with greater amounts of partially hydrolyzed or elemental substrates have a higher osmolality than formulations containing polymeric or intact substrate forms. Therefore formulations that contain sucrose or glucose, dipeptides and tripeptides, and amino acids are considered hyperosmolar. Increased caloric density also increases the osmolality of an enteral formulation. In general, the osmolality of commercially available enteral feeding formulations ranges from 300 to 900 mOsm/kg. The American Academy of Pediatrics recommends that enteral formulations for use in infants have an osmolality of approximately 450 mOsm/kg. An extensive review of the osmolality of formulas and medications commonly used in neonatal intensive care units has been published.⁵⁴

Symptoms of gastric retention, diarrhea, abdominal distention, nausea, and vomiting have been attributed to enteral formulations having high osmolality. This is based on the assumption that a higher

osmolality will draw water into the gut lumen. However, clinical evidence to support the relationship between osmolality and GI tolerance is lacking.⁵⁴ The practice of diluting hyperosmolar formulations has not been shown to enhance tolerance and should be discouraged unless dilution is done to increase fluid intake.⁵⁵ Factors such as concurrent antibiotic therapy, method of enteral feeding administration, and the formulation's composition are likely to play a greater role in GI tolerance.

The renal solute load is made up collectively of the protein, sodium, potassium, and chloride content of the enteral formulation. Formulations that contain a greater solute load increase the obligatory water loss via the kidney. It is estimated that 40 to 60 mL of water is the minimal amount necessary to excrete 1 g of nitrogen.⁵⁶ Those receiving high-protein enteral formulations unable to ingest more water, such as a geriatric patient or a patient with altered mental status, may be at risk for significant dehydration.

CLASSIFICATION OF ENTERAL FEEDING FORMULATIONS

5 Although the majority of a patient's needs can probably be met using three or four different formulations, certain disease states or clinical conditions may warrant the use of a specialty feeding formulation. Development of an effective formulary system should avoid the duplication of enteral feeding formulations and use only those specialty formulations with an established role. Categorizing enteral feeding formulations according to therapeutic class is necessary in developing a formulary system (Tables 138–7 and 138–8).

STANDARD POLYMERIC

A large number of commercially available enteral feeding formulations fall within the category of a standard polymeric formulation. These formulations are approximately isotonic (300 mOsm/L), provide about 1 kcal/mL, and are composed of intact nutrients in a well-proportioned mix of carbohydrate, fat, and protein. They are provided with or without dietary fiber. The nutrient requirements of the majority of adult patients and children older than 10 years of age receiving EN can generally be met using feeding formulations in this category. The nonprotein calorie:nitrogen ratio (NPC:N) of these products is approximately 125:1 to 150:1. This ratio is a useful parameter for assessing protein density in relation to calories provided. Certain feeding formulations in this category may be promoted as high nitrogen, but fall within standard protein amounts. To maintain their isotonicity, products within this category are not sweetened. Therefore they are not very palatable and generally only suited for tube feeding and not oral supplementation; however, flavored products are available.

HIGH PROTEIN

Enteral feeding formulations with an NPC:N ratio less than 125:1 can be categorized as high protein. The lower the ratio, the higher the protein density in relation to calories provided. In patients with high protein requirements, it is generally not acceptable to use a feeding formulation with standard protein amounts because the volume necessary to meet protein requirements will often result in excessive calorie intake. Patients who may be candidates for a high-protein feeding formulation are those with trauma, burns, pressure sores, surgical wounds, high fistula output, and other critically ill patients. In general, adult patients with estimated protein requirements exceeding 1.5 g/kg per day may benefit from a high-protein formulation.

TABLE 138–7. Adult Enteral Feeding Formulation Classification System

| Category | Features | Product Examples |
|----------------------|--|--|
| Standard polymeric | Isotonic 1–1.2 kcal/mL NPC:N 125:1 to 150:1 May contain fiber | Osmolite 1 Cal, Isocal (MJ), Isocal HN (MJ) Osmolite 1 Cal (R), Jevity 1 Cal (R), Ultracal (MJ), Jevity 1.2 Cal (R), Nutren 1.0 (N), Isosource (No), Nutren w/Fiber (N), Fibersource (No) |
| High protein | NPC:N <125:1 May contain fiber | Promote (R), Replete (N), Promote w/Fiber (R), Replete w/Fiber (N), TraumaCal (MJ), Isosource VHN (No) |
| High caloric density | 1.5–2 kcal/mL Lower electrolyte content per calorie Hypertonic | Nutren 1.5 (N), Deliver 2.0 (MJ), Two-Cal HN (R), Nutren 2.0 (N), Novasource 2.0 (No) |
| Elemental | High proportion of free amino acids Low in fat | Tolerex (No), Criticare HN (MJ), Vital HN (R), Vivonex TEN (No) |
| Peptide-based | Contains dipeptides and tripeptides Contain MCTs | Peptamen (N), Subdue (MJ), Peptamen VHP (N), Subdue Plus (MJ), Perative (R), Crucial (N), Peptinex DT (No) |
| Disease-specific | | |
| Renal | Caloric dense Protein content varies Low electrolyte content | Suplena (R), Magnacal Renal (MJ), Nepro (R), Novasource Renal (No), Renalcal (N), NutriRenal (N) |
| Hepatic | Increased branched-chain and decreased aromatic amino acids | Nutri-Hep (N) |
| Pulmonary | High fat, low carbohydrate | Pulmocare (R), Oxepa (R), Respilor (MJ), Novasource Pulmonary (No), NutriVent (N) |
| Diabetic | High fat, low carbohydrate | Glucerna (R), Resource Diabetic (No), Choice DM (MJ), Glytrol (N), Diabetisource AC (No) |
| Metabolic stress | Supplemented with glutamine, arginine, nucleotides, and/or omega-3 fatty acids | Impact varieties (No), Perative (R), Crucial (N), AlitraQ (R) |
| Oral supplement | Sweetened for taste Hypertonic | Ensure varieties (R), Boost (MJ), Resource varieties (No), ProSure (R), NuBasic varieties (N) |

Manufacturers: MJ, Mead Johnson Nutritionals; R, Ross Products Division, Abbott Laboratories; N, Nestlé Clinical Nutrition; No, Novartis; MCT, medium-chain triglyceride; NPC:N, nonprotein calorie:nitrogen ratio.

HIGH CALORIC DENSITY

High caloric density formulations are concentrated to provide less fluid and electrolyte intake in comparison to a standard polymeric formulation. They provide approximately 2 kcal/mL and will achieve similar calorie and protein intake to a standard polymeric formulation, using half the volume. Although generally well tolerated as a tube feeding, the osmolality of caloric dense formulations is about double that of standard isotonic formulations. High caloric density formulations are indicated in patients requiring fluid and/or electrolyte restriction, such as those with renal insufficiency or congestive heart failure. Although specialty enteral formulations targeted for acute and chronic renal failure are also available, many patients with renal failure can be managed using a product in this category.

ELEMENTAL/PEPTIDE-BASED

Formulations in this category contain protein and/or fat components that are hydrolyzed into smaller, predigested forms. Traditionally, enteral formulations in this category were referred to as elemental and contained a high proportion of protein in the form of free amino acids and contained a low amount of fat. Although still commercially available, many of these formulations have been replaced in clinical practice with formulations containing a portion of the protein in the form of dipeptides and tripeptides and less free amino acids. The formula-

tions have been referred to as peptide-based. The alteration was made in an effort to optimize protein absorption in patients with impaired digestive or absorptive capacity. The results from human and animal intestinal perfusion studies indicate that the partially hydrolyzed sources of protein have an absorptive advantage over formulas that contain free amino acids.⁵⁷ Peptide-based formulations are generally higher in fat content than the older, elemental formulations, and use MCTs in varying proportions as the fat source.

Indications for use of peptide-based formulations are not clearly established. Unfortunately, there are few controlled data on the nutritional efficacy of the peptide-based or free amino acid formulations in humans. The routine use of peptide-based or free amino acid formulations is generally not recommended. Patients who do not tolerate standard, intact nutrient formulations due to malabsorption may be candidates for a trial of a peptide-based formulation. In addition, elemental or peptide-based products that have higher percentages of MCTs and small amounts of LCTs may be beneficial for patients with severe pancreatic insufficiency such as chronic pancreatitis and cystic fibrosis, severe abnormalities of the intestinal mucosa such as untreated celiac disease, or chylothorax.

DISEASE-SPECIFIC

Newer enteral feeding formulations have been designed to meet specific nutrient requirements and manage metabolic abnormalities

TABLE 138–8. Pediatric Enteral Feeding Formulation Classification System

| Formula Type | Product Examples | Indications |
|---------------------------------------|--|--|
| Polymeric: Infants | | |
| Cow's milk–based | Enfamil LIPIL, ^a Enfamil Lactofree LIPIL, Enfamil A.R. LIPIL (M); Similac Advance, ^b Similac Lactose Free Advance (R); Nestlé Good Start Supreme (N) | Normal, healthy infant |
| Soy protein–based | Enfamil ProSobee LIPIL (M); Similac Isomil Advance, Similac Isomil DF ^c (R); Nestlé Good Start Supreme Soy (N) | Lactase deficiency or intolerance, galactosemia |
| Prematurity | Enfamil Premature LIPIL (M); Similac Special Care Advance 20 Advance, Similac Special Care Advance 24 Advance (R) | Preterm infant less than 2–3 kg |
| Transition | Enfamil EnfaCare LIPIL (M); Similac NeoSure Advance (R) | Preterm infants less than 3 kg ready for discharge |
| Toddlers | Next Step, Next Step Soy (M); Similac 2, Isomil 2 (R); Nestlé Good Start 2 Essentials, Nestlé Good Start 2 Essentials Soy | Infants ready to transition to cow's milk |
| Special diets | Similac PM 60/40 (R) | Renal, cardiac, or endocrine disorders |
| Polymeric: Children 1–10 years | Enfamil Kindercal ^d (M); PediaSure, PediaSure with Fiber (R); Nutren Jr, Nutren Jr with Fiber (N), Resource Just for Kids (No) | Functioning GI tract requiring tube feedings |

associated with specific disease states. Conditions for which specialized enteral feeding formulations exist include renal failure, hepatic failure, pulmonary disease including acute respiratory distress syndrome (ARDS), diabetes mellitus, wound healing, and metabolic stress. Specific nutrient concerns during organ failure are discussed in Chap. 139. Unfortunately, scientific and clinical research supporting the efficacy of specialized enteral feeding formulations is minimal. A critical evaluation is necessary to determine when, or if, a role exists for their use.

Specialized enteral formulations designed to modulate the inflammatory response in patients with severe metabolic stress have been referred to as immune-enhancing formulations or immunonutrition. These specialized formulations are supplemented with nutrients such as glutamine, arginine, branched-chain amino acids, nucleotides, and omega-3 polyunsaturated fatty acids, due to their potential role in regulating immune function. Systematic literature reviews evaluating the clinical outcome of immune-enhancing formulations compared to standard formulations in critically ill patients have been published.^{13,58–61} A meta-analysis of 12 clinical trials (cumulative n = 1482) demonstrated a significant reduction in infection rate and length of hospital stay for trauma, septic, or surgical patients re-

ceiving immunonutrition formulations.⁵⁸ Likewise, a meta-analysis of 10 clinical trials (cumulative n = 1009) demonstrated significant reductions in infectious complications and overall length of hospital stay for critically ill or cancer patients receiving immunonutrition formulations.⁶⁰ No effect on mortality with immunonutrition was demonstrated from either of the meta-analyses. However, one study documented increased mortality in patients receiving immune-enhancing formulations.⁶² Unfortunately, available studies provide no insight as to which nutrient(s), if any, contributed to any potential improvement in clinical outcome.

CLINICAL CONTROVERSY

The role of immune-enhancing enteral formulations in critically ill patients is controversial. While some clinicians recommend their use based on studies suggesting improvement in measures of immune function, others await more evidence to support safety and improvement in clinical outcome measures. In addition, parameters for determining those critically ill patients most likely to benefit from the use of immune-enhancing enteral formulations are not clearly defined.

In patients with ARDS, improved outcomes have been documented using a low carbohydrate formulation supplemented with specific fatty acids (eicosapentaenoic acid and gamma-linolenic acid) and antioxidants.⁶³ When compared with a high fat formulation, the specialized diet was associated with fewer days of ventilatory support, fewer ICU days, and fewer new organ failures. Therefore it has been recommended that this specialized formulation be considered for patients with ARDS.^{13,64}

There are no disease-specific enteral products currently marketed for use in infants or children from 1 to 10 years of age. The use of modular supplements is often necessary in children with special nutrition needs (see section on modular supplements, below).

ORAL SUPPLEMENTS

In general, oral supplements are not intended for tube feeding, but to enhance an oral diet. They are sweetened to improve taste and are therefore hypertonic (about 450 to 700 mOsm/kg). This is generally not a problem in the patient with a functioning GI tract. However, in the tube-fed patient, a sweetened product is not necessary and may contribute to GI intolerance, particularly diarrhea. Powder supplements that are mixed with milk should be avoided in lactose-intolerant patients. In addition to liquid supplements, puddings, gelatins, bars, and milkshake-like supplements are available.

MODULAR PRODUCTS

A module is a powder or liquid allowing addition of nutrients (i.e., protein, carbohydrate, or fat) to supplement a commercially available enteral formulation (Table 138–9). Addition of a modular product may be necessary, especially in children, to achieve a nutrient mix not supplied by a single commercially available product.⁶⁵ Alternatively, formulations available in powder or concentrate can be mixed with less water than needed for the standard dilution to deliver more nutrients in less volume. Infant formulas generally are concentrated beyond their standard concentration (standard varies depending on type) in this way. However, keep in mind the mixing process required for modular components increases the potential for introducing bacterial contamination. This problem has been particularly identified with the use of blenders and reconstitution of powders.^{66,67} Human milk fortifiers are available for supplementation of human milk so that it meets the needs of a premature infant. Human milk fortifiers add additional calories, protein, and minerals and have been shown to improve nutritional outcomes in human milk–fed premature infants.^{68–70}

REHYDRATION

Oral rehydration formulations are useful in maintaining hydration or treating dehydration in adult and pediatric patients with high GI output. Such formulations are available commercially in powder or liquid form or can be extemporaneously compounded. They can be administered orally or given via a feeding tube. The glucose content of oral rehydration solutions is important because it stimulates active transport systems, which in turn stimulate passive sodium and water uptake simultaneously with the glucose. Therefore oral or enteral administration of rehydration solutions may decrease fecal water loss and generate a positive electrolyte balance.

FORMULARY AND DELIVERY SYSTEM CONSIDERATIONS

In general, no more than one product is necessary per category of enteral feeding formulations and it may be possible to omit certain categories based on the specific population and physician prescribing practices within a given institution. The selection of product should be based on meeting patient nutritional requirements. Additional selection criteria include container size and type, liquid or powder form, shelf life, ease of use, and cost.

The majority of enteral products are available as ready-to-use, prepackaged liquids, whereas others are in a dehydrated, powdered state and require reconstitution prior to use. Advantages of ready-to-use liquid formulations are convenience and lower susceptibility to microbiologic contamination due to less required manipulation. One of the disadvantages is that more storage space is required. The ease or convenience of a ready-to-use liquid is especially important for self-care patients, the disabled, and those who have difficulty receiving or following printed instructions. Ready-to-use liquid enteral formulations are generally available in either cans or closed, ready-to-hang bags or rigid containers. Bolus administration of EN is usually achieved using formulas available in cans. However, when formula from a can is used for continuous or cyclic administration it must first be poured into a bag or bottle to allow for infusion via a pump. This “open system” differs from the closed, ready-to-hang containers from the standpoint of microbial contamination risk. The use of a powder formula is also considered an open system of delivery.

Contaminated enteral feeding formulations have been identified as a potential source of infectious complications.^{66,67,71,72} The GI tract may serve as a portal of entry for bacteria into the systemic circulation, especially in patients who are receiving multiple antibiotics, have undergone a surgical procedure, or have GI tract stasis from a variety of causes. The contamination of enteral feeding formulations has been associated with a lack of attention to proper handling techniques, inability to disinfect preparation equipment, and nonsterile or contaminated tube feeding additives. Unlike liquid formulations, powdered products are not guaranteed to be sterile by the manufacturer. This is due to the inability to properly sterilize the powder without destruction of some of its components. Contamination of one infant formula with *Enterobacter sakazakii* at the manufacturing site was implicated in the death of an infant in a neonatal ICU that prompted FDA warnings regarding the use of powdered formulations in premature neonates and other immunocompromised infants. Because powder formulations require reconstitution, often in a blender that is difficult to sterilize, they are also more susceptible to contamination at the time of preparation. Stringent handling procedures are recommended during all aspects of enteral feeding preparation and delivery to minimize contamination risk. The closed-system containers

supply a ready-to-hang, prefilled, sterile supply of formula in volumes of 1 to 1.5 L, and their use will decrease manipulation required for feeding administration. Numerous, but not all, enteral formulations intended for use in adults are available in the closed-administration system. The closed-administration system also offers the advantage of not requiring refrigeration and allowing hang times beyond 24 to 36 hours, whereas the conventional open delivery system necessitates hang times of generally 4 to 8 hours. If manipulation of a closed-system container is required for the addition of water, electrolytes, or medication, it should follow guidelines for an open system. In that case, use of cans is generally more cost-effective.

INITIATION AND ADVANCEMENT PROTOCOL

Guidelines for the initiation and advancement of enteral feeding formulations vary greatly and scientific support for any of the guidelines is weak or nonexistent. The typical recommendation for continuous administration of EN for adults is to start at 20 to 50 mL/h and advance by 10 to 25 mL/h every 4 to 8 hours until the desired goal is achieved. For intermittent administration, the typical recommendation is to start at 120 mL every 4 hours and advance by 30 to 60 mL every 8 to 12 hours.⁵⁵ In children, the recommendation for continuous administration is initiation of 1 to 2 mL/kg per hour or 20 to 25 mL/kg per bolus with advancement every 4 to 12 hours of similar volumes. In premature infants, feedings are initiated at lower rates or volumes, usually 10 to 20 mL/kg per day. Schedules for progression of tube feeding from initial to target rates are important and may influence tolerance. Conversely, if the protocol is too conservative, it may take an excessively long period of time to reach nutrient goals. The advancement of enteral feeding should be individualized for specific patient issues. As previously discussed, the practice of diluting enteral feeding formulations is not routinely recommended unless necessary to increase fluid intake.⁵⁵ The development of an EN protocol within an institution that outlines initiation and advancement criteria may be a useful strategy to optimize achievement of reaching nutrient goals.¹³

Such a protocol should incorporate assessment of GI tolerance and allow nursing to advance the rate based on pre-established, specific criteria.

COMPLICATIONS AND MONITORING

The majority of complications associated with EN can be categorized as metabolic, GI, and mechanical. The early detection and management of potential complications is necessary to allow for the successful use of EN. In addition, measures to avoid complications should be incorporated into the management of all patients receiving EN and require close monitoring (Table 138–10). The potential causes and guidelines for the prevention and treatment of complications will be discussed.

METABOLIC COMPLICATIONS

Metabolic complications associated with EN are similar to those associated with PN, but the occurrence tends to be lower. Complications related to hydration and electrolyte imbalance and altered glucose control are observed more frequently in patients with underlying organ dysfunction. The micronutrient and water content within enteral feeding formulations are in fixed amounts intended to meet recommended dietary allowances for the average patient. Therefore the frequency of clinical and laboratory assessment to monitor hydration, electrolyte, organ function, and glucose control adequately for a patient who is critically ill is greater than for a stable patient residing in a rehabilitation unit or at home. Patients receiving long-term EN at home may only require laboratory monitoring every 2 to 3 months depending on their clinical status. In addition to macronutrient content, it is important to evaluate the actual content of water and micronutrients provided by the enteral formulations, especially in critically ill patients at high risk for metabolic complications. Supplemental fluid and electrolytes may be required in some patients. Conversely, for patients who have fluid retention or increased serum electrolytes,

TABLE 138–10. Suggested Monitoring for EN Patients to Prevent the Development of Complications

| Parameter | During Initiation of EN Therapy | During Stable EN Therapy |
|---|---------------------------------|--------------------------|
| Vital signs | Every 4–6 h | As needed |
| Clinical assessment | | |
| Weight | Daily | Weekly |
| Length/height (children) | Weekly–monthly | Monthly |
| Head circumference (<3 y of age) | Weekly–monthly | Monthly |
| Total intake/output | Daily | As needed |
| Tube feeding intake | Daily | Daily |
| Enterostomy tube site assessment | Daily | Daily |
| GI tolerance | | |
| Stool frequency/volume | Daily | Daily |
| Abdomen assessment | Daily | Daily |
| Nausea or vomiting | Daily | Daily |
| Gastric residual volumes | Every 4–8 h (varies) | As needed |
| Tube placement | Prior to starting, then ongoing | Ongoing |
| Laboratory | | |
| Electrolytes, BUN/S _{cr} , glucose | Daily | As needed |
| Calcium, magnesium, phosphorus | 3–7 times/wk | As needed |
| Liver function tests | Weekly | As needed |
| Trace elements, vitamins | Patient-specific | Patient-specific |

BUN, blood urea nitrogen; S_{cr}, serum creatinine.

the enteral formulation may need to be changed to one that is more concentrated or provides less of a particular nutrient.

GASTROINTESTINAL COMPLICATIONS

The GI complications associated with tube feeding include high gastric residuals, nausea, vomiting, abdominal distention, cramping, aspiration, diarrhea, and constipation. In general, these side effects can be attributed to drug-related, patient-related, or tube feeding–related factors.

6 A gastric residual volume refers to the volume of contents in the stomach and is measured by using a syringe and aspirating from a large-bore NG or gastrostomy tube. For patients receiving tube feeding into the stomach, gastric residual volumes are widely used as an indicator of tolerance. It is believed, although not well documented, that patients with high gastric residual volumes are at higher risk of vomiting and/or aspiration. It is generally suggested to measure residual volumes every 4 hours in hospitalized patients receiving continuous tube feeding into the stomach.^{73,74}

CLINICAL CONTROVERSY

Clinicians argue about what constitutes an excessive gastric residual volume. In adults, the definition of a high residual volume ranges from greater than 200 mL to greater than 500 mL. In children, residual volumes greater than twice the bolus volume or twice the hourly infusion rate for continuous gastric feedings are considered excessive.

If high gastric residuals occur, the response is often to withhold tube feeding. However, frequent interruptions in the delivery of EN can adversely impact meeting nutrient goals. Because gastric residual volumes are unreliable, symptoms such as abdominal distention, fullness, bloating, and discomfort should also be assessed. A trend in elevated gastric residual volumes is generally more important than an isolated high measurement. If symptoms are present and residual volumes are elevated, a decrease in tube feeding rate may be warranted. It has been recommended that abruptly stopping tube feeding be reserved for patients with overt regurgitation or aspiration.⁷³ Gastric residual volumes should generally be returned to the patient unless they are excessive (greater than 500 mL in adults).⁷³ It may be beneficial to initiate a prokinetic agent such as metoclopramide to increase gastric emptying and enhance tolerance.^{75,76} If high gastric residual volumes persist, a transpyloric feeding tube may be considered for feeding into the small bowel. Other interventions may include a trial of a proton pump inhibitor or histamine₂-receptor antagonist to decrease the volume of gastric secretions, and minimizing the use of narcotics, sedatives, or other agents that may delay gastric emptying.⁵⁵

Aspiration pneumonia is considered the most serious complication associated with tube feeding and is potentially life-threatening. While aspiration is a fairly common event for critically ill patients on tube feeding, progression to aspiration pneumonia is difficult to predict. Risk factors for aspiration include a previous aspiration episode, decreased level of consciousness, neuromuscular disease, structural airway or GI tract abnormalities, endotracheal intubation, vomiting, persistently high gastric residual volumes, and prolonged supine position.⁷⁷ Identification of these risk factors along with close monitoring of gastric residual volumes is recommended for the management of critically ill patients receiving tube feeding. Traditionally, blue food coloring had been added to enteral formulations in an at-

tempt to detect aspiration. However, due to its low sensitivity for detection and association with several serious adverse events, including death, the addition of blue food dye to enteral formulations should no longer be used.^{77,78} An alternative to blue dye is to test the tracheo-bronchial secretions for glucose (the glucose oxidase strip method). This method assumes that the glucose concentration of these secretions is normally less than 5 mg/dL and that higher concentrations are consistent with aspiration of a feeding formulation. Unfortunately, false-positives can occur using this technique due to blood in the specimen or when formulas containing low glucose concentrations (i.e., <200 mg/dL) are used.^{78,79}

Strategies to decrease aspiration risk include those mentioned in the management of high gastric residual volumes. Keeping the patient's head of the bed elevated to a 30- to 45-degree angle during feeding and for 30 to 60 minutes after intermittent boluses is also recommended. This makes it more difficult for feeding to migrate up the esophagus against gravity. Changing from bolus or intermittent to continuous administration may also reduce the risk. Additionally, good oral care is strongly recommended. Aspiration may also occur with improper feeding tube placement or displacement. Therefore regular assessment of tube position is recommended.⁷⁷

The reported incidence of diarrhea in patients receiving EN ranges from 20% to 70% and varies greatly due to the lack of a standard definition.^{55,80} When monitoring for diarrhea, stool frequency, consistency, and volume should be evaluated and previous bowel habits should be considered. One definition of diarrhea is more than three to five liquid stools per day or more than 250 to 500 mL/day (10 mL/kg per day in children) stool output for at least two consecutive days.⁸⁰ A single loose stool does not constitute diarrhea or require intervention.

7 Diarrhea in patients receiving tube feeding may be caused by a number of factors, many of which are unrelated to the feeding. Management should be directed at identifying and correcting the most likely cause(s). Drug therapy is a common cause, particularly broad-spectrum antibiotics. Another drug-related cause is the sorbitol contained in many liquid medication formulations. Sorbitol is used as a sweetening agent to enhance palatability, but acts as an osmotic laxative at a certain dose. In addition, many drugs available in a liquid form are hyperosmolar, which may also contribute to diarrhea. Since many patients receiving tube feeding also receive medications in a liquid form, all medications should be evaluated for their potential contribution. Infectious causes of diarrhea, such as antibiotic-induced bacterial overgrowth by *Clostridium difficile* or other intestinal flora, need to be considered when diarrhea develops. Diarrhea also may occur as a result of malabsorption, owing to the underlying disease state or condition.

Tube feeding–related factors that may contribute to diarrhea include too rapid delivery or advancement of formula, intolerance to the formula composition, administering large volumes of feeding into the small bowel, and formula contamination. Measures to prevent or manage the development of diarrhea related directly to the tube feeding should address these potential causes.⁸¹ If diarrhea occurs when using a fiber-free formulation, consider switching to a fiber-containing formulation. If using a high fat formulation, it may be beneficial to switch to a formulation lower in fat or having a proportion of the fat supplied as MCTs. If protein malabsorption is suspected, switching from an intact protein to a peptide-based source may be beneficial. Avoid lactose-containing enteral formulations, although the majority of products designed for tube feeding are lactose-free. Finally, assess the risk of bacterial contamination of the formula and take steps to minimize any potential risk factors. Once infectious etiologies have been excluded, pharmacologic intervention may be required to

control severe diarrhea, including the use of opiates, diphenoxylate, and loperamide.

MECHANICAL COMPLICATIONS

Mechanical complications of EN are those associated with the feeding tube, including tube occlusion or malposition, and nasopulmonary intubation. Feeding tube occlusion is usually due to the improper administration of medications and/or flushing technique. Kinking of the tube may also cause occlusion. The tube should be flushed with at least 30 mL of water before and after administering any medication. The recommended volume used in children is generally less than 30 mL and depends on the size of the tube. The frequency of flushing should be at least every 8 hours during continuous feeding and before and after each intermittent feeding. If tube occlusion occurs, an attempt to irrigate the tube with warm water should be made. Other fluids such as colas and cranberry juice have been used to irrigate occluded tubes but have not been shown to be any better than warm water. Some success in re-establishing patency has also been shown with the use of pancreatic enzymes mixed in sodium bicarbonate.⁸² In addition, declogging devices specifically designed to unclog feeding tubes are available. They have been designed to either mechanically break through or remove the occlusion or provide an applicator and syringe prefilled with pancreatic enzymes and various powders targeted to restore patency.

Inadvertent tube removal or displacement has been reported to occur in greater than 50% of patients receiving enteral tube feeding.⁸³ An agitated or confused patient may pull at the feeding tube and cause its removal or malposition. Measures to decrease agitation and confusion should be attempted. Various manipulations done to the patient throughout the day may also cause malposition. Securing the tube with tape may be helpful, as well as marking the tube with permanent ink at the exit site to assess for change in position.

When a feeding tube is inserted nasally or orally, there is a risk that the tube may inadvertently enter the tracheobronchial tree. The risk may be higher in patients who have an impaired cough or gag reflex and when a stylet is used for tube insertion. Proper positioning of the tube should always be confirmed by x-ray prior to feeding initiation to avoid inadvertent administration of enteral formula into the lung.

OTHER COMPLICATIONS

A unique complication of tube feedings in children, especially in the first year of life, is the development of feeding disorders due to oral hypersensitivity, poor oral/motor skills, and food aversion. In these children, transitioning from tube to oral nutrition is often difficult and protracted. The involvement of an occupational or speech therapist, behavioral psychologist, or other trained individual, as well as perseverance by the family often is necessary to improve oral intake. Avoidance of a strict nothing by mouth (NPO) status, if possible, and oral stimulation programs for those children who must remain NPO are recommended to avoid this complication.⁸⁴

DRUG DELIVERY VIA FEEDING TUBE

Using enteral feeding tubes to deliver drugs is a common practice. It offers an alternative to parenteral administration in patients unable to take drugs by the oral route. However, in addition to complications of tube occlusion, effects on drug bioavailability and other potential interactions need to be considered when using this route. Medications

have been given as a concomitant bolus administration via the feeding tube or admixed with the enteral feeding formulation.

CONCOMITANT DRUG ADMINISTRATION

8 Concomitant administration of medications with enteral feedings requires awareness of certain limitations. First, determination of tube tip placement should be considered. Medications delivered directly into the stomach allow for the normal capacity of drug dissolution. Medications delivered into the small bowel may result in alterations of drug dissolution because the stomach is bypassed. In addition, therapeutic effect designed to occur within the stomach, such as with antacids and sucralfate, may be influenced by feeding tube route. Because many drugs are best absorbed in the fasted state, they should be administered on an empty stomach as much as possible. Patients receiving bolus gastric feedings may receive medications appropriately spaced between the feedings, but patients receiving continuous feeding will require interruption for drug administration.

Selecting the proper medication dosage form for coadministration with the feeding is another important consideration. Medications in sublingual form, sustained-released capsules or tablets, and enteric-coated tablets should not be crushed and therefore should not be administered via enteral feeding tubes. An extensive list of oral dosage forms that should not be crushed is available in the literature.^{85,86} Solid dosage forms that are appropriate to crush should be prepared as a very fine powder and mixed with 15 to 30 mL of water or other appropriate solvent before administering through the tube. In addition, the content of many capsules may be opened and administered in the same manner. Pellets contained inside microencapsulated dosage forms should generally not be crushed. It may be acceptable to administer intact pellets through the feeding tube, provided that the pellets are small enough and drug absorption is not compromised.^{87,88} To avoid the need to crush a solid dosage form and mix with water, liquid dosage preparations have been used for administration through the feeding tube. However, the risk of GI intolerance should be considered due to hyperosmolality of the liquid formulation and possible sorbitol content.^{87,88} Although the use of a liquid dosage preparation may be more convenient than a solid dosage form, it may not be the best choice if GI intolerance is an issue.

As previously mentioned, adherence to proper flushing technique is necessary to prevent occlusion when administering medication through a feeding tube. At least 30 mL of water in adults and usually 10 to 15 mL in children should be given before and after medication administration to clear the drug through the tube and help get the drug into the stomach. If more than one medication is scheduled for a given time, each should be administered separately and the tube should be flushed with at least 5 mL water between them.^{86,87}

ADMIXTURE OF DRUGS WITH ENTERAL FEEDING

Mixing liquid medications with certain enteral feeding formulations has been associated with several types of physical incompatibilities including granulation, gel formation, separation, and precipitation.^{86,87} Not only can these physical incompatibilities inhibit drug absorption, gel formation potentially may clog small-bore enteral feeding tubes. Physical incompatibility with medications is more common in formulations that contain intact protein than in those with hydrolyzed protein. Also, medication and enteral formula incompatibilities are more common with the use of acidic pharmaceutical syrups. The most prudent recommendation is to avoid the routine admixture whenever possible, especially for nonaqueous preparations and syrups. In the

TABLE 138–11. Medications with Special Considerations for Enteral Feeding Tube Administration

| Drug | Interaction | Comments |
|------------------------|--|--|
| Phenytoin | Reduced bioavailability in the presence of EN | A suggestion to minimize interaction is to hold tube feeding 1–2 h before and after phenytoin, but this has no proven benefit Adjust tube feeding rate to account for time held for phenytoin administration Monitor phenytoin serum concentrations and clinical response closely Consider switching to IV phenytoin route if unable to reach therapeutic level |
| Antibiotics (selected) | Potential for reduced bioavailability due to complexation of drug with divalent and trivalent cations found in enteral feeding | May influence quinolone antibiotics, penicillin, tetracycline, isoniazid, and rifampin Consider holding tube feeding before and after administration Avoid jejunal administration of ciprofloxacin Monitor clinical response |
| Warfarin | Decreased absorption of warfarin due to enteral feeding; therapeutic effect antagonized by vitamin K content of enteral formulations | Adjust warfarin dose based on INR Anticipate need to increase warfarin dose when enteral feedings are started and decrease dose when enteral feedings are stopped |
| Antacids | Altered pharmacologic effect of antacid if administered into the small bowel | Administer antacids only into a feeding tube with the tip placed in the stomach |
| Omeprazole | When omeprazole granules are crushed, the drug rapidly degrades in acid environment of stomach | Omeprazole granules become sticky when moistened with water, but can be mixed with acidic juices to avoid clumping; may be given via large-bore tube, but may occlude small-bore tubes An oral liquid suspension can be extemporaneously prepared for administration via a feeding tube ^a |

^aFrom Phillips et al,⁹² and Quercia et al.⁹³
EN, enteral nutrition; INR, International Normalized Ratio.

clinical setting exceptions do exist, such as adding electrolyte injections of potassium or sodium to enteral formulas to assist in maintaining or repleting the electrolyte requirements for a patient.

DRUG-NUTRIENT INTERACTIONS

9 The most significant drug and nutrient interactions that can occur during continuous enteral feeding are those in which the bioavailability of the drug is reduced and the desired pharmacologic effect is not achieved (Table 138–11). Unfortunately, limited clinical studies are available to document the extent of this problem with enteral feeding. Most of the observations are anecdotal case reports involving few patients. One of the most studied interactions has been the interaction between phenytoin and enteral feeding that results in decreased phenytoin bioavailability. The interaction was first reported in 1982, yet the precise mechanism for the interaction has not been identified.⁸⁹ Phenytoin serum concentrations may decrease by as much as 50% to 75% when phenytoin is given concomitantly with EN. Patients typically require higher than normal phenytoin doses while receiving EN.^{87–90} The patient's clinical response and phenytoin serum concentrations should be monitored closely if phenytoin is given enterally during continuous enteral feeding and after its discontinuation.

CLINICAL CONTROVERSY

A number of methods to minimize the interaction between phenytoin and continuous enteral feeding have been suggested, but no consensus exists. Some clinicians choose holding the feeding for 1 to 2 hours before and after phenytoin administration to minimize the interaction. But since this has not been proven effective and may result in suboptimal nutrition, others choose not to interrupt the feeding.

Decreased bioavailability of certain antibiotics, particularly quinolones, has been documented when coadministered with enteral feeding.^{87,88,91} Although the practice to hold tube feeding for 30 minutes before and 30 minutes after quinolone administration has been recommended, it has not been shown to ultimately improve drug absorption. There is evidence to suggest that ciprofloxacin absorption is significantly decreased when given via a jejunostomy tube, so this practice should be avoided.⁹¹ Warfarin resistance has been documented during enteral feeding, possibly due to decreased absorption or the antagonist effects of vitamin K. Prior to 1980, it was thought that the content of vitamin K in dosages of up to 1330 mcg/1000 kcal of enteral feeding formula was contributing to the pharmacologic interaction with warfarin. Subsequently, the vitamin K content within formulas intended for use in adults has been reformulated to less than 200 mcg/1000 kcal. However, warfarin resistance has continued to be reported and a warfarin dosage increase may be required in patients receiving EN.^{87,88} The patient's International Normalized Ratio should be closely monitored in patients receiving warfarin and enteral feedings. Conversely, when EN is discontinued, a reduction in warfarin dose may be required.

NUTRITION OUTCOME GOALS

Nutrition outcome goals of EN are to reverse protein-calorie malnutrition, maintain an adequate nutritional state, or promote growth and development of infants and children. Assessing the outcome of EN includes monitoring objective measures of body composition, protein and energy balance, and subjective outcome for physiologic muscle function and wound healing (Table 138–12). Besides an improvement in nutrition outcome, another goal of EN is to reduce disease-related morbidity and mortality. Measures of disease-related morbidity include length of hospital stay, infectious complications, and the

TABLE 138–12. Parameters Used to Monitor Enteral Nutrition Efficacy

| Parameter | Comments |
|------------------|--|
| Anthropometrics | Weight (at least weekly; daily in neonates and infants) Serial measurement of triceps skinfold and midarm muscle circumference can be useful in patients on long-term enteral nutrition |
| Muscle function | Physical endurance Grip strength |
| Metabolic | Visceral proteins (albumin and transferrin) at least monthly 24-hour urine urea nitrogen weekly to monthly Indirect calorimetry tailored to patient-specific situations |
| Nutrition intake | Calories, protein, fluid, electrolytes, trace elements, and vitamins |
| Skin integrity | Wound healing Pressure sores |

patient's sense of well-being. Such clinical outcome goals are extremely difficult to document with the use of EN, in part because other factors such as age, underlying comorbidities, extent of injury, immunocompetence, and end-organ complications also affect disease outcome. However, no disease process improves significantly with prolonged starvation. Ultimately, the successful use of EN can avoid the need for PN in patients unable to meet nutrient requirements with an oral diet.

PHARMACOECONOMIC CONSIDERATIONS

Enteral nutrition has consistently been shown to be less expensive than PN. The pharmacoeconomic comparison between EN and PN should include an evaluation of therapeutic outcome relative to the cumulative cost associated with providing the therapy. Therapy costs should include costs related to placement and maintenance of enteral or parenteral access; costs of nutrients and related supplies; the time spent by professional staff in ordering, compounding, delivering, administering, and managing therapy; costs of laboratory monitoring; and costs of managing complications that result from therapy. However, it is very difficult to capture all of these costs and separate cost from charge-based estimates. None of the existing pharmacoeconomic analyses have incorporated all costs related to EN and PN therapy, but selected cost comparisons derived from clinical research trials in institutional settings have been published.^{94–96} The cost of EN has been reported to be approximately one-fourth to one-half that of PN. Incorporating the cost of managing complications related to therapy greatly increases the overall cost of PN compared with EN.⁹⁶ In situations in which improved outcome has not been demonstrated with PN, EN appears preferable on a cost basis.⁷

PEG: percutaneous endoscopic gastrostomy
PEJ: percutaneous endoscopic jejunostomy
PRG: percutaneous radiologic gastrostomy
PN: parenteral nutrition
SCFA: short-chain fatty acid

ACKNOWLEDGMENTS

We gratefully acknowledge Doug Janson, Pharm.D., BCNSP, for his contribution to the previous edition of this chapter.

NUTRITIONAL CONSIDERATIONS IN MAJOR ORGAN FAILURE

Renee M. DeHart and Sunshine J. Yocom

Learning Objectives and other resources can be found at www.pharmacotherapyonline.com.

