NAUSEA AND VOMITING

Cecily V. DiPiro and A. Thomas Taylor

Learning Objectives and other resources can be found at www.pharmacotherapyonline.com.

KEY CONCEPTS

- 1 Nausea and vomiting may be a part of the symptom complex for a variety of gastrointestinal, cardiovascular, infectious, neurologic, metabolic, or psychogenic processes.
- 2 Nausea and vomiting may be caused by a variety of medications or other noxious agents.
- 3 The overall goal of treatment should be to prevent or eliminate nausea and vomiting regardless of etiology.
- 4 Treatment options for nausea and vomiting include drug and nondrug modalities.
- 5 The primary goal with chemotherapy-induced nausea and vomiting (CINV) is to *prevent* nausea and/or vomiting.
- 6 Optimal control of acute nausea and vomiting positively impacts the incidence and control of delayed and anticipatory nausea and vomiting.
- 7 The emetogenic potential of the chemotherapeutic regimen is the primary factor to consider when selecting prophylactic antiemetics for CINV.
- 8 Patients at high risk of vomiting should receive prophylactic antiemetics for postoperative nausea and vomiting (PONV).
- 9 Patients receiving single-exposure, high-dose radiation therapy to the upper abdomen or receiving total or hemi-body irradiation should receive prophylactic antiemetics for radiation-induced nausea and vomiting (RINV).

Nausea and vomiting are common complaints among many individuals with gastrointestinal (GI) disorders. However, because of the variable etiologies of these problems, management may be quite simple or detailed and complex, essentially innocuous or associated with therapy-induced adverse reactions. This chapter provides an overview of nausea and vomiting, two multifaceted problems.

Nausea is usually defined as the inclination to vomit or as a feeling in the throat or epigastric region alerting an individual that vomiting is imminent. Vomiting is defined as the ejection or expulsion of gastric contents through the mouth and is often a forceful event. Either condition may occur transiently with no other associated signs or symptoms; however, these conditions also may be only part of a more complex clinical presentation.

ETIOLOGY

- 1 Nausea and vomiting may be associated with a variety of clinical presentations. In addition to GI diseases, either or both may accompany cardiovascular, infectious, neurologic, or metabolic disease processes. Nausea and vomiting may be a feature of such conditions as pregnancy or may follow operative procedures or administration of certain medications such as those used in cancer chemotherapy. Psychogenic etiologies of these symptoms may be present, especially in young women with an underlying emotional disturbance. Anticipatory etiologies may be involved, such as in patients who have previously received cytotoxic chemotherapy. Specific etiologies associated with nausea and vomiting are presented in Table 35–1.¹

In addition to identifying conditions associated with nausea and vomiting, it is important to address the specific causative medical

problems. For example, nausea and vomiting may occur in as many as 70% of patients with inferior myocardial infarction or diabetic ketoacidosis. Eighty to ninety percent of patients with an Addisonian crisis, acute pancreatitis, or acute appendicitis may present with nausea and vomiting.

The etiology of nausea and vomiting may vary with the age of the patient. For example, vomiting in the newborn during the first day of life suggests upper digestive tract obstruction or an increase in intracranial pressure. Other illnesses associated with vomiting in children include pyloric stenosis, duodenal ulcer, stress ulcer, adrenal insufficiency, septicemia, or diseases of the pancreas, liver, or biliary tree. Also, the hepatocellular failure seen in Reye's syndrome may lead to profound cerebral edema followed by persistent emesis. A common etiology of vomiting in children is viral gastroenteritis caused by rotavirus. Vomiting in infants may be associated with something as simple as overfeeding, rapid feeding, inadequate burping, or lying down too soon after feeding. It should be recognized that these types of vomiting are usually indicative of minor problems and may be altered by changing the approach to feeding.

- 2 Drug-induced nausea and vomiting are of particular concern, especially with the increasing number of patients receiving cytotoxic treatment and the number of agents implicated. Included in Table 35–2 are specific cytotoxic agents categorized by their emetogenic potential. Although some agents may have greater emetogenic potential than others, combinations of agents, high doses, clinical settings, psychological conditions, prior treatment experiences, and unusual stimulus of sight, smell, or taste may alter a patient's response to drug treatment. In this setting, nausea and vomiting may be unavoidable and potentially devastating to the patient's desire to continue treatment. Indeed, some patients experience these problems so

intensely that chemotherapy is postponed or discontinued. In addition to the emetogenic potential of various cytotoxic regimens, a variety of other common etiologies have been proposed for the development of nausea and vomiting in cancer patients. These are presented in Table 35–3.²

PATHOPHYSIOLOGY

The three consecutive phases of emesis include nausea, retching, and vomiting. Nausea, the imminent need to vomit, is associated with gastric stasis and may be considered a separate and singular symptom. Retching is the labored movement of abdominal and thoracic muscles before vomiting. The final phase of emesis is vomiting, the forceful expulsion of gastric contents caused by GI retroperistalsis. The act of vomiting requires the coordinated contractions of the abdominal muscles, pylorus, and antrum, a raised gastric cardia, diminished lower esophageal sphincter pressure, and esophageal dilatation.³ Vomiting should not be confused with regurgitation, an act in which the gastric or esophageal contents rise to the pharynx because of pressure differences caused by, for example, an incompetent lower esophageal sphincter. Accompanying autonomic symptoms of pallor, tachycardia, and diaphoresis account for many of the distressing feelings associated with emesis.

Vomiting is triggered by afferent impulses to the vomiting center, a nucleus of cells in the medulla. Impulses are received from sensory centers, such as the chemoreceptor trigger zone (CTZ), cerebral cortex, and visceral afferents from the pharynx and GI tract.

When excited, afferent impulses are integrated by the vomiting center, resulting in efferent impulses to the salivation center, respiratory center, and the pharyngeal, GI, and abdominal muscles, leading to vomiting.

The CTZ, located in the area postrema of the fourth ventricle of the brain, is a major chemosensory organ for emesis and is usually associated with chemically induced vomiting. Because of its location, blood-borne and cerebrospinal fluid toxins have easy access to the CTZ. Therefore cytotoxic agents stimulate primarily this area rather than the cerebral cortex and visceral afferents. Similarly, pregnancy-associated vomiting probably occurs through stimulation of the CTZ.

Numerous neurotransmitter receptors are located in the vomiting center, CTZ, and GI tract. Examples of such receptors include cholinergic and histaminic, dopaminergic, opiate, serotonergic, neurokinin, and benzodiazepine receptors. Chemotherapeutic agents, their metabolites, or other emetic compounds theoretically trigger the process of emesis through stimulation of one or more of these receptors. Effective antiemetics are able to antagonize or block the emetogenic receptors.

CLINICAL PRESENTATION

Because it is impossible to discuss all clinical settings in which the presence of nausea and vomiting might be a pertinent finding, these processes are presented in Table 35–4 as they might occur together and also as *simple* or *complex* in presentation.

TABLE 35–2. Emetogenicity of Chemotherapeutic Agents

TABLE 35–4. Presentation of Nausea and Vomiting**General**

Depending on severity of symptoms, patients may present in mild to severe distress

Symptoms

Simple: Self-limiting, resolves spontaneously and requires only symptomatic therapy

Complex: Not relieved after administration of antiemetics; progressive deterioration of patient secondary to fluid-electrolyte imbalances; usually associated with noxious agents or psychogenic events

Signs

Simple: Patient complaint of queasiness or discomfort

Complex: Weight loss; fever; abdominal pain

Laboratory tests

Simple: None

Complex: Serum electrolyte concentrations; upper/lower GI evaluation

Other information

Fluid input and output

Medication history

Recent history of behavioral or visual changes, headache, pain, or stress

Family history positive for psychogenic vomiting

▶ TREATMENT: Nausea and Vomiting

■ DESIRED OUTCOME

3 The overall goal of antiemetic therapy is to prevent or to eliminate nausea and vomiting. This should be accomplished without adverse effects or with clinically acceptable adverse effects. Although this goal may be accomplished easily in patients with simple nausea and vomiting, patients with more complex problems require greater assistance. In addition to these clinical goals, appropriate cost issues should be considered, particularly in the management of chemotherapy-induced and postoperative nausea and vomiting.

■ GENERAL APPROACH TO TREATMENT

4 Treatment options for nausea and vomiting include drug and nondrug modalities. The treatment of nausea and vomiting is quite varied depending on the associated medical situation. Even though a number of potentially effective measures are available, most patients receive a medication at some point in their care. For simple nausea and vomiting, patients may choose to do nothing or to select from a variety of nonprescription drugs. As symptoms become worse or are associated with more serious medical problems, patients are more likely to benefit from prescription antiemetic drugs. When prescribed according to reliable clinical information, these agents often provide acceptable relief. However, some patients will never be totally free of symptoms. This lack of relief is most disabling to the patient when it is associated with an unresolved medical problem or when the necessary therapy for this condition is the cause of the nausea or vomiting, as in the case of patients receiving emetogenic chemotherapy.

■ NONPHARMACOLOGIC MANAGEMENT

Nonpharmacologic management of nausea and vomiting may include a variety of dietary, physical, or psychological changes consistent with the etiology of symptoms. For patients with simple complaints, perhaps resulting from excessive or disagreeable food or beverage consumption, avoidance or moderation in dietary intake may be preferable. Patients suffering symptoms of systemic illness may improve dramatically as their underlying condition resolves. Finally, patients in whom these symptoms result from labyrinthine changes produced by motion may benefit quickly by assuming a stable physical position.

Cancer patients undergoing chemotherapy may experience nausea and/or vomiting despite receiving prophylactic antiemetics. The fact that anticipatory side effects rarely occur unless the patient has previously experienced posttreatment nausea or vomiting suggests that the mechanism for anticipatory nausea and vomiting is a learned process involving elements of classic conditioning.⁴ This conditioning model may also be important in understanding the development of pregnancy-related nausea. Nonpharmacologic interventions are classified as behavioral interventions and include relaxation, biofeedback, self-hypnosis, cognitive distraction, guided imagery, and systematic desensitization.⁵⁻⁷

The management of psychogenic vomiting is greatly dependent on psychological intervention. However, because the underlying problems are so complex and intertwined in personal relationships, psychological therapy may require lengthy, in-depth treatment. Pharmacologic therapy offers only minimal benefit in these patients. Surgery, such as gastroenterostomy, is of no value.

■ PHARMACOLOGIC THERAPY

4 Although many approaches to the treatment of nausea and vomiting have been suggested, antiemetic drugs (nonprescription and prescription) are most often recommended. These agents represent a variety of pharmacologic and chemical classes, as well as dosage regimens and routes of administration. With so many treatment possibilities available, factors that enable the clinician to discriminate among various choices must be recognized. These factors include (a) the suspected etiology of the symptoms; (b) the frequency, duration, and severity of the episodes; (c) the ability of the patient to use oral, rectal, injectable, or transdermal medications; and (d) the success of previous antiemetic medications. Information concerning commonly available antiemetic preparations is given in Table 35-5.

The treatment of simple nausea and vomiting usually requires minimal therapy. For these symptoms, patients may choose from a lengthy list of nonprescription products. Both nonprescription and prescription drugs useful in the treatment of simple nausea and vomiting are usually effective in small, infrequently administered doses. Side effects and toxic effects in these settings are also usually minimal. Although suitable for occasional simple nausea and vomiting, nonprescription agents are often abandoned by the patient as symptoms continue or become progressively worse. As the patient's condition warrants, prescription medications may be chosen, either as single-agent therapy or in combination.

The management of complex nausea and vomiting, for example, in patients receiving cytotoxic chemotherapy, may require combination therapy. In combination regimens, agents are prescribed in small-to-moderate dosages, achieving symptomatic control through different pharmacologic mechanisms while avoiding the untoward effects caused by high doses.

■ ANTACIDS

Patients who are experiencing simple nausea and vomiting may use various antacids. In this setting, single or combination nonprescription antacid products, especially those containing magnesium hydroxide, aluminum hydroxide, and/or calcium carbonate, may provide sufficient relief, primarily through gastric acid neutralization.

Common antacid regimens for the relief of acute or intermittent nausea and vomiting include one or more small doses of single- or multiple-agent products. Depending on dose, common products usually supply sufficient ingredients to allow a range of approximately 40 to 180 mEq of acid-neutralizing capacity.⁸⁻¹⁰ Potential adverse effects from antacids are usually related to the presence of magnesium, aluminum, or calcium salts. Specifically, osmotic diarrhea from magnesium and constipation from aluminum or calcium salts may be of concern to patients, particularly those self-medicating with high or frequently administered antacid doses. Generally, however, when

TABLE 35-5. Common Antiemetic Preparations and Adult Dosage Regimens

| Drug | Adult Dosage Regimen | Dosage Form/Route | Availability |

| Ondansetron (Zofran) | 32 mg prior to chemotherapy as a single dose (diluted, give over 15 min), or 0.15 mg/kg prior to chemotherapy, repeat at 4 and 8 h | IV | Rx |
| | OR | | |
| | 8 mg 30 min prior to chemotherapy, repeat at 4 and 8 h and every 12 h for 1–2 days after chemotherapy completion | Tab | Rx |

TABLE 35–5. (continued)

| Drug | Adult Dosage Regimen | Dosage Form/Route | Availability |
|---|---|-------------------|--------------|
| Palonestron (Aloxi) | 0.25 mg 30 min prior to chemotherapy (undiluted over 30 seconds; do not repeat within 7 days) | IV | Rx |
| Miscellaneous Agents | | | |
| Metoclopramide (Reglan), for CINV | 1–2 mg/kg every 2 h × 2, then every 3 h × 3 | IV | Rx |
| Metoclopramide (Reglan), for PONV | 10–20 mg about 10 min prior to anesthesia | IV | Rx |
| Metoclopramide (Reglan), for delayed CINV | 0.5 mg/kg or 20 mg every 6 h prn, days 2 to 4 | Tab | Rx |

^aSee text for current warnings.

^bSee Table 35–7 for PONV dosing.

C-II, C-IV = controlled substance schedule 2 and 4, respectively; cap, capsule; chew tab, chewable tablet; CINV, chemotherapy-induced nausea and vomiting; liquid, oral syrup, concentrate, or suspension; OTC, over the counter; PONV, postoperative nausea and vomiting; Rx, prescription; SR cap, sustained-release capsule; supp, rectal suppository; tab, tablet.

used occasionally for acute episodic relief of nausea and vomiting, antacids do not produce serious toxicities.

■ H₂-RECEPTOR ANTAGONISTS

Patients may use histamine₂-receptor antagonists in low doses to manage simple nausea and vomiting associated with heartburn or gastroesophageal reflux. Individual dosages of cimetidine 200 mg, famotidine 10 mg, nizatidine 75 mg, or ranitidine 75 mg may be used for brief periods. Except for potential drug interactions with cimetidine, these agents cause few side effects when used for episodic relief.

■ ANTIHISTAMINE-ANTICHOLINERGIC DRUGS

Antiemetic drugs from the antihistaminic-anticholinergic category appear to interrupt various visceral afferent pathways that stimulate nausea and vomiting and may be appropriate in the treatment of simple nausea and vomiting. Adverse reactions that may be apparent with the use of the antihistaminic-anticholinergic agents primarily include drowsiness, confusion, blurred vision, dry mouth, and urinary retention, and possibly tachycardia, particularly in elderly patients. Also, as doses are increased or are more frequently administered, patients with narrow-angle glaucoma, prostatic hyperplasia, or asthma are at greater risk of complications from the anticholinergic effects of these drugs.

■ PHENOTHIAZINES

Historically, phenothiazines have been the most widely prescribed antiemetic agents. These agents appear to block dopamine receptors, most likely in the CTZ. Phenothiazines are marketed in an array of dosage forms, none of which appears to be more efficacious than another. These agents may be most practical for long-term treatment and are inexpensive in comparison with newer drugs. Rectal administration is a reasonable alternative in patients in whom oral or parenteral administration is not feasible. In an open-label, randomized, crossover comparison between promethazine in oral syrup and rectal suppositories, the pharmacokinetics were highly variable, but in general the suppositories produced a lower maximum concentration and a later time of maximum concentration than the oral syrup.¹¹

Phenothiazines are most useful in patients with simple nausea and vomiting or in those receiving mildly emetogenic doses of chemotherapy. Intravenous prochlorperazine provides quicker and

more complete relief with less drowsiness than intravenous promethazine in adult patients treated in an emergency department for nausea and vomiting associated with uncomplicated gastritis or gastroenteritis.¹² There are numerous potential side effects with these medications, including extrapyramidal reactions, hypersensitivity reactions with possible liver dysfunction, bone marrow aplasia, and excessive sedation.

■ BUTYROPHENONES

Two butyrophenone compounds that have antiemetic activity are haloperidol and its congener droperidol. Each agent blocks dopaminergic stimulation of the CTZ. Although each agent is effective in relieving nausea and vomiting, haloperidol is not considered first-line therapy, although it has been used in palliative care situations.¹³ After 30 years of clinical use, a “black box” warning was recently added to the labeling for droperidol stating that QT prolongation and/or torsades de pointes have been reported in patients receiving droperidol at doses at or below recommended doses. Some of these cases occurred in patients with no known risk factors for QT prolongation and have been fatal. The warning recommends that droperidol should be reserved for use in the treatment of patients who fail to show an acceptable response to other adequate treatments and that all patients should undergo a 12-lead electrocardiogram prior to administration of droperidol, followed by cardiac monitoring for 2 to 3 hours postadministration.¹⁴ As a result of this change in labeling, the clinical use of droperidol has effectively ceased. After review of the cases, several authors have questioned the justification of this warning.^{15,16}

■ CORTICOSTEROIDS

Corticosteroids have demonstrated antiemetic efficacy since the initial recognition that patients receiving prednisone as part of their Hodgkin’s disease protocol appeared to develop less nausea and vomiting than those patients treated with protocols that excluded this agent. Other corticosteroids showing antiemetic efficacy include methylprednisolone and dexamethasone.

Dexamethasone has been used successfully in the management of chemotherapy-induced and postoperative nausea and vomiting, either as a single agent or in combination with selective serotonin receptor inhibitors (SSRIs). For chemotherapy-induced nausea and vomiting, dexamethasone has demonstrated efficacy in the prevention of both cisplatin-induced acute emesis¹⁷ and delayed nausea and

vomiting associated with moderately emetogenic chemotherapy.¹⁸ For patients with simple nausea and vomiting, steroids are not indicated and may be associated with unacceptable risks.

■ METOCLOPRAMIDE

Metoclopramide, procainamide's congener, provides significant antiemetic effects by blocking the dopaminergic receptors centrally in the CTZ. Peripherally, metoclopramide increases lower esophageal sphincter tone, aids gastric emptying, and accelerates transit through the small bowel, possibly through the release of acetylcholine. Metoclopramide is used for its antiemetic properties in patients with diabetic gastroparesis and as a component of multiagent therapy for prophylaxis of delayed nausea and vomiting associated with chemotherapy administration. Its use as prophylaxis for acute chemotherapy-induced nausea and vomiting was supplanted by the introduction of the SSRIs in the early 1990s. These agents have greater efficacy and decreased toxicity compared with metoclopramide in patients receiving cisplatin-based regimens.^{19–21}

■ CANNABINOIDS

Thirty randomized, controlled trials from 1975 to 1996 were analyzed to quantify the antiemetic efficacy and adverse effects of cannabis when given to 1366 patients receiving chemotherapy.²² Oral nabilone, oral dronabinol, and intramuscular levonantradol were compared with conventional antiemetics (prochlorperazine, metoclopramide, chlorpromazine, thiethylperazine, haloperidol, domperidone, and alizapride) or placebo. Across all trials, cannabinoids were slightly more effective than active comparators and placebo when the chemotherapy regimen was of moderate emetogenic potential, and patients preferred them. No dose-response relationships were evident to the authors. The cannabinoids were also more toxic; side effects included euphoria, drowsiness, sedation, somnolence, dysphoria, depression, hallucinations, and paranoia. The efficacy of cannabinoids as compared to SSRIs has not been studied. Use of these agents should be considered when other regimens do not provide desired efficacy.

■ SUBSTANCE P/NEUROKININ 1 RECEPTOR ANTAGONISTS

Substance P is a peptide neurotransmitter in the neurokinin (NK) family whose preferred receptor is the NK₁ receptor.²³ The acute phase of CINV is believed to be mediated by both serotonin and substance P, whereas substance P is believed to be the primary mediator of the delayed phase. NK₁ antagonists administered as part of a multiple-drug regimen with a SSRI and a corticosteroid improved protection from both acute and delayed emesis.^{24–26} Aprepitant is the first approved substance P/NK₁ receptor antagonist. In two placebo-controlled, randomized trials, patients receiving high-dose cisplatin-based chemotherapy received IV ondansetron on day 1 plus oral dexamethasone on days 1 through 4 with or without oral aprepitant on days 1, 2, and 3. The aprepitant regimen provided significantly superior control of emesis in the overall study period as well as in separate analyses of the acute and delayed phases.^{27,28}

Aprepitant has the potential for numerous drug interactions because it is a substrate, moderate inhibitor, and an inducer of cytochrome isoenzyme CYP3A4 and an inducer of CYP2C9. Aprepitant

can increase serum concentrations of many drugs metabolized by CYP3A4, including docetaxel, paclitaxel, etoposide, irinotecan, ifosfamide, imatinib, vinorelbine, vincristine, and vinblastine. In clinical studies, aprepitant was concomitantly administered with etoposide, vinorelbine, or paclitaxel, with no adjustment in the doses of these agents to account for potential drug interactions. The efficacy of oral contraceptives may be reduced. Concomitant administration with warfarin may result in a clinically significant decrease in the International Normalized Ratio.²⁹ The dose of oral dexamethasone should be reduced 50% when coadministered with aprepitant, due to the 2.2-fold increase in observed area under the plasma-concentration-versus-time curve.³⁰ Aprepitant is not indicated for use in children.

■ SELECTIVE SEROTONIN RECEPTOR INHIBITORS

SSRIs block presynaptic serotonin receptors on sensory vagal fibers in the gut wall, effectively blocking the acute phase of CINV. These agents do not completely block the acute phase of CINV and are less efficacious in preventing the delayed phase, but they are the standard of care in the management of chemotherapy-induced, radiation-induced, and postoperative nausea and vomiting. Issues involved in the use of dolasetron, granisetron, ondansetron, and palonosetron are reviewed in detail in the sections that follow. The most common side effects associated with these agents are constipation, headache, and asthenia. Safety and efficacy in children less than 2 years old have not been established.

■ CHEMOTHERAPY-INDUCED NAUSEA AND VOMITING

CINV can be classified as anticipatory, acute, or delayed. As defined earlier, anticipatory nausea and vomiting is a conditioned response linked to experiencing poor emetic control with previously administered chemotherapy.⁴ The anxiolytic and amnesic properties of lorazepam 1 to 2 mg given orally the evening before and the morning of chemotherapy may help prevent anticipatory nausea and vomiting, but efficacy has not been demonstrated in large, randomized trials.³¹ Use of the most appropriate antiemetic regimen to prevent acute and delayed nausea and vomiting, beginning with the first cycle of chemotherapy, is recommended to prevent future development of anticipatory nausea and vomiting.³²

5 Nausea and vomiting that occurs within 24 hours of chemotherapy administration is defined as acute, whereas when it starts more than 24 hours after chemotherapy administration, it is defined as delayed. The primary goal with CINV is to *prevent* nausea and/or vomiting; optimal control of acute nausea and vomiting positively impacts the incidence and control of delayed and anticipatory nausea and vomiting. Clinical practice guidelines for the use of antiemetics in CINV have been published.^{31–33} Despite the availability of nationally recommended guidelines, individual practice varies from one institution to the next. Product availability and recommended doses are institution-specific and may vary considerably from the doses listed in Table 35–5.

Factors to consider when selecting an antiemetic for CINV include:

- The emetogenic potential of the chemotherapy agent or regimen (see Table 35–2).
- Patient-specific factors.
- Patterns of emesis after administration of specific chemotherapy agents or regimens.

■ Prophylaxis of CINV (Adapted from Reference 31; Used with Permission)

◀ **6** ■ **Recommendation 1.** The emetogenic potential of the chemotherapeutic agent (see Table 35–2) is the primary factor to consider when deciding whether to administer prophylactic agents and which antiemetic(s) to select. When combination therapy is prescribed, the most highly emetogenic agent in the combination should be identified, and the contribution of other agents should be considered by using the following rules:³⁴

- Level 1 agents do not contribute to the emetogenicity of a given regimen.
- Adding one or more level 2 agents increases emetogenicity of the combination by one level greater than the most emetogenic agent in the combination.
- Adding level 3 and 4 agents increases emetogenicity of the combination by one level per agent.

Originally developed for adult patients, these guidelines should be used cautiously in pediatric patients; however, the information is considered generally applicable to children receiving chemotherapy.

■ **Recommendation 2.** Adult and pediatric patients receiving chemotherapeutic agent(s) with emetogenic potential classified as level 2 through 5 should receive prophylaxis against nausea and vomiting each day on which chemotherapy is given. Antiemetic prophylaxis is not required for level 1 agents.

- Adult and pediatric patients receiving level 2 regimens can receive a corticosteroid alone for prophylaxis. Prochlorperazine is also an option for adults.
- Adult and pediatric patients receiving level 3 through 5 regimens should receive a corticosteroid in combination with a SSRI.
- Orally and intravenously administered antiemetics are generally equivalent in efficacy and safety for both adult and pediatric patients. The decision as to which formulation to use should be based on patient-specific factors and cost.
- The decision as to which SSRI to use should be based on the acquisition cost of comparable doses. Dosage recommendations for adult and pediatric patients differ.

At the time the American Society of Health-System Pharmacists (ASHP) guidelines were published, the safety and efficacy of ondansetron, granisetron, and dolasetron for prophylaxis of CINV in adult and pediatric patients receiving moderately emetogenic or highly emetogenic chemotherapeutic regimens were supported by more than 50 clinical studies. The superior efficacy and safety of this class of agents over metoclopramide, with or without dexamethasone, in CINV prophylaxis have been demonstrated in numerous studies. When used in comparable dosage regimens, the choice of whether to use ondansetron, granisetron, or dolasetron should be based primarily on acquisition costs. The oral route of administration is preferred.^{35,36}

The efficacy of ondansetron, granisetron, and dolasetron for the prophylaxis of moderately or highly emetogenic chemotherapy regimens is enhanced when used in combination with dexamethasone.

■ Treatment of CINV

■ **Recommendation 3.** All patients receiving chemotherapy should have antiemetics available on an as-needed basis for rescue of

breakthrough nausea and vomiting. Chlorpromazine, prochlorperazine, methylprednisolone, lorazepam, metoclopramide, dexamethasone, and dronabinol are available for adult patients. Chlorpromazine, lorazepam, and methylprednisolone (or dexamethasone) are recommended for pediatric patients. The choice of agent should be based on patient-specific factors, including potential adverse reactions, and cost. Granisetron, dolasetron, and ondansetron are effective in the treatment of breakthrough nausea and vomiting, but they are not superior to conventional, less expensive antiemetics.

■ Prophylaxis of Delayed CINV

■ **Recommendation 4.** For the prevention of delayed emesis after cisplatin therapy in adults, dexamethasone with metoclopramide or a SSRI is recommended. The choice of agent should be based on patient-specific factors and cost. For delayed emesis after cyclophosphamide, doxorubicin, or carboplatin therapy, a SSRI with dexamethasone is recommended. In pediatric patients, chlorpromazine, lorazepam, or a SSRI can be used in combination with a corticosteroid.

Since the publication of the ASHP and American Society of Clinical Oncologists (ASCO) clinical guidelines,^{31,32} two new agents have been released, aprepitant (Emend) and palonestron (Aloxi). Aprepitant has been studied in combination with ondansetron and dexamethasone for the prophylaxis of acute and delayed nausea and vomiting associated with highly emetogenic chemotherapy, including high-dose cisplatin. The National Comprehensive Cancer Network (NCCN) guidelines³³ also include aprepitant in their guidelines for moderately emetogenic chemotherapy regimens. Palonestron, an injectable SSRI with a prolonged serum half-life and higher receptor binding affinity, is indicated for the prophylaxis of both *acute* nausea and vomiting associated with moderately and highly emetogenic chemotherapy regimens, and *delayed* nausea and vomiting associated with moderately emetogenic chemotherapy. Palonestron 0.25 mg is administered IV over 30 minutes prior to chemotherapy and should not be repeated within 7 days.³⁷ It has not been approved for use in children. Two Phase III trials support the labeled indications.^{38,39} Although proven safe and efficacious, the design of the trials for these two new agents raises many questions and their eventual place in therapy, and inclusion in clinical practice guidelines, remains to be determined.

CLINICAL CONTROVERSY

Current published information describes the experience with aprepitant in highly emetogenic cisplatin-based chemotherapy regimens. The NCCN has also included aprepitant for prophylaxis of nausea and vomiting induced by moderately emetogenic chemotherapy regimens.³³ This recommendation is not supported by the current literature and has been questioned by clinicians.

■ POSTOPERATIVE NAUSEA AND VOMITING

One of the most common complications of surgery is postoperative nausea and vomiting (PONV). Most patients undergoing an operative procedure do not require preoperative prophylactic antiemetic therapy and universal PONV prophylaxis is not cost effective. Consensus therapeutic guidelines for the prophylaxis and treatment of PONV have recently been published.^{31,40} Factors to be considered for PONV

TABLE 35–6. Risk Factors for PONV

| |
|--|
| Patient-specific factors |
| Female gender |
| Nonsmoking status |
| History of motion sickness/PONV |
| Anesthetic risk factors |
| Use of volatile anesthetics |
| Nitrous oxide |
| Use of opioids (intraoperative or postoperative) |
| Surgical risk factors |
| Duration of surgery |
| Operative procedure (intra-abdominal, ear-nose-throat, major gynecologic, orthopedic, or laparoscopic) |

PONV, postoperative nausea and vomiting.

prophylaxis and treatment include: risk factors, potential morbidity, potential adverse events associated with various antiemetics, efficacy of antiemetics, and costs. Risk factors for PONV are summarized in Table 35–6. The incidence of PONV can be significantly decreased by reducing baseline risk factors among patients at highest risk whenever clinically practical. Strategies to reduce baseline risk include use of regional anesthesia, propofol, supplemental oxygen, and hydration, as well as avoiding nitrous oxide, volatile anesthetics, and opioids.

■ Prophylaxis of PONV

7 Although the optimal management of PONV is not known, patients at high risk of vomiting should receive prophylactic antiemetics for PONV. In addition to likely lack of benefit from prophylaxis, patients at low risk for PONV may potentially experience adverse reactions from the medications. Doses for prophylactic antiemetics are summarized in Table 35–7. The consensus panel determined that there is no difference in the efficacy and safety profiles of the SSRI in the prophylaxis of PONV, and that these drugs are most effective when given at the end of surgery. Furthermore, the panel agreed that with equivalent efficacy and safety profiles, acquisition cost was the primary factor that differentiated the SSRIs from each other.⁴⁰

Dexamethasone is an effective prophylactic agent when administered either alone or in combination with other antiemetic drugs before the induction of anesthesia.⁴¹ Droperidol has been one of the most effective agents for PONV prophylaxis. At a dose of 1.25 mg IV, it was more effective and much less costly than combination therapy with ondansetron 4 mg IV and droperidol 0.625 mg IV.⁴² As discussed earlier, the recent FDA black box warning has effectively removed droperidol from clinical use. As a result of conflicting data,

clinicians do not agree on the role of metoclopramide as a prophylactic agent for PONV. Although effective, the use of phenothiazines in ambulatory surgery is limited due to predictable side effects including sedation, dry mouth, and dizziness. Transdermal scopolamine is an effective prophylactic agent for PONV, but its use is limited by the 2- to 4-hour delay in onset of effect in addition to age-related concerns and medical contraindications.^{43,44} Combination therapy is superior to monotherapy, but optimal dosing of agents used in combination as prophylaxis of PONV has not been determined.^{45,46}

■ Treatment of PONV

When PONV occurs in a patient who did not receive prophylaxis or who only received prophylactic dexamethasone, treatment with a SSRI is indicated. Typical adult treatment doses of SSRIs are as follows: dolasetron 12.5 mg, granisetron 0.1 mg, and ondansetron 1 mg.⁴⁷ If prophylaxis with a SSRI is not protective, a treatment dose of a SSRI is not recommended within the first 6 hours after surgery due to lack of proven efficacy.⁴⁸ Patients who experience PONV after receiving prophylactic treatment with a SSRI plus dexamethasone should receive a rescue dose from a different drug class such as a phenothiazine or droperidol.⁴⁹ If more than 6 hours has elapsed between the administration of a prophylactic dose of a SSRI and an episode of PONV, a treatment or prophylaxis dose of a SSRI or droperidol can be administered, but the optimal readministration dose and interval for these two agents have not been determined.

CLINICAL CONTROVERSY

Is the lower dose of droperidol used for PONV safer than a higher dose? Several authors have reviewed the cases used by the FDA as justification for the black box warning. One author has hypothesized that droperidol is more hazardous in the presence of acute psychosis, making the acutely psychotic, severely agitated patient at higher risk of dysrhythmia than the typical perioperative patient receiving a dose of 1.25 mg or less.¹⁵

■ RADIATION-INDUCED NAUSEA AND VOMITING

Nausea and vomiting associated with radiation therapy is not well understood. It is neither as predictable nor as severe as CINV, and many patients receiving radiation therapy will not experience nausea or vomiting. Risk factors associated with the development of RINV include the site of radiation, the dose, dose rate, and field size.

8 Patients receiving single-exposure, high-dose radiation therapy

TABLE 35–7. Recommended Prophylactic Doses of Antiemetics for PONV

| Drug | Adult Dose (IV) | Pediatric Dose (IV) | Timing of Dose ^a |
|----------------|-----------------|----------------------------|-----------------------------|
| Dolasetron | 12.5 mg | 350 mcg/kg up to 12.5 mg | At end of surgery |
| Granisetron | 0.35–1 mg | | At end of surgery |
| Ondansetron | 4–8 mg | 50–100 mcg/kg up to 4 mg | At end of surgery |
| Dexamethasone | 5–10 mg | 150 mcg/kg up to 8 mg | Before induction |
| Droperidol | 0.625–1.25 mg | 50–70 mcg/kg up to 1.25 mg | At end of surgery |
| Dimenhydrinate | 1–2 mg/kg | 0.5 mg/kg | |

^aBased on recommendations from consensus guidelines; may differ from manufacturer's recommendations.

PONV, postoperative nausea and vomiting.

From Gan et al.⁴⁰

to the upper abdomen, or total or hemibody irradiation should receive prophylactic antiemetics for RINV.

■ Prophylaxis of RINV

The ASHP Therapeutic Guidelines³¹ and the ASCO antiemetic practice guidelines³² recommend preventive therapy in patients receiving total or hemibody irradiation or single-exposure, high-dose radiation therapy to the upper abdomen. The efficacy of oral granisetron 2 mg and ondansetron 8 mg was demonstrated in 34 patients undergoing hyperfractionated total body irradiation.⁵⁰ Patients undergoing radiation therapy procedures with low to intermediate risk of nausea or vomiting should receive a SSRI or a dopamine receptor antagonist prior to each fraction.³²

■ Treatment of RINV

Patients who experience nausea and vomiting after radiation therapy should receive prochlorperazine, metoclopramide, or thiethylperazine as rescue agents, and then receive prophylactic treatment with a SSRI prior to subsequent radiation treatment.³¹

■ DISORDERS OF BALANCE

A variety of clinical conditions may be associated with vertigo and dizziness. The etiology of these complaints may include diseases that are infectious, postinfectious, demyelinating, vascular, neoplastic, degenerative, traumatic, toxic, psychogenic, or idiopathic. Therefore symptoms of imbalance or imbalance perceived by the patient present a particular clinical challenge. Whether associated with a minor or complex disorder, motion sickness may be associated with nausea and vomiting.

Although much progress has been made in the management of other illnesses associated with emesis, motion sickness represents an area in which newer agents have provided little benefit. Beneficial therapy for patients in this setting can most reliably be found among the antihistaminic-anticholinergic agents. However, their precise mechanisms of action are unknown to date. Neither the antihistaminic nor the anticholinergic potency appears to correlate well with the ability of these agents to prevent or treat the nausea and vomiting associated with motion sickness. When used for their depressant effects on labyrinth excitability, these agents produce variable efficacy and safety profiles. Oral regimens of antihistaminic-anticholinergic agents given one to several times each day may be effective, especially when the first dose is administered prior to motion.

The utility of scopolamine in preventing motion sickness was enhanced with the development of the transdermal system that increased patient satisfaction and decreased untoward side effects. The efficacy of transdermal scopolamine, oral meclizine, and placebo in protection against motion sickness was compared in a double-blind crossover study in 36 healthy subjects. Transdermal applications were made and tablets were taken at least 12 and 2 hours before exposure to three 90-minute periods in a ship-motion simulator. Transdermal scopolamine provided better protection than placebo or meclizine, with dryness of mouth more frequently reported in the transdermal scopolamine subjects.⁵¹

■ ANTIEMETIC USE DURING PREGNANCY

More than one-half of pregnant women experience nausea and vomiting to some degree during the first trimester of pregnancy (nausea and vomiting of pregnancy; NVP). Teratogenicity is a major consideration for the use of antiemetic drugs during pregnancy and is the primary factor that guides drug selection. A large body of evidence suggests that the histamine₁-receptor antagonists (dimenhydrinate, diphenhydramine, doxylamine, hydroxyzine, and meclizine) have no human teratogenic potential⁵² and are effective in reducing treatment failure.⁵³ Whether used alone or in combination with doxylamine, pyridoxine has not been found to be teratogenic and significantly decreases the nausea score.^{54,55} Other commonly prescribed agents that are effective and not teratogenic include the phenothiazines prochlorperazine and promethazine.⁵³ Studies using the SSRIs in NVP are limited. In a randomized controlled trial of 15 patients exposed during the first trimester to intravenous ondansetron versus promethazine for treatment of severe NVP, ondansetron was no more beneficial than promethazine with respect to the following outcome measures: severity of nausea, daily weight gain, days requiring hospitalization, treatment failures, and voluntary use of the drug.⁵⁶ The limited safety data for ondansetron does not allow it to be recommended as first-line therapy. Nonpharmacologic interventions for NVP include ginger⁵⁷ and acupuncture, although safety and efficacy trials for acupuncture are lacking.

Although many women experience nausea and vomiting during pregnancy, less than 1% develop hyperemesis gravidarum, a serious condition marked by severe physical symptoms and/or medical complications. The etiology of hyperemesis gravidarum is not well understood. In its most severe state, hyperemesis gravidarum may result in volume contraction, starvation, and electrolyte abnormalities. Other clinical strategies include attention to fluid and electrolyte management, the use of vitamin supplements, reduced intake of dietary fats with increased intake of carbohydrates, and methods aimed at reducing psychosomatic complaints.⁵⁸

■ ANTIEMETIC USE IN CHILDREN

As discussed previously, the safety and efficacy of SSRIs have been established in pediatric patients receiving chemotherapy. Their side effect profile has promoted their use in children. The best doses or dosing strategies for children (by age, weight, or body surface area) have not been clearly established. Due to the lack of comparative trials in children, the ASCO antiemetic guidelines recommend that clinicians follow the adult guidelines with dosage adjustments for the pediatric population, with the exception that dopamine receptor antagonists should be avoided because of their potential for dystonic reactions.³² Corticosteroids are often used in combination with SSRIs as prophylaxis for CINV.

For nausea and vomiting associated with pediatric gastroenteritis, there is greater emphasis on rehydration measures than on pharmacologic intervention. Only two prospective studies have been published on the safety or efficacy of antiemetics in pediatric gastroenteritis since 1966.^{59,60} A recent survey of physicians revealed that promethazine suppositories were the most commonly prescribed antiemetic for pediatric gastroenteritis, despite the lack of prospective trials for this agent.⁶¹

PHARMACOECONOMIC CONSIDERATIONS

There are many important variables to consider when attempting to document the overall costs of using a medication in a particular medical situation. Medication costs alone cannot begin to explain the true pharmacoeconomic outcome associated with the use of antiemetic drugs. For example, the costs associated with an unexpected hospital admission because of vomiting after an outpatient surgical procedure

quickly offset the savings related to the selection of an inexpensive antiemetic drug. In this and other similar situations, it is economically and clinically important to develop antiemetic protocols based on appropriate decision analysis and clinical outcomes in order to optimize drug product selection. The clinical practice guidelines that have been previously described are valuable tools when developing institution-specific antiemetic protocols. The availability of new, more expensive agents will only increase the costs associated with the prophylaxis of CINV. The need to control antiemetic costs for hospitals is universal and formulary management strategies have been described.⁶²

EVALUATION OF THERAPEUTIC OUTCOMES

In accordance with the information presented concerning age and clinical condition, individualized therapy is possible through drug selection and dosage adjustment. Monitoring criteria for drug therapy should include the subjective assessment of the patient's severity of nausea, as well as objective parameters, such as changes in patient weight, the number of vomiting episodes each day, the volume of vomitus lost, and evaluation of fluid, acid-base balance, and electrolyte status, with particular attention to serum sodium, potassium, and chloride concentrations. In addition, evaluation of renal function may become important, particularly in patients with volume contraction and progressive electrolyte disturbances. Specific parameters include daily urine volume, urine specific gravity, and urine electrolyte concentrations. Physical assessment of patients should include evaluation of mucous membranes and skin turgor, because dryness of these tissues may be indicative of significant volume loss.

DIARRHEA, CONSTIPATION, AND IRRITABLE BOWEL SYNDROME

William J. Spruill and William E. Wade

Learning Objectives and other resources can be found at www.pharmacotherapyonline.com.

KEY CONCEPTS

- 1 Diarrhea is caused by many viral and bacterial organisms. It is most often a minor discomfort, not life-threatening, and usually self-limited.
- 2 The four pathophysiologic mechanisms of diarrhea have been linked to the four broad diarrheal groups, which are secretory, osmotic, exudative, and altered intestinal transit. The three mechanisms by which absorption occurs from the intestines are active transport, diffusion, and solvent drag.
- 3 Management of diarrhea focuses on preventing excessive water and electrolyte losses, dietary care, relieving symptoms, treating curable causes, and treating secondary disorders.
- 4 Bismuth subsalicylate is marketed for indigestion, relieving abdominal cramps, and controlling diarrhea, including traveler's diarrhea, but contains multiple components that might be toxic if given excessively.
- 5 Underlying causes of constipation should be identified when possible and corrective measures taken (e.g., alteration of diet or treatment of diseases such as hypothyroidism).
- 6 The foundation of treatment of constipation is dietary fiber or bulk-forming laxatives that provide 10 to 15 g/day of raw fiber.
- 7 Irritable bowel syndrome is one of the most common gastrointestinal disorders, and is characterized by lower abdominal pain, disturbed defecation, and bloating. Many nongastrointestinal manifestations also exist with IBS. Recent studies have found that visceral hypersensitivity is a major culprit in the pathophysiology of the disease.
- 8 Diarrhea-predominant IBS should be managed by dietary modification and drugs such as loperamide when diet changes alone are insufficient to control symptoms.
- 9 Several drug classes are involved in the treatment of the pain associated with IBS, including tricyclic compounds and the gut-selective calcium channel blockers.

DIARRHEA

Diarrhea is a troublesome discomfort that affects most individuals in the United States at some point in their lives. Usually diarrheal episodes begin abruptly and subside within 1 or 2 days without treatment. This chapter focuses primarily on noninfectious diarrhea, with only minor reference to infectious diarrhea (see Chap. 111 on gastrointestinal infections). Diarrhea is often a symptom of a systemic disease and not all possible causes of diarrhea are discussed in this chapter.

To understand diarrhea, one must have a reasonable definition of the condition; unfortunately, the literature is extremely variable on this. Simply put, diarrhea is an increased frequency and decreased consistency of fecal discharge as compared to an individual's normal bowel pattern. Frequency and consistency are variable within and between individuals. For example, some individuals defecate as often as three times per day, whereas others defecate only two or three times per week. A Western diet usually produces a daily stool weighing between 100 and 300 g, depending on the amount of nonabsorbable materials (mainly carbohydrates) consumed. Patients with serious diarrhea may have a daily stool weight in excess of 300 g; however, a

subset of patients experience frequent small, watery passages. Additionally, vegetable fiber-rich diets, such as those consumed in some Eastern cultures such as those in Africa, produce stools weighing more than 300 g/day.

Diarrhea may be associated with a specific disease of the intestines or secondary to a disease outside the intestines. For instance, bacillary dysentery directly affects the gut, whereas diabetes mellitus causes neuropathic diarrheal episodes. Furthermore, diarrhea can be considered as acute or chronic disease. Infectious diarrhea is often acute; diabetic diarrhea is chronic. Whether acute or chronic, diarrhea has the same pathophysiologic causes that help identification of specific treatments.

EPIDEMIOLOGY

The epidemiology of diarrhea varies in developed versus developing countries.¹⁻³ In the United States, diarrheal illnesses are usually not reported to the Centers for Disease Control and Prevention (CDC) unless associated with an outbreak or an unusual organism or condition. For example, the acquired immune deficiency syndrome (AIDS) has been identified with protracted diarrheal illness. Diarrhea is a major

problem in day care centers and nursing homes, probably because early childhood and senescence plus environmental conditions are risk factors. However, an exact epidemiologic profile in the United States is not available through the CDC or published literature.

1 Viral and bacterial organisms account for most episodes of infectious diarrhea. Common causative bacterial organisms include *Shigella*, *Salmonella*, *Campylobacter*, *Staphylococcus*, and *Escherichia coli*. Food-borne bacterial infection is a major concern, as several major food poisoning episodes have occurred that were traced to poor sanitary conditions in meat-processing plants. Acute viral infections are attributed mostly to the Norwalk and rotavirus groups.

In developing countries, diarrhea is a leading cause of illness and death in children.⁴ Moreover, diarrhea produces an economic burden because of costs related to hospitalization and loss of productivity. Approximately 1.3 billion episodes occur annually and 4 million deaths result from diarrhea in these countries. Factors associated with these findings include poor sanitation, poor nutrition, and age less than 5 years. Children in underdeveloped countries experience an average of three episodes of diarrhea each year (e.g., 2.7 diarrhea episodes/person/year in Latin America) as compared to 1 episode/person/year in the United States and Western Europe.

PHYSIOLOGY

In the fasting state, 9 L of fluid enters the proximal small intestine each day. Of this fluid, 2 L are ingested through diet, while the remainder consists of internal secretions. Because of meal content, duodenal chyme is usually hypertonic. When chyme reaches the ileum, the osmolality adjusts to that of plasma, with most dietary fat, carbohydrate, and protein being absorbed. The volume of ileal chyme decreases to about 1 L/day upon entering the colon, which is further reduced by colonic absorption to 100 mL daily. If the small intestine water absorption capacity is exceeded, chyme overloads the colon, resulting in diarrhea. In humans, the colon absorptive capacity is about 5 L daily. Colonic fluid transport is critical to water and electrolyte balance.

Absorption from the intestines back into the blood occurs by three mechanisms: active transport, diffusion, and solvent drag. Active transport and diffusion are the mechanisms of sodium transport. Because of the high luminal sodium concentration (142 mEq/L), sodium diffuses from the sodium-rich gut into epithelial cells, where it is actively pumped into the blood and exchanged with chloride to maintain an isoelectric condition across the epithelial membrane.

Hydrogen ions are transported by an indirect mechanism in the upper small intestine. As sodium is absorbed, hydrogen ions are secreted into the gut. Hydrogen ions then combine with bicarbonate ions to form carbonic acid, which then dissociates into carbon dioxide and water. Carbon dioxide readily diffuses into the blood for expiration through the lung. The water remains in the chyme.

Paracellular pathways are major routes of ion movement. As ions, monosaccharides, and amino acids are actively transported, an osmotic pressure is created, drawing water and electrolytes across the intestinal wall. This pathway accounts for significant amounts of ion transport, especially sodium. Sodium plays an important role in stimulating glucose absorption. Glucose and amino acids are actively transported into the blood via a sodium dependent cotransport mechanism. Cotransport absorption mechanisms of glucose-sodium and amino acid-sodium are extremely important for treating diarrhea.

Gut motility influences absorption and secretion. The amount of time in which luminal content is in contact with the epithelium is under neural and hormonal control. Neurohormonal substances, such as angiotensin, vasopressin, glucocorticoid, and aldosterone, and neurotransmitters also regulate ion transport.

PATHOPHYSIOLOGY

2 Four general pathophysiologic mechanisms disrupt water and electrolyte balance, leading to diarrhea, and are the basis of diagnosis and therapy. These are (a) a change in active ion transport by either decreased sodium absorption or increased chloride secretion; (b) change in intestinal motility; (c) increase in luminal osmolality; and (d) increase in tissue hydrostatic pressure. These mechanisms have been related to four broad clinical diarrheal groups: secretory, osmotic, exudative, and altered intestinal transit.

Secretory diarrhea occurs when a stimulating substance either increases secretion or decreases absorption of large amounts of water and electrolytes. Substances that cause excess secretion include vasoactive intestinal peptide (VIP) from a pancreatic tumor, unabsorbed dietary fat in steatorrhea, laxatives, hormones (such as secretin), bacterial toxins, and excessive bile salts. Many of these agents stimulate intracellular cyclic adenosine monophosphate and inhibit Na^+/K^+ -ATPase, leading to increased secretion. Also, many of these mediators inhibit ion absorption simultaneously. Clinically, secretory diarrhea is recognized by large stool volumes (>1 L/day) with normal ionic contents and osmolality approximately equal to plasma. Fasting does not alter the stool volume in these patients.

Poorly absorbed substances retain intestinal fluids, resulting in osmotic diarrhea. This process occurs with malabsorption syndromes, lactose intolerance, administration of divalent ions (e.g., magnesium-containing antacids), or consumption of poorly soluble carbohydrate (e.g., lactulose). As a poorly soluble solute is transported, the gut adjusts the osmolality to that of plasma; in so doing, water and electrolytes flux into the lumen. Clinically, osmotic diarrhea is distinguishable from other types, as it ceases if the patient resorts to a fasting state.

Inflammatory diseases of the gastrointestinal tract discharge mucus, serum proteins, and blood into the gut. Sometimes bowel movements consist only of mucus, exudate, and blood. Exudative diarrhea probably affects other absorptive, secretory, or motility functions to account for the large stool volume associated with this disorder.

Altered intestinal motility produces diarrhea by three mechanisms: reduction of contact time in the small intestine, premature emptying of the colon, and bacterial overgrowth. Chyme must be exposed to intestinal epithelium for a sufficient time period to enable normal absorption and secretion processes to occur. If this contact time decreases, diarrhea results. Intestinal resection or bypass surgery and drugs (such as metoclopramide) cause this type of diarrhea. On the other hand, an increased time of exposure allows fecal bacteria overgrowth. A characteristic small intestine diarrheal pattern is rapid, small, coupling bursts of waves. These waves are inefficient, do not allow absorption, and rapidly dump chyme into the colon. Once in the colon, chyme exceeds the colonic capability to absorb water.

ETIOLOGIC EXAMINATION OF THE STOOL

Stool characteristics are important in assessing the etiology of diarrhea. A description of the frequency, volume, consistency, and color provides diagnostic clues. For instance, diarrhea starting in the small intestine produces a copious, watery or fatty (greasy), and foul-smelling stool; contains undigested food particles; and is usually free from gross blood. Colonic diarrhea appears as small, pasty, and sometimes bloody or mucoid movements. Rectal tenesmus with flatus accompanies large intestinal diarrhea.

TABLE 36–1. Clinical Presentation of Diarrhea**General**

- Usually, acute diarrheal episodes subside within 72 hours of onset, whereas chronic diarrhea involves frequent attacks over extended time periods.

Signs and symptoms

- Abrupt onset of nausea, vomiting, abdominal pain, headache, fever, chills, and malaise.
- Bowel movements are frequent and never bloody, and diarrhea lasts 12 to 60 hours.
- Intermittent periumbilical or lower right quadrant pain with cramps and audible bowel sounds is characteristic of small intestinal disease.
- When pain is present in large intestinal diarrhea, it is a gripping, aching sensation with tenesmus (straining, ineffective and painful stooling). Pain localizes to the hypogastric region, right or left lower quadrant, or sacral region.
- In chronic diarrhea, a history of previous bouts, weight loss, anorexia, and chronic weakness are important findings.

Physical examination

- Typically demonstrates hyperperistalsis with borborygmi and generalized or local tenderness.

Laboratory tests

- Stool analysis studies include examination for microorganisms, blood, mucus, fat, osmolality, pH, electrolyte and mineral concentration, and cultures.
- Stool test kits are useful for detecting gastrointestinal viruses, particularly rotavirus.
- Antibody serologic testing shows rising titers over a 3- to 6-day period, but this test is not practical and is nonspecific.
- Occasionally, total daily stool volume is also determined.
- Direct endoscopic visualization and biopsy of the colon may be undertaken to assess for the presence of conditions such as colitis or cancer.
- Radiographic studies are helpful in neoplastic and inflammatory conditions.

CLINICAL PRESENTATION

Table 36–1 outlines the clinical presentation of diarrhea while Table 36–2 shows common drug-induced causes of diarrhea. A medication

TABLE 36–2. Drugs Causing Diarrhea

| Prostaglandins |
| Colchicine |

history is extremely important in identifying drug-induced diarrhea. Many agents, including antibiotics and other drugs, cause diarrhea, or less commonly, pseudomembranous colitis. Self-inflicted laxative abuse for weight loss is popular. Neurotic or psychotic behavior leads to laxative abuse. Drug side effects (e.g., quinidine side effects) often present as diarrhea.

Most acute diarrhea is self-limiting, subsiding within 72 hours. However, infants, young children, the elderly, and debilitated persons are at risk for morbid and mortal events in prolonged or voluminous diarrhea. These groups are at risk for water, electrolyte, and acid-base disturbances, and potentially cardiovascular collapse and death. The prognosis for chronic diarrhea depends on the cause; for example, diarrhea secondary to diabetes mellitus waxes and wanes throughout life.

▶ TREATMENT: Diarrhea**■ PREVENTION**

Acute viral diarrheal illness often occurs in day care centers and nursing homes. As person-to-person contact is the mechanism by which viral disease spreads, isolation techniques must be initiated. For bacterial, parasite, and protozoal infections, strict food handling, sanitation, water, and other environmental hygiene practices can prevent transmission. If diarrhea is secondary to another illness, controlling the primary condition is necessary. Antibiotics and bismuth subsalicylate are advocated to prevent traveler's diarrhea, in conjunction with treatment of drinking water and caution with consumption of fresh vegetables.

■ DESIRED OUTCOME

3 If prevention is not successful and diarrhea occurs, therapeutic goals are to (a) manage the diet; (b) prevent excessive water, elec-

trolyte, and acid-base disturbances; (c) provide symptomatic relief; (d) treat curable causes; and (e) manage secondary disorders causing diarrhea (Figs. 36–1 and 36–2).

Clinicians must clearly understand that diarrhea, like a cough, may be a body defense mechanism for ridding itself of harmful substances or pathogens. The correct therapeutic response is not necessarily to stop diarrhea at all costs.

■ NONPHARMACOLOGIC MANAGEMENT

Dietary management is a first priority in the treatment of diarrhea. Most clinicians recommend discontinuing consumption of solid foods and dairy products for 24 hours. However, fasting is of questionable value, as this treatment modality has not been extensively studied. In osmotic diarrhea, these maneuvers control the problem. If the mechanism is secretory, diarrhea persists. For patients experiencing

FIGURE 36-1. Recommendations for treating acute diarrhea. Follow these steps: (1) Perform a complete history and physical examination. (2) Is the diarrhea acute or chronic? If chronic diarrhea, go to Fig. 36-2. (3) If acute diarrhea, check for fever and/or systemic signs and symptoms (i.e., toxic patient). If systemic illness (fever, anorexia, or volume depletion), check for an infectious source. If positive for infectious diarrhea, use appropriate antibiotic/anthelmintic drug and symptomatic therapy. If negative for infectious cause, use only symptomatic treatment. (4) If no systemic findings, then use symptomatic therapy based on severity of volume depletion, oral or parenteral fluid/electrolytes, anti-diarrheal agents (see Table 36-4), and diet.