KEY CONCEPTS

- 1 Lipid intolerance is common in acute renal failure, requiring careful monitoring of serum triglyceride concentrations before and during intravenous lipid administration.
- 2 Carbohydrate calories absorbed and protein lost via renal replacement therapy must be accounted for when designing a parenteral or enteral nutrition regimen for the patient with renal disease.
- 3 Standard mixed amino acids should be used rather than essential amino acid preparations in patients with acute renal failure.
- 4 Patients with renal failure will typically require lower amounts of potassium, magnesium, and phosphorus in the nutritional regimen unless refeeding syndrome is present or continuous renal replacement therapies are used.
- 5 Patients with alcoholic hepatitis or cirrhosis are frequently hypermetabolic when energy requirements are adjusted for lean body mass.
- 6 Hyperglycemia is common in cirrhosis. Patients with fulminant hepatitis are, however, prone instead to hypoglycemia.
- 7 Folic acid and thiamine supplementation is important in patients with liver disease for the prevention of anemia and Wernicke's encephalopathy, respectively.
- 8 In short bowel syndrome, parenteral nutrition should be used to meet nutritional needs in the immediate postoperative period after intestinal resection.
- 9 Increased fluid and electrolyte replacement may be necessary in short bowel syndrome patients to replace gastrointestinal losses. Patients may need increased calcium, magnesium, zinc, and other trace elements due to decreased absorption and/or excessive gastrointestinal losses.
- 10 Patients with ileal resection commonly develop vitamin B₁₂ deficiency, necessitating therapy with parenteral cyanocobalamin.
- 11 As small bowel adaptation occurs, some short bowel syndrome patients receiving parenteral nutrition can be transitioned successfully to enteral nutrition. Early initiation of enteral intake affects adaptation because intraluminal nutrients are a stimulus for this process.
- 12 When a patient is fed with carbohydrates, the amount of carbon dioxide produced markedly exceeds the amount of oxygen consumed in comparison to proteins and fats, which can result in increased ventilatory demand in patients with pulmonary disease. Therefore higher-fat enteral formulas should be considered for use in these patients and overfeeding should be avoided.
- 13 Excessive fluid administration should be avoided in patients with pulmonary disease because it may exacerbate already compromised pulmonary function.
- 14 Phosphorus is essential in respiratory disease for its role in the synthesis of adenosine triphosphate, inadequate stores of which can lead to respiratory muscle weakness. Critically ill, malnourished patients are at risk for phosphorus depletion.

Because organ failure may alter absorption, use, and excretion of nutrients, administration of standard nutrients to patients with organ dysfunction may be inappropriate. Individualization of a nutritional regimen for these patients often requires a planned, disease-specific approach. Different laboratory tests or more frequent monitoring of traditional markers may be necessary to ensure that the desired therapeutic goals are achieved. For example, it is impossible to collect a 24-hour urine specimen to measure urea nitrogen and nitrogen balance in an anuric patient. In this situation, an alternative method of calculating urea nitrogen appearance is required.

Patients with acute organ failure requiring nutrition support often are hospitalized in intensive care units (ICUs). With advances in treating chronic organ failure, increasing numbers of older, chronically ill patients will require nutritional support on a long-term basis. It therefore will become increasingly common for nutrition support to be provided in community and ambulatory settings. Regardless of the setting, the clinician needs a firm pathophysiologic foundation on which to build a pharmaceutical care plan to ensure appropriate outcomes for patients requiring nutritional support.

This chapter discusses the nutritional needs of patients with renal, hepatic, gastrointestinal, and pulmonary failure. The predominant approaches to ensure delivery of safe and efficacious nutrients to patients with these disorders are critically reviewed.

RENAL FAILURE

Major differences exist between the metabolic, fluid, and electrolyte management of patients with acute versus chronic kidney disease (CKD). For example, positive nitrogen balance is more difficult to achieve in patients with acute renal failure (ARF) due to the increased rate of protein catabolism. Additionally, patients with acute renal failure are more likely to develop hyperglycemia during nutritional support and frequently are dialyzed by modalities that are not used commonly for the patient with end-stage kidney disease (ESKD). Because of these differences, the nutritional management of patients with ARF is discussed separately.

ACUTE RENAL FAILURE

EPIDEMIOLOGY

Acute renal failure occurs in approximately 5% of all hospitalized patients. The mortality rate of ARF patients who require renal replacement therapy ranges from 40% to as high as 80%.¹ Severe malnutrition has been found in 42% of patients with ARF and is an independent predictor of in-hospital mortality and increased morbidity from sepsis, shock, dysrhythmias, and acute respiratory failure.² Since malnutrition is an important contributor to mortality from ARF, nutrition support remains a cornerstone in the treatment of these patients.³

PATHOPHYSIOLOGY

Energy Requirements

Energy requirements in this patient population ideally should be measured by indirect calorimetry (see Chap. 135) because energy expenditures of patients with ARF are highly variable. Energy expenditure is close to normal in patients with uncomplicated ARF, but resting energy expenditure (REE) increases by 30% in the presence of sepsis and ARF.³ Typically, ARF patients without underlying hypermetabolic conditions should receive 25 to 30 kcal/kg per day. Those with underlying hypermetabolic conditions can receive up to 35 kcal/kg per day, unless indirect calorimetry indicates otherwise.⁴

Carbohydrate

Hyperglycemia and peripheral insulin resistance are common in ARF. These patients usually have a superimposed illness that may cause glucose intolerance. The etiology of glucose intolerance in ARF is thought to be due to increased levels of glucagon, growth hormone, and catecholamines, all known antagonists of insulin. Other proposed mechanisms include an elevated glucagon:insulin ratio secondary to impaired degradation of these hormones and elevated secretion of inflammatory cytokines.

Fat

Intolerance to intravenous lipid emulsion (IVLE), evidenced by increased serum triglyceride concentrations, is common in ARF. Hypertriglyceridemia is thought to be caused by decreased catabolism of triglycerides and increased synthesis from free fatty acids (FFAs).⁵ Hepatic triglyceride lipase and peripheral lipoprotein lipase activ-

ity may be reduced significantly in ARF patients.³ Insulin resistance and metabolic acidosis may contribute to this process by inhibiting lipoprotein lipase.⁶ Triglyceride concentrations therefore should be measured before administering IVLE to patients with ARF. FFA concentrations also are elevated in ARF.

Protein

Urea, the end product of nitrogen metabolism, accumulates rapidly in ARF. Most patients with ARF have a primary stressful illness that results in ureagenesis, and thus protein breakdown is markedly accelerated.¹ Protein catabolism in ARF may be stimulated as the result of insulin resistance, metabolic acidosis, circulating proteases and inflammatory mediators, and the effects of uremic toxins.⁷ The mechanism may be direct, via modulation of protein synthesis, or indirect, by inhibiting the action of anabolic hormones.⁸

Significant amounts of protein and amino acids are also removed by dialysis. Amino acid losses of 5.2 g per conventional hemodialysis (HD), 7.3 g per high-flux HD, and up to 13 to 16 g/day during continuous renal replacement therapy (CRRT) have been reported.⁹ In one study, CRRT removed urea nitrogen to the same degree as functionally normal kidneys.¹⁰ The clearance of histidine and tryptophan are enhanced, whereas the clearance of phenylalanine and valine are reduced in nondialyzed patients with ARF.¹¹ In patients undergoing CRRT, glutamine represents roughly one-third of all amino acid dialysate losses. Serum glutamine concentrations decrease significantly early during CRRT but return to baseline subsequently, suggesting altered glutamine metabolism early in the course of CRRT.¹²

Fluid, Electrolyte, and Acid-Base Disorders

The volume status of patients with ARF depends primarily on residual urine output and the type of dialysis received, if any. The patient with oliguric ARF will have impaired excretion of sodium and water. In nonoliguric ARF, considerable sodium may be lost in the urine, necessitating replacement to maintain sodium balance. This also applies to the patient who is losing considerable gastric fluids. Patients on CRRT will lose sodium via hemofiltration or dialysis and should be given sodium as part of their CRRT replacement fluid regimen.

Hyperkalemia is observed frequently in ARF secondary to protein catabolism and intracellular potassium release. Hyperkalemia also results from the impaired secretion and excretion of potassium by the kidney and the endogenous release secondary to tissue breakdown. If this is severe, emergent dialysis may be indicated. Patients on CRRT, however, usually will require potassium replacement to avoid hypokalemia due to dialytic potassium losses.

Because phosphorus is excreted renally, hyperphosphatemia is common in ARF. Like potassium, large amounts of phosphorus are released into the circulation secondary to tissue breakdown during ARF. Control of hyperphosphatemia is important because as the calcium-phosphorus product (serum calcium in milligrams per deciliter multiplied by serum phosphorus in milligrams per deciliter) exceeds 55, the risk of developing metastatic calcification increases (see Chap. 44). Conversely, with initiation of dialysis, particularly CRRT, patients must be monitored for dialysis-induced hypophosphatemia.

The net removal of calcium during the continuous dialysis modalities depends on the calcium concentration of the dialysate fluid.¹³ Severe hypocalcemia has been reported when regional citrate anticoagulation has been used for CRRT in ARF and hepatic failure patients.¹⁴

Hypermagnesemia is common in ARF secondary to impaired excretion and endogenous release from tissue breakdown. Both magnesium and calcium losses via CRRT have been quantified recently:

average losses were of 24 mmol and 70 mmol of magnesium and calcium, respectively.¹⁰

Patients with ARF usually have metabolic acidosis because of impaired excretion of organic acids. If potassium and sodium are needed in the PN regimen, they should be added as acetate salts, which will be converted to bicarbonate in the liver. This increase in bicarbonate will partially compensate their metabolic acidosis. Intermittent and continuous dialytic therapies also may help improve the metabolic acidosis accompanying ARF by increasing the removal of these endogenously generated acids, as well as by increasing serum bicarbonate levels as the result of diffusion from the dialysate into the blood. Correction of acidosis was greatest when lactate buffers (lactate > bicarbonate > acetate) were used in one study employing continuous veno-venous hemofiltration (CVVH).¹⁵

Trace Elements

The requirements for trace elements during nutritional support of ARF patients are not well established because trace element accumulation or losses during ARF have not been characterized. Additionally, many of the trace element alterations in ARF may in fact represent an “acute phase reaction.”¹⁴ Zinc and chromium are excreted by the kidney and theoretically can accumulate due to reduced excretion and increased intake secondary to impurities in dialysate or intravenous fluids.¹⁶ In ARF patients undergoing CRRT, zinc intake via nutrition support has been shown to exceed patient losses.¹⁰ Selenium concentrations are

reduced in ARF patients and may result in a decrease in thyroxine concentrations.^{17,18} Because manganese and copper are excreted in bile and zinc and copper are removed by peritoneal dialysis (PD) and HD, most ARF patients receiving parenteral nutrition (PN) should receive trace element supplementation.¹⁹ At least one investigator has recommended giving this supplementation only twice weekly, but not all investigators have agreed on this point.⁴

Vitamins

Little information is available concerning alterations in vitamin requirements in ARF. Reduced plasma concentrations of vitamin A, ascorbate, vitamin D, and vitamin E have been reported in patients with ARF, whereas vitamin K concentrations are relatively increased.²⁰ Losses of vitamins via dialysis also must be considered. Traditional HD clears several water-soluble vitamins such as folic acid, vitamins C and B₁₂, and pyridoxine, but not the highly protein-bound vitamins A and D.¹⁹ The clinical significance of these findings in ARF is unknown. Currently, it seems prudent to administer vitamins at least daily in doses recommended by the Nutrition Advisory Group of the American Medical Association for patients receiving PN (see Chap. 137).⁴ Administration of ascorbic acid should be restricted to under 200 mg/day to avoid secondary oxalosis which may worsen renal function.⁴ If the enteral route is used for nutritional support, vitamin administration should at least meet the recommended daily allowances (RDAs).

► TREATMENT: Acute Renal Failure

■ ADMINISTRATION ROUTES

Most patients with ARF have a superimposed illness that requires nutritional support by the parenteral route. Enteral nutrition (EN) should be considered when patients with ARF have functional gastrointestinal tracts. The products used frequently during EN in ARF are the calorically dense, electrolyte-free or electrolyte-reduced formulas (Table 139–1). These formulas are useful in patients with fluid overload, hyperkalemia, and hyperphosphatemia. Unfortunately, EN is impossible for many patients with ARF because they are critically ill and have an ileus.

■ SPECIALTY PRODUCTS

3 Based on the available data, it appears appropriate to use standard mixed amino acids rather than essential amino acid (EAA) solutions in ARF.⁴ Improved survival and return of renal function were observed decades ago when EAAs plus glucose were compared with glucose alone in patients with ARF.²¹ This led to the marketing of parenteral amino acids containing predominantly or solely EAAs. These products were formulated on the hypothesis that significant nitrogen reuse (urea recycling) occurs during ARF to synthesize nonessential amino acids. Subsequently, several prospective, double-blind studies

indicated no significant reduction in mortality when the EAA formulations were used.²¹

DESIGN AND INITIATION OF THE NUTRITIONAL REGIMEN

Patients with ARF typically require 25 to 35 kcal/kg per day, and a higher caloric intake may be necessary if hypermetabolism is present. In the absence of dialysis, the nutritional formula should be concentrated in a small volume and contain minimal sodium (Table 139–2). In the oliguric patient receiving PD or HD, these restrictions may be lessened, but the formula generally will need to be concentrated. When using these high-dextrose-concentration formulas, careful monitoring of glucose homeostasis (every 6 hours) is important because of the predisposition toward hyperglycemia in ARF and glucose intake should not exceed 5 g/kg per day.⁴ Additionally, CRRT, which is increasingly popular in the treatment of ARF (see Chap. 42), contributes significant calories to a nutritional regimen. This is a direct result of the absorption of glucose from the dialysate or ultrafiltrate replacement fluids: Net uptakes of up to 355 g/day have been reported.²²

Acute renal failure is not a contraindication to IVLE use, despite the changes in lipid metabolism seen in ARF. When the serum triglyceride concentration is less than 300 mg/dL, IVLE (3 to 7 kcal/kg per day) is recommended to prevent essential fatty acid deficiency and to provide a balanced caloric intake. Typically, doses of less than 1 g fat/kg per day will not significantly worsen triglyceride concentrations.⁴

Although individual patient assessment for presence of hypercatabolism and dialytic losses is necessary, it is not uncommon for patients to require 2.5 g/kg per day of protein or more to approach nitrogen balance.²³ Protein restriction to reduce the urea nitrogen appearance (UNA) rate from exogenous protein intake should not be used unless the ARF is thought to be very temporary and no hypercatabolism is present.⁴ Once dialysis therapy is instituted, protein intake should be liberalized to 1 to 1.3 g/kg per day for noncatabolic patients and at least 1.2 to 1.5 g/kg per day for catabolic patients.⁴ Patients undergoing CRRT may require up to 2.5 g/kg per day of

protein. Although this can be done safely while providing a greater percentage of patients with a positive nitrogen balance, a reduction in mortality has not been documented.²⁴

4 Several electrolytes (i.e., phosphorus, magnesium, and potassium) warrant special attention when designing the initial nutritional regimen/formula for the ARF patient. During early ARF, PN solutions should not contain potassium unless the patient is hypokalemic or undergoing CRRT. After several days, the serum potassium concentrations tend to decrease, often necessitating cautious addition of potassium to the PN solution. If the enteral route is used, formulas with minimal potassium may be needed. Serum potassium concentrations may decrease more rapidly in patients receiving CRRT. Potassium losses during CRRT are proportional to the potassium gradient between blood and dialysate. Therefore cautious additions of potassium may be considered earlier in the course of ARF for those patients treated with CRRT. Serum magnesium concentrations do not decrease as quickly as potassium concentrations in patients receiving electrolyte-free nutrition regimens. As serum concentrations decrease toward normal and/or renal function returns, magnesium should be added to the PN solution in small amounts (4 to 6 mEq/L).

Phosphorus can be omitted from the nutritional formula of patients receiving PN until the phosphorus level approaches normal (<5 mg/dL). It is prudent to monitor phosphorus concentrations daily and to add phosphorus in small doses once the serum concentration is below 4 mg/dL. Failure to do so can lead to severe hypophosphatemia (see Chap. 49) despite continued renal failure, especially in the patient treated with CRRT. Patients with persistently high serum phosphorus concentrations who have a functional gastrointestinal tract (GIT) can be prescribed phosphate-binding therapy (see Chap. 44) and enteral feedings low in phosphorus to minimize the absorption of exogenous phosphorus.

EVALUATION OF THERAPEUTIC OUTCOMES

Despite recent advances in treatment, acute renal failure is still associated with significant mortality.³

CLINICAL CONTROVERSY

There is no clear consensus on the benefit of nutritional supplementation on mortality in ARF. While some data suggest that malnourished patients with ARF experience a higher mortality rate, not all studies have demonstrated a survival benefit from nutrition support.

To date, there is no clear consensus regarding a benefit of nutritional supplementation on the outcome parameters of renal recovery or mortality. While data suggest that malnourished ARF patients experience significantly higher mortality rates (odds ratio of in-hospital mortality of 7.21) than ARF patients without malnutrition,² not all studies have shown a survival benefit from aggressive nutritional support.²⁴ When nutrition support is used, the evaluation tools used in monitoring ARF patients are similar to those used for other patients receiving PN and EN (see Chaps. 137 and 138).

CHRONIC KIDNEY DISEASE

Chronic kidney disease (CKD), as evidenced by the inability of the kidneys to excrete nitrogenous and other waste products, usually develops over months to years (see Chap. 43). Malnutrition secondary to reduced oral nutrient intake frequently is evident when the glomerular filtration rate (GFR) drops below 20 to 25 mL/min. Patients with CKD are considered to have ESKD when the GFR falls below 15 mL/min (see Chap. 44). Malnutrition is also a common occurrence in ESKD, not only because of decreased oral intake, but also due to increased nutrient losses via the various renal replacement therapies. Because of its chronicity, malnutrition in these patients is treated most frequently in the ambulatory setting with EN.

EPIDEMIOLOGY

Protein-energy malnutrition is very common in the ESKD patient population. Significant malnutrition has been noted in 20% to 36% of ESKD patients undergoing HD and in up to 45% of patients commencing continuous ambulatory peritoneal dialysis (CAPD) or cycling peritoneal dialysis (CPD).^{25,26} In one of the larger studies to date (n = 1397), mean dietary calorie and protein intake in those 50 years of age and older was 22 kcal/kg per day and 0.9 g/kg per day, respectively.²⁷ Both these values are lower than published recommendations for patients with CKD.²⁸ Protein-energy malnutrition is a significant predictor of morbidity and mortality in most studies of patients with ESKD. However, there appears to be a gender difference in nutritional status in ESKD patients: women tend to have a higher prevalence of malnutrition²⁶ and poorer nutritional outcomes, yet a lower mortality rate.²⁹

PATHOPHYSIOLOGY

Carbohydrate

In general, ESKD patients are not as nutritionally stressed as patients with ARF; however, more than one-half of ESKD patients have insulin resistance and hyperglycemia. This has been attributed to the increased glucagon:insulin ratio, resulting in protein breakdown and gluconeogenesis. In patients with normal peritoneal transport on CAPD, roughly 60% of glucose in the dialysate is absorbed. One method of estimating the quantity of glucose absorbed is: glucose absorbed (g/day) = 0.89x (g/day) - 43, where x is the total amount of dialysate glucose instilled daily. This dialysate glucose absorption can worsen existing hyperglycemia and contribute significantly to the patient's energy intake. Therefore, kwashiorkor-type malnutrition is common. Although glucose control is not problematic unless the patient is diabetic, infected, or subjected to operative stress, insulin can be added to CAPD bags to control hyperglycemia (see Chap. 45).

Fat

Hypertriglyceridemia is common in ESKD patients.³⁰ This is mainly due to decreased catabolism of triglycerides secondary to decreased

hepatic lipoprotein lipase activity.⁵ Most ESKD patients receiving HD also receive heparin, which activates lipoprotein lipase and converts triglycerides to FFAs and glycerol. Carnitine, an amino acid necessary for the transport of long-chain fatty acids across mitochondria where oxidation results in energy production, is removed by HD and CAPD, and therefore serum carnitine concentrations typically are reduced in ESKD.³¹

CLINICAL CONTROVERSY

The effect of carnitine supplementation on plasma lipid profiles is controversial. Studies of carnitine for this indication have varied widely. Of 32 studies reviewed, 23 failed to find a change in triglyceride concentrations, whereas one actually demonstrated a 22% increase.³²

Current guidelines do not advocate carnitine administration for the treatment of hypertriglyceridemia.³² Studies of carnitine for this indication have varied widely in duration and have used both oral and intravenous administration in varying doses (1 mg/kg to 2 g/day intravenously, 10 mg/kg per day to 3 g/day orally). Patients receiving long-term dialysis treatment also have been shown to accumulate remnants of triglyceride-rich lipoproteins. This lipoprotein abnormality can result in type III hyperlipidemia with increased intermediate-density lipoprotein.

Leptin, which is produced and secreted by fat cells, appears to function as a lipostat mechanism via regulation of satiety (see Chap. 140). Leptin concentrations often are elevated in ESKD patients, particularly those undergoing CAPD.³³ Hyperleptinemia in ESKD patients may correlate positively with body fat mass³⁴ and negatively with lean body mass.³³ Further study is required to define the relationship between leptin concentrations and nutrition status in patients with CKD.³⁵

Protein

Secondary analysis of the Modification of Diet in Renal Disease Study indicated that in nondiabetics, a reduction of dietary protein intake may slow the rate of renal disease progression and ultimately delay the onset of dialysis³⁶ (see Chap. 43). Meta-analyses of diabetic as well as nondiabetic patients suggest that dietary protein restriction to 0.5 to 0.85 g/kg per day is weakly associated with slowing of the progression of renal disease.³⁷ The recent National Kidney Foundation Kidney Disease Outcomes Quality Initiative guidelines for nutrition in patients with CKD recommend a diet providing 0.6 g/kg of protein per day for those with a GFR of less than 25 mL/min.³² Although the safety of low-protein diets has been questioned, one analysis strongly suggests that for carefully selected and monitored patients, protein intakes of as low as 0.3 g/kg per day supplemented with EAAs can be used safely.³⁸ Although it has been suggested that vegetable-based low-protein diets may further slow progression of renal failure beyond that of animal-based low-protein diets, not all studies have found this to be true.³⁹

ESKD patients receiving CAPD require special attention due to protein losses across the peritoneal membrane. Peritoneal protein losses typically range from 5 to 15 g/day in patients treated by CAPD.³² PD protein losses, however, do not predict risk for malnutrition (as measured by serum albumin concentration) in all patients.³² Nonetheless, these losses should be taken into consideration when designing the PN or EN formula for the CAPD patient. Recent guidelines suggest that dietary protein intake of at least 1.2 to 1.3 g/kg per day (at least 50% of high biologic value) is needed to consistently achieve neutral or positive nitrogen balance in nonacutely ill CAPD patients and clinically stable HD patients.³² Dialysate protein losses also must be examined for the ESKD patient undergoing HD. The amount of protein lost via HD depends on the dialysis membrane used and whether the dialyzer is being reused. Typical losses are 10 to 12 g per dialysis session, but this may be increased by up to 50% with dialyzer reuse.³² These losses must be considered when designing the protein regimen for the patient.

Fluid and Electrolytes

Hyponatremia, often due to overhydration, is common in CKD, but usually does not require additional administration of sodium. Regular dialysis is the principal means for control of body water and serum sodium concentration in the ESKD patient.

Patients with CKD or ESKD who develop hyperkalemia generally have ingested excessive potassium relative to the potassium-removing capacity of the failing kidney (and dialysis, in the case of ESKD). The undernourished CKD or ESKD patient receiving PN, however, may require considerable potassium as new body cell mass is synthesized. When inappropriately low amounts of potassium are given during refeeding, hypokalemia may develop.

Patients with CKD or ESKD often are treated for hyperphosphatemia with phosphorus-restricted diets and phosphate binding agents (see Chaps. 43 and 44). When these patients receive aggressive nutritional support, the combination of refeeding (cellular uptake of phosphorus for synthesis of body cell mass) and vigorous phosphate-binding therapy can result in hypophosphatemia.

Clinically significant hypermagnesemia is less common in patients with CKD and ESKD compared with ARF. It is usually added to the PN solution in reduced doses (4 mEq/L or less), and serum concentrations need to be monitored.

Metabolic acidosis, a common complication of ESKD, is associated with increased protein degradation and decreased synthesis of albumin.³² Correction of acidosis in ESKD patients may be associated with increases in serum albumin, body weight, and midarm muscle circumference, and fewer hospitalizations.^{40,41} Appropriate stabilization of serum bicarbonate concentrations (>22 mEq/L) via alteration of the dialysate bicarbonate concentration or administration of oral bicarbonate salts thus seems a prudent nutritional intervention in these patients (see Chap. 44 and 51).

Trace Elements

There are considerable data regarding trace element requirements in patients with ESKD.¹⁹ Decreased zinc concentrations in dialysis pa-

tients have been linked to taste disturbances and sexual dysfunction.¹⁶ Zinc supplementation, however, has not universally reversed these anomalies. Although serum concentrations of this trace element are decreased, total body stores of zinc in ESKD often are increased.¹⁶ This suggests a redistribution of zinc or increased need to maintain normal enzymatic function in ESKD.

Serum chromium concentrations are elevated in chronic HD and CAPD patients,¹⁶ perhaps due to the fact that needles used during HD and the peritoneal and hemodialysate fluids are sources of chromium. Both HD and CAPD patients have been found to have decreased selenium concentrations⁴² that can be increased with oral selenium supplements of 135 to 140 mcg/day in HD patients.⁴³ It appears that for patients undergoing HD, significant selenium losses occur during dialysis.⁴⁴

The trace element with the most established significance in ESKD is aluminum. Central nervous system toxicity is linked to the presence of aluminum in the dialysate or the excessive use of aluminum-containing medications. Consequently, the concentration of aluminum in dialysis solutions has been reduced and aluminum-containing antacids are no longer routinely used as phosphate binders. Aluminum toxicity can be treated with deferoxamine, as discussed in Chap. 44.

Vitamins

Vitamin status is better defined in CKD patients than those with ARF. CKD patients are prone to develop water-soluble vitamin deficiencies because of decreased dietary intake secondary to anorexia and restriction of certain foods because of their protein, potassium, or phosphorus content. Additionally, in the ESKD patient, HD losses of ascorbic acid, folic acid, and pyridoxine are common. Plasma ascorbic acid concentrations have been found to be normal in CAPD patients⁴⁵ but significantly reduced in HD patients.⁴⁶ The highly protein-bound vitamins (A, D, and B₁₂) are not removed significantly by HD.¹⁹ Vitamin D deficiency is correlated with decreased serum albumin concentrations, and supplementation of vitamin D has increased serum albumin concentrations significantly in deficient patients.⁴⁷ Vitamin A concentrations often are elevated in CKD and ESKD and can lead to hypervitaminosis A and its cirrhosis-like syndrome. Conversely, vitamin E supplementation may have a distinct benefit to patients with ESKD. Increased oxidative stress in ESKD may contribute to the accelerated atherosclerosis in these patients. Vitamin E in doses of 800 international units per day has been shown to decrease low-density lipoprotein oxidation in patients with ESKD, especially in patients undergoing CAPD.⁴⁸ Thiamine concentrations decrease during dialysis; supplementation within the RDA recommendations is sufficient to keep concentrations in the normal range.⁴⁹ Elevated concentrations of homocysteine are associated with an increased risk of cardiovascular disease. Hyperhomocysteinemia is common in patients with ESKD. Folate doses from 2.5 mg three times weekly to 60 mg/day have lowered homocysteine concentrations in ESKD patients, but have not completely reduced concentrations to normal.^{50,51}

► TREATMENT: Chronic Kidney Disease

■ ADMINISTRATION ROUTES

CKD and ESKD patients who require nutritional support rarely need PN because their GIT usually is functional. The calorically dense low-electrolyte enteral formulas (see Table 139–1) are particularly

useful. Even though ESKD patients receive regular dialysis, many are anuric between dialysis sessions, so excess fluid intake is a potential problem. Nepro, Magnacal Renal, NutriRenal, and Re/Neph are marketed specifically (due to their high caloric density and low electrolyte content) for the ESKD patient who receives regular dialysis. Suplena and Renalcal Diet, which are lower in protein, can be used in

protein-restricted CKD patients not yet undergoing HD or CAPD. If there is superimposed illness that precludes EN, standard mixed amino acids should be used as the protein component of the PN solution.

The association of poor nutritional status and increased morbidity and mortality in ESKD has led to the development of alternative nutritional delivery systems for the ESKD patient. One such approach is intradialytic parenteral nutrition (IDPN), or the provision of glucose–amino acid–lipid admixture during HD. IDPN typically allows for the infusion of 650 to 1100 kcal per session (250 mL of 50% to 70% dextrose and 250 mL of 10% to 20% lipids) and 50 to 90 g of protein (500 mL of 10% to 15% amino acids).⁵² An evidence-based evaluation of 24 studies employing IDPN found that the use of IDPN was associated with decreased mortality, but only 3 of the 24 studies were randomized.⁵³ Because of the weaknesses of the data, IDPN should be reserved for malnourished patients who have: serum albumin <3.4 g/dL, weight loss >10% of ideal body weight, dietary history of intake of <25 kcal/kg per day, and failed attempts at oral supplements and enteral tube feedings.⁵²

Amino acid dialysate (AAD) is the IDPN counterpart for the CAPD patient. This technique entails using a 1.1% amino acid solution in place of one or two of the dextrose-containing PD exchanges per day. Improvements in serum transferrin and total protein concentrations have been observed in malnourished CAPD patients; however, no beneficial effect has been noted on patient mortality.⁵⁴ Adverse effects of this therapy have included exacerbations of uremic symptoms (due to increases in blood urea nitrogen) and metabolic acidosis. Not all studies have demonstrated benefits from this intervention.⁵⁵ In summary, AAD may be useful in the treatment of malnourished CAPD patients, but better designed studies are needed.

TABLE 139–3. Initial Enteral Nutrition Prescription for Patients with End-Stage Kidney Disease

| Nutrient | Recommendation |
|---------------------|--|
| Nonprotein calories | 30–35 kcal/kg per day for HD 25–35 kcal/kg per day CAPD (including calories from glucose absorption of dialysate) |
| Protein | 1.1–1.4 g/kg IBW for HD 1.2–1.5 g/kg IBW for CAPD |
| Sodium | 2–3 g/day for HD ^a 2–4 g/day for CAPD ^a |
| Potassium | 40 mg/kg IBW ^a |
| Phosphorus | Less than 17 mg/kg IBW ^a |
| Calcium | 1000–1500 mg/day ^a |
| Fluid | 500–750 mL + daily urine output for HD To maintain appropriate fluid balance for CAPD |

^aIndividualized based on patient’s laboratory values. CAPD, continuous ambulatory peritoneal dialysis; HD, hemodialysis; IBW, ideal body weight. From Wiggins et al.²⁸

Recombinant human growth hormone (rhGH) in doses of 0.2 international unit/kg per day subcutaneously has been used experimentally in adults with ESKD to enhance anabolism; weight gain equal to 1.2 kg and increased transferrin concentrations have been reported after 4 weeks.⁵⁶ In the future there may be a role for rhGH in the treatment of ESKD patients who have inadequate oral

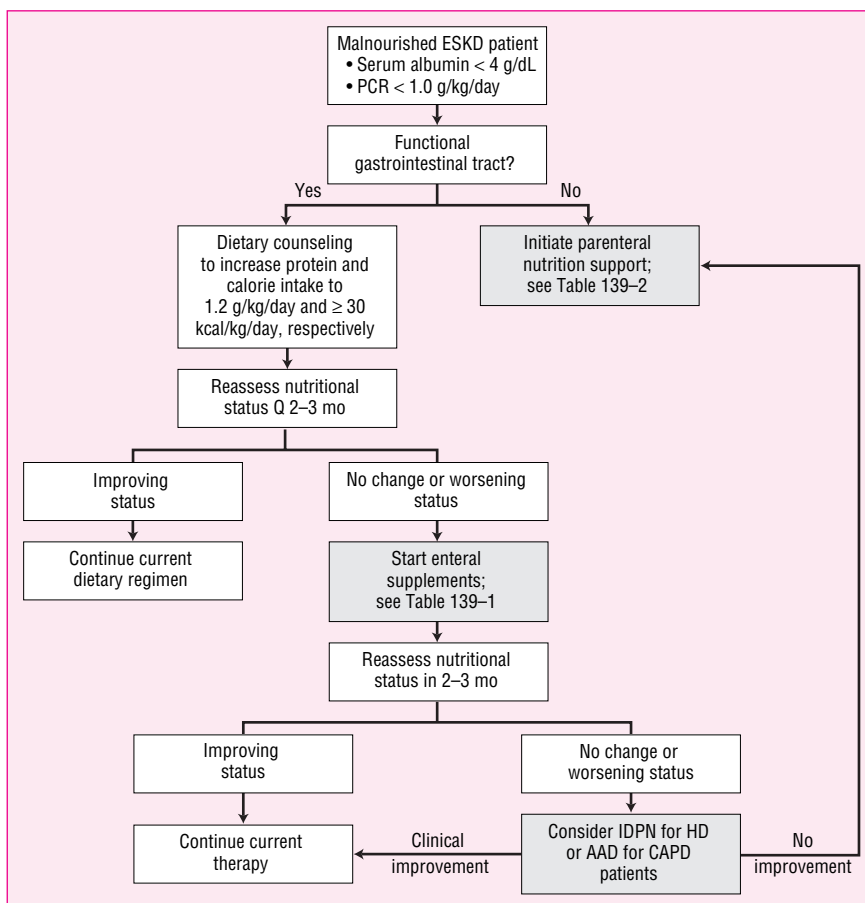

FIGURE 139–1. An algorithmic approach to nutritional support in the patient with end-stage renal disease.

intake despite appropriate dietary counseling and oral supplements.⁵⁷

DESIGN AND INITIATION OF THE NUTRITIONAL REGIMEN

Current recommendations that factor in concurrent illnesses and the likelihood of preexisting malnutrition advocate 35 kcal/kg per day and 1.2 g/kg per day of protein for chronic HD patients and 1.2 to 1.3 g/kg per day of protein for CAPD patients.³² This is higher than the spontaneous dietary intake in most dialysis patients, as previously discussed. Therefore dietary counseling is important to encourage compliance with these recommendations.

Several electrolytes warrant special attention when providing PN or EN to a patient with CKD or ESKD. Generally, sodium should be administered to CKD patients during nutritional support only to replace losses in order to avoid overhydration. Although these patients also are predisposed to hyperkalemia, once anabolism is attained in CKD patients, potassium requirements may be as high as 40 to 80 mEq/day. This dose needs to be given carefully and requires serum potassium concentration monitoring. Clinically significant hypomagnesemia is less common in patients with CKD compared with ARF. It is usually added to the PN solution in reduced doses (4 mEq/L).

4 Patients with CKD or ESKD often are treated for hyperphosphatemia. With aggressive nutritional support, the combination of refeeding and phosphate-binding therapy can result in hypophosphatemia. Decreasing or temporarily discontinuing the phosphate-binding therapy is appropriate if this occurs. Thereafter conservative amounts of phosphorus may need to be administered.

Some practitioners advocate withholding trace elements from CKD and ESKD patients receiving PN. There are no published guidelines specific for the use of trace elements in these patients. Because serum concentrations in ESKD patients of certain trace elements are normal (e.g., manganese) and others are decreased (e.g., zinc and selenium), the standard dietary intake of these trace elements is recommended, and standard trace element supplements should be added to PN regimens.¹⁹ Additional zinc and selenium supplementation may be considered in documented cases of deficiency.

During PN in CKD or ESKD patients, elimination or reduction of the dose of vitamin A is recommended. Dialytic losses of ascorbic acid, folic acid, and pyridoxine are common. Thus ESKD patients should receive ascorbic acid 50 to 100 mg/day, pyridoxine 5 to 10 mg/day, and at least 1 mg/day folic acid in addition to the other essential vitamins.¹⁹ Typical PN and EN prescriptions for a patient with ESKD are presented in Table 139–2 and Table 139–3, respectively.²⁸

HEPATIC FAILURE

The liver is the primary organ involved in the digestion, metabolism, and storage of nutrients. When functional capacity is depressed, profound nutrient intolerance (hyper- or hypoglycemia, hypertriglyceridemia, and hepatic encephalopathy) may result. Other sequelae that accompany the failing liver are fluid and electrolyte imbalances, vitamin deficiencies, and malnutrition. Since it is estimated that 80% of patients with alcoholic liver disease and almost 100% of patients awaiting liver transplantation have some degree of malnutrition, nu-

TABLE 139–4. Routine Nutritional Monitoring in Patients with End-Stage Kidney Disease

| Parameter | Frequency |
|--|---|
| Predialysis serum albumin | Monthly |
| Percentage of usual postdialysis or postdrain body weight | Monthly |
| Subjective global assessment | Every 6 months |
| Protein equivalent of total nitrogen appearance (PNA) ^a | Monthly for HD, every 3–4 months for CAPD |
| Dietary interview and/or diary | Every 6 months |
| Predialysis prealbumin | As needed |
| Anthropometry | As needed |
| Dual energy x-ray absorptiometry | As needed |

BUN, blood urea nitrogen. CAPD, continuous ambulatory peritoneal dialysis; HD, hemodialysis.

^aBeginning of week PNA = $Co/[36.3 + (5.48)(spKt/V) + (53.5/spKt/V)] = 0.168$, where Co is predialysis BUN and spKt/V, the single-pool index of hemodialysis adequacy = $\ln(R - 0.08 \times t) + [4 - (3.5 \times R)] \times UF/W$ (R is postdialysis: predialysis BUN ratio, t is dialysis session in hours, UF is ultrafiltration in liters, and W is postdialysis weight in kilograms) (see Chap. 45).

From National Kidney Foundation.³²

An algorithmic approach to improve nutritional status and ensure optimal outcomes is presented in Fig. 139–1.⁵⁸

EVALUATION OF THERAPEUTIC OUTCOMES

The short- and long-term monitoring plan for the ESKD patient receiving PN or EN needs to be carefully tailored. Special attention should be paid to maintenance of fluid and electrolyte homeostasis. This can be achieved via frequent (daily) monitoring of serum electrolyte concentrations (e.g., sodium, potassium, phosphorus, magnesium, and calcium) and fluid balance. Serum glucose concentrations should be followed frequently (four times daily) in the ESKD patient who develops persistent hyperglycemia.

Because protein-energy malnutrition is a significant predictor of morbidity and mortality in ESKD patients, monitoring to ensure the effectiveness of the long-term nutritional plan becomes critical. Albumin is perhaps the most studied marker of nutritional efficacy in this patient population. Increased serum albumin concentrations are correlated with increased survival. Thus monitoring of serum albumin concentrations should be considered a critical component of the monitoring plan to ensure patient longevity. Appropriate routine monitoring parameters to employ are listed in Table 139–4.³²

tritional support is an important component of the overall care of the patient with liver disease.⁵⁹

EPIDEMIOLOGY

It is estimated that 30% of all cirrhotic patients have protein-energy malnutrition, 40% have protein malnutrition, and 10% have energy malnutrition.⁶⁰ Additionally, among alcoholic cirrhotic patients, 73% of patients have midarm muscle circumferences below the fifth percentile, and 51% have tricep skinfold thickness below the 25th

percentile, which is indicative of protein and energy malnutrition, respectively.⁶¹ Aggressive support is thus imperative to optimize their outcomes and to increase the likelihood of liver transplantation success.

PATHOPHYSIOLOGY

ENERGY

5 Resting energy requirements in stable cirrhotics can appear to be normal, but most are hypermetabolic when the alterations in lean body mass are factored in.⁵⁹ The Harris-Benedict equation for estimating caloric needs usually underestimates their needs by 15% to 20%.⁶² This underscores the need for patient-specific regimen design and monitoring. An initial energy provision of 25 to 35 kcal/kg per day for cirrhotic patients without underlying malnutrition and 35 to 40 kcal/kg per day for those with concurrent malnutrition is recommended.⁵⁹

CARBOHYDRATE

In healthy adults, approximately 60% of absorbed glucose is taken up by the liver and used for glycogen synthesis, triglyceride synthesis, and glycolysis. In general, glycogen synthesis and glycolysis are enhanced by insulin, whereas gluconeogenesis and glycogen breakdown are controlled by glucagon.

6 Hyperglycemia is common in cirrhosis as a result of peripheral insulin resistance, which is mediated by a decreased binding to insulin receptors and defective postreceptor signal handling in peripheral tissues. Plasma concentrations of insulin are elevated with or without a glucose stimulus. This makes administration of large doses of glucose problematic because administration of insulin to control hyperglycemia may not improve use substantially.

Patients with fulminant hepatitis are prone to hypoglycemia because hepatic glucose production is depressed secondary to decreased glycogen stores and diminished gluconeogenesis. Also, impaired degradation of insulin by the damaged liver may contribute to this disorder. A continuous intravenous infusion of glucose usually prevents hypoglycemia in acute hepatitis, but concentrations greater than 10% glucose may be needed in more severe cases.