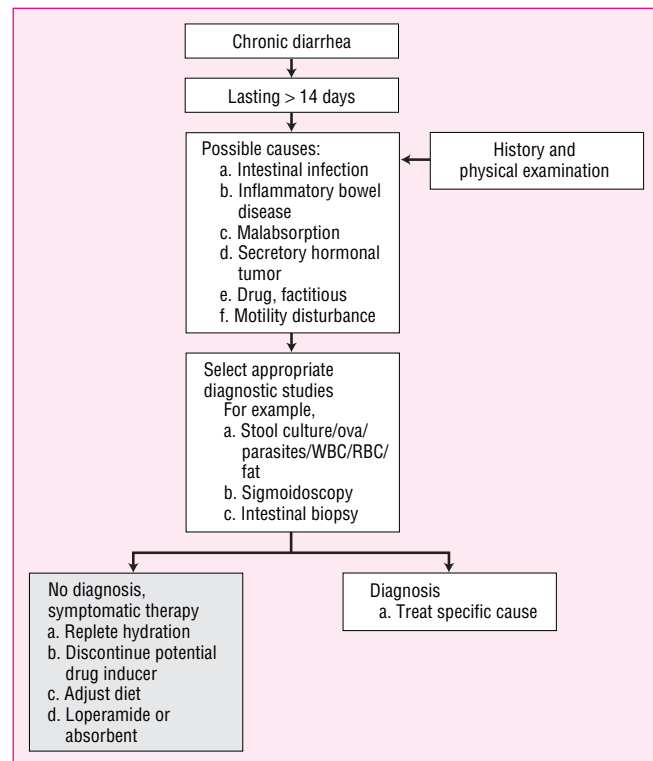

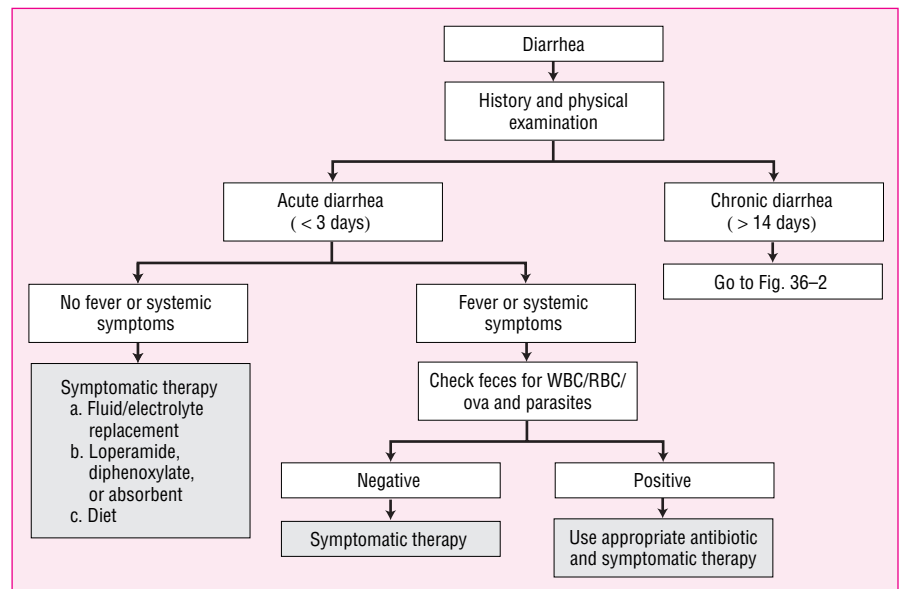

FIGURE 36-2. Recommendations for treating chronic diarrhea. Follow these steps: (1) Perform a careful history and physical examination. (2) The possible causes of chronic diarrhea are many. These can be classified into intestinal infections (bacterial or protozoal), inflammatory disease (Crohn's disease or ulcerative colitis), malabsorption (lactose intolerance), secretory hormonal tumor (intestinal carcinoid tumor or VIPoma), drug (antacid), factitious (laxative abuse), or motility disturbance (diabetes mellitus, irritable bowel syndrome, or hyperthyroidism). (3) If the diagnosis is uncertain, selected appropriate diagnostic studies should be ordered. (4) Once diagnosed, treatment is planned for the underlying cause with symptomatic anti-diarrheal therapy. (5) If no specific cause can be identified, symptomatic therapy is prescribed.

nausea and/or vomiting, a mild, digestible low-residue diet should be administered for 24 hours. If vomiting is present and uncontrollable with antiemetics (see Chap. 35 on nausea and vomiting), nothing is taken by mouth. As bowel movements decrease, a bland diet is begun.

Feeding should continue in children with acute bacterial diarrhea. Fed children have less morbidity and mortality, whether or not they receive oral rehydration fluids. Studies are not available in the elderly or in other high-risk groups to determine the value of continued feeding in bacterial diarrhea.

■ WATER AND ELECTROLYTES

Rehydration and maintenance of water and electrolytes are primary treatment goals until the diarrheal episode ends. If the patient is volume depleted, rehydration should be directed at replacing water and electrolytes to normal body composition. Then water and electrolyte composition are maintained by replacing losses. Many patients will not develop volume depletion and therefore will only require maintenance fluid and electrolyte therapy. Parenteral and enteral routes may be used for supplying water and electrolytes. If vomiting and dehydration are not severe, enteral feeding is the less costly and preferred method. In the United States, many commercial oral rehydration preparations are available (Table 36-3).

Because of concerns about hypernatremia, physicians continue to hospitalize and intravenously correct fluid and electrolyte deficits in severe dehydration. Oral solutions are strongly recommended.^{5,6} In developing countries, the World Health Organization Oral Rehydration Solution (WHO-ORS) saves the lives of millions of children annually.

During diarrhea, the small intestine retains its ability to actively transport monosaccharides such as glucose. Glucose actively carries sodium with water and other electrolytes. Because the WHO-ORS has a high sodium concentration, U.S. physicians have been reluctant to use it in well-nourished children. Yet controlled comparative studies describe more favorable results with the WHO-ORS than with parenteral fluids.⁷ Amino acids promote sodium transport and act as

^cRice syrup solids are carbohydrate source.

an antisecretory agent. Researchers have added glycine to ORS in an attempt to create a “super-ORS.” Reports, however, are disappointing, because glycine causes an osmotic diarrhea and diuresis in experimental concentrations.

Rice-based oral solution is a hypototically active substrate that elutes glucose without increasing stool or urine outflows. Pizarro and associates⁷ reported effective rehydration of infants with acute diarrhea using a rice-based solution. They also reported decreased stool output and greater absorption and retention of fluid and electrolytes. In summary, oral rehydration solution is a lifesaving treatment for millions afflicted in developing countries. Acceptance in developed countries is less enthusiastic; however, the advantage of this product in reducing hospitalizations may prove its use as a cost-effective alternative, saving millions of dollars in health care expenditures.

■ PHARMACOLOGIC THERAPY

Various drugs have been used to treat diarrheal attacks (Table 36–4). These drugs are grouped into several categories: antimitility, adsorbents, antisecretory compounds, antibiotics, enzymes, and intestinal microflora. Usually these drugs are not curative but palliative.

■ OPIATES AND THEIR DERIVATIVES

Opiates and opioid derivatives (a) delay the transit of intraluminal contents or (b) increase gut capacity, prolonging contact and absorption. Enkephalins, endogenous opioid substances, regulate fluid movement across the mucosa by stimulating absorptive processes. Limitations to the use of opiates include an addiction potential (a real concern with long-term use) and worsening of diarrhea in selected infectious diarrhea.

Most opiates act through peripheral and central mechanisms with the exception of loperamide, which acts only peripherally. Loperamide is antisecretory; it inhibits the calcium-binding protein calmodulin, controlling chloride secretion. Loperamide, available as 2-mg capsules or 1 mg/5 mL solution (both are nonprescription

products), is suggested for managing acute and chronic diarrhea. The usual adult dose is initially 4 mg orally, followed by 2 mg after each loose stool, up to 16 mg/day. Used correctly, this agent has rare side effects such as dizziness and constipation. If the diarrhea is concurrent with a high fever or bloody stool, the patient should be referred to a physician. Also, diarrhea lasting 48 hours beyond initiating loperamide warrants medical attention. Loperamide can also be used in traveler’s diarrhea. It is comparable to bismuth subsalicylate for treatment of this disorder.⁸

Diphenoxylate is available as 2.5-mg tablets and as a 2.5 mg/5 mL solution. A small amount of atropine (0.025 mg) is included to discourage abuse. In adults, when taken as 2.5 to 5 mg three or four times daily, not to exceed a 20-mg total daily dose, diphenoxylate is rarely toxic. Some patients may complain of atropinism (blurred vision, dry mouth, and urinary hesitancy). Like loperamide, it should not be used in patients at risk of bacterial enteritis with *Escherichia coli*, *Shigella*, or *Salmonella*.

Difenoxin, a diphenoxylate derivative, is also combined with atropine and has the same uses, precautions, and side effects. Marketed as 1-mg tablet, the adult dosage is 2 mg initially followed by 1 mg after each loose stool, not to exceed 8 mg/day.

Paregoric, tincture of opium, is marketed as a 2 mg/5 mL solution and is indicated for managing both acute and chronic diarrhea. It is not widely prescribed today because of its abuse potential.

■ ADSORBENTS

Adsorbents are used for symptomatic relief. These products, many not requiring a prescription, are nontoxic, but their effectiveness remains unproven. Adsorbents are nonspecific in their action; they adsorb nutrients, toxins, drugs, and digestive juices. Coadministration with other drugs reduces their bioavailability. The Food and Drug Administration over-the-counter review panel recommends only polycarbophil as an effective adsorbent.

Polycarbophil absorbs 60 times its weight in water and can be used to treat both diarrhea and constipation. It is a nonprescription product and is sold as 500-mg chewable tablets. This hydrophilic nonabsorbable product is safe and may be taken four times daily, up to 6 g/day in adults.

TABLE 36-4. Selected Antidiarrheal Preparations

| | Dose Form | Adult Dose |
|--|--|---|
| Antimotility | | |
| Diphenoxylate | 2.5 mg/tablet 2.5 mg/5 mL | 5 mg four times daily; do not exceed 20 mg/day |
| Loperamide | 2 mg/capsule | Initially 4 mg, then 2 mg after each loose stool; do not exceed 16 mg/day |
| Paregoric | 1 mg/5 mL 2 mg/5 mL (morphine) | 5–10 mL 1–4 times daily |
| Opium tincture | 5 mg/mL (morphine) | 0.6 mL four times daily |
| Difenoxin | 1 mg/tablet | Two tablets, then one tablet after each loose stool; up to 8 tablets/day |
| Adsorbents | | |
| Kaolin–pectin mixture | 5.7 g kaolin + 130.2 mg pectin/30 mL | 30–120 mL after each loose stool |
| Polycarbophil | 500 mg/tablet | Chew 2 tablets four times daily or after each loose stool; do not exceed 12 tablets/day |
| Attapulgate | 750 mg/15 mL 300 mg/7.5 mL 750 mg/tablet 600 mg/tablet 300 mg/tablet | 1200–1500 mg after each loose bowel movement or every 2 hours; up to 9000 mg/day |
| Antisecretory | | |
| Bismuth subsalicylate | 1050 mg/30 mL 262 mg/15 mL 524 mg/15 mL 262 mg/tablet | Two tablets or 30 mL every 30 min to 1 h as needed up to 8 doses/day |
| Enzymes (lactase) | 1250 neutral lactase units/4 drops 3300 FCC lactase units per tablet | 3–4 drops taken with milk or dairy product 1 or 2 tablets as above |
| Bacterial replacement (<i>Lactobacillus acidophilus</i> , <i>Lactobacillus bulgaricus</i>) | | 2 tablets or 1 granule packet 3 to 4 times daily; give with milk, juice, or water |
| Octreotide | 0.05 mg/mL 0.1 mg/mL 0.5 mg/mL | Initial: 50 mcg subcutaneously 1–2 times per day and titrate dose based on indication up to 600 mcg/day in 2–4 divided doses |

■ ANTISECRETORY AGENTS

Bismuth subsalicylate appears to have antisecretory, antiinflammatory, and antibacterial effects. As a nonprescription product, it is marketed for indigestion, relieving abdominal cramps, and controlling diarrhea, including traveler's diarrhea. Bismuth subsalicylate dosage strengths are 262-mg chewable tablets, 262 mg/5 mL liquid, and 524 mg/15 mL liquid. The usual adult dose is 2 tablets or 30 mL every 30 minutes to 1 hour up to 8 doses per day.

4 Bismuth subsalicylate contains multiple components that might be toxic if given excessively to prevent or treat diarrhea. For instance, an active ingredient is salicylate, which may interact with anticoagulants or may produce salicylism (tinnitus, nausea, and vomiting). Bismuth reduces tetracycline absorption and may interfere with select gastrointestinal radiographic studies. Patients may complain of a darkening of the tongue and stools with repeat administration. Salicylate can induce gout attacks in susceptible individuals.

Bismuth subsalicylate suspension has been evaluated in the treatment of secretory diarrhea of infectious etiology as well. In a dose of 30 mL every 30 minutes for eight doses, unformed stools decrease in the first 24 hours. Bismuth subsalicylate may also be effective in preventing traveler's diarrhea.

Octreotide, a synthetic octapeptide analog of endogenous somatostatin, is prescribed for the symptomatic treatment of carcinoid tumors and vasoactive intestinal peptide-secreting tumors (VIPomas).⁹ Metastatic intestinal carcinoid tumors secrete excessive

amounts of vasoactive substances, including histamine, bradykinin, serotonin, and prostaglandins. Primary carcinoid tumors occur throughout the gastrointestinal tract, with most in the ileum. Predominant signs and symptoms experienced by patients with these tumors are attributable to excessive concentrations of 5-hydroxytryptophan and serotonin. The totality of their clinical effects is termed the *carcinoid syndrome*. Paroxysmal vasomotor attacks characterize carcinoid syndrome, most notably sudden red to purple flushing of the face and neck. These attacks are often caused by emotional outbursts or by ingestion of food or alcohol. Some patients have a violent, watery diarrhea with abdominal cramping. Initially, diarrhea might be managed with various agents such as codeine, diphenoxylate, cyproheptadine, methysergide, phenoxybenzamine, or methyl dopa. Recently, octreotide has become the drug of choice.

Octreotide blocks the release of serotonin and many other active peptides and has been effective in controlling diarrhea and flushing. It is reported to have direct inhibitory effects on intestinal secretion and stimulatory effects on intestinal absorption. Non-gastrin-secreting adenomas of the pancreas are tumors associated with profuse watery diarrhea. This condition has been referred to as Verner-Morrison syndrome, WDHA (watery diarrhea, hypokalemia, and achlorhydria) syndrome, pancreatic cholera, watery diarrhea syndrome, and VIPoma. Excessive secretion of VIP from a retroperitoneal or pancreatic tumor produces most of the clinical features. Excessive VIP is isolated in about half of patients, along with numerous other peptide hormones (peptide histidine methionine [PHM], serotonin,

somatostatin, gastrin, and glucagon). Surgical tumor dissection is the treatment of choice. In nonsurgical candidates, the profuse watery diarrhea and other symptoms commonly encountered are managed with octreotide.

The dose of octreotide varies with the indication, disease severity, and patient response.⁹ For managing diarrhea and flushing associated with carcinoid tumors in adults, the initial dosage range is 100 to 600 mcg/day in two to four divided doses subcutaneously for 2 weeks. For controlling secretory diarrhea of VIPomas, the dosage range is 200 to 300 mcg/day in two to four divided doses for 2 weeks. Some patients may require higher doses for symptomatic control. Patients responding to these initial doses may be switched to Sandostatin LAR Depot, a long-acting octreotide formulation. This product consists of microspheres containing the drug. Initial doses consist of 20 mg given intramuscularly intragluteally at 4-week intervals for 2 months. It is recommended that during the first 2 weeks of therapy the short-acting formulation also be administered subcutaneously. At the end of 2 months, patients with good symptom control may have the dose reduced to 10 mg every 4 weeks, while those without sufficient symptom control may have the dose increased to 30 mg every 4 weeks. For patients experiencing recurrence of symptoms on the 10-mg dose, dosage adjustment to 20 mg should be made. It is not uncommon for patients with carcinoid tumors or VIPomas to experience periodic exacerbation of symptoms. Subcutaneous octreotide for several days should be reinstated in these individuals. In so-called carcinoid crisis, octreotide is given as an intravenous infusion at 50 mcg/h for 8 to 24 hours.

Because octreotide inhibits many other gastrointestinal hormones, it has a variety of intestinal side effects. With prolonged use, gallbladder and biliary tract complications such as cholelithiasis have been reported. About 5% to 10% of patients complain of nausea, diarrhea, and abdominal pain. Local injection pain occurs with about an 8% incidence. With high doses, octreotide may reduce dietary fat absorption, leading to steatorrhea.

Two other somatostatin analogs, lanreotide and vapreotide, have been studied.¹⁰ Lanreotide is indicated for patients with carcinoid tumors in a dose of 30 mg intramuscularly (as a depot) every 14 days. If necessary the dose can be increased to 30 mg intramuscular every 7 to 10 days. Vapreotide is an orphan drug that is indicated for pancreatic and gastrointestinal fistulas.

■ MISCELLANEOUS PRODUCTS

Lactobacillus preparations replace colonic microflora. This supposedly restores normal intestinal function and suppresses the growth of pathogenic microorganisms. However, a dairy product diet containing 200 to 400 g of lactose or dextrin is equally effective in producing recolonization of normal flora. The dosage varies depending on the brand used and lactobacillus preparations should be administered with milk, juice, water, or cereal. Intestinal flatus is the primary patient complaint experienced with this modality.

Anticholinergic drugs such as atropine block vagal tone and prolong gut transit time. Drugs with anticholinergic properties are present in many nonprescription products. Their value in controlling diarrhea is questionable and limited due to side effects. To stop diarrhea, clinicians have been falsely taught to dose anticholinergics until they decrease salivary and sweat secretion. Angle-closure glaucoma, selected heart diseases, and obstructive uropathies are relative contraindications to the use of anticholinergic agents.

Lactase enzyme products are helpful for patients experiencing diarrhea secondary to lactose intolerance. Lactase is required for

carbohydrate digestion. When a patient lacks this enzyme, eating dairy products causes an osmotic diarrhea. Several products are available for use each time a dairy product, especially milk or ice cream, is consumed.

CLINICAL CONTROVERSY

Long-term use of oral opiates is not routinely recommended for several pharmacologic reasons. Some opioids such as morphine and codeine have the tendency to cause constipation by slowing down the peristaltic action of the bowels, which can also result in a functional ileus. This effect can be minimized by administering laxatives and/or stool softeners in patients who require longer-term opiate therapy. Prokinetic agents may also be helpful in treating opiate-related constipation.

■ INVESTIGATIONAL DRUGS

Many experimental drugs have been used to control diarrhea. Phenothiazines, β -blockers, nonsteroidal anti-inflammatory drugs, calcium channel blockers, and α -adrenergic agonists are only a few agents under investigation in either animals or humans. Nifaladide is an enkephalin analog that delays the onset of castor oil–induced diarrhea and decreases stool frequency. Dizziness and dry mouth are frequent side effects. Enkephalinase inhibitors (e.g., acetorphan or racecadotril) are other therapeutic options that reduce hypersecretion of water and electrolytes into the intestinal lumen. Prostaglandin inhibitors, aspirin and its analogs, and indomethacin are safe and effective in childhood gastroenteritis; studies in animals support indomethacin use in enteropathogen secretory states such as *Vibrio cholerae* infection.

Vaccines are a new therapeutic frontier in controlling infectious diarrheas, especially in developing countries.^{11,12} Cholera vaccine, which is available in the United States in the parenteral form of whole-cell inactivated bacteria, yields some protection but is not totally effective and does not prevent transmission. However, live oral vaccine is thought to be protective against *V. cholerae*. Oral *Shigella* vaccine, although effective under field conditions, requires five doses and repeat booster doses, thereby limiting its practicality for use in developing nations. With about 1,500 serotypes for *Salmonella*, a vaccine is not currently available. There are three parenteral typhoid vaccine formulations available in the United States. In addition, an oral vaccine of *S. typhi* (Tyza) is now available and is administered in 4 doses on days 1, 3, 5, and 7, to be completed at least 1 week before exposure. Rotavirus vaccine is effective in infants and children, and is administered as a three–oral dose sequence.

■ EVALUATION OF THERAPEUTIC OUTCOMES

■ GENERAL OUTCOMES MEASURES

Therapeutic outcomes are directed toward key symptoms, signs, and laboratory studies. Constitutional symptoms usually improve within 24 to 72 hours. Monitoring for changes in the frequency and character of bowel movements on a daily basis in conjunction with vital signs and improvement in appetite are of utmost importance. Also, the clinician needs to monitor body weight, serum osmolality, serum electrolytes, complete blood cell counts, urinalysis, and culture results (if appropriate).

ACUTE DIARRHEA

Most patients with acute diarrhea experience mild to moderate distress. In the absence of moderate to severe dehydration, high fever, and blood or mucus in the stool, this illness is usually self-limiting within 3 to 7 days. Mild to moderate acute diarrhea is usually managed on an outpatient basis with oral rehydration, symptomatic treatment, and diet. Elderly persons with chronic illness and infants may require hospitalization for parenteral rehydration and close monitoring.

SEVERE DIARRHEA

In the urgent/emergent situation, restoration of the patient's volume status is the most important outcome. Toxic patients (fever, dehydration, hematochezia, or hypotension) require hospitalization, intravenous fluids and electrolyte administration, and empiric antibiotic therapy while awaiting culture and sensitivity results. With timely management, these patients usually recover within a few days.

CONSTIPATION

Constipation is a commonly encountered medical condition in the United States for which many patients initiate self-treatment. One reason constipation continues to be a frequent problem in this country is lack of adequate dietary fiber. Another unfortunate problem is that many people have misconceptions about normal bowel function, and think that daily bowel movements are required for health and well being. Others believe that the lack of a daily bowel movement contributes to the accumulation of toxic substances or is associated with various somatic complaints. These misconceptions often lead to the inappropriate use of laxatives by the general public.

Constipation does not have a single, generally agreed upon definition. When using the term, the lay public or health care professional may be referring to several difficult-to-quantify variables: bowel movement frequency, stool size or consistency, and such symptoms as the sensation of incomplete defecation. Stool frequency is most often used to describe constipation; however, the frequency of bowel movements used to define constipation is not well established.

Normal people pass at least three stools per week. Some of the definitions of constipation used in clinical studies include (a) less than three stools per week for women and five stools per week for men despite a high-residue diet, or a period of more than 3 days without a bowel movement; (b) straining at stool greater than 25% of the time and/or two or fewer stools per week; or (c) straining at defecation and less than one stool daily with minimal effort. These varying definitions demonstrate the difficulty in characterizing this problem.

An international committee defined and classified constipation on the basis of stool frequency, consistency, and difficulty of defecation.^{13,14} Functional constipation is defined as two or more of the following complaints present for at least 12 months in the absence of laxative use: (a) straining at least 25% of the time; (b) lumpy or hard stools at least 25% of the time; (c) a feeling of incomplete evacuation at least 25% of the time; or (d) two or fewer bowel movements in a week. Rectal outlet delay is defined as anal blockage more than 25% of the time and prolonged defecation or manual disimpaction when necessary.

EPIDEMIOLOGY

As many as 40% of patients older than 65 years of age report experiencing constipation.¹⁵ The results from 42,375 participants of the National Health Interview Survey on Digestive Disorders demonstrated that there is not an age-related increased incidence of infrequent bowel movements; however, there is an age-related increased incidence of laxative use.¹⁶ The frequency of subjects reporting two or fewer bowel movements per week was 5.9% for those younger than 40 years of age; 3.8% for subjects 60 to 69 years of age; and 6.3% for subjects older than 80 years of age. In a prospective study of 3166 people

older than 65 years of age in a Florida community,¹⁷ 26% of women and 15.8% of men reported recurrent constipation. Factors found to correlate with self-reported constipation were age, sex (higher frequency in females), total number of drugs taken, abdominal pain, and hemorrhoids.

PATHOPHYSIOLOGY

Constipation is not a disease, but a symptom of an underlying disease or problem. Approaches to the treatment of constipation should begin with attempts to determine its cause. Disorders of the GI tract (irritable bowel syndrome or diverticulitis), metabolic disorders (diabetes), or endocrine disorders (hypothyroidism) may be involved. Constipation commonly results from a diet low in fiber or from use of constipating drugs such as opiates. Finally, it is believed that constipation may sometimes be psychogenic in origin.¹⁸ Each of these causes is discussed in the following sections.

Constipation is a frequently reported problem in the elderly, probably the result of improper diets (low in fiber and liquids), diminished abdominal wall muscular strength, and possibly diminished physical activity. However, as previously stated, the frequency of bowel movements is not decreased with normal aging. In addition, diseases that may cause constipation, such as colon cancer and diverticulitis, are more common with increasing age. Table 36-5 lists common causes of constipation in specific disease states.

DRUG-INDUCED CONSTIPATION

Use of drugs that inhibit the neurologic or muscular function of the GI tract, particularly the colon, may result in constipation (Table 36-6). The majority of cases of drug-induced constipation are caused by opiates, various agents with anticholinergic properties, and antacids containing aluminum or calcium. With most of the agents listed in Table 36-6, the inhibitory effects on bowel function are dose dependent, with larger doses clearly causing constipation more frequently.

Opiates have effects on all segments of the bowel, but effects are most pronounced on the colon. The major mechanism by which opiates produce constipation has been proposed to be prolongation of intestinal transit time by causing spastic, nonpropulsive contractions. An additional contributory mechanism may be an increase in electrolyte absorption.

All opiate derivatives are associated with constipation, but the degree of intestinal inhibitory effects seems to differ between agents. Orally administered opiates appear to have greater inhibitory effects than parenterally administered products. Orally administered enkephalins (endogenous opiate-like polypeptides) are recognized to have antimotility properties.

TABLE 36–5. Possible Causes of Constipation

| Conditions | Possible Causes |
|-----------------------------------|---|
| GI disorders | Irritable bowel syndrome Diverticulitis Upper GI tract diseases Anal and rectal diseases Hemorrhoids Anal fissures Ulcerative proctitis Tumors Hernia Volvulus of the bowel Syphilis Tuberculosis Helminthic infections Lymphogranuloma venereum Hirschsprung's disease |
| Metabolic and endocrine disorders | Diabetes mellitus with neuropathy Hypothyroidism Panhypopituitarism Pheochromocytoma Hypercalcemia Enteric glucagon excess |
| Pregnancy | Depressed gut motility Increased fluid absorption from colon Decreased physical activity Dietary changes Inadequate fluid intake Low dietary fiber Use of iron salts |
| Neurogenic causes | CNS diseases Trauma to the brain (particularly the medulla) Spinal cord injury CNS tumors Cerebrovascular accidents Parkinson's disease |
| Psychogenic causes | Ignoring or postponing urge to defecate Psychiatric diseases |
| Drug-induced | See Table 36–6 |

Agents with anticholinergic properties inhibit bowel function by parasympatholytic actions on innervation to many regions of the GI tract, particularly the colon and rectum. Many types of drugs possess anticholinergic action, and these agents are used commonly in both hospitalized and nonhospitalized patients. One study demonstrated that amitriptyline, diphenhydramine, and thioridazine use were associated with laxative needs in 800 nursing home patients.¹⁵

In patients older than 65 years of age, drugs that correlate most often with constipation are anticholinergics, aspirin, furosemide, ni-

TABLE 36–7. Clinical Presentation of Constipation**Signs and symptoms**

- It is important to ascertain whether the patient perceives the problem as infrequent bowel movements, stools of insufficient size, a feeling of fullness, or difficulty and pain on passing stool.
- Signs and symptoms include hard, small or dry stools, bloated stomach, cramping abdominal pain and discomfort, straining or grunting, sensation of blockade, fatigue, headache, and nausea and vomiting.

Laboratory tests

- A series of examinations, including proctoscopy, sigmoidoscopy, colonoscopy, or barium enema, may be necessary to determine the presence of colorectal pathology.
- Thyroid function studies may be performed to determine the presence of metabolic or endocrine disorders.
- With laxative abuse, fluid and electrolyte imbalances (most commonly hypokalemia), protein-losing gastroenteropathy with hypoalbuminemia may be present.

troglycerin, and amitriptyline.²² Serum chloride and aspartate aminotransferase, as well as alcohol consumption, are negatively related to constipation.

CLINICAL PRESENTATION

Table 36–7 shows the general clinical presentation of constipation.

▶ TREATMENT: Constipation**■ GENERAL APPROACH TO TREATMENT**

The patient should be asked about the frequency of bowel movements and the chronicity of constipation. Constipation occurring recently in an adult may indicate significant colon pathology such as malignancy; constipation present since early infancy may be indicative of neurologic disorders. The patient also should be carefully questioned about

usual diet and laxative regimens. Does the patient have a diet consistently deficient in high-fiber items and containing mainly highly refined foods? What laxatives or cathartics has the patient used to attempt relief of constipation? The patient should be questioned about other concurrent medications, with interest focused on agents that might cause constipation.

For most patients complaining of constipation, a thorough physical examination is not required after it is established that constipation

(a) is not a chronic problem, (b) is not accompanied by signs of significant GI disease (e.g., rectal bleeding or anemia), and (c) does not cause severe discomfort. In these circumstances, the patient may be referred directly to the first-line therapies for constipation described in the next section (mainly bulk-forming laxatives and dietary fiber with occasional use of saline or stimulant laxatives). Table 36–8 presents a general treatment algorithm for the management of constipation.

6 The proper management of constipation requires a number of different modalities; however, the basis for therapy should be dietary modification. The major dietary change should be an increase in the amount of fiber consumed daily. In addition to dietary management, patients should be encouraged to alter other aspects of their lifestyles if necessary. Important considerations are to encourage patients to exercise (achieved even by brisk walking after dinner) and to adjust bowel habits so that a regular and adequate time is made to respond to the urge to defecate. Another general measure is to increase fluid intake. This is generally recommended and believed beneficial, although there is little objective evidence to support this measure.

If an underlying disease is recognized as the cause of constipation, attempts should be made to correct it. GI malignancies may be removed via surgical resection. Endocrine and metabolic derangements should be corrected by the appropriate methods. For example, when hypothyroidism is the cause of constipation, cautious institution of thyroid-replacement therapy is the most important treatment measure.

As discussed earlier, many drug substances may cause constipation. If a patient is consuming medications well known to cause constipation, consideration should be given to alternative agents. For

some medications (e.g., antacids), nonconstipating alternatives exist. If no reasonable alternatives exist to the medication thought to be responsible for constipation, consideration should be given to lowering the dose. If a patient must remain on constipating medications, then more attention must be given to general measures for prevention of constipation, as discussed in the next section.

■ NONPHARMACOLOGIC THERAPY

■ DIETARY MODIFICATION AND BULK-FORMING AGENTS

The most important aspect of therapy for constipation for the majority of patients is dietary modification to increase the amount of fiber consumed. Fiber, the portion of vegetable matter not digested in the human GI tract, increases stool bulk, retention of stool water, and rate of transit of stool through the intestine. The result of fiber therapy is an increased frequency of defecation. Also, fiber decreases intraluminal pressures in the colon and rectum, which is thought to be beneficial for diverticular disease and for irritable bowel syndrome. The specific physiologic effects of fiber are not well understood. Patients should be advised to include at least 10 g of crude fiber in their daily diets.¹⁹ Fruits, vegetables, and cereals have the highest fiber content. Bran, a by-product of milling of wheat, is often added to foods to increase fiber content. Raw bran is generally 40% fiber. Medicinal products, often called “bulk-forming agents,” such as psyllium hydrophilic colloids, methylcellulose, or polycarbophil, have properties similar to those of dietary fiber and may be taken as tablets, powders, or granules (Table 36–9). A trial of dietary modification with high-fiber content should be continued for at least 1 month before effects on bowel function are determined. Most patients begin to notice effects on bowel

TABLE 36–9. Dosage Recommendations for Laxatives and Cathartics

| Agent | Recommended Dose |
|--|------------------------------|
| Agents that cause softening of feces in 1–3 days | |
| Bulk-forming agents | |
| Methylcellulose | 4–6 g/day |
| Polycarbophil | 4–6 g/day |
| Psyllium | Varies with product |
| Emollients | |
| Docusate sodium | 50–360 mg/day |
| Docusate calcium | 50–360 mg/day |
| Docusate potassium | 100–300 mg/day |
| Lactulose | 15–30 mL orally |
| Sorbitol | 30–50 g/day orally |
| Mineral oil | 15–30 mL orally |
| Agents that result in soft or semifluid stool in 6–12 h | |
| Bisacodyl (oral) | 5–15 mg orally |
| Phenolphthalein | 30–270 mg orally |
| Cascara sagrada | Dose varies with formulation |
| Senna | Dose varies with formulation |
| Magnesium sulfate (low dose) | <10 g orally |
| Agents that cause watery evacuation in 1–6 h | |
| Magnesium citrate | 18 g 300 mL water |
| Magnesium hydroxide | 2.4–4.8 g orally |
| Magnesium sulfate (high dose) | 10–30 g orally |
| Sodium phosphates | Varies with salt used |
| Bisacodyl | 10 mg rectally |
| Polyethylene glycol-electrolyte preparations | 4 L |

function 3 to 5 days after beginning a high-fiber diet, but some patients may require a considerably longer period of time. Patients should be cautioned that abdominal distention and flatus may be particularly troublesome in the first few weeks of fiber therapy, particularly with high bran consumption. In most cases these problems resolve with continued use.

Bulk-forming laxatives have few adverse effects. The only major caution in the use of bulk-forming laxatives is that obstruction of the esophagus, stomach, small intestine, and colon has been reported when the agents have been consumed without sufficient fluid or in patients with intestinal stenosis.

■ SURGERY

In a small percentage of patients presenting with complaints of constipation, surgical procedures are necessary due to the presence of colonic malignancies or GI obstruction from a number of other causes. In each case, the involved segment of intestine may be resected or revised. Surgery may be required in some endocrine disorders causing constipation, such as pheochromocytoma, which requires removal of a tumor.

■ BIOFEEDBACK

The majority of patients with constipation related to pelvic floor dysfunction can benefit from electromyogram-guided biofeedback therapy.¹⁹ The value of biofeedback in children with chronic constipation has not been well demonstrated.²⁰

■ PHARMACOLOGIC THERAPY

■ DRUG REGIMENS OF CHOICE

Treatment and prevention of constipation should consist of bulk-forming agents in addition to dietary modifications that increase dietary fiber.²³ A variety of products are available that provide adequate bulk. Whichever agent is chosen, it should be used daily and continued indefinitely in most patients, particularly those with chronic constipation. Bulk-forming agents available in combination with diphenylmethane or anthraquinone derivatives should not be used on a routine basis.

For most persons with acute constipation, infrequent use (less than every few weeks) of laxative products is acceptable. Acute constipation may be relieved by the use of a tap-water enema or a glycerin suppository; if neither is effective, the use of oral sorbitol, low doses of diphenylmethane or anthraquinone laxatives, or saline laxatives (e.g., milk of magnesia) may provide relief. If laxative treatment is required for longer than 1 week, the person should be advised to consult a physician to determine if there is an underlying cause of constipation that requires treatment with other modalities.

For some bedridden or geriatric patients, or others with chronic constipation, bulk-forming laxatives remain the first line of treatment, but the use of more potent laxatives may be required relatively frequently. Fiber should be avoided in bedridden patients who are cognitively impaired.¹⁹ When other than bulk-forming laxatives are used, they should be administered in the lowest effective dose and as infrequently as possible to maintain regular bowel function (more than three stools per week). Agents that may be used in these situations include diphenylmethane and anthraquinone derivatives, milk of magnesia, and sorbitol or lactulose. Mineral oil should be avoided,

particularly in bedridden patients, because of the risk of aspiration and lipoid pneumonia. Some patients with chronic constipation may present with fecal impactions. Before vigorous oral laxatives can be used, the impaction needs to be removed using mechanical methods, including tap water or saline enemas and digital extraction.

In the hospitalized patient without GI disease, constipation may be related to the use of general anesthesia and/or opiate substances. Most orally or rectally administered laxatives may be used in these situations. For prompt initiation of bowel evacuation, either a tap-water enema, glycerin suppository, or oral milk of magnesia are recommended.

With infants and children, constipation may occur commonly. In patients with persistent problems, the underlying etiology may be neurologic, metabolic, or secondary to anatomic abnormalities. Management of constipation in this age group should consist of dietary modification with an emphasis on high-fiber foods.

For acute constipation in most age groups, a tap-water enema or glycerin suppository may be helpful. Occasional use of milk of magnesia or an anthraquinone laxative in low doses is justified as well.

■ DRUG CLASSES

The traditional classification system for laxatives and cathartics by suspected mode of action is not very useful, as this is not clearly understood for many agents. In general, most of these products induce bowel evacuation by one or more of the mechanisms associated with the etiology of diarrhea, including active electrolyte secretion, decreased water and electrolyte absorption, increased intraluminal osmolarity, and increased hydrostatic pressure in the gut. Laxatives convert the intestine from primarily an organ that absorbs water and electrolytes to an organ that secretes these substances.

The various classes of laxatives are discussed in this section. These agents are divided into three general classifications: (a) those causing softening of feces in 1 to 3 days (bulk-forming laxatives, docusates, and lactulose); (b) those that result in soft or semifluid stool in 6 to 12 hours (diphenylmethane derivatives and anthraquinone derivatives); and (c) those causing water evacuation in 1 to 6 hours (saline cathartics, castor oil, and polyethylene glycol-electrolyte lavage solution).

■ EMOLLIENT LAXATIVES

Emollient laxatives are surfactant agents, docusate in its various salts, which work by facilitating mixing of aqueous and fatty materials within the intestinal tract. They may increase water and electrolyte secretion in the small and large bowel. These products are generally given orally, although docusate potassium has also been used rectally. These products result in a softening of stools within 1 to 3 days of therapy.

Emollient laxatives are ineffective in treating constipation, but are used mainly to prevent this condition. They may be helpful in situations in which straining at stool should be avoided, such as after recovery from myocardial infarction, with acute perianal disease, or after rectal surgery. It is unlikely that these agents would be very effective in preventing constipation if major causative factors (e.g., heavy opiate use, uncorrected pathology, or inadequate dietary fiber) are not concurrently addressed.

Although docusates are generally safe, a few adverse effects have been noted. They may increase the intestinal absorption of agents administered concurrently and alter toxic potential.

■ LUBRICANTS

Mineral oil is the only lubricant laxative in routine use. This agent, obtained from petroleum refining, acts by coating stool and allowing for easier passage. It inhibits colonic absorption of water, thereby increasing stool weight and decreasing stool transit time. Mineral oil may be given orally or rectally in a dose of 15 to 45 mL. Generally, the effect on bowel function is noted after 2 or 3 days of use.

Mineral oil is helpful in situations similar to those suggested for docusates: to maintain a soft stool and to avoid straining for relatively short periods of time (a few days to 2 weeks); however, it possesses a much greater potential for adverse effects and its routine use should be discouraged. Mineral oil may be absorbed systemically and can cause a foreign-body reaction in lymphoid tissue. Also, in debilitated or recumbent patients, mineral oil may be aspirated, causing lipoid pneumonia.²¹ Mineral oil may decrease the absorption of fat-soluble vitamins (A, D, E, and K) with chronic use by causing retention in the GI tract. Finally, even when given orally, mineral oil may leak from the anal sphincter, causing pruritus and soiling of clothing.

■ LACTULOSE AND SORBITOL

Lactulose is a disaccharide that is used orally or rectally. It is metabolized by colonic bacteria to low-molecular-weight acids, resulting in an osmotic effect whereby fluid is retained in the colon.²² The fluid retained in the colon lowers the pH and increases colonic peristalsis. Lactulose is generally not recommended as a first-line agent for the treatment of constipation because it is costly and not necessarily more effective than such agents as sorbitol or milk of magnesia. It may be justified as an alternative for acute constipation, and has been particularly useful in elderly patients. Occasionally, the use of lactulose may result in flatulence, cramps, diarrhea, and electrolyte imbalances.²⁷ Sorbitol, a monosaccharide, exerts its effect by osmotic action and has been recommended as a primary agent in the treatment of functional constipation in cognitively intact patients.¹⁹ It is as effective as lactulose and much less expensive.

■ DIPHENYLMETHANE DERIVATIVES

The two commonly used diphenylmethane derivatives are bisacodyl and phenolphthalein. Bisacodyl exerts its therapeutic effect by stimulating the mucosal nerve plexus of the colon. Phenolphthalein is thought to inhibit active glucose and sodium absorption, resulting in fluid accumulation in the colon by osmotic action. With both of these agents, significant interpatient variability exists with dosing. A dose that causes no effect in one patient may result in excessive cramping and fluid evacuation in others. With phenolphthalein, a small portion of the dose undergoes enterohepatic recirculation, which may result in a prolonged laxative action.

These agents are not recommended for regular daily use. Their use is acceptable intermittently (every few weeks) to treat constipation or as a bowel preparation before diagnostic procedures in which cleansing of the colon is necessary. These agents may sometimes cause severe abdominal cramping as well as significant fluid and electrolyte imbalances with chronic use. They should not be used for patients in whom appendicitis is a possibility (perforation of the appendix may result) or during pregnancy or lactation. Finally, patients using phenolphthalein-containing laxatives should be cautioned that their urine might turn pink.

■ ANTHRAQUINONE DERIVATIVES

Anthraquinone derivatives include cascara sagrada, sennosides, and casanthrol. Gut bacteria metabolizes these agents to their active compounds, but the exact mechanisms of action are not understood. Effects are limited to the colon, and stimulation of Auerbach's plexus may be involved. Recommendations for the use of these agents are similar to those for the diphenylmethane derivatives. In most cases, intermittent use is acceptable; daily use should be strongly discouraged.

Most of the concerns with the use of diphenylmethane derivatives apply to the anthraquinone derivatives. In addition, the anthraquinone derivatives may cause melanosis coli, an accumulation of dark pigment, mainly in the cecum and rectum, that is evident after 4 to 13 months of use. A pathologic effect of melanosis coli has not been demonstrated, and it appears to be reversible after anthraquinones have been discontinued for 3 to 6 months.

■ SALINE CATHARTICS

Saline cathartics are composed of relatively poorly absorbed ions such as magnesium, sulfate, phosphate, and citrate, which produce their effects primarily by osmotic action in retaining fluid in the GI tract. Magnesium stimulates the secretion of cholecystokinin, a hormone that causes stimulation of bowel motility and fluid secretion. These agents may be given orally or rectally. A bowel movement may result within a few hours after oral doses and in 1 hour or less after rectal administration.

These agents should be used primarily for acute evacuation of the bowel, which may be necessary before diagnostic examinations, after poisonings, and in conjunction with some anthelmintics to eliminate parasites. Such agents as milk of magnesia (an 8% suspension of magnesium hydroxide) may be used occasionally (every few weeks) to treat constipation in otherwise healthy adults. Saline cathartics should not be used on a routine basis. The enema formulations of these agents may be useful in fecal impactions.

As with most laxatives, these agents may cause fluid and electrolyte depletion. Also, magnesium or sodium accumulation may occur when magnesium-containing cathartics are used in patients with renal dysfunction or when sodium phosphate is used in patients with congestive heart failure.

■ CASTOR OIL

Castor oil is metabolized in the GI tract to an active compound, ricinoleic acid, which stimulates secretory processes, decreases glucose absorption, and promotes intestinal motility, primarily in the small intestine. Castor oil usually results in a bowel movement within 1 to 3 hours of administration. Because the agent has such a strong purgative action, it should not be used for the routine treatment of constipation.

■ GLYCERIN

Glycerin is usually administered as a 3-g suppository and exerts its effect by osmotic action in the rectum. As with most agents given as suppositories, the onset of action is usually less than 30 minutes. Glycerin is considered a very safe laxative, although it may occasionally cause rectal irritation. Its use is acceptable on an intermittent basis for constipation, particularly in children.

■ POLYETHYLENE GLYCOL-ELECTROLYTE LAVAGE SOLUTION

Whole-bowel irrigation with polyethylene glycol-electrolyte lavage solution (PEG-ELS) has become popular for colon cleansing before diagnostic procedures or colorectal operations.

Four liters of this solution is administered over 3 hours to obtain complete evacuation of the GI tract. The solution is not recommended for the routine treatment of constipation and its use should be avoided in patients with intestinal obstruction.

■ OTHER AGENTS

Tap-water enemas may be used to treat simple constipation. The administration of 200 mL of tap water by enema to an adult often results

in a bowel movement within 30 minutes. Soap-suds enemas are no longer recommended as their use may result in proctitis or colitis.

■ PREVENTION

For certain groups of patients, such as those recovering from myocardial infarction or rectal surgery, straining at defecation is to be avoided. The basis of preventive therapy in these patients should be bulk-forming laxatives. Additionally, the use of docusate is popular, although its effectiveness is debated. In pregnant patients, constipation may result because of alterations in anatomy or iron supplementation. As described earlier, bulk-forming laxatives and docusates should be the first line of prevention.

LAXATIVE ABUSE SYNDROME

Misconceptions about normal bowel patterns and the effect of laxatives have contributed to a syndrome of laxative abuse that is relatively common in the United States. The availability of laxatives as chocolates or gums conveys to the public that the use of these agents is without adverse consequences. Abuse of laxatives has occurred traditionally in persons trying to maintain daily bowel function, but more recently has extended to others who use laxatives for the purpose of controlling weight. In either case, the consistent abuse of strong laxatives and cathartics may lead to serious illness.

Laxative abuse for the purpose of maintaining daily bowel function begins with misconceptions about the frequency, quantity, or consistency of stools. With the use of strong purgatives, the colon may be so thoroughly cleansed that a bowel movement may not occur normally until a few days later. This delay reinforces the need for more purgatives and the cycle of laxative dependence is begun. Eventually the patient may require daily laxatives to maintain bowel function.

The laxative abuser may present with contradictory findings of diarrhea and weight loss. In addition, long-term abusers of laxatives tend to have vomiting, abdominal pain, lassitude, weakness, thirst, edema, and bone pain (caused by osteomalacia). With prolonged use of laxatives a number of serious illnesses may arise. These include fluid and electrolyte imbalances (including acid-base imbalances and hypokalemia), protein-losing gastroenteropathy with hypoalbuminemia, and syndromes resembling colitis.

The determination of laxative abuse syndrome can be difficult because many laxative abusers vigorously deny laxative use. Middle-aged women tend to be the most common laxative abusers. The chronic laxative abuse problem should be addressed by a combination of measures, including psychiatric evaluation, dietary modification with reliance on bulk-forming laxatives, and specific guidelines to the patient for the withdrawal of stimulant laxatives.

A variation of laxative abuse is seen in persons who use them as a means of weight loss. It appears from the medical literature and daily news sources that this type of abuse is on the increase. Treatment of patients who abuse laxatives in this way has proven very difficult.

EVALUATION OF THERAPEUTIC OUTCOMES

The ultimate goal of treatment for constipation is alteration of lifestyle (particularly diet) to prevent further episodes of constipation. Short-

term goals include alleviation of acute constipation with relief from symptoms. For patients with chronic constipation, the goals are more long-term and include use of proper diet and decreased reliance on laxatives. Effective treatment of constipation requires the patient to become more knowledgeable about the causes of constipation, proper diet, and appropriate use of laxatives.

IRRITABLE BOWEL SYNDROME

Irritable bowel syndrome (IBS) is one of the most common gastrointestinal disorders encountered in clinical practice, affecting as many as 20% of adults, and is more common in women. This latter point is probably a consequence of women being more likely than men to report their symptoms to the medical community. Although a benign disorder, IBS is chronic and recurring in nature.

PATHOPHYSIOLOGY

Although the exact pathophysiologic abnormalities with IBS are still being actively investigated, it is currently thought that IBS results from altered somatovisceral and motor dysfunction of the intestine from a variety of causes. Abnormal central nervous system processing of afferent signals may lead to visceral hypersensitivity, with the specific nerve pathway affected determining the exact symptomatology expressed. This visceral hypersensitivity is a neuroenteric phenomenon that is independent of motility and psychological disturbances.²³ Factors known to contribute to these alterations include genetics, motility factors, inflammation, colonic infections, mechanical irritation to local nerves, and psychological factors.

SEROTONIN-TYPE RECEPTORS

The enteric nervous system contains a significant percentage of the body's 5-hydroxytryptamine (serotonin, 5-HT).²⁴ Two types of serotonin exist within the gut: serotonin type 3 (HT₃) and serotonin type 4 (HT₄), which are responsible for secretion, sensitization, and motility.²⁵ Previous studies show that there is an increase in the postprandial levels of 5-HT in those who suffer from diarrhea-predominant IBS when compared with nonsufferers.²⁴ Therefore stimulation and antagonism of these serotonin receptors has become a focused area for research on new drug therapies for both diarrhea- and constipation-predominant disease.

TABLE 36–10. Clinical Presentation of IBS**Signs and symptoms**

- Lower abdominal pain
- Abdominal bloating and distention
- Diarrhea symptoms, >3 stools/day
- Extreme urgency
- Mucus passage
- Constipation symptoms, <3 stools/wk, straining, incomplete evacuation
- Psychological symptoms such as depression and anxiety

Nongastrointestinal symptoms

- Urinary symptoms
- Fatigue
- Dyspareunia

Other concurrent conditions

- Fibromyalgia
- Functional dyspepsia
- Chronic fatigue syndrome

Reduced health-related quality of life**CLINICAL PRESENTATION**

▶ Irritable bowel syndrome presents as either diarrhea-predominant or constipation-predominant disease and can be defined as lower abdominal pain, disturbed defecation (constipation, diarrhea, or an alternating pattern of both), and bloating in the absence of structural or biochemical factors that might explain these symptoms (Table 36–10).

In the past, diagnosis of IBS was based upon identification of the primary complaints of the patient and excluding other medical condi-

TABLE 36–11. Symptom-Based Criteria for IBS**The Manning Criteria²³**

Chronic or recurrent abdominal pain for at least 6 months and two or more of the following:

1. Abdominal pain relieved with defecation
2. Abdominal pain associated with more frequent stools
3. Abdominal pain associated with looser stools
4. Abdominal distention
5. Feeling of incomplete evacuation after defecation
6. Mucus in stools

Rome II diagnostic criteria for IBS²⁶

At least 12 weeks, which need not be consecutive, in the preceding 12 months, of abdominal discomfort or pain that has two of three features:

1. Relieved with defecation; and/or
2. Onset associated with a change in frequency of stool; and/or
3. Onset associated with a change in form (appearance) of stool

tions having a similar clinical presentation. Currently, the diagnosis of IBS is based upon the use of either the symptom-based Manning²³ or Rome II²⁶ criteria outlined in Table 36–11.

Additional diagnostic steps that can be taken include sigmoidoscopy or colonoscopy; examination of the stool for occult blood and ova and parasites; complete blood cell count; erythrocyte sedimentation rate; and serum electrolytes. In some cases, radiographic imaging studies, such as computed tomography scans or barium swallows or enemas, may also be necessary if the findings of the above assessment are not typical for IBS.²⁸

▶ TREATMENT: Irritable Bowel Syndrome**■ GENERAL APPROACH TO TREATMENT**

The treatment approach to IBS is based upon the predominant symptoms and their severity (Fig. 36–3). Milder, less frequent episodes can be managed with dietary restrictions and a higher-fiber diet with addition of bulk-forming laxatives if necessary. More persistent disease may require prn use of various antispasmodic or antidiarrheal agents such as loperamide. Lastly, the severest forms of this disease may call for pharmacologic agents directed specifically at the underlying neurohormonal imbalance, such as the 5-HT₄ agonists such as tegaserod or the 5-HT₃ receptor antagonists such as alosetron.

CLINICAL CONTROVERSY

The newer serotonin receptor agonists and antagonists tegaserod and alosetron act on GI-specific serotonin receptors to treat constipation-predominant and diarrhea-predominant IBS, respectively. However, both drugs are currently only indicated for women. Efficacy and safety in men has not been established because the initial manufacturer's sponsored clinical trials contained insufficient numbers of men with IBS to provide the necessary statistical power to prove efficacy and safety. Ongoing studies should determine if these drugs are indicated in men.

Alosetron was withdrawn from the U.S. market in 2000 due to serious adverse effects including severe constipation and ischemic colitis that did not appear in the initial clinical trials. Its use is now limited to an FDA-approved restricted use program in lower initial doses, and requires extensive post-marketing surveillance. Results of these trials are necessary to definitively determine alosetron's true safety profile, especially with regard to its association with or causation of fatal ischemic colitis.

■ CONSTIPATION-PREDOMINANT DISEASE

In the constipation-predominant patient, dietary fiber may be beneficial. Patients should be instructed to begin with 1 tablespoonful of fiber with 1 meal daily and gradually increase the dose to include fiber with 2 and 3 meals a day until the desired outcome is achieved. Endpoints that the patient should aim for include bulkier and more easily passed stools. For patients unable to tolerate dietary bran, bulk-forming agents such as psyllium may be substituted.²⁷ Laxative use is not encouraged in these patients, and it should only be used in the smallest dose for the least amount of time in cases of severe constipation.

The 5-HT₄ agonist tegaserod is the first therapy approved by the FDA specifically for the treatment of constipation-predominant

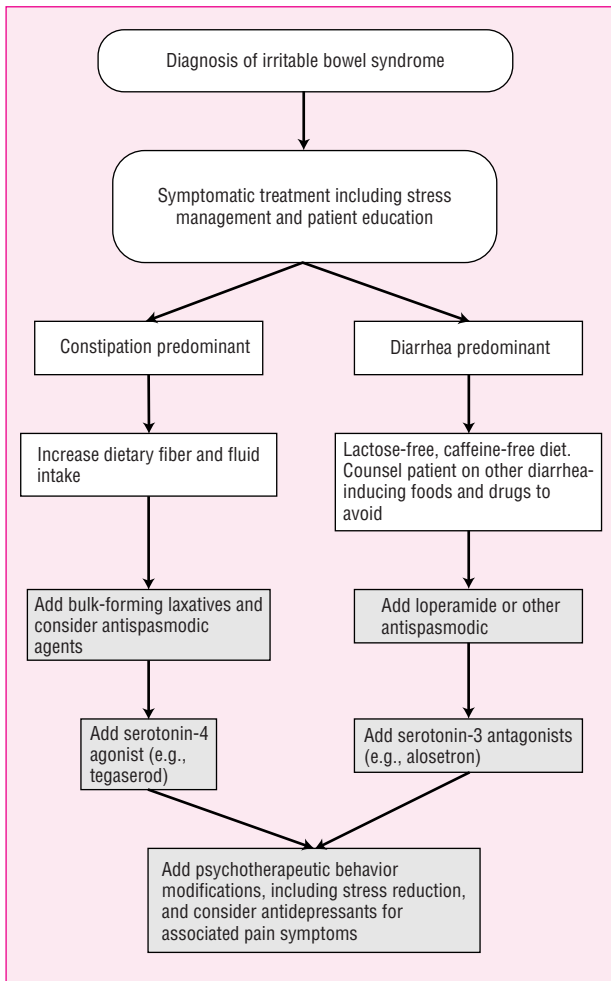

FIGURE 36-3. A general stepwise approach to the management of both constipation- and diarrhea-predominant irritable bowel syndrome.

IBS.²⁸ Tegaserod is a serotonin derivative that activates 5-HT₄ receptors on the neurons in the gastrointestinal tract, increasing GI motility and decreasing visceral sensations. It is approved as 2-mg or 6-mg doses given twice daily 30 minutes prior to a meal with water for up to 12 weeks.²⁹ Stimulation of the 5-HT₄ receptors by tegaserod increases gastric secretions and promotes motility, with improvement in symptoms generally occurring within the first week of therapy. Currently this therapy is only approved for use in women, as efficacy and safety in men has not been established due to inadequate numbers of men enrolled in clinical trials to date.³⁰ In addition, length of effective therapy has only been approved for 12 weeks.³⁷ However, recent evidence suggests that tegaserod may provide safe and effective therapy for up to 12 months.³⁰ Diarrhea was the most common adverse effect, resulting in drug discontinuation in 1.6% of study subjects.

■ DIARRHEA-PREDOMINANT DISEASE

8 For patients in whom diarrhea is the primary complaint, avoidance of certain food products may be necessary. Caffeine, alcohol, and artificial sweeteners (sorbitol, fructose, and mannitol) are known to irritate the gut and produce a laxative effect. Lactose

intolerance should be considered in certain patients; however, the prevalence of this condition may be exaggerated.

Herbal medicines or teas often contain senna, which may produce diarrhea. In patients with disease persistence following dietary modification, loperamide may be used for episodic management of urgent diarrhea, or in situations in which the patient wishes to avoid the possibility of an acute onset of symptoms.²⁹ This drug decreases intestinal transit, enhances water and electrolyte absorption, and strengthens rectal sphincter tone. Some patients may require continuous therapy, and careful dosage titration can usually be undertaken to prevent the development of constipation. Cholestyramine may be useful in patients with diarrhea related to idiopathic bile acid malabsorption or following cholecystectomy.²⁸

Diarrhea-predominant IBS caused by excessive stimulation of the 5-HT₃ receptor can be relieved by the drug alosetron. Alosetron was the first truly effective treatment for diarrhea-predominant IBS. However, in November 2000 it was voluntarily withdrawn from the market due to severe GI adverse effects, including 113 reported cases of serious constipation and 8 cases of possible ischemic colitis and death. This decision was met with a great public outcry, as many who had suffered for years had experienced relief for the first time. Because this drug was highly effective in many patients, the FDA approved restricted use of alosetron in June 2002. Alosetron is now available via an FDA-approved restricted use program in conjunction with GlaxoSmithKline as detailed at <http://www.lotronex.com>. It is now indicated, in lower initial doses of 1 mg daily, for women with diarrhea-predominant symptoms of greater than 6 months' duration that are not relieved by conventional therapy. Health care providers must utilize extreme caution in therapy with this drug, and must follow strict FDA-mandated guidelines.

■ PAIN IN IBS

9 Select patients with IBS suffer significant pain associated with their disease. Data supporting the use of antispasmodic agents in these patients are conflicting.^{31,32} In these cases, a trial of low-dose antidepressant therapy is indicated, especially if pain is associated with eating. Both tricyclic antidepressants and serotonin reuptake inhibitors produce analgesia, and may relieve depressive symptoms if present. Preprandial doses of drugs containing anticholinergic properties may suppress pain (and/or diarrhea) associated with an overactive postprandial gastrocolonic response. Tricyclic antidepressants should be avoided in patients with pain and constipation. In addition, psychotherapy, including cognitive behavioral therapy, relaxation therapy, and hypnotherapy have been shown to decrease IBS symptoms.³³

■ DRUG CLASSES CURRENTLY UNDER INVESTIGATION FOR THE TREATMENT OF IBS

Numerous agents are currently undergoing investigation for the management of IBS.³³ Selective blockade of the muscarinic M₃ receptors as well as β₃-adrenoceptor agonists have been shown to alter gut motility without affecting the cardiovascular system.³⁴ However, two recently tested compounds, zamifenacin and darifenacin have shown limited efficacy to date.³⁵

Other compounds being evaluated include neurokinin 1 and neurokinin 3 receptor antagonists, gut-selective calcium channel

blockers, cholecystokinin A receptor antagonists, and agents capable of stimulating motilin receptors (motilinomimetics).³⁶

EVALUATION OF THERAPEUTIC OUTCOMES

IBS is usually classified as constipation-predominant, diarrhea-predominant, or IBS with abdominal pain and bloating. Therapeutic goals in IBS should focus on the patient's primary complaint. Dietary and drug therapy goals should focus on end-organ treatment to relieve

abdominal pain (antispasmodic drugs) or disturbed bowel habits (antidiarrheals and bulk-forming agents). Additionally, severe symptoms from central nervous system dysregulation should be treated with antidepressants, psychotherapy, relaxation/stress management, cognitive behavior treatment, and/or hypnosis aimed at specific affective disorders.³⁶ Lastly, the serotonin receptor agonists and antagonists can be used in carefully selected patients whose symptoms are not adequately controlled with other agents. The American Gastroenterology Association recommends that patients with severe IBS consider psychological treatments such as psychotherapy, relaxation/stress management, and/or cognitive behavior treatment.

ABBREVIATIONS

HT: serotonin

IBS: irritable bowel syndrome

ORS: oral rehydration solution

PEG-ELS: polyethylene glycol-electrolyte lavage solution

PHM: peptide histidine methionine

VIP: vasoactive intestinal peptide

PORTAL HYPERTENSION AND CIRRHOSIS

Edward G. Timm and James J. Stragand

Learning Objectives and other resources can be found at www.pharmacotherapyonline.com.

KEY CONCEPTS

- 1 Cirrhosis is a severe, chronic, irreversible disease associated with significant morbidity and mortality. However, the progression of cirrhosis secondary to alcohol abuse can be interrupted by abstinence. It is therefore imperative for the clinician to educate and support abstinence from alcohol as part of the overall treatment strategy of the underlying liver disease.
- 2 Patients with cirrhosis and portal hypertension should be considered for endoscopic screening, and patients with large varices should receive primary prophylaxis with β -adrenergic blockade therapy.
- 3 When nonselective β -adrenergic blocker therapy is used to prevent rebleeding, it is essential that the dose be titrated to achieve a heart rate goal of 60 bpm or a heart rate that is 25% lower than the baseline heart rate.
- 4 Octreotide is the preferred vasoactive agent employed in the medical management of variceal bleeding. Vasopressin can no longer be recommended as a first-line agent because of its significant adverse effect profile. Endoscopy employing endoscopic band ligation or endoscopic injection sclerotherapy is the primary therapeutic tool in the management of acute variceal bleeding.
- 5 The combination of spironolactone and furosemide is now the recommended initial diuretic therapy for patients with ascites.
- 6 All patients who have survived an episode of spontaneous bacterial peritonitis should receive long-term antibiotic prophylaxis.
- 7 The mainstay of therapy of hepatic encephalopathy involves therapy to lower blood ammonia concentrations, and includes diet therapy, lactulose, and antibiotics alone or in combination with lactulose.

Many chronic inflammatory diseases of the liver result in diffuse hepatocyte necrosis, cellular regeneration, and replacement with nodular fibrous tissue. As the number of functioning hepatocytes diminishes and fibrous tissue accumulates, a constellation of signs and symptoms develop that is collectively termed *cirrhosis*. The term cirrhosis is derived from the Greek *kirrhos* meaning orange-colored, and refers to the yellow-orange hue of the liver seen by the pathologist or surgeon. Histologically, cirrhosis is defined as a diffuse process characterized by fibrosis and a conversion of the normal hepatic architecture into structurally abnormal nodules.¹ Regardless of the mechanism of injury, the end result is the destruction of hepatocytes and their replacement with fibrous tissue. As fibrotic tissue replaces normal hepatic parenchyma, resistance to blood flow results in the clinical problems of portal hypertension and the development of varices and ascites. Hepatocyte loss and intrahepatic shunting of blood results in diminished metabolic and synthetic function, which leads to hepatic encephalopathy and coagulopathy.

1 While cirrhosis has many causes (Table 37–1), in the United States excessive alcohol intake and chronic viral hepatitis (types B and C) are the most common causes.^{2,3} A breakdown of the indications for liver transplantation (Table 37–2) provides an estimate of the clinical frequency for each of the potential causes of cirrhosis, as transplant represents the definitive therapeutic strategy for cirrhosis.² These data underestimate alcoholic liver disease, as these patients are often not considered suitable transplant candidates.

This chapter elucidates the pathophysiology of cirrhosis and the resultant effects on human anatomy and physiology. Treatment strategies for managing the most commonly encountered clinical complications of cirrhosis are discussed.

EPIDEMIOLOGY

Cirrhosis affects 3.6 per 1000 adults in the United States and is responsible for 26,000 deaths per year.³ Chronic liver disease represents the fourth leading cause of deaths among all races and sexes in the 45- to 54-year-old age group, exceeded only by malignancy, heart disease, and accidents.⁴ Acute variceal bleeding and spontaneous bacterial peritonitis are among the immediately life-threatening complications of cirrhosis. Associated conditions causing significant morbidity include ascites and hepatic encephalopathy. Approximately 50% of patients with cirrhosis who develop ascites die within 2 years of diagnosis.⁵

PATHOPHYSIOLOGY OF CIRRHOSIS

Any discussion of cirrhosis must be based on a firm understanding of hepatic anatomy and vascular supply. Conceptually, the liver can be thought of as an elaborate blood filtration system receiving blood

TABLE 37–1. Etiology of Cirrhosis

| Category | Example |
|---------------------|--|
| Drugs and toxins | Alcohol, methotrexate, isoniazid, methyldopa, organic hydrocarbons |
| Infections | Viral hepatitis (types B and C), schistosomiasis |
| Immune-mediated | Primary biliary cirrhosis, autoimmune hepatitis, primary sclerosing cholangitis |
| Metabolic | Hemochromatosis, porphyria, α_1 -antitrypsin deficiency, Wilson's disease |
| Biliary obstruction | Cystic fibrosis, atresia, strictures, gallstones |
| Cardiovascular | Chronic right heart failure, Budd-Chiari syndrome, veno-occlusive disease |
| Cryptogenic | Unknown |
| Other | Nonalcoholic steatohepatitis, sarcoidosis, gastric bypass |

From Williams and Iredale.¹

from the portal vein and the hepatic artery (Fig. 37–1). Blood enters the liver via the portal triad and drains through the hepatic lobule, the smallest functional unit of this filtration system (Fig. 37–2), and into the central vein. The hepatic lobule is hexagonal in shape, at the angles of which are the sites of the portal triads, which contain the smallest branches of the portal vein and hepatic artery, as well as the bile and lymphatic ducts. Within the lobule, individual hepatocytes are arranged in plates, radiating from the periphery to a central vein. The hepatic lobule can be subdivided into functional zones based on relative oxygen supply. The hepatic artery supplies oxygen-rich blood to the portal triad.^{6,7} Hepatocytes at the periphery therefore receive a higher level of oxygen than the cells near the central vein.

Arterial and venous blood from the portal triad passes through the hepatic lobules to the central veins via the hepatic sinusoids. After passing through the hepatic lobules, blood collects in the central veins, which ultimately coalesce into the hepatic veins, which then enter the inferior vena cava.

In areas of hepatocellular injury, regardless of the nature of the inciting agent, stellate cells, normally involved in the storage of retinoids like vitamin A, become activated, lose their retinoids, and develop features of fibroblasts. They then become a major source of the collagen and other matrix proteins that proliferate during fibrosis.^{9,10} The progressive deposition of fibrous material within the sinusoids disrupts the normal blood flow through the hepatic lobule. As fibrous tissue accumulates, resistance to portal blood flow increases, resulting

**FIGURE 37–1.** The portal venous system.

in persistent and progressive elevations in portal blood pressures, or portal hypertension (PHT). Normal portal venous pressure is 5 to 10 mm Hg.¹¹ Clinically significant PHT exists when the portal venous pressure increases to a point where it is 10 mm Hg greater than the pressure within the inferior vena cava.¹¹

There is also evidence that there are changes in the vasodilatory and vasoconstricting mediators that regulate the hepatic sinusoidal blood flow.⁸ A decrease in the production of nitric oxide, which acts as a vasodilator, and an increase in the levels of the vasoconstrictor endothelin combine to increase the resistance to blood flow. Concurrently, there also appears to be an increase in the blood flow to the splanchnic vasculature through a nitric oxide-mediated effect on the splanchnic arteriole. These physiologic changes are the target of the pharmacologic approach to therapy.

In summary, cirrhosis results in elevation of portal blood pressure because of fibrotic changes within the hepatic sinusoids, changes in the levels of vasodilatory and vasoconstrictor mediators, and an increase in blood flow to the splanchnic vasculature.

ANATOMIC AND PHYSIOLOGIC EFFECTS OF CIRRHOSIS

Cirrhosis and the pathophysiologic abnormalities that cause it result in the commonly encountered problems of ascites, portal hypertension and esophageal varices, hepatic encephalopathy, and coagulation disorders. Other less commonly seen problems in patients with cirrhosis include hepatorenal syndrome, hepatopulmonary syndrome, and endocrine dysfunction, and these are discussed in the section dealing with management of complications.

FIGURE 37-2. The hepatic lobule.

ASCITES

Ascites, from the Greek *askos* meaning waterbag or wineskin, is the pathologic accumulation of lymph fluid within the peritoneal cavity. It is one of the earliest and most common presentations of cirrhosis.¹³ More than one-half of cirrhotic patients develop ascites within 10 years of diagnosis.¹⁴ The mechanism for the development of ascites is not completely understood. The most current unifying theory involves the development of PHT in conjunction with systemic arterial vasodilation.^{13,15–17} The progressive vasodilation then leads to the activation of the baroreceptors in the kidney and an activation of the renin-angiotensin system, with sodium and water retention (Fig. 37-3). The net effect of these changes is plasma volume expansion and the translocation of lymph fluid from the hepatic sinusoids and splanchnic capillaries into the peritoneal cavity.^{13,17}

PORTAL HYPERTENSION AND VARICES

The most important clinical sequelae of PHT are the development of varices or alternative routes of blood flow from the portal to the systemic circulation, bypassing the liver (see Fig. 37-1). Varices decompress the portal venous system and return blood to the systemic circulation. Varices can occur at any level of the GI tract; however, the route with the most clinical significance is through the left gastric vein with the development of esophageal varices. Patients with cirrhosis are at risk for variceal bleeding when portal venous pressure is

12 mm Hg greater than vena cava pressure.¹¹ Hemorrhage from varices occurs in 25% to 40% of patients with cirrhosis, and each episode of bleeding carries a 5% to 50% risk of death.¹⁹ Rebleeding can occur in as many as 60% to 70% of patients within 1 year.²⁰ The risk of bleeding from esophageal varices is related to the tension on the variceal wall, which in turn is related to portal vein pressure and ultimately to the degree of cirrhosis.¹¹ It should be apparent from this

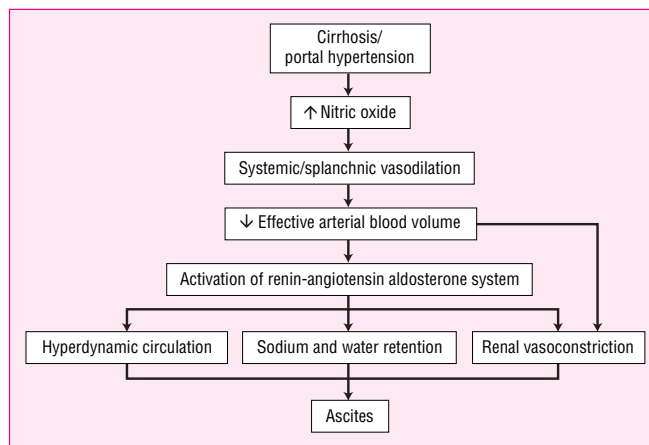

FIGURE 37-3. Pathogenesis of ascites.

understanding that the primary strategy for the treatment of esophageal varices is the reduction of portal hypertension by pharmacologic and surgical approaches.

HEPATIC ENCEPHALOPATHY

Hepatic encephalopathy (HE) is a complex neuropsychiatric syndrome with a broad spectrum of symptoms of neurologic impairment that occurs in cirrhotic patients.¹⁸ The symptoms are thought to result from an accumulation of gut-derived nitrogenous substances in the systemic circulation as a consequence of shunting through portosystemic collaterals, bypassing the liver.¹⁹ These substances then enter the central nervous system and result in alterations of neurotransmission that affect consciousness and behavior.¹⁸ This is often referred to as the “gut-brain” connection. Elevated arterial ammonia concentrations are the most commonly cited causative agent, as ammonia levels tend to be elevated in patients with more advanced liver insufficiency. However, ammonia levels are only poorly correlated with the grade of HE.²⁰ Furthermore, the administration of ammonia failed to induce HE in patients with cirrhosis.²¹ Nevertheless, interventions to lower blood ammonia levels are the mainstay of the treatment of HE.

HE can present in one of three forms: acute, chronic, and subclinical. Acute HE is defined as a distinct event of altered sensorium lasting <4 weeks, followed by complete recovery to the baseline mental status. Chronic encephalopathy is defined as cognitive or neuropsychiatric abnormalities that persist for at least 4 weeks. During this time, the severity of the abnormalities fluctuates, but no episodes of normal mentation are noted. Subclinical encephalopathy refers to subtle alterations in neuropsychiatric function that are not clinically apparent without special testing.¹⁹

The clinical manifestations of HE can range from subtle mental status abnormalities, detectable only with psychological testing, to deep coma.²¹ Additionally, different classifications or patterns of HE can also be described. HE is seen in two broad clinical settings, acute fulminant liver failure and chronic liver failure. In patients with chronic liver failure, HE occurs in three patterns, acute, chronic, and subclinical.^{17,19}

HE associated with acute fulminant liver failure has a rapid onset and a short prodrome, and patients can progress from drowsiness to delirium, convulsions, and finally to coma in as shortly as 24 hours. The prognosis in these cases is dismal.²¹ This pattern of HE usually has no known precipitating factors, and patients who survive the acute insult have an excellent long-term prognosis. HE associated with chronic liver failure has a gradual onset, is commonly associated with known precipitating factors, and has a poor prognosis with the need for long-term treatment of the underlying liver disease.¹⁹

COAGULATION DEFECTS

Complex coagulation derangements can occur in cirrhosis. These include the reduction in the synthesis of coagulation factors and the clearance of activated clotting factors. Vitamin K–dependent clotting factors, including factor VII, are affected early, and occur with sufficient frequency and rapidity that the prothrombin time is a standard component of the Child-Pugh scoring system discussed in the following section. The presence of activated clotting factors in cirrhosis creates a low-grade disseminated intravascular coagulation–like state with fibrinolysis. In addition, the PHT of cirrhosis is accompanied by a qualitative and quantitative reduction in platelets. Approximately 40% of cirrhotic patients have an abnormal prolongation of their bleeding time to values >10 minutes and platelet counts <100,000/mm.^{3,22} The net effect of these events is the development of bleeding diathesis.

CLINICAL PRESENTATION

Cirrhotic patients may present in a variety of ways, from asymptomatic patients with abnormal laboratory tests noted on routine blood donation, to acute life-threatening hemorrhage in an emergency room. The approach to a patient with suspected liver disease begins with a thorough history and physical exam. Table 37–3 describes the prevalence of the presenting signs and symptoms of cirrhosis.²³ Clinical jaundice is often a late manifestation of cirrhosis and its absence does not exclude the diagnosis.

A thorough history of alcohol or drug use, with the input of family and friends is important, as the patient often underestimates the amount of alcohol consumed. Family history can also provide clues regarding problems such as hemochromatosis. The social history provides information regarding potential occupational exposures to toxic agents. A history of acute pain and fever may indicate an obstructive process due to gallstones or an inflammatory condition such as viral or alcoholic hepatitis.

The classic clinical signs of cirrhosis, such as palmar erythema, spider angiomas, and gynecomastia, are neither sensitive nor specific for this disease.^{12,23} Only a combination of physical and laboratory findings provides a reasonable indicator of liver disease. A decreased albumin level was the most common finding in patients with cirrhosis, but was nonspecific and occurred in a variety of conditions. An elevated prothrombin time was the single most reliable manifestation of cirrhosis. The combination of thrombocytopenia, encephalopathy, and ascites was found in just over half of cirrhotics, but had the highest predictive value.¹⁹

LABORATORY ABNORMALITIES

There are no laboratory or radiographic tests of hepatic function despite the commonly ordered *liver function tests*. These commonly measured markers are substances produced by the liver and released into the bloodstream during hepatocellular injury, and are more correctly termed *liver dysfunction tests*. True liver function tests that assess the ability of the liver to eliminate substances that undergo hepatic metabolism, such as the ¹⁴C-aminopyrine breath test, are limited by complexity and availability.

Routine liver tests include alkaline phosphatase, bilirubin, aspartate transaminase (AST), alanine transaminase (ALT), and γ -glutamyl transpeptidase (GGT). Additional markers of hepatic synthetic activity include albumin and prothrombin time. Liver function tests are

TABLE 37–3. Clinical Presentation of Cirrhosis

Signs and symptoms (percent of patients)^a

- Fatigue (65%), pruritus (55%)
- Hyperpigmentation (25%), jaundice (10%)
- Hepatomegaly (25%), splenomegaly (15%)
- Palmar erythema, spider angiomas, gynecomastia
- Ascites, edema, pleural effusion, and respiratory difficulties
- Malaise, anorexia, and weight loss
- Encephalopathy

Laboratory tests

- Hypoalbuminemia
- Elevated prothrombin time
- Thrombocytopenia
- Elevated alkaline phosphatase
- Elevated aspartate transaminase (AST), alanine transaminase (ALT), and γ -glutamyl transpeptidase (GGT)

^aFrom Talwalkar and Lindor.²³

often the first step in the evaluation of patients who present with symptoms or signs suggestive of cirrhosis. Liver function tests will typically be elevated in chronic inflammatory liver disease such as hepatitis C, but may be normal in patients with a previous toxic exposure or resolved infectious process such as hepatitis B. The individual liver tests are discussed in more detail in Chap. 31, on evaluation of the gastrointestinal tract.

The use of liver function tests in the diagnosis and management of cirrhosis is discussed in the following sections. It may be useful to group the tests into two broad categories: markers of hepatocyte damage such as the transaminases; and markers of hepatocellular synthetic function, prothrombin time and albumin.

AMINOTRANSFERASES

The aminotransferases, AST and ALT, are enzymes located in the cytoplasm of hepatocytes and their levels will be elevated with hepatocellular injury. The degree of elevation of the aminotransferases is helpful in suggesting possible etiologies. The highest levels (>20-fold increase above normal) are typically seen in acute viral, drug-induced, or ischemic events associated with circulatory catastrophes. Alcoholic liver disease rarely presents with ALT values >500 units/L, and higher values should alert the clinician to complicating problems.²⁰

The ratio of AST to ALT also provides information in patients with suspected alcoholic liver disease. Seventy percent of patients with alcoholic liver disease had ratios greater than 2, compared to 4% of patients with viral hepatitis.²⁴

ALKALINE PHOSPHATASE AND GAMMA-GLUTAMYL TRANSPEPTIDASE

Elevated levels of alkaline phosphatase and GGT occur with obstructive disorders that disrupt the flow of bile from the hepatocytes to the bile ductules, or from the biliary tree to the intestines. Examples of the former include primary biliary cirrhosis and drug-induced cholestasis; examples of the latter include gallstone disease and malignancies of the pancreas and bile ducts. In liver disease, the levels of GGT correlate well with elevations of the alkaline phosphatase, and their combination is a sensitive and specific marker for biliary tract disease.²²

CHILD-PUGH CLASSIFICATION

The Child-Pugh classification system has gained widespread acceptance as a means of quantifying the myriad effects of the cirrhotic process on the laboratory and clinical manifestations of this disease.²⁸ The system employs a combination of physical and laboratory findings (Table 37-4). This classification system is important because it is used to assess and define the severity of the cirrhosis, and as a predictor for patient survival, surgical outcome, and risk of variceal bleeding.

TABLE 37-4. Criteria and Scoring for the Child-Pugh Grading of Chronic Liver Disease

| Score | 1 | 2 | 3 |
|--------------------------------------|------|---------|----------|
| Bilirubin (mg/dL) | 1–2 | 2–3 | >3 |
| Albumin (mg/dL) | >3.5 | 2.8–3.5 | <2.8 |
| Ascites | None | Mild | Moderate |
| Encephalopathy (grade) | None | 1 and 2 | 3 and 4 |
| Prothrombin time (seconds prolonged) | 1–4 | 4–6 | >6 |

Grade A, <7 points; grade B, 7–9 points; grade C, 10–15 points.

TABLE 37-5. Etiology of Hyperbilirubinemia

| Etiology | Diagnosis |
|---------------------------------|---|
| Unconjugated bilirubin | |
| Excessive production | Hemolysis |
| Immature enzyme systems | Jaundice of newborn |
| | Jaundice of prematurity |
| Inherited defects | Gilbert syndrome |
| | Crigler-Najjar syndrome |
| Drug effects | |
| Conjugated bilirubin | |
| Impaired intrahepatic excretion | |
| Hepatocellular disease | Hepatitis, cirrhosis, drugs |
| Intrahepatic cholestasis | Drugs, pregnancy |
| Congenital | Dubin-Johnson syndrome |
| | Rotor’s syndrome |
| Obstruction | |
| Extrahepatic | Calculus, stricture, neoplasm |
| Intrahepatic | Sclerosing cholangitis, cirrhosis, neoplasm |

BILIRUBIN

Bilirubin is a breakdown product of hemoglobin derived from senescent red blood cells. Elevations of the serum bilirubin are common in end-stage liver disease and obstruction of the common bile duct due to gallstones or malignancy; however, there are other causes of an elevated bilirubin (Table 37-5).

When cirrhosis has been established, the degree of bilirubin elevation has prognostic significance and is used as a component of the Child-Pugh scoring system for quantifying the degree of cirrhosis.

Figure 37-4 describes a general algorithm for the interpretation of liver function tests. The algorithm first separates the tests into two categories based on the underlying pathology (pattern of elevations): obstructive (alkaline phosphatase, GGT, and bilirubin) versus hepatocellular (AST and ALT). If a hepatocellular pattern predominates, the magnitude of elevation provides diagnostic assistance. If the degree of elevation is >20 times normal, the etiology is likely a result of drugs or other toxins, ischemia, or acute viral hepatitis. Elevations <20 times normal have a broad differential. Unfortunately, most liver

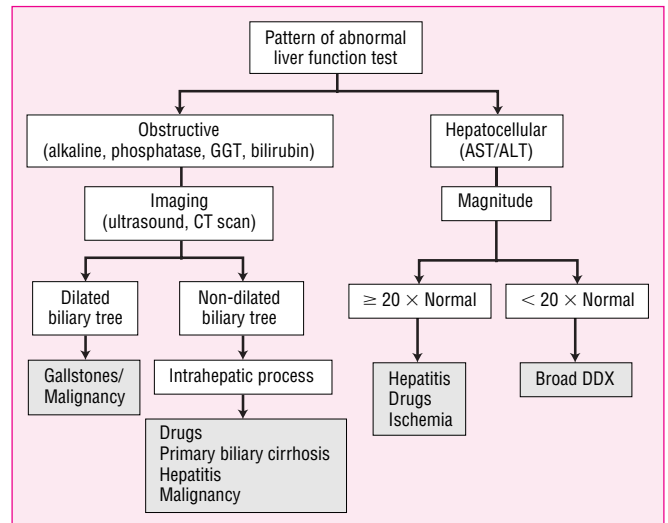

FIGURE 37-4. Interpretation of liver function tests.

enzyme abnormalities will fall into a mixed pattern, providing limited diagnostic assistance.

ALBUMIN AND COAGULATION FACTORS

These proteins are markers of hepatic synthetic activity and are therefore used to estimate the level of functioning hepatocytes in cirrhosis. They are employed in the Child-Pugh scoring system for liver disease. Albumin levels can be affected by a number of factors, including the patient's nutritional status, acute illnesses, which result in redistribution of albumin, and protein losses from renal and intestinal sources.

The liver synthesizes coagulation factors I, II, V, VII, IX, and X.²⁰ The prothrombin time is prolonged when any of these factors are absent. In acute liver disease the prothrombin time can be used as an outcome measurement in acetaminophen overdose and acute alcoholic hepatitis.²⁵ In chronic liver disease, the prothrombin time is employed as a marker of decreased synthetic capacity.

THROMBOCYTOPENIA

Thrombocytopenia is a relatively common feature in both acute and chronic liver disease and is proportional to the extent of liver disease.²⁶ The etiology of thrombocytopenia in liver disease is multifactorial, but involves primarily hypersplenism with pooling of platelets, immune-mediated destruction, and the inability of the bone marrow to compensate for the accelerated removal. The bone marrow depression may be related to alcohol, drugs, and nutritional deficiencies associated with the cirrhotic process.²⁷

► TREATMENT: Cirrhosis

■ GENERAL APPROACHES TO TREATMENT

As is discussed below, the clinical manifestations of cirrhosis are protean and it is difficult to provide overall management guidelines. General approaches to therapy should include:

1. Identify and eliminate where possible the causes of cirrhosis (e.g., alcohol abuse).
2. Assess the risk for variceal bleeding and begin pharmacologic prophylaxis when indicated, reserving endoscopic therapy for high-risk patients or acute bleeding episodes. Variceal obliteration with endoscopic techniques is the recommended treatment of choice in patients with acute bleeding.
3. Evaluate the patient for clinical signs of ascites and manage with pharmacologic therapy (e.g., diuretics and paracentesis). Careful monitoring for spontaneous bacterial peritonitis should be employed in patients with ascites who undergo acute deterioration.
4. Hepatic encephalopathy is a common complication of cirrhosis and requires clinical vigilance and treatment with dietary restriction, elimination of central nervous system depressants, and therapy to lower ammonia levels.

ENDOSCOPIC AND RADIOGRAPHIC ABNORMALITIES

The use of imaging techniques can provide useful information regarding the presence of liver disease and portal hypertension. The modality chosen is often determined by the clinical presentation. Examples include the use of ultrasound for the detection of gallstones and biliary duct abnormalities in patients presenting with acute pain and jaundice, or endoscopic retrograde cholangiopancreatography (ERCP) for patients with known choledocholithiasis. Upper endoscopy can be employed to detect the presence of esophageal or gastric varices as an indicator of portal hypertension. Computed tomography is a sensitive means of detecting hepatic metastases and is used for directing liver biopsy.

LIVER BIOPSY

Liver biopsy plays a central role in the diagnosis and staging of liver disease; however, for the diagnosis of cirrhosis, percutaneous liver biopsy has a significant false-negative rate because of the presence of regenerating nodules within the liver.

MANAGEMENT OF THE COMPLICATIONS OF CIRRHOSIS

The major complications of cirrhosis that require therapeutic intervention include:

- Portal hypertension and variceal bleeding
- Ascites and spontaneous bacterial peritonitis
- Hepatic encephalopathy
- Other systemic complications

5. Frequent monitoring for signs of hepatorenal syndrome, pulmonary insufficiency, and endocrine dysfunction is necessary.

■ DESIRED OUTCOMES

The desired therapeutic outcomes can be viewed in two categories: *resolution of acute complications*, such as tamponade of bleeding and resolution of hemodynamic instability for an episode of acute variceal hemorrhage; and *prevention of complications*, through lowering of portal pressure with medical therapy using β -adrenergic blocker therapy, or supporting abstinence from alcohol. Treatment endpoints and desired therapeutic outcomes are presented for each of the recommended therapies discussed.

■ PORTAL HYPERTENSION AND VARICEAL BLEEDING

The propensity of esophageal varices to bleed when a threshold pressure is exceeded is a potentially life-threatening complication of cirrhosis. Mortality after the first variceal bleed ranges from 5% to 50% and is dependent upon the severity of the underlying liver disease.¹² Cirrhotic patients who have experienced their first episode of variceal

bleeding have an approximately 60% to 70% risk of rebleeding.¹² The Child-Pugh scoring system is a predictor for rebleeding and mortality.

MANAGEMENT OF PORTAL HYPERTENSION AND VARICEAL BLEEDING

The management of varices involves three strategies: (a) primary prophylaxis (prevention of the first bleeding episode); (b) treatment of acute variceal hemorrhage; and (c) secondary prophylaxis, prevention of rebleeding in patients who have previously bled.^{29,30}

Primary Prophylaxis

β -Adrenergic Blockade. The mainstay of primary prophylaxis is the use of nonselective β -adrenergic blocking agents such as propranolol or nadolol. These agents reduce cardiac output via blockade of the β_1 cardiac receptors and the blockade of the adrenergic dilatory tone of the mesenteric arterioles, resulting in unopposed α -adrenergic-mediated vasoconstriction. The net effect is the decreased blood flow to the mesenteric vascular system and decreased portal vein pressure.²⁹

A meta-analysis of nine randomized controlled trials evaluating the effectiveness of either propranolol or nadolol as primary prophylaxis demonstrated effectiveness in the prevention of bleeding and a trend toward a reduction in mortality.^{30–34} The average reduction in the incidence of initial bleeding achieved by nonselective β -adrenergic blockade is approximately 25%.³⁴ β -Blockade was effective irrespective of the presence of ascites and variceal size, and another study suggested that patients with a higher risk for bleeding, larger varices, or any size varices with a portal pressure >12 mm Hg, are the best candidates for prophylactic β -adrenergic blocker therapy.³⁴ β -Adrenergic blocker therapy should be lifelong unless it is not tolerated, because bleeding can occur when β -blocker therapy is abruptly discontinued.³⁵

CLINICAL CONTROVERSY: THE USE OF NITRATES

Nitrates are known to cause smooth muscle vasodilation and to reduce portal pressures; however, the role of nitrates in primary prophylaxis is controversial. Isosorbide-5-mononitrate was compared with propranolol for primary prophylaxis in cirrhosis.³⁶ Equivalent reductions in bleeding were reported, but short-term survival was improved with isosorbide therapy. This report was met with great enthusiasm because it offered an effective alternative for patients who did not tolerate β -adrenergic blockers. Follow-up on the patients in the study was continued for up to 7 years with the finding that the early mortality benefit was lost. In fact, the use of isosorbide-5-mononitrate resulted in higher long-term mortality than propranolol in patients >50 years of age.³⁷ These findings are not entirely surprising because it was appreciated that a potential existed for nitrates to increase portal blood flow and consequently portal pressure by enhancing nitric oxide-mediated vasodilation of the mesenteric vasculature. Considering that vasodilation in liver disease is the hemodynamic expression of liver failure and is a prognostic indicator of morbidity and mortality, this may explain, at least in part, the negative effects on long-term survival.³⁸

Another therapeutic issue arises because β -adrenergic blockers alone do not adequately lower portal pressure in all patients. A number of trials have shown that the combination of nitrates and β -adrenergic blockers is superior to β -adrenergic blockers alone in lowering portal pressures.³⁸ β -Adrenergic blocker therapy may suppress the neurohormonal activation associated with the relative hypovolemia induced by the vasodilation from the nitrate therapy and thereby minimize its detrimental effects.³² With such disparate study findings the role of nitrates in primary prophylaxis is controversial and firm recommendations are difficult. Nevertheless, for patients with an inadequate response to β -adrenergic blockers alone, a long-acting nitrovasodilator should be added to try to achieve adequate lowering of portal pressure. For patients with contraindications or intolerance to β -adrenergic blockers, treatment decisions are uncertain. Groszmann suggests that nitrates can probably be used safely in this situation in younger patients who have well-compensated cirrhosis.³⁸

Treatment Recommendations: Variceal Bleeding-Primary Prophylaxis

2 All patients with cirrhosis and portal hypertension should be considered for endoscopic screening, and patients with large varices should receive primary prophylaxis with β -adrenergic blockers. Initiate therapy with oral propranolol 10 mg three times daily or nadolol 20 mg once daily and titrate to a reduction in the resting heart rate of 20% to 25%, an absolute heart rate of 55 to 60 beats per minute (bpm), or the development of adverse effects. Patients with contraindications or intolerance to β -adrenergic blockers should be considered for trials of alternative prophylactic therapy.³⁹ Nitrates may be considered for these patients provided they are younger than 50 years of age and have well-compensated cirrhosis. Initiate therapy with isosorbide-5-mononitrate 20 mg orally twice daily and increase to 20 mg three times a day after 1 week if tolerated. Combination therapy with β -blockers and nitrates is recommended for patients with an inadequate lowering of portal pressure in response to β -adrenergic blockers alone. Currently, no evidence supports the use of sclerotherapy, band ligation, surgical shunting, or transjugular intrahepatic portosystemic shunt (TIPS) as primary prophylaxis.^{31,39} However, one recent study comparing variceal band ligation versus β -blockers as a primary prophylaxis did show a decreased rate of bleeding at 1 year in the banding group.⁴⁰

ACUTE VARICEAL HEMORRHAGE

Variceal hemorrhage typically presents with hematemesis or melena. Important risk factors include active alcohol abuse, use of nonsteroidal anti-inflammatory agents or aspirin, or previous variceal hemorrhage.³⁹ It is important to note, however, that variceal bleeding secondary to portal hypertension can occur in patients without signs of liver disease; for example, in patients with portal vein thrombosis. The initial assessment should determine the severity of the bleeding, severity of other organ dysfunction, and the severity of the liver disease. The Child-Pugh scoring system (see Table 37–4) is the most reliable means of assessing the severity of chronic liver disease.³⁹

■ MANAGEMENT OF ACUTE VARICEAL HEMORRHAGE

Initial treatment goals include: (a) adequate fluid resuscitation; (b) correction of coagulopathy and thrombocytopenia; (c) control of bleeding; (d) prevention of rebleeding; and (e) preservation of liver function. Prompt stabilization and aggressive fluid resuscitation of patients with active bleeding is followed by endoscopic examination. General resuscitation measures should be applied in the initial management of variceal hemorrhage. Airway management is critical in patients with variceal hemorrhage because of depressed reflexes and/or combative behavior associated with drug and alcohol use. The endoscopic approach to bleeding also requires a quiet and cooperative patient, and elective intubation for airway control and adequate sedation is often necessary. Clinical practice guidelines approved by the American College of Gastroenterology recommend esophagogastroduodenoscopy (EGD) employing endoscopic injection sclerotherapy (EIS) or endoscopic band ligation (EBL) of varices as the primary diagnostic and treatment strategy for upper GI tract hemorrhage secondary to portal hypertension and varices.⁴¹

Fluid resuscitation involves colloids initially and subsequent blood products after blood bank matching procedures are completed. Packed red blood cells, fresh frozen plasma, and platelets may be employed both as volume expanders and corrective therapy for underlying clotting abnormalities. Vasoactive drug therapy (somatostatin, octreotide, or terlipressin) to stop or slow bleeding is routinely employed early in patient management to allow stabilization of the patient and to permit endoscopy to proceed under more favorable conditions. Antibiotic therapy to prevent sepsis should also be implemented early, especially for patients with signs of infection or ascites. Figure 37–5 presents an algorithm for the management of variceal hemorrhage.

■ DRUG THERAPY

Drug therapy for acute variceal bleeding is based on the principle that it is possible to reduce portal, and consequently variceal, pressure by

reducing portal vein blood flow via splanchnic vasoconstriction.⁴² Drugs employed to manage acute variceal bleeding include octreotide or somatostatin, vasopressin, and terlipressin (triglycyl-L-lysine vasopressin).

■ Somatostatin and Octreotide

Somatostatin is a naturally occurring 14-amino acid peptide and octreotide is a synthetic octapeptide analog that is significantly more potent than native somatostatin. Octreotide shares four amino acids with somatostatin and these moieties are responsible for its pharmacologic activity. Somatostatin increases vascular tone in the gastrointestinal tract by inhibiting vasodilatory peptides such as vasoactive intestinal peptide, producing mesenteric vasoconstriction.⁴³ Both somatostatin and octreotide are widely used in the treatment of variceal hemorrhage because of their reported ability to decrease splanchnic blood flow, and thereby reduce portal and variceal pressures, without significant adverse effects.^{30,39} Unlike vasopressin, systemic vasoconstriction and elevations in blood pressure are not seen because the vasoconstriction that occurs with somatostatin and octreotide is selective for the mesenteric circulation. Other reports, however, have failed to demonstrate reductions in gastric mucosal blood flow or intravariceal pressure.³⁹ Consequently, the precise mechanism of action by which these agents may beneficially impact variceal bleeding still remains unclear.⁴⁴ Placebo-controlled clinical trials found somatostatin to be no more effective than placebo, whereas other studies show a clear benefit with somatostatin.^{45–47} A meta-analysis of clinical trials comparing somatostatin and octreotide with vasopressin or terlipressin has demonstrated equivalent efficacy, but the side effect profile of somatostatin and octreotide was superior to vasopressin.⁴⁸ This analysis also reported that somatostatin was more effective in achieving initial and sustained control of bleeding.

Vasopressin (also known as antidiuretic hormone) is a potent, nonselective vasoconstrictor that has been recommended for many

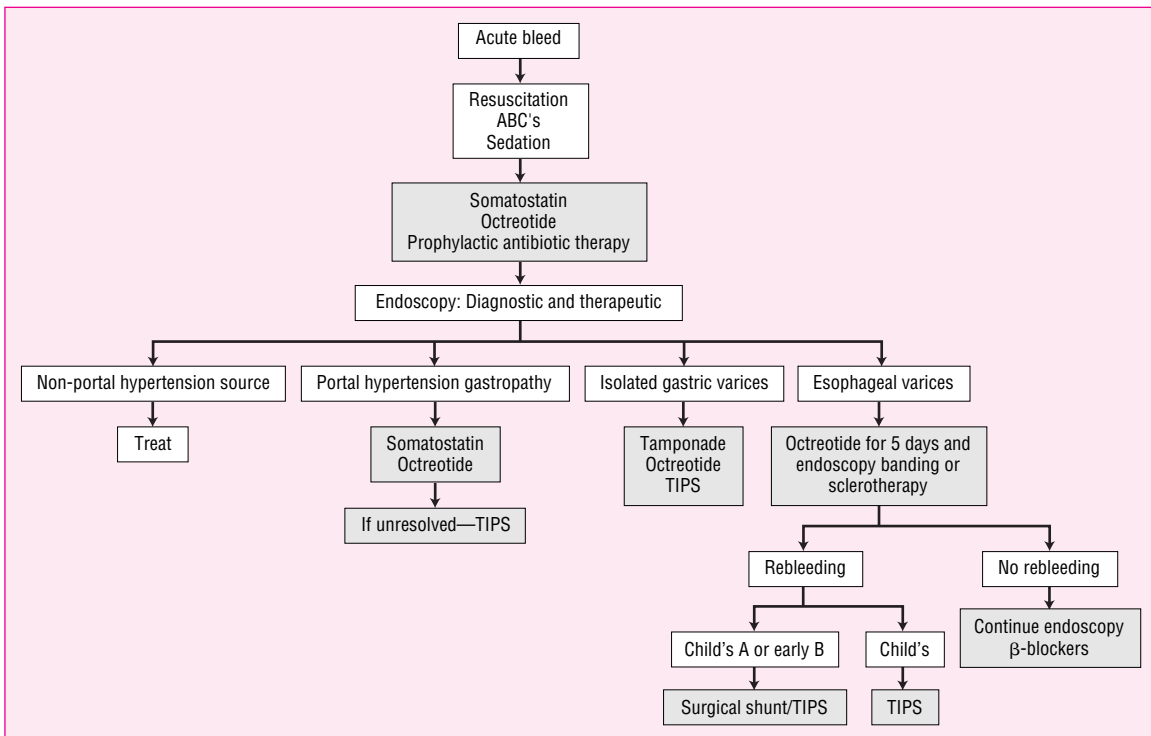

FIGURE 37–5. Management of acute variceal hemorrhage.

years for the management of acute variceal bleeding. Vasopressin reduces portal pressure by causing splanchnic vasoconstriction, which reduces splanchnic blood flow. Unfortunately, the vasoconstrictive effects of vasopressin are nonselective—the vasoconstriction produced is not restricted to the splanchnic vascular bed. Potent systemic vasoconstriction occurs in the coronary and mesenteric circulation as well, resulting in hypertension, severe headaches, coronary ischemia, myocardial infarction, and arrhythmias. A meta-analysis of 15 randomized controlled clinical trials of vasopressin for variceal hemorrhage demonstrated that vasopressin was significantly more effective than no treatment; however, control of hemorrhage was achieved in only 50% of the bleeding episodes.⁴⁸ Adverse effects were reported in 45% of patients, and vasopressin was discontinued in 25% of patients secondary to adverse effects. To minimize adverse effects associated with the peripheral vasoconstriction secondary to vasopressin, and to further lower portal pressure, the combination of vasopressin and intravenous nitroglycerin has been evaluated.¹³ The combination trended toward improved control of hemorrhage with reduced side effects when compared to vasopressin alone. However, with the recent addition of safer and equally effective treatment alternatives, vasopressin, alone or combined with nitroglycerin, can no longer be recommended as first-line therapy for the management of variceal hemorrhage.³⁹

Terlipressin (Glypressin), triglycyl-lysine vasopressin, is a synthetic prodrug of vasopressin with intrinsic vasoconstrictor activity that was developed in an attempt to provide an analogue of vasopressin with lower toxicity. The glycl residues are enzymatically cleaved in vivo, resulting in the slow conversion into lysine vasopressin. This process results in the availability of lysine vasopressin with a longer half-life, permitting bolus dosing every 4 hours.³⁹ In a number of unblinded clinical trials, terlipressin was associated with a significantly lower rate of adverse effects as compared to vasopressin alone, or as compared to vasopressin combined with nitroglycerin.⁴⁵ Terlipressin produces a marked and sustained reduction in portal pressures. This prolonged biologic effect allows intravenous administration as an intermittent infusion every 4 hours, whereas somatostatin requires administration as a continuous intravenous infusion.⁴⁹ In clinical trials that have been criticized for small sample size and unclear timing of treatments, terlipressin has demonstrated a beneficial effect on the control of bleeding compared with placebo, and is the only drug that has been shown to reduce mortality.³⁹ Terlipressin, the preferred drug in Europe for acute variceal bleeding, is not currently available in the United States.

Cirrhotic patients with active bleeding are at high risk of infection and sepsis secondary to aspiration, the placement of multiple intravascular access devices, sclerotherapy, translocation, and defects in humoral and cellular immunity.³⁹ Prophylactic antibiotic therapy to reduce the risk of sepsis during episodes of bleeding is reported to decrease the incidence of rebleeding and to increase short-term survival.⁵⁰ All patients with variceal hemorrhage should be screened for infection and pan-cultured. Patients should be evaluated at admission and observed throughout therapy for signs and symptoms of spontaneous bacterial peritonitis.³¹

■ ENDOSCOPIC INTERVENTIONS: SCLEROTHERAPY AND BAND LIGATION

The American College of Gastroenterology published clinical practice guidelines in 1997 recommending EGD employing EIS or EBL of varices as the primary diagnostic and treatment strategy for upper GI tract hemorrhage secondary to portal hypertension and varices.⁴¹ EIS involves injection of 1 to 4 mL of a sclerosing agent into the lumen

of the varices to tamponade blood flow. EBL consists of placement of rubber bands around the varix through a clear plastic channel attached to the end of the endoscope. After the rubber bands are in place, the varix will slough off after 48 to 72 hours. Endoscopic approaches can successfully stop bleeding in up to 95% of cases, but rebleeding may occur in 50% of cases. A recent meta-analysis of comparative clinical trials found both techniques equally effective in controlling acute variceal bleeding, but indicated that EBL was superior to EIS in reducing the rebleeding rate, and that EBL was associated with fewer posttreatment complications.³⁹ Sclerosing agents employed in EIS include ethanolamine, sodium tetradecyl sulfate, polidocanol, and sodium morrhuate. There are no data establishing clinical superiority of any of the sclerosants.⁵¹

Eight published clinical trials have compared endoscopic sclerotherapy with vasoactive drug therapy for active variceal bleeding. Drug treatment controlled bleeding in 58% to 95% of cases, and sclerotherapy controlled bleeding in 68% to 94% of cases. Rebleeding was slightly less common in patients receiving sclerotherapy, and sclerotherapy was associated with a lower mortality rate. Clinical trials of sclerotherapy plus vasoactive drugs versus sclerotherapy alone show a significant advantage for combination therapy; however, there was no beneficial effect on mortality.³⁹

■ INTERVENTIONAL AND SURGICAL TREATMENT APPROACHES

If standard therapy fails to control bleeding (after two failed endoscopic procedures, further attempts are unlikely to be of benefit) a salvage procedure, such as balloon tamponade, TIPS, or surgical shunting is necessary. Sengstaken-Blakemore tubes are balloon devices designed to tamponade gastric and esophageal varices that can be effective in 70% to 90% of cases of variceal bleeding.³⁹ However, these devices have a 10% to 30% complication rate and will be ineffective if the bleeding source is nonvariceal, a situation which occurs in 10% to 50% of patients with portal hypertension.³⁹ Balloon tamponade should be reserved as a temporizing measure until a TIPS procedure or surgical shunt can be performed.³¹

The development of the TIPS provided a major improvement in the management of refractory or severe cases of esophagogastric variceal bleeding and other complications of portal hypertension.⁵² The TIPS procedure involves the placement of one or more stents between the hepatic vein and the portal vein (Fig. 37–6). This procedure is widely used because it provides an effective decompressive shunt without laparotomy, and can be employed regardless of Child-Pugh score. Survival rates with TIPS in patients refractory to endoscopic treatment are comparable to rates achieved with portacaval

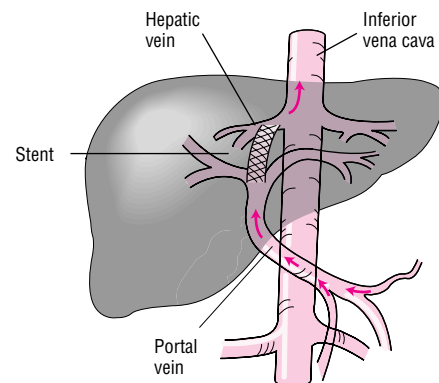

FIGURE 37–6. Transjugular intrahepatic portosystemic shunt (TIPS).

shunts.³⁹ Patients undergoing TIPS experience a 30% incidence of encephalopathy, and approximately 50% of shunts malfunction.³¹

Various surgical shunts have been developed and are effective for the prevention of recurrent variceal hemorrhage in patients refractory to β -adrenergic blockade and endoscopy.³¹

■ TREATMENT RECOMMENDATIONS: VARICEAL HEMORRHAGE

Patients require prompt resuscitation with colloids and blood products to correct intravascular losses and to reverse existing coagulopathies. Drug therapy with octreotide or somatostatin should be initiated early to control bleeding and facilitate diagnostic and therapeutic endoscopy. Based on availability octreotide is preferred. Therapy is initiated with an IV bolus of 50 to 100 mcg and is followed by a continuous infusion of 25 mcg/h, up to a maximum rate of 50 mcg/h. Monitor patients for hypo- or hyperglycemia, especially patients with diabetes, and assess for cardiac conduction abnormalities. Vasopressin is no longer recommended for control of variceal bleeding. Endoscopy employing EBL or EIS is the primary therapeutic tool in the management of acute variceal bleeding.^{30,39,53} Antibiotic prophylaxis is recommended if ascites is present and EIS is planned. Appropriate choices include a third-generation cephalosporin (e.g., ceftazidime or ceftriaxone), a penicillin/ β -lactamase inhibitor combination (e.g., piperacillin-tazobactam), or a fluoroquinolone (e.g., ofloxacin). Surgical shunts and TIPS are employed as salvage therapy in patients who have failed repeated endoscopy and vasoactive drug therapy.

■ Secondary Prophylaxis: Prevention of Rebleeding

Because the risk of rebleeding after initial control of variceal hemorrhage can approach 80%, and rebleeding significantly increases the risk of death, it is inappropriate to simply observe patients for evidence of further bleeding. Traditionally, pharmacologic therapy using β -adrenergic blockers was recommended as the initial approach for prevention of rebleeding. A major shift in therapy is underway; endoscopic therapy using EBL or EIS, repeated at regular intervals with the goal of obliteration of varices, is emerging as the preferred treatment option. Alternatives for the secondary prevention of rebleeding include surgical or interventional shunting.

The objective of both EIS and EBL in prevention of rebleeding is the obliteration of esophageal varices. The majority of rebleeding occurs in the interval between the primary endoscopic session and the time to complete obliteration. Therefore the patient should have repeat endoscopy with either EIS or EBL every 2 weeks until no further varices are identified. After this is achieved, repeat exams at 3 and 6 months are appropriate. The rebleeding rate after EBL is less than EIS, 27% versus 45%.⁵⁴

■ **Drug Therapy.** Drug therapy of variceal hemorrhage is less expensive, offers fewer serious complications, and is usually preferred by patients. In patients without contraindications, β -adrenergic blocking agents should be the initial step in secondary prophylaxis, along with endoscopy.^{39,54} A meta-analysis of 11 randomized controlled clinical trials demonstrated a significant 21% reduction in rebleeding with β -blockers as compared to untreated controls, and a 5.4% improvement in the 2-year overall survival rate.⁵⁵ Secondary prophylaxis with β -adrenergic blockade therapy also resulted in a significant

7.4% reduction in death as a consequence of rebleeding. Propranolol was used in 10 trials; nadolol was used in one trial. Patients treated with β -adrenergic blocking agents experienced significantly more adverse events, 22% versus 9% compared to untreated controls,⁵⁵ with 5.7% requiring discontinuation of β -adrenergic blockade therapy.

When considering the benefits associated with β -adrenergic blockers, it is important to appreciate that approximately 25% of cirrhotic patients either have contraindications or exhibit intolerance to β -adrenergic blockers, and portal pressures are not adequately lowered in all patients treated with β -adrenergic blockade.⁵⁶ Use of a long-acting β -blocker (such as nadolol) is usually recommended to improve compliance, and gradual, individualized dose escalation may help to minimize side effects. Ideally, portal pressure monitoring can help to assess the response to β -adrenergic blocker therapy and identify nonresponders earlier in the treatment course. This is important because patients with sinusoidal portal hypertension (the type encountered in cirrhosis) do not bleed when the hepatic venous pressure gradient is <12 mm Hg. Also, protection against rebleeding has been demonstrated when the hepatic venous pressure gradient is reduced by 20%.⁵⁷ However, the procedure for measuring portal pressures is invasive, expensive, and not available in most facilities. In addition, the cost-effectiveness of this approach (baseline and posttherapy) has not been compared with simply monitoring heart rate reduction with β -blockers.⁵⁸ For patients who fail to achieve sufficient reductions in portal pressure with β -blocker therapy alone, combination therapy with nitrates or spironolactone may more effectively lower portal pressures.⁵⁹ However, combination therapy for secondary prophylaxis has not been evaluated in randomized clinical trials.

Comparisons of β -adrenergic blocker therapy alone with EIS suggest that less variceal rebleeding is seen with EIS, but this benefit is offset by an increase in complications.^{39,54} A recent study comparing nadolol plus isosorbide mononitrate with EIS suggested that combined drug therapy offered substantial advantages over EIS.⁶⁰ Rebleeding was significantly less common with nadolol and isosorbide mononitrate, and treatment-associated complications occurred significantly less often as well. However, because EBL is now increasingly preferred over EIS for secondary prophylaxis due to superior efficacy and safety, data from comparative trials with medical therapy are needed. In one series the rebleeding rate for EBL was superior to standard medical therapy.⁶¹

■ **Shunting.** When drug therapy and endoscopy fail, alternatives include TIPS placement or shunt surgery. Regular documentation of patency and the requirement of repeat procedures make it an unsuitable long-term solution. In patients with well-compensated hepatic function (Child-Pugh grade A or B) surgical shunting is an excellent option.

■ Treatment Recommendations: Secondary Prophylaxis

The preferred initial approach is currently unsettled and may depend on local experience and expertise.⁵⁴ Endoscopic therapy using either EIS or EBL and pharmacologic therapy are both effective in reducing the risk of rebleeding. As a consequence of decreased complications, bleeding, and possibly mortality, EBL has emerged as the endoscopic treatment of choice.^{39,54} Either approach alone or the combination of endoscopy with pharmacologic therapy can be considered appropriate initial therapy. Pharmacologic therapy should be initiated with a nonselective β -blocker such as propranolol 20 mg three times a day, or nadolol at a dose of 20 to 40 mg once daily, and titrated weekly to achieve a goal heart rate of 55 to 60 bpm or a heart rate that is 25%

lower than the baseline heart rate. Assessment of portal pressures can identify nonresponders for whom combination therapy with β -blockers and nitrates or spironolactone may be attempted to achieve portal pressure gradients <12 mm Hg. Monitor patients for evidence of heart failure, bronchospasm, and glucose intolerance, particularly hypoglycemia in patients with insulin-dependent diabetes.

■ ASCITES AND SPONTANEOUS BACTERIAL PERITONITIS

Patients with cirrhosis fail to maintain normal extracellular fluid volumes secondary to abnormal sodium and fluid retention and an impaired capacity to eliminate water.¹³ Patients usually present with ascites, edema, or both, and most commonly complain of discomfort from abdominal or leg swelling, respiratory difficulties, malaise, anorexia, and weight loss. The development of ascites in patients with cirrhosis is an indication of advanced liver disease and is a poor prognostic sign. Treatment goals for patients with ascites include prevention of serious complications (spontaneous bacterial peritonitis and rupture of an umbilical hernia) and improving the patient's sense of well-being and quality of life by minimizing respiratory difficulties, loss of appetite, and discomfort from abdominal distention or leg swelling.⁶² Treatment of ascites is expected to have little effect on survival, however. Pleural effusions are common, and in some cases can be the primary manifestation of the fluid retention. Work-up includes a history and physical exam, laboratory tests to assess liver function, abdominal ultrasound to rule out hepatocellular carcinoma, endoscopy to evaluate esophageal and gastric varices, abdominal paracentesis with analysis of ascitic fluid, and a complete evaluation of circulatory and renal function. Treatment of ascites has risks. Depending on the treatment approach and the goals selected, significant adverse reactions can occur, including electrolyte disturbances, acid-base abnormalities, hepatic encephalopathy, hypovolemia, and renal insufficiency.

Spontaneous bacterial peritonitis (SBP), infection of preexisting ascitic fluid, in the absence of any evidence of a primary intra-abdominal source of infection, is a common complication in patients with ascites, developing in 10% to 25% of patients followed prospectively for at least 1 year.¹³ The incidence of SBP is substantially higher in patients with ascitic fluid protein levels <1 g/dL and with serum bilirubin levels above 2.5 mg/dL.⁶³ Because the antibacterial activity of ascitic fluid is proportional to the level of ascitic fluid protein, patients with low ascitic fluid protein levels are at increased risk of SBP. The pathogenesis of SBP is unknown, but presumably results from hematogenous seeding (cirrhosis permits enteric organisms direct access to the bloodstream via the portosystemic collaterals) of the ascitic fluid that offers a favorable growth medium.⁶⁴ Consequently, most episodes of SBP are caused by gram-negative Enterobacteriaceae, with *Escherichia coli* most commonly isolated. The clinical presentation of SBP can vary from patients who present with all of the signs and symptoms of peritonitis, including fever, leukocytosis, abdominal pain, hypoactive or absent bowel sounds, and rebound tenderness, to those patients who have no signs or symptoms at all. For this reason, a diagnostic paracentesis with analysis of ascitic fluid should be performed in all patients admitted with ascites or in patients with cirrhosis who suddenly deteriorate.^{5,13} Spontaneous bacterial peritonitis is diagnosed when ascitic fluid cell counts show an absolute polymorphonuclear (PMN) leukocyte count of ≥ 250 cells/mm³, a positive ascitic fluid culture is obtained, or a patient with cirrhotic ascites presents with convincing signs or symptoms of infection.⁶⁴

■ MANAGEMENT OF ASCITES AND SPONTANEOUS BACTERIAL PERITONITIS

The following treatment guidelines for the management of adult patients with ascites and spontaneous bacterial peritonitis were developed and approved by the Practice Guidelines Committee of the American Association for the Study of Liver Diseases (AASLD).⁵

■ Ascites

In adult patients with new-onset ascites as determined by physical exam or radiographic studies, abdominal paracentesis should be performed and ascitic fluid analysis should include a cell count with differential and a serum-ascites albumin gradient (SAG). If infection is suspected, ascitic fluid cultures should be obtained at the time of the paracentesis. The SAG can accurately determine whether ascites is a result of portal hypertension or another process. If the SAG is >1.1 g/dL, portal hypertension is present with 97% accuracy.⁵ If the SAG is <1.1 g/dL, with similar certainty the patient does not have portal hypertension. This is important because patients without portal hypertension will not respond to salt restriction and diuretics. The treatment of ascites secondary to portal hypertension is relatively straightforward and includes abstinence from alcohol, sodium restriction, and diuretics. This strategy is effective in approximately 90% of patients. Fifteen percent of patients will respond to dietary sodium restriction alone, and an additional 75% of patients will respond to the addition of diuretics.⁶⁵

1 Abstinence from alcohol is an essential element of the overall treatment strategy. Abstinence from alcohol can result in improvement of the reversible component of alcoholic liver disease and normalize portal pressures in some patients.⁵ Even in those patients with cirrhosis from another cause (e.g., autoimmune hepatitis) abstinence from alcohol can reverse alcohol-related effects and result in substantial improvement of the underlying liver disease. Patients with cirrhosis not caused by alcohol have less reversible liver disease, and by the time ascites is present, given the poor prognosis these patients may be best managed with liver transplantation rather than protracted medical therapy.⁵

Beyond avoidance of alcohol, the primary treatment is salt restriction and oral diuretic therapy. Achieving the desired fluid losses in patients with ascites caused by portal hypertension is directly related to sodium balance, not fluid restriction.⁶⁶ To monitor these patients, evaluation of urinary sodium excretion, utilizing a 24-hour urine collection, is recommended.⁵ However, severe hyponatremia, serum sodium <120 mEq/L, does warrant fluid restriction; rapid correction of asymptomatic hyponatremia (patients with cirrhosis usually are not symptomatic until their serum sodium concentrations are <110 mEq/L) is not recommended.