FAT

The liver is responsible for synthesis of cholesterol, high-density lipoproteins, and very-low-density lipoproteins. The enzymes lipoprotein lipase and lecithin-cholesterol acyltransferase also are synthesized in this organ. Increased serum triglyceride and FFA concentrations are encountered in patients with hepatic failure, primarily due to the increased lipolysis. The significant insulin resistance that can be seen in cirrhosis causes a shift to lipids as a fuel source.⁵⁹ Whereas only 35% of total calories are derived from fat in normal patients after an overnight fast, this can increase to 75% in patients with cirrhosis.⁶² Incorporation of late evening snacks in patients with liver cirrhosis may correct abnormal substrate metabolism, increase carbohydrate, and decrease fat oxidation rates.^{63,64}

Patients with severe liver failure may be at increased risk for essential fatty acid deficiency: the ratio of nonessential to essential fatty acids was found to be increased in patients with acute and chronic liver failure. Poor oral intake of fat and dietary fat malabsorption in patients with cirrhosis both contribute to essential fatty acid deficiency. These changes were due to decreased linoleic acid and increased serum

oleic acid concentrations.⁶⁵ The concentrations of linoleic acid can be increased with administration of an average of 33 g/day of IVLE supplementation.⁶⁶ Despite concerns of impaired clearance of long-chain triglycerides in IVLE due to impaired synthesis of apoprotein CII in cirrhotic patients, IVLE solutions have been given safely to patients with fulminant hepatic failure.⁵⁹

Diarrhea and steatorrhea are common in patients with hepatic cholestasis because of intestinal malabsorption (due in part to mucosal edema from hypoalbuminemia), inadequate bile acid delivery to the duodenum, and pancreatic dysfunction with decreased secretion of lipase.⁶² Micelle formation is impeded, and thus the long-chain fatty acids pass through the colon, resulting in a foul-smelling, soapy diarrhea.

PROTEIN

Nitrogen requirements for the patient with liver failure are not unlike those of normal subjects, but intolerance to protein is common, and protein restriction has been used successfully as part of the therapy. A dilemma arises when the diet becomes so restrictive that malnutrition results, and the patient becomes susceptible to infection and other complications. Overzealous use of protein to correct nutritional deficits invariably results in hepatic encephalopathy.

Because the liver metabolizes the aromatic amino acids (i.e., phenylalanine, tyrosine, and tryptophan), methionine, and glutamine, the plasma concentrations of these amino acids are elevated in cirrhotic patients. Plasma concentrations of the branched-chain amino acids (BCAAs) (i.e., valine, leucine, and isoleucine) often are depressed because these amino acids are metabolized by skeletal muscle. This altered plasma aminogram contributes to the development of hepatic encephalopathy.

FLUID AND ELECTROLYTES

Patients with severe cirrhosis often have ascites and peripheral edema. The excess of total body sodium in the presence of an even greater excess of total body water results in hyponatremia. Salt and fluid restrictions are required in order to avoid exacerbating this overhydrated state (see Chap. 49). Caution must be exercised, however, because severe sodium and fluid restriction may result in intravascular depletion, which may cause or exacerbate hepatic encephalopathy.

Hypokalemia is common in the patient with liver failure who has normal renal function. Poor nutritional intake and vomiting may initiate this disorder. Severe vomiting may lead to volume contraction metabolic alkalosis, with increased renal excretion of potassium. Secondary hyperaldosteronism, seen in the liver failure patient with intravascular depletion, also increases renal excretion of potassium. Loop diuretic therapy causes increased renal excretion of potassium, whereas diarrhea from lactulose therapy increases fecal excretion of potassium. All these conditions can lead to profound hypokalemia. Therefore, potassium requirements in the liver failure patient receiving specialized nutritional support often are increased substantially.

Poor nutritional intake secondary to alcohol abuse and increased excretion of magnesium secondary to diuretic therapy contribute to hypomagnesemia. Even in cirrhotic patients with normal serum magnesium concentrations, muscle magnesium has been found to be depleted and independently associated with hepatic encephalopathy.⁶⁷ During nutrition support, requirements for phosphorus are also substantially supranormal because synthesis of body cell mass occurs. Therefore this population is at risk for developing hypophosphatemia during refeeding.

TRACE ELEMENTS

Many patients with liver failure have a malabsorption syndrome and chronic diarrhea. Chronic diarrhea causes zinc deficiency because stool contains substantial quantities of zinc. Cytokines such as tumor necrosis factor, interleukin-1, and interleukin-6 may stimulate metallothionein, an intestinal zinc-binding protein, thereby inhibiting zinc absorption. Considering the importance of zinc in metalloenzyme reactions, wound healing, immunocompetence, and the senses of taste and smell, patients with chronic diarrhea or large ostomy losses should be suspected of having zinc deficiency; measurement of serum concentrations may be used to confirm such deficiencies. Patients receiving a protein-restricted diet may be at additional risk because substantial amounts of zinc are found in red meat.

Because copper and manganese are excreted in the bile, it has been recommended that these two trace elements not be administered or be administered in reduced doses to patients with serious cholestasis. Direct measurements of manganese in the globus pallidus of cirrhotic patients who died in hepatic coma were two- to sevenfold higher than expected.⁶⁸ These findings suggest that reduced quantities of manganese should be provided in the nutritional formulation to avoid exacerbating encephalopathy in the patient with chronic liver disease.

An association between alcoholism and low serum selenium concentrations has been reported.⁶⁹ Because selenium is important in

maintaining the enzyme glutathione peroxidase, a deficiency of this trace element has been implicated as a cause of hepatic injury in the alcoholic patient. However, because human serum contains at least three fractions of selenium, the use of serum selenium concentrations as an accurate marker for selenium deficiency is controversial.

VITAMINS

▶ Folic acid deficiency, the most common vitamin deficiency, may lead to megaloblastic anemia, whereas thiamine deficiency may result in Wernicke’s encephalopathy after rehydration with intravenous glucose. Depletion of hepatic stores of vitamin A, pyridoxine, folic acid, riboflavin, pantothenic acid, vitamin B₁₂, and thiamine have been reported in patients with hepatic failure. Poor intake and malabsorption are the principal causes of vitamin deficiencies in patients with chronic liver disease.

Because vitamin D is metabolized to one of the active forms, 25-hydroxyvitamin D, in the liver, low concentrations of this vitamin are seen in patients with biliary cirrhosis. Impaired absorption of dietary vitamin D also may contribute to these low serum concentrations and the resulting osteoporosis. It is unclear whether vigorous supplementation of these fat-soluble vitamins should be provided during nutritional support, but clearly, therapeutic doses are indicated when a deficiency is documented.

▶ TREATMENT: Hepatic Failure

■ ADMINISTRATION ROUTE

If the GIT is functional and accessible, EN should be attempted. The indications for PN in the patient with liver failure are similar to those for general hospitalized patients. In most cases, PN in the patient with liver failure can be accomplished via the administration of standard mixed amino acids (Fig. 139–2).

An enteral product is marketed as a supplement for patients with hepatic encephalopathy (NutriHep). It has increased amounts of BCAAs and reduced amounts of aromatic amino acids (AAAs)

and methionine. NutriHep meets the U.S. RDA vitamin and mineral requirements, contains a high percentage of medium-chain triglycerides (MCTs), and is supplemented with carnitine. Clinical trials using BCAA products have yielded inconsistent outcomes with regard to both short-term improvement in encephalopathy as well as mortality benefit.⁷⁰ Studies investigating the longer-term effects of using BCAAs preferentially are lacking to date.

There has been considerable interest in the use of vegetable-protein diets in the chronic management of patients with cirrhosis and hepatic encephalopathy. Enthusiasm for this therapy is based on the reduced amounts of AAAs and methionine in vegetable protein. The

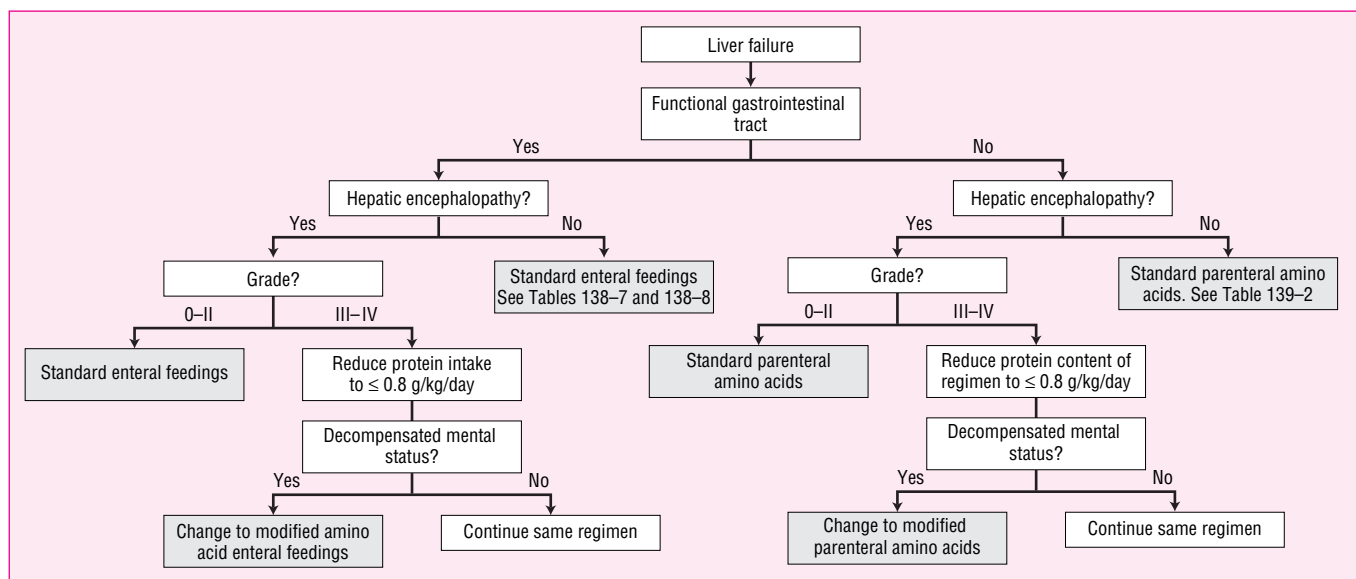

FIGURE 139–2. An algorithmic approach to nutritional support for the patient with hepatic failure.

beneficial effects of vegetable protein also may result from decreased nitrogen absorption in response to decreased gastrointestinal transit time or an increased fecal nitrogen excretion by colonic bacterial flora. However, compliance is more difficult to achieve with vegetable-based than animal-based protein diets in a large number of patients.

SPECIALTY PRODUCTS

The major controversy in nutritional support of the patient with liver failure has centered around the use of protein products. Modified amino acid solutions for PN (HepatAmine, others) are marketed for patients with liver failure and hepatic encephalopathy. They are enriched with BCAAs and have reduced amounts of AAAs and methionine. The products are formulated on the basis of the false neurotransmitter hypothesis, which concludes that hepatic encephalopathy may be due to increased AAA concentrations in the central nervous system.

BCAA products have not universally improved nitrogen balance. Standard amino acid mixtures can be used successfully without worsening encephalopathy. Studies examining improvement in encephalopathy or mortality rates with use of these modified amino acids have yielded conflicting results. This, coupled with the increased cost of these products, has led most clinicians to reserve these products for patients with severe encephalopathy who decompensate on standard amino acids despite continued lactulose-neomycin therapy.

CLINICAL CONTROVERSY

While specialty BCAA solutions have been shown to improve encephalopathy and reduce mortality in the short term, many clinicians reserve their use for patients who decompensate on standard amino acid solutions or fail temporary protein restriction attempts.

DESIGN AND INITIATION OF THE NUTRITIONAL REGIMEN

Patients with alcoholic hepatitis or cirrhosis are frequently hypermetabolic. Indirect calorimetry quantification may be preferred to empiric estimates of caloric requirements in this setting to avoid under-

overfeeding calories. Excessive calorie provision actually may promote liver dysfunction and increased production of carbon dioxide with an associated increased work of breathing. When dextrose-based PN is started in these patients, additional thiamine may be needed to prevent Wernicke's encephalopathy.

IVLE should be used in patients with liver failure only to prevent essential fatty acid deficiency when initial serum triglyceride concentrations exceed 300 mg/dL. If serum triglyceride concentrations are low or normal, IVLE should be used as a calorie source. Monitoring serum triglyceride concentration and FFA oxidation (not available in all facilities) to ensure that lipid is both cleared and oxidized appropriately has been suggested. Triglyceride concentrations are the only available marker in most clinical practices at this time. Oral MCTs have been used occasionally with success because they do not require pancreatic enzymes or micelle formation before absorption. However, these products do not provide essential fatty acids.

Most clinicians routinely use standard mixed amino acids and reserve BCAA products for patients with severe encephalopathy who decompensate on standard amino acids despite continued lactulose-neomycin therapy. Protein restriction temporarily to ≤ 0.8 g/kg per day is usually attempted before BCAA products in the patient with severe encephalopathy (see Fig. 139–2).

The electrolytes that warrant the most careful monitoring in liver disease include sodium, potassium, phosphorus, and magnesium. During fluid and salt restriction, patients (especially those receiving concurrent lactulose therapy) should be observed for symptoms of volume depletion (e.g., increased pulse rate, decreased blood pressure, or dry mucous membranes). The magnesium dose should be individualized to maintain concentrations in the normal range. This often requires magnesium concentrations as high as 24 mEq/L in the PN solution, which is two to three times the standard daily dose.

Trace elements that warrant individual attention include zinc, copper, and manganese. Oral supplementation of zinc sulfate (600 mg/day) capsules or intravenous zinc chloride may be needed to prevent deficiency or correct deficits. For patients receiving PN, withholding copper from the solution until a copper serum concentration in the normal range is documented or the cholestasis resolves is appropriate. Patients who have chronic cholestasis may require copper in reduced doses (e.g., 0.6 mg/day); however, they should have serum copper concentrations checked regularly (once per month in the acute care setting and every 6 months in the ambulatory setting). Manganese restriction also may be required in these patients. The nutritional requirements of patients with liver failure secondary to cirrhosis are

TABLE 139–5. Nutrition Recommendations for Patients with Liver Disease

| Patient Type | Calorie Energy (kcal/kg per day) | Protein (g/kg per day) | Comments |
|---|----------------------------------|--|--|
| Compensated cirrhosis | 25–35 | 1–1.2 | Use a bedtime snack and frequent small meals |
| Decompensated cirrhosis | 25–35 | 0.5–1.5 for mild encephalopathy; 0.5 for severe encephalopathy | Use BCAAs for refractory cases of encephalopathy unresponsive to protein restriction |
| Decompensated cirrhosis with malnutrition | 35–40 | 1.5 | May have to temporarily decrease protein for encephalopathy worsening |

Decompensated cirrhosis: cirrhosis accompanied by significant ascites or encephalopathy.

BCAA, branched-chain amino acid.

From Matos et al.⁵⁹ and Dudrick et al.⁶²

listed in Table 139–5 and an empiric PN formula for the patient with hepatic failure is presented in Table 139–2.^{59,62}

EVALUATION OF THERAPEUTIC OUTCOMES

Prealbumin and retinol-binding protein, traditionally sensitive markers of protein-energy malnutrition, may not be as reliable in patients with hepatic failure. Liver failure can cause decreased concentrations of both, independent of nutritional status.⁷¹ Indeed, many of the commonly used markers of nutritional status correlate poorly with body cell mass in those with end-stage liver disease. Midarm muscle circumference and handgrip strength have been found to be the best

predictors of body cell mass.⁷¹ The poor correlation of other markers suggests that they are of limited value for patients with changing hepatic function.

QUALITY-OF-LIFE ISSUES

Nutritional supplementation provided to patients with alcoholic cirrhosis has been demonstrated to reduce the frequency of hospitalizations. Therefore nutrition supplementation in liver failure should be viewed as a method of reducing nutrition-related complications, as well as improving quality of life and decreasing cost of care.

HEPATIC TRANSPLANTATION

Orthotopic liver transplantation (OLT) has become an important intervention for the patient with end-stage liver disease. Many patients receive nutrition support following this operation because of their poor preoperative nutritional status and the postoperative stress. Although hypermetabolism in the early postoperative period has been reported, a caloric intake of only 1.2 times basal energy expenditure (BEE) typically meets caloric needs in the short-term after transplantation.⁷² Increased protein catabolism has been noted in response to the stress of liver transplantation and the administration of large doses of corticosteroids following surgical intervention.⁷³

EPIDEMIOLOGY

The percentage of OLT patients requiring nutritional support has been well documented. In one report of 427 OLT patients, 32.7% received at least one form of nutritional support: 8.9% received tube feedings alone, 11.9% received PN alone, and a combination of tube feedings and PN was provided to 11.9%. In one group of patients undergoing elective OLT, 79% were at or below the 25th percentile of anthropometric measurements and 28% were below the fifth percentile.⁷⁴ This indicates a high prevalence of malnutrition in patients awaiting OLT. Severe malnutrition as assessed by subjective global assessment pre-OLT is associated with increased packed red blood cells, fresh frozen plasma, and cryoprecipitate transfusions, as well as longer postoperative hospital stays.⁷⁵ However, whether preoperative nutritional interventions improve outcomes post-OLT is still an area of controversy.

CLINICAL CONTROVERSY

Despite the high incidence of malnutrition pre-OLT, data supporting a mortality benefit from pre-OLT nutrition support are relatively lacking. Studies thus far have been limited by small sample size, so it is uncertain whether nutritional interventions in these patients truly convey a survival benefit long term. Larger controlled clinical trials are needed.

The majority of pre-OLT nutrition intervention studies demonstrate a morbidity benefit post-OLT (per anthropometric tests, hospital stay, and postoperative infections), but typically fail to demonstrate a mortality benefit that reaches statistical significance (although this may be due to small sample sizes).^{72,73,76} Preoperative obesity is known to increase morbidity,⁷⁷ and in some studies, mortality perioperatively.⁷⁶ It is for these reasons that some centers consider

morbid obesity a relative contraindication to OLT and a reason for advocating weight loss pre-OLT in this patient group.

PATHOPHYSIOLOGY

CARBOHYDRATE, PROTEIN, AND FAT

Postoperative hyperglycemia is common after OLT. Corticosteroids administered to prevent organ rejection may contribute to the hyperglycemia observed during the postoperative period. Alterations in glucose uptake in peripheral tissue also may be present in these patients and thereby contribute to hyperglycemia after OLT.⁷⁸

Most patients will tolerate standard amino acids following OLT because the new liver is functioning properly, and hepatic encephalopathy is not problematic. The excessive nitrogen losses associated with this procedure warrant the provision of 1.3 to 2 g/kg per day of protein immediately post-OLT.⁷² Modified amino acids should be reserved for patients with marginal hepatic function associated with rejection or hepatic encephalopathy.

A combination of MCTs and long-chain triglycerides (LCTs) has been studied in post-OLT patients. No significant differences in carbohydrate or lipid oxidation rates were seen, thus suggesting that MCT-specific emulsion is not needed for the PN regimen of the OLT patient.⁷⁹ Large amounts of LCTs should be given cautiously, however, since it has been suggested that LCTs may impair reticulo-endothelial function/recovery after OLT, which could contribute to increased postoperative infections.⁸⁰

FLUID, ELECTROLYTE, AND ACID-BASE DISORDERS

Patients undergoing OLT receive a substantial amount of crystalloid and blood products during the operative procedure. This often results in an edematous state in the postoperative period, especially in patients who had ascites preoperatively. The large citrate load from administered blood products has been implicated in causing hypocalcemia (due to citrate binding of ionized calcium) and metabolic alkalosis (due to conversion of citrate to bicarbonate) in the postoperative period. Low serum concentrations of magnesium are common in the postoperative period.⁷² Reduced intake from restricted diets and increased urinary excretion secondary to cyclosporine therapy contribute to hypomagnesemia.

TRACE ELEMENTS AND VITAMINS

Low serum concentrations of zinc are common in the postoperative period. Restricted diets before surgery and hyperzincuria secondary

to liver disease both contribute to hypozincemia in this population. Serum zinc concentrations have been found to recover rapidly after transplantation, obviating the need for further supplementation.⁸¹ On the other hand, patients who have severe cholestasis before and after OLT should have copper and manganese restricted because they are excreted in the bile and thus serum concentrations may be elevated.

Low serum vitamin A concentrations are present in many patients with chronic liver disease. Mean serum vitamin A concentrations measure less than one-half normal in pre-OLT patients, but normalize within 2 weeks after transplantation.⁸²

Osteoporosis and fracture risk increase in patients after liver transplantation. Patients awaiting OLT have a 15% to 40% incidence of osteoporosis.⁷³ This incidence increases to as much as 46% post-

OLT, with roughly 20% of patients experiencing a fracture within 1 year of transplant. Poor diets, lack of physical activity, reduced serum 25-hydroxyvitamin D and 1,25-dihydroxyvitamin D, and abnormal parathyroid hormone concentrations are all thought to contribute pretransplant.⁷³ Post-OLT corticosteroid therapy will also negatively impact bone metabolism, but may not be the sole reason for continued bone loss post-OLT. Mean bone mineral density (BMD) has taken a mean of 85 months to return to pre-OLT levels.⁸³ Single-dose bisphosphonate infusion did not alter bone formation or resorption in the early (30 days) post-OLT period.⁸⁴ It is likely that lowering steroid doses, BMD screening, preventive measures, and calcium and vitamin D supplementation will be the mainstay treatment options for this problem.⁸⁵

► TREATMENT: Hepatic Transplantation

■ ADMINISTRATION ROUTES

The least invasive method of feeding should always be employed pre-OLT. If oral intake is inadequate, enteral feedings should be given via small-bore nasogastric or nasojejunal feeding tubes, unless the patient has active esophageal variceal bleeding. More permanently placed feeding tubes (gastrostomy, others) in patients with ascites should be avoided to minimize infection and fluid leakage risks.⁷²

Post-OLT, if patients were not malnourished to start, oral diets with liquid supplements as needed can be attempted. In patients with pre-existing malnutrition, enteral nutrition via feeding tube is the therapy of choice; however, small bowel access is needed for this to occur, since postoperative gastric ileus is common. This would necessitate placement of a nasoduodenal or nasojejunal tube during or immediately after surgery. Calorie counts of oral intake can be used to determine when oral intake is sufficient to discontinue tube feedings. If no bowel function is present postoperatively, PN therapy is appropriate.

■ DESIGN AND INITIATION OF THE NUTRITIONAL REGIMEN

OLT patients should be given a nutritional formula that provides at least 1.2 times BEE per day postoperatively, with a mix of energy sources (typically 70% of calories given as carbohydrates once at goal rate). Because of the significant incidence of hyperglycemia immediately postoperatively, it is recommended to wait 24 hours if using PN, or to begin very slowly with a relatively low concentration of dextrose (e.g., 10% or 15% dextrose in water) and titrate as tolerated over a week.⁷² These patients also should be provided with at least 1.3 g/kg per day dry weight of protein via standard amino acid solutions. Because OLT patients frequently are edematous postop-

eratively, the nutritional regimen may need to be volume-restricted. Citrate-containing blood products bind ionized calcium, mandating supplemental doses of calcium in PN. Supplemental doses of potassium and phosphorus may also be needed if refeeding occurs in the malnourished OLT patient. Additionally, OLT patients receiving cyclosporine therapy often will require magnesium in amounts that exceed standard doses during postoperative nutritional support. Lastly, routine multivitamin and trace element supplements should be given daily in the PN formula as outlined in Chap. 137. An example empiric PN for the OLT patient is presented in Table 139–2.

Given the increased rates of obesity seen post-OLT, dietary counseling on the long-term appropriateness of a low-fat, lean meat diet that is low in sodium and rich in calcium and vitamin D should be provided to these patients.⁷³ If intake of calcium and vitamin D is inadequate, supplements should be given to assure a total intake of 1,500 mg of elemental calcium and 400 to 800 international units of vitamin D.

■ EVALUATION OF THERAPEUTIC OUTCOMES

The monitoring plan of the OLT patient needs to be individualized. Patients receiving cyclosporine or corticosteroids should be monitored closely (at least every 6 hours) for hyperglycemia. Following successful OLT, hepatic encephalopathy is no longer problematic. Thus nitrogen balance should be evaluated to determine the optimal amount of protein to be provided. Fluid balance should be followed carefully to avoid volume overload, especially in patients who received large volumes of fluids intraoperatively. Serum magnesium levels should be monitored daily or more frequently if deficiency is documented, especially in patients receiving cyclosporine therapy. Serum potassium and phosphorus concentrations should also be followed carefully in the malnourished OLT patient because of the risk of the refeeding syndrome (see Chap. 137).

support with parenteral and enteral nutrition is to maintain nutritional status and/or correct nutritional deficiencies.

SHORT BOWEL SYNDROME

An intact functional GIT is essential for complete absorption and digestion of nutrients. Short bowel syndrome (SBS) is a disease state imposed by significant resection of the small bowel, which results in the malabsorption of nutrients and fluids. Morbidity and mortality due to gastrointestinal failure in SBS patients has been improved by interventional nutrition with PN and EN. The goal of nutritional

EPIDEMIOLOGY

In the United States there are at least 10,000 patients who have SBS.⁸⁶ In adults, the most common etiologies of surgery leading to SBS are Crohn's disease, mesenteric vascular disease, and cancer. In infants,

necrotizing enterocolitis, midgut volvulus, and intestinal atresia are the most common etiologies for resection leading to SBS.⁸⁷ This condition also may be functional as opposed to anatomic and occur in individuals who have not had resections, but who have a decreased small bowel absorptive capacity due to etiologies such as radiation enteritis or severe inflammatory bowel disease.⁸⁸ Symptoms of SBS may vary between patients, but generally include diarrhea, dehydration, electrolyte disturbances, and progressive malnutrition.^{87,88}

PATHOPHYSIOLOGY

The average length of small intestine in adults is 600 cm. The majority of nutrients are absorbed in this part of the GIT, and the general consensus is that a diagnosis of SBS should occur when greater than 70% of the small intestine has been resected. Losing this absorptive capacity leads to deficiencies in multiple nutrients which requires the initiation of interventional nutrition.

8 PN must be used at least during the phase immediately following resection of the small intestine while the GIT is healing. EN may be used later during the transition to oral feedings since other areas of the intestinal tract are able to compensate with time.⁸⁶ The length and type of nutritional support a patient may require long term is based on such factors as the length of remaining small intestine and the presence or absence of a functional colon. Wilmore and colleagues estimate that for adult patients to transition off of PN, the residual jejunum-ileum length needs to be greater than 120 cm for individuals without a colon, or greater than 60 cm if a portion of the colon is in continuity with the remaining small intestine.⁸⁸ Factors that may predict a poor outcome include older age, disease in the residual bowel, and removal of the ileocecal valve, the physiologic sphincter that controls the rate of passage of intestinal contents from small to large bowel and prevents small bowel bacterial overgrowth.⁸⁷

INTESTINAL ADAPTATION

The adaptation process of the residual small intestine to compensate for the resected area begins 12 to 24 hours after bowel resection.⁸⁸ The changes in the GIT to compensate for the lost absorptive area are gradual and may continue to occur for 1 to 2 years. Factors that act as stimuli for adaptation include luminal nutrients, pancreaticobiliary secretions, and intestinal hormones.^{87,88} The ability of the remaining intestine to adjust after resection is also influenced by the area of bowel loss. The jejunum is the primary site for absorption of most nutrients, but if it is removed the ileum usually can accommodate and take on the structural characteristics and functional roles. Even with this compensation, patients with less than 50 to 60 cm of jejunum will typically need indefinite PN. With ileal resection, the jejunum has a decreased capacity to adapt and perform the functions of the ileum.^{86,89}

ENERGY REQUIREMENTS

Caloric intake and energy needs of SBS patients are variable. Individuals who have lost more than 50% of their small intestine typically require an EN input of 30 to 40 kcal/kg of ideal body weight per day.⁸⁷ The average recommendation for patients with SBS who are receiving PN is 32 kcal/kg of ideal body weight per day.⁸⁶

CARBOHYDRATE

Carbohydrate malabsorption plays a major role in diarrhea associated with SBS. Unabsorbed carbohydrates are broken down by intestinal bacteria to short-chain fatty acids (SCFAs), producing an osmotic load in the distal small intestine and colon that can lead to protracted diarrhea.⁹⁰ However, the colon is able to use these SCFAs as a source of energy, thus complex carbohydrates may provide a significant caloric source for patients with a massive resection and a preserved colon.^{90,91}

FAT

Fat malabsorption is common in SBS as well. The pathophysiology of this problem is complex and related to alterations in pancreatic enzyme secretion and bile salt absorption. The ileum is the major site of the latter process, and with its removal bile salt malabsorption is common. Eventually, the total bile salt pool may be depleted, resulting in increased fat malabsorption and steatorrhea.⁸⁹ There has been much debate regarding the restriction of oral fats, which may decrease steatorrhea, number of stools, and stool weight in some patients. Fats have the highest number of kilocalories per gram, make the diet more palatable, and patients with SBS without a colon should not be restricted in the amount of fats they take in. Small bowel patients with continuity of healthy colon have shown that a diet higher in complex carbohydrates and lower in fat may have less stool volume and electrolyte loss, so this type diet may be more beneficial.⁸⁷ However, there is concern with patients on long-term PN with regard to the development of essential fatty acid deficiency. Biochemical evidence of this deficiency has been proven, even with appropriate intake of long-chain fatty acid lipid emulsions in grams per kilogram per day.⁹²

PROTEIN

Protein typically is well tolerated as a caloric source in SBS patients. For those SBS patients on EN it is controversial what molecular form of the macronutrient maximizes protein absorption. In the past, EN often was initiated with elemental products that contained free amino acids as the protein source because the efficiency of protein uptake was perceived to be better. However, total protein absorption is faster and more complete with dipeptide and tripeptide formulations.⁹⁰ It appears that the absorption of free amino acids by the enteral route is a saturable process, whereas the absorption of small peptides is not. These more complex protein sources also may stimulate intestinal adaptation.⁹⁰

FLUID, ELECTROLYTE, AND ACID-BASE DISORDERS

9 After substantial resections of the small bowel, the postoperative course is complicated by fluid and electrolyte imbalances that typically last 1 to 3 weeks.⁸⁷ Patients may have high-volume gastric fluid loss from nasogastric tubes and small intestine fluid loss from ostomies. Sodium content usually is elevated in these secretions, with concentrations of approximately 80 to 100 mEq/L.⁹⁰ Acute gastric hypersecretion may occur after massive resection and contribute significantly to these deficits.⁸⁷ Secretory diarrhea also results in fluid and electrolyte losses that may be difficult to quantify.

Patients with end jejunostomies or proximal ileostomies can have recurrent dehydration and electrolyte deficiencies. A high jejunostomy can have output of 3 L/day of fluid, with sodium loss of 90 mEq/L. To overcome the net secretion of sodium and water into

the jejunum, the sodium content of fluids within the GI lumen must reach 90 mEq/L. In patients who have small intestine in continuity with the colon, the malabsorbed bile and fatty acids stimulate sodium and water excretion into the large bowel, but in general these patients are at less risk for sodium and water depletion.⁹¹

Patients with a jejunostomy are at risk of hypokalemia as well, so potassium levels must be monitored closely for supplementation. Other patients at risk for potassium depletion include individuals with long-term sodium depletion, magnesium deficiency, or excessive loss from diarrhea.⁹¹ Metabolic alkalosis, which may occur when a patient becomes dehydrated, accelerates the renal excretion of potassium, as all hydrogen ions are conserved in an attempt to correct the acid-base disorder. As bicarbonate ions are excreted renally, potassium is taken with them to maintain osmotic balance.

The unusually large amount of unabsorbed fatty acids within the remaining intestine and colon of the patient with SBS will cause increased binding to calcium, resulting in a deficiency. This also may result in hyperoxaluria because dietary oxalate usually complexes with the intraluminal calcium and is excreted in the stool. As the result of decreased calcium available for binding, more oxalate is absorbed and available for renal excretion and formation of calcium oxalate renal stones.⁸⁸ Vitamin D deficiency results in insufficient calcium absorption; thus SBS patients requiring long-term PN are at risk for metabolic bone disease. Other potential causes of this disorder include aluminum toxicity, suppression of parathyroid hormone by parenteral vitamin D, disruption of parathyroid hormone regulation, and cytokine effects on bone resorption.⁹³

Magnesium deficiency is common in SBS patients with large ostomy or diarrheal losses. This deficiency should be corrected aggressively because of the correlation between low magnesium and potassium concentrations, and magnesium supplementation decreases the formation of calcium oxalate kidney stones. Serum concentrations are most commonly monitored, but urinary magnesium concentrations may decrease earlier with deficiency, and may be a better estimate of total body stores than serum levels. Oral supplementation may be difficult because it can contribute to increased diarrhea or ostomy output. However, repletion is necessary to correct potassium deficits in addition to magnesium losses.⁸⁶

SBS patients can lose substantial amounts of chloride (60 to 140 mEq/L) in addition to sodium from ostomy output. Dehydration occurs when there are stable losses from an ostomy that are not replaced, or when the patient is noncompliant with a restricted diet, resulting in loss of more fluid than is taken in. These individuals have a high risk of developing hypochloremic metabolic alkalosis.

Noncompliance with the infusion of appropriately prescribed fluids also can lead to dehydration. Patients who have SBS complicated by a pancreatic fistula and severe diarrhea lose considerable potassium and bicarbonate and may develop metabolic acidosis. Patients with severe diarrhea who have an intact colon will conserve sodium and chloride, resulting in considerable loss of potassium and bicarbonate and the development of metabolic acidosis. Quantifying fluid losses with particular attention to the sources of loss will aid in the acid-base management of these patients (see Chap. 51).

Lactic acidosis can occur in patients with SBS and may result in symptoms of ataxia and delirium.⁹⁴ D-Lactic acid is produced by the fermentation of malabsorbed carbohydrates by colonic bacteria, and increased concentrations are associated with small bowel bacterial overgrowth.^{87,94} The diagnosis of D-lactic acidosis should be considered in patients with a functional colon who have an unexplained metabolic acidosis and an elevated anion gap.⁸⁷

TRACE ELEMENTS

Patients with SBS are particularly prone to zinc deficiency as a result of excessive losses from stool, ostomy outputs, and fistula drainage. Signs of inadequate zinc include acrodermatitis and impaired wound healing. Although serum zinc concentrations are not always reflective of body zinc status, a low serum zinc concentration requires an adjustment in replacement amount.⁹¹ Significant bowel resection, GI losses, and impaired intestinal absorption also contribute to imbalances of other trace elements, such as copper, selenium, and manganese. Trace element deficiencies and the need for supplementation of these micronutrients are essential for SBS patients, including those receiving PN, EN, or an adequate diet.⁸⁶

VITAMINS

10 Patients with ileal resection commonly develop vitamin B₁₂ deficiency, necessitating therapy with parenteral cyanocobalamin. Most other water-soluble vitamins are absorbed in the proximal jejunum, and deficits of these vitamins are found only in more severe SBS.⁸⁷ Small bowel bacterial overgrowth can contribute to diminished vitamin B₁₂ because bacteria may metabolize the nutrient within the intestine, decreasing its availability for absorption.⁸⁸ SBS patients with fat malabsorption can acquire deficiencies in vitamins A, D, E, and K. These fat-soluble vitamins depend on bile salt micelles for effective absorption, and malabsorption with depletion of the bile salt pool can lead to their deficits.⁸⁹

▶ TREATMENT: Short Bowel Syndrome

■ ADMINISTRATION ROUTES

After intestinal resection, the clinical course and nutritional management of SBS patients may be described in three stages, or phases. The first stage, or acute phase, occurs during the initial postoperative period. This phase lasts at least 1 week, and may continue from 3 weeks to 3 months. It is complicated by major fluid and electrolyte losses (up to 5 L/day) and the parenteral route should be used to supply nutritional needs.

11 The second stage lasts from a few months to over a year, and institution of enteral or oral intake early during this stage is

important because intraluminal nutrients are essential stimuli for intestinal adaptation. As the amount of enteral/oral nutrition is advanced as the patient tolerates, the duration of the daily infusion of PN may be decreased. In the third and final stage, adaptation is maximized and the patient is maintained with nutritional support tailored for long-term ambulatory management. If patients are unable to achieve full oral nutrition, home PN may be used. However, PN may not be required on a daily basis. If a PN regimen is to be reduced or discontinued, it should be done slowly; initially one to two nights of PN may be eliminated each week. Eventually, some patients may be able to tolerate administration on an every-other or every-third-night basis.^{86,87,90} During the different phases of management PN is administered through a

peripherally inserted central catheter or surgically placed indwelling central venous catheter⁸⁸ (see Chap. 137). Use of proper aseptic technique is vital in the care of these access sites because SBS patients have been shown to have significantly higher rates of catheter sepsis.⁹⁵

DESIGN AND INITIATION OF NUTRITIONAL REGIMEN

The early phase of SBS is associated with large day-to-day variations in fluid and electrolyte losses. Strict output records should be assessed, as well as all intake including intravenous medications. Initially, it is recommended to start a standard PN solution that meets the patient’s maintenance metabolic, fluid, and electrolyte needs, and a separate intravenous replacement solution is typically necessary to keep the patient euvolemic based on actual fluid losses.⁹⁵ Insensible losses should be estimated between 300 and 800 mL/day above measured output,^{87,95} and daily urine output should be kept at least 1 L.⁸⁷ As fluid and electrolyte losses stabilize over time it becomes possible to incorporate these replacement requirements into the PN solution. The PN solution typically is composed of standard crystalline amino acids, glucose, and intravenous lipids. A generic caloric breakdown for SBS patients based on a need of 30 to 40 kcal/kg per day may be 1.5 g/kg of protein per day, approximately 20% to 30% of calories from intravenous lipids, and the remainder of calories from carbohydrates.⁸⁶ An example of a PN formula for the patient with SBS is given in Table 139–2.

The amounts of chloride versus acetate salt forms chosen for cation delivery should be based on assessment of the acid-base balance of the patient and sources of GI losses. More proximal GI losses generally are associated with increased chloride needs and more dis-

tal outputs with increased bicarbonate (i.e., acetate) requirements. Sodium losses may be extreme in SBS patients as already mentioned, requiring supplementation above what a typical PN patient requires. In addition, supplementation of potassium, calcium, magnesium, zinc, or other micronutrients over their maintenance amounts may be necessary to meet replacement needs.^{86–88}

The transition from PN to enteral feedings is desirable because it is a stimulus for adaptation, and should be instituted as the patient progresses throughout the postoperative period. EN, given as a continuous infusion through a nasogastric or gastric feeding tube, may be advantageous over bolus feedings because it can maximize absorptive capacity, and may decrease recovery time and minimize diarrhea.^{86,87} Formulas with protein hydrolysates and a combination of MCTs and LCTs, as well as elemental formulas have been suggested for these patients.^{90,96} Because SBS may exacerbate lactose intolerance, lactose-free isotonic polymeric enteral formulas also have been recommended.⁸⁷

Oral intake should be considered in small amounts, but must be regulated carefully at this point. Small volumes (600 to 1000 mL/day) of oral electrolyte solutions such as low-carbohydrate sports drinks and sugar- and caffeine-free beverages are optimal. Frequent, small amounts of solid food composed primarily of complex carbohydrates and proteins (600 to 1000 kcal/day) have been recommended, with avoidance of concentrated sweets and dairy products.^{88,95} When a patient begins to consume greater than 1000 kcal/day orally without protracted diarrhea, PN may begin to be tapered, as well as EN (Fig. 139–3). Many factors must be considered once a patient begins to transition off interventional nutrition when determining the content of a long-term oral diet for an SBS patient. Factors such as the site and length of remaining intestine, tolerance, and patient acceptance must be considered. Fat generally is not restricted in patients without

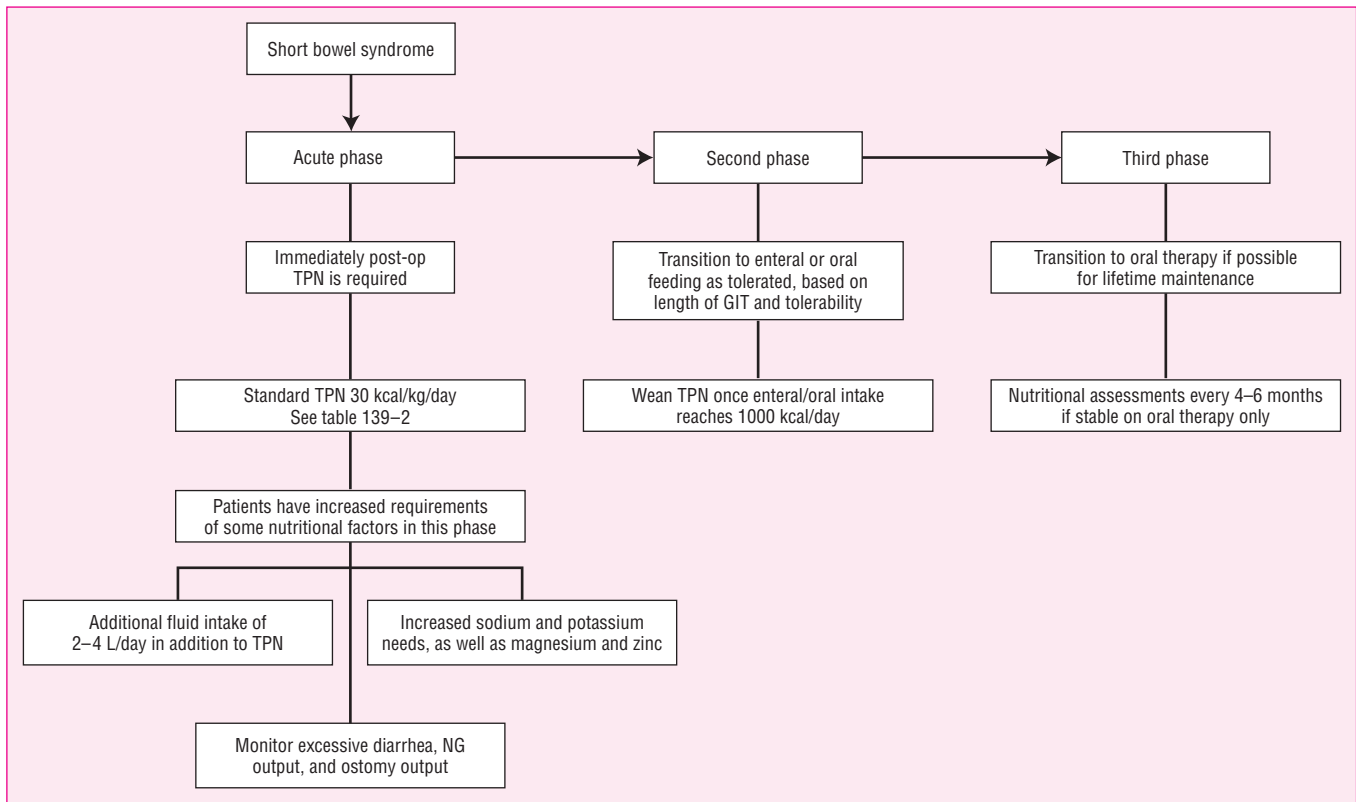

FIGURE 139–3. An algorithmic approach to nutritional support for the patient with short bowel syndrome.

a colon. However, patients with a colon may experience more diarrhea with a high-fat diet and may benefit from oral intake that has more calories from carbohydrates and less fat content.⁸⁷ The oral diet for patients with remaining functional colon also must account for oxalate content, and patients should avoid foods with high amounts of oxalate (e.g., spinach, parsley, rhubarb, cocoa, and tea) to decrease calcium oxalate renal stones.⁹¹ Finally, oral diets in SBS patients often need to be supplemented to maintain electrolyte, mineral, vitamin, and trace element balance.