■ Diuretic Therapy

5 The AASLD practice guidelines recommend that diuretic therapy be initiated with the combination of spironolactone and furosemide. Spironolactone alone was commonly recommended for initial therapy, but clinical trials have demonstrated a 14-day delay in the onset of action, as well as the development hyperkalemia when spironolactone is used alone.⁶⁷ Administering spironolactone in single daily doses is justified based on its pharmacokinetics and helps to improve patient compliance.⁶⁷ If tense ascites is present, paracentesis

should be performed prior to institution of diuretic therapy and salt restriction.⁵ For patients who respond to diuretic therapy, this approach is preferred over the use of serial paracenteses.⁶⁸ In patients with refractory ascites, serial paracenteses may be employed as needed. Albumin infusion postparacentesis is controversial but should be employed for volumes exceeding 5 L.⁶⁸ Laboratory tests for renal function and electrolytes need to be monitored during therapy. Liver transplantation should be considered in patients with refractory ascites. For patients who are not transplant candidates and who fail repeated paracentesis because of loculated ascites, TIPS or peritoneal venous shunts may be considered. Both of these procedures have significant complication rates and are not recommended for the routine treatment of ascites.⁵

■ Spontaneous Bacterial Peritonitis

Patients with documented or suspected SBP should receive broad-spectrum antibiotic therapy, which must adequately cover the three most commonly encountered pathogens: *Escherichia coli*, *Klebsiella pneumoniae*, and *Streptococcus pneumoniae*.^{5,68} Delaying antibiotic therapy while awaiting evidence of a positive ascitic fluid culture is not recommended and can result in overwhelming infection and death.⁵ In some patients, signs and symptoms of infection are present at the bacterascites stage (i.e., signs and symptoms present before the PMN count in the ascitic fluid is elevated⁶⁹). In these patients, signs and symptoms of infection justify empiric antibiotic therapy, regardless of the PMN count in the ascitic fluid.⁶⁹

Cefotaxime or a similar third-generation cephalosporin are considered the drugs of choice.⁵ Cefotaxime is more effective than aztreonam or the combination of ampicillin and tobramycin.¹³ Fluoroquinolone antibiotics provide good activity against the usual pathogens encountered in SBP, excellent oral bioavailability, and high penetration into ascitic fluid. Ofloxacin 400 mg every 12 hours administered orally is equivalent to intravenous cefotaxime in terms of resolution of infection as well as survival.⁷⁰ For many patients, oral ofloxacin therapy offers a simple, cost-effective alternative to intravenous therapy with third-generation cephalosporins. However, intravenous therapy with an agent such as cefotaxime is preferred for severely ill patients, or for patients with gastrointestinal hemorrhage or ileus, because oral bioavailability may be compromised.⁶⁹ Antibiotic therapy should be continued until all signs of infection have resolved and the ascitic fluid PMN count decreases below 250/mm³.⁶⁹ However, in patients who respond clinically to antibiotics, routine follow-up paracentesis is not necessary. A 5-day course of antibiotic therapy was reported to be as efficacious as 10 days of therapy in a randomized trial involving 100 patients with SBP.⁶⁹

Secondary bacterial peritonitis, ascitic fluid infection caused by a treatable intra-abdominal source, can masquerade as SBP and should be considered when multiple or atypical organisms are cultured, a very high ascitic fluid PMN count is seen, or in patients who fail to respond to appropriate antibiotic therapy. Uncomplicated SBP usually responds rapidly to appropriate therapy and the 48-hour PMN count, if obtained, is predictably lower than the initial count.⁶⁴ In this setting a follow-up paracentesis revealing a PMN count that continues to rise despite antibiotic therapy can be helpful in detecting secondary peritonitis.⁵

6 Antibiotic therapy for the prevention of SBP should be considered in all patients at high risk for this complication, including those who have experienced a prior episode of SBP or variceal hemorrhage, and those with low-protein ascites (<1 g/dL). Norfloxacin

400 mg intravenously once daily, or 400 mg every 12 hours orally or by nasogastric tube; ofloxacin 400 mg intravenously once daily; or the combination of ciprofloxacin and amoxicillin-clavulanic acid markedly reduces the risk of SBP as compared to untreated patients in these high-risk groups.⁶⁸ Long-term norfloxacin, 400 mg orally once daily, reduces the risk of recurrent SBP from 70% to 20% at 1 year, primarily by reducing the incidence of SBP caused by gram-negative bacilli from 60% to 3%.⁷¹ However, antibiotic prophylaxis does not prolong survival and it selects resistant organisms that may subsequently cause SBP.^{68,72} Fortunately, episodes of SBP caused by resistant organisms are uncommon.⁷³ Prolonged therapy with ciprofloxacin is a risk factor for fungal infections in patients subsequently undergoing liver transplantation.⁶⁸ Intermittent prophylactic strategies, including ciprofloxacin 750 mg orally once a week, trimethoprim-sulfamethoxazole 1 DS tablet five times a week, or inpatient norfloxacin with discontinuation at discharge, are effective and may be less likely to select resistant organisms.^{5,68,74}

■ TREATMENT RECOMMENDATIONS: ASCITES AND SPONTANEOUS BACTERIAL PERITONITIS

Adult patients admitted to the hospital with new-onset ascites should have an abdominal paracentesis performed to establish the serum-ascites albumin gradient, the ascitic fluid PMN count, and to obtain ascitic fluid cultures. Patients who drink alcohol should be strongly discouraged from further alcohol use. Sodium restriction to 2000 mg/day, together with spironolactone and furosemide, is the mainstay of therapy. Diuretic therapy should be initiated with single morning doses of spironolactone 100 mg and furosemide 40 mg administered orally with the goal of a 0.5-kg maximum daily weight loss. Titrate diuretic therapy using the 100 mg:40 mg ratio, to a maximum daily dose of 400 mg spironolactone and 160 mg furosemide. This combination ratio is used because it usually maintains normokalemia. Fluid restriction, unless the serum sodium is <120 mEq/L, and bed rest are not recommended. Monitor urinary sodium excretion using a 24-hour urine collection, and monitor serum potassium and renal function frequently. Avoid rapid correction of asymptomatic hyponatremia in patients with cirrhosis. If tense ascites is present, a 4- to 6-L paracentesis should be performed prior to institution of diuretic therapy and salt restriction. For patients who respond to diuretic therapy this approach is preferred over the use of serial paracenteses. Discontinue diuretic therapy in patients who experience encephalopathy, severe hyponatremia (serum sodium <120 mEq/L) despite fluid restriction, or renal insufficiency (serum creatinine >2 mg/dL). Serial paracenteses may be considered for patients with refractory ascites with albumin infusion postparacentesis when volumes exceeding 5 L are removed.

Patients with documented SBP, positive ascitic fluid cultures, or ascitic fluid PMN count ≥ 250 cells/mm³, regardless of symptoms, should receive broad-spectrum empiric antibiotic therapy with cefotaxime 2 g every 8 hours, or a similar third-generation cephalosporin. Patients with ascitic fluid PMN counts <250 cells/mm³, but with signs and symptoms of infection (abdominal pain, tenderness, fever, encephalopathy, renal failure, acidosis, or peripheral leukocytosis), should also receive empiric antibiotic treatment with cefotaxime 2 g every 8 hours, or a similar third-generation cephalosporin. Outpatient oral therapy of SBP with fluoroquinolones or amoxicillin-clavulanic acid awaits further clinical trials. Short-term inpatient quinolone therapy should be considered for the prevention of SBP in patients with low-protein ascites (<1 g/dL), variceal hemorrhage, or prior SBP.

TABLE 37–6. Grading System for Hepatic Encephalopathy

| Grade | Level of Consciousness | Personality/Intellect | Neurologic Abnormalities | EEG Abnormalities |
|-------------|--------------------------------------|---|---|--------------------------------|
| 0 | Normal | Normal | None | None |
| Subclinical | Normal | Normal | Psychological only | None |
| 1 | Inverted sleep patterns/ restless | Forgetful, mild confusion, agitation, irritable | Tremor, apraxia, incoordination, impaired handwriting | Triphasic waves (5 cycles/s) |
| 2 | Lethargic, slow responses | Disorientation for time, amnesia, decreased inhibitions, inappropriate behavior | Asterixis, dysarthria, ataxia, hypoactive reflexes | Triphasic waves (5 cycles/s) |
| 3 | Somnolent but rousable, confused | Disorientation for place, aggressive | Asterixis, hyperactive reflexes, Babinski’s sign, muscle rigidity | Triphasic waves (5 cycles/s) |
| 4 | Coma/unrousable | None | Decerebrate | Delta activity, (2–3 cycles/s) |

6 All patients who have survived an episode of SBP should receive long-term antibiotic prophylaxis.⁵

HEPATIC ENCEPHALOPATHY

Although management strategies are similar for both acute and chronic HE, the urgency of treatment interventions and goals of therapy are different.²¹ Patients with subclinical HE often experience only minor motor and attentional deficits and compensate on their own without the need for therapy. Those with more significant deficits that impact activities of daily living can benefit from intervention.¹⁹

The prevalence of clinically apparent HE is unknown; however, between 50% and 80% of patients with cirrhosis demonstrate neurologic dysfunction by electroencephalography or by psychological testing.⁷⁵ To determine the severity of HE, a grading system that relates neurologic and neuromuscular signs can be used (Table 37–6). The pathogenesis of HE is unknown. It is believed to be a multifactorial metabolic/neurophysiologic abnormality.^{19,21}

TABLE 37–7. Portosystemic Encephalopathy: Precipitating Factors and Therapy

| Factor | Therapy Alternatives |
|---------------------------|--|
| Gastrointestinal bleeding | |
| Variceal | Band ligation/sclerotherapy Octreotide |
| Nonvariceal | Endoscopic therapy Proton pump inhibitors |
| Infection/sepsis | Antibiotics Paracentesis |
| Electrolyte abnormalities | Discontinue diuretics Fluid and electrolyte replacement |
| Sedative ingestion | Discontinue sedatives/tranquilizers Consider reversal (flumazenil/ naloxone) |
| Dietary excesses | Limit daily protein Lactulose |
| Constipation | Cathartics Bowel cleansing/enema |
| Renal insufficiency | Discontinue diuretics Discontinue NSAIDs, nephrotoxic antibiotics Fluid resuscitation |

MANAGEMENT OF HEPATIC ENCEPHALOPATHY

Acute HE usually develops in a clinically stable cirrhotic patient as the result of an acute precipitating event.¹⁹ Table 36–7 lists the most commonly encountered precipitating factors and suggests general treatment alternatives. Chronic HE, by definition, occurs and persists in the absence of precipitating factors. It can occur in patients who have undergone a TIPS procedure or surgical shunting or in patients with advanced cirrhosis. Patients with acute HE have potentially reversible causes of their encephalopathy, whereas patients with chronic HE usually do not. Nevertheless, the mediators of the encephalopathy are the same, justifying similar treatment strategies. The major difference is the need for urgent inpatient intervention for management of the precipitating event in acute HE, and the expectation for normal mentation after recovery. Patients with chronic HE typically exhibit a high prevalence of chronically abnormal mentation.⁷⁵

Table 37–8 describes the treatment goals for patients with HE and contrasts the differences between acute and chronic HE. The general approach to the management of HE is to first identify and treat any precipitating factors, which often results in prompt resolution of the encephalopathy. The development of mental status changes in cirrhosis is associated with increased morbidity and mortality.¹⁹ However, universal treatment of patients with subclinical HE is not recommended because the consequences of motor and attention deficits are considered minor, and prevention of progression to more severe HE has not been studied.¹⁹

Treatment approaches for HE evolve from the various hypotheses advanced to explain the pathogenesis of HE and include: (a) reducing ammonia blood concentrations by dietary restrictions and drug therapy aimed at inhibiting ammonia production or enhancing its removal; (b) inhibition of the γ -aminobutyric acid

TABLE 37–8. Treatment Goals: Acute and Chronic HE

| Acute HE | Chronic HE |
|--|--|
| Control precipitating factor | Reverse encephalopathy |

(GABA)-benzodiazepine receptors by flumazenil; and (c) inhibition of false neurotransmitters by optimizing amino acid balance.^{17,19}

■ Hyperammonemia

Despite criticisms of the ammonia hypothesis, treatment interventions to reduce ammonia blood concentrations are beneficial in patients with HE.¹⁹ Decreasing ammonia blood concentrations by limiting its availability and production, or by enhancing its metabolism, remains a mainstay of therapy for patients with both acute and chronic HE.¹⁹

Decreasing ammonia blood concentrations can be attempted by reducing ammonia production or by decreasing the availability of ammonia in the colon. Limiting dietary protein acutely usually results in a lowering of ammonia concentrations and improvement in HE.

Guidelines for nutritional support of patients with liver disease have been published by the European Society for Parenteral and Enteral Nutrition. Protein is added back to the diet initially with 0.5 to 0.6 g/kg per day and advanced by 0.25 to 0.5 g/kg per day every 3 to 5 days until a target of 1 to 1.5 g/kg per day is reached or progression of HE occurs.⁷⁶ Vegetable-source protein may be preferable to animal-source protein because it contains fewer aromatic amino acids, which are implicated in generating false neurotransmitters (see below). Also, the higher fiber content of vegetable protein increases colonic transit time and lowers colonic pH secondary to its fermentation by colonic bacteria.⁷⁶ In patients with chronic HE, dietary therapy with restricted protein should be used in an attempt to prevent malnutrition and prevent exacerbation of HE. Protein intolerance is a common problem in patients with chronic liver disease and HE.^{19,77} Bowel cleansing using cathartics or lactulose enemas (see below) results in rapid removal of ammonia substrate from the colon.

The use of lactulose, a nonabsorbable disaccharide, (and lactitol, not available in the United States) is standard therapy for both acute and chronic HE.^{19,78} Lactulose, when administered orally, passes through the gastrointestinal tract and reaches the colon unchanged. For patients unable to take lactulose orally or via tube administration it may be administered as an enema. In the colon, lactulose lowers colonic pH and exerts a cathartic effect. Fermentation of lactulose by bacteria present in the colon results in the production of organic acids, decreasing colonic pH to approximately 5.¹⁷

Urease-producing bacteria metabolize dietary protein and endogenous protein substrates (epithelial cells), producing ammonia. Acidification of the colon inhibits the viability of these urease-producing bacteria (and may promote the growth of non-urease-producing lactobacilli) decreasing the absorption of ammonia. Acidification also enhances the net movement of ammonia from the blood into the bowel.¹⁷ The cathartic effect of lactulose then eliminates the ammonia and protein substrates, inhibiting ammonia production.⁷⁸ More than 30 clinical trials have demonstrated the efficacy of lactulose in the management of acute HE, and more than 20 studies support its use in chronic HE.²³ Clinical improvement is noted in approximately 86% of patients with acute HE, and in approximately 77% of patients with chronic HE.

Inhibiting the activity of urease-producing bacteria by using neomycin, metronidazole, or vancomycin can decrease production of ammonia.¹⁷ Neomycin at doses of 2 to 8 g daily in divided oral doses results in clinical improvement in as many as 80% of patients.⁷⁷ At these doses, however, absorption is 1% to 5% and can result in irreversible ototoxicity and nephrotoxicity.⁷⁹ As such, even though efficacy is equivalent to lactulose, neomycin should not be first-line therapy. Metronidazole produces response rates similar to neomycin, but side effects, particularly gastrointestinal, limit its use.¹⁷ In patients

with an inadequate response to lactulose alone, combination therapy with neomycin may provide additive effects and improved clinical response.¹⁷

Decreasing ammonia production by replacement of urease-producing bacteria in the colon with non-urease-producing strains has been attempted with the oral administration of *Lactobacillus acidophilus* and *Enterococcus faecium*.⁸⁰ The data supporting this therapy are limited, especially for patients with acute HE. However, for patients with less severe HE, *Enterococcus faecium* was as effective as lactulose, treatment effects persisted during drug-free periods, and no adverse effects were reported.⁸⁰ Ammonia generated by *H. pylori* in the stomach has been associated with precipitating or worsening HE in patients with cirrhosis.⁸¹ Routine eradication of *H. pylori* is recommended in patients with cirrhosis and a history of HE.^{17,19}

Enhancing ammonia removal by stimulating its detoxification by supporting alternative metabolic pathways can reduce blood ammonia concentrations. Centrilobular periportal hepatocytes responsible for ammonia metabolism via ureagenesis are impaired in patients with cirrhosis.⁸² L-Ornithine L-aspartate enhances ureagenesis and results in reductions in ammonia concentrations and clinical benefits in patients with grade 1 and grade 2 HE. Clinical response rates similar to those of lactulose were reported in one trial involving patients with chronic HE.⁸³ Studies in patients with more severe HE are needed.

Zinc deficiency is common in patients with cirrhosis and has been reported to cause overt HE.⁸⁴ Zinc is a required cofactor for ammonia metabolism; two of the five metabolic pathways are zinc dependent. Both supportive and nonsupportive studies evaluating the efficacy of zinc replacement have been published.¹⁷ In a controlled trial in cirrhotic patients with mild HE, the administration of zinc sulfate 600 mg/day for 3 months resulted in increased urea formation and lower ammonia levels, along with improvement in psychological test scores.⁸⁵ Zinc supplementation is recommended for long-term management in patients with cirrhosis who are zinc deficient.^{17,19}

■ Inhibition of γ -Aminobutyric Acid-Benzodiazepine Receptors

The GABA-receptor complex, the primary inhibitory neural network within the central nervous system, is associated with HE.^{17,19} This receptor complex is composed of a GABA-binding site, and a benzodiazepine receptor site, which mediate chloride conductance. Based on evidence of an increase in benzodiazepine receptor ligands in patients with hepatic encephalopathy, flumazenil has been evaluated in uncontrolled studies and has demonstrated significant clinical improvement, with one case report documenting long-term benefit.⁸⁶ In these reports, discontinuation of flumazenil resulted in prompt clinical deterioration.

Among five prospective, placebo-controlled trials, three reported benefit with flumazenil, whereas two found no difference when compared to placebo. With dosages of 0.2 to 15 mg IV, response rates were variable, ranging from 17% to 78%; improvements, however, were often transient.⁸⁷ Flumazenil, which is only available in an intravenous dosage form, may be considered for short-term therapy in refractory patients, but cannot be recommended for routine clinical use.

CLINICAL CONTROVERSY: USE OF BRANCHED-CHAIN AMINO ACIDS

A great deal of controversy surrounds the issue of whether or not exogenous protein rich in branched-chain amino acids

(BCAAs) is superior to standard protein solutions that are higher in aromatic amino acids (AAAs).¹⁹ Metabolism of AAAs into false neurotransmitters that penetrate the blood-brain barrier (which itself may be perturbed in patients with HE) has been implicated as a cause of HE.⁸⁸ A number of clinical trials have evaluated the use of BCAAs in the treatment of HE, with conflicting results. Reviews of these trials have also arrived at different conclusions.^{19,88,89} BCAAs may have a role in the malnourished patient with cirrhosis who is intolerant of protein supplementation, but the current data do not justify routine use of BCAAs for the treatment of HE.¹⁹ Impairment of dopaminergic transmission has also been proposed to cause HE, but trials with bromocriptine and levodopa failed to provide any benefit and are not recommended.¹⁷

■ TREATMENT RECOMMENDATIONS: HEPATIC ENCEPHALOPATHY

Treatment recommendations depend on the type of HE being managed, acute HE, chronic HE, or subclinical HE. The general approach to the management of HE is to first identify patients with acute HE and then to provide aggressive management of any precipitating events (see Table 36–7). When the precipitating event has been discovered and appropriate therapy initiated, then steps to rapidly reverse the encephalopathy should be implemented. Remember that the altered sensorium associated with HE itself is associated with increased morbidity and mortality.

➤ The mainstay of therapy of HE involves measures to lower blood ammonia concentrations, and includes diet therapy, lactulose, and antibiotics, alone or in combination with lactulose. Other adjunctive therapies include zinc replacement.

In patients with acute HE, protein is withheld or limited to 10 to 20 g/day while maintaining the total caloric intake, until the clinical situation improves. Titrate protein based on tolerance, increasing intake in increments of 10 to 20 g/day every 3 to 5 days to a total of 0.8 to 1 g/kg per day. In patients with chronic HE, restrict protein to 40 g/day. Consider the addition of dietary fiber to animal-source protein diets.

In acute HE, lactulose is initiated at a dose of 45 mL orally every hour (or by retention enema, 300 mL lactulose syrup in 700 mL water, held for 30 to 60 minutes) until catharsis begins. The dose is then decreased to 15 to 45 mL orally every 8 to 12 hours (enemas every 6 to 8 hours) and titrated to produce two to four soft, acidic stools per day. In patients with chronic HE, lactulose may be initiated at a dose of 30 to 60 mL/day with titration to the same endpoint. Monitor electrolytes periodically, follow patients for changes in mental status, and titrate to the number of stools as above.

Antibiotic therapy with either metronidazole or neomycin is reserved for patients who have not responded to diet and lactulose therapy, where the combination may provide additive effects and improved clinical response. Zinc supplementation at a dose of 600 mg/day is recommended for long-term management in patients with cirrhosis who are zinc deficient.

Other adjunctive therapies that may be considered for patients refractory to standard therapy include eradication of *H. pylori* in patients with cirrhosis and a history of HE, administration of *Lactobacillus acidophilus*, L-ornithine L-aspartate, or flumazenil 0.2 mg up to 15 mg IV. Universal treatment of patients with subclinical HE is not recommended; however, therapy to improve performance of daily activities, or in patients with more significant deficits, may be considered with

close monitoring for adverse effects. Finally, supportive measures to manage the underlying liver failure need to be implemented.

■ SYSTEMIC COMPLICATIONS

In addition to the more common complications of chronic liver disease discussed above, a number of other complications can occur, including hepatorenal syndrome, hepatopulmonary syndrome, coagulation disorders, and endocrine dysfunction.

Hepatorenal syndrome, functional renal failure in the setting of cirrhosis in the absence of intrinsic renal disease, occurs in patients with cirrhosis as a result of intense vasoconstriction within the renal cortical vasculature. It is common and develops in approximately 40% of patients with cirrhosis and ascites within 5 years.⁹² The resultant reduction in blood supply to the kidneys causes avid sodium retention and oliguria. The vasoconstriction that occurs in the kidneys is in stark contrast to the state of systemic vasodilation that is characteristic of chronic liver failure.⁹⁰ The pathophysiologic mechanism responsible for these effects is unknown, but is linked to the systemic vasodilation, hypovolemia, and hyperkinetic circulation seen in chronic liver failure.^{91,92}

Management of hepatorenal syndrome consists of excluding all other potential nephrotoxins such as nonsteroidal anti-inflammatory agents and aminoglycosides, and assessment for prerenal azotemia secondary to overaggressive diuretic use. Withholding diuretic therapy and administering a fluid challenge has been recommended for early diagnosis and therapy.⁹⁰ Case reports describe successful resolution of hepatorenal syndrome with low-dose dopamine (3 to 5 mcg/kg per minute intravenously) and the combination of dopamine and norepinephrine.⁹² Liver transplantation, which if successful results in full recovery of renal function, remains the treatment of choice for refractory hepatorenal syndrome.

Hepatopulmonary syndrome affects 20% to 40% of patients with cirrhosis, and is characterized by alterations in lung mechanics caused by ascites and by intrapulmonary shunting and gas exchange.⁹² These patients present with profound fatigue and dyspnea. In the absence of intrinsic cardiopulmonary disease, cirrhotic patients with these findings should be evaluated for hepatopulmonary syndrome. Physical findings of tense ascites or pleural effusions not associated with pulmonary parenchymal disease are suggestive of hepatopulmonary syndrome. A prompt resolution of symptoms after large-volume paracentesis is characteristic.⁹² Long-term management requires control of ascites (see management of ascites, discussed earlier), supportive therapy with supplemental oxygen, and optimizing fluid status. The prognosis for these patients is poor. Ultimately, liver transplantation offers the best chance for long-term recovery.

Coagulation disorders are common in patients with chronic liver disease. These disorders increase the risk of bleeding and tend to become more profound as the liver failure becomes more severe. Correction of the coagulopathy is essential for patients actively bleeding (see management of variceal hemorrhage, discussed earlier), but is not required for patients who present with only minor symptoms such as bruising or nose bleeds and who are not actively bleeding. The pathophysiology of the coagulopathy is complex and involves abnormalities of platelet function, clotting factor deficiencies, and fibrinolysis.⁹³ Acute therapy involves platelet transfusions for thrombocytopenia, and fresh frozen plasma for prolongation of the prothrombin time because of clotting factor deficiencies. Long-term management of cirrhotic patients with identified coagulopathies is supportive for the

management of the underlying cause of cirrhosis; for example, encouraging abstinence from alcohol.

The presence of cirrhosis can produce abnormal regulation and function of multiple endocrine systems.⁹² Most common are feminization and hypogonadism, and hypothyroidism. Cirrhosis perturbs the hypothalamic-pituitary-axis, which is required for normal regulation of sex and thyroid hormones. In men with cirrhosis, testosterone levels are depressed, while estrogen levels are increased. The clinical manifestations of these changes include loss of libido, muscle wasting, and gynecomastia. These clinical findings are commonly seen and have been reported to occur in up to 60% of cirrhotic patients.⁹² In women, feminization changes are less well studied. Alcohol use complicates and can worsen sex hormone abnormalities.

Both central and peripheral defects in thyroid secretion are noted in patients with cirrhosis. Alcohol plays a major role with direct toxic effects on the thyroid gland. Management includes thyroid hormone

replacement for hypothyroidism with the usual doses (levothyroxine 50 to 100 mcg/day) and testosterone replacement (testosterone 200 mg three times daily) may be attempted to improve libido, well-being, and gynecomastia. Routine hormone replacement has not been shown to impact survival or disease progression.⁹²

■ LIVER TRANSPLANTATION

The complications seen in patients with chronic liver disease are essentially functional as a secondary effect of the circulatory and metabolic changes that accompany liver failure. Consequently, liver transplantation is the only treatment that can offer a cure for complications of end-stage cirrhosis. However, patient selection, evaluation, and pre- and postsurgical management are beyond the scope of this review. Refer to Chap. 87 on transplantation.

PHARMACOKINETIC AND PHARMACODYNAMIC CHANGES IN LIVER FAILURE

The liver plays a major role in the absorption, biotransformation, and elimination of many drugs. In addition, patients with cirrhosis may exhibit pharmacodynamic changes with increased sensitivity to the effects of certain drugs.⁹⁴ These pharmacodynamic changes are separate and distinct from the enhancement of drug effects seen in these patients as a result of the altered serum concentrations of both total and free drug that occur because of the pharmacokinetic changes in these patients. Hepatic drug clearance is primarily dependent upon protein binding, hepatic blood flow, and intrinsic hepatic metabolic activity.⁹⁵ The pathophysiologic changes that occur in patients with cirrhosis, including reduced liver blood flow, altered microcirculatory distribution of blood flow within the liver, diminished metabolic and synthetic function, and changes in the endothelial lining of the sinusoids, can have a significant impact on each of these factors. The consequence of these changes is a reduction in intrinsic metabolic activity, a reduction in the delivery of blood to the liver that decreases clearance and prolongs half-life, and a reduction in the degree of protein binding that increases the fraction of unbound drug in the serum. Finally, patients with cirrhosis frequently accumulate large amounts of interstitial fluid resulting in substantial changes in the volume of distribution, which also prolongs drug half-life. These changes occur most commonly in combination in patients with cirrhosis and are dynamic throughout the disease course. The effect that these changes will have depends on the drug and the type of biotransformation that the drug undergoes.

Drugs with a high extraction ratio (high-extraction drugs) are dependent on blood flow for metabolism and the rate of metabolism will be sensitive to changes in blood flow. Drugs with a low extraction ratio (low-extraction drugs) are dependent on intrinsic metabolic activity for metabolism and the rate of metabolism will reflect changes in intrinsic clearance.⁹⁵ Furthermore, hepatic biotransformation involves two types of metabolic processes: phase I reactions and phase II reactions. Phase I reactions involve the cytochrome P450 system and include hydrolysis, oxidation, dealkylation, and reduction reactions. Phase II reactions involve conjugation of the drug with an endogenous molecule such as sulfate or an amino acid, rendering it more water soluble and enhancing its elimination. Drugs metabolized by phase I reactions, especially oxidation, tend to be significantly impaired in patients with cirrhosis, whereas drugs eliminated by conjugation are relatively unaffected.⁹⁶

The variability and complexity of the interaction between the extent and severity of liver disease and individual characteristics of the drug makes it very difficult to predict the degree of pharmacokinetic perturbation in an individual patient. Unfortunately, there are no sensitive and specific clinical or biochemical markers that allow us to quantify the extent of liver insufficiency or the degree of metabolic activity. In addition, renal insufficiency and alterations that commonly accompany cirrhosis further complicate empiric dosing recommendations in these patients.⁹² Most of the studies conducted to assess the effects of liver disease on pharmacokinetics have included only patients with Child-Pugh grades of A (mild cirrhosis) or B (moderate cirrhosis).⁹⁵ Dosing recommendations are most commonly nonspecific, with recommendations labeled for patients with mild to moderate liver impairment. Dosing information for patients with more severe liver impairment is not available. As a result, when patients with cirrhosis require therapy with drugs that undergo hepatic metabolism (e.g., benzodiazepines), monitoring response to therapy and anticipating drug accumulation and enhanced effects is essential. In the case of benzodiazepines, selection of an agent such as lorazepam, an intermediate-acting agent that is metabolized via conjugation and has no active metabolites, is easier to monitor than a drug such as diazepam, a long-acting benzodiazepine that is oxidized in the liver and has an active metabolite with a long half-life of its own.

A number of publications provide up-to-date analyses of the pharmacokinetic and pharmacodynamic considerations in patients with liver disease and provide the most recent data on individual drug-dosing recommendations.^{97–99}

PHARMACOECONOMIC CONSIDERATIONS

Cost-benefit and cost-effectiveness analysis were highlighted as shortcomings of clinical trials in the field of cirrhosis.⁵³ However, a number of issues relating to drug therapy of cirrhosis have been studied. The cost-effectiveness of long-term antibiotic prophylaxis for the prevention of SBP, especially for high-risk patients as determined by simple laboratory analysis (serum bilirubin and ascitic fluid protein levels) was found to provide significant cost savings.¹⁰⁰ In a comparison of propranolol, sclerotherapy, and shunt surgery for prophylaxis against the first variceal bleed, propranolol was the only cost-effective alternative.¹⁰¹ Because treatment approaches for patients with cirrhosis can range from supportive medical therapy, to repeated endoscopic procedures with serious complications, to liver transplantation, the need for application of economic analysis is obvious. Of critical

TABLE 37–9. Management Approach and Outcome Assessments

| Complication | Treatment Approach | Monitoring Parameter | Outcome Assessment |
|-----------------------------------|--|---|---|
| Ascites | Diet, diuretics, paracentesis, TIPS | Daily assessment of weight | Prevent or eliminate ascites and its secondary complications |
| Spontaneous bacterial peritonitis | Antibiotic therapy, prophylaxis if undergoing paracentesis | Evidence of clinical deterioration (e.g., abdominal pain, fever, anorexia, malaise, fatigue) | Prevent/treat infection to decrease mortality |
| Variceal bleeding | Pharmacologic prophylaxis | Child-Pugh score, endoscopy, CBC | Appropriate reduction in heart rate and portal pressure |
| | Endoscopy, vasoactive drug therapy (octreotide), sclerotherapy, volume resuscitation, pharmacologic prophylaxis | CBC, evidence of overt bleeding | Acute: control acute bleed Chronic: variceal obliteration, reduce portal pressures |
| Coagulation disorders | Blood products (PPF, platelets), vitamin K | CBC, prothrombin time, platelet count | Normalize PT time, maintain/improve hemostasis |
| Hepatic encephalopathy | Ammonia reduction (lactulose, cathartics), elimination of drugs causing CNS depression, limit excess protein in diet | Grade of encephalopathy, EEG, psychological testing, mental status changes, concurrent drug therapy | Maintain functional capacity, prevent hospitalization for encephalopathy, decrease ammonia levels, provide adequate nutrition |
| Hepatorenal syndrome | Eliminate concurrent nephrotoxins (NSAIDs), decrease or discontinue diuretics, volume resuscitation, liver transplantation | Serum and urine electrolytes, concurrent drug therapy | Prevent progressive renal injury by preventing dehydration and avoiding other nephrotoxins |
| | | | Liver transplantation for refractory hepatorenal syndrome |
| Hepatopulmonary syndrome | Paracentesis, O ₂ therapy | Dyspnea, presence of ascites | Acute: relief of dyspnea and hypoxia Chronic: manage ascites as above |

CBC, complete blood cell count; CNS, central nervous system; EEG, electroencephalogram; PT, prothrombin time; NSAID, nonsteroidal anti-inflammatory drug; PPF, plasma protein fraction; TIPS, transjugular intrahepatic portosystemic shunt.

importance to this question is when in the course of chronic liver disease are the various treatment interventions employed. Should liver transplantation be attempted earlier, avoiding most if not all of the complications discussed in this chapter, and would it prove to be the most cost-effective approach?

EVALUATION OF THERAPEUTIC OUTCOMES

Table 37–9 summarizes the management approach for patients with cirrhosis, including monitoring parameters and therapeutic outcomes. Cirrhosis is generally a chronic progressive disease that requires aggressive medical management to prevent or delay common complications. Table 37–9 lists monitoring criteria that need to be carefully followed in order to achieve the maximum benefit from the medical therapies employed and prevent adverse effects. A therapeutic plan including therapeutic endpoints for each medical and diet therapy needs to be developed and discussed with the patient.

ABBREVIATIONS

AAA: aromatic amino acid
 AASLD: American Association for the Study of Liver Diseases
 ALT: alanine transaminase
 AST: aspartate transaminase
 BCAA: branched-chain amino acid
 EBL: endoscopic band ligation
 EGD: esophagogastroduodenoscopy
 EIS: endoscopic injection sclerotherapy
 ERCP: endoscopic retrograde cholangiopancreatography
 GABA: γ -aminobutyric acid

GGT: γ -glutamyl transpeptidase
 HE: hepatic encephalopathy
 PHT: portal hypertension
 PMN: polymorphonuclear leukocyte
 SAG: serum-ascites albumin gradient
 SBP: spontaneous bacterial peritonitis
 TIPS: transjugular intrahepatic portosystemic shunt

DRUG-INDUCED LIVER DISEASE

William R. Kirchain and Mark A. Gil

Learning Objectives and other resources can be found at www.pharmacotherapyonline.com.

KEY CONCEPTS

- 1 Drug-induced liver disease occurs as several different clinical presentations: idiosyncratic reactions, allergic hepatitis, toxic hepatitis, chronic active toxic hepatitis, toxic cirrhosis, and liver vascular disorders.
- 2 The mechanisms of drug-induced liver disease are diverse, representing many phases of biotransformation, and are susceptible to genetic polymorphism.
- 3 The assessment of a possible liver injury due to drugs should include what is known in the literature, the timing involved, the clinical course, and always an exploration for pre-existing conditions that may have encouraged the lesion's development.
- 4 Liver enzyme assays can help determine if a particular type of liver damage is present.
- 5 Monitoring for drug-induced liver disease must be tailored to the drug and the patient's potential risk factors.

The number of drugs associated with adverse reactions involving the liver is extensive.¹ One of the more common reasons for the withdrawal of a drug from the marketplace is an elevation of liver enzymes.² Alcohol-induced liver disease is the most common type of drug-induced liver disease. All other drugs together account for less than 10% of patients hospitalized for elevated liver enzymes.³ In approximately 75% of these cases liver transplantation is ultimately required for patient survival.² The liver's function affects almost every other organ system in the body. It is important to know the patterns of drug-related pathology in order to assess adverse reactions when they occur. It is also important to understand how and when to monitor for these reactions.

PATTERNS OF DRUG-INDUCED LIVER DISEASE

IDIOSYNCRATIC REACTIONS

2 For some drugs, a genetic or acquired abnormality must exist in a particular metabolic pathway for a toxic reaction to take place (Fig. 38–1).² In other cases, the reactions are typically associated with a drug concentration and often respond to simply lowering the dose of the drug. Idiosyncratic reactions tend to occur without association to particular blood concentrations or specifically identified metabolic abnormalities. For example, sulfonylureas like glipizide and antibiotics like ciprofloxacin have caused severe liver disease, resulting in the need for transplantation in a very small group of patients.^{4,5} Idiosyncratic reactions are rare and are sometimes described as liver hypersensitivity to a drug.

ALLERGIC HEPATITIS

1 Allergic reactions in the liver can be caused by many drugs and result in many different kinds of hepatic damage. Trimethoprim-sulfamethoxazole and penicillinase-resistant penicillins such as

dicloxacillin induce a reaction typical of hepatic hypersensitivity in a few patients. The reaction usually develops within 4 weeks of the start of therapy.^{6,7} It is marked by fever, pruritus, rash, eosinophilia, arthritis, and hemolytic anemia. The formation of granulomas within the liver is often seen on biopsy.⁸ The reaction reverses with discontinued therapy and reappears upon rechallenge. Most antibiotics have been associated with this type of reaction, including the fluoroquinolones, macrolides, and β -lactams.³ Allopurinol also has been associated with a number of reports of hypersensitivity reactions involving the liver. The onset of symptoms is 1 to 6 weeks after initiation of therapy. The incidence, like all the allergic liver reactions, is low, estimated at less than 1%. The clinical presentation includes eosinophilia, fever, rash, and arthritis, as previously mentioned. The biopsy may show a pattern of fibrin-ring granulomas similar to those seen in Q fever.⁹

TOXIC HEPATITIS

1 Toxic reactions are predictable, often dose-related effects in the liver due to specific agents. When taken in overdose, acetaminophen becomes bioactivated to a toxic intermediate known as *N*-acetyl-*p*-benzoquinone imine (NAPQI). NAPQI is very reactive, with a high affinity for sulfhydryl groups. The amino acid glutathione provides a ready source of available sulfhydryl groups within the hepatocyte. When the liver's glutathione stores are depleted and there are no longer sulfhydryl groups available to detoxify this metabolite, it begins to react directly with the hepatocyte (see Fig. 38–1). Replenishing the liver's sulfhydryl capacity through the administration of *N*-acetylcysteine early after ingestion of the overdose halts this process.¹⁰ Acetaminophen's toxicity occurs in four stages.¹¹ During the first hours after ingestion, some patients report mild symptoms of nausea and vomiting, but no elevations of the commonly measured liver enzymes are seen. Not for 40 to 50 hours after ingestion do elevations in the liver enzymes begin.¹¹

FIGURE 38-1. A general diagram of biotransformation. (1) The drug is actively transported into the hepatocyte by the organic anion transport pump, a transmembrane protein. (2) The metabolite (drug) interacts with one of a number of enzymes, the most common being CYP3A4. The CYPx family of phase I enzymes are regulated by the complementary DNA xenobiotic receptor. The xenobiotic receptor is in turn upregulated by other drugs, changes in cholesterol catabolism, and bile acids. (3) The immediate result of the action of the phase I enzyme is the production of an unstable metabolite. (4) The unstable metabolite then reacts with glucuronidase, various transferases, or hydroxylases to form a conjugated metabolite. The efficacy of these enzymes is affected by the patient's nutritional state and genetic polymorphism, leading to variations in individual risk for toxicity. (5) The conjugated metabolite is removed from the hepatocyte by the canaliculus membrane export pump, one of a large family of membrane proteins (other members of this family pump conjugated metabolites back into the blood for excretion by the kidney). These proteins are subject to genetic polymorphism as well, again leading to some patients having an increased risk for toxicity. (6) If unable to form a conjugate, the unstable metabolite can participate in oxidative reactions that damage lipids, proteins, or even DNA. (7) Alternatively the unstable metabolite may form damaging covalent bonds with available anions or cations.

Reye's syndrome is an aggressive form of toxic hepatitis often associated with aspirin use in children. Valproate toxicity can also present in this pattern. Early in the process of Reye's syndrome, mitochondrial dysfunction leads to the depletion of acyl coenzyme A and carnitine. Fatty acids accumulate and gluconeogenesis is impaired, resulting in hypoglycemia. A concurrent disruption of the urea cycle occurs, leading to a decrease in the removal of ammonia and a slowing of protein use. A threefold rise in the blood ammonia level and an increase in the prothrombin time are common findings. In advanced stages of Reye's syndrome, many patients develop intracranial hypertension that can be life threatening and refractory to therapy.^{12,13}

CHRONIC ACTIVE TOXIC HEPATITIS

⚠ Dantrolene, isoniazid, phenytoin, nitrofurantoin, and trazodone have been reported in association with a type of autoimmune-mediated disease in the liver.^{14,15} Patients experience periods of symptomatic hepatitis followed by periods of convalescence, only to repeat the experience months later. It is a progressive disease with a high mortality rate and is more common in females than males. Antinuclear antibodies appear in most patients. These drugs appear to form

antiorganelle antibodies.¹⁶ The exact identification of a causative agent is sometimes difficult since diagnosis requires multiple episodes occurring long after exposure to the offending drug.

TOXIC CIRRHOSIS

⚠ The scarring effect of hepatitis in the liver leads to the development of cirrhosis. Some drugs tend to cause such a mild case of hepatitis that it may not be detected. Mild hepatitis can be easily mistaken for a more routine generalized viral infection. If the offending drug or agent is not discontinued, this damage will continue to progress. The patient eventually presents not with hepatitis, but with cirrhosis. Methotrexate causes periportal fibrosis in most patients who experience hepatotoxicity.

The lesion results from the action of a bioactivated metabolite produced by cytochrome P450.¹⁷ This process has most commonly been noted in patients treated for psoriasis and arthritis. The extent of damage can be reduced or controlled by increasing the dosage interval to once weekly or by routine use of folic acid supplements.¹⁸ Vitamin A is normally stored in liver cells, and causes significant

hypertrophy and fibrosis when taken for long periods in high doses. Hepatomegaly is a common finding, along with ascites and portal hypertension. In patients with vitamin A toxicity, gingivitis and dry skin are also very common. This is accelerated by ethanol, which competes with retinol for aldehyde dehydrogenase.¹⁹

LIVER VASCULAR DISORDERS

1 Focal lesions in hepatic venules, sinusoids, and portal veins occur with various drugs. The most commonly associated drugs are the cytotoxic agents used to treat cancer, the pyrrolizidine alkaloids, and the sex hormones. A centralized necrosis often follows and can result in cirrhosis. Azathioprine and herbal teas that contain comfrey (a source of pyrrolizidine alkaloids) are associated with the development of veno-occlusive disease. The exact incidence is rare and may be dose related.³ Peliosis hepatitis is a rare type of hepatic vascular lesion that can be seen as both an acute and a chronic disease. The liver develops large, blood-filled lacunae within the parenchyma. Rupture of the lacunae can lead to severe peritoneal hemorrhage. Peliosis hepatitis has been associated with exposure of the liver to androgens, estrogens, tamoxifen, azathioprine, and danazol. Androgens with a methyl alkylation at the 17 carbon position of the testosterone structure are the most frequently reported agents that cause peliosis hepatitis, usually after at least 6 months of therapy.²⁰

MECHANISMS OF DRUG-INDUCED LIVER DISEASE

CENTROLOBULAR NECROSIS

2 Centrolobular necrosis is often a dose-related, predictable reaction secondary to drugs such as acetaminophen; however, it also can be associated with idiosyncratic reactions, such as those caused by halothane. Also called *direct* or *metabolite-related hepatotoxicity*, centrolobular necrosis is usually the result of the production of a toxic metabolite (see Fig. 38–1). The damage spreads outward from the middle of a lobe of the liver.

Patients suffering from centrolobular necrosis tend to present in one of two ways, depending on the extent of necrosis. Mild drug reactions, involving only small amounts of parenchymal tissue, may be detected as asymptomatic elevations in the serum transaminases. If the reaction is diagnosed at this stage, most of these patients will recover with minimal cirrhosis and thus minimal chronic liver impairment. More severe forms of centrolobular necrosis are accompanied by nausea, vomiting, upper abdominal pain, and jaundice.^{15,21}

STEATOHEPATITIS

2 Steatohepatitis (also known as steatonecrosis) is a specialized type of acute necrosis resulting from the accumulation of fatty acids in the hepatocyte. Drugs or their metabolites that cause steatonecrosis do so by affecting fatty-acid oxidation within the mitochondria of the hepatocyte (see Fig. 38–1). Hepatic vesicles become engorged with fatty acids, eventually disrupting the homeostasis of the hepatocyte. The liver biopsy is marked by a massive infiltration by polymorphonuclear leukocytes, degeneration of the hepatocytes, and the presence of Mallory bodies.³

Alcohol is the drug that most commonly produces steatonecrotic changes in the liver. When alcohol is converted into acetaldehyde, the synthesis of fatty acids is increased.^{19,22} When the hepatocyte has become completely engorged with microvesicular fat, it often breaks open, spilling into the blood. If enough hepatocytes break open, an

inflammatory response begins. If the offending agent is withdrawn before significant numbers of hepatocytes become necrotic, the process is completely reversible without long-term sequelae. In nonalcoholic steatohepatitis the same endpoint is often achieved through oxidation of lipid peroxidases.²³

Tetracycline produces steatohepatitis and steatosis.²⁴ The lesions are characterized by large vesicles of fat found diffused throughout the liver. The development of this reaction is related to the high concentrations achieved when tetracycline is given intravenously and in doses greater than 1.5 g/day. The mortality of tetracycline steatohepatitis is very high (70% to 80%), and those who do survive often develop cirrhosis. Sodium valproate also can produce steatonecrosis through the process of bioactivation. Cytochrome P450 converts valproate to D-4-valproic acid, a potent inducer of microvesicular fat accumulation.²⁵

Patients experiencing steatohepatitis may present with abdominal fullness or pain as their only complaint. Patients with more severe steatonecrosis will present with all the symptoms characteristic of alcoholic hepatitis such as nausea, vomiting, steatorrhea, abdominal pain, pruritus, and fatigue.

PHOSPHOLIPIDOSIS

Phospholipidosis is the accumulation of phospholipids instead of fatty acids. The phospholipids usually engorge the lysosomal bodies of the hepatocyte.²⁶ Amiodarone has been associated with this reaction. Patients treated with amiodarone who develop overt hepatic disease tend to have received higher doses of the drug. These patients also have higher amiodarone to N-desethyl-amiodarone ratios, indicating a greater accumulation of the parent compound. Amiodarone and its major metabolite N-desethyl-amiodarone remain in the liver of all patients for several months after therapy is stopped. Usually the phospholipidosis develops in patients treated for more than 1 year. The patient can present with either elevated transaminases or hepatomegaly; jaundice is rare.^{3,27}

GENERALIZED HEPATOCELLULAR NECROSIS

2 Generalized hepatocellular necrosis mimics the changes associated with the more common viral hepatitis. The onset of symptoms is usually delayed as much as a week or more after exposure to toxin. Bioactivation is often important for toxic hepatitis to develop, but may not be the immediate cause of damage. Many drugs that are associated with toxic hepatitis produce metabolites that are not inherently toxic to the liver. Instead, they act as haptens, binding to specific cell proteins and inducing an autoimmune reaction (see Fig. 38–1).¹⁶

The rate of bioactivation can vary between males and females and between individuals of the same sex.^{28,29} The cytochrome P450 system (CYP) tends to metabolize lipophilic substrates which are actively pumped into the hepatocyte by an organic anion (or cation) transporting protein. The CYP subspecies 1A, 2B, 3A, and 4A are regulated by the highly inducible xenobiotic receptor on complementary DNA. The receptor is found in the liver, and to a lesser extent in the cells lining the intestinal tract, and is responsible for cholesterol catabolism and bile acid homeostasis. The activity of this receptor is subject to genetic polymorphism as well. This results in a wide variation in the sensitivity of the population to generalized hepatocellular necrosis and other forms of hepatic damage.^{23,30}

The long-term administration of isoniazid can lead to hepatic dysfunction in 10% to 20% of those receiving the drug. Yet severe toxic hepatitis develops in only 1% or less of this population.³¹ The

N-acetyltransferase 2 (NAT2) genotype appears to play a role in determining a patient's relative risk. In one study, patients with the slow-type NAT2 genotype had a 28-fold greater risk of developing serum aminotransferase elevations than did patients with the fast-type NAT2 genotype.³² Isoniazid is metabolized by several pathways, acetylation being the major pathway. It is acetylated to acetylisoniazid, which, in turn, is hydrolyzed to acetylhydrazine.³³ The acetylhydrazine, and to a lesser extent the acetylisoniazid, are directly toxic to the cellular proteins in the hepatocyte, but rapid acetylators also detoxify acetylhydrazine very rapidly, converting it to diacetylhydrazine (a nontoxic metabolite).

Ketoconazole produces generalized hepatocellular necrosis or milder forms of hepatic dysfunction in 1% to 2% of patients treated for fungal infections. This reaction is fatal in high numbers of patients infected with the human immunodeficiency virus. The onset is usually early in therapy, although it can be delayed until several months into therapy. In immune-compromised patients in whom ketoconazole is used for long periods of time, special care should be taken to watch for changes in liver function.³⁴

CHOLESTATIC JAUNDICE

2 Cholestatic jaundice, or cholestasis, can be classified by the area of the bile canalicular or ductal system that is impaired. Canalicular cholestasis is very often associated with long-term high-dose estrogen therapy. Clinically, these patients are often asymptomatic and present with mild to moderate elevations of serum bilirubin.³⁵ An intravenous form of vitamin E, α -tocopherol acetate, causes cholestatic jaundice primarily involving the canalicular duct in premature infants. The incidence of this reaction in those receiving this formulation was high (>10%) and the mortality even higher (>50%).³⁶ Hepatocellular cholestasis is a much more serious form of cholestatic jaundice that involves both the parenchyma and bile canalicular cells.

The administration of total parenteral nutrition for periods greater than 1 week induces cholestatic changes and nonspecific enzyme elevations in some patients. Patients with low serum albumin concentrations may be at greater risk than patients with normal serum albumin concentrations.³ This reaction also has been reported to occur rarely with sulfonamides, sulfonylureas, erythromycin estolate and ethylsuccinate, captopril, lisinopril, and other phenothiazines.⁶

MIXED HEPATOCELLULAR NECROSIS AND CHOLESTATIC DISEASE

Patients infrequently present with a purely hepatocellular necrosis or cholestatic damage, but rather with a mixed picture of damage. Flutamide causes a mix of lesions that appear at or about the forty-eighth week of treatment.³⁷ Niacin in doses greater than 3 g/day, or in doses greater than 1 g/day of sustained-release formulations, causes the same mixed pattern of damage.³⁸ These patients often present with only a few signs or symptoms at first, but can progress rapidly to fulminant hepatic failure. Additionally, niacin-induced and other drug-induced mixed hepatocellular disease can be misinterpreted as hepatobiliary cancers.³⁹

NEOPLASTIC DISEASE

A large body of the current literature on adverse reactions and the liver addresses the development of neoplasms following drug therapy. Both carcinoma- and sarcoma-like lesions have been identified. Fortunately, hepatic tumors associated with drug therapy are usually benign and remit when drug therapy is discontinued. Except in rare instances, these lesions are associated with long-term exposure to the offend-

ing agent.⁴⁰ Androgens, estrogens, and other hormonal-related agents are the most frequently associated causes of neoplastic disease. The model for drug-induced hepatic cancer is polyvinyl chloride exposure. Used in the production of many types of plastic products, polyvinyl chloride induces angiosarcoma in exposed workers after as few as 3 years of exposure.⁴¹

ASSESSMENT

3 The best and most important technique for assessing and monitoring drug-induced liver disease is the patient's history. Questions addressing the patient's drug use along with a thorough review of systems are essential. The use of a protocol, such as that proposed by Danan and Benichou, can significantly improve the accuracy of the assessment (Table 38-1).⁴² The use of drugs for recreational purposes must not be overlooked. Cocaine has been directly linked to liver disease.⁴³ Ecstasy, the street name of methylenedioxymethamphetamine, has induced fulminant hepatitis which has led to death in some cases.⁴⁴ The more pervasive impact of street drugs on the incidence of hepatic disease is the concomitant injection or ingestion of adulterants. Many of these adulterants are either directly toxic or serve to enhance the toxicity of the drug.

It is also good to try to determine nondrug hepatic disease risk. Arsenic, for example, is known to induce both acute and chronic hepatic reactions. Arsenic in low concentrations is found in insect-resistant lumber.⁴⁵ Following Occupational Safety and Health Administration guidelines should decrease the danger of using these products, but will not eliminate it. Even if exposure to an environmental toxin in and of itself does not produce a hepatic reaction, it may predispose a patient to a hepatic reaction when a drug is added. Table 38-2 lists some of the more common hepatic toxins found in occupational or environmental exposures that can add to a patient's risk for developing a hepatic lesion.⁴⁵

A person's use of alternative medicine must be solicited. Many herbal remedies were once wisely abandoned because of their common adverse reactions. Comfrey tea is a common cause of hepatocellular damage. As in the case of the Chinese remedy jin bu huan, or as in the case of the more elegantly presented chaparral capsules containing grease wood leaves, the end of therapy with these types of agents is occasionally severe disability or death from fulminant hepatic failure.⁴⁶ Pennyroyal oil, maragosa oil, and clove oil cause a dose-related hepatotoxicity.⁴⁶

The nutritional status of a patient can be as important to the development of a drug-induced liver disease as the hepatotoxin itself.⁴⁷ Patients who are malnourished because of illness or long-term alcohol abuse make up the most troublesome group.⁴⁸ Low serum levels of vitamins E and C along with lutein and the α - and β -carotenes are associated with asymptomatic elevations in transaminases. Conversely, high serum iron, transferrin, and selenium levels are also associated with asymptomatic elevations of transaminases.⁴⁹

All potential drug reactions should be judged as to the timing of the reaction versus drug administration, pharmacokinetic considerations, the information in the literature records about previous reactions, the inclusion of alternative nondrug causes, and close clinical observation when the drug in question is stopped. It is also important to keep in mind that most elevations in liver enzymes will not be associated with a drug. In a study of all patients admitted to a hospital in the United Kingdom with elevated liver transaminase, only 9% cases involved a drug other than alcohol as the possible cause.³ In all cases, titers of serum antibodies to hepatitis A, B, and C should be drawn. Even in cases in which the drug is absolutely targeted as the cause, viral hepatitis may be a complication.

TABLE 38–1. An Approach to Evaluating a Suspected Hepatotoxic Reaction Using a Clinical Diagnostic Scale

| Patient presents with elevated liver enzymes | Score | Component subscore |
|---|-------|--------------------|
| <i>Literature</i> | | |
| Literature supports this drug (drug combination) and pattern of liver enzyme elevation | +2 | — |
| No literature supports this, but the drug has been on the market less than 5 years | +0 | |
| No literature supports this and the drug has been on the market for 5 years or more | –3 | |
| <i>Alternative causes</i> | | |
| Alternative causes (i.e., viral, alcohol, etc.) are completely ruled out | +3 | — |
| Alternative causes are partially ruled out | +0 | |
| Alternative causes cannot be ruled out and are possible or even probable | –1 | |
| <i>Presentation</i> | | |
| The presentation includes 4 or more extrahepatic (fever, malaise, etc.) symptoms | +3 | — |
| The presentation includes 2–3 extrahepatic symptoms | +2 | |
| The presentation includes only 1 identifiable extrahepatic symptom | +1 | |
| The presentation is essentially a laboratory abnormality, with no extrahepatic symptoms | +0 | |
| <i>Temporality</i> | | |
| Temporality: Initiation of drug therapy to onset is 4–56 days | +3 | — |
| Temporality: Initiation of drug therapy to onset is <4 or >56 days | +1 | |
| Temporality: Discontinuance of therapy to onset is 0–7 days | +3 | |
| Temporality: Discontinuance of therapy to onset is 8–15 days | +0 | |
| Temporality: Discontinuance of therapy to onset is >15 days | –1 | |
| | | |
| <i>Rechallenge</i> | | |
| Rechallenge was positive | +3 | — |
| Rechallenge was negative or not attempted | +0 | |
| <i>Total Score</i> | | |
| | | — |

The likelihood that this presentation is an adverse reaction in the liver increases linearly with an increasing score. The maximum score is 14, and scores below 7 are associated with an ever decreasing likelihood that the drug or drug combination in question caused the problem. This approach is not designed for the assessment of hepatic cancers or cirrhotic conditions.