■ DRUG THERAPY

The delivery of medications to patients with SBS may present many challenges, not the least of which is the questionable absorption of oral therapies. It is important to avoid oral products that contain sorbitol or mannitol as inactive ingredients to avoid medication-related diarrhea. Loperamide and octreotide may be used to control diarrhea (see Chap. 36), and proton pump inhibitors and H₂-receptor antagonists are frequently required to reduce gastric hypersecretion (see Chap. 33).

The use of specialized nutrients and growth factors to enhance small bowel adaptation has been a focus of recent research. The amino acid glutamine is a fuel for intestinal cells, and may be necessary for maintaining intestinal structure in normal and stressed states.⁸⁸ Byrne and colleagues published an uncontrolled clinical study of patients who received glutamine in combination with recombinant human growth hormone (rhGH) and a high-carbohydrate/low-fat diet.⁹⁷ Recombinant growth hormone was added to the regimen because of its stimulant properties in bowel adaptation. Initial results showed that use resulted in significantly increased protein absorption in several patients and after a follow-up period of 1 year, 40% of patients were able to maintain nutrition status off PN with a continued high-carbohydrate and low-fat diet and glutamine supplementation.⁹⁷

Other researchers have investigated the effects of glutamine and rhGH, with and without high-carbohydrate/low-fat diets, on body composition and intestinal absorption. In these randomized, double-blind, placebo-controlled crossover studies, which were done in small numbers of patients, the beneficial results of glutamine and rhGH were not duplicated.^{98–100}

CLINICAL CONTROVERSY

Despite the lack of controlled clinical trials supporting its use, many clinicians supplement PN therapy with glutamine and recombinant growth hormone in an attempt to increase intestinal absorption and facilitate transition off PN. Recombinant growth hormone is a costly product with adverse effects, but PN is more costly and also has a serious adverse-effect profile. Larger controlled clinical trials are needed to determine the benefit of glutamine and rhGH in this patient population.

■ SURGICAL THERAPY AND INTESTINAL TRANSPLANTATION

The surgeon is one of the primary specialists caring for the SBS patient. Initially surgical management focuses on preventing GI resections and then preserving as much GIT as possible.¹⁰¹ Intestinal

transplantation is currently considered a high-risk proposition, and is reserved for those patients with life-threatening complications of their intestinal failure, including irreversible PN-related liver disease, or lack of venous access.¹⁰² Over 500 patients have received an intestinal transplant, the majority being children. The overall survival rate is almost 60%, with 77% of the survivors achieving full nutritional autonomy. Partial gastrointestinal recoveries have been documented in approximately 15%, resulting in a rehabilitation rate greater than 90% in survivors. The majority of deaths were due to postoperative infections. In the absence of life-threatening complications, intestinal transplantation is difficult to justify at this time except for selected SBS patients.¹⁰³

■ EVALUATION OF THERAPEUTIC OUTCOMES

Therapeutic monitoring of SBS patients for metabolic complications should follow the guidelines outlined in Chap. 137. This patient population differs in that serum electrolytes should be obtained daily until the patient has stabilized postoperatively. Special consideration should also be given to the fluid status of SBS patients, especially in the period immediately following surgery, when fluid losses are extreme. Monitoring of stool output is such a large factor it must be taken into consideration throughout the acute phase, as well as the entire life of all SBS patients. Because many patients with SBS remain on PN for extended periods of time, clinicians must be careful to monitor for elevations in liver enzymes, and cycling PN for 12 to 14 hours daily should be considered in those patients receiving IV nutrition to minimize these complications. Obtaining a serum fatty acid profile may be judicious in those patients on long-term PN without oral intake to ensure they do not have essential fatty acid deficiency.⁹⁵

Long-term outcomes of adults with SBS on PN have been examined. Survival rates have been reported at 2 and 5 years to be 86% and 75%, respectively. In these same patients, the probability of requiring continued PN support was 49% at 2 years and 45% at 5 years.¹⁰⁴ Dependence on PN was related to residual intestinal length of less than 100 cm and absence of the terminal ileum and/or colon in continuity with the remaining small intestine.

The most comprehensive and thorough analysis of the clinical outcomes of patients receiving home PN or EN comes from Medicare and the North American Home Parenteral and Enteral Patient Registry.¹⁰⁵ It was estimated that 40,000 and 152,000 patients in the United States were receiving home PN and EN support, respectively. Patients with GI failure, which included those with Crohn's disease, ischemic bowel disease, motility disorders, and congenital bowel defects had relatively good outcomes, especially when compared with the groups with cancer or AIDS. The patients with GI failure had an 87% annual survival rate and a 50% to 75% likelihood of complete rehabilitation. Sepsis, metabolic disorders, and mechanical problems with catheters resulted in one to two hospitalizations per year for all patients.¹⁰⁵

■ QUALITY-OF-LIFE ISSUES

Education of patients with SBS and their caregivers is essential, particularly in the setting of home PN and/or EN with its associated technology. In addition, quality-of-life (QOL) issues should be addressed with these individuals. Initially those patients on extended

PN therapy have a significant gain in QOL when transitioning from the hospital to their home setting. This is often followed by the reality of restrictions in daily living, dehydration and malnutrition despite PN, and complications such as sepsis and liver dysfunction. Patients with SBS on home PN have been shown to report that QOL is signif-

icantly reduced in comparison to those with anatomic or functional SBS not on home PN.¹⁰⁶ Preparing patients and their caregivers for the possible stresses associated with this therapy (e.g., financial challenges, fatigue, depression, complications, and social or emotional problems) may help to increase QOL.

PULMONARY FAILURE

The provision of nutritional support plays a direct role in the management of patients with significant pulmonary disease. Patients with malnutrition are at increased risk of acute respiratory distress syndrome (ARDS), and malnutrition in patients with chronic obstructive pulmonary disease (COPD) is well documented. There has also been a proven correlation between the outcomes of patients with alterations in nutritional status and pulmonary diseases.¹⁰⁷ Loss of lean muscle mass is detrimental because the depletion of diaphragm and intercostal muscles make the effort of breathing harder, and progression of weight loss leads to muscle fatigue and respiratory failure. The ventilatory drive, as well as compensation to hypoxia, is depressed in COPD patients who are malnourished, and nutritional support plays a key role in optimizing respiratory muscle function in patients with pulmonary disease.¹⁰⁸

EPIDEMIOLOGY

Greater than 10% of the U.S. population older than 45 years of age suffers from COPD, resulting in significant cost to the health care system.¹⁰⁸ Weight loss and protein-calorie malnutrition may occur in up to one-half of those patients suffering from COPD, and weight loss often progresses with disease progression.^{108,109} In those patients suffering from acute respiratory failure, nutritional abnormalities have been reported in up to 70%.¹¹⁰ Engelen and colleagues studied body composition in patients with COPD, specifically emphysema and chronic bronchitis. They found a higher incidence of lean mass depletion in those with emphysema compared to those with chronic bronchitis. Body weight and body mass index (BMI) were also lower in the group with emphysema.¹¹¹ In a further evaluation of these patients, the same investigators reported that skeletal muscle weakness was associated with wasting of extremity fat free mass (FFM) that was independent of COPD subtype.¹¹² Regarding mortality, a relationship has been shown between COPD patients with decreasing BMI, especially in more severe cases of COPD.¹¹³

PATHOPHYSIOLOGY

ENERGY

Several mechanisms have been proposed for the weight loss and malnutrition associated with COPD. First, several studies have shown that patients with COPD have an increased resting energy expenditure (REE). Those who are losing weight tend to have significantly higher REE adjusted for FFM compared with weight-stable patients.¹¹⁴ Total daily energy expenditure (TDEE) also was found to be elevated in clinically stable COPD patients with both normal and increased REE. The cause of elevated TDEE despite a normal REE is still unknown, although factors that may contribute include oxygen cost of breathing, acute or chronic systemic inflammation, and medications.^{115,116} Hypermetabolism through elevated REE and TDEE may be partially at fault for decreased body weight and FFM, although it has been shown that in this patient population intake

may be suboptimal. During meals hypoxic patients tend to experience decreases in oxygen saturation and increased dyspnea. Gastric filling may also be impaired due to diaphragmatic expansion and a false feeling of fullness.¹¹⁰ These problems, combined with increased daily requirements, may result in the negative energy balance seen in many COPD patients. Several specialized equations have been developed to estimate requirements in this patient population, and indirect calorimetry may be used, but clinical benefit is questionable. Patients with acute respiratory failure also may have alterations in energy expenditure, but the situation is similar in that predictive formulas for energy needs exist, and indirect calorimetry may be used, but there is no optimal approach to estimate energy needs in this patient population. Providing excess calories to the acutely ill patient in respiratory failure should be avoided because this may increase carbon dioxide production and associated work of breathing.¹⁰⁸

CARBOHYDRATE

Malnutrition in patients with pulmonary disease and failure has been consistently identified in the literature, and nutrition support should be considered as part of the overall treatment plan. However, increasing nutritional intake can be complicated because it may elevate the respiratory quotient (RQ), which may lead to a corresponding increase in work of breathing and resulting hypercapnia. The RQ is the ratio of the amount of CO₂ produced divided by the amount of O₂ consumed. This is in response to the metabolism of macronutrients by the human body. Carbohydrates generate 1 mole of CO₂ for every mole of O₂ consumed (the RQ for carbohydrate is 1). Protein and fat metabolism produce RQs of 0.8 and 0.7, respectively. When a subject is overfed, the amount of CO₂ produced markedly exceeds the amount of O₂ consumed, which can result in increased ventilatory demand.¹¹⁷ Ventilatory drive may be improved in some patients with pulmonary disease with moderate infusions of carbohydrates; however, administration of glucose formulas >5 mg/kg per minute has been shown to increase production of CO₂, and has been associated with the inability to wean from mechanical ventilation.¹⁰⁸

FAT

Fats have the lowest RQ, but administration of intravenous fat emulsions to mechanically ventilated patients may have the potential to adversely affect pulmonary gas exchange in some clinical conditions.¹¹⁶

CLINICAL CONTROVERSY

There are conflicting data on the safety of administration of lipid emulsions to patients with ARDS. Discrepancies in trial data may be due to the use of differing lipid infusion rates and duration, as well as pre-existing lung status.

The administration of lipid emulsions to patients with ARDS either has no effect on oxygenation, or may possibly decrease oxygenation. A recent trial assessing both long-chain triglyceride and combination long-chain triglyceride/medium-chain triglyceride

administration showed that there was no deleterious effect on oxygenation. Discrepancies in trial data may be due to differing lipid infusion rates and duration, and pre-existing lung status.¹¹⁸ Rapid administration of intravenous lipids should be avoided; a rate of 3 mg/kg per minute has been shown to increase pulmonary vascular resistance in patients with ARDS.¹⁰⁷ In a review of nutritional intervention in ambulatory COPD patients, studies investigating the effects of dietary intake with varying percentages of fat content were evaluated. Diets high in fat were found to place a lower demand on the respiratory system in comparison to diets with a higher carbohydrate content, both immediately after a meal and when continued for a short duration (~2 weeks).¹¹⁹ In addition to an improvement in forced expiratory volume, the number of breaths needed per minute has been shown to decrease within 3 weeks in COPD patients who switched to a high-fat/low-carbohydrate diet.¹¹⁷

PROTEIN

Undernourished patients have demonstrated a blunted response to hypercapnia that improves after as little as 1 week of adequate nutritional support. This response is thought to result from protein administration, as evidenced by decreased partial CO₂ pressure, increased minute ventilation, and improved breathing patterns after the start of PN. Protein administration also may influence ventilatory demand by increased ventilatory response to hypoxia and hypercapnia. This stimulation may be altered by the amino acid composition of the protein source, with increased amounts of BCAAs having a greater effect compared with standard amino acids.¹¹⁶ Although this protein effect is potentially beneficial in some patients, excessive protein administration could theoretically lead to increased work of breathing and fatigue.¹⁰⁸

FLUID, ELECTROLYTE, AND ACID-BASE DISORDERS

13 In patients with ARDS or pulmonary edema, excessive fluid intake should be avoided, and fluid accumulation is associated with a poor outcome. It may be beneficial to restrict fluid intake.¹⁰⁸ Patients in the ICU often receive substantial fluid loads from medica-

tion administration, and when possible it is important to limit intake by concentrating these sources.

14 Alteration of micronutrient requirements in respiratory failure is commonly focused on phosphorus replacement. Phosphorus has an essential role in the synthesis of adenosine triphosphate (ATP) and 2,3-diphosphoglycerate (2,3-DPG). Inadequate stores of ATP can lead to respiratory muscle weakness, and normal contractility of the diaphragm muscles is dependent on phosphate.¹⁰⁸ Finally, a significant percentage of critically ill patients can experience hypophosphatemia from refeeding.¹²⁰ Most patients with moderate to severe hypophosphatemia and respiratory failure should be treated with intravenous sodium or potassium phosphate. Correction of hypophosphatemia in ICU patients receiving nutritional support with a graduated weight-based dosing scheme of phosphorus replacement has been reported (see Chap. 49). Clark and associates reported that use of this dosing regimen in ICU patients receiving nutritional support resulted in significant increases in serum phosphorus at all levels of deficiency.¹²¹

Ventilator-dependent patients and those with stable COPD often have respiratory acidosis. A balanced mixture of chloride and acetate salts often is appropriate in these patients. The acid-base status of the ICU patient with pulmonary compromise should be monitored daily, whereas every 2 to 3 days may be adequate for the stable COPD patient.

VITAMINS AND TRACE ELEMENTS

Patients with pulmonary disease usually do not have significant alterations in vitamin and trace element requirements, and they can receive standard doses of these micronutrients. There are some data that support the additional supplementation of antioxidants vitamin C, vitamin E, and β -carotene in pulmonary patients due to a correlation with moderately improved pulmonary function.¹²² COPD patients may have an increased burden of oxidants from cigarette smoke or release of oxygen free radicals from inflammatory leukocytes in the lungs, and deficiencies of antioxidants may contribute to oxidant/antioxidant imbalances in these individuals.¹²³ The value of supplementation of these substances in COPD will require further clarification.

► TREATMENT: Pulmonary Failure

■ ADMINISTRATION ROUTES

When oral feedings are not adequate, the enteral route is preferred for nutritional support in pulmonary patients who have a functional gut and can meet their needs through this route. In acute respiratory failure PN is often recommended when the GI tract is not usable, or as a supplement to EN if sufficient energy intake is otherwise not possible.¹⁰⁸

■ SPECIALTY PRODUCTS

Most general EN formulas contain an equal balance of nonprotein energy between carbohydrate and fat. Elemental or chemically defined products are the exception because they are intended to be high-carbohydrate, low-fat formulas to enhance absorption and digestion. In pulmonary patients administration of a high-carbohydrate formula

may result in a significant increase in minute ventilation, heat production, and CO₂ production when compared with a high-fat formula. Because most general formulas contain balanced nonprotein calories, moderate doses of these products may be appropriate in most patients with pulmonary disease.

Enteral formulas (e.g., Pulmocare, NutriVent, and Respalor) marketed for use specifically by patients with pulmonary disease are also available. In comparison with standard formulas, these products contain a higher percentage of nonprotein calories as fat (>50%). Several studies have evaluated the use of these high-fat/low-carbohydrate products in patients with COPD and acute respiratory failure, and general results have been favorable.^{117,124–126} These specialized pulmonary EN products are calorically dense (1.5 kcal/mL), which may be helpful in feeding patients with severe ARDS or pulmonary edema and in others who may require fluid restriction.

An additional concentrated formula (Oxepa) has been marketed specifically for critically ill patients on mechanical ventilation. The macronutrient composition of Oxepa is similar to that of the other specialized pulmonary enteral formulas, with 55% of caloric content from fat. However, the lipid blend in the formula has been altered to

potentially decrease the production of proinflammatory cytokines by including eicosapentaenoic acid from fish oil and γ -linolenic acid from borage oil. Nutrients with antioxidant properties (i.e., vitamin C, vitamin E, and β -carotene) also have been supplemented in the product.¹²⁷

DESIGN AND INITIATION OF THE NUTRITIONAL REGIMEN

In the patient with pulmonary failure, nutritional support should be given to meet energy and protein requirements and limit wasting of respiratory muscles. No major alterations in substrate disposition have been noted in patients with pulmonary failure; thus moderate doses of carbohydrate, fat, and protein are appropriate in most conditions. Total calorie provision 30% above BEE does not have any untoward effects on pulmonary status, although patients who are overfed two times BEE produce excessive CO₂, even in uncomplicated respiratory failure. In patients with borderline ventilatory status the nutritional regimen should be monitored closely to prevent excessive CO₂ production, and increasing the proportion of nonprotein calories as fat to the amount of carbohydrates may be beneficial in some patients to decrease CO₂ production.¹⁰⁸ In general, patients with ARDS who need PN may receive nonprotein calories administered within the following ranges: 55% to 80% carbohydrate and 20% to 45% lipid. A reasonable protein dose is 1 to 1.5 g/kg per day for the patient with stable COPD. Patients who are mechanically ventilated with superimposed illness may require higher doses of protein (1.5 to 2.5 g/kg per day). An approach to the patient with respiratory failure requiring PN or EN support is shown in Fig. 139–4. An empirical PN formula for the patient with respiratory failure is shown in Table 139–2.

DRUG THERAPY

Recombinant human growth hormone is known to induce general muscle growth, lipolysis, and protein anabolism. When used as adjunctive therapy to EN support, COPD patients have shown improvements in lean body mass, maximal inspiratory pressure, and exercise capacity.¹²⁸ The benefit of rhGH is debatable, with trials having differing results, but body mass and FFM typically will increase in patients after use of this product. The benefit in pulmonary patients as shown by improvements in respiratory muscle function and pulmonary function testing is questionable. The effects of anabolic steroids have also been evaluated for use in COPD as an adjunct to nutritional intervention. Patients on anabolic steroids tend to have larger increases in FFM and more favorable distributions in weight gain in comparison to interventional nutrition alone.¹²⁹ More studies are needed to characterize the benefits of rhGH, as well as anabolic steroids, and to determine the risk associated with the possible clinical benefits.

EVALUATION OF THERAPEUTIC OUTCOMES

Pulmonary patients are at extreme risk of malnutrition, therefore monitoring the progression of the patient on interventional nutrition is extremely important. Therapeutic monitoring of pulmonary patients on PN for metabolic complications should follow the guidelines presented in Chapter 137, and those patients on EN should be monitored as described in Chapter 138. Pulmonary status must be assessed for any changes, especially with the initiation of higher carbohydrate formulas of PN or EN. Weights should be charted frequently, and it

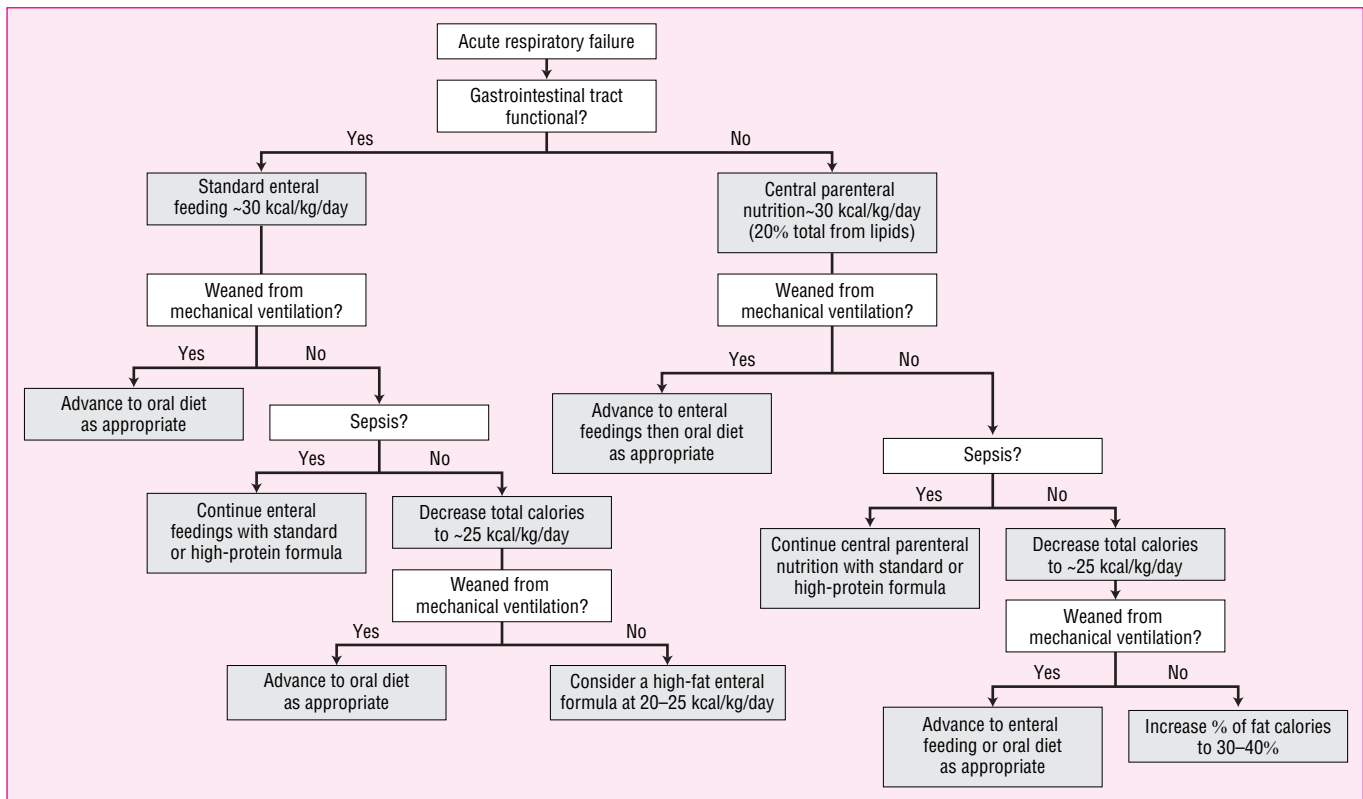

FIGURE 139–4. An algorithmic approach to nutritional support for the patient with acute respiratory failure.

is important that pre-albumin concentrations are assessed weekly for those patients in the hospital. It is important to remember that patients with ARDS in critical care units are prone to fluid overload due to medication administration, so careful monitoring of intake and output is necessary to avoid pulmonary edema. Nutritional status should be monitored every 4 to 6 months for those patients with stable pulmonary disease and COPD.

Long-term outcome assessments of pulmonary patients on PN are not available or applicable because PN is typically a short-term intervention in this patient population. There is an abundance of literature supporting interventional nutrition due to the improvement of FFM, body weight, and respiratory function in ambulatory pulmonary patients. In addition, a low BMI in this patient population has been shown to be associated with increased mortality rates in some

patients, but with appropriate intervention the negative effects of low body weight may be reversed.¹³⁰

QUALITY-OF-LIFE ISSUES

Patients with FFM depletion have shown through subjective testing that they have a decreased health-related QOL. Decreased activity and exercise capacity appeared to be associated with low FFM, which appears to be related to decreasing patient satisfaction.¹¹⁰ Dyspnea has also been shown to be correlated strongly with health-related QOL in patients with decreased FFM, and may be the strongest predictor of patient satisfaction in correlation with malnutrition.¹³¹

ABBREVIATIONS

AAA: aromatic amino acid
 AAD: amino acid dialysate
 ARDS: acute respiratory distress syndrome
 ARF: acute renal failure
 ATP: adenosine triphosphate
 BCAA: branched-chain amino acid
 BEE: basal energy expenditure
 BMD: bone mineral density
 BMI: body mass index
 CAPD: continuous ambulatory peritoneal dialysis
 CKD: chronic kidney disease
 COPD: chronic obstructive pulmonary disease
 CPD: cycling peritoneal dialysis
 CRRT: continuous renal replacement therapy
 CVVH: continuous veno-venous hemofiltration
 EAA: essential amino acid
 EN: enteral nutrition
 ESKD: end-stage kidney disease
 FFA: free fatty acid
 FFM: fat free mass
 GFR: glomerular filtration rate
 GIT: gastrointestinal tract
 HD: hemodialysis
 ICU: intensive care unit
 IDPN: intradialytic parenteral nutrition
 IVLE: intravenous lipid emulsion
 LCT: long-chain triglyceride
 MCT: medium-chain triglyceride
 OLT: orthotopic liver transplantation
 PD: peritoneal dialysis
 PN: parenteral nutrition
 QOL: quality-of-life
 RDA: recommended daily allowance
 REE: resting energy expenditure
 rhGH: recombinant human growth hormone
 RQ: respiratory quotient
 SCFA: short-chain fatty acid
 SBS: short bowel syndrome
 TDEE: total daily energy expenditure
 UNA: urea nitrogen appearance

OBESITY

John V. St. Peter and Mehmood A. Khan

Learning Objectives and other resources can be found at www.pharmacotherapyonline.com.

KEY CONCEPTS

- 1 Two clinical measures of excess body fat, regardless of sex, are the body mass index (BMI) and the waist circumference (WC). BMI and WC provide a better assessment of total body fat than weight alone and are independent predictors of obesity-related disease risk.
- 2 Excessive central adiposity increases risk for development of type 2 diabetes, hypertension, and dyslipidemia.
- 3 Weight loss of as little as 5% of total body weight can significantly improve blood pressure, lipid levels, and glucose tolerance in overweight and obese patients.
- 4 It is appropriate to consider medication therapy if 6 months of diet, exercise, and behavioral modification fail to stimulate weight loss.
- 5 A sufficient degree of obesity (BMI = 30 kg/m² and/or WC = 40 inches for males or 35 inches for females, or BMI of 27 to 30 kg/m² with concurrent risk factors) should be present before pharmacotherapy-facilitated weight loss is considered.
- 6 Some herbal and food supplement diet agents contain sources of pharmacologically active substances that should be used with caution or avoided in obese patients with conditions such as diabetes, hypertension, and significant cardiovascular disease.
- 7 The FDA does not regulate labeling of herbal and food supplement diet agents, and content is not guaranteed.
- 8 There is a high probability of weight regain when obesity pharmacotherapy is discontinued.

It is now estimated that over 95 million adults are overweight or obese in the United States.¹ Additionally, significant numbers of adolescents are developing overweight and obesity status.^{1–4} Overweight and obesity significantly increase risk for development of many diseases, worsen outcomes in the presence of comorbid disease states, and most likely increase health care costs (Table 140–1).⁵ Observational epidemiologic studies show that overall mortality parallels body weight increases above an optimal level.^{6–8} This evidence is strongest for adults between the ages of 30 and 44 years. In older age groups, excess body weight increases the risk of death, but the degree of impact diminishes with age.⁹ Annually, an estimated 15% to 35% of the American population resolve to lose weight, spending between \$30 and \$50 billion with little or no documented improvement.^{10–12} The recent report of the Surgeon General and the inclusion of several aggressive Healthy People 2010 goals have helped to stimulate national initiatives aimed at reversing the rising rate of obesity through implementation of consensus guidelines and best practices.^{13–16} This chapter reviews the epidemiology, pathophysiology, and therapeutic approaches for the management of obesity. Although nonpharmacologic treatment modalities are discussed, the pharmacotherapy of obesity is highlighted, and the role of pharmacotherapy relative to the other therapeutic options is discussed.¹⁷

EPIDEMIOLOGY

Obesity is increasing in prevalence in the United States. The National Health and Nutrition Examination Survey (NHANES) II data

(1976–1980) estimated a prevalence of overweight persons in the United States at 25.4% of adults, representing 34 million individuals. During NHANES III (1988–1991), the prevalence had increased to 33.3%, representing 55 million American adults.¹ The prevention of obesity therefore is a public health priority.¹⁴ This has been further emphasized by the continued pursuit of safe and effective long-term therapy for obesity. Individuals who were “fat” as children tend to remain overweight as adults.^{4,18} Recent data from a large British study have provided further evidence for the relationship between an overweight childhood and subsequent excess weight as an adult.¹⁹ In contrast to body weight, adult BMI was not well predicted from childhood weight. The fattest children had the highest risks of adult obesity. However, most obese adults had not been fat at earlier ages: Only 17% and 18% of obese 33-year-old men and women, respectively, had been fat at age 7 years. Thus most obese adults were not fat children. In contrast, early adulthood may be an important time for intervention to prevent future obesity. Of 4519 men and 4806 women in the study by Power and associates, obesity increased in prevalence from 2% to 11% in men and from 3% to 12% in women during the 10-year period between ages 23 and 33 years.¹⁹ The prevalence of overweight varies between races within the United States.^{20–22} Mexican-American women and black women had the highest prevalence, 48.1% and 49.1%, respectively. The prevalence of obesity also increases with age, reaching a maximum by the sixth decade in women and the seventh decade for men. Beyond this age, the prevalence progressively falls for both genders. Socioeconomic status also affects the prevalence of obesity in those between the ages of 25 and 54 years. The prevalence of overweight in nonpregnant women for

TABLE 140–1. Conditions More Prevalent in Obese Populations

each respective decade of life—25 to 34 years, 35 to 44 years, and 45 to 54 years—is 30.8%, 49.1%, and 54.1% of women with incomes below the poverty line versus 18.4%, 23.7%, and 30.3% of those above the poverty line.¹⁹ Educational achievement, which is linked to socioeconomic status, is also correlated with the fraction of people who are overweight; prevalence of overweight is greatest in those with less than a high school education versus those with some college education.

ETIOLOGY

The etiology of obesity in the vast majority of individuals is unknown. However, studies in twins confirm the presence of genetic contributions.²³ It is likely multifactorial in origin, with genetic, environmental, and physiologic factors contributing to various degrees in different individuals. A definitive diagnosis of an underlying medical condition can be made in only a small minority of individuals. Even then, the diagnosed condition may or may not be treatable. One of the current controversies is the extent that genetic traits influence the risk of developing obesity, as well as how these genetic traits interact with environmental factors to cause obesity.²⁴

GENETIC PREDISPOSITION

Family studies show a clear correlation of body weight between parents and children. The correlation between siblings is even higher. In monozygotic twins, BMI is almost always identical, and there is a strong correlation in the accumulation of visceral fat. These twin studies demonstrate the strong role of genetics in determining both obesity and distribution of body fat. The incidence of obesity in adopted individuals relative to their adopted parents provides insight into the role of genetics versus family environment. These studies show a clear correlation between the BMI of adult adoptees and their biologic parents. This relationship does not exist between an adoptee and his or her adoptive parent. These observations further support the notion that genes are primarily responsible for determining adult body weight. The relative impact of genetic versus environmental factors varies between persons. In some individuals, genetic factors are the primary determinants of obesity, whereas in others, the obesity may be caused primarily by environmental factors. The actual variance in body fat

between individuals determined by genes is not known. Estimates for this variance range from 20% to a high of almost 80%. Yet, clearly, without adequate caloric intake, obesity cannot occur. Thus the role of the environment is to facilitate expression of an underlying genetic trait for obesity. However, the specific gene or genes that code for obesity are unknown.²⁵ Most investigators would agree that more than one gene is involved in the development of human obesity.

ENVIRONMENTAL FACTORS

Economic development is associated with lifestyle changes.³ Many of these societal changes may contribute to the observed rise in the prevalence of obesity throughout the world. Those which are most probably related to obesity include reduced physical activity or work (sedentary lifestyle), abundant and readily available food supply, increased fat intake, increased consumption of refined simple sugars, and decreased ingestion of vegetables, fruits, and complex carbohydrates. These changes in our environment likely contribute to a state of positive energy balance in many individuals (Fig. 140–1).²⁶ Observations from public health studies support this concept. For example, the prevalence of obesity in Copenhagen remained stable during the period between 1925 and 1942 at approximately 0.1%. However, since the end of World War II, there has been a steady increase in the prevalence of obesity.²⁶ These observational data suggest an environmental role for the development of obesity.

NUTRITION

Decades of research have led to several thousand publications regarding nutrition therapy for obesity. Yet the appropriate diet that leads to long-term weight loss in ambulatory self-sufficient individuals is not known. The consensus is that weight regain is almost always inevitable. It is clear that excess caloric intake is a prerequisite to weight gain and obesity, but not all individuals with high caloric intake gain weight. There is an ongoing debate whether the primary consideration is total calorie intake or macronutrient composition of the diet (i.e., percentage of calories as carbohydrates, protein, or fat). Of the three macronutrients, dietary fat has received the most attention. Both animals and humans prefer and often will seek out foods high in fat. High-fat foods have a desirable texture and sensory characteristics in the mouth. Although fat is itself tasteless, fats enhance the flavor of

FIGURE 140–1. Net energy stores are determined by various inputs and outputs. Simply stated, obesity occurs when imbalance occurs between energy intake and expenditure.

other foods. Clearly, one way that fatty foods promote weight gain is by increased energy intake because fat is more energy dense than other macronutrients. Furthermore, fats are stored with greater efficiency than protein or carbohydrates. Nutritional management of obesity as discussed in this chapter is based on reducing calorie intake. Because the Western diet is high in fat, and because fat contains more than twice the calories per gram of carbohydrate and protein, in almost all diets the fat content is reduced by necessity.²⁷

APPETITE

Central Receptor Systems

Multiple receptor systems, including those of the biogenic amines, are known to either stimulate or decrease food intake in both animals and humans. Serotonin, also known as 5-hydroxytryptamine (5-HT), and cells known to respond to 5-HT are found throughout the central nervous system and the periphery. At least seven distinct subfamilies of 5-HT receptors have been cloned to date, with each of these seven exhibiting one or more subtypes. Currently, two major noradrenergic receptor subtypes are recognized (α and β), each with multiple subtypes. Histamine and dopamine also demonstrate multiple receptor subtypes, but their role in regulation of human eating behaviors and food intake is less well documented. Direct stimulation of 5-HT_{1A} and noradrenergic α_2 -receptors will increase food intake, whereas the opposite occurs with 5-HT_{2C} and noradrenergic α_1 - or β_2 -receptor activation. In animal models, stimulating histamine receptor subtypes 1 or 3 and dopamine receptor subtypes 1 or 2 results in lowering of food intake. Table 140–2 summarizes the major effects of direct receptor stimulation, inhibition, or changes in synaptic cleft amine concentrations on food intake.

Peptides

Since the 1950s, it has been conjectured that weight is controlled via a hormone interaction at the level of the hypothalamus.²⁸ The protein product of the mouse obese gene (*ob*) described in 1994 appears to be the signaling mechanism between peripheral energy storage and hypothalamic feeding centers.^{28,29} This protein was called *leptin* (after *leptos*, the Greek word for “thin”). The *ob/ob* genetically obese

TABLE 140–2. Effects of Various Neurotransmitters, Receptors, and Peptides on Food Intake

| Neurotransmitter/Receptor/Peptide | Action | Food Intake |

mouse does not produce leptin, and this animal’s marked hyperphagia subsides with leptin supplementation. Adrenalectomy reverses the obese phenotype and restores the hypothalamic melanocortin tone in the *ob/ob* mouse, suggesting that glucocorticoids have a facilitative role in the development of obesity.³⁰ The human leptin homologue has been cloned, and various animal studies have demonstrated that leptin is produced in the periphery by white and possibly brown adipocytes. Additionally, it appears that the sympathetic nervous system (SNS), via β_3 -adrenoceptors, inhibits leptin expression (Fig. 140–2). Unlike the leptin-deficient *ob/ob* mouse, obese human serum leptin levels increase as fat cell mass increases. There is a direct relationship between serum leptin concentrations and various markers of obesity such as percentage of body fat, BMI, and serum insulin concentrations. Thus humans appear to be resistant to the satiety effects of leptin, and recent studies of leptin supplementation in humans have not significantly decreased obesity.³¹ Figure 140–2 shows the peripheral link that leptin appears to provide in signaling the central nervous system about the status of fat cell mass. However, there is increasing evidence of the complicated nature of leptin effects both within and outside the central nervous system.^{32–34} A second peptide, neuropeptide Y (NPY), is being studied intensely for its effects on feeding.³⁵ NPY elicits many effects both peripherally and centrally, including appetite stimulation. Messenger RNA for two new appetite-stimulating proteins called *orexins* has been observed to be concentrated in the lateral hypothalamus.³⁶ An understanding of the relationships between the sympathetic nervous system, leptin, NPY, orexins, and other hormones such as insulin and glucocorticoids is still evolving.³⁷ Exogenous manipulation of these proteins may provide future pharmacotherapeutic approaches to obesity management.

ACTIVITY

It is generally accepted that increased physical activity is an important component in the management of obesity.³⁸ Similarly, a sedentary lifestyle predisposes to weight gain and obesity. Yet the question of whether obese individuals are less physically active compared with age-matched lean individuals remains unanswered. Some studies show no difference in physical activity between lean and obese individuals, whereas others suggest that obese persons are less active. Although some studies suggest that obese persons are less active, it is unclear whether less physical activity leads to obesity or physical inactivity is itself secondary to the physical effects of obesity. Physical

activity includes voluntary work, recreational activity, and spontaneous physical activity including involuntary movements. Some authors have suggested that obese individuals have reduced levels of spontaneous physical activity leading to lower daily energy expenditure. However, results from studies designed to measure total daily energy expenditure remain controversial. A recent literature review found only a modest beneficial effect of exercise in preventing weight gain, with or without previous weight reduction.³⁹

WEIGHT GAIN SECONDARY TO MEDICAL CONDITIONS

Occasionally patients present with obesity secondary to an identifiable acquired medical condition. The most common endocrine condition associated with weight gain is hypothyroidism (see Chap. 73). These patients lose significant weight within weeks of thyroxin replacement therapy. However, many patients will not achieve a normal or ideal body weight despite adequate thyroid hormone replacement. Indeed, it is not uncommon for patients to request higher than physiologic replacement doses of thyroxin to artificially suppress their weight. It is important to remember that excess thyroid therapy can be associated with complications, including osteoporosis and cardiac disorders. Cushing's syndrome, another cause of obesity, is seen most commonly in patients receiving exogenous glucocorticoid therapy. These agents often are prescribed for a chronic condition such as chronic obstructive pulmonary disease (COPD), organ transplantation, or arthritis. Idiopathic Cushing's disease due to excess endogenous steroid secretion is, in contrast, very rare. In both iatrogenic and idiopathic Cushing's disease, the weight gain is in part due to fluid retention as well as increased adiposity. The adiposity associated with glucocorticoid excess has a particular body distribution in that it is central with relative loss of body muscle mass and thinning of the skin, leading to the characteristic purple skin striae and a buffalo hump behind the neck.

Occasionally patients can present with lesions of the hypothalamus that lead to hyperphagia and obesity. This disorder is rare and should not be confused with behavioral disorders of eating that are associated with psychopathology. These include binge eating disorders, which may respond to psychotherapy and in some cases pharmacotherapy (see Chap. 62). Obesity is itself associated with a higher prevalence of affective disorders, which if untreated may impair the success of any weight loss program. The clinician managing obesity must be aware of the presence of psychosocial disorders both as a cause and effect of obesity. Counseling strategies need to be incorporated into the management of selected obese individuals.⁴⁰ Furthermore, medications used to manage affective disorders, such as the selective serotonin reuptake inhibitors, have not been studied extensively with regard to combination use with appetite suppressant agents.

GENETIC SYNDROMES

Syndromes in which obesity is a major component are extremely rare. Prader-Willi, Simpson-Golabi-Behmel, Cohen's, Bardet-Biedl, Carpenter's, Börjeson's, and Wilson-Turner syndromes have all been associated with obesity. Of these, Prader-Willi syndrome is the most common and has a frequency of 1 in 20,000 live births. Other phenotypic features include changes in stature, mental retardation, and developmental abnormalities (e.g., hypogonadism). Because the incidence of these syndromes is rare, even collectively they contribute very little to the incidence of obesity. The clinician evaluating a

patient for obesity needs to be aware of their existence, and the physical examination of obese patients always should include an assessment for secondary causes of obesity including genetic syndromes (Fig. 140–3).

PATHOPHYSIOLOGY

ENERGY BALANCE

The net balance of energy ingested relative to energy expended by an individual over time determines the degree of obesity. Figure 140–1 represents the interplay between energy intake and expenditure. Energy stores will increase if there is imbalance between intake and expenditure. An individual's metabolic rate is the single largest determinant of energy expenditure. It is important to determine metabolic rate under standardized conditions, giving rise to terms such as resting energy expenditure (REE) and basal metabolic rate (BMR). REE is defined as the energy expended by a person at rest under conditions of thermal neutrality. BMR is more precisely defined as the REE measured soon after awakening in the morning, at least 12 hours after the last meal. Metabolic rate increases after eating, based on the size and composition of the meal. It reaches a maximum approximately 1 hour after the meal is consumed and is essentially back to basal levels 4 hours after the meal. This increase in metabolic rate is known as the *thermogenic effect of food*. The REE may include the residual thermic effect of a previous meal and may be lower than BMR during quiet sleep. In practice, BMR and REE differ by less than 10%, and the terms frequently are used interchangeably.

PERIPHERAL STORAGE AND THERMOGENESIS

Adipose tissue generally is divided into two major types, white and brown. The primary function of white adipose tissue is lipid manufacture, storage, and release. Lipid storage occurs in response to insulin with lipid release occurring during periods of calorie restriction, when insulin levels are suppressed. Brown-type tissue is notable for its ability to dissipate energy via a process of uncoupled mitochondrial respiration.⁴¹ Currently, the exact roles of each of these tissue subtypes are better defined in animal models than in humans. Adipose tissue is highly innervated by the sympathetic nervous system, and adrenergic stimulation is known to activate lipolysis in fat cells as well as increase energy expenditure in adipose tissue and skeletal muscle. These properties provide a potential pharmacologic avenue for altering energy balance and changing weight status. A major focus of research in obesity pharmacotherapy has centered on the activity of adrenergic receptors and their effect on adipose tissue with respect to energy storage and expenditure or thermogenesis.⁴² All three subtypes of β -adrenergic receptors (β_1 , β_2 , and β_3) appear to be active in fat cell function. The β_3 -receptor appears to be less responsive than β_1 and β_2 with respect to activation via norepinephrine. This has led to the development of specific β_3 -adrenoceptor agonists. However, apparent differences in selectivity and responsiveness between animal and human β_3 -receptors have complicated the drug development process. In vivo studies in humans suggest that the β_3 -receptor may be largely responsible for adipose tissue adrenergic-mediated increases in thermogenesis.⁴³ Genetic polymorphisms have been identified in both the β_2 - and β_3 -receptor systems that are associated with obesity or excess weight gain.⁴⁴ Thus genetic susceptibility for excess weight status may in part be related to adrenergic dysfunction. The development of effective pharmacotherapies involving these receptor

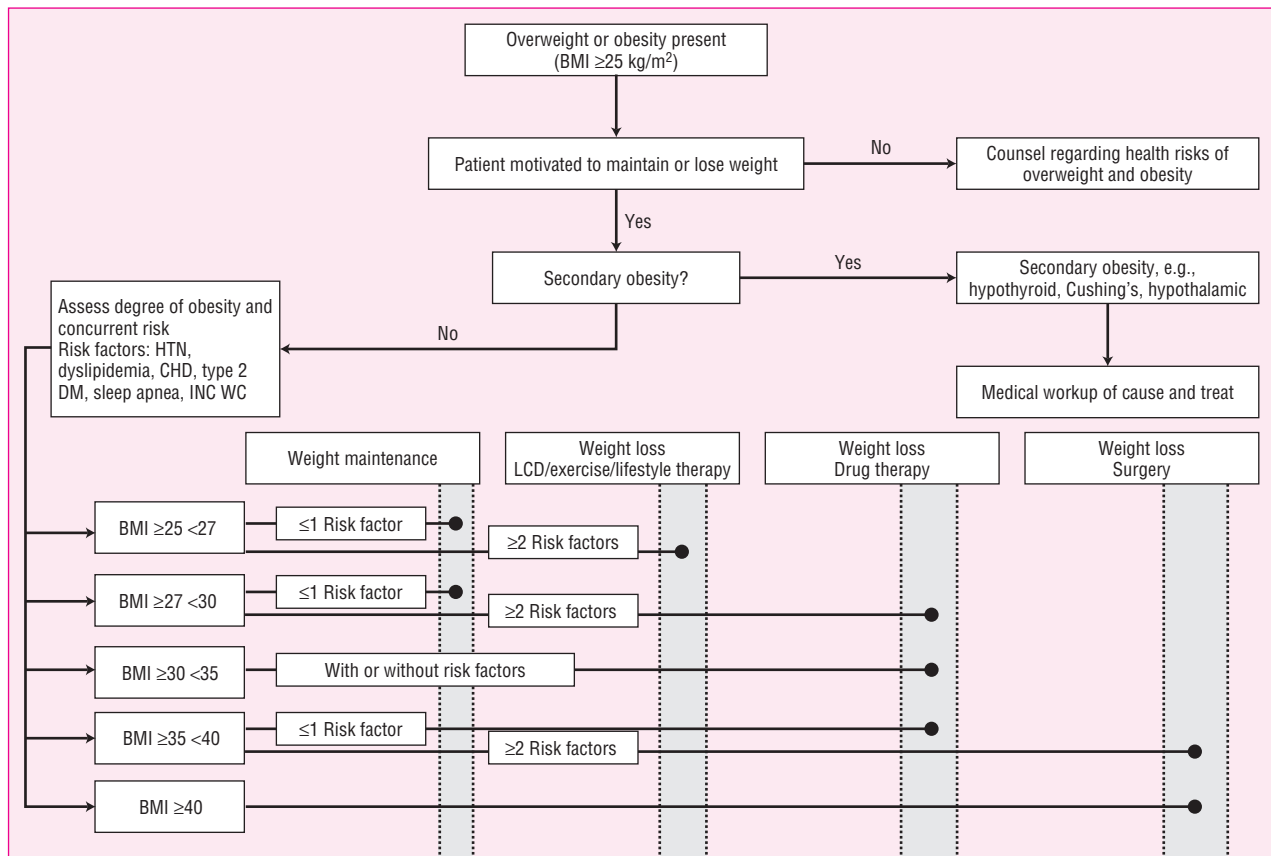

FIGURE 140-3. Pharmacotherapy treatment algorithm. A select population of individuals, based on BMI and WC together with concurrent risk factors, may benefit from medication therapy as an adjunct to a program of weight loss that includes diet, exercise, and behavioral modification. Abbreviations: WC, waist circumference; INC WC, >40 inches for males and >35 inches for females; BMI, body mass index; CHD, coronary heart disease; DM, diabetes mellitus; HTN, hypertension; LCD, low-calorie diet.

systems may be delayed pending definitive identification of receptor subtype contributions.

CLINICAL PRESENTATION

1 A consistent and reproducible description of weight status is essential in the diagnosis and management of obesity. For over two decades a clear distinction has been made between obesity and overweight by the National Center for Health Statistics (NCHS), yet clinicians and researchers often use the two terms interchangeably. *Overweight* refers to an excess body weight relative to a person's height. In contrast, *obesity* refers to a state of excess body fat as determined by measures of skinfold thickness, body density using underwater body weight, bioelectric impedance and conductivity, dual-energy x-ray absorptiometry (DEXA), computed tomography (CT), and magnetic resonance imaging (MRI). Many of these measurement techniques that determine body fat directly are too expensive and time-consuming to be used in population studies or for application in clinical medicine. Two measures which have been recognized as acceptable markers of excess body fat and have application regardless of sex are the body mass index (BMI) and the waist circumference (WC). While BMI and WC are related, each measure independently predicts disease risk. Both measurements should be taken at initial assessment and during routine follow-up of therapy for obesity.

Notably, epidemiologic studies demonstrate that WC adds little in terms of risk prediction once BMI reaches 35 kg/m². Thus, routine collection of WC should be implemented in those with BMI between 25 and 35 kg/m².

BMI is a measure of total body weight relative to height. Using metric units, it is defined as weight in kilograms divided by height in meters squared (kg/m²). Using pounds and inches, BMI (kg/m²) is estimated as: weight [pounds]/height [inches²] × 703. The BMI may overestimate the degree of excess body fat in various clinical situations (edematous states, extreme muscularity, muscle wasting, short-stature, etc), therefore clinical judgment is required.

Weight relative to height (BMI) is an acceptable measure of obesity; however, it does not always correspond to excess fat. Generally, central obesity reflects high levels of intra-abdominal or visceral fat. Intra-abdominal fat is best estimated by imaging techniques such as CT or MRI. More recent studies suggest that subcutaneous fat may be heterogeneous in its metabolic effects. In these studies, superficial subcutaneous fat had a weak association with metabolic markers of insulin production and release resistance, whereas deep subcutaneous fat had a strong relationship with insulin resistance.⁴⁵ This pattern of obesity is associated with an increased propensity for the development of hypertension, dyslipidemia, type 2 diabetes, and cardiovascular disease. Thus, in addition to the absolute excess fat mass, the distribution of this fat regionally in the body has an important effect on the mortality of obese individuals.

TABLE 140–3. Classification of Overweight and Obesity by BMI, Waist Circumference, and Associated Disease Risk

| | BMI (kg/m ²) | Obesity Class | Disease Risk ^a (Relative to Normal Weight and Waist Circumference) | |
|---------------------|--------------------------|---------------|---|-------------------------------------|
| | | | Men ≤40 in (≤102 cm) Women ≤35 in (≤88 cm) | >40 in (>102 cm) >35 in (>88 cm) |
| Underweight | <18.5 | | — | — |
| Normal ^b | 18.5–24.9 | | — | — |
| Overweight | 25.0–29.9 | | Increased | High |
| Obesity | 30.0–34.9 | I | High | Very high |
| | 35.0–39.9 | II | Very high | Very high |
| Extreme obesity | ≥40 | III | Extremely high | Extremely high |

^aDisease risk for type 2 diabetes, hypertension, and cardiovascular disease.

^bIncreased waist circumference can also be a marker for increased risk even in persons of normal weight.

Adapted from Preventing and Managing the Global Epidemic of Obesity. Report of the World Health Organization Consultation on Obesity. Geneva, World Health Organization, 1997. Reprinted with permission from NLH-NHLBI, http://www.nhlbi.nih.gov/guidelines/obesity/ob_home.htm

Waist circumference (WC) is the most practical method of characterizing central or visceral adiposity. Clinically, WC is the narrowest circumference measured in the area between the last rib and the top of the iliac crest.²⁷ The current definition for high-risk WC is greater than 40 inches in males and greater than 35 inches in females.²⁷

The importance and clinical applicability of these measurements continue to evolve as there are probably racial and ethnic differences in the relationship between BMI, WC, and risk for development of disease and enhanced comorbidity.^{20–22,46} Table 140–3 outlines the current classification of overweight and obesity using BMI and WC. The table identifies risk for development of type 2 diabetes, hypertension, or cardiovascular disease at various stages of BMI or WC. Note that increased WC confers increased risk even in normal-weight individuals.

COMORBIDITIES

2 Obesity is associated with serious health risks and increased mortality. Several disease states and/or conditions are more prevalent in obese patients (see Table 140–1). Increased body fat, increased total body weight, and a central distribution of body fat are all associated with an increased incidence of mortality, primarily due to cardiovascular disease. Hypertension, hyperlipidemia, insulin resistance, and glucose intolerance are all known cardiac risk factors that tend to cluster in obese individuals. Therefore, the obese individual is exposed to multiple risk factors. Some of the earliest studies from Framingham have confirmed the relationship between obesity and increased risk of stroke and coronary heart disease in both men and women.⁴⁷ This increased mortality is seen even with modest excess body weight. Blood pressure frequently is elevated in obese individuals and may in part explain the increased incidence of stroke and cardiovascular disease observed with obesity. Hypertension in lean individuals is associated with concentric hypertrophy due to an increased afterload, which increases the risk of cardiac ischemia. In contrast, with obesity eccentric dilatation is observed, leading to an increased volume load. This dilated cardiomyopathy is associated with a reduction in ventricular ejection fraction and a high-output cardiac state. The combination of obesity and hypertension is associated with thickening of the ventricular wall, ischemia, and increased heart volume. This leads more rapidly to heart failure and has been recognized for more than two decades.⁴⁸ Alterations in pulmonary function are common in patients with obesity. Most significant and costly in terms of morbidity and mortality is sleep apnea.⁴⁹ This disorder is

more common in men. The exact mechanism by which obesity leads to sleep apnea is unknown, but weight loss often results in significant and sometimes dramatic improvements in sleep apnea.

Diabetes mellitus and impaired glucose tolerance are associated with insulin resistance and obesity. The cellular mechanism by which obesity causes insulin resistance is unknown. Proposed mechanisms include downregulation of insulin receptors, abnormal postreceptor signals, circulating antagonists to insulin such as fatty acids or cytokines, and impaired gene transcription in insulin-responsive cells. Regardless of the mechanism of the insulin resistance, as insulin response becomes impaired, the pancreatic β cells respond by increasing insulin production and release, resulting in a state of relative hyperinsulinemia. Although hyperinsulinemia is known to be associated with an increased risk of cardiovascular disease, it is not known whether the increased insulin levels contribute directly to cardiac disease or if they are just a marker for the underlying defect of insulin resistance and glucose intolerance. Insulin resistance in turn also frequently leads to impaired lipid metabolism (increased cholesterol, increased triglycerides, and low circulating high-density lipoprotein) and hypertension. As with cardiovascular disease, fat distribution is an important factor in determining the risk of developing type 2 diabetes. Central obesity has been shown to increase the risk of diabetes. Intentional weight loss has been shown to reduce mortality substantially in obese individuals with diabetes.⁵⁰

Osteoarthritis in weight-bearing joints, such as the knees, may be related directly to the mechanical effects of excess body weight and the resulting forces exerted on these joint surfaces. The increase of osteoarthritis in non-weight-bearing joints, however, suggests that obesity may lead to altered cartilage, collagen, and even bone metabolism. Osteoarthritis and its symptoms, such as pain, are a significant barrier to physical activity and a key impediment to sustained weight loss.

Obesity affects the human reproductive system in a number of ways. Obesity is associated with earlier menarche in girls and hyperandrogenism, hirsutism, and anovulatory menstrual cycles in women. In some women this disorder manifests as overt polycystic ovary syndrome (PCOS).⁵¹ Insulin resistance is common in these women. Weight loss, and more recently therapy with insulin-sensitizing drugs such as the thiazolidinediones and biguanides, can restore normal ovulation in some women.⁵¹ These observations suggest that insulin resistance plays a part in the causation of PCOS-associated with obesity.

▶ TREATMENT: Obesity

■ DESIRED OUTCOME

3 Weight management is commonly considered successful when a predefined amount of weight has been lost such that a final goal is achieved. However, desired outcomes are fully dependent upon the clinical situation. Success may also include endpoints of decreasing the rate of weight gain or maintaining a weight-neutral status. A significant number of web-based resources for supporting both patient and practitioner weight management activities are available.^{14,16,27,52–54}

■ GENERAL APPROACH TO TREATMENT

The success of obesity therapy has been measured most often as weight loss over study periods of up to 12 months. Successful obesity treatment plans have incorporated diet, exercise, behavior modification (with or without pharmacologic therapy), and/or surgical intervention. Figure 140–4 shows the sites of action of these therapies within the energy intake, storage, and expenditure cycle.

Patients seeking help for obesity do so for many reasons, including improvement in their quality of life, a reduction in associated morbidity, and to prolong their life. Yet numerous individuals seek therapy for obesity primarily for cosmetic purposes and often have unreasonable goals and expectations. Aggressive marketing of weight loss programs, therapies, and diets—parallel to the fashion industry’s

standards of desirable body profiles—has led many individuals to set impossible goals and expectations. In some cases these persons will go to extreme measures to achieve weight loss, even at the risk of injury to themselves. Clinicians therefore must be careful not only to fully discuss risks of therapies, but also to clearly define achievable benefits and magnitude of weight loss. Criteria for weight loss vary from the most aggressive goal of trying to achieve an “ideal weight” to the more reasonable goals of modest (e.g., loss of 5% of body weight) but sustained weight loss. In practice, the goal has to be set based on many factors, including initial body weight, patient motivation and desire, presence of comorbid conditions, and age. For example, in patients with diabetes, even modest weight loss can improve glucose control and reduce mortality significantly,^{50,51} yet in individuals with osteoarthritis, significantly more weight reduction may be required to improve symptoms. Indeed, dietary modification and exercise have been shown to ameliorate hyperglycemia, hyperlipidemia, and hypertension with weight loss of less than 5% of initial body weight. These data emphasize the importance of defining endpoints and measures of success in any weight loss plan.

Most weight loss interventions consist of a combination of lifestyle changes, diet, drug therapy if indicated, and in some cases surgery (see Fig. 140–3). Prior to recommending any therapy, the clinician must evaluate the patient for the presence of secondary causes of obesity. If a secondary cause is suspected, then a more complete diagnostic work-up and appropriate therapy are paramount. The next step in the patient evaluation is to determine the presence and severity of other medical conditions either directly associated with obesity

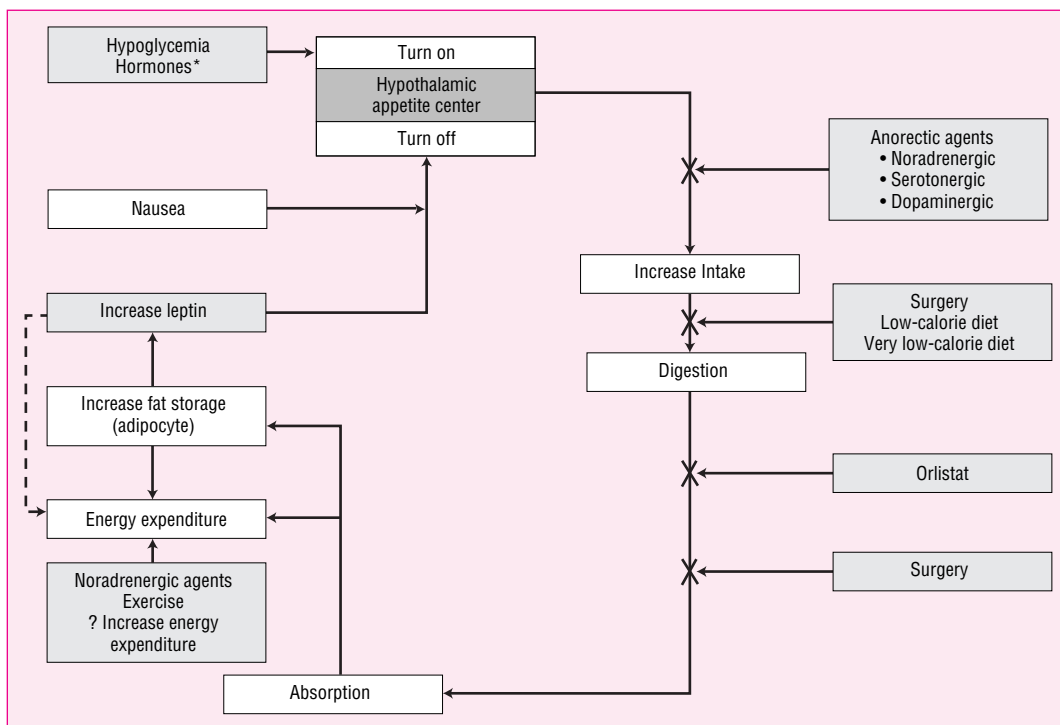

FIGURE 140–4. Hypothalamic appetite centers in the brain modulate both central and peripheral signals. This figure demonstrates the sites of action for various obesity treatment modalities within the cycle of energy intake and storage. Leptin, while signaling the central nervous system of the status of peripheral fat cell mass, may also have functions with regard to energy expenditure. Some appetite suppressant agents, alone or in combination, also modulate energy expenditure. *Including insulin, thyroxine, glucocorticoids, and progesterones.

(e.g., diabetes), or which have an impact on therapeutic decision making (e.g., history of liver disease or cardiac arrhythmia). Appropriate laboratory tests to exclude and/or quantify the degree of specific conditions such as diabetes, liver dysfunction, and nephropathy should be done as indicated by the history and physical examination. Based on the outcome of this medical evaluation, the patient then should be counseled on treatment options, benefits, and risks. The ultimate goals of treatment must be defined clearly. These goals may be absolute weight loss if obesity is present without other comorbid conditions. If improvement in blood glucose, blood cholesterol, and hypertension are primary goals, then these must be defined appropriately, such as target levels for low-density-lipoprotein cholesterol, glycosylated hemoglobin, or blood pressure. For these patients, weight loss goals may be as little as 5% of starting weight. In contrast, if obesity is causing physical problems such as impaired mobility, osteoarthritis, or sleep apnea, then 10% to 20% of starting weight may be more appropriate. All too often patients expect to lose weight overnight, only to be disappointed. Thus it is important to set a time course for the plan. A reasonable rate of weight loss is typically about 0.5 kg per week.

■ NONPHARMACOLOGIC THERAPY

■ BEHAVIORAL MODIFICATION

4 Behavior modification is common to almost all weight loss interventions. The primary aim is to help patients choose lifestyles that are conducive to safe and sustained weight loss. Behavioral therapy is based on principles of human learning and therefore attempts to substitute learned undesirable habits with desirable behaviors using a combination of stimulus control and reinforcement. Most such programs use self-monitoring of diet and exercise both to increase patient awareness of behavior, and as a tool for the clinician to determine patient compliance as well as patient motivation.^{55,56} Behavior is reinforced by techniques including behavioral contracting, social support, relapse prevention, and in some cases booster treatments. Behavioral contracts are written agreements jointly developed by the patient and clinician. Components of these agreements include goals of therapy, methods to achieve these goals, and rewards for achieving these goals successfully. Social support requires the active participation of a close friend or relative who is involved in monitoring compliance and reinforcing behavior. Relapse prevention is geared to identifying high-risk situations for relapse such as social events, and training the individual to avoid these circumstances. Eventually, the patient is trained to deal with these situations actively, such as refusing high-fat foods assertively rather than avoiding such social events.

■ DIET

Numerous diet or nutrition plans exist to aid in weight loss.^{56,57} The lay press is replete with many diet routines that fall into and out of favor.

CLINICAL CONTROVERSY

Due to the popularity of diets such as Atkin's New Diet Revolution (high fat, low carbohydrate, high protein) and The New Pritikin Program (low fat, high carbohydrate, medium protein), there is extensive discussion in the lay media and academic circles regarding the risks, benefits, and outcomes

related to diets that preferentially employ macronutrient extremes (i.e., high protein vs. high carbohydrate vs. low fat). Ultimately, overall energy balance will determine the rate and extent of weight change.

Few, if any, of the popular "fad" diets have been objectively studied in a randomized, controlled fashion, with sufficient power to clearly determine their acute and chronic effects on human physiology. Additionally, the relative efficiency of these diets for weight loss and chronic weight maintenance remain ill-defined. However, recent efforts to better understand the acute and chronic effects of these extremes in macronutrient intake are being reported.^{58,59} Whichever diet program is selected, it is clear that energy consumption must be less than energy expenditure to achieve weight loss (see Fig. 140–1). The challenge has been to develop a diet plan that leads to consistent adherence by the patient and therefore sustained weight loss and/or maintenance. Two broad categories of diet have been used in clinical practice: low calorie and very low calorie. The low-calorie diet (LCD) or Step 1 Diet, is recommended as part of the recent National Heart, Lung and Blood Institute (NHLBI) Obesity Education Initiative. This LCD recommends from 1000 to 1200 kcal/day for women and 1200 to 1600 kcal/day for men, based on estimated needs and weight maintenance or reduction goals. Very-low-calorie diets (VLCDs) generally contain less than 800 kcal/day. These highly restrictive diets often result in early weight loss, but have been disappointing in the long term in part because it is difficult for individuals to maintain compliance. Additionally, VLCDs require intensive medical monitoring, and are no more effective and possibly less effective for long-term weight reduction than LCDs. Other investigators have proposed total or modified fasts. The obvious problem with total fasts is that both fat and lean body mass are lost. In addition, because of diuresis, significant mineral losses occur. Because of the problem with total fasting, alternate regimens called protein-supplemented modified fasts (PSMFs), became popular. With a PSMF, the protein is given in the form of either formula or natural foods such as fish or lean meat. The consensus is that it is dangerous to allow these diets to be continued for longer than 16 weeks at a time. Patients may lose 1.5 to 2.3 kg per week on these diets. All these types of severe calorie-restricted diets need vitamin and mineral supplementation.^{27,53}

A more reasonable goal for individuals is weight reduction of about 0.5 to 1 kg per week achieved by a negative calorie balance of approximately 500 to 1000 kcal/day. This translates into a diet of approximately 20 kcal/kg of desirable body weight for most adults. The dietary regimen should be well balanced in fat, carbohydrates, and proteins as well as micronutrients. Generally 0.8 g of protein per kilogram of desirable body weight is recommended, with at most 30% of calories from fat.

■ SURGERY

Surgery remains the most effective intervention for the treatment of obesity. However, due to its related morbidity and mortality, this intervention is reserved for those with BMI greater than 40 kg/m² or 35 kg/m² and significant comorbidity.^{60–62} Surgical procedures either reduce the stomach volume and/or reduce the absorptive surface of the alimentary tract, resulting in some degree of malabsorption. Currently, the three major types of procedures are: stapled gastroplasty, adjustable gastric banding, and conventional Roux-en-Y gastric bypass.⁶³

CLINICAL CONTROVERSY

The superiority of conventional Roux-en-Y bypass versus adjustable gastric banding in terms of efficacy, morbidity, and mortality is actively debated. However, given the nature of bariatric surgery and available alternatives, the probability that randomized controlled trials will be completed to answer these questions is low.

Gastroplasty and adjustable gastric banding are designed to reduce the volume of the stomach and thus restrict the rate of nutrient intake. Conventional bypass combines a restrictive approach with a degree of malabsorption induced by excluding 90% to 95% of the stomach, the entire duodenum, and a portion of the proximal jejunum. Conventional Roux-en-Y bypass yields greater and more long-lasting weight loss than the other two methods. Ultimately, reductions in total body weight of approximately 35% can be achieved. Less optimal weight loss, late weight gain, the need for surgical revision in 15% to 20% for outlet stenosis or severe reflux, and long-term failure rates of up to 80% have dampened interest in gastroplasty.⁶³ Similarly, gastric banding is plagued by frequent reoperation for stenosis and erosion or both of the band. Improvements in the peri- and postoperative care of gastric surgery patients has reduced morbidity and mortality with conventional bypass to approximately 10% and 1%, respectively.⁶³ Some of the most common early complications of conventional gastric bypass include: deep venous thrombosis, anastomotic leaks, and wound infections. Approximately one-third of patients develop significant vitamin B₁₂ and iron deficiency with a large proportion demonstrating microcytic anemia. Dumping syndrome, characterized by colic, nausea, diarrhea, and bloating, does occur in a small number of patients and can complicate provision of drug therapy in some cases. Classically, Roux-en-Y gastric bypass was only performed as an open surgical procedure. However, recent developments in surgical technique have allowed this procedure to be performed via laparoscope.⁶² Long-term results comparing the outcomes of open versus laparoscopic methods are not yet available. After experiencing weight loss, many gastric surgery patients are able to discontinue pharmacotherapy for glucose lowering, dyslipidemia, and hypertension. Frequently

however, hypertension medications must be restarted at various time periods postsurgery, in spite of the fact that weight regain has not or has only minimally occurred. The reasons and mechanisms for this are unclear, but reiterate the need for intensive follow-up by all clinical specialties involved in the care of these patients.

Selection of the appropriate patients for surgery and subsequently identifying the most appropriate procedure for each patient is critical. The input of an experienced surgeon working with a multidisciplinary team is invaluable.

CLINICAL CONTROVERSY

The debate regarding the appropriateness of obesity pharmacotherapy remains heated, fueled by the recognized national need to treat a growing epidemic, the lack of long-term outcomes studies, and the medical and litigious fallout from the failed use of fen-phen (fenfluramine-phentermine) and dexfenfluramine (Redux).

PHARMACOLOGIC THERAPY

5 The debate regarding the appropriateness of obesity pharmacotherapy remains heated, fueled by the recognized national need to treat a growing epidemic and the medical and litigious fallout from the failed use of fen-phen (fenfluramine-phentermine) and dexfenfluramine (Redux).^{64,65} Strategies for the pharmacologic management of obesity have been focused on modulating central and/or peripheral sites that regulate human energy balance. Figure 140–4 depicts sites of action and Table 140–4 lists the most common classes of agents currently in use. Since the 1970s, numerous studies of the effects of central appetite suppressant agents on weight status have been completed.¹⁷ The National Task Force on the Prevention and Treatment of Obesity concluded that short-term anorexic agent use was difficult to justify because of the predictable weight regain that occurs on discontinuation of pharmacotherapy.⁶⁶ However, long-term pharmacotherapy may have a place in the treatment of obesity for

TABLE 140–4. Pharmacotherapeutic Agents for Weight Loss

| Class | Availability | Status | Daily Dosages (mg) |
|--|-----------------|-----------------|--------------------|
| Gastrointestinal lipase inhibitor | | | |
| Orlistat (Xenical) | Rx | Long-term use | 360 |
| Noradrenergic/serotonergic agent | | | |
| Sibutramine (Meridia) | Rx | Long-term use | 5–15 |
| Noradrenergic agents | | | |
| Phendimetrazine (Prelu-2, Bontril, Plegine, X-Trazine) | Rx | Short-term use | 70–105 |
| Phentermine (Fastin, Oby-trim, Adipex-P, Ionamin) | Rx | Short-term use | 15–37.5 |
| Diethylpropion (Tenuate, Tenuate Dospan) | Rx | Short-term use | 75 |
| Methamphetamine HCl (desoxyephedrine HCl) | Rx ^a | Not recommended | 5–15 |
| Amphetamine sulfate | Rx ^a | Not recommended | 5–30 |
| Dextroamphetamine sulfate (Dexedrine) | Rx ^a | Not recommended | 5–30 |
| Amphetamine/dextroamphetamine mixtures (Adderall) | Rx ^a | Not recommended | 5–30 |
| Benzphetamine (Didrex) | Rx ^a | Not recommended | 25–150 |
| Ephedrine (various) | OTC | Unlabeled use | 20–60 |
| Serotonergic agents | | | |
| Fluoxetine (Prozac) | Rx | Unlabeled use | 60 |
| Sertraline (Zoloft) | Rx | Unlabeled use | 200 |

^aHigh abuse potential.

patients who have no obvious contraindications to available drug therapy.^{17,27,66} Additionally, the American Association of Clinical Endocrinologists (AACE) and the American College of Endocrinology (ACE) have developed a guideline for multidisciplinary obesity team approach to therapy.⁶⁷ Most recently, the U.S. Preventive Services Task Force has recently published an exhaustive summary of evidence related to screening and interventions for adult obesity that incorporates a graded assessment of obesity pharmacotherapy randomized controlled trials.⁵⁶ Routine implementation awaits the development of medications that are effective and safe with long-term exposure. The discovery of cardiac valve disease in relation to serotonergic appetite suppressant use and its resulting multibillion dollar class action litigation affirms the task force's warning for further study of available therapies prior to widespread implementation of routine obesity pharmacotherapy.^{64,65} A recent five-state survey demonstrated the relatively common concurrent use of both prescription and non-prescription weight loss medications.⁶⁸ Therefore, clinicians should maintain a high degree of sensitivity towards the potential polypharmacy practices of patients with obesity. The next sections outline the recent and current status of pharmacologic agents for obesity therapy, focusing on proposed mechanisms, dosing recommendations, potential side effects, and monitoring parameters.

■ LIPASE INHIBITORS

■ Orlistat

The percentage of dietary intake as fat has been implicated as a contributing factor in the development of obesity. Fat represents an extremely dense energy source; 9 kcal/g as compared with approximately 4 kcal/g from protein or carbohydrate. In humans, most of accumulated body fat excess is derived from dietary sources because of a limited capacity to synthesize fat from carbohydrate. Gastrointestinal (gastric, pancreatic, and carboxylester) lipases are essential in the absorption of the long-chain triglycerides commonly found in Western diets. Additionally, lipase is known to play a role in facilitating gastric emptying and secretion of other pancreaticobiliary substances. Orlistat (Xenical, RO 18-0647) is a synthetic derivative of lipstatin, a natural lipase inhibitor produced by *Streptomyces toxytrincini*. Orlistat is minimally absorbed and selectively inhibits gastrointestinal lipases. Lipase inhibition results in decreased formation of free fatty acids from dietary triglyceride. Additionally, lower luminal free fatty acid concentrations result in malabsorption of cholesterol. Orlistat induces weight loss by a persistent lowering of dietary fat absorption. Clinical studies employing orlistat as an adjunct to diet therapy demonstrate dose-dependent reductions in fat absorption. Up to 30% reduction in fat absorption occurred with daily doses of 360 mg.⁶⁹ No additional decreases in fat absorption occur with doses above 400 mg/day. The drug must be taken with foods that contain fat in order to exert its effect.

At least one gastrointestinal complaint (soft stools, abdominal pain/colic, flatulence, fecal urgency, or incontinence) is reported initially in up to 80% of individuals using orlistat. These complaints are most common in the first 1 to 2 months of therapy, are mild to moderate in severity, and tend to improve with continued orlistat use. Appropriately limiting dietary fat prior to initiation of orlistat therapy may be beneficial in decreasing initial gastrointestinal complaints. Orlistat-induced malabsorption of fat-soluble vitamins has been documented.⁶⁹ Therefore, vitamin supplementation should be considered during therapy with this agent. Orlistat does not appear to change the pharmacokinetic or dynamic profiles of numerous other

agents including oral contraceptives, digoxin, glyburide, phenytoin, paravastatin, warfarin, nifedipine, captopril, atenolol, furosemide, and ethanol. A notable exception is cyclosporine, wherein case reports suggest significant decreases in cyclosporine serum concentrations with concurrent orlistat use.⁶⁹

Overall, results from clinical trials demonstrate that orlistat effectively increases the amount of weight lost and decreases the amount of weight regained during medically supervised weight loss programs.^{70,71} Significant improvements in lipid profile, glucose control, and other markers of metabolism are seen in spite of the relatively small 2- to 4-kg differences in weight lost when using orlistat in addition to diet. In patients with impaired glucose tolerance, weight loss using orlistat significantly decreased the rate of conversion to type 2 diabetes.⁷² Additionally, improved glycemic control can be attained in patients with type 2 diabetes by inducing or increasing weight loss with orlistat in addition to diet management. In some cases, dosages or the number of agents required for glucose lowering may be decreased.⁷³ Finally, orlistat is the first agent for the chronic treatment of obesity with an indication for use in adolescents aged 12 to 16 years.

■ NORADRENERGIC-SEROTONERGIC AGENTS

■ Sibutramine

An orally active racemic mixture, sibutramine, became available in the United States in early 1998.⁷⁴ The parent compound and two active metabolites appear to increase synaptic concentrations of serotonin, norepinephrine (NE), and dopamine via reuptake inhibition. The active metabolites (M₁ and M₂) are more potent than the parent sibutramine. Reuptake inhibition appears to be greatest for NE, followed by serotonin, with dopamine the least inhibited. Sibutramine, M₁, and M₂ do not directly stimulate serotonergic (5-HT₁ or 5-HT₂), noradrenergic (α_1 , α_2 , β_1 , β_2 , and β_3), or dopamine receptors. It is thought that sibutramine induces weight loss by both decreasing appetite and maintaining or increasing thermogenesis via the combined effects on 5-HT and NE reuptake inhibition. In humans, the degree to which these effects can be attributed to central versus peripheral activity is currently unknown. Sibutramine is subject to hepatic first-pass metabolism via cytochrome P450 3A4. Moderate changes in sibutramine and/or metabolite disposition have been seen with ketoconazole coadministration. M₁ and M₂ area under the curve increased by 58% and 20%, respectively, with concurrent ketoconazole (200 mg twice daily for 7 days). Smaller changes have been noted with concurrent erythromycin and cimetidine. The active metabolites M₁ and M₂ exhibit elimination half-lives of 14 and 16 hours, respectively. Further metabolism of the active metabolites results in conjugates that are eliminated renally. The pharmacokinetics of sibutramine allow for once-daily oral dosing.

Sibutramine has been studied in clinical trials in doses from 1 to 30 mg daily and demonstrates a relatively clear dose-response relationship. Weight loss from daily doses of 1 mg is, on average, no different than from placebo. The recommended starting dose is 10 mg daily, with a recommended dose range of 5 to 15 mg daily. Dry mouth, anorexia, insomnia, constipation, appetite increase, dizziness, and nausea were noted two- to threefold more frequently in sibutramine-treated subjects than in placebo-treated subjects. Significant increases in both systolic and diastolic blood pressure and pulse rate have been noted with sibutramine use.⁷⁴ Baseline blood pressure should be established prior to beginning therapy, and close monitoring is required when using this agent. Sibutramine product labeling indicates that it should not be used in patients with a history of coronary artery

disease, stroke, congestive heart failure, or arrhythmias. Like other centrally acting appetite suppressants, sibutramine should not be used in patients receiving MAO inhibitor therapies. Sibutramine is listed as a schedule IV prescription substance despite being noted as having no street value by recreational substance users. Primary pulmonary hypertension has not been reported with sibutramine use. Echocardiographic assessments of a small cohort of patients from clinical trials with approximately 6 months of exposure do not demonstrate the cardiac valve problems seen with the fenfluramine derivatives. Based on 12-month clinical trials, weight loss with sibutramine therapy appears to be most significant during the first 6 months of therapy. Twenty-nine percent of placebo-treated patients in these trials attained a 5% reduction in total body weight after 12 months. Using sibutramine at 10 and 15 mg/day resulted in 56% and 65% of patients, respectively, achieving at least a 5% reduction in total body weight. A 10% reduction in body weight was achieved by 8% of placebo-treated patients, whereas 30% and 39% of those taking sibutramine 10 and 15 mg/day, respectively, obtained this level of weight reduction. There is, on average, a tendency for weight regain after 6 months of treatment. As with other centrally active appetite suppressants, weight regain occurs with cessation of therapy. Safety and efficacy beyond 1 year of exposure to sibutramine are currently uncertain.

■ NORADRENERGIC AGENTS

■ Phentermine

Phentermine is structurally similar to amphetamine, but it has less severe CNS stimulation and a lower abuse potential. Its mechanism of action is related to enhanced norepinephrine and dopamine neurotransmission. Phentermine is available in both immediate-release and sustained-release formulations. However, the value of sustained-release formulations can be questioned based on the reported phentermine plasma half-life of 12 to 24 hours.¹⁷ Phentermine is an effective adjunct to diet, exercise, and behavior modification for producing weight loss in excess of that seen with placebo.¹⁷ Intermittent phentermine therapy appears to elicit comparable weight loss when compared with continuous use. However, most individuals experience weight regains during therapy and generally always after discontinuing use.¹⁷ A single dose of 30 mg once daily in the morning provides effective appetite suppression throughout the day. Divided doses of 8 mg immediately prior to meals, however, are common. Doses above 30 mg daily do not improve effectiveness.⁷⁵ Evening or nighttime dosing should be avoided because of insomnia. Significant increases in blood pressure, palpitations, and arrhythmias can occur with phentermine administration. Use is not advisable in hypertensive patients and those with unstable cardiovascular function. The potential for hypertensive crisis with coadministration of phentermine and monoamine oxidase (MAO) inhibitors is noted in product labeling because of the documented cases of this syndrome seen with coadministration of amphetamine or noradrenergic derivatives and MAO inhibitors.⁷⁶ Similar warnings have been noted regarding concomitant use of tricyclic antidepressants, but this is less well documented. With MAO inhibitors, a minimum washout time of 14 days prior to use of any adrenergic agent is suggested to avoid excessive adrenergic stimulation syndromes. Phentermine use is contraindicated in patients who are abusers of substances such as cocaine, phencyclidine, and methamphetamine, again because of the potential for excessive adrenergic stimulation syndromes and abuse potential. Mydriasis from adrenergic stimulation can worsen glaucoma, and patients diagnosed with glaucoma should not receive phentermine. Diabetic patients may

experience altered insulin or oral hypoglycemic dosage requirements soon after beginning therapy and prior to any substantial weight loss.