4 Often there is no good clinical test available to determine the exact type of hepatic lesion, short of liver biopsy. There are certain patterns of enzyme elevation that have been identified and can be helpful (Table 38–3).^{50,51} The specificity of any serum enzyme depends on the distribution of that enzyme in the body. Alkaline phosphatase is found in the bile duct epithelium, bone, and intestinal and kidney cells. 5'-Nucleotidase is more specific for hepatic disease than alkaline phosphatase, because most of the body's store of 5'-nucleotidase is in the liver. Glutamate dehydrogenase is a good indicator of centrolobular necrosis because it is found primarily in centrolobular mitochondria. Most hepatic cells have extremely high concentrations of transaminases. Aspartate aminotransferase (AST) and alanine aminotransferase (ALT) are commonly measured. Because of their high concentrations and easy liberation from the hepatocyte cytoplasm, AST and ALT are very sensitive indicators of necrotic lesions within the liver. After an acute hepatic lesion is established, it may take weeks for these concentrations to return to normal.⁵¹

Serum bilirubin concentration is a sensitive indicator of most hepatic lesions and has significant prognostic value. High peak bilirubin concentrations are associated with poor survival. Other important findings that indicate poor survival are a peak prothrombin time greater than 40 seconds, elevated serum creatinine, and low arterial pH. The presence of encephalopathy or prolonged jaundice are not good signs for the survival of the patient and are strong indicators for transplantation.⁵²

Bilirubin concentrations and serum enzyme elevations give a static picture of the liver's condition and are not good indicators of hepatic function. Clinically available tests to predict hepatic function include measurement of serum proteins (albumin or transferrin). As a hepatic function decreases, serum protein concentrations in the body decrease at a rate determined by each protein's own elimination rate. Overhydration and starvation can also decrease serum protein concentrations. Changes in the prothrombin time often occur earlier than the changes in albumin or transferrin. The response of the prothrombin

TABLE 38–2. Environmental Hepatotoxins and Associated Occupations at Risk for Exposure

| Hepatotoxin | Associated Occupations at Risk for Exposure |
|--------------------------------|--|
| Arsenic | Chemical plant, construction, agricultural workers |
| Carbon tetrachloride | Chemical plant workers, laboratory technicians |
| Copper | Plumbers, outdoor sculpture artists, copper foundry workers |
| Dimethylformamide | Chemical plant workers, laboratory technicians |
| 2,4-Dichlorophenoxyacetic acid | Horticulturists |
| Fluorine | Chemical plant workers, laboratory technicians |
| Toluene | Chemical plant, agricultural workers, laboratory technicians |
| Trichloroethylene | Printers, dye workers, cleaners, laboratory technicians |
| Vinyl chloride | Plastics plant workers, also found as a river pollutant |

TABLE 38–3. Relative Patterns of Hepatic Enzyme Elevation versus Type of Hepatic Lesion

| Enzyme | Abbreviations | Necrotic | Cholestatic | Chronic |

time to the administration of 10 mg of parenteral vitamin K is often used to differentiate between hepatic and extrahepatic disease.

MEASUREMENT OF LIVER FUNCTION

A good compound for a liver function test would theoretically be (a) nontoxic and lacking any pharmacologic effect; (b) either rapidly and completely absorbed orally or easily administered via a peripheral vein; (c) eliminated only by the liver; and (d) easily measured (drug and its metabolite) in blood, saliva, or urine.⁵³

Several tests are used in research settings and in liver transplant patients to indicate liver function. Tests such as sulfobromophthalein, indocyanine green, or sorbitol measure qualities of hepatic clearance. There are also a few drugs that have been used to test liver function. Sorbitol's advantage over indocyanine green is a much lower incidence of allergic reactions. It is partially cleared by the kidney, and urine levels must also be determined during the test.⁵⁴ A good estimate of hepatic clearance can be obtained by serial blood levels of a variety of hepatically eliminated drugs if an assay is locally available. Ultrasound and CT imaging can be used on a periodic basis to monitor for the development of fibrosis or vascular lesions in the liver and for hepatocellular carcinomas.⁵⁵

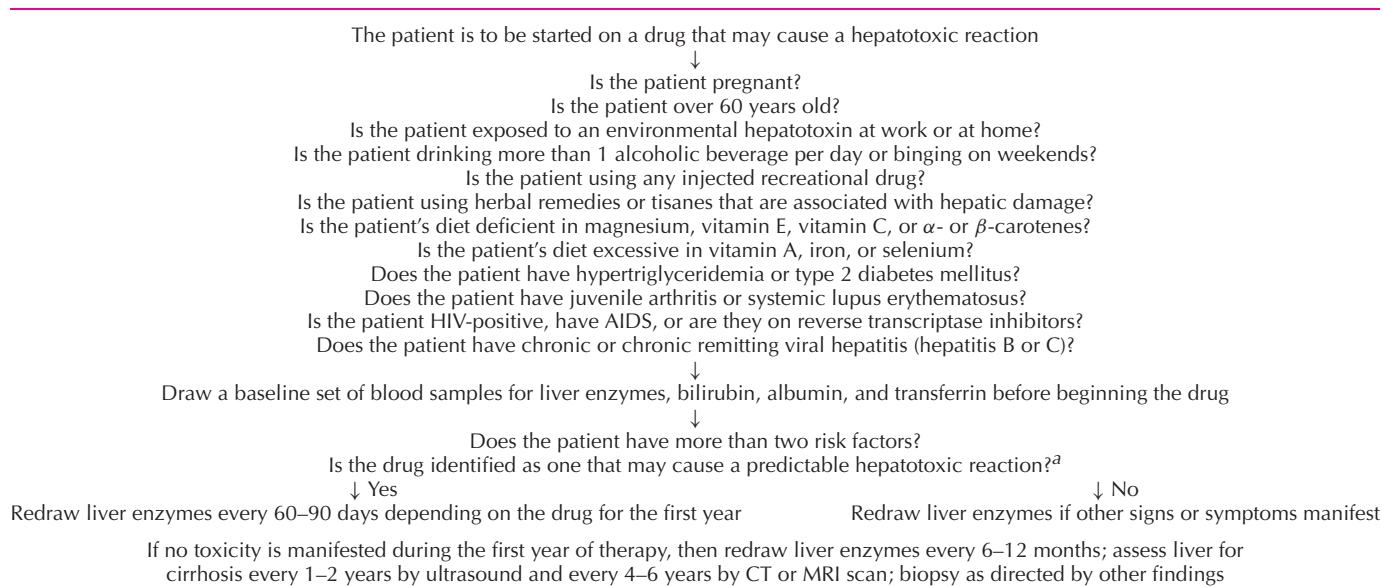

If a liver biopsy has been performed, the injury should be classified by the histologic findings. In cases in which there is no biopsy, the pattern of liver enzyme elevation can estimate the type of injury. Hepatocellular injuries are marked by elevations in transaminase that are

at least two times normal. If the alkaline phosphatase is also elevated, then a hepatocellular lesion is still suspected when the elevation of ALT is notably higher than the elevation of alkaline phosphatase. If the magnitude of elevation is nearly equal between ALT and alkaline phosphatase, then the lesion is likely cholestatic.

A liver injury is acute if it lasts less than 3 months, and it is considered chronic after 3 months of consistent symptoms or enzyme elevation. A liver injury is severe if the patient has marked jaundice, if the prothrombin time does not improve by more than 50% after the administration of vitamin K, or if encephalopathy is detectable. If an acute liver injury progresses from normal to severe in a matter of a few days or weeks, it is considered fulminant.⁵⁶

MONITORING

▶ The serum transaminases AST and ALT are the most commonly used transaminases in the clinical setting. There are often no set rules available for a particular drug. The general guidelines found in Table 38–4 can help in determining a monitoring schedule for drugs where no prior recommendations are published. Concentrations of these enzymes should be obtained about every 4 weeks, depending on the reported characteristics of the reaction in question. Methotrexate should be monitored every 4 weeks, because toxicity usually develops over a period of several weeks to months.⁵⁷ In addition, some recommend that sulfobromophthalein or indocyanine-green excretion

TABLE 38–4. An Approach to Determining a Drug Monitoring Plan to Detect Hepatotoxicity

^aA drug can become a predictable risk if it is administered concurrently with another drug or food that is known to induce or inhibit its metabolism.

studies be performed on a regular basis and that patients treated for very long periods of time should have a liver biopsy performed every 12 months.⁵⁸

ABBREVIATIONS

ALT: alanine aminotransferase
 AST: aspartate aminotransferase
 CYP: cytochrome P450 liver enzyme system
 NAPQI: *N*-acetyl-*p*-benzoquinone imine
 NAT2: *N*-acetyltransferase 2 genotype

PANCREATITIS

Rosemary R. Berardi and Patricia A. Montgomery

Learning Objectives and other resources can be found at www.pharmacotherapyonline.com.

KEY CONCEPTS

ACUTE PANCREATITIS

- 1 Patients with severe acute pancreatitis require early and aggressive intravenous fluid resuscitation.
- 2 Treatment of pancreatitis requires that if at all possible, medications that may potentially cause pancreatitis should be discontinued.
- 3 Use parenteral narcotic analgesics to control abdominal pain. Despite some theoretical advantages, meperidine is not recommended as a first-line agent because of dosing limitations and the risk for seizures in patients with renal failure.
- 4 Ocreotide may be used in severe acute pancreatitis, but its efficacy in decreasing mortality remains uncertain.
- 5 Antibiotics should not be used in the absence of signs of infection except in patients with severe acute pancreatitis when pancreatic necrosis is present.
- 7 Initiate pain control with non-narcotic analgesics such as acetaminophen, nonsteroidal anti-inflammatory agents, or selective cyclooxygenase-2 inhibitors. The dose and frequency of administration should be increased before the patient is switched to a narcotic. Parenteral narcotics should be reserved for patients with severe pain that is unresponsive to oral agents. Patients with frequent or constant pain should receive the lowest effective analgesic dose scheduled around the clock.
- 8 A trial of pancreatic enzymes and acid suppression with either an H₂-receptor antagonist or proton pump inhibitor should be attempted in patients with mild to moderate disease.
- 9 Pancreatic enzyme supplementation and a reduction of dietary fat are used to treat malabsorption and steatorrhea. An initial lipase dose of about 30,000 international units should be given with each meal.

CHRONIC PANCREATITIS

- 6 Abstinence from alcohol is an important factor in preventing abdominal pain in the early stages of alcohol-induced chronic pancreatitis.
- 10 Symptomatic patients whose steatorrhea is not corrected by pancreatic enzyme supplementation and a reduction in dietary fat may benefit from the addition of an H₂-receptor antagonist or a proton pump inhibitor. An H₂-receptor antagonist should be used before trying a proton pump inhibitor.

Pancreatitis is defined as an acute or chronic inflammation of the pancreas with variable involvement of peripancreatic tissues and remote organs.¹ Acute pancreatitis (AP) is characterized by severe pain in the upper abdomen and elevations of pancreatic enzymes in the blood.² AP may be mild or severe based on clinical findings, laboratory tests, and diagnostic imaging studies. Mild AP is usually not associated with complications or organ dysfunction and recovery is uneventful. Severe AP is associated with impaired pancreatic function, local and systemic complications, and increased mortality. About 10% to 15% of patients develop a systemic inflammatory response syndrome and multiple organ failure.¹ Mortality, however, has decreased over the past 20 years, due in part to improved diagnosis, advances in antibiotic therapy, advances in intensive care medical management, and improved nutritional support.³ Although exocrine and endocrine pancreatic function may remain impaired for variable periods after an attack, AP rarely progresses to chronic pancreatitis.^{2,4–6}

Chronic pancreatitis (CP) is characterized by permanent damage to pancreatic structure and function because of progressive inflammation and long-standing pancreatic injury.^{1,7–10} In the early

stages of the disease, recurrent acute symptomatic exacerbations resemble attacks of AP and may not be distinguishable. Most patients with CP have periods of intractable upper abdominal pain, which is the dominant feature. Progressive pancreatic exocrine and endocrine insufficiency leads to maldigestion and diabetes mellitus. CP patients are at an increased risk of developing pancreatic cancer.^{7,8} Patients with AP and CP suffer from many of the same complications.

EPIDEMIOLOGY

The prevalence of pancreatitis varies widely with geographic area, etiologic factors (e.g., alcohol consumption), and environmental or hereditary factors. The overall prevalence of AP in males and females in the United States is estimated to be less than 1%, whereas the prevalence of CP is 0.05% in males and 0.01% in females.⁸ The reported prevalence of AP and CP most likely underestimates the true spectrum of these diseases.⁸ Alcoholic CP is more common in men and has a peak incidence between 35 and 45 years of age. Blacks are two to

three times more likely than whites to be hospitalized for CP than for alcoholic cirrhosis, but the underlying genetic factor remains elusive.⁸

PHYSIOLOGY OF EXOCRINE PANCREATIC SECRETION

The pancreas possesses both endocrine and exocrine functions. The islets of Langerhans, which contain the cells of the endocrine pancreas, secrete insulin, glucagon, somatostatin, and other polypeptide hormones. The exocrine pancreas is composed of acini that secrete about 1 to 2 L/day of isotonic fluid that contains water, electrolytes, and pancreatic enzymes necessary for digestion. Bicarbonate is secreted primarily by the centroacinar (ductular) cells, and is the principal ion of physiologic importance. Pancreatic juice is delivered to the duodenum via the pancreatic ducts (Fig. 39–1) where the alkaline secretion (pH about 8.3) neutralizes gastric acid and provides an appropriate pH for maintaining the activity of pancreatic enzymes.¹¹

The major pancreatic exocrine enzyme groups are:

- Proteolytic: trypsinogen, chymotrypsinogen, procarboxypeptidase, and proelastase
- Amylolytic: amylase
- Lipolytic: lipase, phospholipase A₂, and carboxylesterase lipase
- Nucleolytic: ribonuclease
- Other: trypsin inhibitor and colipase

The proteolytic enzymes are synthesized within the acinar cells and secreted as zymogens (inactive enzymes), which are activated in the lumen of the duodenum. Enterokinase secreted by the duodenal mucosa converts trypsinogen to trypsin, which then activates all other proteolytic zymogens. Two important mechanisms protect the pancreas from the potential degradative action of its own digestive enzymes. The synthesis of proteolytic enzymes as zymogens requires extrapancreatic trigger enzymes for activation. In addition, pancreatic juice contains a low concentration of trypsin inhibitor, which inactivates trypsin and partially inhibits chymotrypsin. Proteolytic activity in the intestinal lumen is not inhibited because the concentration is minimal. Lipase, amylase, and ribonuclease are secreted by the acinar cells in their active form. Colipase facilitates the action of lipase by binding to the bile salt-lipid surface and lowering the optimum pH of lipase from 8.5 to 6.5, the normal luminal pH in the duodenum.¹¹

The regulation of exocrine pancreatic secretion is complex and depends on stimulatory and inhibitory factors exerted through

FIGURE 39–1. Anatomic structure of the pancreas and biliary tract.

hormonal and neuronal mechanisms. Two hormones, secretin (SC) and cholecystokinin (CCK), play an important role in mediating postprandial pancreatic secretion and have synergistic effects: SC stimulates ductular cells to increase water and bicarbonate; CCK stimulates acinar cells to secrete a juice that is low in volume and bicarbonate, but rich in enzyme content. The release of SC from the intestinal mucosa is pH dependent and occurs when the duodenal pH is approximately 4.5. Below this pH, titratable acid in the duodenum governs pancreatic bicarbonate output. Although the postprandial release of SC is small, nonacid factors such as products of fat digestion and bile can also stimulate SC release. The release of CCK from the small intestine depends on the presence of fatty acids and amino acids in the duodenum. Vasoactive intestinal polypeptide is structurally similar to SC and exhibits weak secretin-like effects on exocrine pancreatic secretion. Gastrointestinal peptides such as somatostatin inhibit enzyme secretion by modulating cholinergic transmission. Intestinal serotonin (5-hydroxytryptamine) is released in response to a number of stimuli, including duodenal acidification, and may play a role in postprandial pancreatic secretion.¹¹

There are three phases of pancreatic exocrine secretion: cephalic, gastric, and intestinal. In the fasted state, basal secretion occurs at a low rate; output fluctuates in cycles with the interdigestive migrating motor complex (IMMC), so that peak secretions occur during phase III of the IMMC.¹¹ The cephalic phase is stimulated by the sight and smell of food and is mediated by vagal pathways. Gastric distention and the rate of gastric emptying stimulate an increase in enzyme-rich pancreatic fluid. In the intestinal phase, chyme and acid stimulate pancreatic secretion through the release of SC and CCK. A more in-depth discussion of pancreatic physiology can be found elsewhere.¹¹

ACUTE PANCREATITIS

AP varies from mild disease, which is usually self-limiting, to severe disease, in which the severity of the attack correlates with the degree of pancreatic involvement and complications. The morphologic appearance of the pancreas and surrounding tissue ranges from interstitial edema and inflammatory cells (interstitial pancreatitis) to pancreatic and extrapancreatic necrosis (necrotizing pancreatitis), which has a higher risk of infection, organ failure, and mortality.^{2,4} The rupture of blood vessels within or around the pancreas may lead to a collection of blood in the retroperitoneal spaces.

ETIOLOGY

The etiologic risk factors associated with AP are presented in Table 39–1. Gallstones account for more than 90% of cases worldwide.¹ Although alcohol abuse is often cited as the next most common cause, it is controversial as to whether acute alcoholic pancreatitis occurs in the absence of underlying chronic pancreatic damage. In some patients, a cause cannot be determined (idiopathic pancreatitis). Pregnancy is not considered a cause of AP because pregnant women develop pancreatitis as a result of coincident processes, most commonly cholelithiasis. AP occurs in 5% to 7% of patients who have undergone endoscopic retrograde cholangiopancreatography (ERCP).¹²

MEDICATIONS

Many medications have been implicated in AP, but a causal association is difficult to confirm because ethical and practical considerations prevent rechallenge with the suspected agent.^{4,13–36} Table 39–2 lists medications according to their certainty of causing AP. A “definite” association implies a temporal relationship of drug administration to

TABLE 39–1. Etiologic Risk Factors Associated with Acute Pancreatitis

| | |
|-------------------------|---|
| Structural | Gallstone disease, sphincter of Oddi dysfunction, pancreas divisum, pancreatic tumors |
| Toxins | Alcohol (ethanol) consumption, scorpion venom, organophosphorus insecticides |
| Infectious | Bacterial, viral (including AIDS), parasitic |

abdominal pain and hyperamylasemia, or to a positive response to rechallenge with the offending agent. Suggestive evidence exists for medications with a “probable” association, whereas evidence is inadequate or contradictory for drugs having a “possible” association. Certain medications, such as proton pump inhibitors and histamine₂-receptor antagonists, may be initiated in response to early symptoms of unrecognized pancreatitis. This may have led to erroneously attributing the pancreatitis to these medications.³⁶ Allergic reactions (e.g., urticaria) usually do not accompany drug-induced AP.

The pathogenesis of drug-induced pancreatitis does not appear to differ from other causes of AP. Exactly how medications induce AP is unknown, but postulated mechanisms include immune-mediated inflammatory response, direct cellular toxicity, pancreatic duct

constriction, arteriolar thrombosis, and metabolic effects. It is possible that thiazide diuretics lead to hypotension and pancreatic ischemia. Combination therapy with several medications has also been reported to cause AP.^{26–28} Although AP is an infrequent complication of drug therapy, it is prudent to withdraw medication when an association is suspected. Discussion of the specific medications associated with AP can be found elsewhere.^{13–36}

PATHOPHYSIOLOGY

The pathophysiology of AP is based on events that initiate the injury and secondary events that establish and perpetuate the injury (Fig. 39–2). The premature activation of pancreatic zymogens within the acinar cells, pancreatic ischemia, or pancreatic duct obstruction initiates AP and leads to a series of secondary events that determine the duration and severity of the injury. Trypsinogen autoactivation and trypsinogen activation by the lysosomal enzyme cathepsin B account for the intracellular activation of trypsinogen and the zymogen cascade.^{1,2} Hereditary abnormalities in pathways that protect the pancreas from autodigestion are also associated with an increased risk of pancreatitis.¹ The release of active pancreatic enzymes directly causes local or distant tissue damage, or may enhance inflammation by activating the alternate complement pathway. Trypsin digests cell membranes and leads to the activation of other enzymes within the pancreas. Lipase damages the fat cells, producing noxious substances that cause further pancreatic and peripancreatic injury. The release of cytokines by the acinar cell or the inflammatory cells directly injures the acinar cell and enhances the inflammatory response.^{37,38} Injured acinar cells liberate chemoattractants that attract neutrophils, macrophages, and other cells to the area of inflammation. Vascular damage and ischemia causes the release of kinins, which makes capillary walls permeable and promotes tissue edema. The release of damaging oxygen-free radicals appears to correlate with the severity of pancreatic injury.² Pancreatic infection may result from increased intestinal permeability and translocation of colonic bacteria.

TABLE 39–2. Medications Associated with Acute Pancreatitis

| Definite Association | Probable Association | Possible Association | |
|-----------------------|--|-------------------------------------|-----------------|
| 5-Aminosalicylic acid | Ampicillin | Acetaminophen | Ibuprofen |
| Asparaginase | Angiotensin-converting enzyme inhibitors | Amiodarone | Indomethacin |
| Azathioprine | Bumetamide | Amoxapine | Interleukin-2 |
| Didanosine | Calcium | Angiotensin II receptor antagonists | Isoniazid |
| Estrogens | Chlorthalidone | Carbamazepine | Isotretinoin |
| Furosemide | Cimetidine | Cholestyramine | Ketoprofen |
| Mercaptopurine | Cisplatin | Clarithromycin | Ketorolac |
| Methyldopa | Clozapine | Clonidine | Lipid emulsion |
| Metronidazole | Corticosteroids | Cyclosporine | Mefenamic acid |
| Pentamidine | Cytarabine | Cyproheptadine | Metolazone |
| Sulfonamides | Ethacrynic acid | Danazol | Nitrofurantoin |
| Sulindac | Ifosfamide | Diazoxide | Octreotide |
| Tetracycline | Interferon alfa-2b | Diphenoxylate | Ondansetron |
| Thiazides | Losartan | Ergotamine | Opiates |
| Valproic acid/salts | Meglumine antimoniate | Erythromycin | Oxyphenbutazone |
| | Piroxicam | Famciclovir | Paclitaxel |
| | Procainamide | Glyburide | Penicillin |
| | Salicylates | Gold therapy | Propoxyphene |
| | Sodium stibogluconate | Graniestron | Ranitidine |
| | Zalcitabine | Hepatitis A vaccination | Tryptophan |
| | | | Warfarin |

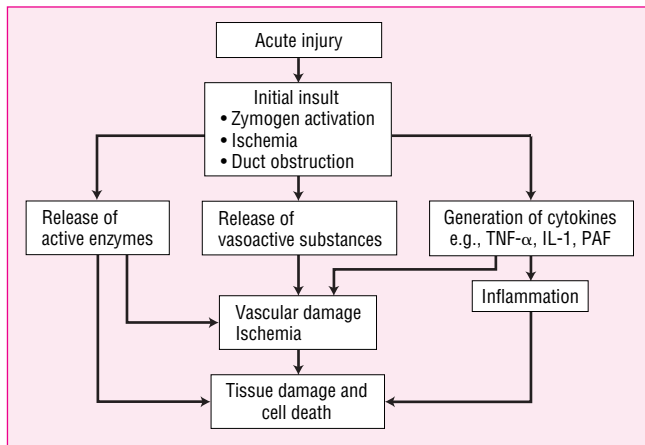

FIGURE 39–2. Pathophysiology of acute pancreatitis: initiating and secondary events. PAF, platelet-activating factor; TNF- α , tumor necrosis factor- α ; IL-1 β , interleukin-1 β ; IL-6, interleukin-6; IL-8, interleukin-8.

COMPLICATIONS

Local complications—including acute fluid collection, pancreatic necrosis, abscess, and pseudocyst (collection of pancreatic juice and tissue debris enclosed by a wall of fibrous or granulation tissue)—develop about 4 to 6 weeks after the initial attack. Pancreatic abscess is usually a secondary infection of necrotic tissue or pseudocysts and correlates with the severity of the pancreatitis. Most deaths result from

infected necrosis and sepsis.^{2,4} Pancreatic ascites occurs when pancreatic secretions spread throughout the peritoneal cavity. Systemic complications include cardiovascular, renal, pulmonary, metabolic, hemorrhagic, and central nervous system abnormalities.² Of the early complications, shock is the main cause of death. Hypotension results from hypovolemia, hypoalbuminemia, the release of kinins, and sepsis. Renal complications are usually caused by hypovolemia. Pulmonary complications develop when fluid accumulates within the pleural space and compresses the lung and the acute respiratory distress syndrome (ARDS) restricts gas exchange. The most common cause of hypoxemia in patients with AP is ARDS. Pleural effusions occur in 4% to 17% of patients with AP and occur more frequently on the left.² Gastrointestinal bleeding occurs secondary to numerous causes including rupture of a pseudocyst. Severe AP is associated with confusion and coma.

CLINICAL PRESENTATION

SIGNS AND SYMPTOMS

The clinical presentation of AP varies depending on the severity of the inflammatory process and whether damage is confined to the pancreas or involves contiguous organs (Table 39–3).^{2,5}

DIAGNOSIS

The definitive diagnosis of AP is surgical examination of the pancreas or pancreatic histology. In the absence of these procedures, the

TABLE 39–3. Presentation of Acute Pancreatitis

General

- The patient may have acute mild symptoms or present with a severe acute attack with life-threatening complications.

Symptoms

- The patient may present initially with moderate abdominal discomfort to excruciating pain, shock, and respiratory distress.
- Abdominal pain occurs in 95% of patients and is usually epigastric, often radiating to either of the upper quadrants or the back. The onset is usually sudden and the intensity is often described as “knife-like” or “boring.” The pain tends to be steady and persists for several days. Repositioning the patient relieves very little of the pain.
- Nausea and vomiting occur in 85% of patients and usually follows the onset of abdominal pain.

Signs

- Marked epigastric tenderness, abdominal distention, hypotension, and low-grade fever are observed with widespread pancreatic inflammation and necrosis.
- In severe disease, bowel sounds are diminished or absent; dyspnea and tachypnea are signs of acute respiratory complications.

Laboratory tests

- Leukocytosis, hyperglycemia, hypoalbuminemia, and mild hyperbilirubinemia may be present, as well as elevations in serum alkaline phosphatase and liver transaminases.
- Dehydration leads to hemoconcentration with elevated hemoglobin, hematocrit, blood urea nitrogen, and serum creatinine concentrations.
- The total serum calcium is usually normal initially, but hypocalcemia out of proportion to the hypoalbuminemia may develop. Marked hypocalcemia is an indication of severe necrosis and a poor prognostic sign.
- Thrombocytopenia and a prolongation in the prothrombin time are seen in some patients with severe AP.
- C-reactive protein is elevated by 48 hours after the onset of symptoms and may be useful in differentiating between mild and severe pancreatitis.

Markers of pancreatic injury

- The serum amylase concentration usually rises within 4 to 8 hours of the initial attack, peaks at 24 hours, and returns to normal over the next 8 to 14 days. Persistent elevations suggest extensive pancreatic necrosis and related complications.
- Serum lipase is specific to the pancreas and concentrations are usually elevated. Because of its longer half-life, elevations of serum lipase can be detected after the serum amylase has returned to normal.

Other diagnostic tests

- The Acute Physiology and Chronic Health Evaluation (APACHE) II score should be calculated upon admission. After 48 hours, use either the APACHE II or Ranson’s criteria.
- Contrast-enhanced computed tomography distinguishes interstitial from necrotizing pancreatitis, but does not distinguish between fat necrosis and acute fluid collection.
- Endoscopic retrograde cholangiopancreatography is used to visualize and remove bile duct stones in patients with gallstone pancreatitis.

TABLE 39–4. Prognostic Indicators for Severe Acute Pancreatitis

| Prognostic Factor | Criterion |
|--|-----------|
| Ranson's criteria | |
| <i>On admission</i> | |
| Age (y) | >55 |
| White cell count/mm ³ | >16,000 |
| Glucose (mg/dL) | >200 |
| Lactic dehydrogenase (international units/L) | >350 |
| Aspartate aminotransferase (units/L) | >250 |
| <i>Within 48 hours</i> | |
| Decrease in hematocrit (% points) | >10 |
| Increase in blood urea nitrogen (mg/dL) | >5 |
| Calcium (mg/dL) | <8 |
| Partial pressure of oxygen (mm Hg) | <60 |
| Base deficit (mmol/L) | >4 |
| Estimated fluid deficit (L) | >6 |
| Additional criteria | |
| <i>Organ failure (shock)</i> | |
| Systolic blood pressure (mm Hg) | <90 |
| Pulmonary insufficiency (mm Hg) | ≤60 |
| Renal failure [creatinine (mg/dL)] | >2 |

diagnosis depends on the recognition of an etiologic factor, the clinical signs and symptoms, abnormal laboratory tests, and imaging techniques that predict the severity of the disease. In most patients, the diagnosis of AP is based on the clinical presentation, an elevated serum amylase or lipase, and the results of either computed tomography (CT) or an ultrasound of the pancreas.^{1,2} Evaluation of the patient with recurrent AP requires systematic identification and elimination of correctable inciting factors.³⁹

Prognostic Indicators of Disease Severity

Patients should be categorized into either prognostically mild or severe disease using any one of a number of validated multiple-factor scoring systems (Table 39–4).^{2,4–6} Two widely used measures include Ranson's criteria and the Acute Physiology and Chronic Health Evaluation (APACHE II). The APACHE II (≥8 points) system is more sensitive and specific than Ranson's criteria (≥3 criteria), but it is also more complex.^{2,6} The APACHE II system uses 14 indicators of physiological and biochemical function that can be readily calculated upon admission to an intensive care unit. Ranson's criteria includes 11 variables that must be monitored at the time of admission and during the initial 48 hours of hospitalization. Patients with fewer than three Ranson criteria have a mortality rate of less than 1%, while

those with six or more have a 100% mortality rate.^{2,5} Some modifications of Ranson's criteria have dropped the base deficit and fluid requirements, while others have added obesity as an independent risk factor.² Additional criteria enhance the predictability of these scoring systems (see Table 39–4).

Laboratory Tests

Laboratory test results vary depending on the severity of the inflammatory process, whether damage is confined to the pancreas or involves contiguous organs, and the time course from the onset of the acute attack (see Table 39–3). Serum concentrations of proinflammatory cytokines such as tumor necrosis factor- α and interleukin-6 are markers of disease severity, but elevations are not specific for pancreatitis and the tests are not widely available.^{37,38}

Markers of Pancreatic Injury. Serum amylase and lipase are most widely used to detect elevations of pancreatic enzymes in AP, but elevations do not necessarily correlate with either the etiology or severity of the disease (see Table 39–3). In addition, many nonpancreatic diseases may be associated with hyperamylasemia, including salivary, renal, hepatobiliary, metabolic, female reproductive tract, and neoplastic diseases.² Pancreatic isoamylase studies assist in determining the origin of elevated serum amylase concentrations, but are not useful for the diagnosis of AP because the diseases that simulate pancreatitis cause pancreatic rather than nonpancreatic amylase concentration to rise. Newer markers (e.g., urinary trypsinogen activation peptide) provide both diagnostic and prognostic information, but are not routinely used in practice. A number of other tests have been used to detect pancreatic enzymes in the serum (e.g., elastase) and urine (e.g., amylase), but most of these are not considered useful in the diagnosis of AP.^{1,2}

Imaging

A number of radiologic imaging techniques reveal pancreatic abnormalities during the disease course (see Table 39–3). Although no single imaging technique provides a positive diagnosis for AP, CT is considered the gold standard.

CLINICAL COURSE AND PROGNOSIS

The majority of patients with mild AP recover uneventfully. Mortality increases with unfavorable early prognostic signs, organ failure, and local complications. The mortality of patients with infected pancreatic necrosis approximates 30% and is higher than in sterile necrotizing pancreatitis or interstitial pancreatitis.^{2,4–6} Mortality rates are also influenced by the etiology, as patients with idiopathic or postoperative AP have higher mortality rates than those with gallstone- or alcoholic-induced disease. Mortality is higher during the first or second attacks than during recurrent acute episodes. Death during the first few days often results from systemic complications. When death occurs after this period, it is usually associated with local complications.

► TREATMENT: Acute Pancreatitis

■ DESIRED OUTCOME

Treatment of AP is aimed at relieving abdominal pain, replacing fluids, minimizing systemic complications, and preventing pancreatic necrosis and infection. Management varies depending on the severity

of the attack (see Table 39–4; Fig. 39–3). In patients with mild AP, the disease is usually self-limiting and subsides spontaneously within 2 to 7 days of the initiation of supportive care and the reduction of pancreatic secretions. Patients with severe AP typically follow a more fulminant course and should be treated aggressively and monitored closely.

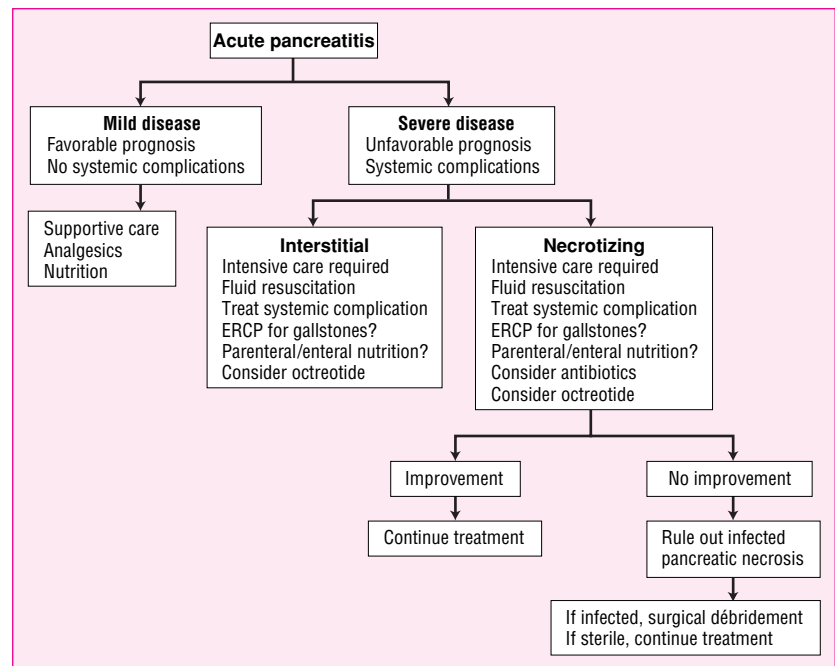

FIGURE 39–3. Algorithm of guidelines for evaluation and treatment of acute pancreatitis. ERCP, endoscopic retrograde cholangiopancreatography.

GENERAL APPROACH TO TREATMENT

All patients with AP should receive supportive care, including effective pain control, fluid resuscitation, and nutritional support. However, initial treatment usually involves withholding foods or liquids in order to minimize exocrine stimulation of the pancreas. The use of nasogastric aspiration offers no clear advantage in patients with mild AP, but is beneficial in patients with profound pain, severe disease, paralytic ileus, and intractable vomiting.^{2,4}

Patients predicted to follow a severe course will require treatment of any cardiovascular, respiratory, renal, and metabolic complications. Aggressive fluid resuscitation is essential to correct intravascular volume. The prognosis of the patient often depends on the rapidity and adequacy of volume restoration, as large quantities of fluid are sequestered within the peritoneal and retroperitoneal spaces. Vasodilation from the anti-inflammatory response, vomiting, and nasogastric suction contribute to hypovolemia and fluid and electrolyte losses. Intravenous colloids may be required to maintain intravascular volume and blood pressure because fluid losses are rich in protein. Patients with pancreatitis and systemic inflammatory response syndrome may benefit from treatment with drotrecogin alfa. Intravenous potassium, calcium, and magnesium are used to correct deficiency states. Insulin is used to treat hyperglycemia. Local complications resolve as the inflammatory process subsides; however, patients with necrotizing pancreatitis may require antibiotics and surgical intervention.

NONPHARMACOLOGIC THERAPY

Patients with mild AP can begin oral feeding within several days of the onset of pain.¹ In severe disease, nutritional deficits develop rapidly and are complicated by tissue necrosis, organ failure, and surgery. Enteral or parenteral nutrition should be initiated if it is anticipated that oral nutrition will be withheld for more than 1 week, as nutritional depletion can impair recovery and increase the risk of complications.⁶ Although total parenteral nutrition is very effective in critically ill

patients, it can cause serious problems such as catheter sepsis and hyperglycemia.⁴⁰ In the past, there was concern that enteral feeding would stimulate pancreatic enzyme secretion and exacerbate the underlying disease. However, studies in patients with pancreatitis have demonstrated that the stimulatory effect of nutrients is minimized if administered distally into the jejunum.⁴⁰ Results of clinical trials in patients with AP confirm that jejunal feedings are safer and less expensive than parenteral nutrition.^{40–42}

Enteral feedings may also prevent infection by decreasing translocation of bacteria across the gut wall.⁴³ Preliminary data suggest that probiotics such as lactobacillus (along with a fiber supplement) may reduce bacterial translocation and possibly decrease pancreatic necrosis and abscess.⁴⁴ If enteral feeding is not possible, total parenteral nutrition (TPN) should be implemented before protein and calorie depletion becomes advanced. Intravenous lipids should not be withheld unless the serum triglyceride concentration is greater than 500 mg/dL.^{2,6} At present, there is no clear evidence that nutritional support alters outcome in most patients with AP unless malnutrition exists.⁴²

Removal of an underlying biliary tract gallstone with ERCP or surgery usually resolves AP and reduces the risk of recurrence. Surgery may be indicated in AP to treat pseudocyst, pancreatic abscess, and to drain the pancreatic bed if hemorrhagic or necrotic material is present.

PHARMACOLOGIC THERAPY

RECOMMENDATIONS

Patients with AP should receive aggressive supportive care, including effective pain control, fluid resuscitation, and nutritional support. **2** When possible, discontinue medications listed in Table 39–2. Antisecretory drugs may be used to prevent stress-related mucosal bleeding. Octreotide may be tried in severe AP, but its efficacy remains uncertain (see Fig. 39–3). Antibiotics should not be used in the absence of signs of infection except in patients with biliary tract gallstones, or in severe AP when pancreatic necrosis or abscess is

likely. Patients with life-threatening complications require additional intensive medical therapy or surgery.

■ RELIEF OF ABDOMINAL PAIN

Analgesics are administered to reduce the severity of abdominal pain. The most important factors to consider in selecting an analgesic are efficacy and safety. Although the administration of some narcotics is associated with mild and transient increases in serum amylase and lipase, these effects are not deleterious to the patient. In the past, treatment was usually initiated with parenteral meperidine (50 to 100 mg every 3 to 4 hours) because it does not cause pancreatitis or significantly alter the function of the sphincter of Oddi.^{4,45} Today **3** many hospitals have either restricted or eliminated the use of meperidine because it is not as effective as other narcotics and because it is contraindicated in patients with renal failure. Because meperidine is less effective than other narcotics in relieving pain, higher and more frequent daily dosages are generally required. Most importantly, active metabolites of meperidine accumulate in patients with renal impairment and may cause seizures or psychosis. The maximum recommended parenteral dose of meperidine is 600 mg/day in patients with normal renal function, but it should not be used in patients with renal failure.

Parenteral morphine is often recommended for pain control, but its use in AP is sometimes avoided because it can cause spasm of the sphincter of Oddi, increases in serum amylase, and rarely pancreatitis.² Although not as well-studied, hydromorphone is often preferred because it has a longer half-life than meperidine and can be given parenterally by a patient-controlled analgesia pump. Patient-controlled analgesia should be considered in patients who require frequent narcotic dosing (e.g., every 2 to 3 hours) and usually achieves adequate pain control. Dosing should be monitored carefully and adjusted daily. There is no evidence that antisecretory drugs (such as H₂-receptor antagonists or proton pump inhibitors) prevent an exacerbation of abdominal pain.⁶

■ LIMITATION OF SYSTEMIC COMPLICATIONS AND PREVENTION OF PANCREATIC NECROSIS

Vigorous fluid resuscitation and support of respiratory, renal, cardiovascular, and hepatobiliary function may limit systemic complications.^{2,46–48} However, there is no proven method to prevent these complications.⁶ While hemoconcentration (decreased intravascular volume) is strongly associated with pancreatic necrosis, it is not clear whether aggressive fluid resuscitation alone during the first 24 hours can prevent pancreatic necrosis.⁴⁹ Procedures such as ERCP, hypothermia, nasogastric suction, pancreatic irradiation, peritoneal lavage, and thoracic duct drainage remain unproven.^{2,6}

A number of drugs have been investigated to determine their efficacy in limiting the severity of AP by either directly or indirectly reducing pancreatic secretion, inhibiting the action of circulating inflammatory mediators, or increasing pancreatic microcirculation. The use of parenteral H₂-receptor antagonists or proton pump inhibitors is no more effective than nasogastric suction to diminish pancreatic exocrine secretion. Corticosteroids are not helpful in limiting systemic complications and altering the course of the disease.⁴⁷ Clinical studies with protease inhibitors such as aprotinin and gabexate fail to reduce mortality in AP.^{46–48} However, the results of two meta-analyses and a multicenter comparative study with gabexate demonstrate a decrease in complications.^{2,50} Clinical trials fail to demonstrate a decrease in mortality with lexipafant, a platelet-activating

factor antagonist.⁴⁷ Low-molecular-weight dextran increases pancreatic microcirculation in experimental animal models, but its efficacy in preventing pancreatic necrosis in humans requires further study.⁵¹ Conflicting or inconclusive data exist regarding the efficacy of antioxidants, glucagon, calcitonin, atropine, α -aminocaproic acid, 5-fluorouracil, and indomethacin.⁴⁸

■ Somatostatin and Octreotide

The use of somatostatin and its synthetic analog octreotide in severe AP may reduce mortality, but does not appear to decrease complication rates.^{2,52} Although these agents are potent inhibitors of pancreatic enzyme secretion, they may have detrimental effects in patients with AP because they may increase sphincter of Oddi pressure and decrease splanchnic blood flow.⁴⁷ Many of the studies that evaluated the efficacy of somatostatin and octreotide in AP have yielded conflicting results. Most of these studies had small numbers of patients, were not placebo-controlled, and included patients with mild disease. Preliminary results of a randomized, open-label trial in severe AP indicates that octreotide 0.1 mg subcutaneously every 8 hours decreased mortality, sepsis, and length of hospital stay.⁵³ In a study using higher dosages (0.5 mcg/kg per hour given by continuous intravenous infusion), octreotide provided a more pronounced decrease in serum amylase, greater improvement in pancreatic edema, and earlier return to oral intake than controls.⁵⁴ Until there is evidence to support its **4** efficacy in patients with mild disease, the use of octreotide should be limited to patients with severe AP, as it may decrease mortality and possibly the length of hospital stay.

CLINICAL CONTROVERSY

Some clinicians believe that octreotide should be used to decrease pancreatic secretions in patients with AP, while others believe that this is unnecessary. Octreotide should only be used in patients with severe AP.

■ PREVENTION OF INFECTION

5 Patients with severe AP complicated by necrosis should receive prophylactic treatment with a broad-spectrum antibiotic (Fig. 39–4).^{1,2,55} Pancreatic infections occur in about 30% of patients who have greater than 30% necrosis and account for 80% of the deaths associated with AP.⁴⁶ However, the use of antibiotics in patients without definite proof of an infection remains controversial. Prophylactic antibiotics do not offer any benefit in mild AP or those who do not have necrosis.

Early clinical trials showed no benefit from antibiotic prophylaxis, but studies were flawed, as they included patients with all degrees of disease severity and did not have a sufficient number of patients with severe necrotizing AP.^{1,47} In addition, the studies utilized ampicillin, which does not penetrate well into pancreatic tissue.⁴⁷ Imipenem-cilastatin, metronidazole, cefotaxime, piperacillin, mezlocillin, ofloxacin, and ciprofloxacin all achieve satisfactory bactericidal tissue concentrations, whereas aminoglycosides have poor penetration.^{46,47} However, the importance of antibiotic penetration into pancreatic tissue has been debated, as it is the peripancreatic retroperitoneal necrotic fat and debris, not the pancreas itself, that becomes infected.

At present there is sufficient evidence to recommend that patients with severe acute necrotizing pancreatitis should receive antibiotic prophylaxis as soon as possible after diagnosis. Three

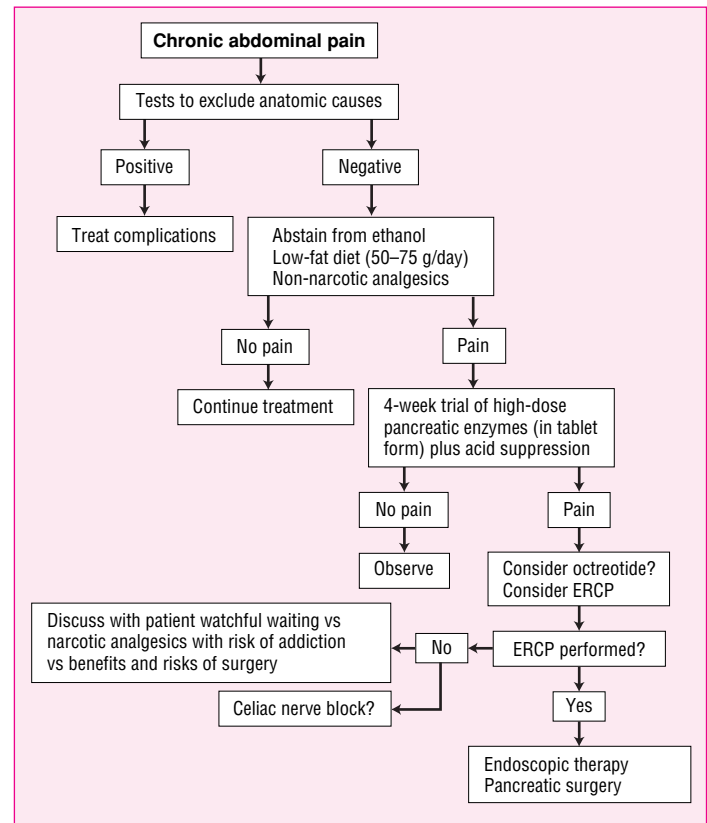

FIGURE 39-4. Algorithm of guidelines for the treatment of chronic abdominal pain in chronic pancreatitis. ERCP, endoscopic retrograde cholangiopancreatography.

randomized clinical trials have compared antibiotic prophylaxis with no antibiotics in patients with acute necrotizing pancreatitis, with varying results.⁵⁶⁻⁵⁸ In one study, prophylaxis with cefuroxime 4 to 5 g/day lowered mortality, length of hospital stay, and the overall infection rate, but a decrease in the total number of infections was attributed to fewer urinary tract infections in the antibiotic group.⁵⁶ In contrast, prophylaxis with either ceftazidime, amikacin, and metronidazole or imipenem-cilastatin decreased the incidence of sepsis and reduced the length of stay, but had no effect on mortality.^{57,58} Despite differences among the studies, the results of two meta-analyses conclude that prophylaxis with broad-spectrum antibiotics decreases sepsis and mortality in patients with severe AP and necrosis.^{59,60} In a randomized comparison of pefloxacin and imipenem-cilastatin, pancreatic sepsis was reduced in the imipenem group, but mortality did not differ between groups.⁶¹ Selective gut decontamination may be of benefit, but randomized controlled trials are needed to confirm its effectiveness when compared to parenteral antibiotic prophylaxis.^{1,2,47} Because the source of bacterial contamination is most likely the colon, the choice of antibiotic should be broad-spectrum, covering the range of enteric aerobic gram-negative bacilli and anaerobic microorganisms. Treatment should be initiated within the first 48 hours and continued for 2 to 3 weeks. Imipenem-cilastatin (500 mg every 8 hours) is probably the most effective agent, but a quinolone (such as ciprofloxacin or levofloxacin) with metronidazole should be considered for the penicillin-allergic patient.^{1,47}

Antibiotic prophylaxis is not always effective in eliminating the risk of infected pancreatic necrosis. Widespread use of antibiotics may lead to multiresistant bacterial and fungal infections, thus worsening the course of the disease. There appears to be a shift toward gram-positive infections (primarily enterococci and staphylococci) in AP patients who receive antibiotic prophylaxis as compared to

earlier studies when patients did not receive antibiotic prophylaxis.⁶² The use of prophylactic antibiotics may also alter the bacteriology of infected necrosis and is associated with an increase in the incidence of fungal and β -lactam-resistant gram-positive organisms.⁶³ The rise in fungal infections has led some clinicians to consider the addition of an antifungal agent to the prophylactic regimen.⁶⁴ Although fluconazole demonstrated adequate penetration of pancreatic tissue, there is no evidence to support its efficacy in the prophylaxis of pancreatic fungal infections in patients with acute necrotizing pancreatitis.

CLINICAL CONTROVERSY

Some clinicians believe that antibiotic prophylaxis is necessary in patients with severe AP in order to prevent pancreatic infection, while others believe that this practice is unnecessary. Antibiotic use in AP remains controversial in patients without definite proof of an infection. Patients with severe AP complicated by necrosis should receive prophylactic treatment with a broad-spectrum antibiotic.

POST-ERCP PANCREATITIS

The clinical characteristics of post-ERCP pancreatitis are similar to those of AP from other causes. In most cases the pancreatitis is mild and resolves in several days. Pretreatment with octreotide, calcium channel blockers, and aprotinin has been disappointing, but somatostatin and gabexate have shown some benefit.^{1,66} To date, there have not been any studies to evaluate the cost effectiveness of prophylactic therapy.

CHRONIC PANCREATITIS

CP is an inflammatory condition that usually results in functional and structural damage to the pancreas. In most patients CP is progressive and loss of pancreatic function is irreversible. Permanent destruction of pancreatic tissue usually leads to exocrine and endocrine insufficiency.^{7–10} Cystic fibrosis may be associated with pancreatic exocrine insufficiency in children and is discussed in Chap. 30.

ETIOLOGY

Etiologic risk factors associated with CP are identified in Table 39–5. Prolonged alcohol consumption accounts for 70% of all cases in the United States, about 20% are idiopathic, and the remaining 10% constitute other less frequent causes.^{7–10} Recent evidence suggests that there is a strong association between cigarette smoking and CP.^{7,8} Autoimmune pancreatitis may be isolated or occur in association with immune-mediated disorders. Although cholelithiasis may coexist with CP, gallstones rarely lead to chronic disease.

PATHOPHYSIOLOGY

The exact mechanism by which alcohol causes CP is uncertain. It appears that alcohol-induced pancreatitis progresses from inflammation to cellular necrosis, and that fibrosis occurs over time. Chronic alcoholism results in a number of changes in pancreatic fluid that creates an environment for the formation of intraductal protein plugs that block small ductules.⁷ Blockage of the ductules produces progressive structural damage in the ducts and the acinar tissue. Calcium complexes to the protein plugs, first in the small ductules and then in the main pancreatic duct (see Fig. 39–1), eventually resulting in injury and destruction of pancreatic tissue. Other theories have been hypothesized, all of which lead to pancreatic destruction and insufficiency.⁷

The pathogenesis of the abdominal pain associated with CP is multifactorial and related in part to increased intraductal pressure secondary to continued pancreatic secretion, pancreatic inflammation, and abnormalities involving pancreatic nerves. Malabsorption of protein and fat occurs when the capacity for enzyme secretion is reduced by 90%.⁷ Lipase secretion decreases more rapidly than the proteolytic enzymes. Bicarbonate secretion may be decreased, leading to a duodenal pH of less than 4.⁷ A minority of patients develop

TABLE 39–5. Etiologic Risk Factors Associated with Chronic Pancreatitis

| | |
|-------------------------|--|
| Toxic | Alcohol (ethanol), tobacco, organotin compounds (e.g., di- <i>n</i> -butyltin dichloride) |
| Metabolic | Chronic hypercalcemia associated with hyperparathyroidism, chronic hypertriglyceridemia (controversial), chronic renal failure |
| Obstructive | Pancreas divisum, pancreatic duct obstruction (e.g., tumor), sphincter of Oddi (controversial) |
| Idiopathic | Tropical pancreatitis |
| Genetic | Autosomal dominant, autosomal recessive/modifier genes (e.g., cystic fibrosis) |
| Autoimmune | Isolated autoimmune, syndromic autoimmune (e.g., Sjögren syndrome, inflammatory bowel disease, primary biliary cirrhosis) |
| Other etiologies | Postirradiation, postnecrotic pancreatitis, vascular diseases |

complications, including pancreatic pseudocyst, abscess, and ascites or common bile duct obstruction, leading to cholangitis or secondary biliary cirrhosis. Bleeding is associated with a variety of causes.

CLINICAL PRESENTATION

SIGNS AND SYMPTOMS

The clinical presentation of CP varies depending on the etiology of the disease, the severity of the inflammatory process, and the extent of irreversible damage to the pancreas (Table 39–6).^{7–10} The classic features of CP are abdominal pain, malabsorption, weight loss, and diabetes. Most alcoholic patients have chronic pain, while others have intermittent attacks or painless pancreatitis. Abstinence from ethanol may provide relief from pain, but does not prevent exocrine

TABLE 39–6. Presentation of Chronic Pancreatitis

General

- The patient may appear well-nourished or have coexistent signs of malnutrition and chronic alcoholic liver disease.

Symptoms

- Dull epigastric or abdominal pain that radiates to the back is seen. Pain is the most prominent clinical feature and may be either consistent or episodic.
- Characteristically the pain is deep-seated, positional, frequently nocturnal, and unresponsive to medication. The intensity of the pain varies from mild to severe, and does not usually correlate directly with the inflammatory process or other physical findings. Severe attacks last from several days to several weeks and may be aggravated by eating.
- Nausea and vomiting often accompany the pain.

Signs

- Steatorrhea (excessive loss of fat in the feces) and azotorrhea (excessive loss of protein in the feces) are seen in most patients. Steatorrhea is often associated with diarrhea and bloating.
- Weight loss may be seen.
- About 50% of patients with advanced pancreatic insufficiency present with vitamin B₁₂ malabsorption.
- Jaundice occurs in about 10% of patients.
- Pancreatic diabetes is usually a late manifestation that is commonly associated with pancreatic calcification. Ketoacidosis, vascular complications, and nephropathy are uncommon with this form of diabetes.
- Neuropathy is sometimes seen.
- Complications, including pancreatic pseudocysts, pleural effusions, and ascites, may be detected on physical examination.

Laboratory tests

- The white blood cell count, fluids, and electrolytes usually remain normal unless fluids and electrolytes are lost as a result of vomiting and diarrhea.
- Serum amylase and lipase concentrations usually remain normal unless the pancreatic duct is blocked or a pseudocyst is present.

Other diagnostic tests

- Malabsorption of fat can be detected by Sudan staining of the feces or by a 72-hour quantitative measurement of fecal fat.
- Ultrasound is the simplest and least expensive of the imaging techniques. Abdominal computed tomography is often used in patients who have a negative or unsatisfactory ultrasound examination.
- Endoscopic retrograde cholangiopancreatography is the most sensitive and specific test for the diagnosis of CP. However, because it is expensive and is associated with complications, it is reserved for patients for whom the diagnosis cannot be established by imaging techniques.

dysfunction.^{7,10} The course of pain is unpredictable, but it frequently lessens as pancreatic insufficiency progresses.⁶⁷

DIAGNOSIS

Most patients with CP have a history of heavy alcohol use and attacks of recurrent upper abdominal pain. The classic triad of calcification, steatorrhea, and diabetes usually confirms the diagnosis.^{7,10} Surgical biopsy of pancreatic tissue through laparoscopy or laparotomy is the gold standard for confirming the diagnosis of CP.⁷ In the absence of histologic samples, imaging techniques (see Table 39–6) are helpful in detecting calcification of the pancreas, other causes of pain (ductal obstruction secondary to stones, strictures, or pseudocysts), and in differentiating CP from pancreatic cancer. Direct tests of pancreatic exocrine function involve the collection of pancreatic fluid after stimulation with exogenous hormones such as secretin or cholecystokinin. These functional tests are not diagnostic of CP, but serve as a sign of CP and a measure of the severity of injury.^{7,8} Because these tests are

complicated and require intubation and special collection techniques, they are not routinely performed.