Phentermine currently remains on the market as a short-term pharmacotherapy for obesity despite recognition of cardiac valvulopathy in a high percentage of patients who used phentermine in combination with fenfluramine derivatives. Phentermine remains one of the most widely prescribed weight management medications in spite of product labeling that indicates short-term, monotherapy use only.⁷⁷ This usage pattern persists in spite of the current federal recommendations that promote only long-term drug intervention when obesity pharmacotherapy is appropriate.⁵³

■ Mazindol

Chemically distinct from amphetamines and phentermine, mazindol's tricyclic structure resulted in amphetamine-like appetite suppression.¹⁷ Despite demonstrated efficacy as a short-term therapy for weight reduction, mazindol is no longer available in the United States.⁷⁸

■ Diethylpropion

Diethylpropion stimulates norepinephrine release from presynaptic storage granules. Increased adrenergic neurotransmitter concentrations activate hypothalamic centers, which result in decreased appetite and food intake. This drug undergoes extensive first-pass hepatic metabolism. Active metabolites are eliminated renally and account for approximately 70% of the administered dose. The elimination half-life of these metabolites is approximately 8 hours.⁷⁵ Less than 10% of the parent compound is recovered in urine. No specific dosing recommendations exist for use in patients with renal or hepatic insufficiency. Diethylpropion can be taken in divided daily doses, generally 25 mg three times daily before meals. An extended-release formulation is also employed by some clinicians, usually as 75 mg taken once daily in the morning or midmorning. Both dosing regimens are effective in achieving short-term weight loss in excess of placebo.¹⁷ Complaints of insomnia increase if late afternoon dosing is used. Diethylpropion causes less CNS stimulation than mazindol and generally causes less insomnia than phentermine. Patients with severe hypertension or significant cardiovascular disease should not receive diethylpropion. Diabetic patients may experience decreased insulin or oral hypoglycemic dosage requirements soon after beginning therapy and prior to any substantial weight loss. More frequent blood glucose self-monitoring and medical follow-up are warranted when treating diabetic patients with diethylpropion.

■ Amphetamines

Appetite suppressant effects of the amphetamines were well recognized in the 1930s. Amphetamines activate central noradrenergic receptor systems as well as dopaminergic pathways at higher doses, by stimulating neurotransmitter release. Increases in blood pressure and mild bronchodilation are attributed to peripheral α - and β -receptor activation. The central nervous system stimulant and addiction potential of amphetamine relative to other compounds has been described as amphetamine > methamphetamine > phentermine > mazindol > diethylpropion.⁶⁷ The powerful stimulant and addictive potential of the amphetamines relative to other available agents has resulted in their general avoidance for the treatment of obesity.⁶⁷

■ Phenylpropanolamine

Although commonly classified as a noradrenergic anorexic, phenylpropanolamine (PPA) is atypical with regard to its mechanism and site of action. PPA racemates, D- and L-norephedrine, have chemical structures quite similar to amphetamine.¹⁷ PPA has been used for many years as a constituent of over-the-counter appetite suppressants and various cough and cold preparations. However, because of persistent case reports of hemorrhagic stroke related to PPA exposure, the U.S. Food and Drug Administration and pharmaceutical manufacturers partnered to complete a case-control study known as the Hemorrhagic Stroke Project (HSP) during the 1990s. In October 2000, the Nonprescription Drugs Advisory Committee discussed the HSP report and concluded that PPA was not safe for continued use. A peer-reviewed publication based on the HSP report suggests that PPA in appetite suppressants and possibly cough and cold preparations appears to increase the risk of hemorrhagic stroke in women.⁷⁹ No increased risk was noted in men. Based on the accepted background prevalence of stroke and the odds ratios defined by the HSP report, Kernan and colleagues estimate that 1 woman may experience PPA-related stroke for every 107,000 to 3,268,000 women exposed to PPA appetite suppressants.⁷⁹ Despite the very low risk of hemorrhagic stroke, the FDA believes that a favorable risk-benefit no longer exists for any PPA-containing products. As such, PPA-containing products have either been reformulated without PPA or removed from the market in the United States. However, due to the voluntary nature of the request for reformulation or removal from the market, the FDA recommends that all consumers review product labels to ensure the absence of PPA from weight loss and cough or cold preparations.⁸⁰

■ Ephedrine

Chemically related to PPA (\pm norephedrine), ephedrine may be a viable obesity pharmacotherapy. It appears to suppress appetite and increase energy expenditure via release of presynaptic norepinephrine and direct stimulation of thermogenic β -adrenergic receptors.⁸¹ The efficiency of ephedrine stimulation is somewhat blunted by physiologic feedback systems involving adenosine and various prostaglandins. This notion has stimulated research to characterize the effect of ephedrine in the presence of adenosine and prostaglandin antagonists such as caffeine and aspirin.⁸² Ephedrine in combination with caffeine has enhanced appetite suppression and thermogenesis as compared with placebo and other anorectics over time periods of up to 6 months.^{81,83} Oral doses of 20 mg ephedrine and 200 mg caffeine up to three times daily have been studied.⁸⁴ The spectrum of side effects with ephedrine and ephedrine-caffeine combinations is similar to that seen with other noradrenergic agents. Side effects are more notable at higher doses and most commonly include tremor, agitation, nervousness, increased sweating, and insomnia; palpitations and tachycardia have also been reported. Patients with diabetes, hypertension, or cardiovascular disease (including arrhythmic conditions) should not self-medicate with ephedrine-containing products without evaluation by a qualified physician. Ephedrine is available both with and without a prescription; neither form is labeled by the FDA for use as an obesity therapy.

■ SEROTONERGIC AGENTS

Serotonin is an important neurotransmitter involved in many human physiologic systems. Sleep-wake cycles, sensitivity to pain, blood

pressure, mood, and eating behaviors have links to serotonin activity. Increasing central serotonin levels decreases the amount of food consumed and prolongs the time between food intake. Some serotonergic agents increase central serotonin concentrations via stimulating release of presynaptic stores and/or inhibition of reuptake into storage granules. Additionally, either the parent compound or metabolites of these agents also may stimulate postsynaptic 5-HT receptors directly. Peripheral serotonin effects that have an impact on appetite, such as slowing gastric motility, also have been described. A major distinction between serotonergic and noradrenergic anorexigents is that serotonergic agents lack the central stimulant effects and thus the abuse potential seen with the noradrenergic compounds.¹⁷ Conversely, decreased wakefulness, altered sleep patterns, and changes in affect can be seen.

■ Antidepressants: Selective Serotonin Reuptake Inhibitors

It is interesting to note that some of the serotonergic appetite-suppressing agents were first studied as antidepressants and then noted subsequently to have effects on weight. As a class, the serotonin reuptake inhibitors generally are weight neutral as opposed to other commonly used compounds such as the tricyclic antidepressants (see Chap. 67). The National Task Force on the Prevention and Treatment of Obesity has reviewed multiple randomized, double-blinded, placebo-controlled weight loss clinical trials using fluoxetine and one with sertraline.^{66,85} Patients receiving fluoxetine (60 mg/day) demonstrate initial weight loss of up to 2 to 4 kg on average, but weight regain occurs despite continued medication use such that no difference is noted between fluoxetine and placebo over periods of up to 1 year.⁸⁶ Similar findings are noted using sertraline (200 mg/day) as an adjunct to help maintain weight lost with a very-low-calorie diet.⁸⁵ A direct relationship exists between amount of weight lost and the sum of fluoxetine and norfluoxetine plasma concentrations. Higher plasma concentrations are associated with greater weight loss. The antidepressant serotonin reuptake inhibitors are not approved by the FDA as weight management agents and are not recommended currently for routine treatment of obesity. Some practitioners continue to prescribe these agents for the treatment of obesity “off label” either alone or in combination with phentermine.⁸⁷ The safety and efficacy of phentermine-serotonin reuptake inhibitor combinations is currently unclear. A case report of adverse experiences (e.g., impaired mentation, tremor, hyperreflexia, and gastrointestinal symptoms) with unintentional concurrent use of phentermine and fluoxetine reinforces the need for caution by prescribers of unlabeled combination therapy.⁸⁸ Serious adverse effects such as primary pulmonary hypertension and cardiac valve abnormalities in excess of background prevalence have not been reported in relation to selective serotonin reuptake inhibitor use for obesity therapy.

■ Fenfluramine and Dexfenfluramine

Fenfluramine is an orally active racemic mixture (D, L-fenfluramine) that was used extensively as monotherapy for appetite suppression for many years. Its D-isomer, dexfenfluramine, was used extensively in Europe prior to its release in the United States in 1996, and was the first agent in the United States to receive labeling for chronic use. Both agents increased synaptic serotonin concentration via reuptake inhibition and possibly by increasing serotonin release. In studies sponsored by the National Institutes of Health (NIH), it was demonstrated that the combination of fenfluramine with phentermine (fen-phen) resulted in significant weight loss with fewer side effects, using

TABLE 140–5. Herbal/Natural Products and Food Supplements Used for Weight Loss^a

| Herbal/Natural/ Food Supplements | Active Moiety | Proposed Mechanism |
|-------------------------------------|-------------------------|---|
| Chromium picolinate | Chromium | Unclear |
| St. John's wort | Hypericin | Serotonergic/monoamine oxidase inhibition |
| Hoodia | P57 | Unclear |
| White willow bark | Salicylate | Inhibit norepinephrine breakdown |
| Calcium pyruvate | Pyruvate | Unclear |
| Guarana extract | Caffeine | Noradrenergic |
| Various tea extracts | Caffeine | Noradrenergic |
| Garcinia gambogia extract (citrin) | Hydroxycitric acid | Unclear |
| Chitosan | Cationic polysaccharide | Block fat absorption |

^aSafety and efficacy not documented.

doses lower than commonly employed individually.⁸⁹ These placebo-controlled studies stimulated widespread use of fen-phen. Outside of product labeling, some clinicians also chose to use dexfenfluramine in combination with phentermine. Both fenfluramine derivatives were withdrawn from worldwide markets in 1997 due to a relationship with cardiac valvular insufficiency, valvular structural abnormalities, and pulmonary hypertension.^{90,91}

■ PEPTIDES

Multiple different endogenous peptides, which play a role in the regulation of food intake, have been identified in animals and humans. Leptin originates in the adipocyte and is proposed to function as a peripheral feedback messenger with respect to fat storage (discussed earlier in the chapter). NPY and galanin are two CNS peptides that appear to similarly stimulate food consumption, but have differing effects on preference of carbohydrate or fat, as well as substrate metabolism.^{37,92} Currently, NPY and galanin are thought to exert minimal effects on protein intake, but a third, less well-described CNS peptide, growth hormone-releasing factor, stimulates protein ingestion. Carbohydrate ingestion and use are related to NPY hypothalamic activity, specifically in the arcuate and medial paraventricular nucleus.^{37,92} Galanin activity, centering in the lateral paraventricular nucleus and medial preoptic areas, increases both carbohydrate and fat intake with preferential effects on fat consumption and utilization.³⁷ NPY enhances fat synthesis via increased respiratory quotient and use of carbohydrate. Galanin appears to slow energy expenditure. NPY and galanin modulate the release of insulin, corticosterone, and vasopressin, further affecting nutrient intake behaviors and substrate metabolism. NPY is associated with increased levels of insulin, corticosterone, and vasopressin, whereas decreases are seen with galanin.³⁷ The macronutrient intake, energy use, and endocrine effects of NPY are most consistent with those seen in chronic obesity. Future pharmacotherapies may be developed based on knowledge of the effects of these endogenous peptides.

■ HERBAL, NATURAL, AND FOOD SUPPLEMENT WEIGHT LOSS THERAPIES

6 Many individuals choose to undertake weight loss regimens that incorporate the ingestion of herbal, natural, or food supplement products without medical monitoring. It is important to remember that the FDA does not strictly regulate the manufacture and

labeling of these products. The problem with many marketed products is the lack of consistency in labeling versus actual product content. Table 140–5 lists some of the common constituents found in many of these products.

■ CHROMIUM

The inclusion of chromium as an effective agent for weight loss is unclear. The hexavalent form of this trace element is thought to be carcinogenic, whereas the trivalent form found in human food sources is essentially nontoxic.⁹³ Chromium is considered an essential nutrient and experimentally in animals is an insulin cofactor active in carbohydrate, protein, and lipid metabolism.⁹³ In humans, insulin resistance has been reported in a few cases of apparent severe chromium deficiency during long-term total parenteral nutrition (see Chap. 137). Currently, there is no reliable means of assessing total body chromium status, making diagnosis of deficiency difficult. The tryptophan metabolite, picolinic acid, forms a complex with trivalent chromium, which improves bioavailability. Food sources with highly available chromium include brewer's yeast, calf liver, American cheese, and wheat germ.⁹³ A double-blind, placebo-controlled study of chromium picolinate as a supplement to aerobic exercise in the treatment of obesity failed to demonstrate any effectiveness.⁹⁴

■ EPHEDRA ALKALOIDS

Based on the known effects of ephedrine (see ephedrine, above), dietary supplements claiming weight management effects have employed plant sources of ephedra alkaloids. Various parts of the Ephedraceae, ma huang, *Sida cordifolia*, and *Pinellia ternata* plants are known to produce ephedra alkaloids, including L-ephedrine, D-pseudoephedrine, L-norephedrine, D-norpseudoephedrine, L-N-methylephedrine, and D-N-methylpseudoephedrine.⁹⁵ Common names routinely included in dietary supplement labeling for these alkaloid sources include joint fir, popotillo, country mallow, sea grape, and yellow horse. From 1994 through July 1997, the FDA received over 800 reports of serious adverse events, including seizures, stroke, and death, coincident with ephedrine alkaloid-containing dietary supplement use. An in-depth review of 140 reports of adverse events related to ephedrine alkaloid-containing dietary supplements demonstrated that approximately half the reports involved cardiovascular symptoms.⁹⁶ As of 2004, the FDA has determined that all sources of ephedra alkaloids must be excluded from dietary supplements because they present an unreasonable high health risk.⁹⁷

■ ST. JOHN'S WORT

A perennial flowering plant (*Hypericum perforatum*), St. John's wort has been employed as a medicinal herb for thousands of years. Its use in weight loss and herbal supplements probably is based on the proposed effects of its constituent naphthodianthrones (hypericin and pseudohypericin). These are thought to be inhibitors of MAO and would be expected to increase synaptic concentrations of monoamines such as serotonin and NE. Consistent with these assumptions, *Hypericum* extracts appear to be more effective than placebo in the treatment of depression.⁹⁸ However, in vitro studies have not been able to substantiate direct MAO inhibition at physiologic hypericin concentrations, and recognized antidepressant effects may be due to other constituents.⁹⁹ The risks of concurrent use of *Hypericum* derivatives and other adrenergic and serotonergic compounds have not been characterized. Currently, St. John's wort has not been studied with respect to its role in obesity management, and its safety and efficacy as a treatment modality in the self-management of obesity are unclear.

■ PYRUVATE

Pyruvate is a commonly listed ingredient in many herbal weight management preparations. Multiple salt forms are used, including sodium, magnesium, potassium, and calcium. Other names include α -ketopropionic acid, 2-oxypropanoic acid, and acetylformic acid. Pyruvate is a three-carbon intermediate formed during normal glucose metabolism and/or during glycolysis. It is advertised in the lay press for its ability to "increase metabolism" and thus promote weight loss. Objective data documenting these effects are lacking. While most pyruvate nutritional weight management supplements contain less than 2 g per dose, large exposures (more than 20 g) are known to cause noticeable gastrointestinal side effects including bloating and diarrhea.

■ HOODIA

Hoodia is a desert cactus of the Apocynaceae plant family. Natives indigenous to the Kalahari Desert are purported to consume the stems and roots of this plant for their appetite suppressant effects. Other names appearing on product labels include Kalahari cactus, Hoodia cactus or extract, Hoodia gordonii cactus, and Kalahari diet. Hoodia extract, sometimes also referred to as P57, is rumored to elicit weight loss; however, no peer-reviewed reports of effectiveness are currently available.

■ WHITE WILLOW BARK

White willow bark is a source of salicylate, a prostaglandin inhibitor. Prostaglandin inhibition may enhance adrenergic stimulation via inhibition of NE breakdown (see the earlier discussion of ephedrine).

■ GUARANA EXTRACT AND VARIOUS TEA EXTRACTS

Guarana and tea are sources of caffeine that have inherent adrenergic properties as well as increasing the effects of stimulant substances such as ephedrine or ephedra alkaloids (see the earlier discussion of ephedrine).

■ CHITOSAN

Chitosan is a cationic polysaccharide, specifically a partially *N*-deacetylated form of chitin. This nonhydrolyzable fiber exhibits properties similar to those of cellulose.¹⁰⁰ In vitro and preclinical data have indicated that chitosan may be effective in blocking absorption of fat from the gut. It has been suggested that orally administered chitosan may be an effective weight reduction agent by blocking calories ingested as fat. Chitosan is a major constituent in several heavily advertised weight management food supplements and over-the-counter preparations. However, a small number of properly randomized and blinded or open-label investigations currently demonstrate that orally administered chitosan is not an effective inhibitor of fat absorption in humans.^{101,102} While further research may be warranted with respect to the appropriate dose in humans needed to impair fat absorption, current claims of chitosan effectiveness in humans are unsubstantiated.

■ PHARMACOECONOMIC CONSIDERATIONS

There are few data regarding economic consequences of treating obesity. One study evaluated the savings in prescription costs following a 12-week weight reduction program in 40 type 2 diabetic patients. Patients lost an average of 33.7 lb over the study period. A cost analysis was completed on 32 of 40 patients who were taking antihypertensive and/or antidiabetic medications using the out-of-pocket costs for these medications at the beginning of the study and after 1 year. The patients sustained a mean weight loss of 19.8 lb over the next year. The average cost of these prescriptions at the beginning as compared to the 1-year follow-up was \$63.30 versus \$32.50 per month. The estimated annual average saving in prescription costs per patient was \$443. A more objective assessment of costs related to orlistat use has been published based on data obtained from three peer-reviewed publications. In this report from the United Kingdom, the cost utility of orlistat was estimated at £46,000 (approximately \$75,000) per quality-adjusted life year gained. Sensitivity analysis from this report demonstrated variability in this estimate of £14,000 to £132,000 (approximately \$23,000 to \$215,200). The authors raised questions about the potential long-term value of pharmacotherapy for obesity.¹⁰³

Finally, Martin and colleagues compared the costs associated with medical and surgical treatment of obesity.¹⁰⁴ Medical therapy groups received diet therapy only (no medications), and cost included weekly clinic visits for behavioral modification. A successful outcome was defined as loss of at least one-third of excess body weight above ideal body weight. They monitored all patients for 2 years and some for as long as 7 years so that long-term weight control could be addressed. As expected, the costs of surgery were much higher than medical therapy over the first 2 years (\$24,000 vs. \$3,000). However, when costs were extrapolated out to 6 years, the cost per pound lost for medical therapy exceeded surgical therapy (about \$313 vs. \$261 per pound lost). It is clear from the preceding data that weight loss can be expensive for the consumer. Prospectively designed cost-benefit or cost-effectiveness analyses are needed to determine if costs of weight loss therapy or surgery are balanced by lower costs of hospitalizations for other medical problems associated with obesity or the additional life years gained. Quality-of-life measures also need to be taken into consideration when evaluating these types of data.

Third-party payor and insurance reimbursement for provision of obesity treatment services continues to be inconsistent. However,

these issues are under active discussion and specific information regarding reimbursement for obesity treatment from multiple different perspectives including the Centers for Medicaid and Medicare Services and the IRS are freely available via the Web.^{105–107}

EVALUATION OF THERAPEUTIC OUTCOMES

MONITORING THE PHARMACEUTICAL CARE PLAN

Outcome Measures

Specific weight goals should be established that are consistent with medical needs and patient personal desire. For most obese patients, a weight loss goal of 5% to 10% to no more than 30% of initial weight is reasonable. An average rate of weight loss after the first month of therapy is around 1 lb per week. Patients should not be allowed to attain weight less than their estimated ideal weight. Assessment of patient progress should be documented in a health care setting once or twice monthly for 1 to 2 months and then monthly thereafter.^{27,67} Each encounter should document weight, WC, BMI, blood pressure, medical history, and patient assessment of obesity medication tolerability.^{27,67} Chronic use of obesity medications should be consistent with the approved product labeling. Medication therapy should be discontinued after 3 to 4 months if the patient has failed to demonstrate weight loss or maintenance of prior weight. A recent AACE/ACE statement on obesity provides a patient evaluation checklist, a validated survey of general well-being, and sample informed consent that could be used in screening and follow-up of patients receiving obesity pharmacotherapy as part of a weight loss program.⁶⁷ Additionally, numerous tools for both patient and practitioner are readily available through the Department of Human Services, NIH-NHLIB Obesity Education Initiative, and several other agencies.¹⁶ The Short Form 36 (SF-36) also has been used as a quality-of-life evaluation tool for obese patients undergoing programmatic weight loss. Quarterly assessments of well-being and quality of life using validated assessment tools can be helpful in objectively quantifying the effectiveness of therapy as well as potential drug-induced side effects (e.g., depression).⁶⁷

Diabetic patients receiving weight loss medication require more intense medical monitoring and self-monitoring of blood glucose. Some centrally acting weight loss agents, such as the serotonergic agents, have direct effects that immediately improve glucose tolerance, even prior to significant weight loss. Insulin therapy therefore may need to be adjusted with the start of obesity medication therapy. Peripherally active agents, such as orlistat, have also been shown to decrease oral hypoglycemic agent requirements in type 2 diabetic patients.⁷³ However, this effect was noted later in therapy and correlated more directly with weight loss. Some diabetic patients may require daily telephone contact with a health care provider to assist in adjusting their hypoglycemic therapy. Weekly patient visits to a health care setting may be necessary for 1 to 2 months until the effects of diet, exercise, and weight loss medication become more predictable. As frequent as quarterly assessment of hemoglobin A_{1c} may be

appropriate in type 2 diabetics who lose weight to aid in adjustment of hypoglycemic therapy. Lipid profiles can normalize or improve with weight loss. Lipid status should be assessed semiannually or annually in patients with hyperlipidemia to determine need for continued hyperlipidemia therapies. Weight loss also can result in normalization of blood pressure in hypertensive obese patients. Assessment of appropriateness of antihypertensive therapy should occur with each follow-up visit.

An expert committee of the National Institutes of Health, Heart, Lung, and Blood Institute has completed an extensive summary of clinical guidelines for the assessment and treatment of obesity.⁵³ This report provides guidance with evidence-based, graded assessment and treatment recommendations from an extensive meta-analysis of the available obesity literature to date. The evaluation and management of a patient with obesity requires careful clinical, biochemical, and if necessary psychological evaluation. The evaluation must include an assessment of current medical conditions and medications the patient uses. Clearly, a multidisciplinary team including but not limited to a physician, nutritionist, psychologist, and pharmacist best achieves this. The algorithm in Figure 140–3 shows an approach to determining appropriate types of treatment for the overweight individual. The decision to treat any overweight/obese patient depends on the degree and distribution of obesity present, the motivation of the patient to lose weight, and the potential benefits and risks of weight loss. The initial step in this process should be to verify the presence of clinically significant excess body weight. In the clinical setting, this is done most often by measuring height, weight, and WC of the individual and calculating BMI. If the BMI is greater than 25 kg/m² and/or WC is greater than 40 inches for males or 35 inches for females, it is likely that the patient will benefit from weight maintenance or loss. The next step is to assess whether the patient actually is motivated to lose weight. No matter what the treatment options are, they all require significant effort on the part of the patient to change lifestyle and comply with the management plan. If it is clear that the patient is not yet ready to meet these expectations, then early counseling will reduce the chance of frustration for the patient, clinician, and in some cases other family members. This does not exclude the possibility of educating the patient about potential risks of obesity and the benefits of weight loss. This type of basic information in certain cases can lead to a significant change in motivation and desire to lose weight and improved compliance.

Pharmacotherapy may be appropriate for some overweight individuals (e.g., those with a BMI of 30 kg/m² or more without weight-related, immediate life-threatening medical conditions). It also should be considered for those with BMI of 27 kg/m² or more or an increased WC who have two or more risk factors. From the health care providers' perspective, drug therapy for obesity always should be considered as a supplement to an integrated program of diet, exercise, and behavior modification (including group support). A complete medical and medication history is essential in determining appropriate obesity drug therapy. Consideration must be given to alcohol, nicotine, caffeine, and herbal or food supplement use as well as prescription and nonprescription drugs.

CONCLUSIONS

8 The prevalence of obesity has increased dramatically in the latter part of this century. Obesity is determined by a combination of genetic and environmental factors. Epidemiologic studies provide evidence for a causative role of environmental factors in the develop-

ment of obesity in those individuals who are genetically susceptible. Furthermore, there are clear differences in racial susceptibility to obesity and its complications such as diabetes. The precise role of genetic and environmental factors in the development is unknown. It is clear, though, that obesity is a lifelong condition. Currently, orlistat and sibutramine are available in the United States and are indicated for

the long-term treatment of overweight and obesity. However, clinicians should keep in mind that long-term results over periods of 3 or more years regarding these therapies will require further research. Weight regain occurs in the majority of individuals regardless of the therapeutic modalities used. Nevertheless, in recent years, increasingly effective treatments have been developed. These agents have augmented the role of lifestyle changes and diet and therefore serve a useful role as adjunct therapies for obesity.

Every patient seeking help for the management of obesity should be evaluated for secondary causes of obesity. Although a secondary cause is rare, it is important to identify and manage. Treatment of obesity needs to be individualized. It is important to consider factors such as patient desires, age, degree and duration of obesity, and the presence or absence of medical conditions both directly related to obesity and those which may have an impact on the therapeutic decisions. Whatever combinations of therapeutic modalities are used, it is clear that management is a lifelong process requiring patient support and careful monitoring for safety and efficacy.

GLOSSARY

2,3-bisphosphoglycerate—An intermediate in the Rapoport-Luebering shunt, formed between 1,3-bisphosphoglycerate and 3-phosphoglycerate; an important regulator of the affinity of hemoglobin for oxygen.

5 α -reductase—Enzyme responsible for conversion of testosterone to its active metabolite dihydrotestosterone. Two types of this enzyme exist. Type 2 is predominant in prostate cells.

α -hydroxy acids—Exfoliating products such as lactic, glycolic, malic, mandelic, and tartaric acid used in cosmetics.

β -hydroxy acid—Salicylic acid.

Abscess—A purulent collection of fluid separated from surrounding tissue by a wall comprised of inflammatory cells and adjacent organs. It usually contains necrotic debris, bacteria, and inflammatory cells.

Abstinence—Refraining from the indulgence in something, as sexual intercourse or substances, by one's own choice. The absence of genital contact that could permit a pregnancy (i.e., penile penetration into the vagina).

Acetabular—Relating to the acetabulum, the hollow, cuplike portion of the pelvis into which the head of the thigh bone (femur) fits.

Acne—Inflammatory eruption of the sebaceous gland.

Acnegenicity—Product effect that causes irritation of follicles resulting in papules and pustules.

Acquired resistance—See *Secondary resistance*.

Acromegaly—A pathologic condition characterized by excessive production of growth hormone.

Activities of daily living—Dressing, bathing, getting around inside the home, feeding, toileting, and grooming. See also *Instrumental activities of daily living*.

Acute coronary syndrome (ACS)—Ischemic chest discomfort at rest most often accompanied by ST-segment elevation, ST-segment depression or T-wave inversion on the 12-lead electrocardiogram and caused by plaque rupture and partial or complete occlusion of the coronary artery by thrombus. Acute coronary syndromes include infarction and unstable angina. Former terms used to describe types of ACS include *Q-wave myocardial infarction*, *non-Q-wave myocardial infarction* and *unstable angina*.

Acute pain—May be a useful physiologic process warning individuals of disease states and potentially harmful situations. Severe, unremitting, undertreated, acute pain, when it outlives its biologic usefulness, can produce many deleterious effects (e.g., psychological problems). It usually subsides when the healing process decreases the pain-producing stimuli.

Acute pancreatitis—Acute inflammation of the pancreas which may be mild with minimal or no organ dysfunction or severe with organ failure and local complications.

Acute stress disorder—The development of characteristic anxiety, dissociative, and other symptoms that occur within 1 month after exposure to an extreme traumatic stressor.

Acute tubular necrosis—Acute renal failure as the result of renal tubular epithelial cell damage, which may be caused by either direct toxic or ischemic effects of drugs.

Addiction—A primary, chronic, neurobiologic disease, with genetic, psychosocial, and environmental factors influencing its development and manifestations. It is characterized by behaviors that include one or more of the following: impaired control over drug use, compulsive use, continued use despite harm, and craving.

Adolescents—Pediatric patients who are 12 to 16 years of age.

Adoptive immunotherapy—Administration of immune cells for the purpose of cancer treatment.

Adrenergic—Neuronal or neurologic activity caused by neurotransmitters such as epinephrine, norepinephrine, and dopamine.

Adrenocorticotrophic hormone (ACTH)—A polypeptide hormone secreted by the anterior pituitary that controls secretion of cortisol from the adrenal glands.

Adverse drug events—Injuries resulting from administration of a drug or other circumstances surrounding use of the drug, but not necessarily caused by the drug itself. See also *Adverse drug reaction*.

Adverse drug reaction—Any noxious, unintended, and undesired effect of a drug that occurs at doses used in humans for prophylaxis, diagnosis, or therapy.

Affect—Pattern of behaviors that a clinician can observe that expresses a person's current state of emotion.

Afterload—The pressure or the "load" the heart must generate to eject blood into the systemic circulation. Although approximated by the systemic vascular resistance, it is a complex measure that includes blood viscosity, aortic impedance, and ventricular wall thickness. Along with preload, it is an important determinant of cardiac output.

Aganglionosis—The state of being without ganglia.

Agnosia—Cardinal symptom of Alzheimer's disease; inability to recognize or identify a familiar object in the absence of impaired sensory function.

Agoraphobia—Anxiety about, or avoidance of, places or situations from which escape might be difficult (or embarrassing) or in which help may not be available in the event of having a panic attack or panic-like symptoms.

Akathisia—The sensation of inner restlessness resulting in the need to make movements such as pacing or moving the legs. Akathisia has subjective and objective components.

Albumin—The major protein in plasma, with a molecular weight of 65 kDa.

Albuminuria—A condition where a large amount of albumin (>300 mg/day) is present in the urine, often indicating glomerular damage in the kidney.

Alcoholism—A chronic, progressive, and potentially fatal biogenic and psychosocial disease characterized by tolerance and physical dependence and manifested by a total loss of control, as well as diverse personality changes and social consequences.

Allergic interstitial nephritis—Inflammation of the interstitial region of the kidney often associated with acute onset of renal insufficiency.

Allergic salute—Constant upward rubbing of the nose as a result of allergies.

Allergic shiners—Dark circles under the eyes as a result of nasal congestion leading to venous pooling.

Allodynia—Painful response to normally non-noxious stimuli.

Allogeneic transplantation—Transfer of cells between different individuals.

Allograft—An organ or tissue transplanted from one individual to another.

Alloimmunization—Rapid consumption of transfused platelets via an immune mediated reaction.

Amenorrhea—Absence of menstruation.

American Urological Association (AUA) symptom index—Validated questionnaire in which the patient assesses the level of annoyance of 7 obstructive and irritative voiding symptoms.

Amygdala—A small almond-shaped temporal lobe structure, which plays a role in emotions and fear control.

Anaphylactoid—Anaphylaxis-like reactions that do not involve IgE-mediated mechanisms.

Anaphylaxis—Acute, life-threatening allergic reaction involving multiple organ systems.

Anastomosis—The surgical connection of two tubular structures, such as blood vessels, in a transplanted organ.

Anemia of chronic disease—Mild to moderate anemia not associated with blood loss or hemolysis. Usually with normal cell size. May be seen with chronic inflammation (e.g., rheumatoid arthritis, chronic infection) or malignancy.

Anemia of chronic kidney disease—A decrease in red blood cell production caused by a deficiency in the hormone erythropoietin normally produced by progenitor cells of the kidney. As kidney function declines, less erythropoietin is available to stimulate red blood cell production (erythropoiesis) in the bone marrow. Contributing factors include iron deficiency and a shortened red blood cell lifespan.

Angioedema—An allergic reaction characterized by edema of a tissue such as the lips, eyes, mouth, joints or other structures due to leak of fluid from blood vessels.

Anhedonia—A lack of pleasure or interest in usual activities.

Anisocytosis—Considerable variation in the size of cells that are normally uniform, especially with reference to red blood cells.

Ankylosis—Bony fusion resulting from chronic joint inflammation.

Antibiogram—A summary of antimicrobial susceptibilities.

Anticipatory anxiety—The fear of having an anxiety attack, which is often a trigger by itself; “fear of fear.”

Antimicrobial cycling—A predetermined change in an antimicrobial recommendation for empiric therapy of a specific infection at a predetermined time.

Antimycotic—Inhibiting fungal growth.

Antithrombotic—A pharmacologic agent that prevents thrombus/clot formation. This category includes both antiplatelet agents and anticoagulants.

Anuria—Production of less than 50 mL of urine/day.

Anxiety—A state of apprehension, uncertainty, and fear resulting from the anticipation of a realistic or fantasized threatening event or situation, often impairing physical and psychological functioning.

Aphasia—Cardinal symptom of Alzheimer’s disease; inability to generate or comprehend spoken language.

Aphthous ulcers—Small ulcers (canker sores) that form on the inside of the mouth.

Apical pulse—Point at the apex (bottom portion) of the heart impacts the chest wall.

Appendageal—Referring to hair, sweat glands, and nails.

Apraxia—Cardinal symptom of Alzheimer’s disease; inability to carry out a motor task in the absence of impaired motor function.

Arteriovenous malformations—A tangle of blood vessels, both arterial and venous, that can rupture and cause hemorrhage in the brain.

Arthrodesis—The surgical immobilization of a joint (i.e., joint fusion).

Ascites—Abnormal buildup of fluid in the abdomen.

Aspiration pneumonitis—The inflammation of lung tissue caused by the aspiration of fluids and gastric contents that often leads to dyspnea, pulmonary edema, secondary infections and adult respiratory distress syndrome. Hydrocarbon pneumonitis is caused by the pulmonary aspiration of hydrocarbons such as kerosene and gasoline.

Ataxia—An inability to coordinate muscle activity during voluntary movement; most often due to disorders of the cerebellum or the posterior columns of the spinal cord; may involve the limbs, head, or trunk.

Atelectasis—Pulmonary parenchymal collapse due to alveolar or bronchial obstruction.

Atopic dermatitis—Skin inflammation that causes itching, scales, and erythema.

Atopy—An allergic syndrome characterized by asthma, hay fever, and urticaria or eczema.

Atrial fibrillation—Rapid beating of the atria which results in variable ventricular rates.

Atropinism—Symptoms of poisoning by atropine or belladonna.

Aura—Sensory or somatosensory alteration without loss of consciousness.

Auscultation—Listening to the heart or other organs with a stethoscope.

Autologous transplantation—Readministration of the same person's cells which were previously collected.

Autosomal—Pertaining to a chromosome.

Azotemia—Term referring to elevated levels of urea in the serum or blood.

Azotorrhea—An excessive loss of protein in the feces.

Bacteremia—Presence of viable bacteria (fungi) in the bloodstream.

Bacterial prostatitis—An inflammation of the prostate gland and surrounding tissue as a result of infection.

Bacteriuria—The presence of bacteria in the urine.

Barrett esophagus—Inflammatory changes in the esophagus resulting in replacement of epithelial lining by columnar-type cells that can lead to stricture or adenocarcinoma.

Benign prostatic hyperplasia—Nonmalignant enlargement of the prostate gland in elderly men.

Biliverdin—A green bile pigment formed from the oxidation of heme.

Binge eating—Excessive intake of calorie laden food over a short period of time.

Biochemical markers—Intracellular macromolecules released into the peripheral circulation from necrotic myocytes as a result of myocardial cell death (infarction). These laboratory tests are used in the diagnosis of myocardial infarction. Examples include troponin I, troponin T, creatinine kinase MB and myoglobin.

Biofilm—A population or community of microorganisms adhering to a surface by a secreted coating. This coating also reduces microorganism vulnerability to antibiotics.

Biopsy—A procedure in which a tiny piece of a body part, such as the kidney or bladder, is removed for examination under a microscope.

Bipolar I—Characterized by one or more manic or mixed episodes, and is usually accompanied by major depressive episodes.

Bipolar II—Characterized by one or more major depressive episodes and accompanied by at least one hypomanic episode.

Blood-brain barrier (BBB)—The relative lack of permeability of large molecules (and those molecules lacking lipid solubility) into the central nervous system because of the nonfenestrated capillary beds of the cerebral vasculature.

Blood urea nitrogen (BUN)—A waste product in the blood that comes from the breakdown of food protein. The kidneys filter blood to remove urea and thus maintain homeostasis. As kidney function decreases, the BUN level increases.

Borborygmi—Rumbling or gurgling noises produced by movement of gas, fluid, or both in the alimentary canal, and audible at a distance.

Bradykinesia—Slowness of motor movements as seen in Parkinsonism.

Breakthrough bleeding—The unpredictable and irregular bleeding associated with hormone therapy.

Bronchiectasis—Dilation of a bronchus or bronchi, usually related to excessive secretions.

Bronchioles—A subdivision of bronchi; smaller in diameter and without cartilage.

Bronchiolitis—Inflammation of the bronchioles; the small elements of the tracheobronchial tree.

Bronchoalveolar lavage—Instilling and then removing a lavage fluid to reveal the secretory and/or cellular contents from deep in the lung.

Bronchorrhea—Excessive bronchial secretions that can impair pulmonary ventilation.

Bruit—An abnormal and often harsh sound heard over a blood vessel, usually an artery, on examination with a stethoscope caused by turbulent blood flow.

Bursitis—Inflammation of the bursa, a fluid-filled soft tissue structure which usually results in pain and swelling.

Caffeinism—A clinical syndrome produced by acute or chronic overuse of caffeine characterized by anxiety, psychomotor alterations, sleep disturbances, mood changes, and psychophysiological complaints.

Calcimimetics—A class of agents that stimulate calcium-sensing receptors on the parathyroid gland and “mimic” the effects of extracellular calcium. They suppress PTH release and increase the sensitivity of the receptor to extracellular calcium.

Calcium-sensing receptor—The calcium receptor on the chief cells of the parathyroid gland, activation of which leads to suppression of PTH release.

Candidiasis—Fungal infection involving *Candida*.

Cardiac index—Cardiac output standardized for body surface area. Mathematically, cardiac index = cardiac output/body surface area.

Cardiac output—The volume of blood pumped by the heart per unit of time. Cardiac output is the product of heart rate and stroke volume.

Cardioembolic stroke—An ischemic stroke thought to be caused by an embolism arising from the heart. Cardioembolic stroke can be assumed in patients with significant cardiovascular disease including atrial fibrillation, dilated cardiomyopathy, prosthetic valves, recent MI and patent foramen ovale.

Cardiopulmonary arrest—The abrupt cessation of spontaneous and effective ventilation and circulation following a cardiac or respiratory event.

Cardiopulmonary bypass—The use of extracorporeal devices to pump blood and oxygenate the blood while the heart or lungs are not functional. Extracorporeal membrane oxygenation (ECMO) is a form of long-term cardiopulmonary bypass that is typically used for days to weeks.

Carotid Doppler—A technique that provides information about the presence and severity of atherosclerosis of the carotid artery, using noninvasive sound wave technology.

Carotid endarterectomy—Removal of the atherosclerotic plaque from the inside of a stenotic carotid artery by a surgical technique. The vessel is surgically opened and sewn and/or patched after removal of the plaque.

Case-control study—An observational study of persons with the disease of interest (cases) and a suitable control group of persons without the disease to establish the extent of association between exposure(s) of interest and disease.

Cataplexy—Sudden loss of bilateral muscle tone resulting in an individual collapsing, and precipitated by situations resulting from high emotion (e.g., laughter, anger, excitement).

Cellulitis—An acute, infectious process that initially affects the epidermis and dermis and may subsequently spread within the superficial fascia.

Centrilobular—Affecting the central portion of the lobe.

Cerebral autoregulation—The process by which cerebral blood flow is maintained in a tight range over a wide range of peripheral blood pressures. It is accomplished by reactive dilation and constriction of cerebral arteries.

Cerebral blood flow (CBF)—The volume of blood perfusing a given brain mass as a function of time.

Cerebral blood volume (CBV)—The total volume of blood within the cerebral vasculature at a given point in time.

Cerebral metabolic rate of oxygen consumption (CMRO₂)—The cerebral metabolic rate for oxygen calculated as the mean hemispheric CBF and the arteriojugular venous O₂ difference (AVDO₂).

Cerebral microdialysis—A sampling method which allows continuous acquisition of small volume cerebral extracellular fluid specimens utilizing a microdialysis probe inserted into the brain.

Cerebral oxygen delivery (CDO₂)—The product of CBF and arterial oxygen content.

Cerebral perfusion pressure (CPP)—The difference between mean arterial pressure (MAP) and intracranial pressure (ICP).

Cerebrospinal fluid—The clear, colorless fluid that bathes and cushions the brain and spinal cord.

Cervical cap—A thimble-shaped latex rubber device which is held on the cervix by suction, thus acting as a barrier to reduce the risk of pregnancy.

Cervical effacement—During the first stage of labor, as the cervix is opening, it is also thinning. The thinning of the cervix is termed effacement.

Cervical ripening—Prior to inducing labor, the cervix must be favorable, approximately 2 cm dilated and 80% thinned out. If this is not the case, an agent must be used to induce histochemical changes to make the cervix more favorable.

Cervicitis—Inflammation of the cervix.

Chancre—A sore or ulcer, the dermal lesion of primary syphilis.

Chancroid—A venereal dermal lesion caused by agents other than syphilis.

Children—Pediatric patients who are 1 to 11 years of age.

Cholinesterase inhibitors—Class of medication that inhibits enzymatic activity of acetylcholinesterase, butyrylcholinesterase, or both in order to prevent the degradation of acetylcholine.

Chronic condition—An illness or impairment that cannot be cured.

Chronic kidney disease (CKD)—Slow and progressive loss of kidney function that takes several years, often resulting in permanent kidney failure requiring dialysis or transplantation.

Chronic pain/persistent pain—Pain persisting for months to years.

Chronic pancreatitis—Chronic inflammation of the pancreas caused by the many sequelae of long-standing pancreatic injury leading to irreversible pancreatic damage.

Chvostek's sign—A facial twitch produced by tapping on the cheek over the branches of the facial nerve.

Circumstantial speech—Speech pattern whereby the expressed ideas are characterized by unnecessary detail. The speaker ultimately makes his or her point, but in a very roundabout manner.

Clinical proteinuria—Total protein in the urine in amounts greater than 300 mg/day.

Clinical resistance—Refers to failure of an antifungal agent in the treatment of a fungal infection, that arises from factors other than microbial resistance, such as failure of the antifungal agent to reach the site of infection, or inability of a patient's immune system to eradicate a fungus whose growth is retarded by an antifungal agent.

Cognitive-behavioral therapy—A form of psychotherapy that is instructional in approach and is based on the theory that thoughts cause feelings and behaviors, not external influences such as people, situations, and events. Patients learn to identify the thinking that causes the negative feelings and behaviors and then learn how to replace the thinking with thoughts that lead to more desirable reactions.

Cohort study—Assembly of a group of persons without a disease(s) of interest at the onset of the study, determination of the exposure status of each person, and observation of the cohort over time to determine the development of disease in exposed and nonexposed persons.

Colectomy—Surgical removal of the colon.

Colonization resistance—Preservation of anaerobic flora by selective gut decontamination to prevent colonization by potentially pathogenic gram-negative organisms.

Colony-stimulating factors—Proteins that regulate the proliferation, maturation, and differentiation of stem cells to red blood cells, white blood cells, and platelets.

Coma—A state of unconsciousness whereby a patient is not opening his or her eyes, not obeying commands, and not uttering understandable words.

Comedo, comedones (pl.)—Plug of sebum and keratinous material in a hair follicle; blackhead.

Comedogenicity—Product effect that causes follicular plugging resulting in comedones.

Comedolytic—Prevents shed keratinocytes from aggregating in follicle and clogging pores.

Comorbidity—The presence of co-existing diseases.

Complex partial seizure—A seizure beginning in one hemisphere of the brain. It is manifested by automatisms, periods of memory loss, or aberrations of behavior.

Compulsion—Repetitive ritualistic behavior such as ordering or hand washing or a mental act such as repeating words silently with the intent of preventing or reducing distress or some dreaded event or situation. Actions performed in response to the obsessions or to control anxiety associated with the obsession.

Condom—A sheath, usually made of thin rubber, used to cover the penis during sexual intercourse to prevent conception or infection.

Confounding—A situation in which the effects of two processes are not separated. The distortion of the apparent effect of an exposure on risk brought about by the association of other factors that can influence the outcome.

Continuation therapy—The second phase in drug therapy during which the goal is to eliminate any remaining symptoms and prevent a relapse.

Continuous-combined estrogen-progestogen therapy—Daily administration of both estrogen and a progestogen.

Continuous-long cycle estrogen-progestogen therapy—Estrogen is given daily and a progestogen is given six times a year (every other month for 12 to 14 days).

Convulsion—Specific seizure type where the seizure is manifested by involuntary muscle contractions.

Corneocytes—Flattened, dead, keratin filled epidermal cells.

Coronary artery bypass graft surgery (CABGS)—Thoracic surgery where parts of a saphenous vein from a leg or internal mammary artery from the arm are placed as conduits to restore blood flow between the aorta and one or more coronary arteries to “bypass” the coronary artery stenosis (occlusion).

Cor pulmonale—Right-sided heart failure caused by lung disease.

Corpus cavernosum—Two chambers on the dorsal side of the penis. Chambers composed of sinusoidal tissue, which can fill with arterial blood to produce an erection.

Corpus spongiosum—One chamber on the ventral side of the penis. Chamber is composed of sinusoidal tissue, which can fill with arterial blood to produce an erection. The urethra passes through the corpus spongiosum.

Cortical necrosis—Acute renal failure secondary to ischemic necrosis of the renal cortex usually caused by significantly diminished renal arterial perfusion.

Corticotropin-releasing hormone (CRH)—A trophic hormone released by the hypothalamus that stimulates release of adrenocorticotropic hormone (ACTH).

Cost-effectiveness ratio—The outcome of cost-effective analysis. The numerator of the ratio summarizes the costs and financial savings associated with the therapy, including the costs of the therapy itself, side effects, medical costs and savings from avoided illness and disability. The denominator of the cost-effectiveness ratio reflects the health effect of the intervention. The year of life saved is probably the most commonly used measure of the health effect.

Craniectomy (for stroke)—Removal of part of the skull overlying an area of injury in order to relieve the pressure of cerebral edema.

C-reactive protein—An endogenous marker released by the body in response to inflammation.

Creatine kinase, creatine kinase MB—Creatine kinase (CK) enzymes are found in many isoforms, with varying concentrations depending on the type of tissue. Creatine kinase is a general term used to describe the non-specific total release of all types of CK, including that found in skeletal muscle (MM), brain (BB) and heart (MB). Creatine kinase MB is released into the blood from necrotic myocytes in response to infarction and is a useful laboratory test for diagnosing myocardial infarction. If the total CK is elevated, then the relative index (RI), or fraction of the total that is composed of CK MB, is calculated as follows:

$$RI = (CK\ MB / CK\ total) \times 100$$

A RI greater than 2 is typically diagnostic of infarction.

Creatinine—The breakdown of protein metabolic by-product obtained from the diet or generated from muscle of the body. Creatinine is removed from blood by the kidneys; as kidney disease progresses, the level of creatinine in the blood increases.

Creatinine clearance—A test that measures how efficiently the kidneys excrete creatinine. Low creatinine clearance usually indicates the presence of kidney damage.

Crepitus—A crinkly, crackling, or grating feeling or sound in the joints, skin, or lungs.

Crossmatch—A test to determine if a recipient has antibodies against donor antigens. A positive crossmatch indicates that the recipient has antibodies against the donor and the two are incompatible. A negative crossmatch means the recipient does not have antibodies against the donor and the two are considered compatible.

Crust—Dried exudate, secretion or hemorrhage; scab.

Culture negative endocarditis—Describes a patient in whom a clinical diagnosis of infective endocarditis is likely, but blood cultures do not yield a pathogen.

Cutaneous—Pertaining to the skin.

Cutis—Skin.

Cyanosis—Bluish tint to the skin or mucous membranes due to lack of oxygen.

Cyclic estrogen-progestogen therapy—Estrogen is taken continuously, with a progestogen added cyclically the last 10 to 14 days during each 28-day cycle.

Cyst—Sac or closed cavity containing fluid, semifluid, or solid material.

Cystitis—Inflammation of the bladder, usually caused by infection.

Cytokine—Any of numerous hormone-like, low-molecular-weight proteins secreted by various cell types (e.g., T-lymphocytes or monocytes) that regulate the intensity and duration of immune response and mediate cell-cell communication.

Dactylitis—Erythema and swollen hand, feet, fingers, and toes. Also known as *hand and foot syndrome*.

Defibrillation—The therapeutic use of electric current in an attempt to completely depolarize the myocardium and provide an opportunity for the natural pacemaker centers of the heart to resume normal activity.

Delayed cerebral ischemia—A worsening in neurologic function in a subarachnoid hemorrhage patient, occurring several days after the initial bleed, not due to another cause.

Delusion—Fixed, false beliefs that are not based in reality or consistent with the patient's religion or culture. Delusions can be classified as paranoid, somatic, or grandiose in nature. Delusions are often unshakable.

Dementia—A decrease in cognitive function, usually with memory and intellectual deficits and confusion.

Depersonalization—A change in an individual's self-awareness, during anxiety disorder, such that one feels detached from his or her own experiences, with the self, body, and mind seeming alien or distant. Persistent or recurrent experiences as if one is an outside observer of one's mental processes or body (e.g., feeling like one is in a dream).

Derealization—A feeling of estrangement or detachment from one's environment.

Dermatitis—Inflammation of the skin.

Dermatophyte—Fungal infection of the skin.

Dermis—The inner layer of skin between the epidermis and hypodermis.

Desensitization—Administration of increasing doses of drug to achieve patient tolerance and avoidance of hypersensitivity reactions.

Detoxification programs—A medically supervised treatment program for alcohol or drug addiction designed to purge the body of intoxicating or addictive substances. Such a program is used as a first step in overcoming physiological or psychological addiction.

Detumescence—Process by which an erect penis becomes flaccid.

Diaphragm—(1) A flexible ring covered with rubber or other plastic material, fitted over the cervix of the uterus to prevent pregnancy. (2) Muscular membrane separating the abdominal and thoracic cavities, used for respiration.

Diffusion-weighted imaging—A type of MRI that can sensitively detect changes in water movement in tissue. It is particularly sensitive to the early changes seen during brain ischemia.

Digital clubbing—Rounded and swollen tip of finger usually associated with long-term pulmonary disease.

Dihydrotestosterone—Metabolic conversion of testosterone by 5 α reductase produces dihydrotestosterone. This is the primary androgen stimulant of prostate cell growth.

Disinhibition—A physiologic effect that occurs during psychoactive substance use characterized by a loss of normal, executive functioning and normal behavior. An increase in behaviors with the propensity to harm the individual is common.

Dissociative amnesia—Inability to remember some important aspect of an event.

Diverticulitis—Inflammation of a diverticulum, especially of the small pockets in the wall of the colon which fill with stagnant fecal material and become inflamed; rarely, they may cause obstruction, perforation, or bleeding.

Dopamine—A monoamine neurotransmitter formed in the brain by the decarboxylation of dopa and essential to the normal functioning of the central nervous system.

Drug addiction—A chronic disorder characterized by the compulsive use of a substance resulting in physical, psychological, or social harm to the user and continued use despite that harm.

Dysentery—Diarrhea characterized by blood, mucus, and leukocytes in the stool with tenesmus and fever.

Dyskinesia—Choreiform abnormal involuntary movements involving usually the face, neck, trunk, and extremities.

Dysmenorrhea—Difficult and painful menstruation with cramps and backache at the onset of menses.

Dyspepsia—Literally means "bad digestion," but refers to persistent or recurrent pain or discomfort centered in the upper abdomen. Symptoms may include epigastric pain, bloating, abdominal distention, postprandial fullness, early satiety, and nausea.

Dysphoria or dysphoric—A feeling of discomfort or an unpleasant mood, such as sadness, anxiety, or irritability.

Dystonia—Sustained muscular spasm or abnormal postures.

Early empirical therapy—The administration of systemic antifungal agents at the onset of fever and neutropenia.

Edema—Accumulation of fluid in tissues.

Effective renal plasma flow (ERPF)—The flow of plasma through the kidneys; often measured by para-amino hippurate (PAH) clearance and expressed in volume per unit of time (mL/min). The ERPF is less than the true renal plasma flow (RPF) because plasma flow through renal connective and adipose tissue is not measured and the extraction of PAH, although high (>0.9), is not complete.

Electroencephalogram (EEG)—Used to evaluate brain electrical activity.

Electroencephalography—A test that measures electrical brain wave activity through the use of multiple scalp electrodes.

Electromyography—Test of muscle function due to either primary muscle disease or secondary to nerve injury.

Elevated—An exaggerated feeling of well-being, euphoria, or elation.

Emergency contraception—Any method of contraception that acts after intercourse to prevent pregnancy.

Emesis—See *Vomiting*.

Empirical therapy—With systemic antifungal agents is administered to granulocytopenic patients with persistent or recurrent fever despite the administration of appropriate antimicrobial therapy.

Encephalitis—Inflammation of the brain tissue.

Endocarditis—An inflammation of the endocardium, the membrane lining the chambers of the heart and covering the cusps of the heart valves.

Enkephalins—Pentapeptide endorphins, found in many parts of the brain, that bind to specific receptor sites, some of which may be pain-related opiate receptors.

Enteric fever—Intestinal inflammation and ulceration with high fever and abdominal complaints caused by infection.

Enterocolitis—Inflammation of the small intestine and colon.

Enterotoxin—A cholera-like disease that produces secretory diarrhea.

Enuresis—Urinary incontinence, especially at night.

Enzymuria—Presence of enzymes in the urine.

Epidermis—The outer layer of skin.

Epilepsy—Two or more unprovoked seizures, symptoms of disturbed electrical activity in the brain.

Epilepsy syndrome—The combination of seizure type with other components of the patient history such as age of onset, intellectual development, findings on neurologic examination, and results of neuroimaging.

Epithelial cells—Cells that make up epithelium.

Epithelium—Layer of avascular cells covering body surfaces.

Erectile dysfunction—Failure to achieve a penile erection suitable for sexual intercourse. Also known as *impotence*.

Erysipelas—Infection of the more superficial layers of the skin and cutaneous lymphatics.

Erythema—Redness.

Erythema multiforme—Symmetrical patches of raised, red skin.

Erythema nodosum—Raised, red, tender nodules on the skin that vary in size from 1 cm to several centimeters.

Erythroderma—Generalized redness of the skin.

Erythropoiesis—The production of erythrocytes (red blood cells) within the bone marrow.

Erythropoietic agents—Agents developed with recombinant DNA technology that have the same biological activity as endogenous erythropoietin to stimulate red blood cell production. Available agents in the United States include epoetin alfa and darbepoetin alfa.

Erythropoietin—A hormone made by the kidneys that is required for red blood cell formation in the bone marrow. Lack of this hormone leads to anemia.

Esophageal—Involving the esophagus.

Esophagitis—Inflammation of the esophagus.

Estrogen therapy—Unopposed estrogen regimens administered to postmenopausal women following hysterectomy.

Euphoria—A mood state characterized by an exaggerated, superficial sense of well-being, characterized extreme happiness, sometimes more than is reasonable in a particular situation.

Euthymia or euthymic—A mood in a “normal” range without depression or mood elevation.

Evoked potentials—EEG-based technique involving measurement of brain wave activity in response to stimuli, usually visual or auditory.

Fasciculations—The localized contractions of muscle groups, often visible through the skin, due to excessive neuronal discharge.

Fear—A direct, focused response to a specific event or object of which an individual is consciously aware.

Felty’s syndrome—Rheumatoid arthritis associated with splenomegaly and neutropenia.

Fibrosis—Formation of fibrous tissue as a reparative or reactive process.

Fistula—An abnormal connection between two internal organs or between an internal organ and the skin.

Flight of ideas—An accelerated flow of speech with thoughts that change rapidly from one topic to another. An almost continuous flow of pressured and rapid speech that abruptly changes from topic to topic. The associations between the topics are usually understandable.

Focal seizures—Partial seizures.

Follicle-stimulating hormone (FSH)—A polypeptide hormone secreted by the anterior pituitary gland that promotes ovarian follicle development and stimulates estradiol and progesterone.

Fungemia—The presence of fungi in the blood.

“Freezing”—Intermittent immobility lasting a few seconds, particularly in walking, seen in Parkinsonism.

Gamma-aminobutyric acid (GABA)—The major inhibitory neurotransmitter in the central nervous system.

Gastroesophageal reflux disease (GERD)—Symptomatic clinical condition or histologic alteration that results from episodes of gastroesophageal reflux.

Generalized anxiety disorder (GAO)—Excessive anxiety and worry occurring more days than not for a period of at least 6 months.

Generalized seizures—Seizures occurring in both hemispheres of the brain. They may be primary or secondarily generalized.

Genotypes—The structure of deoxyribonucleic acid (DNA) that determines the expression of a trait.

Genu valgum—A deformity marked by lateral angulation of the leg in relation to the thigh.

Genu varum—A deformity marked by medial angulation of the leg in relation to the thigh; an outward bowing of the legs.

Gigantism—Excess secretion of growth hormone prior to epiphyseal closure in children.

Glaucoma—Any of a group of ocular disorders that lead to an optic neuropathy characterized by changes in the optic nerve head (optic disk) that is associated with loss of visual sensitivity and field. Open angle and closed angle are the two major types of glaucoma.

Glomerular filtration rate (GFR)—The primary index of overall kidney function; the volume of plasma that is filtered by the glomerulus per unit of time; often reported in mL/min or mL/min/1.73 m².

Glomerulonephritis—Glomerular lesions characterized by inflammation of the capillary loops in the glomerulus caused by immunologic, vascular, and other idiopathic diseases (may be diffuse or membranoproliferative).

Glomerulosclerosis—Fibrosis of the glomeruli.

Glomerulus—A coiled capillary bed in the kidney that is responsible for filtering water and small molecular weight substances from the blood.

Gonadotropin-releasing hormone (GnRH)—A trophic hormone released by the hypothalamus that stimulates release of follicle-stimulating hormone (FSH) and luteinizing hormone (LH).

Gout—A disease spectrum that includes hyperuricemia, recurrent attacks of acute arthritis associated with monosodium urate crystals in leukocytes found in synovial fluid, deposits of monosodium urate crystals in tissues (tophi), interstitial renal disease, and uric acid nephrolithiasis.

gp120—The glycoprotein structure on the surface of HIV that binds to CD4 on human cells.

Grandiosity—An inflated self-appraisal of one's status, power, or identity.

Granuloma inguinale—Granuloma lesions affecting the genital area.

Growth hormone (GH)—A polypeptide hormone secreted by the anterior pituitary gland that stimulates IGF-I production and promotes growth of all body cells.

Growth hormone-releasing hormone (GH-RH)—A trophic hormone released by the hypothalamus that stimulates release of growth hormone.

Gumma—A granulomatous lesion found in organs or tissues as a result of syphilis.

Hallucinations—Abnormal sensory perceptions that occur while a person is awake and conscious and without external stimulation of the relevant sensory organ. Some common hallucinations are hearing voices when no one has spoken, seeing patterns, lights, beings or objects that aren't there, or feeling a crawling sensation on the skin. Many recreational drugs, including psychedelic drugs such as LSD and certain potent types of marijuana, can cause hallucinations.

Haptocorrin—A group of carrier proteins which bind with vitamin B₁₂ in the blood and aid in its transport.

Haptoglobin—A group of α_2 -globulins in human serum, so called because of their ability to combine with hemoglobin, preventing loss in the urine; levels are decreased in hemolytic disorders and increased in inflammatory conditions or with tissue damage.

Hay fever—See *Rhinitis*.

Heart failure—A clinical syndrome that can result from any disorder that impairs the ability of the heart to fill with or eject blood. Although heart failure may be caused by numerous cardiac disorders, the primary clinical signs and symptoms of dyspnea, fatigue, and volume overload are similar regardless of the initial cause.

Heinz bodies—Intracellular inclusions usually attached to the red cell membrane, composed of denatured hemoglobin.

Hematemesis—Vomiting up blood that may be bright red or similar to coffee grounds in appearance.

Hematochezia—The presence of blood in the stool.

Hematopoiesis—The formation and maturation of blood cells and their derivatives.

Hematopoietic growth factors—See *Colony-stimulating factors*.

Hematuria—Presence of red blood cells in the urine.

Homocysteine—A homolog of cysteine, produced by the demethylation of methionine, and an intermediate in the biosynthesis of l-cysteine from l-methionine via l-cystathionine. Elevated levels of homocysteine have been associated with certain forms of heart disease.

Hemolytic uremic syndrome—A condition characterized by the breakup of red blood cells (hemolysis) and kidney failure. Platelets clump together within the kidney's small blood vessels resulting in ischemia leading to kidney failure.

Hemosiderin—A golden yellow or yellow-brown insoluble protein produced by phagocytic digestion of hematin; found in most tissues, especially in the liver, spleen, and bone marrow, in the form of granules much larger than ferritin molecules (of which they are believed to be aggregates), but with a higher content, as much as 37%, of iron.

Hepatosplenic candidiasis—Clinical presentation often manifested only as fever while a patient remains neutropenic (<1000 WBC/mm³). When the WBC count increases to >1000 cells/mm³, imaging studies can detect the presence of abscess or microabscesses in the liver and spleen, often found with acute suppurative and granulomatous reactions. Infection may persist for months and ultimately cause the patient's death despite aggressive systemic therapy with antifungal agents. Also known as *chronic systemic candidiasis*.

Heterozygous—Presence of different (alleles) genes at one location.

Hippocampus—A sea horse-shaped structure located within the brain that is an important part of the limbic system. The hippocampus is involved in some aspects of memory, in the control of the autonomic functions, and in emotional expression.

Hollenhorst plaque—Cholesterol emboli that usually dislodges from the carotid arteries, or calcific fragments from a stenosed aortic valve that can be visualized on a retinal exam.

Homozygous—Presence of identical genes (alleles) at one location.

Hormone therapy—Either estrogen-only therapy or combined estrogen/progestogen therapy.

Hot flashes—A sensation of warmth, frequently accompanied by skin flushing and perspiration.

Human leukocyte antigens (HLA)—The "self antigens," the histocompatibility antigens found on human leukocytes and tissues that enable the body to differentiate "self" from "foreign" cells. The HLA antigens are used in histocompatibility testing to determine the suitability of an organ for transplant.

Hyperalgesia—Exaggerated painful response to normally noxious stimuli.

Hyperarousal—A state of elevated or increased alertness, awareness, or wakefulness.

Hypercapnia—Elevation of carbon dioxide gas in the blood.

Hyperkalemia—Serum potassium concentration above 5.5 mEq/L.

Hypermagnesemia—Serum magnesium concentration above 1.8 mEq/L or 2.3 mg/dL.

Hyperpigmentation—Excess pigment in skin causing an area of darker color than surrounding skin.

Hyperprolactinemia—A state of persistent serum prolactin elevation characterized by prolactin concentrations greater than 20 micrograms/liter observed on multiple occasions.

Hyperresponsiveness—In the airways, the characteristic of an exaggerated response to stimuli.

Hypervigilance—An enhanced state of sensory sensitivity accompanied by an exaggerated intensity of behaviors whose purpose it is to detect threats.

Hypnagogic hallucinations—Dreamlike experiences on the threshold of sleep that intrude into wakefulness.

Hypnopompic hallucinations—Dreamlike experiences on the threshold of awakening that intrude into wakefulness.

Hypochlorhydria—Presence of an abnormally small amount of hydrochloric acid in the stomach.

Hypokalemia—Serum potassium concentration below 3.5 mEq/L.

Hypomagnesemia—Serum magnesium concentration below 1.4 mEq/L or 1.7 mg/dL.

Hypomania—An abnormally and persistently elevated, expansive, or irritable mood that lasts at least 4 days, but does not cause marked impairment in functioning.

Hypomimia—Decreased facial expression often associated with decreased blink rate.

Hypophonia—Decreased volume of speech.

Hypothalamus—A small region at the base of the brain that controls the release of hormones from the anterior and posterior regions of the pituitary gland and regulates limbic functions, fluid balance, body temperature, cardiovascular function, respiratory function, and diurnal rhythms.

Iatrogenesis or iatrogenic disease—A disease produced as a consequence of medical or surgical treatment.

Ictal—The period during a seizure.

Icteric—Relating to or marked by jaundice.

Ileitis—Inflammation of the ileus.

Illusions—Visual perceptions that are misinterpreted but have a real sensory stimulus.

Immunocompromised host—A patient with defects in host defenses that predisposes him or her to infection (risk factors may include neutropenia, immune system defects from disease or immunosuppressive drug therapy, compromise of natural host defenses, environmental contamination, and changes in normal flora of the host).

Immunoglobulin—Structurally related glycoproteins that function as antibodies and are divided into classes on the basis of structure/biological activity.

Impaction—An immovable packing; a lodgment of something in a strait or passage of the body; as, impaction of the fetal head in the strait of the pelvis; impaction of food or feces in the intestines of man or beast.

Impetigo—A superficial skin infection that is seen most commonly in children.

Inanition—Severe weakness and wasting as occurs from lack of food, defect in assimilation, or neoplastic disease.

Induction—Administration of a highly intense level of immunosuppression in the perioperative period or use of antibody therapy to provide enough immunosuppression to delay administration of nephrotoxic calcineurin inhibitors.

Infant mortality—Deaths occurring before the age of one year per 1000 live births.

Infants—Pediatric patients who are 1 month to 1 year of age.

Infection—Inflammatory response to invasion of normally sterile host tissue by the microorganisms.

Information bias—A flaw in measuring exposure or outcome data that results in systematic differences in the quality of information gathered for study and comparison groups. See also *Selection bias*.

Instrumental activities of daily living—Housekeeping chores, shopping, going outside, medication management. See also *Activities of daily living*.

Insulin-like growth factor-I—An anabolic peptide that acts as a direct stimulator of cell proliferation and growth in all body cells.

Integumentary system—Skin, subcutaneous tissue, and skin appendages.

Interleukin—A type cytokine, usually influencing a white blood cell.

Intermittent-combined estrogen-progestogen therapy—A regimen that combines a daily estrogen with a progestogen administered intermittently in cycles of 3 days on and 3 days off (which is then repeated without interruption).

Interpersonal psychotherapy (IP)—IP is a psychological intervention that focuses on interpersonal relationships and psychosocial functioning.

Intertriginous areas—Body fold areas (e.g., between buttocks, beneath breasts, between toes, under arms).

Intoxication—The development of a substance-specific syndrome after recent ingestion and presence in the body of a substance, and it is associated with maladaptive behavior during the waking state caused by the effect of the substance on the central nervous system.

Intracavernosal injection—Injection into the corpus spongiosum.

Intracranial pressure—The pressure of the cerebral spinal fluid that is essentially the same as the pressure within the brain tissue (i.e., intraparenchymal pressure).

Intrauterine device—A device inserted in the uterus to prevent pregnancy, either through spermicidal action (copper device) or thickening cervical mucus to inhibit sperm penetration and migration (progestosterone device).

Intrinsic resistance—See *Primary resistance*.

Intussusception—Invagination of one portion of the intestine into an adjacent part of the intestines.

Inulin—A fructose polysaccharide that is filtered by the glomerulus; its clearance is often used as an index of GFR.

Iothalamate—A nonradiolabeled or radiolabeled iodinated contrast agent that is filtered by the glomerulus; its clearance is often used as an index of GFR.

Irritable—Easily annoyed and provoked to anger.

Janeway lesion—These lesions appear as flat, painless, red to bluish-red spots on the palms and soles of patients with acute bacterial endocarditis.

Jarisch-Herxheimer reaction—An increase in symptoms of spirochetal disease caused by the initiation of treatment.

Jugular venous oxygen saturation (SjvO₂)—Oxygen hemoglobin saturation of blood in the jugular bulb which is a key element in estimating CMRO₂.

K complexes—Electronegative waves followed by electropositive waves seen on the EEG during sleep.

Keratinization—Keratin formation.

Keratinized—Skin that has developed thicker areas of keratin in the stratum corneum.

Keratinocyte—Cell of the epidermis that produces keratin.

Keratoconjunctivitis sicca—Dry itchy eyes resulting from atrophy of the lacrimal ducts, which may be seen in inflammatory arthritis.

Keratolytic—Agent that solubilizes intracellular cement of keratin cells in the stratum corneum.

Ketogenic diet—A special antiseizure diet that is high in fat and low in carbohydrates and protein.

Kleptomania—An impulse-control disorder whereby patients have an uncontrollable urge to steal, along with recurrent failure to resist these urges.

Lactation—The production of milk.

Lanugo—Fine body hair normally found on a fetus. The hair develops in patients with anorexia nervosa when they are very underweight and malnourished.

Laryngospasm—The spasmodic closure of the larynx due to a variety of causes such as allergic reactions, response to irritants, and pharmacologic actions.

Lavage—Washing out.

Left ventricular ejection fraction—Also known simply as the *ejection fraction*, it is the fraction or percentage of the end diastolic blood volume ejected by the left ventricle during systole. It is a measurement of cardiac systolic function with a normal ejection being >60%. It can be determined noninvasively by an echocardiogram.

Left ventricular hypertrophy—Enlargement of the left ventricle, which is seen in heart failure and may give rise to arrhythmias.

Leptospirosis—A bacterial disease that affects humans and animals caused by the genus *Leptospira*.

Lichenification—Thickening of epidermis due to irritation.

Lipid peroxidation—A pathophysiologic process involving the iron-catalyzed attack of lipid membranes by reactive oxygen species.

Liposomes—Spherical amphiphilic vesicles capable of sustained release of water-soluble substances.

Locus ceruleus—A small area in the brainstem containing norepinephrine neurons that is considered to be a key brain center for anxiety and fear.

Lower urinary tract symptoms—Term that collectively refers to obstructive and irritative urinary voiding symptoms of benign prostatic hypertrophy (BPH).

Lumbar puncture—The procedure used to withdraw cerebrospinal fluid via a needle inserted in the lumbar region of the spinal column.

Luteinizing hormone (LH)—A polypeptide hormone secreted by the anterior pituitary gland that stimulates ovulation and maintains the corpus luteum.

Lymphangitis—An inflammation involving the subcutaneous lymphatic channels.

Lymphocytosis—Increased blood concentration of lymphocytes (> 4 × 10⁹ cells/L) commonly observed in mononucleosis, pertussis, measles, chickenpox or lymphoid malignancies.

Lymphogranuloma venereum—Inflammation of the lymph nodes caused by *Chlamydia trachomatis* resulting in destruction and scarring of tissue.

Macule—Flat, nonpalpable, variable colored lesion.

Maculopapular—Skin eruption containing both macules and papules.

Magnetic resonance angiography (MRA)—A noninvasive method to evaluate the patency of blood vessels using magnetic resonance imaging.

Magnetic resonance imaging (MRI)—An imaging technique based upon the magnetic properties of the hydrogen atom. It provides an accurate, computer-processed image that can be more sensitive than computed tomography.

Major histocompatibility complex (MHC)—A set of genes responsible for most of the proteins on the surface of cells in the body that are responsible for recognition of “self.”

Mania—An abnormally and persistently elevated, expansive, or irritable mood that lasts at least one week, and causes marked impairment in functioning.

Mass effect—An increase in intracranial pressure due to a space-occupying lesion in the brain, usually leading to a “shift” in brain contents, evident by imaging techniques.

Mastalgia or mastodynia—Pain in the breast.

Mean arterial pressure—The mean arterial pressure is the product of the cardiac output and systemic vascular resistance. Since the cardiac output is pulsatile, rather than continuous, and since 2/3 of the normal cardiac cycle is spent in diastole, the mean arterial pressure is not the arithmetic mean of the systolic and diastolic blood pressures. Mean arterial pressure = diastolic blood pressure + 1/3 (systolic blood pressure–diastolic blood pressure).

Meconium ileus—Intestinal obstruction due to meconium.

Megakaryocytes—Precursors of platelets.

Melanin—Dark pigment that is part of determining skin color.

Melena—Dark-colored stools resulting from upper gastrointestinal bleed.

Membrane stripping—When the cervix is dilated, a practitioner can use a hand to separate the amniotic membranes from the uterus. This technique has been shown to reduce the need for labor induction.

Menarche—The time of the first menstrual period or flow.

Meningitis—Inflammation, usually infectious, of the meninges, a covering of the brain.

Menopause—The permanent cessation of menses following the loss of ovarian follicular activity.

Menses—Periodic bloody discharge from the uterus.

Methionine—The l-isomer is a nutritionally essential amino acid and the most important natural source of “active methyl” groups in the body, hence usually involved in methylations in vivo.

Microalbuminuria—A condition in which a small amount of albumin (30 to 300 mg/day) is present in the urine; indicative of an early stage of chronic kidney disease (CKD).

Microcomedo—Microscopic lesion formed from the combination of sloughed, clumping keratinocytes reacting with sebum and fatty acids from the sebaceous gland.

Micrographia—Handwriting that is small, trails off in size, or very slow.

Midsystolic—Middle of systole.

Milia—Small, white, cysts containing keratin.

Mixed states—Rapidly alternating mood states (mania and major depressive episodes) that last at least one week, and cause marked impairment in functioning.

Molds—Fungal organisms that grow as multicellular branching, thread-like filaments (hyphae) that are either *septate* (divided by transverse walls) or *coenocytic* (multinucleate without cross walls). On agar media, molds grow outward from the point of inoculation by extension of the tips of filaments, and then branch repeatedly, interweaving to form fuzzy, matted growths called *mycelium*. Germ tubes are the beginning of *hyphae*, which arise as perpendicular extensions from the yeast cell, with no constriction at their point of origin.

Molybdenum (Mo)—A bioelement found in a number of proteins.

Mood—A more pervasive and sustained emotional state that colors a person’s perception of the world.

Morbiliform—Maculopapular lesions that becomes confluent on the face and body.

Mucolytic—The ability to break down mucus.

Mucositis—Inflammation of the mucosa.

Multiple organ dysfunction syndrome (MODS)—Presence of altered organ function requiring intervention to maintain homeostasis.

Multiple sclerosis (MS)—A demyelinating disease, caused by inflammation, leading to neurologic deficits and often, disability.

Mutism—A state in which a person either had the inability or they refuse to speak or vocalize sounds.

Myoclonic seizures—Brief shock-like muscular contractions of the face, trunk, and extremities. They usually begin in adolescence and are referred to as *juvenile myoclonic epilepsy* (JME).

Myoclonus—A sudden twitching of muscles or parts of muscles, without any rhythm or pattern.

Mycotic—A fungal infection.

National Kidney Foundation (NKF)—A voluntary health organization that seeks to prevent kidney and urinary tract diseases, improve the health and well being of individuals and families affected by these diseases, and increase the availability of all organs for transplantation.

Nausea—An unpleasant sensation associated with an awareness of the urge to vomit.

Necrosis—Local death of cells or tissue.

Necrotizing fasciitis—A rare, but very severe infection of the subcutaneous tissue that may be caused by aerobic and/or anaerobic bacteria and results in progressive destruction of the superficial fascia and subcutaneous fat.

Neonates—Newborns who are 1 day to 1 month of age.

Nephritis—Inflammation of the kidney.

Nephrolithiasis—Presence of one or more stones in the renal pelvis, collecting system, or ureters.

Nephron—The working unit of the kidney that is comprised of a glomerulus and tubule. Each kidney is made up of about 1 million nephrons, which collectively remove drugs, toxins, and fluid from the blood.

Nephropathy—Refers to a pathologic alteration of the kidney.

Nephrotic range proteinuria—Proteinuria >3 grams/day associated with glomerular disease and nephrotic syndrome.

Nephrotoxicity—Toxic insult to the kidney.

Nerve conduction studies—Measurement of the speed of electrical conduction through a nerve.

Neuritic plaques—Hallmark pathological marker of Alzheimer’s disease comprised of beta amyloid protein and masses of broken neurites.

Neurofibrillary tangles—Hallmark pathological marker of Alzheimer’s disease derived from abnormal phosphorylation of tau protein filaments.

Neuropathic pain—Pain sustained by abnormal processing of sensory input by the peripheral or central nervous system.

Neutropenia—An abnormally reduced number of neutrophils circulating in peripheral blood; although exact definitions of neutropenia often vary, an absolute neutrophil count of <1000 cells/mm³ indicates a reduction sufficient to predispose patients to infection.

N-methyl-D aspartate antagonists (NMDA)—Class of medications that decreases the activity of synaptic glutamate, thus decreasing the likelihood of cell death.

N-methyl-D-aspartate (NMDA) receptor—A cellular receptor complex involved in the intracellular passage of calcium into CNS cells upon stimulation by amines such as glutamate and aspartate.

Nocturia—Frequent nighttime urination (>2 micturitions per night).

Nodule—Elevated, palpable, solid, round or oval lesion more than 0.5 cm in diameter.

Nonoliguria—Production of >450 mL urine/day.

Nonulcer dyspepsia—Ulcer-like dyspepsia that has been investigated, but endoscopic findings yield no evidence of mucosal injury (ulcer).

Norepinephrine (NE)—A hormone secreted by the adrenal medulla and also released at synapses.

Nosocomial infection—An infection acquired in a health care facility.

NSAID—Nonsteroidal anti-inflammatory drug.

Oblique lie—The fetus is at an angle to the cervix. The head is not the presenting part, and often the patient will need to be delivered by cesarean section.

Obsession—Recurrent and persistent thoughts, images, or impulses experienced as intrusive and distressing. Unwanted thoughts or ideas that intrude into a person's thinking.

Obsessive-compulsive disorder (OCD)—An anxiety disorder characterized by obsessions and/or compulsions that are time-consuming and interfere significantly with normal routine, social, or occupational functioning or relationships.

Oliguria—Diminished volume of urine output (volume <400 to 500 mL/day).

Onychomycosis—Fungal infection of the nail apparatus.

Ophthalmia neonatorum—Inflammation of the conjunctiva resulting from acquisition of gonococcal infection at birth.

Opportunistic infection (OI)—Infection with microorganism that occurs due to altered physiologic state of the patient.

Organic erectile dysfunction—Term used to refer to erectile dysfunction that is due to vascular, neurologic, and/or hormonal causes.

Orthopnea—Difficulty breathing after lying down.

Orthostatic hypotension—A reduction of blood pressure when the patient changes position, usually from lying down to sitting up; often indicative of hypovolemia.

Osler's nodes—Osler's nodes are red, raised tender nodules usually 5 mm in diameter on the pulps of toes or fingers. Seen in patients with endocarditis, they are thought to be due to the deposition of immune complexes.

Osteomalacia—A disease characterized by abnormal bone mineralization (e.g., gradual softening and bending of the bones) with varying severity of pain. Referred to as *rickets* in children.

Osteopenia—Low bone density, DXA T score of -1 to -2.5

Osteophyte—A bony outgrowth or protuberance.

Osteoporosis—(1) Reduced bone mass associated with architectural deterioration of the skeleton and increased risk for fracture. (2) A chronic, progressive disease characterized by very low bone density (DXA T score <-2.5), microarchitectural deterioration and decreased bone strength, bone fragility, and a consequent increase in fracture risk.

Osteotomy—The surgical cutting of a bone.

Otitis media—Inflammation of the middle ear.

Oxytocin—A polypeptide hormone secreted by the posterior pituitary gland that stimulates uterine contraction.

Pain—An unpleasant sensory and emotional experience associated with actual or potential tissue damage or described in terms of such damage.

Palpation—Touching the skin to feel the outline of an organ.

Pan- or holo-systolic—Throughout the end time of systole.

Pancreatitis—An acute or chronic inflammation of the pancreas with variable involvement of local tissues and remote organs.

Panel of reactive antibodies (PRA)—The percentage of cells from a panel of donors with which a potential recipient's blood stream reacts. The more antibodies in the recipient's blood stream, the higher the PRA. The higher the PRA, the higher the risk for a positive cross-match.

Panhypopituitarism—A condition of complete or partial loss of anterior and posterior pituitary function resulting in a complex disorder characterized by multiple pituitary-hormone deficiencies.

Panic attack—A discrete period in which there is the sudden onset of intense apprehension, fearfulness, or terror, often associated with feelings of impending doom.

Panic disorder—The presence of recurrent, unexpected panic attacks followed by at least 1 month of persistent concern about having another panic attack, worry about the possible implications or consequences of the panic attacks, or a significant behavioral change related to the attacks.