CLINICAL COURSE AND PROGNOSIS

Patients with alcoholic CP usually present with an initial acute attack followed by successive attacks that are slower to resolve. Continued alcohol use leads to chronic abdominal pain and progressive exocrine and endocrine insufficiency. In about 50% of patients, the pain diminishes 5 to 10 years after the onset of symptoms.⁶⁸ Steatorrhea, calcification, and diabetes usually develop after 10 to 20 years of heavy ethanol ingestion. Most patients present with varying degrees of pain, malnutrition, and glucose intolerance. The mortality rate of CP is approximately 50% within 20 to 25 years of the diagnosis.¹⁰ About 15% to 20% actually die of complications associated with acute attacks. Most deaths occur as a consequence of malnutrition, infection, or ethanol, narcotic, and tobacco use. The clinical course of idiopathic CP is more favorable than that of alcoholic pancreatitis.^{7,8}

► TREATMENT: Chronic Pancreatitis

■ DESIRED OUTCOME

The treatment of uncomplicated CP is aimed primarily at the control of chronic abdominal pain (see Fig. 39–4) and the correction of malabsorption with pancreatic enzymes (Fig. 39–5). Diabetes associated with CP may require exogenous insulin.

■ GENERAL APPROACH TO TREATMENT

The majority of patients with alcohol-related CP require pain control and pancreatic enzyme supplementation.^{7,9,10,68–71} Avoidance

of alcohol usually decreases pain, but oral analgesics remain the cornerstone of therapy. Non-narcotic analgesics such as acetaminophen, nonsteroidal anti-inflammatory drugs (NSAIDs), selective cyclooxygenase-2 (COX-2) inhibitors, or tramadol should be tried initially. The dose and frequency of administration should be increased before the patient is switched to a narcotic. Patients unresponsive to non-narcotic analgesics should be given a trial of pancreatic enzymes prior to using narcotics. Narcotics are required for patients with severe pain. Specific endoscopic or surgical procedures may be necessary in patients refractory to drug therapy. Patients with malabsorption require pancreatic enzymes to reduce steatorrhea and azotorrhea. Most patients achieve satisfactory results with standard-dosage regimens. In patients who remain symptomatic, dietary fat should be reduced. Consideration may also be given to increasing the pancreatic

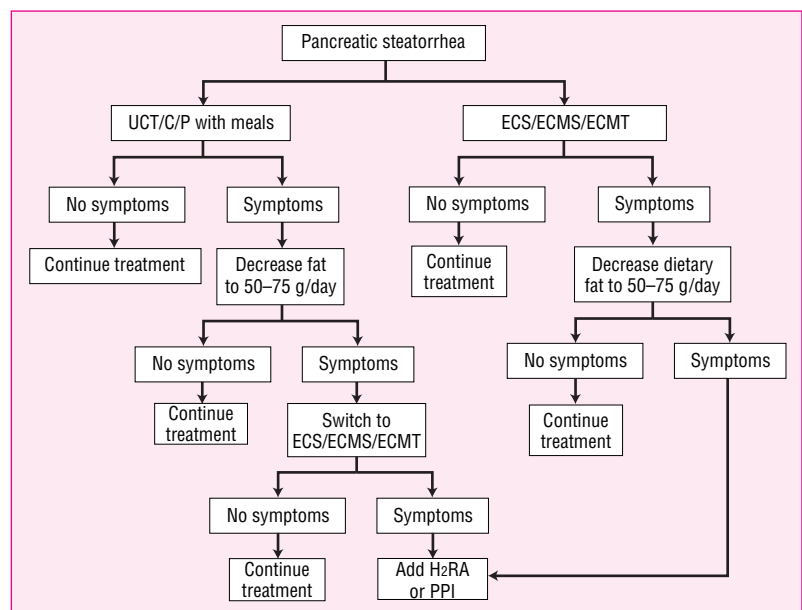

FIGURE 39–5. Algorithm of guidelines for the treatment of pancreatic steatorrhea in chronic pancreatitis. UCT, uncoated tablet; C, capsule; P, powder; ECS, enteric-coated sphere; ECMS, enteric-coated microsphere; ECMT, enteric-coated microtablet; H₂RA, H₂-receptor antagonist; PPI, proton pump inhibitor.

enzyme dose or switching from an uncoated tablet to a microencapsulated enteric-coated dosage form. The addition of an antisecretory drug should be reserved for those patients who do not respond to these maneuvers or who have documented low duodenal pH levels.

NONPHARMACOLOGIC THERAPY

6 Abstinence from alcohol is the most important factor in preventing abdominal pain in the early stages of alcoholic CP, although reports of the effect of abstinence from alcohol have varied.^{7,19,68} Small and frequent meals (six meals per day) and a diet restricted in fat (50 to 75 g/day) are recommended to minimize postprandial pancreatic secretion and resulting pain.⁷¹ Parenteral or enteral nutrition (elemental diets) may be necessary, especially if the patient is chronically debilitated, and these nutritional approaches are less likely than oral ingestion of ordinary food to simulate pancreatic secretion, as stimulation of the pancreas is of some concern in that it may contribute to pain.⁴¹

In some patients pain may be associated with pseudocysts, peptic ulcer, cholelithiasis, biliary or duodenal obstruction, or pancreatic cancer, and if detected may be amenable to other forms of treatment (see Fig. 39–4), including endoscopic procedures such as sphincterotomy, pancreatic duct stenting, and lithotriptic destruction of pancreatic calculi.^{7,10,68,72} The most common indication for surgery is abdominal pain that is refractory to medical therapy. Surgical procedures that alleviate pain include a subtotal pancreatectomy, decompression of the main pancreatic duct, or interruption of the splanchnic nerves.^{7,10,68,72} Although the pain may diminish as the gland deteriorates, it is unreasonable that a patient wait years for spontaneous relief. A percutaneous injection of a corticosteroid or local anesthetic into the celiac ganglion (celiac nerve block) may be attempted. Unfortunately, pain relief obtained by this procedure lasts only a few months, and repeated treatments are not as effective.^{68,72,73}

PHARMACOLOGIC THERAPY

RECOMMENDATIONS

Pain management should begin with non-narcotic analgesics such as acetaminophen, NSAIDs, or selective COX-2 inhibitors (see Fig. 39–4). If pain persists, the response to exogenous pancreatic enzymes should be evaluated in patients with mild to moderate CP. If these measures fail, an oral narcotic should be added to the drug regimen. Parenteral narcotics should be reserved for patients with severe pain that is unresponsive to oral analgesics. Non-narcotic modulators of chronic pain should be considered in patients with difficult-to-manage pain.

Most patients with malabsorption will require pancreatic enzyme supplementation and a reduction in dietary fat in order to achieve satisfactory nutritional status and become relatively asymptomatic. An initial prandial dose of 30,000 international units of lipase (uncoated tablet, capsule, or powder) is recommended to be given with each meal (see Fig. 34–5). Alternatively, the use of microencapsulated enteric-coated dosage forms may be used. The total daily lipase dose should be titrated to reduce steatorrhea. In some patients a reduction in dietary fat may be necessary. The addition of an antisecretory drug should be reserved for patients resistant to enzyme therapy (see Fig. 39–5). If these measures are ineffective, documentation of the diagnosis and exclusion of other diseases should be undertaken.

RELIEF OF CHRONIC ABDOMINAL PAIN

Analgesics

7 Non-narcotic analgesics such as acetaminophen, NSAIDs, or selective COX-2 inhibitors should be given before meals to prevent postprandial exacerbation of pain (Table 39–7).^{7,9,69–72} Treatment should be individualized and should begin with the lowest effective dose. The dosage regimen should be maximized before switching to narcotic alternatives. Analgesics should be scheduled around the clock, because they may be more effective and the total amount of medication required over 24 hours may be less. If the non-narcotic analgesic is ineffective, consideration should be given to using tramadol or adding a low-dose narcotic to the regimen (e.g., acetaminophen and codeine). Severe pain relief necessitates the use of opiate analgesics. Narcotics should not be withheld because of the risk of inducing addiction. Oral agents should be used before parenteral narcotics are administered. Non-narcotic modulators of chronic pain such as selective serotonin reuptake inhibitors (e.g., paroxetine) or tricyclic antidepressants should be considered in difficult-to-manage patients.^{1,72} Tricyclic antidepressants are useful adjuncts, as they not only treat depression, but have a direct effect on pain and potentiate the effect of opioid narcotics.⁷² Referral to a dedicated pain clinic should be considered when available.

Pancreatic Enzymes

8 The use of pancreatic enzymes to relieve pain remains controversial (see Table 39–7). Results from clinical trials are conflicting, especially when non-enteric-coated preparations were compared to enteric-coated enzyme products.^{7,69–72,74,75} The administration of non-enteric-coated pancreatic enzymes early in the course of the disease may afford pain relief by suppressing pancreatic enzyme secretion through a negative feedback mechanism involving proteases present in the duodenum. Effective enzyme therapy should reduce pancreatic stimulation, diminish intraductal pressure, and decrease pain. Possible reasons for failure of enzymes to relieve abdominal pain include insufficient concentrations of trypsin in the pancreatic enzyme preparation, a delayed release of trypsin from pH-dependent dosage forms, and gastric acid inactivation or proteolytic destruction of trypsin.^{7,72,74,75} Suppression of gastric acid with an antisecretory drug is recommended, as it reduces the degradation of proteases in the stomach.^{7,69} Beneficial effects occur in a subset of individuals, primarily those with mild to moderate disease and in patients with a nonalcoholic etiology.^{7,9,68,72}

CLINICAL CONTROVERSY

Some clinicians believe that pancreatic enzyme supplementation should be used to relieve mild to moderate abdominal pain, while others believe that these agents are ineffective. A trial of pancreatic enzyme supplementation should be given before initiating treatment with narcotics.

Other Agents

A number of other agents, including octreotide, allopurinol, and antioxidant therapy (e.g., organic selenium, vitamin E, vitamin C, or β -carotene), have been investigated for the purposes of relieving pain in chronic pancreatitis.^{7,9,68} There is insufficient evidence to support the use of these agents.

TABLE 39–7. Guidelines for the Pharmacologic Treatment of Chronic Pancreatitis**Treatment of chronic pain (oral drug regimens)***Non-narcotic*

- Acetaminophen: Dosage should be limited to 500 mg four times a day if patient drinks more than two alcoholic beverages per day; increased risk of hepatotoxicity, especially in chronic heavy alcohol use
- Nonsteroidal anti-inflammatory drugs (NSAIDs): Standard dosage regimens of aspirin or traditional NSAIDs (e.g., ibuprofen); selective cyclooxygenase-2 (COX-2) inhibitors should be used in patients at risk for upper GI bleeding; use with caution in renal insufficiency
- Tramadol: 50–100 mg every 4–6 hours not to exceed 400 mg/day; has narcotic-like effect; contraindicated in alcohol or hypnotic intoxication; drug interactions; expensive
- Consider use of selective serotonin reuptake inhibitors (e.g., paroxetine) or tricyclic antidepressants in difficult-to-manage patients

Narcotics

- Codeine 30–60 mg every 6 h; hydrocodone 5–10 mg every 4–6 h; oxycodone 5–10 mg every 6 h; fentanyl patch 25–100 mcg/h; pentazocine 25–50 mg every 4–6 h; propoxyphene 65 mg every 4–6 h not to exceed 390 mg/day; methadone 2.5–10 mg every 4–6 h; morphine sulfate (extended-release) 30–60 mg every 8–12 h; hydromorphone 2–4 mg every 4–6 h
- Risk of potentiation with alcohol; impaired respiration; constipation; hypotension
- Dosing is usually based on providing continuous pain relief; consider combining narcotic with acetaminophen, NSAIDs, or selective COX-2 inhibitors; narcotic dependence is common; narcotic abuse is a concern in alcoholics; tolerance to narcotics may develop

Pancreatic enzymes

- Requires that high doses of proteases be delivered to the duodenum for relief of pain; non-enteric-coated pancreatic enzymes are recommended and should be taken with each meal and at night if needed; recommend name brands with proven efficacy and safety, as generic products have been associated with treatment failure; add H₂-receptor antagonist or proton pump inhibitor
- Viokase-8 tablets or Ku-Zyme HP capsules: 6–8 with each meal (see Table 39–8); acid suppression adds to cost
- May cause nausea, cramping, hyperuricemia; hypersensitivity to pork protein

Treatment of maldigestion and steatorrhea*Non-enteric-coated pancreatic enzymes*

- Viokase-8 tablets or Ku-Zyme HP capsules, 6–8 with each meal and at bedtime if needed (see Table 39–8)
- May cause nausea, cramping, hyperuricemia; hypersensitivity to pork protein
- Addition of antisecretory drug (H₂-receptor antagonist or proton pump inhibitor) may increase efficacy, but will also increase cost

Enteric-coated pancreatic enzymes

- Enteric-coated spheres, microspheres, and microtablets are available (see Table 39–8)
- May cause nausea, cramping, hyperuricemia; hypersensitivity to pork protein
- Fibrosing colonopathy has occurred in children using preparations that contain the methacrylic acid copolymer coating
- Usually requires fewer capsules or tablets per meal; compliance issues
- Does not usually require additional antisecretory agents; may be less expensive than non-enteric-coated plus H₂-receptor antagonist or proton pump inhibitor

Antisecretory drugs

- May improve enzyme treatment of abdominal pain or steatorrhea
- Proton pump inhibitors may be more effective than H₂-receptor antagonists, but they are also more costly

Compiled from Owyang,⁷ Toskes,⁹ Amann,⁶⁹ Whitcomb et al,⁷⁰ American Gastroenterological Association,⁷¹ Conwell and Zuccaro,⁷² Brown et al,⁷⁴ Mossner,⁷⁵ Greenberger,⁷⁶ Keller and Layer,⁷⁷ and Layer et al.⁷⁸

■ TREATMENT OF MALABSORPTION

Malabsorption requires treatment when steatorrhea is documented (>7 g of fat in the feces per 24 hours while on a diet of 100 g/day of fat) and persistent weight loss occurs despite efforts to correct it. The combination of pancreatic enzymes (lipase, amylase, and protease) and a reduction in dietary fat (to <25 g/meal) enhances the patient's nutritional status and reduces (but does not totally correct)  steatorrhea. The success of a pancreatic enzyme preparation requires that it contain a high concentration of lipase and proteases, be enteric-coated to avoid destruction by gastric acid, and be the

appropriate size to permit efficient delivery of the enzymes to the small intestine.^{7,76–79} A critical amount of enzymes must be delivered to the duodenum in sufficient concentrations for digestion to occur. The maximal delivery of pancreatic lipase following a meal is approximately 140,000 international units per hour for 4 hours.⁷ Malabsorption is minimized if the concentration of enzymes delivered to the duodenum is at least 5% of normal maximal enzyme output. This requires that about 30,000 international units of lipase and 10,000 international units of trypsin be delivered during the 4-hour postprandial period.^{7,76} In many cases the lipase dose will need to be increased (up to a maximum of 75,000 international units) because of insufficient

lipolytic activity.⁷⁷ Most exogenous lipase is rapidly and irreversibly destroyed at an intragastric pH below 4.^{7,76–79} Enteric-coating is an effective way to protect the acid-labile enzymes, but the enzymes must be emptied from the stomach at the same rate as the ingested food and released in the duodenum. The polymer used to coat the enzyme is pH-dependent and dissolves in the duodenum at a pH of >5, where the enzymes are released.^{7,76} If an intragastric pH of <4 prevails, the enteric-coating will remain intact and the enzymes will be released in the upper portion of the small intestine. A duodenal pH of <4 may prolong dissolution of the enteric coating and release of the enzymes. The size of the enteric-coated enzyme preparation influences the timing of enzyme delivery to the duodenum.^{7,76,80,81} Microencapsulated enteric-coated preparations with a microcapsular diameter of about 1.4 mm empty from the stomach in synchrony with food and mix effectively with intestinal chyme.^{7,76} Large enteric-coated tablets and some microspheres (microcapsular diameter >2 mm) do not empty at the same rate as stomach contents, and thus are not as effective in treating steatorrhea.

■ Pancreatic Enzyme Supplements

Oral pancreatic enzyme supplements are available as a powder, uncoated or coated tablet, capsule, enteric-coated sphere (ECS) and microsphere (ECMS), or enteric-coated microtablet (ECMT) encased in a cellulose or gelatin capsule (Table 39–8). Recommended dosages of microencapsulated enteric-coated products are not necessarily more effective than recommended dosages of the non-enteric-coated enzyme preparations.^{7,76} This is because a lesser quantity of lipase is usually administered at each meal with the enteric-coated preparations.

Thus the most important determinant in reducing steatorrhea is the total amount of active lipase that reaches the duodenum and empties with the meal. Generic pancreatic enzyme preparations have been associated with treatment failures when substituted for brand-name products.⁸³

Pancreatic enzyme supplements differ in enzyme content and activity, bioavailability, clinical efficacy, patient acceptance, and cost. Compliance is often a problem because of the number of tablets or capsules required per dose, the need to take them with each meal or snack, and the cost of pancreatic enzyme therapy. Consideration should be given to selecting a product that contains higher lipase activity (see Table 39–8) so that fewer tablets or capsules are required. However, reports of colonic strictures and intestinal obstruction in cystic fibrosis patients taking high-dose pancreatic enzymes (>20,000 international units lipase per capsule) have led to their withdrawal from the market in the United States.^{7,69,82} Pancreatic enzymes contain nucleic acids, and when given in high therapeutic doses, they have been associated with hyperuricosuria, hyperuricemia, and kidney stones.^{7,69,70} Impaired folic acid absorption by oral pancreatic enzymes may lead to folic acid deficiency. Gastrointestinal side effects appear to be dose-related, but occur less frequently with the enteric-coated products. Sensitization and allergic reactions are uncommon but may occur in patients taking the powder.

■ Adjuncts to Enzyme Therapy

The concurrent use of antisecretory drugs may improve the efficacy of pancreatic enzyme supplementation.^{7,76} The beneficial effects of an H₂-receptor antagonist or proton pump inhibitor result from

TABLE 39–8. Frequently Used Pancreatic Enzyme Preparations

| Product | Dosage Form | Enzyme Content (Units) ^a | | |
|----------------------|-------------|-------------------------------------|---------|----------|

| Viokase 16 | UCT | 16,000 | 60,000 | 60,000 |

^aAll listed products contain pancreatic lipase. Pancreatic lipase contains not less than 24 USP units of lipase activity, not less than 100 USP units of amylase activity, and not less than 100 USP units of protease activity per milligram.

^bUnits of 0.7 g of powder.

C, powder encased in a cellulose capsule; ECS, enteric-coated sphere encased in a cellulose capsule; ECMS, enteric-coated microspheres encased in a cellulose or gelatin capsule; ECMT, enteric-coated microtablets encased in a cellulose capsule; UCT, uncoated tablet; P, powder.

both an increase in pH and a decrease in intragastric volume.^{7,84} These agents should maintain luminal gastric and duodenal pH above 4 and enhance lipase activity. Increased duodenal pH also prevents bile acid precipitation, increasing fatty acid solubility. Antacids appear to have little or no added effect in reducing steatorrhea.⁷ Symptomatic patients whose steatorrhea is not corrected by enzyme replacement therapy and a reduction in dietary fat may benefit from the addition of an H₂-receptor antagonist. A proton pump inhibitor should be considered in patients who fail to benefit from the addition of an H₂-receptor antagonist. The additional cost of antisecretory therapy and the potential for adverse effects and drug interactions should be considered.

PHARMACOECONOMIC CONSIDERATIONS

The pharmacoeconomic issues associated with the medical treatment of AP and CP have not been extensively examined. Aggressive medical and surgical care decreases mortality in AP, but the overall cost

effectiveness of a specific treatment is unknown. The relief of abdominal pain in AP and CP, as well as pancreatic enzyme supplementation in patients with CP, improves quality of life and nutritional status. Although the efficacy of octreotide in AP remains uncertain, its use in severe AP is reasonable and potentially cost effective. Antibiotic prophylaxis of targeted patients may reduce mortality and length of hospital stay, but pharmacoeconomic studies have not confirmed this suspicion. However, a reduction in the length of stay could offset the cost of antibiotic therapy.

In some cases, medications that cost more may be more cost effective. This is particularly true with pancreatic enzymes and the microencapsulated enteric-coated dosage forms. These latter products may cost more per unit, but they offer greater patient acceptance and compliance when compared to uncoated tablets. In addition, when cost is based on the total number of tablets or capsules per day, rather than the cost of a single tablet or capsule, the high-potency preparations are usually similar in price to the uncoated products. The addition of an H₂-receptor antagonist or proton pump inhibitor may actually be cost effective for patients who are not adequately controlled on maximal enzyme therapy.

EVALUATION OF THERAPEUTIC OUTCOMES

ACUTE PANCREATITIS

In patients with mild AP, pain control, fluid and electrolyte status, and nutrition should be assessed periodically, depending on the degree of abdominal pain and fluid loss. Patients with severe AP should be transferred to an intensive care unit for close monitoring of vital signs, prothrombin time, fluid and electrolyte status, white blood cell count, blood glucose, lactic dehydrogenase, aspartate aminotransferase, serum albumin, hematocrit, blood urea nitrogen, and serum creatinine. Continuous hemodynamic and arterial blood gas monitoring is essential. Serum lipase, amylase, and bilirubin require less frequent monitoring. The patient should be monitored for signs of infection, relief of abdominal pain, and adequate nutritional status. Therapeutic outcome depends on the severity of the acute attack, medical management (which is primarily supportive), and prevention or treatment of infection. Despite appropriate supportive therapy, deterioration of respiratory, renal, and cardiovascular function may lead to death.

CHRONIC PANCREATITIS

The severity and frequency of abdominal pain should be assessed periodically in order to determine the efficacy of the patient's pain control regimen. Most patients with abdominal pain can be adequately controlled with acetaminophen, NSAIDs, or selective COX-2 inhibitors. A trial of pancreatic enzymes and either an H₂-receptor antagonist or proton pump inhibitor may relieve pain in patients with mild to moderate disease. Patients with severe pain will require narcotics. In these patients, pain should be monitored daily and medications adjusted accordingly. Some patients will require endoscopic therapy or pancreatic surgery.

The effectiveness of pancreatic enzyme supplementation in treating malabsorption is measured by improvement in body weight and stool consistency or frequency. The 72-hour stool test for fecal fat may be used when there is concern regarding the adequacy of treatment. Serum uric acid and folic acid concentrations should be monitored yearly in patients prone to hyperuricemia or folic acid deficiency. Blood glucose must be closely monitored in the diabetic patient.

Therapeutic outcome depends in part on the ability of the patient to discontinue alcohol and tobacco use and to maintain adequate nutrition. Pain control and pancreatic enzyme supplementation are important therapeutic measures that contribute to the patient's quality of life. A small number of patients die from complications associated with an acute attack.

CONCLUSIONS

Important advances have been made in recent years regarding our understanding of acute and chronic pancreatitis, especially as it relates to genetics, pathogenesis, and the natural history of the diseases. Although there has been a reduction in the mortality of patients with severe AP, controversy remains regarding the use of antibiotic prophylaxis. Patients with CP now benefit from improved strategies for managing pain and treating malabsorption. In the future, new and improved diagnostic techniques and medical treatments will replace many of the procedures and drugs we use today.

ABBREVIATIONS

AP: acute pancreatitis
 ARDS: acute respiratory distress syndrome

VIRAL HEPATITIS

Manjunath P. Pai, Renee-Claude Mercier, and Marsha A. Raebel

Learning Objectives and other resources can be found at www.pharmacotherapyonline.com.

KEY CONCEPTS

- 1 Hepatitis A is transmitted via the fecal-oral route. Conditions in which transmission is more likely to occur include travel to countries with high rates of hepatitis A, poor conditions and hygiene, and overcrowded areas.
- 2 Hepatitis A causes an acute illness and does not lead to chronic liver disease. The infection can be divided into three stages: incubation, acute hepatitis, and convalescence. The disease is typically self-limited and rarely progresses to liver failure.
- 3 Treatment of acute hepatitis A infection is primarily supportive, as pharmacologic treatment with antiviral agents is of no benefit.
- 4 Hepatitis B virus can cause both an acute and chronic illness and is more difficult to clear if acquired as an infant compared to acquisition as an adult.
- 5 The choice of first-line therapy for hepatitis B virus when comparing interferon- α 2b and lamivudine is controversial. The duration of interferon- α 2b therapy is finite (16 to 52 weeks) relative to lamivudine (52 weeks or longer) for chronic hepatitis B, but is associated with significant side effects.
- 6 Long-term therapy with lamivudine is associated with the development of hepatitis B virus strains that are resistant to this agent. Although the impact of developing lamivudine-resistant hepatitis B virus is not known, adefovir may be used to treat these resistant strains.
- 7 All infants should be immunized against hepatitis B. Older children and adults in high-risk groups who have not been previously immunized should also receive the vaccine.
- 8 Hepatitis C is a significant public health problem associated primarily with illicit injection drug use in the United States.
- 9 No vaccines exist for the prevention of hepatitis C compared to the individual and combined vaccines that are available for the prevention of hepatitis A and B.
- 10 The availability of pegylated versions of interferon has allowed for less frequent dosing and better therapeutic response in chronic hepatitis C. However, therapeutic response of patients with chronic hepatitis C to combination pegylated interferon- α and ribavirin therapy is expected in less than half of treated patients with genotype 1.

Hepatitis is a major cause of morbidity and mortality in the United States. *Viral hepatitis* refers to the clinically important hepatotropic viruses responsible for hepatitis A (HAV), hepatitis B (HBV), hepatitis C (HCV), delta hepatitis, and hepatitis E. Hepatitis G virus has also been described; however, its role in clinical illness is still not clear. Viral hepatitis has acute, fulminant, and chronic clinical forms, defined by duration or severity of infection. The clinical, biochemical, immunoserologic, and histologic features of viral hepatitis follow similar patterns regardless of the virus responsible for the patient's illness. Hepatocellular response to injury and the resulting physical signs and symptoms are nonspecific.

HAV is primarily responsible for acute hepatitis. It is most often linked to sporadic events of contaminated food in the United States and to international travel, and is usually a self-limited disease. HBV and HCV are primarily responsible for the development of chronic hepatitis, cirrhosis, and hepatocellular carcinoma. Immunomodulatory therapy and direct antiviral agents have been developed for both HBV and HCV. These therapeutic modalities require long courses of therapy and are associated with limited success. This chapter will focus on the pathophysiology, clinical course, and management of these three primary causes of viral hepatitis, namely HAV, HBV, and HCV.

HEPATITIS A VIRUS

HAV has been associated with significant morbidity and occasional mortality for centuries as a known cause of acute hepatitis.¹ Despite the availability of an effective vaccine against HAV, hepatitis A continues to be one of the most frequently reported vaccine-preventable diseases in the United States.² Epidemiologic data in the United States from 1997 estimated that hepatitis A infections were responsible for 255 deaths, approximately 2.5 million days of symptomatic illness, 829,000 working days lost, and costs in the range of 330 to 580 million dollars.³

EPIDEMIOLOGY AND ETIOLOGY

HAV causes both epidemics and sporadic infections. Both are related to overcrowded conditions and person-to-person spread or ingestion of contaminated food or water. HAV is transmitted by the fecal-oral route. The incidence of HAV correlates directly with poor sanitary conditions and hygienic practices.⁴ For international travelers, longer lengths of stay in a country with a high rate of hepatitis A also correlates with increased risk. In the United States, groups at increased risk of HAV, in addition to travelers, include men who have sex

with men, injecting drug users, and persons working with nonhuman primates.²

HAV infection in the United States occurs primarily from person-to-person transmission in communitywide outbreaks, in lower socioeconomic groups, and in sporadic common-source outbreaks (outbreaks in which all infected patients contract the infection from a single person or source).² Children between the ages of 5 and 14 years are more likely to be involved in communitywide outbreaks, whereas common-source outbreaks primarily involve young adults. Both children and young adults can be infected from common-source outbreaks at day care centers.⁴ HAV infection in children is often asymptomatic or unrecognized. Therefore, children serve as an important source for transmitting the infection to others.² Rarely, HAV is transmitted by transfusion of contaminated blood products collected while the donor is viremic with HAV.² Cases of HAV associated with parenteral drug abuse are increasing.⁵

HAV are small, nonenveloped, single-stranded ribonucleic acid (RNA) viruses belonging to the *Hepatovirus* genus of the Picornaviridae. Four genotypes are known to infect humans. Most infections are caused by strains from either genotype I or III, although the genotypes do not appear to confer important biological differences.⁶

PATHOPHYSIOLOGY

HAV usually causes a self-limiting disease with a low case-fatality rate. The disease is a systemic viral infection of up to (but not exceeding) 6 months in duration, producing inflammatory necrosis of the liver. The natural history of the infection is divided into three stages based on viral serologic markers: incubation, acute hepatitis, and convalescence. Incubation begins shortly after parenteral or oral inoculation with the virus. After the virus reaches the circulation, infective virions accumulate in hepatic sinusoids and are internalized by the hepatocytes. HAV replication occurs exclusively in the hepatocytes and gastrointestinal epithelial cells.⁶ Viral antigens are found in the hepatocyte cytoplasm during incubation. They are subsequently shed into bile and feces. The largest concentration of viral particles is found in stool specimens during the 1 to 2 weeks preceding clinical illness or elevation of liver enzymes. Infected persons are at peak infectivity at this time.² Viral shedding declines as clinical symptoms appear. During the incubation stage, the host is asymptomatic.

Acute hepatitis begins with a preicteric phase (before the onset of jaundice), which parallels initiation of the host immune response and occurs before significant liver cell injury. The preicteric phase is frequently associated with nonspecific influenza-like symptoms consisting of anorexia, nausea, fatigue, and malaise.⁶ Most patients with acute viral hepatitis develop only a few mild symptoms and minimal hepatocyte damage. This mild disease is called *acute anicteric hepatitis*. The minimal degree of liver cell damage is reflected by mild elevations of serum bilirubin, γ -globulin, and hepatic transaminase (alanine transaminase [ALT], aspartate transaminase [AST]) values to about twice normal. Subsets of patients experience enough hepatocyte destruction to produce significant liver dysfunction characterized by interruption of bilirubin metabolism and flow. This results in clinical jaundice and acute icteric hepatitis. Icteric hepatitis is generally accompanied by fever, right upper quadrant abdominal pain, nausea, vomiting, dark urine, acholic (light colored) stools, and worsening of systemic symptoms. Clinical symptoms are accompanied by elevations of the serum bilirubin, γ -globulin, and hepatic transaminases from 4 to 10 times above normal. Most patients with either acute anicteric or icteric hepatitis go through the convalescence stage

to complete recovery without developing complications or chronic sequelae.

Liver injury is immune mediated with cytolytic T cells maintaining the primary role in cell destruction.⁶ Death of hepatocytes results in viral elimination and eventual resolution of the clinical illness. Viremia begins soon after infection and continues throughout the time liver enzymes are elevated.² The host antibody response to HAV initially appears as the viral particles begin to disappear from stool. Like most host antibody responses, antibodies of the IgM class appear first and imply recent infection. IgM anti-HAV usually is detectable 5 to 10 days before symptoms appear. After 2 to 6 months, the IgM antibodies are replaced with IgG antibodies, which usually persist throughout life and confer immunity to HAV.² Patients who receive immunoglobulin will have low titers of anti-HAV for several weeks after inoculation.² Patients who receive hepatitis A vaccine will also have anti-HAV.²

CLINICAL PRESENTATION

Hepatitis A infection usually results in an acute, self-limited disease that rarely leads to fulminant hepatic failure. The clinical features of acute hepatitis A are summarized in Table 40–1. After an average incubation period of 28 days, with a range of 15 to 50 days, symptomatic individuals will experience an abrupt onset of anorexia, nausea, vomiting, malaise, fever, headache, and right upper quadrant abdominal pain.² Patients with underlying liver disease such as chronic hepatitis C infection are more likely to develop fulminant hepatic failure.⁷ Clinical symptoms also vary with age. Children younger than 6 years old are usually asymptomatic or have a mild influenza-like illness without clinical jaundice.² In contrast, more than 70% of infected adults and older children display the characteristic clinical syndrome of acute hepatitis with elevated hepatic transaminase levels and jaundice.²

The vast majority of people who become ill with HAV completely recover. HAV infection usually produces a self-limited illness that lasts less than 2 months, although 10% to 15% of patients exhibit a cholestatic illness with predominant elevations of alkaline phosphatase, γ -glutamyl transferase, and total bilirubin that continues or is relapsing for up to 6 months.² Pruritus is often a major complaint

TABLE 40–1. Clinical Presentation of Acute Hepatitis A

Signs and symptoms

- The preicteric phase brings nonspecific influenza-like symptoms consisting of anorexia, nausea, fatigue, and malaise
- Abrupt onset of anorexia, nausea, vomiting, malaise, fever, headache, and right upper quadrant abdominal pain with acute illness
- Icteric hepatitis is generally accompanied by dark urine, acholic (light-colored) stools, and worsening of systemic symptoms
- Pruritus is often a major complaint of icteric patients

Physical examination

- Icteric sclera, skin, and secretions
- Mild weight loss of 2 to 5 kg
- Hepatomegaly

Laboratory tests

- Positive serum IgM anti-HAV
- Mild elevations of serum bilirubin, γ -globulin, and hepatic transaminase (alanine transaminase [ALT], and aspartate transaminase [AST]) values to about twice normal in acute anicteric disease
- Elevations of alkaline phosphatase, γ -glutamyl transferase, and total bilirubin in patients with cholestatic illness

of these patients.⁵ A relapse is rarely associated with extrahepatic manifestations such as cryoglobulinemia, arthritis, and vasculitis. No cases of a chronic carrier state or chronic hepatitis have been reported.

The gold standard method of diagnosis of an acute HAV infection involves detection of serum IgM anti-HAV that becomes positive at the onset of symptoms. The antibody peaks during the early phase

of convalescence and remains positive for 4 to 6 months after the onset of the disease. In addition to the presence of antibody, the diagnosis is based on the clinical suspicion, characteristic symptoms, and elevated aminotransferases and bilirubin. HAV infection cannot be differentiated from other types of viral hepatitis by clinical or epidemiologic features.²

▶ TREATMENT: Hepatitis A Virus Infection

■ DESIRED OUTCOME

The ultimate goal in treating acute viral hepatitis is to return the individual to the previous state of health. Intermediate goals while the individual is acutely symptomatic and infectious include decreasing morbidity and acute mortality, normalizing aminotransferases (to stop hepatic inflammation), stopping viral replication in the host, and ultimately eradicating the virus.

■ GENERAL APPROACH TO THERAPY

Management of acute HAV infection is primarily supportive, as the disease is usually self-limited and the majority of patients infected with HAV will have full clinical and biochemical recovery within 12 weeks.⁶ General measures include a healthy diet, rest, maintaining fluid balance, and avoiding hepatotoxic drugs and alcohol. Special diets are of no benefit. Management includes laboratory tests (International Normalized Ratio and liver function tests) aimed at identifying the group of patients at risk of developing fulminant liver failure. Hospitalization is necessary only for those who have prolonged vomiting, coagulation defects, or fulminant hepatitis.

■ PHARMACOLOGIC THERAPY

3 Pharmacologic agents offer no clear benefit in the treatment of patients infected with HAV. Corticosteroids have been used in patients with acute HAV when cholestatic hepatitis or fulminant hepatic failure is evident. However, controlled trials have failed to demonstrate any benefit and in some cases the use of corticosteroids may worsen clinical outcomes.⁸

■ FULMINANT HEPATITIS (ACUTE LIVER FAILURE)

Liver injury that results in fulminant hepatic necrosis and acute liver failure is relatively rare. When it occurs, death results in days or weeks in nearly 80% of cases.⁹ Any potential hepatotoxic agent (e.g., acetaminophen) can be responsible, although viral hepatitis is the most common cause worldwide, especially HBV (1% of patients with acute hepatitis B develop fulminant hepatitis).^{9–11} Fulminant hepatitis caused by HAV occasionally occurs; acute liver failure caused by HCV is rare.⁹

Patients with fulminant hepatic necrosis typically develop signs and symptoms of viral hepatitis, and then rapidly develop evidence of hepatic failure. The clinical syndrome is usually a 1- to 3-week

course of hepatic failure and encephalopathy with coma developing within 8 weeks of the onset of acute hepatitis. Hyperexcitability, insomnia, somnolence, irritability, and impaired mental status are evidence of impending hepatic failure. Ominous signs include a rapid decrease in liver size, a rapid decline in aminotransferase levels, prolonged International Normalized Ratio or prothrombin time, and hypoglycemia. Manifestations of hepatic failure include metabolic encephalopathy, coma, coagulation defects, ascites, and edema. In fulminant liver failure, complications include gastrointestinal hemorrhage, sepsis, cerebral edema, renal failure, lactic acidosis, and disseminated coagulopathy, with death resulting from bleeding, cerebral edema, hypoglycemia, infection, and/or multisystem organ failure.⁹

Prompt referral for liver transplantation is the therapy of choice for most patients with fulminant hepatic failure.⁹ Transplantation should be considered in all cases in which the patient demonstrates progressive clinical deterioration (encephalopathy, hypoglycemia, metabolic acidosis, renal failure, and coagulation defects).¹¹ Patients should be transferred at the first sign of altered mental status, because these patients often worsen very rapidly. One-year survival rates with liver transplantation for fulminant hepatitis are 50% to 80% (as compared to <20% with medical management alone).¹¹

There is no specific medical treatment for fulminant hepatic failure. The goal of medical management is to support organ function in the interim until the liver recovers or a donor organ is available.¹¹ Management therefore focuses on recognition coupled with prevention and aggressive management of complications. Cerebral edema occurs in 75% to 80% of cases that progress to grade IV encephalopathy, and is the leading cause of death in these patients.¹¹ Management includes intracranial pressure monitoring and administration of mannitol (0.3 to 1 g/kg body weight as a 20% solution administered intravenously over 20 minutes) when intracranial pressure increases above 20 mm Hg.¹¹ Pentobarbital lowers intracranial pressure, but it also can cause severe hypotension, and its use is limited to cases with elevated intracranial pressure that is unresponsive to mannitol and with good cerebral blood flow.¹¹ Corticosteroids and hyperventilation are of little value in cerebral edema related to acute liver failure.¹¹ Fresh frozen plasma should be administered for bleeding, histamine₂-blocker therapy should be given to prevent GI bleeding, and aggressive antibiotic therapy should be used for infections. Renal replacement therapy is used for acute renal failure, while fluid replacement (with pulmonary artery wedge pressure and cardiac output monitoring) and vasopressors provide circulatory support.¹¹ Metabolic abnormalities (e.g., hypoglycemia) should be treated with standard metabolic support. For further information on medical therapy, drug dosing, and adverse effects, the reader is referred to the corresponding topics in appropriate chapters of this textbook. New treatment options being evaluated include artificial liver support systems and hepatocyte transplantation. These options are at an early stage of development and further controlled clinical trials are needed to determine safety and efficacy.¹¹

PREVENTION OF HEPATITIS A

GENERAL APPROACH TO PREVENTION OF HEPATITIS A

Highly effective inactivated vaccines against HAV have been available in the United States since 1995. These vaccines can substantially lower the incidence of HAV infection, and potentially even eradicate the disease.² The most effective means of achieving control of HAV infection is to vaccinate all children by incorporating hepatitis A vaccination into routine childhood immunizations. However, a vaccine formulation is currently not available for children younger than 2 years old. Until routine infant vaccination is feasible, the vaccination strategy in the United States includes vaccinating: (a) children in states, counties, and communities with consistently elevated rates of hepatitis A; (b) persons in groups at increased risk for HAV infection, such as international travelers; and (c) persons at risk of adverse outcomes, such as persons with chronic liver disease.²

Even though effective active and passive immunity agents are available for HAV, the importance of avoiding exposure cannot be overemphasized. The most important measures to avoid exposure include good hand-washing techniques and good personal hygiene practices. Travelers can minimize risk by avoiding uncooked shellfish, uncooked fruits and vegetables, and by avoiding drinking water (and other beverages with ice) of unknown purity. If exposure occurs, postexposure prophylaxis is with immune globulin injection.

Immuglobulin to Prevent Hepatitis A

Immuglobulin (Ig) provides protection against HAV by passive transfer of concentrated antibodies (immunoglobulins) against HAV (anti-HAV). Ig is effective in modifying the course and preventing the spread of HAV in 85% or more of exposures when used within 2 weeks following the exposure.² Pregnancy and lactation are not contraindications to receiving Ig; however, when Ig is administered to pregnant women or infants, thimerosal-free preparations should be used.² Both Ig given intramuscularly and Ig for intravenous administration contain anti-HAV, but only the intramuscular formulation is used for prevention of HAV infection.²

International travelers are the major group receiving preexposure prophylaxis with Ig. Ig is recommended for susceptible persons traveling to developing countries. A single dose of Ig of 0.02 mL/kg IM (in the deltoid or gluteus muscle) is recommended if travel is for less than 3 months. For lengthy stays, 0.06 mL/kg IM should be given every 3 to 5 months.² Dosing is the same for adults and children. The concentrations of anti-HAV achieved after administration of Ig (or after active vaccination) are 10 to 100 times lower than those achieved after natural infection and are often below the limits of detection for commercial assays.²

The availability of an effective hepatitis A vaccine has reduced the use of Ig in travelers. However, Ig is less expensive than vaccination, and remains an alternative for the traveler who does not need long-term protection. If the interval between the first dose of the hepatitis A vaccine and travel is less than 2 weeks, administration of Ig should be considered to provide passive immunity during the interval before active vaccine-induced immunity develops. In this situation, the lower dose of Ig is used. The postexposure prophylactic benefit from Ig is greatest early in the incubation period and is of no benefit more than 2 weeks after exposure.² In most situations, serologic screening of contacts for anti-HAV is not recommended before Ig administration because screening is costly and delays prophylaxis. A single Ig dose of 0.02 mL/kg IM is used for postexposure prophylaxis. Again, the dose is the same for adults and children. People

who have been given one dose of hepatitis A vaccine at least 1 month before exposure do not need Ig.

Ig should be given to previously unvaccinated people who have had (a) close personal contact with a person who has hepatitis A; (b) all staff and attendees of day care centers when hepatitis A is documented; (c) common-source exposures (other food handlers at locations where a food handler has hepatitis A; patrons, if the infected food handler handled food and had diarrhea or poor hygienic practices); (d) classroom contacts of an index case patient; and (e) schools, hospitals, and work settings at which close contact occurs with index patients.²

Serious adverse events with Ig are rare. Anaphylaxis has been reported in individuals with IgA deficiency who have received repeated doses of Ig.²

Hepatitis A vaccine can be given concomitantly with Ig; however, the antibody titer obtained is lower (but still protective) than when the vaccine is given alone. Ig can interfere with the response to measles, mumps, rubella (MMR), and varicella vaccines.² Administration of MMR vaccine should be delayed for at least 3 months after administration of Ig (5 months for varicella vaccine).² Conversely, Ig should not be administered within 2 weeks after the administration of MMR (3 weeks for varicella vaccine), unless the benefits of Ig clearly outweigh the benefits of vaccination. If Ig is administered within 2 weeks after administration of MMR (3 weeks for varicella vaccine), the person should be revaccinated—but no sooner than 3 months (5 months for varicella) after Ig.²

Vaccines to Prevent Hepatitis A

Inactivated HAV vaccines, Havrix (SmithKline Beecham) and Vaqta (Merck) both demonstrate protective efficacy in 94% to 100% of vaccinees within 1 month after primary vaccination.^{12,13} When a booster dose is given 6 or more months later, essentially 100% of recipients develop high antibody levels. Both vaccines are indicated for immunization of individuals 2 years of age or older. Groups recommended for preexposure protection against HAV with hepatitis A vaccine are shown in Table 40–2. Hepatitis A vaccine is useful in preventing secondary infection in household contacts of primary cases of HAV infection.¹⁴ However, no recommendations exist for use of hepatitis A vaccine for postexposure protection.

The two vaccine products have different formulations and the dosing differs according to the person's age. Table 40–3 lists the approved dosing for these vaccines. The primary vaccination is a single dose, with a booster dose 6 to 12 months later for children and adults. Both vaccines are injected intramuscularly into the deltoid muscle. The primary immunization should be given at least 2 weeks (preferably 4 weeks) prior to expected exposure to HAV. The vaccine can be given at the same time as many other vaccines (diphtheria, tetanus, live or inactivated polio, oral and injectable typhoid, cholera, Japanese encephalitis, rabies, yellow fever, and hepatitis B) without interfering with the immune responses. If one dose is given with one brand and the other dose given with the other brand, protective antibody levels do not differ;² the two brands are interchangeable. As with other inactivated vaccines, hepatitis A vaccine can be administered to immunocompromised persons.

To date, the vaccines are known to have protective levels of anti-HAV for at least 5 to 8 years.^{2,14} Based on kinetic models of antibody decline, protective anti-HAV levels should be present for 20 years to life.² The vaccine is safe. Side effects include local reactions at the injection site (soreness, induration, redness, and swelling) and headache.² Finally, the recent development of a multivalent combination vaccine against both HAV and HBV (Twinrix) provides a more rapid method of vaccinating individuals at risk for both diseases. The

TABLE 40–2. Groups at Increased Risk of Hepatitis A and Recommended for Preexposure Hepatitis A Vaccination

|---|
| Children living in states, counties, or communities where rates of hepatitis A are at least twice the national average (≥ 20 cases per 100,000 population). For 1987–1997, these states included Arizona, Alaska, Oregon, New Mexico, Utah, Washington, Oklahoma, South Dakota, Idaho, Nevada, and California. |
| Children living in states, counties, or communities where rates of hepatitis A are greater than the national average but lower than twice the national average should be considered for routine vaccination (≥ 10 cases but < 20 cases per 100,000 population). For 1987–1997, these states included Missouri, Texas, Colorado, Arkansas, Montana, and Wyoming. |
| Persons traveling to or working in countries that have high or intermediate endemicity of infection. ^a |
| Men who have sex with men. |
| Illegal-drug users. |
| Persons who have occupational risk for infection (e.g., persons who work with HAV-infected primates or HAV in a research laboratory setting). |
| Persons who have clotting-factor disorders. |
| Persons who have chronic liver disease (e.g., persons with chronic liver disease caused by hepatitis B or C and persons awaiting liver transplants). |

^aTravelers to Canada, Western Europe, Japan, Australia, or New Zealand are at no greater risk for HAV infection than they are while in the United States. All other travelers should be assessed for hepatitis A risk.
From Centers for Disease Control.²

vaccine can be administered on days 0, 7, and 21 to provide 99% and 82% immunity against HAV and HBV within 1 month, respectively. Immunity rises to 100% for both HAV and HBV within 13 months of the end of the vaccination regimen.¹⁵

ECONOMIC CONSIDERATIONS IN PREVENTION OF HEPATITIS A

Vaccination against HAV without prior screening is only cost-saving for groups of young adults who are exposed to a relatively high risk of HAV infection; for example, in communities with high rates of HAV.^{2,16,17} Prior screening for HAV antibodies can only be recommended from a cost-effectiveness point of view at expected levels of natural immunity exceeding 35% (moderately endemic countries or in older travelers).^{13,14} Passive immunization remains the most cost-effective option for occasional short-duration travel to highly

TABLE 40–3. Recommended Dosing of Havrix and Vaqta

| Vaccine | Vaccinee's Age (years) | Dose | Volume (mL) | Number Doses | Schedule (months) ^b |
|---------|------------------------|------------------------------|-------------|--------------|--------------------------------|
| Havrix | 2 to 18 | 720 ELISA units ^a | 0.5 | 2 | 0, 6–12 |
| | >18 | 1440 ELISA units | 1 | 2 | 0, 6–12 |

| | >17 | 50 Units | 1 | 2 | 0, 6 |

^aHavrix previously was also available as 360 ELISA units per dose. This formulation was administered as a three-dose schedule for persons 2 to 18 years of age. It is no longer available.

^b0 months represents the timing of the initial dose; subsequent numbers represent months after the initial dose.

From Centers for Disease Control.²

endemic areas. Vaccination is cost effective for individuals who are likely to spend several or prolonged periods in highly endemic countries. On average, vaccination of the U.S. general public is unlikely to be cost-saving, as the cost per infection prevented can be several thousands of dollars.^{16,17} In contrast, vaccination programs targeted to patients at risk for developing hepatitis may be cost effective. For example, substitution of HBV vaccination programs in sexually transmitted disease clinics serving a million patients with a combined HAV/HBV vaccine was anticipated to prevent 2263 occult HAV infections and cost \$13,397 per quality-adjusted life year (QALY) gained.¹⁸ Similarly, targeted vaccination of patients with chronic HCV with HAV vaccination has been deemed cost-effective.¹⁹

HEPATITIS B VIRUS

Worldwide, over 400 million people are infected with some form of chronic HBV. HBV is a leading cause of chronic hepatitis, cirrhosis, and hepatocellular carcinoma. The economic consequences of infection with HBV are staggering. Primary prevention through universal vaccination of neonates and adolescents is likely to have the largest impact on curtailing this disease.²⁰

EPIDEMIOLOGY

HBV infection is a worldwide public health problem. The prevalence of HBV infection varies in different geographic areas of the world, with carrier rates ranging from 0.1% to 15%.²⁰ A review of National Health and Nutrition Examination Survey (NHANES) II (1976–1980) and NHANES III (1988–1994) reported a 5.5% prevalence of HBV infection in the United States.²¹ Black participants had the highest prevalence (12.8%) compared to whites and Hispanics (3% to 5%).²¹ In highly endemic areas (China, Southeast Asia, the Middle East, and parts of Africa and South America), HBV spread is predominantly by mother-to-infant perinatal transmission and by child-to-child transmission. In highly endemic areas high rates of chronic viral carriage and virus-associated primary hepatocellular carcinoma are seen. In parts of the world in which the endemicity of HBV is relatively low (North America, Australia, Western Europe, and temperate South America), the chronic viral carriage rate is correspondingly low, mother-to-infant transmission is relatively uncommon, and HBV transmission occurs either through intimate contact or parenterally. High-risk groups in low endemic areas include intravenous drug abusers, multitransfused patients, health care providers, male homosexuals, heterosexual partners of HBV-infected people, and heterosexual partners of human immunodeficiency virus (HIV)-infected individuals.²⁰ Transmission of HBV in the United States occurs predominantly through contact with infected blood products or body secretions (e.g., saliva, vaginal fluids, and semen). The routine practice of screening blood donors for hepatitis B surface antigen (HBsAg) has essentially eliminated HBV as a cause of posttransfusion hepatitis. However, products or concentrates of blood such as clotting factors can remain infective despite prescreening for HBsAg. Excluding cases resulting from clotting factor concentrates, most blood-borne HBV transmissions are a consequence of accidental inoculation by health care workers or the sharing of needles by intravenous drug abusers (percutaneous exposure).²⁰ The chief obstacles to eradication of HBV include the carrier state and infections in utero, **4** neither of which is preventable. Individuals who acquire HBV as children (postnatally) have a very high rate of becoming chronic HBsAg carriers.³² A small percentage of these children develop complications such as cirrhosis or hepatocellular carcinoma within

20 years of being infected.²² Unfortunately, for infants who acquire HBV in utero, progression to chronic liver disease occurs in about 90% of cases. Immunization of neonates and adolescents is now the current standard of care in the United States; however, only half of the world's countries have such a policy in place.²³

ETIOLOGY

HBV is the smallest known deoxyribonucleic acid (DNA) virus, with roughly 3200 base pairs in its genome.²⁴ It is an enveloped, double-stranded DNA virus belonging to the Hepadnaviridae family. This family of viruses replicates in the liver and cause hepatic dysfunction cycles that ultimately lead to chronic hepatitis, cirrhosis, and hepatocellular carcinoma. A small spherical and tubular particle known as HBsAg can be found circulating in the bloodstream of infected patients. The viral core contains a single molecule of partially double-stranded DNA referred to as the *HBV core antigen* (HBcAg). A DNA polymerase viral peptide is also found in the core and is referred to as the *HBV e antigen* (HBeAg).²⁴ Clearance of HBV is highly dependent on expression of HBeAg, which when expressed on the hepatocellular surface induces a potent immunologic response. A lack of HBeAg expression in certain precore mutants results in more aggressive hepatic disease which is resistant to interferon- α (IFN- α) therapy and a higher probability of graft failure after liver transplantation.²⁵ In addition, HBV has been classified into seven genotypes (A through G) with geographic variance in distribution of these genotypes; specifically, genotype A, which is predominantly found in North America, compared to genotypes B and C, which are found in Southeast Asia. HBV genotype C has been associated with more active necroinflammation in the liver compared to genotype B. The role of other HBV genotypes on the natural history of HBV is not well characterized.²⁶

PATHOPHYSIOLOGY

HBV is not directly cytopathic; instead liver injury is immune related, and T lymphocytes are important for both the host cellular and humoral responses.²⁷ Recovery from acute HBV infection depends on both B-cell and T-cell responses. B-cell-dependent antibodies are produced to presurface and surface antigens. Cytotoxic T lymphocyte response is mounted against multiple epitopes in the HBV envelope, nucleocapsid, and polymerase regions.²⁷ Cytotoxic T lymphocyte-mediated lysis of infected hepatic cells occurs, resulting in liver injury. Immune clearance of virus is often accompanied by worsening liver disease, known as a flare. An extreme example of this is seen in fulminant hepatitis B, when there is often no evidence

of HBV replication when the patient presents—the virus has been rapidly and aggressively cleared by the infected individual's immune system. Immune-mediated viral clearance can also occur through non-cytolytic pathways via cytokine release.²⁷ In contrast, development of chronic HBV is hypothesized to be a function of poor cytotoxic T-lymphocyte response to viral antigens.

HBV is not considered a cytopathic virus; in certain circumstances, however, it can cause direct cytotoxic liver injury. Direct cytopathic liver injury can occur when the viral load is very high, as in the rare fibrosing cholestatic hepatitis.²⁷ After the HBV enters the vascular compartment, it migrates to the liver, where primary replication occurs. The incubation period of HBV is 1 to 6 months—much longer than HAV.²⁷ HBV replication occurs in liver cell nuclei, with HBsAg produced in the cell cytoplasm and expressed on the cell surface. These particles are also found circulating in the plasma of patients with acute HBV, the chronic carrier state, and chronic HBV infection.²⁷

In acute HBV infection, serologic markers proceed in sequence from the development of HBsAg followed by HBeAg (30 to 60 days prior to onset of clinical symptoms) through to the appearance of anti-HBs in late convalescence (Table 40–4).²⁰ Antibody to HBsAg (anti-HBs) is initially detected as the concentration of HBsAg in plasma wanes (but is probably present much earlier than detected by standard serologic assays). The presence of anti-HBs without HBsAg indicates protective immunity (see Table 40–4).²⁰ Other antigen markers of HBV infection include pre-Surface 1 and pre-Surface 2 for the envelope, and the functional X protein. These markers are not routinely used clinically. Anti-HBc, the antibody directed against HbcAg, is first detected shortly after the onset of acute cellular injury (see Table 40–4). Anti-HBc is initially of the IgM class and signifies acute HBV infection. IgG-class anti-HBc antibodies become detectable several months following the acute HBV infection and persist along with HBs antibody for life. Anti-HBc is detectable in essentially all patients who have been exposed to HBV.²⁰ The presence of plasma anti-HBc IgG antibodies signifies prior infection, but it is not protective (see Table 40–4).^{20,28}

HBeAg is a protein subunit of the viral core detected in plasma immediately prior to or at the onset of hepatocyte injury and correlates with a high degree of infectivity. In contrast, the presence of antigen against HBe (anti-HBe) correlates with a very low degree of infectivity and portends complete recovery. Anti-HBe becomes detectable either immediately after the peak of liver injury or in early convalescence, and can persist for years. HBV may also play an indirect role in the malignant transformation of hepatocytes through mechanisms related to expression of viral surface markers with oncogenic potential or through integration of viral DNA into the cell.²⁸

TABLE 40–4. Interpretation of the Laboratory Profile in Hepatitis B Virus (HBV) Infection

| Pattern | Is Patient Infectious? | HBV Markers | | | Anti-HBc | |
|---|------------------------|-------------|-------|-------|----------|----------|
| | | HBsAg | HBeAg | Total | Anti-HBs | Anti-HBe |
| Not infected/early incubation | No | – | – | – | – | – |

CLINICAL PRESENTATION

ACUTE HEPATITIS B

The clinical course of HBV infection and the associated clinical features cannot be differentiated from other types of viral hepatitis based on symptoms. The duration of incubation is highly dependent on age and can vary between 6 and 24 weeks. Infants do not develop any symptoms and children between the ages of 1 and 5 years are asymptomatic in 85% to 95% of the cases.²⁹ Symptomatic infections vary in severity and include fever, anorexia, nausea, vomiting, jaundice, dark urine, clay-colored or pale stools, and abdominal pain. Extrahepatic manifestations of HBV infection rarely occur and may include skin rash, arthralgias, and arthritis. Hepatic failure occurs rarely, with a case fatality rate of 0.4%.³⁰

Acute HBV infection is diagnosed by the presence of anti-HBc IgM (see Table 40–4). There are periods during the course of acute HBV infection when specific serologic markers are absent; the lack of such markers complicates diagnosis. These “window” periods can be seen in the early incubation phase when HBsAg and HBeAg are not detectable despite the presence of ongoing viral replication, and early in convalescence when these two antigens are cleared prior to the appearance of anti-HBs antibody. Markers of HBV replication (HBV DNA and DNA polymerase) are sensitive indicators, and are occasionally obtained when a patient is suspected to be in the serologic window period. Low levels of HBV DNA can be detected in peripheral mononuclear cells and livers of patients several years after recovery from acute HBV. These data indicate that HBV is not eradicated in these patients and can be reactivated when their immune systems are suppressed.²⁹

CHRONIC HEPATITIS B

The presence of HBsAg in serum for at least 6 months or the presence of HBsAg and the absence of anti-HBc IgM meets the definition of chronic HBV infection. In addition, the presence of HBV DNA greater than 10^5 copies/mL and persistent or intermittent elevation in AST/ALT levels meet the diagnostic criteria for HBV.³⁰ Risks associated with development of chronic HBV include the presence of **4** renal failure, diabetes, or HIV.³¹ The probability of developing chronic HBV is inversely proportional to age; infants have a 90% risk while adolescents and adults have ~10% risk. Patients who develop chronic HBV are subsequently predisposed to developing chronic liver disease, cirrhosis, and hepatocellular carcinoma (HCC). The clinical presentation of chronic HBV is summarized in Table 40–5. Progression from chronic HBV to HCC is also age dependent, with prospective studies indicating a 25% risk in patients who acquire the disease as infants, compared to a 15% risk if contracted as

TABLE 40–5. Clinical Presentation of Chronic Hepatitis B^a

Signs and symptoms

- Easy fatigability, anxiety, anorexia, and malaise
- Ascites, jaundice, variceal bleeding, and hepatic encephalopathy can manifest with liver decompensation
- Hepatic encephalopathy is associated with hyperexcitability, impaired mentation, confusion, obtundation, and eventually coma
- Vomiting and seizures

Physical examination

- Icteric sclera, skin, and secretions
- Decreased bowel sounds, increased abdominal girth, and detectable fluid wave
- Asterixis
- Spider angiomas

Laboratory tests

- Presence of hepatitis B surface antigen for at least 6 months
- Intermittent elevations of hepatic transaminase (alanine transaminase [ALT] and aspartate transaminase [AST]) and hepatitis B virus DNA greater than 10^5 copies/mL
- Liver biopsies for pathologic classification as chronic persistent hepatitis, chronic active hepatitis, or cirrhosis

^aChronic hepatitis B can be present even without all the signs, symptoms, and physical examination findings listed being apparent.

an adolescent.²⁹ In addition, very high HBV DNA levels, normal ALT, and the presence of HBeAg characterize chronic HBV acquired through perinatal transmission. This immune-tolerant phase can last for 10 to 30 years, allowing for individuals with perinatal acquisition to be infectious in their adulthood and perpetuate vertical transmission of the disease. In contrast, children and adults who acquire chronic HBV infection present in the immune-clearance phase, which is marked by clearance of HBeAg, in 70% of cases within 10 years. Most patients who seroconvert remain HBeAg-negative and anti-HBe-positive with normal ALT and low HBV DNA, and are considered to be in an “inactive carrier state.”²⁹

Liver biopsies performed in patients with chronic HBV infection are classified as chronic persistent hepatitis, chronic active hepatitis, and cirrhosis.³³ Histologic results do not correlate with symptoms and often patients are asymptomatic until the development of cirrhosis.³⁴ Cirrhosis is manifested by interlacing strands of fibrous tissue with nodules of regenerating cells resulting in a characteristic small and knobby-appearing liver. This form of injury is irreversible and can be exacerbated by heavy alcohol consumption and concomitant infection with HCV or HIV.³⁵ Hepatic decompensation as a result of cirrhosis includes ascites, jaundice, variceal bleeding, and hepatic encephalopathy. The 5-year risk of decompensation after the development of cirrhosis is estimated to be 20%.²⁶

► TREATMENT: Hepatitis B Virus Infection

■ DESIRED OUTCOME

No specific therapy is available for the management of acute HBV infection. Development of fulminant hepatitis secondary to acute HBV is rare and is managed with supportive care (see section on fulminant hepatitis). The long-term complications of chronic HBV include development of cirrhosis, liver failure, and HCC. The key goal of therapy for chronic HBV is to eradicate or permanently suppress HBV. The short-term objective is to limit hepatic inflammation and to reduce

the risk of fibrosis and/or decompensation. The longitudinal goal is to prevent transaminase flares and the development of long-term complications, as well as to prolong survival. Loss of HBeAg, either spontaneously or with pharmacologic therapy, is independently associated with improved survival in patients with chronic HBV. Thus HBeAg loss and development of anti-HBeAg is a critical outcome measure in patients with chronic HBV. In addition, durability of specific pharmacologic therapy for maintenance of HBeAg seroconversion is also important. Therapeutic strategies include the use of immunomodulators such as α -interferons and nucleoside analogs. Prevention of HBV

resistance to nucleoside analogs during therapy is vital for adequate management of these patients.

■ GENERAL APPROACH TO TREATMENT

Acquisition of HBV within the first 5 years of life is associated with a higher risk for development of cirrhosis.²⁶ Consequently, early treatment of infants and children should be attempted, given that clearance of HBsAg rarely occurs spontaneously in this group. Spontaneous clearance of HBeAg occurs at a rate of approximately 10% per year in older groups.³⁶ Individuals with long-standing disease with hepatic inflammation are likely to be poor responders to therapy and require the most intensive management.

Numerous pharmacologic agents with varying modes of action are in clinical development. Three agents are currently approved for use in the United States by the Food and Drug Administration and include interferon- α 2b (IFN- α 2b), lamivudine, and adefovir dipivoxil.³⁷ No drug therapy is recommended for patients with normal ALT values because this group responds poorly to therapy. Instead quarterly to biannual follow-up of these patients for HCC surveillance and ALT assessment should be considered. Patients with persistent ALT levels greater than twice the upper limit of normal should be considered for treatment. Patients with rising ALT levels, specifically rising to greater than five times the upper limit of normal, are considered to be having an exacerbation. Lamivudine therapy should be used for exacerbations because it has a rapid onset of effect. In contrast, IFN- α 2b onset of action may not be rapid enough to prevent hepatic decompensation.³⁸

5 Therapeutic choice between lamivudine and interferon is more controversial for patients who are HBeAg-positive with ALT levels two to five times the upper limit of normal. Notably, the relative risk of relapse after HBeAg seroconversion with lamivudine therapy is about four times higher than with an α -interferon-containing regimen.³⁹ The decision to treat individuals is ultimately a function of disease severity, history of flares, hepatic function, drug cost, side-effect profile, and patient choice. The long-term effects of IFN- α 2b are better known than those of lamivudine. In addition, extending the duration of lamivudine therapy with the intent to improve response risks development of resistant HBV mutations. The availability of adefovir dipivoxil is promising as rescue therapy after lamivudine because it is active against both wild-type and select mutants of HBV. However, well-controlled comparative trails of lamivudine to adefovir dipivoxil are not available. The role of combination therapy has yielded conflicting results and requires further evaluation.^{38,40}

■ NONPHARMACOLOGIC THERAPY

About 75% of the 400 million people with chronic HBV live in Asia. Herbal medication use is a common therapeutic modality in many parts of the world and has been studied extensively in China. A meta-analysis of over 500 papers, including randomized controlled trials, concluded that existing studies were of poor quality, limiting the definitive interpretation of results.⁴¹ However, the meta-analysis did identify that bufotoxin and kurorinone were associated with increased seroconversion of HBeAg and clearance of HBV DNA. Further evaluation of these active components as a possible therapeutic alternative is warranted, but they are not currently being recommended for routine use.

■ PHARMACOLOGIC THERAPY

Patients considered for treatment are those who are HBsAg-positive for greater than 6 months with persistent elevations in serum aminotransferases, detectable markers of viral replication (HBeAg and HBV DNA) in serum, and signs of chronic hepatitis on liver biopsy. Although symptomatic patients are more apt to seek medical attention and to have these irregularities discovered, symptoms alone are not a basis for treatment. To be treated with IFN- α , patients should not have decompensated liver disease or any specific contraindications to the therapy being considered.

Current strategies to eradicate HBV include the use of antiviral agents that alter viral replication or immunomodulatory agents that modify the host immune response. IFN- α 2b (Intron A) was approved by the FDA for use in chronic HBV in 1992. IFN- α 2b monotherapy 5 now is used only in selected subgroups of patients with HBV. Lamivudine (Epivir-HBV) was approved for use in chronic HBV in 1998, and has broader indications for use, but questions remain regarding optimal duration of use and management of resistant viruses. 6 Adefovir dipivoxil (Hepsera) was approved for use in chronic HBV, including lamivudine-resistant HBV, in 2002. End points of therapy for HBV include disappearance of HBV DNA and elimination of HBeAg (virologic response), resolution of elevated aminotransferases (biochemical response), and improvement of liver histology.³⁸ HBeAg seroconversion, an even stricter marker of viral response, denotes the loss of both HBeAg and HBV DNA and the appearance of anti-HBe. Loss of HBsAg can occur even years after completion of therapy.

■ FIRST-LINE THERAPY

The American Association for the Study of Liver Diseases (AASLD) has published its guidelines for the management of chronic HBV.³² In addition, the Asian Pacific Association for the Study of the Liver (APASL) has updated a consensus statement on the management of 5 chronic HBV.³⁸ The choice of first-line therapy between IFN- α 2b and lamivudine is dependent on the categorization of specific patient populations by HBeAg positivity and ALT level. As stated earlier, factors such as disease severity, history of flares, hepatic function, drug cost, side-effect profile, and patient choice ultimately drive drug selection.

In patients with chronic HBV who are HBeAg-positive and have intermittent or persistent elevation of ALT, either interferon or lamivudine may be used as first-line therapy. Lamivudine should be selected in patients at risk for decompensation given its rapidity of onset. A meta-analysis of 15 randomized controlled trials demonstrated that 33% of patients had loss of HBeAg with 12 to 24 weeks of therapy with IFN- α 2b compared to 12% in controls.⁴² Pretreatment ALT levels of greater than 100 international units per liter and low HBV DNA levels (<200 copies/mL) were predictive of improved response to interferon- α . Similarly, these parameters predict response to lamivudine therapy. Three randomized controlled trials evaluating lamivudine for a similar patient population have demonstrated a loss of HBeAg in up to 32% of patients treated for 52 weeks.^{43–45} Consequently, current guidelines do not specifically favor one agent over the other due to a lack of distinct differences in efficacy. The choice of lamivudine or interferon- α is a function of assessing the limitation of each agent. IFN- α 2b is advantageous because its use follows a defined course of therapy and it lacks susceptibility to resistant HBV mutants, but it is limited by its cost and side-effect profile. In addition, IFN- α 2b

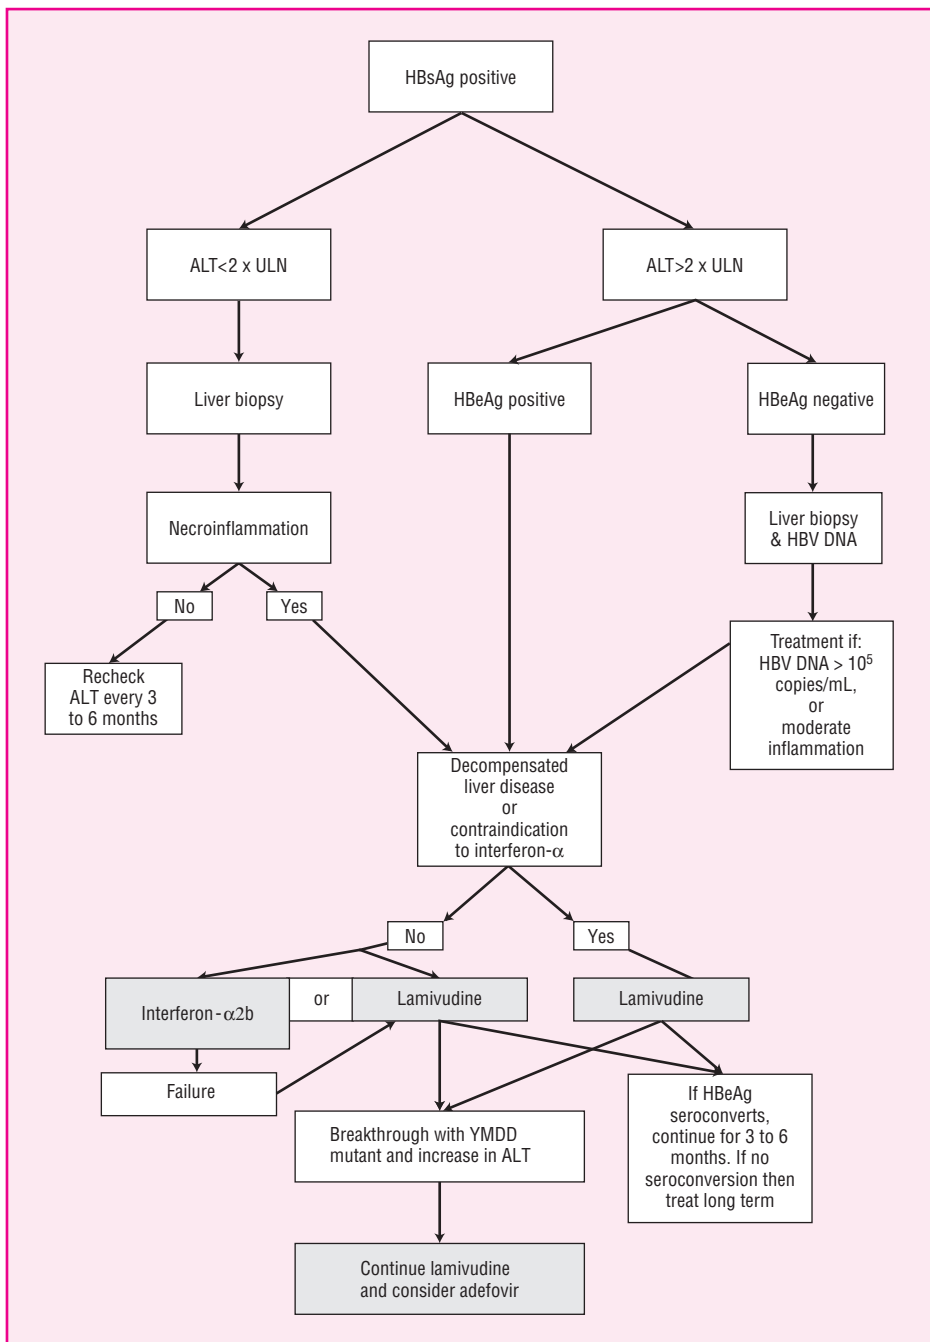

FIGURE 40–1. Treatment algorithm for the management of patients with chronic hepatitis B virus infection. ALT, alanine transaminase; HBeAg, hepatitis B e antigen; ULN, upper limit of normal.

cannot be used in patients with decompensated cirrhosis. Lamivudine is better tolerated but does not sustain a durable response and may be affected by resistant HBV mutants. Specific recommendations from the AASLD and APASL are summarized as follows and apply to both adults and children (Fig. 40–1).

1. Patients with HBeAg-positive chronic HBV: ALT >2 times the upper limit of normal (ULN) or moderate to severe hepatitis on biopsy: Treatment may be initiated with either lamivudine or interferon- α . ALT >2 times ULN: Treatment with lamivudine or interferon- α should be limited to patients with significant necroinflammation on liver biopsy. Patients should have their ALT assessed every 3 to 6 months.

2. Patients with HBeAg-negative chronic HBV: Only patients with ALT >2 times ULN, HBV DNA >10⁵ copies/mL, or moderate to severe hepatitis on biopsy should be considered for treatment with lamivudine or interferon- α .
3. Patients who fail to respond to a course of interferon- α and have ALT >2 times ULN, HBV DNA >10⁵ copies/mL, or moderate to severe hepatitis on biopsy may be treated with a course of lamivudine.
4. Patients with decompensated cirrhosis: Interferon- α should not be used and lamivudine may be considered in these patients.
5. Patients in an inactive HBsAg carrier state: No treatment is indicated.

ALTERNATIVE DRUG TREATMENTS

Adefovir dipivoxil is the prodrug of adefovir, a nucleotide analog active against HBV. In vitro and preliminary clinical evidence demonstrate that adefovir is effective in suppressing HBV replication, including lamivudine-resistant mutants. Two randomized double-blind placebo-controlled trials were conducted in both HBeAg-positive and HBeAg-negative patients with approximately 50% of cases with ALT levels greater than 2 times ULN.^{46,47} Loss of HBeAg was noted in 24% of patients receiving adefovir dipivoxil 10 mg daily compared to 11% in the placebo group at week 48.⁴⁷ A similar loss was noted with adefovir dipivoxil 30 mg daily; however, the higher dose was associated with an 8% incidence of reversible nephrotoxicity (≥ 0.5 mg/dL increase in serum creatinine). Given that HBeAg loss cannot be assessed in HBeAg-negative patients with chronic HBV, other endpoints such as HBV DNA reduction, normalization of ALT, and changes in liver biopsy inflammatory scores were assessed. Improvement in histologic liver abnormalities were noted in twice as many adefovir dipivoxil-treated patients compared to those on placebo.⁴⁶ Undetectable HBV DNA levels were noted in 51% of patients on adefovir dipivoxil compared to none in the placebo arm. ALT normalization was also significantly higher in the adefovir dipivoxil group. No development of resistance to adefovir was noted in these trials. Comparative trials of adefovir dipivoxil to lamivudine have not been conducted to ascertain the placement of this agent.

Famciclovir, an oral prodrug of penciclovir, is an effective agent for suppression of HBV, but is associated with a low rate of HBeAg clearance compared to lamivudine. Its use is limited by the need for thrice-daily administration, cross-resistance with lamivudine, and low efficacy.⁴⁸ Combination therapy with lamivudine or thymosin- α_1 is associated with improved HBeAg seroconversion compared to famciclovir alone.⁴⁹ Thymosin- α_1 is an immunomodulatory agent that enhances the activity of T-helper₁ cells. A meta-analysis of studies evaluating thymosin- α_1 indicated that it has limited activity during therapy, but induces a virologic response 12 months after the end of therapy.⁵⁰ More data are necessary to evaluate the role of thymosin- α_1 . Prednisone administration as a tapering course prior to antiviral therapy has been found to be beneficial in small subset of patients.⁵¹ However, patients with underlying cirrhosis are at an increased risk for fatal exacerbations when prednisone priming is given, and its use is not recommended in these patients. Other antiviral agents that have shown promising results in clinical trials include emtricitabine, entecavir, and clevudine.³⁸ In addition, therapeutic vaccines against specific HBV epitopes and proinflammatory cytokines are being evaluated.⁵²

SPECIAL POPULATIONS

In contrast to IFN- $\alpha 2b$ with its significant adverse side-effect profile, almost all patients are candidates for lamivudine therapy. Patient groups in which lamivudine has shown benefit include various transplant patients, those with decompensated cirrhosis, and patients with HBV mutants with mutations in the precore region of the viral genome who present as HBeAg-negative and HBV DNA-positive.

Patients with normal aminotransferase levels should not be treated. Monitoring of this group, with treatment if disease progresses, is more advantageous than treatment, because many of these patients will not have progression of liver disease, while therapy is associated with cost and adverse event risk.

Whereas the use of IFN- $\alpha 2b$ is discouraged in patients with decompensated cirrhosis, an open trial of 35 such patients with lamivudine demonstrated significant benefit in laboratory and clinical

markers in the 23 patients who were maintained on therapy for greater than 6 months. HBV DNA was undetectable in all patients after 6 months and adverse effects were minimal.⁵³ Lamivudine also showed no decrease in its activity in patients who had active replication, but were HBeAg-negative. After a year of treatment, 65% became HBV DNA-negative and had normal transaminases.

Patients coinfecting with HIV may not respond as well to IFN- $\alpha 2b$ because HIV-associated immunosuppression can block the antiviral actions of IFN- $\alpha 2b$. These patients can be considered for therapy if their disease is relatively well controlled.⁵⁴

Only a small proportion of cases of HBV infection in the United States are in children. The efficacy of IFN- $\alpha 2b$ in children seems comparable to that in adults and those with elevated ALT levels at initiation of therapy are more likely to respond. A comparative trial of IFN- $\alpha 2b$ 5 million units/m² versus 10 million units/m² three times weekly for 6 months showed greater HBeAg clearance with the higher dose (53% vs. 7%).⁵⁵ Children tolerate IFN- $\alpha 2b$ therapy better than adults.

Although some schemes of induction therapy dosing of IFN- $\alpha 2b$ have been successful in patients who had not responded to previous IFN- $\alpha 2b$ therapy, a course of lamivudine should be tried first before trying increased IFN- $\alpha 2b$ doses.⁵⁶ There are insufficient data to clarify management of pregnant patients, immunosuppressed patients, and patients coinfecting with HCV.

DRUG CLASS INFORMATION

Interferons

Interferon- α was first demonstrated to have benefits in patients with chronic HBV in the early 1970s. Development of recombinant technology and eventual availability of commercial forms of IFN- α have led to several randomized clinical trials in various countries. For a more detailed review of currently available interferon formulations including their pharmacology and disposition, please refer to the HCV section on interferons. IFN- $\alpha 2b$ is currently the only interferon approved by the FDA for management of chronic HBV. As compared to a placebo response of 12% to 17%, 33% to 37% of patients respond to IFN- $\alpha 2b$ therapy by losing HBeAg and HBV DNA.⁴² Even though most of these patients will maintain a long-term response, the low overall response rates combined with the adverse effects and need for subcutaneous dosing make IFN- $\alpha 2b$ a less-than-ideal agent. Pre-treatment predictors of response to IFN- $\alpha 2b$ include low viral load (HBV DNA <200 copies/mL) and high ALT (>100). For this subset of chronic HBV patients, an IFN- $\alpha 2b$ regimen is a rational option, although these same parameters predict response for lamivudine, an alternative agent.

Resolution of HBV viremia with IFN- $\alpha 2b$ is associated with a transient exacerbation of the hepatitis, marked by a rise in serum ALT levels during the second or third month of therapy. Although IFN- $\alpha 2b$ may have direct antiviral effects, this flare is related to immunomodulatory effects resulting in an increased host response (Fig. 40-2). In patients who respond to interferon, HBV DNA levels decrease within days of starting therapy. After 8 to 12 weeks, ALT levels increase, and the patient loses HBV DNA and HBeAg. ALT levels then normalize, and the patient develops anti-HBe.²⁹ Without the flare, loss of viral replication rarely occurs. Patients infected with precore HBV mutants that prevent HBeAg expression (HBeAg-negative and HBV DNA-positive) are less likely to respond to IFN- α therapy and have a higher rate of relapse upon discontinuation.³⁷ About 10% of the responders to IFN- α therapy also clear HBeAg in the first year, and although

FIGURE 40-2. Typical sustained response to IFN- α in a patient with chronic hepatitis B. ALT, alanine transaminase; Anti-HBe, antibody to hepatitis B e antigen; Anti-HBs, antibody to hepatitis B surface antigen; HBeAg, hepatitis B e antigen; HBsAg, hepatitis B surface antigen.

biochemical and histologic responses also occur, they are more frequent in the group responding virologically. Long-term follow-up of patients treated with IFN- α has shown that response is sustained in about 90% of patients at least 5 years after therapy, and that a distinct survival benefit is present in those who have a virologic response.

IFN- α 2b should be administered by subcutaneous injection as 5 million units daily or 10 million units thrice weekly in adults. In children, thrice-weekly subcutaneous injections of 6 million units/m² to a maximum of 10 million units per dose is recommended. Patients with HBV who are HBeAg-positive should be treated for 16 weeks, while HBeAg-negative patients should be treated for 12 months.²⁶

Administration of interferon is associated with significant side effects, which diminish with continued treatment. Flu-like symptoms such as fevers, chills, and myalgias should be expected during the first month of therapy, typically several hours after administration. Consequently administration of IFN- α 2b at bedtime along with a nonsteroidal anti-inflammatory agent improves tolerability. Pegylated formulations of interferon (see discussion in HCV section) are likely to be more tolerable but have not been studied sufficiently in patients with HBV. Additional adverse events associated with long-term IFN- α therapy include cytopenia, alopecia, thyroid dysfunction, and depression. Depression is a very common complication of IFN- α therapy, especially during the last third to fourth month of therapy. A high index for suspicion for the mental well being of patients should be maintained, as suicides have been linked to IFN- α therapy.⁵⁷

Lamivudine

Lamivudine (Epivir-HBV, 3TC) is a nucleoside analog that competitively inhibits viral reverse transcriptase and terminates proviral DNA chain extension. Because it does not affect host response, it suppresses viral replication but does not directly eliminate the virus from the hepatocytes. Its efficacy is also not associated with, or dependent upon, the flare response seen with interferon. Like IFN- α 2b though, lamivudine demonstrates higher response rates in patients with elevated transaminases (ALT >100) and lower viral loads.⁵⁸

Two double-blind randomized controlled trials in adults compared lamivudine 100 mg by mouth daily for 52 weeks versus placebo in previously untreated patients.^{43,44} The results are comparable except that one trial in Asia had a higher biochemical response in both treatment and placebo groups.⁴⁴ Both trials demonstrated significant histologic, virologic, and biochemical responses with lamivudine. Lamivudine also prevented histologic worsening or the development of hepatic fibrosis. The results of the Asian trial are especially impressive because it was previously thought that this was a difficult population to treat because of acquisition of disease at an early age.⁴⁴ Long-term outcomes are not proven, but the results of these trials are encouraging. Of note, the 32% rate of HBeAg loss in the American trial is similar to the response demonstrated with IFN- α 2b.

Upon discontinuation of lamivudine HBV DNA tends to rebound, but to levels less than the original baseline. Virologic responses were maintained in about 75% of lamivudine-treated patients 16 weeks posttherapy. Treatment beyond 1 year increases the rate of HBeAg loss and slows the rate and extent of HBV DNA return. However, extending the duration of therapy would be associated with a possible increase in adverse effects, increased cost, and increased development of resistance to lamivudine. But a recent pilot study evaluating a 3-year lamivudine regimen in 16 patients noted histologic improvement despite development of lamivudine-resistant mutants and virologic breakthrough.⁵⁹

Mutations in regions of reverse transcriptase, primarily the YMDD locus, confer resistance against lamivudine. These mutations occur after about 6 months of lamivudine therapy, are usually accompanied by increases in ALT and HBV DNA, and are more common in patients with elevated baseline viral loads. In the two lamivudine trials, the incidence of these mutations was 14% and 32%, respectively, after 1 year of therapy.^{43,44} It is thought that the mutant viruses are relatively less harmful because they are not able to replicate as effectively, but the mutants are replaced by wild-type virus upon treatment discontinuation. Despite the development of resistance, with continued lamivudine therapy the ALT and HBV DNA often remain below baseline levels and some patients may still convert from a HBeAg-positive state.

In the foregoing studies, one reported no association between treatment and transaminase level changes, whereas the other reported posttreatment levels greater than three times baseline in 25% of the treatment group, compared to 8% in the placebo group. A different cohort of 55 patients had much a higher mutation rate (58% after 2 years of lamivudine therapy), with 13 patients (24%) experiencing an ALT spike over 10 times the normal range, and 3 patients (5%) demonstrating hepatic decompensation during the flare.^{60,61}

Lamivudine has a much less toxic adverse effect profile than IFN- α 2b, with serious side effects occurring at rates similar to those of placebo.⁵⁸ The most commonly reported are fatigue, nausea and vomiting, headache, cough, and diarrhea. It is administered as a tablet or oral suspension at a dose of 100 mg orally once daily. Lamivudine is well absorbed and has renal elimination, requiring dosage adjustment if the creatinine clearance is <50 mL/min. Response to lamivudine is more rapid than that of IFN- α 2b, with HBV DNA levels decreasing by 97% after 2 weeks of therapy, and it has demonstrated success in patient subgroups that typically do not respond to interferons.

In summary, lamivudine is more convenient, has fewer adverse effects, and demonstrates at least comparable virologic, histologic, and biochemical activity compared to IFN- α 2b. The optimal duration of therapy with lamivudine is not known, especially considering that the correct course of action when resistance occurs is still unknown. With little comparative data, one is left to choose between a relatively short course of an injectable agent with demonstrated

adverse effects but documented long-term outcomes, versus a well-tolerated oral agent with activity across a greater spectrum of patients, but whose long-term effects and optimal duration of therapy are unknown.

■ Adefovir Dipivoxil

Adefovir is a nucleotide analog of deoxyadenosine monophosphate that is active against retroviruses (like HIV), herpes viruses, and hepadnaviruses. Adefovir dipivoxil 10 mg by mouth once daily for 48 weeks has been approved for use in adult patients with chronic HBV who are either treatment naïve or have lamivudine-resistant

HBV. This agent is also active against HIV but requires higher (125 mg daily) doses for treatment. Consequently, the use of adefovir in HBV patients coinfecting with HIV may induce antiretroviral resistance. However, in contrast to lamivudine, the long-term use of adefovir has not been associated with the development of resistance in HBV. Adefovir is generally well tolerated with primary adverse effects including headache and abdominal pain. Nephrotoxicity is associated with adefovir and appears to be a dose-related effect. The incidence of nephrotoxicity defined as a 0.5-mg/dL increase in serum creatinine has not been noted in patients treated with 10 mg for 48 weeks. In contrast, a 120-mg daily dose of adefovir was associated with nephrotoxicity in 35% of patients with 48 weeks of therapy.⁶²

PHARMACOECONOMIC CONSIDERATIONS

Treatment of chronic HBV in patients with favorable predictors of response is cost effective, especially among younger individuals. The direct cost of management of chronic HBV with IFN- α 2b would be approximately \$7,500 and \$25,000 for a 16-week and 12-month course, respectively.⁶³ In contrast the annual cost of lamivudine and adefovir would be approximately \$2,000 and \$6,400, respectively.⁶³ However, acquisition cost alone cannot be used to evaluate the expected value of using each agent. Using data from a meta-analysis of nine trials with 552 chronic HBV patients, IFN- α 2b treatment would increase life expectancy by 3.1 years and decrease lifetime costs by more than \$2,100.⁶⁴ A more recent comparative evaluation of the cost per additional HBeAg seroconversion was estimated to be \$12,703 with lamivudine compared to \$39,922 with IFN- α 2b.⁶⁵ However, this assessment included a decision tree model limited to 1 year of evaluation and so did not take into account the relapse rates post lamivudine discontinuation. Pharmacoeconomic analyses of the impact of adefovir have not been published. Given that lamivudine resistance emerges in 15% to 30% of persons treated in the first year, it is likely that future regimens may include either early combination regimens of adefovir and lamivudine, or a stepwise approach. Future pharmacoeconomic analyses must compare the cost-effectiveness of IFN- α 2b to potential combination regimens of adefovir and lamivudine.

CLINICAL CONTROVERSIES

Some clinicians believe that adefovir should be used as first-line therapy or at least in combination with lamivudine to prevent development of YMDD mutants. However, others argue that adefovir should be used after the development of breakthrough YMDD mutants during lamivudine therapy.

The impact of HBeAg clearance and seroconversion on the long-term outcome of patients is not clearly defined. Some clinicians would argue that the true impact of therapy may be limited given that hepatocellular carcinoma may develop in patients even after many years of serologic recovery.

EVALUATION OF THERAPEUTIC OUTCOMES

HBeAg, HBsAg, and HBV DNA should all be measured at the start of therapy, at the end of therapy, and 6 months thereafter. Aminotransferases are measured at monthly intervals in conjunction with clinical monitoring for possible decompensation (development of ascites, encephalopathy, and esophageal varices). The monthly

monitoring of ALT should detect the presence or absence of a flare, and may also help signal the development of lamivudine resistance. When lamivudine therapy is discontinued virologic and biochemical monitoring should still occur at 6 months posttherapy.⁵⁸ Similar monitoring parameters apply with the use of adefovir, with the added provision of routine renal function assessment.⁶²

Baseline and ongoing monitoring of IFN- α toxicity includes complete blood counts with platelets weekly during the first 2 weeks of therapy and monthly thereafter. Thyroid tests should be checked at baseline and every 3 to 6 months during treatment. Patients should be asked about their level of performance, mood changes, ability to concentrate, and symptoms.⁵⁷

PREVENTION OF HEPATITIS B

GENERAL APPROACH TO PREVENTION

The two types of products available for prevention of hepatitis B infection include hepatitis B vaccine (provides long-lasting active immunity) and hepatitis B immunoglobulin (HBIG; provides temporary passive immunity).⁶⁶ The vaccine is used in preexposure prophylaxis. It is also used in postexposure prophylaxis in combination with HBIG. Vaccination is the most effective method for preventing hepatitis B (Tables 40–6, 40–7, 40–8, and 40–9).^{66,67}

HBIG and Ig to Prevent Hepatitis B

HBIG is used only in postexposure prophylaxis. Postexposure prophylaxis for HBV is recommended for perinatal exposure, sexual exposure to HBsAg-positive persons, percutaneous or permucosal exposure to HBsAg-positive blood, and exposure of an infant to a caregiver who has acute hepatitis B (see Table 40–7).⁶⁶ HBIG is given to immunocompromised patients for the same indications and in the same doses as immunocompetent individuals.⁶⁶ The recommended dose is 0.06 mL/kg administered intramuscularly. Guidelines for use are listed in Tables 40–6 and 40–7.⁶⁶

Use of Ig for prophylaxis of HBV infection is only recommended when HBIG is not available. Ig contains anti-HBs in titers of 1:100 to 1:1000, in comparison to the 1:100,000 or greater anti-HBs titer found in HBIG. Ig and HBIG available in the United States do not transmit HBV, HIV, or other viruses.

Vaccines to Prevent Hepatitis B

7 The comprehensive vaccination strategy in the United States targets interruption of transmission at all age groups through routine infant immunization, continued vaccination of high-risk older adolescents and adults (e.g., HIV-infected individuals), routine screening of pregnant women for HBsAg, and vaccination of all

TABLE 40–6. Recommended Schedule of Immunoprophylaxis to Prevent Perinatal or Sexual Transmission of HBV Infection

| Vaccine Recipient | Immunoprophylaxis | Timing |
|--|--|--|
| Infant born to HBsAg-positive mother | Vaccine dose 1 | Within 12 hours of birth |
| | HBIG (0.5 mL intramuscularly at a site different from that used for the vaccine) | Within 12 hours of birth |
| Infant born to mother not screened for HBsAg | Vaccine doses 2 and 3 | Usual schedule |
| | Vaccine dose 1 ^a | Within 12 hours of birth |
| | HBIG (0.5 mL intramuscularly at a site different from that used for the vaccine) | If mother is found to be HBsAg-positive, administer dose to infant as soon as possible, but no later than 1 week after birth |
| Sexual exposure | Vaccine doses 2 and 3 ^a | Usual schedule |
| | HBIG (0.06 mL/kg intramuscularly at a site different from that used for the vaccine) | Single dose within 14 days of sexual contact |
| | Vaccine dose 1 | At time of HBIG treatment |
| | Vaccine doses 2 and 3 | Usual schedule |

^aThe first dose of vaccine is the same as that for the infant of an HBsAg-positive mother. If the mother is found to be HBsAg-positive, that dose is continued. If the mother is found to be HBsAg-negative, the remaining vaccine doses are those appropriate for other infants and children.

TABLE 40–8. Recommended Doses and Schedules of Currently Licensed Hepatitis B Vaccines

| Group | Vaccine | | |
|--|---|---|------------------------------------|
| | Recombivax HB ^a dose, mcg (mL) | Engerix-B ^{a,b} dose, mcg (mL) | Comvax ^c dose, mcg (mL) |
| Infants of HBsAg-positive mothers | 5 (0.5) | 10 (0.5) | Not indicated |
| All other infants, children and adolescents ≤19 years of age | 5 (0.5) ^d | 10 (0.5) | 5 (0.5) ^e |
| Adults age 20 years and older | 10 (1) | 20 (1) | Not indicated |
| Dialysis patients and other immunocompromised persons | 40 (1) ^f | 40 (2) ^{g,h} | Not indicated |

^aUsual schedules: Infants: Three doses given at birth, at 1 to 2 months, and at 6 to 18 months of age; or, for infants, with other routine immunizations at 1 to 2 months, 4 months, and 6 to 18 months of age. Older children and adults: Three doses given at 0-, 2-, and 6-month or, at 0-, 2-, and 4-month intervals. Higher titers of HBsAg are achieved with the last two doses of vaccine being spaced at least 4 months apart.

^bAlternative approved schedule: Four doses, one given at 0, then one each given at 1-, 2-, and 12-month intervals. HBsAg, hepatitis B surface antigen.

^cContains 5 mcg 0.5 mL HBsAg and 7.5 mcg *Haemophilus influenzae* type B purified capsular polysaccharide fragments conjugated to 125 mcg *Neisseria meningitidis* outer membrane protein complex.

^dAn alternate two-dose schedule can be used for adolescents aged 11 to 15 years. If the two-dose schedule is used, the adult dose (1 mL containing 10 mcg of HBsAg) is administered with the second dose given 4 to 6 months after the first dose.

^eUsually given at 2, 4 and 12 to 15 months of age. Comvax is not used when immunizing older children or adolescents.

^fSpecial formulation for dialysis patients.

^gTwo 1-mL doses given at different sites.

^hFour-dose schedule recommended at 0 then at 1-, 2-, 6-month intervals.

unvaccinated children ages 0 to 18 years of age (see Tables 40–8 and 40–9).⁶⁷ Several states have laws mandating hepatitis B immunization prior to entry into kindergarten or middle school.

In countries where the risk of hepatitis B is relatively low, such as the United States, determining who to vaccinate prior to exposure depends on the risk of infection in that group and the relative cost of pretesting versus the cost of vaccination. Everyone in high-risk low-prevalence groups (such as health care professionals in training) can be vaccinated without screening.⁶⁷ To comply with federal guidelines, employers offer health care workers with potential exposure to blood hepatitis B vaccination at no cost.

In addition to vaccinating health care workers against hepatitis B, other infection control practices are important in preventing transmission of the virus because up to 10% of people do not develop an adequate antibody response to the vaccine. The most important infection control measure is the use of universal precautions. These precautions prevent exposure to blood and blood-derived body fluids via use of a variety of barrier precautions, measures to prevent needlesticks, environmental control measures, and good hand-washing techniques. However, if a worker is exposed to material that potentially contains HBV, recommendations for percutaneous exposure to HBV should be followed (see Table 40–7).⁶⁶

The two recombinant hepatitis B vaccine products available in the United States (Recombivax HB, Merck; Engerix-B, SmithKline Beecham) have comparable immune responses and safety profiles.⁶⁶ The vaccines contain 5 to 40 mcg HBsAg protein per milliliter adsorbed onto aluminum. Neither brand of hepatitis B vaccine contains thimerosal. The recent availability of a combined HAV and HBV vaccine allows for a more accelerated schedule for immunization. For a more detailed comparison of the potential vaccination schedules refer to the cited reference.¹⁵ These vaccines are some of the safest available.⁶⁸ Side effects of the vaccine are soreness at the injection site, headache, fatigue, irritability, and fever. The number of patients experiencing adverse reactions decreases with each vaccine dose, and adverse reactions are less common in infants and children than in adults. There is no association between Guillain-Barré syndrome and the recombinant vaccine, and the vaccine does not transmit HIV. The hepatitis B vaccine is contraindicated for patients with anaphylaxis to

TABLE 40–9. Groups Recommended for Preexposure Hepatitis B Vaccination

| |
|---|
| All infants via routine infant vaccination |
| Unvaccinated 11- to 12-year-old children |
| Unvaccinated children ages <11 years of age who are Pacific Islanders of who reside in households of first-generation immigrants from countries where HBV is of high or intermediate endemicity |
| Health care and public safety workers who have occupational exposure to blood |
| HIV-infected individuals |
| Injection drug users |
| Heterosexual individuals who have had more than one sexual partner in the previous 6 months and/or those with a recent episode of a sexually transmitted disease |
| Sexually active homosexual or bisexual males |
| Hemodialysis patients |
| Recipients of certain blood products (i.e., patients with hemophilia and other clotting disorders) |
| Clients and staff of institutions for the developmentally disabled |
| Household, sexual, and blood exposure contacts of either HBsAg-positive persons or those with acute HBV infection |
| Household contacts of adoptees from countries where HBV is highly endemic |
| Populations where HBV is highly endemic (e.g., Alaskan Eskimos) |
| Inmates of long-term correctional facilities |
| International travelers to highly endemic HBV regions for >6 months and who have close contact with the local population; also short-term travelers who have contact with blood, or sexual contact with residents in high- or intermediate-risk areas |
| Unvaccinated infants under 12 months of age exposed to acute HBV infection through primary caregiver |

HBsAg, hepatitis B surface antigen; HBV, hepatitis B virus; HIV, human immunodeficiency virus.

common baker's yeast. Hepatitis B vaccines are inactivated and can be simultaneously administered with other vaccines.⁶⁸ Breast-fed infants can be vaccinated with hepatitis B vaccine, as can immunocompromised infants and children.⁶⁶ The vaccine can be given to pregnant and lactating women. In the last several years, a small number of claims of serious adverse effects after hepatitis B vaccine administration have occurred. Complaints cover a spectrum of autoimmune and nervous system disorders such as rheumatoid arthritis, optic neuritis, and neurodegenerative disorders similar to multiple sclerosis. Public health officials are confident the vaccine is safe, but because claims of vaccine-induced injury are likely to continue, several epidemiologic studies are underway to evaluate association. Millions of people receive hepatitis B vaccine each year, and some will blame the vaccine for any adverse event that is temporally related to vaccine administration.⁶⁸

HEPATITIS C VIRUS

- ◀8 Chronic hepatitis as a consequence of HCV has reached epidemic proportions worldwide. The indolent course of HCV, which is primarily asymptomatic, has contributed to its transmission.
- ◀9 The lack of an in vitro model and its mutability has prevented the development of a prevention strategy through vaccination. Therapeutic agents against HCV have provided limited success and have been tempered by their significant adverse event profiles.

EPIDEMIOLOGY

◀8 HCV is found worldwide and is transmitted primarily through injecting drug use and contaminated blood products. In the United States, HCV is the most common chronic blood-borne infection—40% of chronic liver disease is related to HCV, and an estimated 8,000 to 10,000 HCV-related deaths occur per year.^{69,70} NHANES completed the largest population-based household survey to date from 1988 to 1994.⁷¹ This survey revealed that 3.9 million persons (1.8% of the general population) were infected with HCV and 2.7 million Americans from this group were estimated to have chronic disease. However, this survey did not include data from homeless and incarcerated persons known to have a higher risk for HCV infection.^{72,73} Currently, persons in their third and fourth decades of life have the highest prevalence of acute HCV, while chronic HCV has the highest prevalence rates in persons in the fifth and sixth decades of life.^{70,74} Given that most patients with chronic HCV have yet to be diagnosed, a fourfold increase in the number of adults diagnosed with HCV is projected between 1990 and 2015.⁷⁵

Injecting drug use now accounts for about 60% of new HCV cases in the United States.⁷⁰ Thirty percent of people with HCV report sexual, hemodialysis, household, occupational, or perinatal exposure.⁷⁰ No recognized source of exposure can be determined for the remaining 10% of HCV infections. Other potential methods of transmitting HCV infection include contact with other instruments capable of penetrating the skin or mucous membranes, such as shared contaminated razors, intranasal cocaine (“snorting”) use, tattooing, and body piercing. Snorting cocaine with heroin is associated with nasal ulceration and bleeding thought to promote transmission of HCV.⁷⁶ Perinatal transmission rates of HCV are very low (<6%), increase with increasing maternal viral load, and are higher when the mother is coinfecting with HIV.^{70,77} The virus is inefficiently spread by sexual contact. In studies of long-term spouses of patients with chronic HCV and no other risk factors, HCV infection prevalence is about 1.5%.⁷⁰ Transmission of HCV is higher in those with

high-risk sexual practices.⁷⁰ Homosexual men do not have a higher risk for HCV acquisition even when they have a higher number of sexual partners.⁷⁸

ETIOLOGY

HCV is an enveloped, spherical, single-stranded RNA virus that belongs to the Flaviviridae family.⁷⁹ There are six known genotypes (numbered 1 through 6) and greater than 50 subtypes (designated by letter: 1a, 1b, and so forth) of HCV.⁷⁹ Genotype 1b often results in the most aggressive form of liver disease, is resistant to interferon therapy, and is associated with a worse prognosis posttransplantation.⁸⁰ Frequent errors in RNA transcription coupled with mutations driven by host immunologic pressure lead to generation of extensive genetic heterogeneity. This ability of HCV to change rapidly to host pressure permits the ultimate development of chronic infection.^{79,80}

PATHOPHYSIOLOGY

After HCV gains access to the host, the virus enters hepatocytes. The virus then uncoats and releases the genome to begin replication. The viral genome serves as a template for translation of the polyprotein. The processed nonstructural protein forms a complex with the genome and begins synthesis for the negative strand. The negative strand functions as the template for synthesis of the positive strand. The RNA intermediate matures and interacts with the envelope and core proteins to assemble into new virus. Most of the replicative processes are not clearly understood.⁸¹

In comparison to other viruses, HCV is more likely to cause clinically chronic silent infection in immunocompetent people. HCV accomplishes this despite active humoral and cellular immune responses that are generally targeted against all viral proteins. In acute HCV infection, specific T-cell receptors are activated and HCV-specific helper T cells assist with activation, differentiation, and induction of B cells, as well as stimulating virus-specific cytotoxic T cells.⁸¹ These effects are mediated by various immunoregulatory cytokines. CD8⁺ cytotoxic T cells recognize HCV peptides synthesized in infected cells, with resulting lysis of the infected cells.⁸¹ Both the strength and quality of helper T-cell and cytotoxic T-cell responses appear to differ between patients who recover and those who develop chronic HCV infection. HCV elicits only a weak T-cell response in patients who develop chronic infection.⁸¹ Individuals who clear HCV have a stronger type 1 T-helper response that upregulates cellular immunity. The reasons for this are unclear, but are unrelated to general immune tolerance or immunosuppression.

Virus-specific antibodies interfere with viral entry into host cells and opsonize the virus for elimination by macrophages; however, they cannot eliminate the virus from infected cells. In addition, the humoral immune response can select HCV variants with sequence changes that allow escape from antibody recognition.⁸¹ Antibodies to one genotype confer no resistance to another genotype. As a consequence of these factors, HCV is able to escape immune surveillance and establish persistent infection more readily. These characteristics of HCV also contribute to poor interferon response and make it difficult to develop a vaccine. Furthermore, the absence of an in vitro cell culture system has limited studies designed to screen newer antiviral compounds.

HCV is found in both serum and in an intracellular reservoir. Whereas the half-life of HCV in serum is only hours, HCV in the infected cell can have a half-life between 2 and 70 days.⁸² HCV production can occur in infected cells at a rate of $>3.7 \times 10^{11}$ virions per day. Therefore therapy may have to be targeted to eradication of HCV-infected cells or administered for prolonged periods.

CLINICAL PRESENTATION

ACUTE HEPATITIS C

Patients with acute hepatitis C are often asymptomatic, but they may have malaise, anorexia, and jaundice, which occur in up to 25% of cases.⁸³ The mean incubation period of HCV is 50 days and viremia can be detected within 3 weeks of initial exposure. Hepatic transaminase values, specifically serum ALT, can be elevated within 4 to 12 weeks of exposure.⁸³ Acute hepatitis C can be associated with severe symptoms, but fulminant disease is rare.⁸³ Coinfection with HIV and a history of chronic alcohol consumption are associated with more severe disease during acute HCV infection.⁸⁴ An important feature of hepatitis C infection is that up to 70% of cases develop chronic hepatitis.⁸⁴ Of note, patients with asymptomatic acute HCV infection may be more likely to develop chronic HCV.⁸⁵

Several diagnostic tests are available to detect acute HCV infection through detection of antibodies or viral target amplification.⁸⁶ Antibody detection methods include enzyme immunoassay (EIA) and the recombinant immunoblot assay (RIBA). Specific antibodies to HCV by EIA are positive in only 50% to 70% of patients during the initial onset of symptoms, but 90% of patients have HCV antibodies after 3 months. A number of viral antigens are included in the current version of EIA, resulting in a 99% sensitivity and specificity for detection of HCV antibodies in immunocompetent patients.⁸⁶ Patients with autoimmune disorders may have a false-positive EIA and no detectable HCV RNA, in which case the RIBA may be used as a supplemental test to rule out HCV. Viral target amplification techniques are used to detect HCV RNA either qualitatively or quantitatively. Qualitative tests are more sensitive with a detection limit of up to 100 copies/mL and should be reserved to determine spontaneous clearance of acute infection.⁸⁶ Spontaneous clearance of HCV can occur in 50% of patients within 3 months of the acute onset of symptoms.⁸⁵

CHRONIC HEPATITIS C

Most patients with HCV remain asymptomatic until the development of progressive liver fibrosis leading to cirrhosis, end-stage liver disease, and HCC.⁸⁴ Current estimates indicate that 10% to 30% of patients with HCV infection develop cirrhosis, and 1% to 5% develop hepatocellular carcinoma.⁸³ If an HCV patient is symptomatic, fatigue, malaise, anorexia, and weight loss are common. Many patients have a history of jaundice. On physical examination, hepatomegaly is usually present, but the stigmata of chronic liver disease (spider nevi, splenomegaly, palmar erythema, testicular atrophy, and caput medusae) are generally absent until late in the disease course. Mild but persistent elevations of the serum aminotransferases, bilirubin, and γ -globulin levels can be seen. Physical symptoms do not correlate well with the severity of liver injury. The diagnosis of

HCV is made by detecting anti-HCV via EIA, with confirmatory RIBA testing reserved for low-risk populations to exclude potential false-positive EIA results.⁸⁴

In chronic hepatitis C, there is frequently little clinical evidence that the disease is progressing. The patient is asymptomatic, yet viral RNA remains positive, and if a liver biopsy is performed it demonstrates ongoing liver injury and progressive histologic changes. To assess chronic HCV, liver biopsy is the only reliable indicator of disease progression.^{83,84} Importantly, a liver biopsy contributes information on the possible interplay between steatosis and concurrent alcoholic liver disease toward the progression of chronic hepatitis C to cirrhosis. Serum transaminases are prone to fluctuation and can even normalize, confounding the diagnosis. Unfortunately, the patient can be on an insidious course that progresses to complications after a period of years to decades. It is not uncommon for a patient to present to a physician with cirrhosis or portal hypertension secondary to HCV infection that occurred years to decades prior, yet the patient may have had few or no clinical signs or symptoms during the intervening years. HCC may present as a nonspecific right upper quadrant pain in patients with cirrhosis. Specific screening guidelines have not been validated to predict the development of HCC. Hepatic ultrasound is more sensitive for the diagnosis of HCC compared to serum α -fetoprotein concentrations.⁸⁷ Diagnostic procedures for the evaluation of HCC should be reserved for patients with cirrhosis, as the development of this disease is very rare in noncirrhotic patients.

A variety of rare extrahepatic clinical syndromes have been associated with chronic HCV infection.⁸⁸ These syndromes include cryoglobulinemia, cutaneous vasculitis, renal disease, neuropathy, lymphoma, and Sjögren's syndrome. Cryoglobulinemia involves the presence of circulating immunoglobulins that reversibly precipitate at $\leq 37^{\circ}\text{C}$. These cryoglobulins can precipitate in small blood vessels and induce a vasculitis. The cutaneous manifestation typically includes a palpable purpura in the lower extremities, and is diagnosed as a leukocytoclastic vasculitis on biopsy of the lesions.⁸⁸ Renal disease typically manifests as nephrotic syndrome with pathology consistent with membranoproliferative glomerulonephritis.

Peripheral neuropathy is the most common neurologic symptom in patients with HCV. Sensory loss may manifest bilaterally or may affect multiple isolated nerves. HCV-related non-Hodgkin's lymphoma is the most common lymphoproliferative disorder recognized in patients with HCV. Interestingly, extranodal involvement in the liver and salivary glands may be 3 to 4 times higher in patients with HCV versus non-HCV-infected patients with non-Hodgkin's lymphoma.⁸⁸ Finally, symptoms of Sjögren's syndrome such as xerostomia and xerophthalmia may occur in up to 10% of patients with HCV. HCV-associated Sjögren's syndrome appears to affect women more than men. Interferon therapy with ribavirin has been reported to have beneficial effects on these extrahepatic manifestations, with the exception of neuropathy and Sjögren's syndrome.⁸⁸

► TREATMENT: Hepatitis C Virus Infection

■ DESIRED OUTCOME

The ultimate goal in treating acute HCV is to return the individual to the previous state of health, and prevent the development of chronic infection. Intermediate goals, while the individual is acutely symptomatic and infectious, include decreasing morbidity and acute mortality, minimizing the chance that the infected person is infecting

others, normalizing aminotransferases (cease hepatic inflammation), stopping viral replication in the host, and ultimately eradicating the virus. The goal of treatment is to prevent the morbidity and mortality associated with end-stage liver disease by eradicating HCV. Effective treatment of chronic viral hepatitis should also increase the quality of life and prevent infected patients from serving as reservoirs of infection. Because the complications of chronic hepatitis may take decades to manifest, clinical trials primarily use outcomes of

virologic response (clearance of virus), biochemical response (return of transaminases to normal levels), and histologic response as surrogate markers for decreased risk of cirrhosis, HCC, or death. Long-term outcome studies show that the response to therapy can be maintained for years and that progression of liver disease can be halted. Even regression of fibrosis, once thought to be irreversible, is possible.⁸³ Sustained virologic or biochemical response is also associated with a reduced risk of HCC.

■ GENERAL APPROACH TO TREATMENT

Management of acute HCV is primarily supportive. General measures include a healthy diet, rest, maintaining fluid balance, and avoiding hepatotoxic drugs and alcohol. Hospitalization is sometimes required in patients with prolonged vomiting, coagulation defects, or fulminant hepatitis. Upon the diagnosis of chronic viral hepatitis, the patient should be informed about the disease risks and a program of regular monitoring established. Depending upon where in the course of infection the disease is diagnosed, monitoring for progression is important for selection of patients for pharmacologic treatment, because many more patients die with chronic viral hepatitis than from it. The relative benefits of pharmacologic therapy and their attendant adverse effects and risks need to be discussed as well.

■ NONPHARMACOLOGIC THERAPY

Liver transplantation is currently the only definitive therapy for the management of hepatic failure. However, transplants cannot be performed in all patients that require them due to the shortage of cadaveric organs. Consequently, the use of liver support systems can provide specific liver functions until an orthotopic liver transplantation is performed. The molecular adsorbents recycling system is a novel technologic system that uses albumin to remove water-soluble and albumin-bound toxins such as bile acid and bilirubin from the bloodstream. This liver dialysis system improves the maintenance of electrolytes, acid-base and fluid balance, glucose concentrations, and removes ammonia. The system benefits patients with liver failure who have renal complications as well. Prospective trials evaluating the efficacy and cost-effectiveness of the molecular adsorbents recycling system versus standard care are currently being completed.⁸⁹

■ PHARMACOLOGIC THERAPY

Patients seropositive for HCV with elevated ALT and inflammation on liver biopsy are candidates for antiviral therapy. A more difficult treatment decision occurs when a patient has elevated ALT, but the histologic changes are mild. In that situation the patient may be closely monitored and treatment withheld. Because relapse frequently occurs shortly after IFN- α monotherapy is stopped, response to HCV treatment is broken into three general categories:

Response: Reduction of HCV RNA to undetectable levels and normalization of ALT during treatment and 6 months after completion of therapy

Nonresponse: HCV RNA remains detectable or ALT fails to normalize during the course of therapy

Relapse: HCV RNA becomes undetectable and ALT normalizes during treatment, but either ALT or HCV RNA re-emerge in the 6 months after therapy

Occasionally, different time points are used to record results as end-of-therapy responses or as sustained virologic response (SVR; at least 6 months after therapy). SVR has been acknowledged as the best predictor of a long-term clinical outcome.

The National Institutes of Health consensus panel published recommendations on the management of HCV infection in 2003.⁹⁰ Combination therapy has been recognized to be better than monotherapy. In addition, many of the early treatment recommendations have been supplanted by comparative data showing the superiority of pegylated interferon in conjunction with ribavirin. The duration of therapy has now become a function of the specific genotype of HCV. A review of the published guidelines and the data supporting these recommendations are presented below.