Panlobular—Affecting the entire lobe.

Papillary—Upper layer of the dermis.

Papule—Solid, elevated, lesion more than 0.5 cm in diameter.

Papulovesicular—Raised plaque or papule with scaling.

Para-aminohippurate (PAH)—A small molecule which is completely secreted from the tubules into urine, so that blood leaving the kidney is virtually free of PAH; a marker that is often used to measure renal plasma flow (RPF).

Parenchyma—Specific cells or tissue of an organ.

Paresthesia—An abnormal sensation, such as of burning, pricking, tickling, or tingling.

Parkinsonism—A constellation of symptoms with atypical features such that a diagnosis of idiopathic Parkinson's disease cannot be made.

Parous—Having borne one or more children.

Paroxysmal nocturnal dyspnea—Onset of difficulty breathing after lying down for several hours.

Partial seizure—A seizure that begins in one hemisphere of the brain. It may be simple, complex, or secondarily generalized.

Patch—Large macule (more than 2 cm in diameter).

Pelvic inflammatory disease (PID)—Infection of the lining of the uterus, the fallopian tubes, or the ovaries.

Penumbra (ischemic)—The area of brain tissue around the core of the infarct that has decreased function but remains viable. It is proposed that reperfusion of this tissue will allow survival of the affected neurons and other brain cells.

Peptic ulcer—Cellular distribution of the gastrointestinal mucosa, submucosa, and muscular layer. Chronic peptic ulcers usually occur as a "single hole" and are found most often in the stomach and duodenum.

Percussion—Tapping on a structure to elicit a sound.

Percussion and postural drainage—Tapping on the thorax to physically loosen pulmonary secretions and posturing the body to facilitate expectoration.

Percutaneous coronary intervention (PCI)—A minimally invasive procedure whereby access to the coronary arteries is obtained through the femoral artery up the aorta to the coronary os. Contrast media is used to visualize the coronary artery stenosis using a coronary angiogram. A guidewire is used to cross the stenosis and small balloon is inflated and/or stent is deployed to break up atherosclerotic plaque and restore coronary artery blood flow. The stent is left in place to prevent restenosis of the coronary artery.

Perimenopause—The period immediately prior to the menopause and the first year after menopause. Reflects the transition to menopause (with irregular menstrual cycles) and includes the 3 to 5 years before and 1 year after the cessation of menstrual flow.

Perioral dermatitis—Rash around the mouth. In patients with anorexia nervosa or bulimia nervosa, the rash is secondary to repeated vomiting that creates skin irritation from exposure to the gastric contents.

Peripheral arterial disease (PAD)—Atherosclerotic occlusive disease of the extremities, usually diagnosed by symptoms (claudication) or assessment of the blood flow to an extremity.

Peripheral blood progenitor cells—Immature blood cells, which are capable of producing white blood cells, platelets, and red blood cells.

Peritonitis—The acute, inflammatory response of the peritoneal lining to microorganisms, chemicals, irradiation, or foreign body injury.

Perseveration—Persistent repetition of the same verbal or motor response despite differing stimuli.

Petechiae—Pinpoint, flat, round, red spots under the skin caused by intradermal hemorrhage.

Pharmacoepidemiology—The study of the use of and the effects of drugs in large numbers of people with the purpose of supporting safe and effective drug therapies. This type of observational research is useful when more rigorous, experimental designs are not feasible.

Pharyngitis—An acute infection of the oropharynx or nasopharynx.

Pharmacovigilance—The science and activities relating to the detection, assessment, understanding and prevention of adverse effects or any other drug related problems.

Phenotypes—How a gene is expressed (e.g., eye color, height, drug metabolism capacity). The expression of genetic alleles (genotype) as an observable physical or biochemical trait.

Phobia—A persistent, abnormal, and irrational fear of a specific thing or situation that compels one to avoid it, despite the awareness and reassurance that it is not dangerous.

Photic stimulation—Stimulation of the visual cortex through visual stimulation with bright and alternating light.

Photoallergy—Photosensitivity disorder of skin (light and photoallergic agent).

Phototoxicity—Photosensitivity disorder of skin (light and phototoxic agent).

Physical dependence—(1) A state of adaptation that is manifested by a drug class specific withdrawal syndrome that can be produced by abrupt cessation, rapid dose reduction, decreasing blood level of the drug, and/or administration of an antagonist. (2) A pharmacologic effect of a drug defined by the occurrence of an abstinence syndrome

following administration of an antagonist drug or abrupt dose reduction or discontinuation.

Pilonidal—Hair-containing cyst.

Pilosebaceous—Sebaceous gland and adjacent hair follicle.

Placenta previa—The placenta is located over the cervical opening. In this situation, the mother and baby can hemorrhage because the placenta will separate from the uterus before the baby is born. Women who have a placenta previa must be delivered by cesarean section.

Plaque—Raised, flat lesion (more than 2 cm in diameter).

Pneumonitis—Inflammation of lung tissue.

Poikilocytosis—The presence of irregularly shaped red blood cells in the peripheral blood.

Poikilothermia—Inability to maintain normal body temperature.

Polyarteritis nodosa—A systemic necrotizing vasculitis of small and medium-sized arteries.

Polycythemia—An increase in the number of red cells present in the blood.

Porphyria—A group of disorders involving heme biosynthesis, characterized by excessive excretion of porphyrins or their precursors; may be inherited or may be acquired, as from the effects of certain chemical agents.

Porphyryns—Pigments widely distributed throughout nature (e.g., heme, bile pigments, cytochromes) consisting of four pyrroles joined in a ring (porphin) structure.

Postrenal ARF—Acute renal failure with an anatomical cause that is in the urinary tract.

Postictal—The recovery period after a seizure, where a patient may be lethargic or confused. Duration can be variable.

Posttraumatic stress disorder—An anxiety disorder in which exposure to an exceptional mental or physical stressor is followed by persistent re-experiencing of the event, avoidance of reminders of the event, and arousal symptoms.

Postvoid residual urine volume—Urine left in the bladder after the patient has been asked to completely empty urine out of the bladder. Normally the postvoid residual urine volume should be zero. A high postvoid residual urine volume is associated with recurrent urinary tract infection.

Preload—Along with afterload, it is an important determinant of cardiac output. It is the degree of stretch of the myocardial fibers (sarcomeres) at the end of diastole. As the sarcomeres are stretched, the force of contraction increases. Preload is approximated by the left ventricular end diastolic volume or pressure.

Premature infants—Those born before 37 weeks' gestational age.

Premature ovarian failure—Amenorrhea, sex-steroid deficiency, and infertility in women younger than 40 years of age.

Premenstrual dysphoric disorder (PMDD)—A severe form of premenstrual syndrome and is listed in the appendix of the *Diagnostic and Statistical Manual of Mental Disorders*, Fourth Edition Revised. The diagnostic criteria require prospective documentation of symptoms, a specific constellation of symptoms, and functional impairment.

Premenstrual molimina—Includes premenstrual symptoms such as breast tenderness, pelvic heaviness or bloating, and food cravings that are not distressing and do not interfere with daily functioning.

Premenstrual syndrome (PMS)—Variably defined and usually requires a history of a single physical or mood symptom that occurs cyclically during the luteal phase of the menstrual cycle.

Prerenal ARF—Acute renal failure caused by a reduction of renal blood flow. Often associated with volume depletion or poor cardiac function.

Presbycusis—Progressive bilateral loss of hearing that occurs in the aged.

Pressured speech—More and faster speech that is difficult or impossible to interrupt.

Priapism—Painful prolonged erection.

Primary amenorrhea—Absence of menses in a girl who has reached the age of 16.

Primary hypogonadism—Failure of the testes to produce an adequate supply of testosterone to meet physiologic needs.

Primary lesion—Basic skin lesion that appears at the beginning of skin disorder.

Primary resistance—Refers to resistance recorded prior to drug exposure in vitro or in vivo, as determined by in vitro susceptibility testing using standardized methodology.

Progestogen—A term referring to progesterone and the synthetic progestational compounds (sometimes referred to as *progestins*).

Prolactin—A polypeptide hormone secreted by the anterior pituitary gland that stimulates lactation.

Proprioception—A sense or perception, usually at a subconscious level, of the movements and position of the body and especially its limbs, independent of vision; this sense is gained primarily from input from sensory nerve terminals in muscles and tendons and the fibrous capsule of joints combined with input from the vestibular apparatus.

Protease—An enzyme in HIV that cleaves large precursor polypeptides into functional proteins that are necessary to produce a complete virus.

Proteinuria—A condition in which the urine contains measurable amounts of protein (>150 mg/day); often a sign of glomerular or tubular damage in the kidney.

Proteolytic—The ability to break down protein.

Pruritus—Itching.

Pseudoaddiction—Behavior suggestive of addiction but caused by unrelieved pain.

Pseudoallergic—Adverse reactions that appear like allergic reactions but do not have an immunologic mechanism.

Pseudocyst—Collection of pancreatic juice and tissue debris enclosed by a wall of fibrous or granulation tissue.

Pseudomembranous colitis—Inflammation of the colon caused by the toxin of *Clostridium difficile* and resulting in bloody diarrhea.

Psychogenic erectile dysfunction—Erectile dysfunction due to failure of central nervous system to perceive or process sexually stimulating information.

Psychomotor retardation—A slowing or limitation of motor functioning or muscular movements.

Psychosocial stressor—Any significant life event or change that may be associated with the onset, occurrence, or exacerbation of a mental disorder.

Psychotherapy—A general term used to describe a form of treatment based on talking with a therapist. Psychotherapy aims to relieve distress by discussing and expressing feelings, to help the patient to change attitudes, behavior and habits and to develop better ways of coping.

Pulmonary artery occlusion pressure—It is usually determined by a balloon-tipped Swan-Ganz catheter that is advanced into a distal branch of the pulmonary artery. Inflation of the balloon at the catheter tip occludes the pulmonary artery and allows measurement of the left atrial pressure which reflects the left ventricular diastolic pressure. Therefore, it is a measure of the left ventricular preload.

Pulmonary aspiration—The inhalation of fluids and gastric contents into the lungs that may cause aspiration pneumonitis.

Pulseless electrical activity (PEA)—The absence of a detectable pulse and the presence of some type of electrical activity other than ventricular fibrillation (VF) or paroxysmal ventricular tachycardia (PVT).

Purgatives—An agent used for purging the bowels.

Purpura—Discoloration of skin due to hemorrhagic spot more than 0.5 cm in diameter.

Pustule—Small, raised lesion containing pus or exudates.

Pyelonephritis—An infection involving the kidneys and representing upper tract infection.

Pyoderma—Purulent skin disease.

Pyoderma gangrenosum—Skin ulceration with necrotic edges.

Pyuria—Presence of pus or white blood cells in the urine.

Quality-adjusted life year (QALY)—A humanistic assessment of quantity and quality of life. An adjusted life year is calculated by multiplying the number of years by the “utility” of the health state. For patients who have had a moderate stroke, the “utility” of their health state is usually less than 0.5. This means that it would take 2 years at their health state to equal one year at normal health (utility of 1.0).

Rational polytherapy—The concurrent use of two or more drugs for patients not responding to monotherapy. The combination of drugs is based on a consideration of mechanism of action, clinical pharmacokinetics, adverse reactions, and drug interactions.

Rebound vasodilation or congestion—See *Rhinitis medicamentosa*.

Rejection—The response of the immune system, usually involving T or B lymphocytes, to the recognition of foreign antigens in transplanted tissue, which destroys the cells in the transplanted organ and ultimately leads to organ failure, if not treated successfully.

Relative risk reduction—The amount of risk reduced when compared to a control. When one sees a 5% event rate in the control group and a 4% event rate in the treatment group, the relative risk reduction is 20%. The absolute risk reduction is 1%.

Renal—General term referring to the kidneys.

Renal osteodystrophy (ROD)—The condition resulting from sustained metabolic changes that occur with chronic kidney disease including secondary hyperparathyroidism, hyperphosphatemia, hypocalcemia, and vitamin D deficiency. The skeletal complications associated with ROD include osteitis fibrosa cystica (high bone turnover disease), osteomalacia (low bone turnover disease), adynamic bone disease, and mixed bone disorders.

Renal replacement therapy—Any form of dialysis or hemofiltration used to support patients without adequate kidney function. Goals of renal replacement therapy are to remove excess fluid; remove waste products and toxins; and control electrolyte concentrations.

Renovascular—Pertaining to blood vessels located within the kidney, such as the afferent and efferent arterioles, and renal arteries.

Retching—Contractions of the diaphragm, thoracic and abdominal muscles without expulsion of gastric contents.

Retinitis—Inflammation of the retina, often due to infection with cytomegalovirus.

Retrograde pyelography—A procedure where radiocontrast dye is injected into the ureter to produce detailed x-ray pictures of the ureter and kidneys.

Reverse transcriptase—The enzyme in HIV that synthesizes a complementary strand of DNA.

Rhabdomyolysis—The breakdown of muscle tissue and release of myoglobin and intracellular electrolytes into the circulation due to a variety of causes such as crush injuries, drug-induced immobilization, and status epilepticus. It often leads to acute renal failure.

Rheumatoid arthritis (RA)—A systemic, symmetric autoimmune disease with swelling, pain, and inflammation of joints as key findings.

Rhinitis—Inflammation of the nasal mucous membrane. Can be seasonal (“hay fever”) or perennial (increasingly called *intermittent* or *persistent*).

Rhinitis medicamentosa—Nasal congestion associated with tolerance to and resulting overuse of topical decongestants. Also known as *rebound vasodilation* or *rebound congestion*.

Rickets—See *Osteomalacia*.

Rigidity—Increased muscular resistance to passive range of motion.

Roth’s spot—A hemorrhage in the retina with a white center. Roth’s spots are often associated with bacterial endocarditis.

Russell’s sign—Callus on dorsum of the hand secondary to self-induced vomiting.

Salicylism—Poisoning by salicylic acid or any of its compounds.

Scale—Flake of stratum corneum.

Scar—Fibrous tissue formed during healing of injury to skin.

Scleritis—Inflammation of the white portion of the eyeball which may be superficial (episcleritis) or involve deeper layers of the eye.

Sebaceous gland—Gland that secretes sebum.

Sebosuppressive—Decreasing amount of sebum produced by the sebaceous gland.

Sebum—Oil produced by the sebaceous gland.

Secondary amenorrhea—Cessation of menses in a woman previously menstruating for 6 months or more.

Secondary hypogonadism—Failure of hypothalamus or pituitary gland to produce adequate amount of luteinizing hormone-releasing hormone (LHRH) or luteinizing hormone (LH). Thus, testicular production of testosterone is reduced.

Secondary prophylaxis (or suppressive therapy)—Refers to administration of systemic antifungal agents (generally prior to and throughout the period of granulocytopenia) to prevent relapse of a documented invasive fungal infection that was treated during a previous episode of granulocytopenia.

Secondary resistance—Develops upon exposure to an antifungal agent and can be either reversible, due to transient adaptation, or acquired as a result of one or more genetic alterations.

Seizure—Paroxysmal disorder of central nervous system, characterized by abnormal neuronal discharges with or without loss of consciousness. They vary in cause, presentation, consequences, duration, and management.

Selection bias—Systematic differences in characteristics between those selected for study and those who are not. See also *Information bias*.

Sepsis—The systemic inflammatory response syndrome (SIRS) secondary to infection. See also *Systemic inflammatory response syndrome*.

Septic shock—Sepsis with persistent hypotension despite fluid resuscitation, along with the presence of perfusion abnormalities. Patients who are on inotropic or vasopressor agents may not be hypotensive at the time perfusion abnormalities are measured.

Serotonin [5-hydroxytryptamine (5-HT)]—An inhibitory neurotransmitter originating in the raphe nucleus of the brainstem and projecting diffusely throughout the brain.

Serum urea nitrogen (SUN)—See *Blood urea nitrogen*.

Severe sepsis—Sepsis associated with organ dysfunction, hypoperfusion, or hypotension. Hypoperfusion and perfusion abnormalities may include, but are not limited to, lactic acidosis, oliguria, or acute alteration in mental status.

Short stature—A broad term describing a condition commonly defined by a physical height that is more than two standard deviations below the population mean and lower than the third percentile for height in a specific age group.

Sickle cell disease—A group of inherited RBC disorder in which HbS is present. Hemolytic anemia and painful vaso-occlusion are the main features.

Simple partial seizure—A seizure beginning in one hemisphere of the brain. It is manifested by alterations in motor functions, sensory or somatosensory symptoms without loss of consciousness. It may progress to a complex partial seizure or to a secondarily generalized seizure with loss of consciousness.

Single nephron GFR (SNGFR)—The rate of filtration through a single glomerulus of a nephron; often reported in nL/min.

Sinus ostia—The pathways that drain the sinuses.

Sinusitis—An inflammation and/or infection of the paranasal sinus mucosa.

Sjogren's syndrome—Rheumatoid arthritis with keratoconjunctivitis sicca.

Sleep spindles—Brief burst of electrical activity seen on the EEG, 12–14 Hz.

Slipped capital femoral epiphysis (SCFE)—Increased width of the femoral plate observed during GH treatment resulting in hip or knee pain.

Social anxiety disorder (SAD)—A disorder characterized by clinically significant anxiety provoked by exposure to certain types of social or performance situations, often leading to avoidance behavior.

Social phobia—See *Social anxiety disorder*.

Somatic pain—Pain arising from skin, bone, joint, muscle, or connective tissue.

Specific phobia—A phobia characterized by clinically significant anxiety provoked by exposure to a specific feared object or situation, often leading to avoidance behavior.

Spermicide—A substance (nonoxonyl-9 in the United States) placed in the vagina to inhibit the activity of sperm, thus reducing the risk of pregnancy; available as vaginal creams, films, foams, gels, suppositories, sponges, and tablets.

Spirochete—The class of microorganism that is the agent of syphilis (*Treponema pallidum*).

Status epilepticus—30 minutes of continuous seizure activity or sequential seizures without full recovery between seizures.

Steatorrhea—Excessive loss of fat in stool.

Stevens-Johnson syndrome—A serious dermatologic reaction characterized by blistering of the mucous membranes (mouth, eyes, vagina) with patchy rashes that can cover most of the body. Patients may also experience fever, headache, and cough.

Stress-related mucosal damage—Superficial gastritis-like lesions associated with critical illness in hospitalized patients.

Striae—Linear, atrophic, pink, purple, or white lesions of skin secondary to changes in connective tissue.

Stroke—A sudden onset, focal neurologic deficit, of presumed vascular origin, lasting longer than 24 hours.

Stroke volume—The volume of blood ejected from the heart during systole.

Subarachnoid hemorrhage—Bleeding into the subarachnoid space, where cerebrospinal fluid resides. It is often due to an aneurysm rupture or trauma.

Substance abuse—A maladaptive pattern of substance use indicated by repeated adverse consequences related to the repeated use of the substance. Examples include failure to fulfill important obligations at work, school, or home; repeated use in situations in which it is physically dangerous, such as driving under the influence; legal problems; and social or interpersonal problems such as arguments and fights.

Substance dependence—The continued use of the substance despite adverse substance-related problems. The criteria for substance dependence are the same for each of the drugs or drug classes, varying only to fit the unique pharmacologic properties of each drug.

Suppressive therapy—See *Secondary prophylaxis*.

Swan-Ganz catheter—A catheter (tube) inserted into the heart to measure pressure and cardiac output.

Symptomatic intracerebral hemorrhage—Collection of blood in the brain, usually after an ischemic stroke, that is associated with neurologic worsening.

Syncope—Fainting.

Synechiae—A “creeping” angle closure that sometimes occurs in patients between attacks of closed-angle glaucoma.

Synergism—The combination of two drugs (such as antibiotics) that produces an effect greater than the sum of the two drugs if used alone.

Synesthesias—The overflow of one sensory modality to another. For example, colors are heard, sounds are seen.

Synovitis—Inflammation of the synovial lining of the joint. It is usually painful, particularly on motion, and is characterized by a fluctuating swelling due to effusion within a synovial sac.

Synovium—Synovial membrane, the inner of the two layers of the articular capsule of a synovial joint, composed of loose connective tissue and having a free smooth surface that lines the joint cavity. It secretes the synovial fluid.

Systemic inflammatory response syndrome (SIRS)—Systemic inflammatory response to a variety of clinical insults, which can be of infectious or noninfectious etiology.

Systemic vascular resistance (SVR)—The resistance to blood flow that is primarily determined by the vascular tone of the arteriolar blood vessels.

Tangential speech—Speech pattern whereby the connections between expressed ideas are unrelated or have little relationship to each other.

Taper—To gradually decrease the dosage of a drug over a period of time.

Tendonitis—Inflammation of tendons.

Tenesmus—A painful spasm of the urogenital diaphragm with an urgent desire to evacuate the bowel or bladder, involuntary straining, and the passage of little fecal matter or urine.

TEWL (transepidermal water loss)—The rate of water loss by evaporation from the skin.

Thalassemia—Any of a group of inherited disorders of hemoglobin metabolism in which there is impaired synthesis of one or more of the polypeptide chains of globin.

Third-spacing—The shift of fluid and protein into the peritoneal cavity and bowel wall lumen that occurs as a result of peritonitis.

Thought blocking—Interruption of a train of thought whereby the person stops speaking suddenly and without warning, even in the middle of a sentence. Person may report that the thoughts were taken out of his or her head.

Thought broadcasting—Belief that one's thoughts are audible to others.

Thrombopoiesis—The process of platelet production from immature cells.

Thrombotic thrombocytopenic purpura—A life-threatening disease involving embolism and thrombosis of the small blood vessels in the brain and kidney.

Thrush—Fungal infection of the oral mucosa.

Thyroid-stimulating hormone (TSH)—A polypeptide hormone secreted by the anterior pituitary gland that stimulates iodine uptake and thyroid hormone synthesis.

Thyrotropin-releasing hormone (TRH)—A trophic hormone released by the hypothalamus that stimulates release of thyroid-stimulating hormone (TSH).

Tibia vara—See *Genu valgum* and *Genu varum*.

Tinea barbae—Fungal infection of the hair follicles of the beard or mustache.

Tinea capitis—Fungal infection of the scalp, hair follicles, or adjacent skin.

Tinea corporis—Fungal infection of the glabrous skin of the trunk and extremities.

Tinea cruris—Fungal infection of the proximal thighs and buttocks.

Tinea manuum—Fungal infection of the palmar surface of the hands.

Tinea pedis—Fungal infection of the feet.

Tinnitus—A noise in the ears, as ringing, buzzing, roaring, clicking, etc. Such sounds may at times be heard by those other than the patient.

Tolerance—(1) A state of adaptation in which exposure to a drug induces changes that result in a diminution of one or more of the drug's effects over time. (2) The ability of the immune system to accept a transplanted allograft as part of "self."

Tonic-clonic seizure—Sharp tonic contraction of muscles followed by a period of rigidity and clonic movement.

Tophi—Urate deposits.

Toxic epidermal necrolysis—A syndrome similar to Stevens-Johnson syndrome characterized by blistering of skin and mucous membranes in response to administration of a drug. Large areas of skin may peel off.

Toxic megacolon—A segmental or total colonic distension of >6 cm with acute colitis and signs of systemic toxicity.

Toxic shock syndrome—Sudden onset of fever, muscle ache, vomiting and diarrhea, accompanied by a peeling rash and followed by low body temperature and shock; caused by staphylococcal endotoxin, especially from infection of the vagina associated with tampon use.

Toxoplasmosis—Clinical infection with *Toxoplasma gondii*.

Transverse lie—The fetus is perpendicular to the mother. Usually the shoulder is the presenting part. Fetuses in this position must be delivered by cesarean section.

Traveler's diarrhea—Diarrhea caused by contaminated food or water and usually attributed to enterotoxigenic *Escherichia coli* (ETEC), *Shigella*, *Campylobacter*, *Salmonella*, or viruses.

Troponin—A protein found predominately in cardiac, but not skeletal, muscle which regulates calcium-mediated interaction of actin and myosin. Troponin I and T are released into the blood from the myocytes at the time of myocardial cell necrosis secondary to infarction. These biochemical markers become elevated and are used in the diagnosis of myocardial infarction. Troponin I and T are more sensitive and specific for infarction than creatinine kinase which is found in both skeletal and myocardial cells. The exact value of troponin I or T which is diagnostic of infarction differs based upon assay.

Trousseau's sign—A hand spasm produced by placing a blood pressure cuff over the forearm and inflating the pressure above the systolic pressure for 3 minutes.

Tubule—Section of the nephron that is responsible for secretion and reabsorption of water, electrolytes, and drugs.

Tumor—Elevated, solid lesion.

Tumor necrosis factor alpha (TNF- α)—A proinflammatory cytokine.

Type I reaction—An immediate, IgE-mediated allergic reaction.

Ulcer—Loss of epidermis and dermis caused by sloughing of necrotic tissue.

Upper respiratory tract infection—Otitis media, sinusitis, pharyngitis, laryngitis (croup), rhinitis, or epiglottitis.

Uremia—An array of symptoms associated with accumulation of metabolic by-products and endogenous toxins in the blood due to impaired kidney function. Symptoms include nausea, vomiting, loss of appetite, weakness, and mental confusion.

Urethritis—Inflammation of the urethra.

Urinalysis—The diagnostic analysis of urine and its components; can be microscopic or macroscopic in nature.

Urinary incontinence—Involuntary leakage of urine. May result from urethral underactivity (stress urinary incontinence), urethral overactivity (overflow incontinence), or mixed pathophysiologic mechanisms.

Urine—Fluid waste resulting from filtration of blood by the kidneys; transferred to the bladder by ureters and expelled from the body through the urethra by the act of voiding or urinating.

Urticaria—A dermatologic reaction noted by elevated, erythematous patches that are pruritic.

Vacuum erection device—Medical device used to manually induce an erection.

Vagal nerve stimulator (VNS)—A medical device that is surgically implanted in patients with refractory epilepsy.

Vasculitis—A hypersensitivity process characterized by inflammation and necrosis of blood vessels.

Vasopressin—A posterior pituitary hormone that controls fluid balance by acting on the renal collecting ducts to prevent water loss.

Vegetation—Bacterial growth on heart valves.

Ventricular remodeling—Alterations in myocardial cells and the extracellular matrix that result in changes in the size, shape, structure, and function of the heart. The remodeling process leads to reductions

in myocardial systolic and/or diastolic function that, in turn, leads to further myocardial injury, perpetuating the remodeling process and the decline in ventricular dysfunction and progression of heart failure.

Vesicle—Clear blister (<0.5 cm in diameter) filled with fluid.

Visceral pain—Pain arising from internal organs such as the large intestine or pancreas.

Vomiting—Contraction of the abdominal muscles, descent of the diaphragm, and opening of the gastric cardia resulting in expulsion of stomach contents from the mouth.

Vulgaris—Ordinary, common.

Withdrawal—The development of a substance-specific syndrome after cessation of or reduction in intake of a substance that was used regularly by the individual to induce a state of intoxication. Withdrawal causes significant distress to the individual and is associated with impairment in social, occupational, or other areas of functioning. Withdrawal is usually associated with substance dependence. Withdrawal generally is also associated with a craving to readminister the drug to relieve the symptoms.

Withdrawal bleeding—The predictable bleeding that results from cessation of a progestogen.

Withdrawal syndrome—The onset of a predictable constellation of signs and symptoms involving alerted activity of the central nervous system after the abrupt discontinuation of, or rapid decrease in, dosage of a drug.

Xerosis—Dry skin.

Xerostomia—Oral mucosal dryness.

Yeasts—Oval or spherically shaped unicellular forms that generally produce pasty or mucoid colonies on agar media, similar to those observed with bacterial cultures. Yeasts have rigid cell walls that reproduce by budding, a process in which daughter cells arise from pinching off a portion of the parent cell.

Zeitgebers—Environmental cues.

Zollinger-Ellison syndrome—Gastric acid hypersecretory disease caused by a gastrin-secreting tumor and leading to multiple, severe duodenal ulcers.

 for patient on continuous renal replacement therapy, 928t

- pharmacokinetics of, 251
thrombocytopenia with, 1884, 1884t
- Amyl nitrate, adverse effects of, 1827
- Amyl nitrite, abuse of, 1186
- Amylase, 2616t
serum, in pancreatitis, 724t, 725
- Amyloid A, serum, 435
- Amyloid precursor protein, 1158–1159, 1159f
- Amyloidosis, 220t
cardiomyopathy in, 371
clinical presentation in, 895t
proteinuria in, 897f
- Anabolic steroids
carcinogenicity of, 2281t
in COPD, 2654
hyperlipidemia with, 435t
hypertension with, 186t
hypophosphatemia with, 961, 961t
in osteoporosis, 1660
- Anaerobes
in diabetic foot infections, 1986, 1986t
in intraabdominal infections, 2058, 2061t, 2065
in osteomyelitis, 2121–2122, 2125
in pneumonia, 1953, 1957t
in sepsis, 2133
in skin and soft tissue infections, 1978t
in surgical site infections, 2222t
- Anaerobic metabolism, 989
- Anaerobic threshold, 501, 501t
- Anakinra
adverse effects of, 1678t
dosing of, 1677t
monitoring therapy with, 1677t–1678t
in rheumatoid arthritis, 1676, 1677t–1678t, 1680
- Anal carcinoma, treatment of, 2290t
- Analgesic(s). *See also specific drugs*
in migraine, 1110t, 1111–1113
- Analgesic nephropathy, 886
- Anaphylatoxin, 1602
- Anaphylaxis
allergic drug reaction, 1601, 1603, 1608
reaction to hemodialysis, 857
treatment of, 1608, 1609t
- Anaplastic large cell lymphoma, 2441t
- Anaplastic large T/null cell lymphoma, 2452t
- Anastrozole
adverse effects of, 2312t
in breast cancer, 2350–2351, 2353–2354, 2353t
mechanism of action of, 2312t
uses in cancer treatment, 2312t
- Ancylostoma duodenale*, 2074–2075
- Androgen(s)
acne vulgaris and, 1755
adrenal
in adrenal insufficiency, 1400–1403
production of, 1391–1392, 1392t
regulation of, 1393
insufficiency in women, 1499–1500, 1500t
- Androgen receptors, 1536–1537
genetic variations in, 2421–2423, 2433
- Androgen source ablation, in prostate cancer, 2424, 2424t, 2429, 2433
- Androgen therapy
adverse effects of, 827, 1500
in anemia of chronic kidney disease, 827
in breast cancer, 2353t
breast cancer and, 1500
drug interactions of, 1245t
emetogenicity of, 667t
gastrointestinal effects of, 606t
heart failure with, 227t
hepatotoxicity of, 715
for menopausal symptoms, 1499–1500, 1500t
in premature ovarian failure, 1509
- Androstenedione, 1392t, 1536
- Anemia, 1799–1800, 1805–1829. *See also specific types of anemia*
cardio-renal anemia syndrome, 814
caused by abnormal hemoglobin synthesis, 1828
chemotherapy-induced, 2321–2323, 2322f
in children, 1825–1827
classification of, 1806, 1806t
clinical presentation in, 1809
in cystic fibrosis, 593
diagnosis of, 1809–1813, 1811f
epidemiology of, 1805–1806
etiology of, 1806t
in geriatric patients, 1824–1825
heart failure and, 227
in inflammatory bowel disease, 660–661
laboratory evaluation of, 1810–1813, 1811f
morphology of red cells in, 1806t
pathophysiology of, 1806t
treatment of, pharmacoeconomics of, 1828–1829
- Anemia of chronic disease, 1822–1823
epidemiology of, 1822, 1822t
etiology of, 1822
laboratory findings in, 1823
pathophysiology of, 1822
in rheumatoid arthritis, 1675
treatment of, 1823
- Anemia of chronic kidney disease, 806, 814, 823, 826–833
resistance to erythropoietic therapy, 831
treatment of, 814
androgen therapy in, 827
approach to, 826–827
L-carnitine in, 827–828
erythropoietin in, 828f, 831–833, 832t
evaluation of, 833
goals of, 826
iron therapy in, 826–830, 827f
pharmacoeconomics of, 833
red blood cell transfusion in, 827
- Anemia of critical illness, 1823–1824
epidemiology of, 1823
etiology of, 1823
laboratory findings in, 1823–1824
pathophysiology of, 1823
treatment of, 1824
- Anergy, 2565
- Anesthesiologist, as CPR team member, 173t
- Anesthetics, apnea with, 578t
- Aneurysm, intracranial, 419
- Angina pectoris. *See also Ischemic heart disease*
classification of, 262, 262t, 276t
clinical presentation in, 266–267, 267t–268t, 269f
effort, 268t
epidemiology of, 261–262
first effort, 273
grading of, 262t
heart failure and, 239
rest, 268t
risk factors for, 266, 267t
stable exertional, treatment of, 272–284, 274f
unstable, 261, 266. *See also Acute coronary syndromes*
heparin in, 384t
risk of death or myocardial infarction in, 267t
variant (Prinzmetal's), 261, 266
diagnosis of, 284
electrocardiogram in, 269
treatment of, 284–285
- Anginal syndrome, 266
- Angioedema, with ACE inhibitors, 82, 206, 241
- Angiogenesis
cancer and, 2285
therapeutic, in ischemic heart disease, 284
- Angiogenesis inhibitors, 2318
- Angiography. *See also specific types and organs*
definition of, 161

 skin necrosis with, 393
 stereoisomers of, 59t, 389
 in stroke, 420t, 421, 424t
 teratogenicity of, 405
 in venous thromboembolism, 380t, 388–395, 398, 399t, 403
 in venous thromboembolism prevention, 396t, 397, 403
- Warning arrhythmia, 340–341
 Water brash, 616t
 Water deprivation test, 945f, 946
 Water loss, insensible, 944–945
 Water purification, 2071
 Wechsler Adult Intelligence-Revised, 1131t
 Wechsler Intelligence Scale for Children-Revised, 1131t
 Wegener's granulomatosis, 897t, 911–912
 Weight, 2561–2562
 Weight gain
 with antipsychotics, 1221–1222
 with insulin therapy, 1346
- secondary to medical conditions, 2662
 with sulfonyleureas, 1347–1349
 with thiazolidinediones, 1351
 in transplant patient, 1622t
- Weight loss
 in cancer, 2581
 in hypertension, 195, 195t
 nutrition assessment of, 2560
 in sleep apnea, 1326
- Well years, 19
 Wernicke's encephalopathy, 1053
 West Nile virus, 1937–1938
 Western Ontario and McMaster Universities Arthritis Index, 1700
 Wet dressings, in atopic dermatitis, 1789
 Wheals, 1748f
 Wheezing, in asthma, 509
 White blood cell(s), in CSF, 1924, 1925t
 White blood cell count, 1892, 1910
 normal range of, 1794t, 1892, 1910
 White blood cell count with differential, 1574, 1574t, 1892
 White coat hypertension, 191–192
 White willow bark, 2671t, 2672
 "Who cares" test, 31–32, 31t
 WHO classification, of acute myeloid leukemia, 2488t
 WHO oral rehydration therapy, 680, 681t, 2036–2037, 2037t
- Whole-bowel irrigation
 in calcium channel blocker poisoning, 139
 in iron poisoning, 142
 in poisoning, 130
- Widow's hump, 1651
 Wild yam, 1475, 1477
 Wild-type allele, 77, 77f
 Willingness-to-pay method, estimating indirect nonmedical costs, 3
 Wilms' tumor, treatment of, 2290t
 Wilson's disease, 694t, 1078t, 2566t
 Wilson-Turner syndrome, 2662
 Witch hazel, in contact dermatitis, 1744–1745
 Withdrawal, definition of, 1178
 Withdrawal syndrome. *See also specific substances*
 treatment of, 1187, 1188t
 Wolff-Chaikoff effect, 1378
 Wolff-Parkinson-White syndrome, 156, 336, 339, 349
- Women
 epilepsy in, 1034–1035
 hyperlipidemia in, 445
 hypertension in, 202
 postmenopausal, 1494
 Women's Health Initiative, 119–120
 World Wide Web, evidence-based medicine on, 26, 27t
- Wound
 clean, 2218t–2219t
 clean-contaminated, 2218t–2219t
 contaminated, 2218t–2219t
 dirty, 2218t–2219t
 wound healing, malnutrition and, 2581, 2581t
 Wrist circumference, 2561
- X**
- Xamoterol, in heart failure, 224
 Xanthine oxidase inhibitors, in gout, 1710
 Xanthoma, in hyperlipidemia, 434, 449
 Xenobiotic receptors, 714f, 716
 Xerostomia, 2152
 oral candidiasis and, 2149t
- Ximelagatran
 adverse effects of, 388
 in atrial fibrillation/flutter, 334
 chemical and pharmacokinetic properties of, 380t, 387–388
 in heparin-induced thrombocytopenia, 410
 in venous thromboembolism, 387–388, 399t
- X-rays
 in gastrointestinal tract disease, 607–608, 607f
 in osteomyelitis, 2123
- Xylometazoline, in allergic rhinitis, 1736t
- Y**
- Yale Global Tic Severity Scale, 1141
 Yale-Brown Obsessive Compulsive Scale, 1130t, 1313
- Years of healthy life, 19
 Yeasts, 2162
 Yellow azo dye, 579
 Yellow fever vaccine, 2232, 2247–2248
 Yellow horse, 2671
 Yersiniosis, 2038t, 2047
 clinical presentation in, 2047
 food-borne, 2050t
 treatment of, 2039, 2047
- Yohimbine
 adverse effects of, 1530
 in erectile dysfunction, 1521t, 1530
- Young Mania Rating Scale, 1282
- Z**
- Zafirlukast
 adverse effects of, 531
 in asthma, 531, 580
 drug interactions of, 390t
- Zalcitabine
 dosing of, 2262t
 in HIV infection, 2261, 2262t, 2263
 mechanism of action of, 2258f
 pancreatitis with, 723t
- Zaleplon
 drug interactions of, 1324
 in insomnia, 1477
- Zamifenacin, in irritable bowel syndrome, 691
- Zanamivir
 in acute bronchitis, 1946
 in prevention of influenza, 1960, 2238
- ZAP-70 (tumor marker), 2520
- Zeitgebers, 1321
- Zidovudine
 agranulocytosis with, 1879t
 dosing of, 2262t
 drug interactions of, 1914t, 2263
 gastrointestinal effects of, 606t
 in HIV infection, 1434, 2261, 2261t–2262t, 2263–2264
 mechanism of action of, 2258f
 metabolism of, 923t
 for patient with renal insufficiency, 922t
 in pregnancy, 1434, 2264
- Ziehl-Neelsen stain, 1894, 2016
- Zileuton
 in aspirin-sensitive asthma, 580
 in asthma, 531
 effect on cytochrome P450, 60
- Zinc
 deficiency of, 2565, 2566t, 2581–2582, 2581t
 in cirrhosis, 706–707
 drug interactions of, 1913t
 excess of, 2581
 in multiple sclerosis, 1018
 in parenteral nutrition, 2597–2598
 recommended daily allowance for, 2573t
 toxicity of, 2566t
- Zinc oxide, in diaper dermatitis, 1746
- Zinostatin
 bronchospasm with, 578t
 pulmonary toxicity of, 584t
- Ziprasidone
 adverse effects of, 1137t, 1141, 1221t, 1222, 1224, 1270
 in Alzheimer's disease, 1168–1169
 in attention-deficit/hyperactivity disorder, 1137t, 1138
 in bipolar disorder, 1265, 1265t, 1267–1268, 1270, 1273t
 doses and dosage forms of, 1215t
 dosing of, 1137t, 1273t
 drug interactions of, 1228, 1229t
 mechanism of action of, 1219, 1273t
 pharmacokinetics of, 1220, 1220t
 in schizophrenia, 1214, 1215t, 1216, 1221–1229
 in Tourette's disorder, 1140–1141
- Zoledronate
 in hypercalcemia, 954, 954t
 in osteoporosis, 1658
 in prevention of osteoporosis, 1502, 1502t
 in prostate cancer, 2433
- Zollinger-Ellison syndrome, 632, 644–645
 clinical presentation in, 644
 diagnosis of, 644
 treatment of, 644–645

- Zolmitriptan
 - in cluster headaches, 1119
 - dosing of, 1110t
 - in migraine, 1110t, 1114
 - pharmacokinetics of, 1114t
- Zolpidem
 - adverse effects of, 1324
 - dosing of, 1324
 - drug interactions of, 2029t
 - in insomnia, 1324, 1477
- Zomepirac
 - nephrotoxicity of, 883t
 - for patient with renal insufficiency, 920t
- Zonisamide
 - administration of, 1045
 - advantages and disadvantages of, 1045
 - adverse effects of, 1032t, 1045
 - in bipolar disorder, 1265t, 1268, 1281
 - dosing of, 1036t, 1045
 - drug interactions of, 1032t, 1045
 - in epilepsy, 1028t, 1030t, 1033, 1036t, 1045
 - mechanism of action of, 1045
 - pharmacokinetics of, 1030t, 1045