■ FIRST-LINE THERAPY

The pharmacologic management of acute HCV is confounded by limitations in the ability to recognize the infection in mainly asymptomatic patients. Trials evaluating the role of interferon therapy included small sample sizes and used heterogeneous end-points to evaluate outcomes. Despite these limitations, SVRs in the range of 83% to 100% have been reported with IFN- α monotherapy in small uncontrolled trials, suggesting the potential advantages of early therapy.⁹⁰ However, the timing, type of regimen, and duration of therapy remain undefined. The management of treatment-naïve patients with chronic HCV is better defined with recent large randomized controlled trials comparing pegylated interferon plus ribavirin to interferon and ribavirin.^{91,92}

Interferon is an immunomodulatory protein that works by binding to specific cell surface receptors that stimulate a host of gene transcriptions to prevent de novo infection in hepatocytes. In addition, IFN- α is thought to reduce HCV heterogeneity while stimulating proinflammatory systems to help increase viral eradication. Interferon is commercially available as IFN- α 2a, IFN- α 2b, pegylated versions of both products, and as IFN alfacon-1. The process of pegylation includes the attachment of inert polyethylene glycol to protein, resulting in an increase in net molecular size. This decreases the rate of subcutaneous absorption, decreases systemic clearance, increases exposure, and thus allows less frequent administration of the product. Ribavirin is a guanosine nucleotide analog that inhibits viral replication and works synergistically with IFN- α .⁹³

The pegylated forms of IFN- α 2a and IFN- α 2b have distinct pharmacokinetic profiles. Both forms have been compared to monotherapy, in combination with ribavirin, and against IFN- α 2b plus ribavirin. However, pegylated IFN- α 2a has not been directly studied against pegylated IFN- α 2b. These trials excluded patients with comorbid conditions such as HIV infection, autoimmune disorders, preexisting psychiatric illness, cytopathies, and patients with decompensated liver disease. In general, both pegylated IFN- α products plus ribavirin were more effective than IFN- α plus ribavirin or pegylated IFN- α alone. Patients with HCV genotype 1 demonstrated an SVR in about 40% of cases, while close to 80% of patients with HCV genotypes 2 and 3 had an SVR. In addition, patients with lower baseline HCV RNA levels, less fibrosis on liver biopsy, and a lower body surface area or weight were more likely to have a successful clinical outcome. A 24-week course of pegylated IFN- α plus ribavirin results in similar outcomes to a 48-week course for patients with HCV genotypes 2 and 3. However, a 48-week course of therapy results in a higher response rate than 24 weeks of therapy in patients with HCV genotype 1. In

addition, 800 mg of ribavirin daily is sufficient for management of patients with genotypes 2 and 3, but a higher dose of 1000 to 1200 mg daily is required for patients with HCV genotype 1.⁸⁹

■ ALTERNATIVE DRUG TREATMENTS

Current therapeutic options for chronic hepatitis C are limited to ribavirin, IFN- α , IFN alfacon-1, and pegylated IFN- α . As stated, monotherapy is inferior in attaining SVR compared to combination therapy. However, combination therapy with ribavirin may be limited by its contraindication for men whose female partners are pregnant, patients with hemoglobinopathies like sickle cell anemia, or known hypersensitivity to this agent. Consequently monotherapy with pegylated IFN- α may be considered. This is especially true in patients with HCV genotypes 2 and 3, in whom SVR was achieved in 45% of patients managed with pegylated IFN- α 2a for 48 weeks. However, **10** the same regimen was associated with an SVR in only 21% of patients with HCV genotype 1. Ribavirin monotherapy using doses of 600 to 1200 mg daily has demonstrated a reduction in necroinflammation. However, patients treated with such a regimen do not achieve an undetectable HCV RNA level, and these levels usually rebound to baseline upon completion of therapy.

The preclinical evaluation of new antivirals is hindered by a lack of animal models of HCV infection. Development of novel interferons and delivery systems, nucleoside analogues with reduced hemolytic potential compared with ribavirin, and inosine 5' monophosphate dehydrogenase inhibitors are being studied as adjunctive therapy to interferon- α -based regimens. In addition, compounds that inhibit specific HCV enzymes like serine proteases, RNA polymerase, and helicase are being evaluated. Prevention of disease progression through the use of antifibrotic agents in patients in whom HCV RNA cannot be eradicated is in development. The safety and efficacy of these newer therapies are currently being investigated, and it is likely that these treatment modalities will not be available for at least 3 to 5 years.⁹⁴ Herbal medications for the management of HCV were recently systematically reviewed, but none of the 14 tested agents demonstrated benefit.⁹⁵

■ SPECIAL POPULATIONS

The strict inclusion and exclusion criteria in most studies to date would exclude more than half of all HCV-infected patients.⁹⁶ Patients with mild liver disease and normal ALT levels are less likely to progress to cirrhosis. Consequently the role of HCV therapy remains controversial. Some experts believe documentation of disease progression through liver biopsies should serve as the impetus for therapy. However, decisions to treat in such populations should be driven by the patient's desire to eradicate HCV or their unwillingness to undergo sequential liver biopsies to assess progression.

Children and adolescents with chronic HCV are likely to be asymptomatic. Pegylated IFN- α has not been studied in children, and most studies evaluating IFN- α have been uncontrolled with small sample sizes. These studies have demonstrated a better response in children compared to adults receiving IFN- α monotherapy, with SVR rates of 26% with HCV genotype 1 and 70% with genotypes 2 and 3.⁹⁰

Active illicit injection drug use should not be used to exclude patients from receiving HCV therapy and should be assessed on an individual basis. This is critically important given that this group of patients represents the majority of new cases of HCV in the United

States, and treatment may reduce potential transmission. However, data are limited when evaluating the role of HCV therapy in patients with active illicit drug use who are not in a drug treatment program. Use of substance abuse programs such as methadone treatment centers should be encouraged to help reduce risky behaviors.

Coinfection with HIV is common in patients with HCV given the shared risk factors for transmission. Patients coinfecting with these viruses have a more accelerated progression of their HCV disease. Most trials to date have excluded patients with HIV or limited them to patients with stable HIV infection. Combination therapy using ribavirin is considered to be superior; however, enhancement of antiretroviral adverse events such as lactic acidosis limits therapy. Concurrent use of ribavirin therapy with didanosine, stavudine, or zidovudine is relatively contraindicated.⁹³

Obesity has been recognized as a poor prognostic variable for outcomes associated with therapy for chronic HCV. Patients with a body mass index of $>30 \text{ kg/m}^2$ had a 77% lower chance of response to therapy compared to overweight and normal-weight patients.⁹⁷ The exact mechanism of this interaction between weight and effect is not known. However, the natural progression of disease may be faster in obese patients and may be related to nonalcoholic steatohepatitis.^{98,99}

■ DRUG CLASS INFORMATION

■ Interferons

Three FDA approved IFN- α preparations are currently available in the United States and include IFN- α 2a (Roferon-A), IFN- α 2b (Intron A), and IFN alfacon-1 (Infergen). IFN- α 2a and IFN- α 2b are naturally occurring cytokines that have been manufactured using human recombinant techniques in *Escherichia coli*.¹⁰⁰ In contrast, IFN alfacon-1 is a non-naturally occurring type 1 interferon also produced using human recombinant techniques, but it has a tenfold higher affinity for cell surface receptors.¹⁰⁰ Despite this theoretical higher activity, IFN alfacon-1 has not been found to be superior to IFN- α 2b. The mechanism of action of these interferons includes activation of tyrosine kinases that upregulate production of several gene products like 2'-5' oligoadenylate synthetase, β_2 -microglobulin, neopterin, and p68 kinases. These gene products are responsible for the immunomodulatory, antiviral, and antiproliferative properties of these agents. All of these products have to be administered subcutaneously three times a week. The dosage of 3 to 5 million units of IFN- α 2a and IFN- α 2b corresponds to 9- to 15-mcg doses of IFN alfacon-1. The expected rate of SVR response of these products is less than 20% when monotherapy is employed for 24 weeks. Flu-like symptoms such as headache, fatigue, and chills occur in more than two thirds of patients. Psychiatric adverse events such as nervousness and depression and hematologic toxicities such as neutropenia occur in almost a third of patients.¹⁰¹

■ Pegylated Interferons

Peginterferon- α 2a (Pegasys) and peginterferon- α 2b (PEG-Intron) are FDA approved for use as monotherapy and in combination with ribavirin for the treatment of chronic HCV in patients with compensated liver disease who are interferon-treatment-naïve. Their mechanism of action is similar to that of IFN- α , but they offer the advantage of higher and sustained concentrations compared to their nonpegylated versions.⁹³ The size and branching of the polyethylene glycol structure affects tissue distribution and elimination of the parent compound. The polyethylene glycol moiety with peginterferon- α 2a is

TABLE 40–10. Side Effects of Interferon- α

| Early (in First 2 Weeks of Therapy) | Hematologic | Neuropsychiatric | Autoimmune | Miscellaneous |
|-------------------------------------|------------------|------------------|--|-----------------------------|
| Fever | Neutropenia | Irritability | Development of autoantibodies | Chronic fatigue |
| Chills | Thrombocytopenia | Mood lability | Hepatitis | Infections |
| Myalgias | Anemia | Depression | Thyroid dysfunction | Increased sleep requirement |
| Fatigue | | Tearfulness | Thyroiditis | Anorexia |
| Malaise | | Delirium | Arthropathy | Weight loss |
| Nausea | | Paresthesias | Type I diabetes mellitus | Myalgias |
| Sleep disturbance | | Seizures | Exacerbation of psoriasis or lichen planus | Low-grade fevers |
| Abdominal pain | | Psychosis | Exacerbation of other autoimmune phenomena | Decreased libido |
| Diarrhea | | | | Alopecia |
| Headache | | | | Hypertriglyceridemia |
| Appetite changes | | | | Irritability |
| | | | | Anxiety |
| | | | | Depression |
| | | | | Attention span deficits |

Absolute contraindications to use of interferon include current or past psychosis or severe depression, neutropenia or thrombocytopenia, organ transplant (except liver), symptomatic heart disease, decompensated cirrhosis, and uncontrolled seizures. Relative contraindications to interferon include uncontrolled diabetes and autoimmune disorders.

approximately twice the size of that of peginterferon- α 2b. Consequently the elimination half-life of peginterferon- α 2a and peginterferon- α 2b are 80 and 40 hours, respectively. This extension in half-life is in stark contrast to the nonpegylated interferons, which have a half-life of \sim 5 hours. Peginterferon- α 2a should be administered as a 180-mcg dose subcutaneously once weekly for 48 weeks. In contrast, peginterferon- α 2b follows a weight-based dosing strategy of 1.5 mcg/kg subcutaneously for 1 year. Other pharmaceutical differences include a requirement for reconstitution of lyophilized peginterferon- α 2b prior to administration, and a requirement for refrigeration for storage of peginterferon- α 2a. In addition, peginterferon- α 2a contains benzyl alcohol and so its use is contraindicated in neonates and infants. The adverse event profile of both agents is comparable to their respective nonpegylated versions. A summary of the incidence of specific adverse events is displayed in Table 40–10. Interferons can significantly decrease the clearance of theophylline, resulting in an increased area under the plasma concentration-versus-time curve. Caution should be used when α -interferons are initiated in patients on theophylline, as they are likely to require dosage reductions based on therapeutic drug monitoring.¹⁰¹

Ribavirin

Ribavirin is a synthetic nucleoside antagonist that is administered orally in combination with α -interferons. Ribavirin has limited utility as monotherapy and should be administered twice daily with food when used in combination with α -interferons. Ribavirin is currently available in two 200-mg oral formulations, as a capsule (Rebetol) and as a tablet (Copegus). When ribavirin is used with peginterferon- α 2a for patients with HCV genotype 1, it is dosed as 400 mg orally every morning and 600 mg orally every evening in patients up to 75 kg, and 600 mg orally twice daily for patients weighing more than 75 kg. For patients with genotypes 2 and 3 ribavirin is administered 400 mg orally twice daily when administered with peginterferon- α 2b or peginterferon- α 2a. Hemolytic anemia is a common complication of ribavirin therapy. Dosage reductions of ribavirin are recommended for changes in hemoglobin values when used in combination with peginterferon- α 2a. In general, the combination of ribavirin with α -interferons is associated with numerous adverse events to multiple organ systems, and these should be discussed with patients prior to initiation of therapy.¹⁰¹

PHARMACOECONOMIC CONSIDERATIONS

Ten to thirty percent of patients progress to cirrhosis after 30 years. Most individuals with chronic HCV in the United States are between the ages of 30 and 49 years and have yet to manifest sequelae of the disease. As a result, the impact of HCV on future health care costs is anticipated to be high. Unfortunately, clinical decisions to treat individual patients are confounded by the inconsistent progression and a lack of ability to predict clinical deterioration. Therapy with pegylated interferons and ribavirin can be very expensive and associated with serious adverse events. Consequently, assessing the cost, benefits, and cost-effectiveness of the various therapies is vital.

The cost of medications based on average wholesale prices with the use of a pegylated interferon plus ribavirin is approximately \$30,000 for a 48-week course of therapy.⁶³ The cost of using nonpegylated interferon plus ribavirin is approximately \$15,000 to \$20,000.⁶³

Assuming conservatively that 10% of all chronic hepatitis C patients (2.7 million) were eligible for therapy in the United States, with 70% of patients having HCV genotype 1, the estimated cost for the pharmaceuticals alone would be approximately \$4 billion. However, the cost of not treating HCV could lead to future costs associated with hospitalizations related to ascites, cirrhosis, variceal hemorrhage, HCC, and liver transplantation.

A recent pharmacoeconomic analysis to examine the clinical benefits and cost-effectiveness of newer treatments for chronic HCV infection evaluated the incremental cost-effectiveness of using peginterferon- α 2b plus ribavirin compared to IFN- α 2b plus ribavirin, and monotherapy regimens of both interferons.¹⁰² The incremental cost per quality-adjusted life year (QALY) saved for combination therapy with peginterferon- α 2b compared to standard therapy was \$36,000 and \$55,000 for men and women with HCV genotype 1, respectively. A QALY is defined as a patient's desire for a year of life at

a diminished state of health compared with life at an optimal state of health. The use of the QALY as a measure helps create a uniform set of values that can be applied to cost-effectiveness data from heterogeneous patient groups. Interpretation of data defining cost per QALY is further hampered by a lack of a standard benchmark to define when a therapeutic regimen should or should not be used. Historically, a cost-effectiveness threshold of $\leq \$50,000$ has been used to define a cost-effective regimen, but this remains controversial when applied clinically. The QALY gains ranged from 0.6 months with IFN- α 2b monotherapy to 6 months with combination peginterferon- α 2b and ribavirin therapy in men.

The key points of contention when evaluating any pharmacoeconomic analysis are the basic underlying assumptions. A lack of clear understanding of the natural course of chronic HCV, including the probability of progression, impairs such studies. For the time being, patient selection on the basis of predictors of response coupled with informed patient decision making regarding benefits and risks is appropriate.

CLINICAL CONTROVERSIES

Clinicians argue that a noninvasive dynamic measure of hepatic fibrosis is necessary given that the probability of progression of chronic HCV is unclear. Others argue that the development of such tests will still not predict when to initiate therapy.

The role of long-term continuous therapy with peginterferon alone or in combination with ribavirin is unknown. Some clinicians believe that long-term combination therapy may improve clinical outcomes in select nonresponders.

EVALUATION OF THERAPEUTIC OUTCOMES

To carry out the plans outlined above requires that viral genotyping be performed at baseline, with a viral load being assessed if the patient has HCV genotype 1. Before treatment, all patients should have a viral genotype performed, have thyroid function assessed, and women should have a negative pregnancy test. Liver biopsy is a useful test to evaluate the stage of fibrosis and may aid with the decision of when to initiate or defer therapy. The value of a pretreatment liver biopsy in patients with HCV genotypes 2 and 3 is limited given that antiviral therapy may lead to a favorable response in up to 80% of patients.⁹⁰

During treatment, a complete blood count with platelets should be performed weekly for the first 4 weeks and monthly thereafter. Thyroid tests should be checked every 3 to 6 months during treatment and 6 months after.¹⁰¹ HCV RNA should be evaluated at baseline and 12 weeks of combination therapy, and additionally depending on the intended duration. This is because early virologic response, defined as a minimum two \log_{10} reduction in the viral load in the first 12 weeks of therapy, is predictive of SVR in patients with HCV genotype 1. Consequently, patients without an early virologic response should have their treatment discontinued to reduce cost and prevent unnecessary adverse events.⁹⁰ Aminotransferase and qualitative HCV RNA should be performed at the end of therapy and 6 and 18 months after the cessation of therapy. Follow-up biopsy is not indicated. In patients with established or suspected cirrhosis, screening for HCC with abdominal ultrasound and serum α -fetoprotein is recommended.⁹⁰ However, neither the time frame nor cost-effectiveness of such screening has been defined. For patients not started on therapy because of mild histologic disease or normal ALT, liver biopsy should be repeated in 4 to 5 years and ALT at 6-month intervals, respectively.

The side effects of α -interferons occur frequently enough that the patient should be informed about them before treatment begins (see Table 40–10). Many side effects are dose related. The most common and predictable effects are influenza-like and can be counteracted by premedication with a single dose of acetaminophen around the time of injection. Severity decreases with subsequent injections and usually abates in 1 to 2 weeks.¹⁰¹ Later common adverse effects are fatigue, malaise, and cognitive changes.

Because α -interferon therapy can exacerbate autoimmune disorders, it is important to exclude autoimmune diagnoses before initiating therapy. Thrombocytopenia and granulocytopenia are more common in patients with cirrhosis and hypersplenism. The psychiatric complications are especially severe in those with severe liver disease, occur in up to 20% of patients, and are the most common dose-limiting side effects. Therapy should be discontinued if serious complications occur. The dose of α -interferon must be reduced in 10% to 40% of patients. Treatment must be discontinued because of adverse effects in 5% to 10% of patients. For many patients, reassurance that the side effects are therapy related, not severe, and will disappear when therapy is stopped is sufficient. It is always important to reassure both patient and family, especially when psychiatric side effects are evident. These points are critical given that patient adherence is crucial to the ultimate success of HCV treatment.¹⁰¹

Ongoing monitoring of α -interferon toxicity includes weekly complete blood counts during the first 2 weeks of therapy and monthly thereafter. Patients should be asked about level of performance, mood changes, ability to concentrate, and symptoms. The dose of α -interferon should be decreased by 50% if any of the following develop: fatigue that interferes with the daily routine, serious mood changes, daily nausea with occasional vomiting, granulocytopenia ($<750/\text{mm}^3$), and/or thrombocytopenia ($<50,000/\text{mm}^3$). Interferon should be immediately discontinued if fatigue is so severe that it requires bed rest, vomiting occurs more than twice daily, or if profound granulocytopenia ($<500/\text{mm}^3$) or thrombocytopenia ($<30,000/\text{mm}^3$) occurs.¹⁰¹

PREVENTION OF HCV INFECTION

No vaccine for hepatitis C is available. Vaccine development for HCV is difficult because of the extensive genomic variability of the virus, viral mutants, and the lack of efficacy of serum antibodies. Current recommendations for prevention of HCV include universal precautions for the prevention of blood-borne infections, and anti-HCV screening of blood, organ, and tissue donors. Screening of blood donors has virtually eliminated HCV transmission through blood and blood products. Programs that focus on reducing HIV transmission are also likely to decrease transmission of HCV in high-risk groups. No clear policy for counseling women of childbearing age exists.

Benefit associated with identification of HCV infections in health care workers is limited. However, the CDC, in collaboration with the Hospital Infection Control Practices Advisory Committee, recommends that health care institutions consider implementing policies and procedures for follow-up for HCV infection after percutaneous or permucosal exposures to blood.^{66,69} Follow-up should include testing the source for anti-HCV; baseline and 6-month follow-up testing for anti-HCV and AST for the person exposed to an anti-HCV–positive source; confirmation by supplemental anti-HCV testing of all anti-HCV–reactive results; and education of health care workers about blood-borne infections. Postexposure prophylaxis with Ig or interferon is not recommended. There are no specific recommendations for HCV immune prophylaxis for exposed individuals. Prophylaxis with Ig after needlestick exposure to hepatitis C is not recommended.⁶⁶

QUANTIFICATION OF RENAL FUNCTION

Thomas C. Dowling and Thomas J. Comstock

Learning Objectives and other resources can be found at www.pharmacotherapyonline.com.

KEY CONCEPTS

- 1 For patients with chronic kidney disease (CKD) the stage of disease should be determined based on the level of kidney function, independent of etiology, according to the National Kidney Foundation Kidney Disease Outcomes Quality Initiative (NKF K/DOQI) CKD classification system.
- 2 Persistent proteinuria indicates the presence of CKD.
- 3 Semiquantitative methods of urine protein excretion, such as the spot urine albumin:creatinine ratio, are recommended for determining the severity of CKD and monitoring the rate of disease progression.
- 4 The glomerular filtration rate (GFR) is the single best indicator of overall renal function.
- 5 Measurement of the GFR is ideally performed using the exogenous administration of inulin, iothalamate, or radioisotope techniques such as ^{99m}Tc -DTPA.
- 6 Measurement of creatinine clearance is not routinely recommended; however pretreatment with cimetidine improves the accuracy of this estimate of GFR.
- 7 Equations to estimate creatinine clearance or GFR are commonly used in ambulatory and inpatient settings, and incorporate patient demographic variables such as serum creatinine, age, gender, weight, and ethnicity.
- 8 Longitudinal assessment of kidney function is important for monitoring the efficacy of therapeutic interventions, such as angiotensin-converting enzyme inhibitors (ACEIs) and angiotensin receptor blockers, that are intended to slow the progression of kidney disease.
- 9 The serum creatinine concentration (S_{Cr}) or the reciprocal of S_{Cr} versus time should be used with caution to estimate the rate of decline in renal function in CKD patients, as these indices do not consider patient age, lean body mass, gender, diet, concomitant diseases and drug therapy, circadian rhythm, stability of kidney function, tubular secretion of creatinine, or analytic method.
- 10 Qualitative assessments of renal function, such as x-ray, computed tomography, magnetic resonance imaging, sonography, and biopsy, are useful for determining the etiology and structural aspects of kidney disease.

It is estimated that nearly 20 million people in the United States have impaired renal function, and in most cases the disease is undiagnosed. Evaluation of renal function is an important part of pharmaceutical care that can be performed in clinical and research settings using both qualitative and quantitative methods. Estimation of creatinine clearance is often considered the clinical standard for assessment of renal function. Other tests, such as the urinalysis, radiographic procedures, and biopsy, are also valuable tools in the assessment of renal disease, and these qualitative assessments are useful for determining the pathology and etiology of kidney disease. The urinalysis, for example, may give clues to the primary location, such as glomerular or tubular, of the renal disease. Follow-up studies such as imaging procedures or kidney biopsy may then further differentiate the specific cause, thereby pointing to the appropriate therapeutic intervention.

1 Quantitative indices such as creatinine clearance or glomerular filtration rate (GFR) are most useful for determining the degree of renal insufficiency and stage of chronic kidney disease (CKD) in accordance with the National Kidney Foundation (NKF) classification system. These indices can also be used to measure changes in

function that may occur as a result of disease progression, therapeutic intervention, or toxic insult.¹ Moreover, the design of dosage regimens for drugs eliminated by the kidneys is also dependent on the availability of a quantitative measure of kidney function.

Renal “function” includes the processes of filtration, secretion, and reabsorption, as well as endocrine and metabolic functions. Alterations of all five renal functions, whether declining or improving, have been associated primarily with GFR. This chapter critically evaluates the various methods that can be used for the quantitative assessment of kidney function (Table 41–1). Where appropriate, discussion regarding the qualitative assessment of kidney function is also presented, including specialized tests such as kidney biopsy.

EXCRETORY FUNCTION

The most important contribution of the kidney to overall maintenance of body homeostasis is the urinary excretion of water, endogenous

TABLE 41–1. Markers of Renal Function

| | |
|----------------------------|--|
| Renal plasma/blood flow | <i>p</i> -Aminohippurate (PAH) ¹³¹ I-Orthoiodohippurate (¹³¹ I-OIH) ^{99m} Tc-mercaptoacetyltriglycine (^{99m} Tc-MAG3) |
| Glomerular filtration rate | Inulin, sinistrin Iothalamate Iohexol ^{99m} Tc-diethylenetriaminepentaacetic acid (^{99m} Tc-DTPA) ¹²⁵ I-Iothalamate Creatinine Cystatin C |
| Tubular function | <i>p</i> -Aminohippurate <i>N</i> -1-Methylnicotinamide (NMN) Tetraethylammonium (TEA) β_2 -Microglobulin Retinol-binding protein (RBP) Protein HC (α_1 -microglobulin) <i>N</i> -Acetylglucosaminidase (NAG) Alanine aminopeptidase (AAP) Adenosine binding protein (ABP) |

substances, and toxins. Through the combined processes of glomerular filtration, tubular secretion, and tubular reabsorption, the nephron, as the functional unit of the kidney, maintains balance between input and output of water and solutes from the body. Thus the kidney is the key organ responsible for maintenance of homeostasis. This is represented as:

$$\text{Rate of excretion} = \text{rate of filtration} + \text{rate of secretion} \\ - \text{rate of reabsorption}$$

FILTRATION

Glomerular filtration occurs through the passive diffusion of water and low-molecular-weight ions and molecules across the glomerular-capillary membrane into Bowman's capsule and the proximal tubule (Fig. 41–1). Because most proteins are too large to be substantially filtered (>60 kDa), or their filtration is impeded by the electronegative charge of the glomerulus, compounds presented to the glomerulus in the protein-bound state are not filtered and enter the peritubular circulation.

SECRETION

Secretion occurs primarily along the proximal tubule and facilitates elimination of compounds from the plasma into the tubular lumen via active transport. Highly efficient anionic and cationic transport systems for a wide range of endogenous and exogenous substances yield renal clearance values that greatly exceed the GFR. Examples include probenecid, *p*-aminohippurate (PAH), and penicillin as anions; and creatinine, cimetidine, and procainamide as cations.² These systems are not mutually exclusive, as probenecid has been observed to compete with the tubular secretion of cimetidine.³ Other transport pathways, such as P-glycoprotein (P-gp) and multidrug resistance protein (MRP), are distributed in tissues including kidney, liver, jejunum, colon, and brain. These efflux proteins are being recognized as an important element in drug elimination by the kidneys.⁴ For example, P-gp is located on the apical membrane of the proximal tubule and

may play an important role in the renal elimination of a wide range of drugs such as cimetidine, digoxin, and procainamide. Blockade of P-gp could result in decreased renal elimination of such compounds, leading to an increased drug exposure. Verapamil, cyclosporine, and the P-gp-specific inhibitor PSC 833 all reduce the activity of this tubular transport mechanism.⁵ Further investigations into the exact role of the P-gp and MRP efflux pathways on drug elimination are presently underway.

Measurement of GFR may not be an appropriate assessment for the prediction of renal clearance of a drug that undergoes active tubular secretion, or for a drug that is extensively reabsorbed. As an example, Hori and associates^{6,7} demonstrated that the postfiltration renal handling of ampicillin, which is secreted, and cephalixin, which is secreted and reabsorbed, remained normal in patients with renal failure caused by glomerulonephritis, but was reduced in patients with renal failure associated with tubular dysfunction. They concluded that dosage adjustment based on creatinine clearance would be inappropriate for drugs eliminated by tubular secretion. Maiza and Daley-Yates⁸ observed glomerulotubular imbalance in experimentally induced renal failure in rats based on differential effects on inulin (an index of filtration), PAH (an index of anionic secretion), and *N*-1-methylnicotinamide clearance (an index of cationic secretion). Using an experimental nephrotoxic (uranyl nitrate) acute renal failure rat model, Lin and Lin⁹ and Gloff and Benet¹⁰ demonstrated differential handling of tetraethylammonium (TEA) bromide and PAH, with greater impairment of tubular secretion than of GFR. Lin and Lin⁹ further studied an ischemic acute renal failure model (glycerol) and showed a parallel decline of secretion and GFR for TEA, whereas secretion of PAH decreased at a greater rate than did GFR. These results support the hypothesis that the integrity of different pathways for elimination of compounds may be dependent on the mode of injury as well as the chemical characteristics of the compound. Thus the kidney should not be considered as a single homogeneously functioning organ, but one with several different discrete functions. It is thus analogous to the liver, in which the multiple metabolic pathways may be impaired to variable degrees, depending on the type of injury or disease. Despite these observations, the clinical impact of the findings has not been fully evaluated.

REABSORPTION

Reabsorption of water and solutes occurs throughout the nephron, whereas drug reabsorption occurs predominantly along the distal tubule and collecting tubules. Urine flow rate and physicochemical characteristics of the molecule influence these processes. Highly ionized compounds are not reabsorbed unless pH changes within the urine increase the fraction that is un-ionized, so that reabsorption may be facilitated.

INTACT NEPHRON HYPOTHESIS

The homeostasis afforded by the kidneys is affected by catecholamines, prostaglandins, renin, antidiuretic hormone, natriuretic hormone, and the number of functioning nephrons. The "intact nephron hypothesis" described by Bricker,¹¹ which was first published more than 30 years ago, proposes that kidney function of patients with renal disease is the net result of a reduced number of appropriately functioning nephrons. As the number of nephrons is reduced from the initial complement of 2 million, those that are unaffected compensate for those that are damaged by disease or toxic

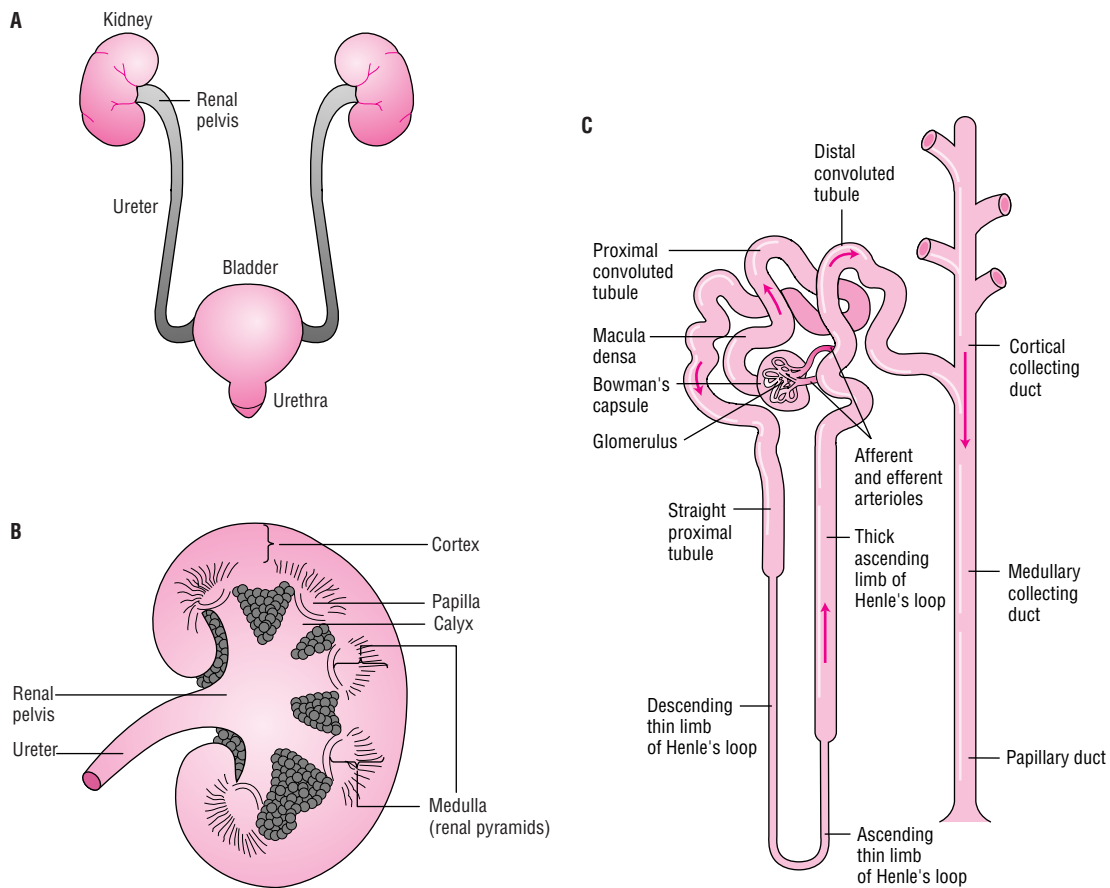

FIGURE 41-1. Structures of the (A) urinary system, (B) kidney, and (C) nephron, which is the functional unit of the kidney.

insult. The cornerstone of this hypothesis is that glomerulotubular balance is maintained, such that those nephrons capable of functioning will continue to perform in an appropriate fashion. As GFR declines, tubular reabsorption must decrease to allow for elimination of the solute load. Single nephron GFR (SNGFR) increases in the remaining nephrons, whereas the whole-kidney GFR represents the sum of the SNGFR of the remaining functional nephrons. Based on this, one would presume that a measure of one component of nephron function could be used as an estimate of all renal functions. This, indeed, has been and remains our clinical approach.

FILTRATION CAPACITY

It is recognized that GFR is dependent on numerous factors, one of which is protein load. Bosch¹² suggested that an appropriate measure of renal function should reflect the “filtration capacity” of the kidney, and not the “resting GFR.” Subjects with normal renal function administered an oral or intravenous protein load prior to measurement of GFR have increased their GFR by as much as 50%.¹² As renal function declines, the kidneys compensate by increasing SNGFR. The renal reserve, the maximal degree by which GFR can be increased, usually declines and thus may be a complementary measure of renal function for these patients.

Quantification of renal function is not only an important diagnostic index, but it also serves as an important parameter for monitoring therapy directed at the etiology of the diminished function itself,

thereby allowing for objective measurement of the success or failure of treatment. Measurement of renal function also serves as a useful indicator of the ability of the kidneys to eliminate drugs from the body. Furthermore, alterations of drug distribution and metabolism are associated with the degree of renal function. See Chap. 48 for a discussion of pharmacokinetic changes in renal disease. Although several indices have been used for the quantification of renal function in the research setting, GFR, and more specifically creatinine clearance, are the primary markers of renal function in the clinical arena.^{13–15}

ENDOCRINE FUNCTION

The kidney synthesizes and secretes many important hormones involved in maintaining homeostasis. Secretion of renin by the cells of the juxtaglomerular apparatus and production and metabolism of prostaglandins and kinins are among the kidney's endocrine functions. In response to decreased oxygen tension in the blood, erythropoietin (EPO) is produced and secreted by peritubular fibroblasts. Because these functions are related to renal mass, decreased endocrine activity is associated with the loss of viable EPO-producing cells. In the presence of nephropathy, secretion of EPO is impaired, leading to reduced red blood cell mass formation, normocytic anemia, and symptoms of reduced oxygen delivery to tissues such as fatigue, dyspnea, and angina (see Chap. 44). Renal anemia is clearly associated with

comorbidities such as left ventricular hypertrophy, which is present in nearly 40% of CKD patients.¹⁶ Here, renal hypoxia leads to the release of hypoxia-induced factors that cause EPO gene activation, tubular necrosis, apoptosis, or sublethal renal cell injury.¹⁷

METABOLIC FUNCTION

The kidneys are capable of a wide variety of metabolic activities, including the activation of vitamin D₃, gluconeogenesis, and metabolism of endogenous compounds such as insulin and steroids, as well as xenobiotics. Impaired renal function results in decreased formation of activated vitamin D₃ and decreased insulin metabolism. It is common for patients with diabetes and chronic renal failure to have reduced requirements for exogenous insulin,¹⁸ and supplemental therapy with activated vitamin D₃ (calcitriol) or other vitamin D analogs (paricalcitol or doxercalciferol) is often necessary in the management of renal osteodystrophy.¹⁹ Numerous enzymes have been identified in the kidneys, primarily the cortex. These include cytochrome P450, *N*-acetyltransferase, glutathione transferase, renal peptidases, and others.²⁰ The cytochrome P450 system in the kidneys is as active as that in the liver, when corrected for organ mass. Furthermore, the accumulation of uremic toxins is associated with decreased cytochrome activity for selected isoenzymes. In vitro studies demonstrate impaired function of cytochrome P450 3A4 and 2C9, whereas 1A2, 2C19, and 2D6 are not affected. These data are supported by a recent study in patients with end-stage renal disease by Dowling and colleagues. In this study hepatic cytochrome P450 3A activity (measured by the erythromycin breath test) was reduced by 28% ($p < 0.05$) compared to that of healthy age-matched controls.²¹ Reversible metabolism may also be affected by renal disease when normal enzyme function is disrupted. This has been observed with clofibrate,²² and may apply to other compounds eliminated by the same route, such as ketoprofen.²³ See Chap. 48 for a more detailed discussion.

QUALITATIVE AND SEMIQUANTITATIVE INDICES OF KIDNEY FUNCTION

Patients who develop renal disease remain relatively asymptomatic until impairment has progressed to the point that systemic manifestations and/or secondary complications become evident (Table 41–2).

Diabetes mellitus and hypertension are the two most common causes of end-stage kidney disease (ESKD), and as renal function declines, patients may experience development or exacerbation of hypertension, edema, electrolyte abnormalities, anemia, or other com-

plications (see Chaps. 43 and 44). The NKF currently recommends that all patients with CKD, and those at increased risk for CKD, undergo comprehensive laboratory assessment for: (1) serum creatinine to estimate GFR, (2) albumin:creatinine ratio in a spot urine specimen, (3) examination of urine sediment for red and white blood cells, (4) renal ultrasonography, (5) serum electrolytes including sodium, potassium, chloride, and bicarbonate, (6) urine pH, and (7) urine specific gravity.²⁴ Each of these indices will be discussed in more detail below.

LABORATORY EVIDENCE FOR KIDNEY DISEASE

URINALYSIS

Examination of the urine includes assessment of its chemical and physical composition, most of which can be completed with dipstick testing.

pH

The normal urine pH typically ranges from 4.5 to 7.8, and an elevation above this may suggest the presence of urea-splitting bacteria.²⁵ In patients with renal tubular acidosis, urine pH is usually >5.5 due to impaired hydrogen ion secretion in the distal tubule or collecting duct.

Specific Gravity

The measure of urine weight relative to water ($H_2O = 1.00$) is its specific gravity and is dependent on water intake and urine-concentrating ability. Normal values range from 1.003 to 1.030. Osmolality, which is a measure of the number of solute particles, is a more accurate measure of the kidney's ability to make concentrated urine. Generally the two values are correlated; however, when large quantities of heavier molecules such as glucose are in the urine, the specific gravity may be elevated relative to the osmolality. These values are used in the assessment of urine concentrating ability and are most informative when interpreted along with the hydration status of the patient and plasma osmolality.²⁵

Glucose

Glucose is normally absent in the urine, because the kidney normally completely reabsorbs all the glucose filtered at the glomerulus. In patients with plasma glucose concentrations that exceed the maximum threshold for glucose reabsorption (~ 180 mg/dL), glucosuria will be present. In the past, patients with diabetes mellitus would use the urine glucose level as a guide to insulin therapy. However, fingerstick methods for direct blood glucose measurements have now

TABLE 41–2. Presentation of Chronic Kidney Disease (CKD)

| | Early CKD (Stages 1–2) | Late CKD (Stages 3–4) |
|------------------|--|---|
| General Symptoms | The patient may not appear in distress Not likely present | Patient may have edema The patient may have fatigue, malaise, pruritus, nausea |
| Signs | Not likely present | May present with fluid retention, anemia, dyspnea, reduced urine output |
| Laboratory tests | Microalbuminuria Mildly-elevated S_{Cr} and BUN | Persistent proteinuria Reduced GFR or CL_{Cr} Abnormal urinalysis Renal ultrasound shows reduced kidney mass |

BUN, blood urea nitrogen; CL_{Cr} , creatinine clearance; GFR, glomerular filtration rate; S_{Cr} , serum creatinine concentration.

replaced the urine tests as a guide to therapy in most clinical settings.²⁶ Urine glucose testing still remains a valuable tool for the detection of diabetes.

Ketones

Acetoacetate and acetone are excreted in patients with diabetic ketoacidosis. They are also produced under conditions of fasting or starvation.

Nitrite

Nitrite is formed by conversion from nitrate by urinary bacteria. The presence of nitrite may indicate that the patient has a urinary tract infection.

Leukocyte Esterase

Leukocyte esterase is released from lysed granulocytes in the urine; its presence is suggestive of urinary tract infection. If the processing of the urine sample is delayed, a false-positive leukocyte esterase may be reported if the sample is contaminated.

Heme

The heme test indicates the presence of hemoglobin or myoglobin. A positive test without the presence of red blood cells suggests either red cell hemolysis or rhabdomyolysis.²⁵

Protein or Albumin

❖ Persistent proteinuria is now considered the principal marker of kidney damage.^{24,25} Evaluation of proteinuria is needed to characterize the severity of CKD and to monitor the rate of disease progression. Under normal conditions, large quantities of plasma proteins pass through the glomerular capillaries but do not enter the urinary space. These proteins are retained by the glomerulus due to charge and size selectivity, preventing filtration of large proteins (>40 kDa) such as albumin and globulins. Smaller proteins (<20 kDa) pass across the capillary wall but are readily reabsorbed by the proximal tubule. Most healthy individuals excrete between 30 and 150 mg/day of total protein, consisting of approximately 30 mg/day of albumin. The remainder of the protein in the urine is secreted by the tubules (Tamm-Horsfall, IgA, and urokinase), or filtered by the glomerulus such as β_2 -microglobulin, apoproteins, enzymes, and peptide hormones. Increased excretion of these low-molecular-weight proteins is considered a sensitive marker of tubulointerstitial disease.

Historically, the sulfosalicylic acid test was used as a crude measure of proteinuria. This test can be performed by adding five drops of 20% sulfosalicylic acid to 3 mL of urine in one test tube. The specimen tube is then visually compared with a tube of untreated urine held against a dark background, with the presence of turbidity indicating proteinuria.

More recently, dipstick tests to measure total protein and albumin have been developed to provide a semiquantitative measure of daily urine protein excretion. Here, urine proteins react with an indicator dye-impregnated test strip yielding a color change from yellow (negative) to green. False-positive results can occur in the presence of alkaline urine (pH >7.5), when the dipstick is immersed too long; in highly concentrated urine; with gross hematuria; in the presence of drugs such as penicillin, sulfonamides or tolbutamide; and with pus, semen, or vaginal secretions. False-negative results occur with dilute urine (specific gravity <1.015) and when proteinuria is caused by nonalbumin or low-molecular-weight proteins such as heavy or light chains or Bence Jones proteins. The results of most urine protein dipsticks are graded as negative (<10 mg/dL), trace (10 to 20 mg/dL), 1+ (30 mg/dL), 2+ (100 mg/dL), 3+ (300 mg/dL) or 4+ (>1,000

mg/dL). Portable desktop analyzers such as the Chemstrip 101 Urine Analyzer and Clinitek 50 Urine Chemistry Analyzer can also be used as an alternative to visual urinalysis test-strip evaluation.

All patients with CKD and those with risk factors should be tested for albuminuria using an albumin-specific dipstick test. Since most dipstick methods are not specific for albumin, newer tests for microalbuminuria (30 to 300 mg/day) should be employed.²⁷ Microalbuminuria test strips, such as the Chemstrip Micral-Test II strip, are optically read immunoassay-based methods. Here, the test strip is dipped into a urine sample and albumin present in the sample binds to gold-labeled antibodies. The detection field assumes a color ranging from white (0 mg/L) to red (100 mg/L).

In patients with a positive protein or albumin dipstick test, a 24-hour urine collection with measurement of albumin excretion can be used to further define the degree of proteinuria.

CLINICAL CONTROVERSY

In the past, measurement of the urinary protein excretion rate was accomplished using a 24-hour urine collection in patients at risk for CKD. Use of an untimed "spot" urine sample with either an albumin-specific dipstick or measurement of albumin:creatinine ratio is now recommended by some because it is more convenient than the extended-interval urine collection.

❖ The 24-hour collection requires patient compliance and is being replaced by a similarly accurate but less cumbersome ratio of protein or albumin (mg) to creatinine (g) obtained from an untimed (spot) urine specimen.^{28,29} The ratio is used to correct for changes in urine volume since creatinine production per day is constant in those with stable kidney function. The normal ratio is <30 mg albumin or 200 mg protein per gram of creatinine in the urine, with values between 30 and 300 mg albumin:1 g creatinine considered to be in the microalbuminuria range.³⁰ Positive test results should be confirmed, particularly in patients without an underlying cause for renal disease, such as diabetes or hypertension. Ruggenti and associates³¹ observed a positive correlation between the degree of proteinuria (using the spot morning protein:creatinine ratio) and rate of progression of renal disease in patients with nondiabetic chronic renal disease. For continued monitoring of proteinuria in CKD patients, the albumin:creatinine ratio is recommended. In patients with clinical proteinuria (albumin:creatinine ratio >500 mg/g), the protein:creatinine ratio can be used.

Microscopic Analysis of Urine

Formed elements that may be detected in the urine include erythrocytes and leukocytes, casts, and crystals. An important consideration in the assessment of hematuria is whether the cells are of renal origin. More than two cells per high-power field is abnormal, and dysmorphic cells suggest renal parenchymal origin, either because of damage as they pass through the glomerulus, or during exposure to the varying osmotic environment of the tubular lumen. White blood cells may be present in the urine in association with infection or inflammatory conditions, such as interstitial nephritis, and more than one cell per high-power field may be considered abnormal. For both red and white cells, contamination of the sample should also be considered, such as during menses or with inadequate sample collection. *Casts* are cylindrical forms composed of protein, with or without cells that take the shape of the collecting tubules, where they are formed. Casts without cells are called *hyaline casts* and consist of the Tamm-Horsfall mucoprotein secreted by the renal tubules. They are nonspecific and may

appear in concentrated urine. In the presence of red or white blood cells, casts may be formed that include the cells, indicating that the cells were of renal origin. Solubility of the Tamm-Horsfall protein is increased as urine pH rises; therefore sample collection for casts should occur with the first morning void when the urine is most acidic. Otherwise casts may dissolve and elude detection.^{25,32}

A variety of crystals may be present in the urine, including uric acid, calcium oxalate, calcium phosphate, calcium magnesium ammonium pyrophosphate, and cystine. Many of these have a unique crystalline form which permits them to be identified with microscopy.

SERUM OR BLOOD UREA NITROGEN

Amino acids metabolized to ammonia are subsequently converted in the liver to form urea, the production of which is dependent on protein availability (diet) and hepatic function. Renal handling of urea includes glomerular filtration followed by reabsorption of up to 50% of the filtered load in the proximal tubule. As urea is able to cross cell membranes by passive diffusion, its reabsorption rate is variable and dependent on the reabsorption of water. The excretion of urea may therefore be decreased under conditions of water conservation by the kidneys, although the GFR may be reduced only slightly. This condition is evident when a patient exhibits prerenal azotemia, or a greater increase in the blood urea nitrogen (BUN) than the serum creatinine. The normal BUN:creatinine ratio is 10 to 15:1, and an elevated ratio is suggestive of a decreased effective circulating volume, which stimulates increased water, and hence urea reabsorption.²¹ Creatinine is not reabsorbed to any significant extent by the kidneys. Despite these limitations, the BUN is often used as a simple screening tool for the detection of renal dysfunction, but particularly in combination with the serum creatinine concentration.

SERUM CREATININE

Creatinine is the standard laboratory marker for the detection of kidney disease. The third National Health and Nutrition Examination Survey revealed a mean serum creatinine of 0.96 mg/dL in women, and 1.16 mg/dL in men in the United States.³³ Values were lower among Mexican-Americans and higher among non-Hispanic blacks. For all groups the serum creatinine increased with age. The report also noted that among noninstitutionalized adults, 10.9 million have a serum creatinine greater than 1.5 mg/dL, 3 million have a serum creatinine greater than 1.7 mg/dL, and 0.8 million have a serum creatinine >2 mg/dL. While the serum creatinine concentration alone is not an optimal measure of kidney function, it is often used as a marker for referral. There is presently no accepted single standard for an “abnormal” serum creatinine, as it is gender, race, and age dependent.

The concentration of creatinine in serum is a function of creatinine production and renal excretion. Creatinine is a product of creatine metabolism from muscle; therefore its production is directly dependent on muscle mass. At steady state, the “normal” serum creatinine concentration is approximately 0.5 to 1.5 mg/dL for males and females.²⁵ Creatinine is eliminated primarily by glomerular filtration, and as GFR declines, the serum creatinine concentration rises (Fig. 41–2).

Several methods may be used for the determination of the serum creatinine concentration, most of which are based on the nonspecific Jaffé reaction, a colorimetric method based on the reaction of creatinine with alkaline picrate. This nonspecific method also reacts with noncreatinine chromogens in the serum, which may result in a falsely high Jaffé serum creatinine concentration.²⁵ The noncreatinine chromogens are not present in the urine in sufficient quantities to interfere

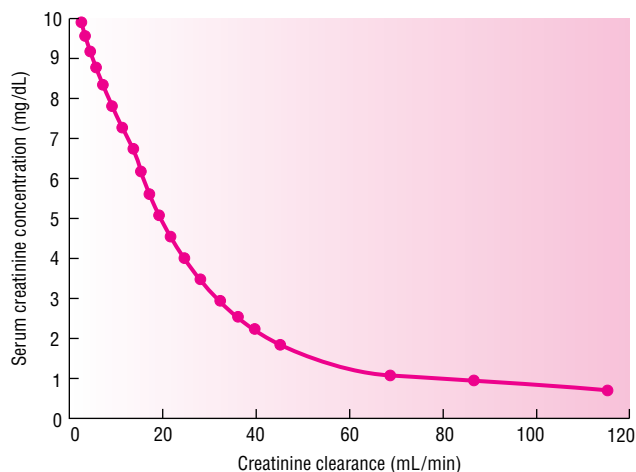

FIGURE 41–2. Relationship between serum creatinine and creatinine clearance.

with the creatinine measurement, which will be severalfold greater than the serum concentration. The impact of this interference is seen with the creatinine clearance (CL_{cr}) calculation:

$$CL_{cr} = (U_{cr} \times V) / (S_{cr} \times t)$$

where U_{cr} = urine creatinine concentration, V = urine volume, S_{cr} = serum creatinine concentration, and t = duration of the urine collection.

This “normal” interference results in an increase in the serum creatinine concentration of approximately 10%, and thereby the creatinine clearance would underestimate the GFR by 10%. In subjects with normal renal function, this tends to counterbalance the effect of the contribution of tubular secretion of creatinine, which increases urine creatinine by nearly 10%. Thus CL_{cr} may serve as a good measure of GFR in subjects with normal renal function. However, this false increase in serum creatinine becomes less noticeable as the true creatinine concentration rises, due to the increasing contribution of tubular secretion to the renal clearance of creatinine.³⁴ This becomes important when kidney function is reduced to less than 50% of normal.

Diabetic ketoacidosis may produce increased concentrations of acetoacetate, which serves as a chromophore in the Jaffé reaction, thereby increasing the serum creatinine concentration.²⁵ Other substances in the serum that affect this reaction include glucose, protein, pyruvate, fructose, uric acid, and ascorbic acid (Table 41–3).²⁵ In

TABLE 41–3. Factors That May Alter Creatinine Clearance Determinations

| Analytical | Physiologic |
|--|--|
| Acetoacetate | Age, weight, gender |
| Ascorbic acid | Diet |
| Cephalosporins (cephalothin, cefazolin, cephalexin, cefoxitin, cefaclor, cephadrine) | Diurnal variation |
| Dobutamine | Drugs (cimetidine, trimethoprim, probenecid) |
| Dopamine | Exercise |
| 5-Flucytosine | |
| Fructose | |
| Glucose | |
| Protein | |
| Pyruvate | |
| Uric acid | |

addition, some cephalosporin antibiotics are associated with a false increase in the serum creatinine concentration, including cephalothin, cefazolin, cephalexin, cefoxitin, cefaclor, and cephadrine,³⁵ whereas other antibiotics such as the fluoroquinolones (ciprofloxacin, fleroxacin, lomefloxacin, ofloxacin, levofloxacin, sparfloxacin, and temafloxacin) do not produce a false elevation in serum creatinine.³⁶ The degree of interference is dependent on the serum concentration of the antibiotic, so blood samples for creatinine should be obtained when the antibiotic concentration is lowest (at the end of a dosing interval). These interferences are not observed when the serum creatinine is measured using an enzymatic technique. The antifungal agent 5-flucytosine causes an increase in the serum creatinine when measured using the Ektachem enzymatic system, but does not interact with the Jaffé method.³⁷ Daly and associates³⁸ reported a false-negative effect of dobutamine and dopamine on the serum creatinine value when measured using the Ektachem system. The interference is concentration dependent, and results in a 10% to 100% decrease of the serum creatinine concentration. The authors hypothesized that both drugs compete with the chromogenic dye for oxidation by hydrogen peroxide in a concentration-dependent manner. The problem is most evident when blood samples are contaminated with residual IV solution containing the interfering drug. These differences emphasize the need to standardize a method within the research or clinic setting, and to be aware of methods employed in the laboratory for the determination of creatinine concentrations.

Other compounds are known to interfere with the serum creatinine concentration through inhibition of the active tubular secretion of creatinine. Among these are cimetidine and trimethoprim, which compete for creatinine secretion by the cationic transport system.²⁵ Both trimethoprim and cimetidine demonstrate dose dependency with respect to competition with creatinine for secretion. Ranitidine, an H₂-receptor antagonist similar to cimetidine, was evaluated for its effect on creatinine clearance in 10 healthy subjects. There was no effect following single doses of 300 or 1200 mg as determined by the ratio of CL_{cr} to inulin clearance (CL).³⁹ Cimetidine, given as a single 400-mg dose in six of the same subjects, resulted in a reduction of the ratio of CL_{cr} to CL inulin from 1.30 to 1.03, without any change in CL inulin.

The serum creatinine concentration is dependent on the “input” function, or formation rate, and “output” function, or elimination rate. Its formation rate depends on the zero-order production from creatine metabolism, as well as input from other sources such as dietary intake.⁴⁰ Creatine metabolism is directly proportional to muscle mass; therefore individuals with more muscle mass have a higher serum creatinine concentration at any given degree of kidney function than those with less muscle mass. Exercise is associated with an increase of approximately 10% in the serum creatinine concentration. As the result of minimal muscle mass patients who are cachectic will have very low serum creatinine concentrations, as do those with spinal cord injuries.⁴¹ Elderly patients and those with poor nutrition may also have low serum creatinine concentrations (<1 mg/dL) secondary to decreased muscle mass. Other factors that influence the serum creatinine concentration include the dietary intake of creatine. During the cooking of meat, some creatine is converted to creatinine, which is rapidly absorbed following ingestion.

Serum creatinine concentrations may rise as much as 50% within 2 hours of a meat meal and remain elevated for as long as 8 to 24 hours.⁴⁰ Ingestion of creatine as an ergogenic dietary supplement is currently popular. There are conflicting reports on the effect of creatine ingestion on the serum creatinine concentration. Poortsmans and Francaux⁴² evaluated a short-term regimen of 20 g creatine per day for 5 days in healthy subjects, and reported no significant change

in the serum creatinine, creatinine excretion rate, or creatinine clearance. Robinson and associates,⁴³ however, reported a 25% to 40% increase in the serum creatinine concentration after ingestion of 20 g creatine per day for either 5 days or 8 weeks. The renal excretion rate of creatinine was not measured. The issue of whether creatine ingestion adversely affects kidney function was studied by Edmonds and coworkers.⁴⁴ They noted that creatine supplementation led to an increase in renal disease progression in a rat model for renal cystic disease, suggesting that creatine supplementation may be a risk factor in patients with preexisting renal disease. These conditions present a problem only when a single serum creatinine concentration is used to represent the entire 24-hour collection period, which is usually the case. An alternative is to obtain multiple samples and calculate the area under the serum concentration time curve and divide this by the collection time interval to obtain the average plasma creatinine concentration. This is rarely done in clinical practice, but points out the need to question patients regarding dietary intake for the 24 hours preceding the measurement of CL_{cr}.

Diurnal variation in serum creatinine concentration may also affect the accuracy of the CL_{cr} determination. Although the fluctuation is minimal, the observed peak plasma creatinine concentration generally occurs at approximately 7:00 PM, whereas the nadir is in the morning. To minimize this effect, the CL_{cr} is usually measured over a 24-hour period with the plasma creatinine obtained in the morning, as long as the patient has stable kidney function. Collection of urine remains a limiting factor in the 24-hour CL_{cr} because of incomplete collections and interconversion between creatinine and creatine that can occur if the urine is not maintained at a pH <6.

CYSTATIN C

The newest endogenous marker of renal function to be proposed is serum cystatin C, a 132-amino-acid (13.3-kDa) cysteine protease inhibitor. It is produced by all nucleated cells of the body and serum concentrations appear to be independent of gender, age, body mass, nutritional status, and acute inflammatory conditions.^{45–47} Although it is freely filtered at the glomerulus, like other low-molecular-weight proteins it undergoes reabsorption and catabolism in the proximal tubule. Originally used in Europe, it has been recommended as a test of kidney function due to findings that serum concentrations were significantly correlated with GFR as well as serum creatinine.^{45–47} The recent development of an automated immunoassay technique has led to suggested reference ranges of 0.70 to 1.38 mg/L in children over 1 year of age, and 0.54 to 1.21 mg/L in adults.⁴⁷ It may be a more sensitive indicator of reduced renal function than creatinine, so cystatin C may have future clinical utility in the assessment of renal function.^{46,47} However, comparison of ¹²⁵I-iothalamate with serum creatinine and cystatin C showed that the serum creatinine began to increase when the GFR was 75 mL/min per 1.73 m² as compared to 88 mL/min per 1.73 m² for cystatin C.⁴⁵ Keevil and associates⁴⁸ reported that serum cystatin C had greater intra-individual variability than serum creatinine in healthy individuals, which may limit its use in longitudinal evaluations of renal function. In patients being treated for malignant disease, Page and coworkers⁴⁹ reported increased concentrations that were independent of CL_{cr}. In pediatric and adult renal transplant recipients, cystatin C concentrations were independent of GFR and weakly associated with measured creatinine clearance, possibly due to formation of cystatin-immunoglobulin complexes or reduced tubular catabolism.^{50,51} These mixed observations suggest that cystatin C requires further evaluation in populations such as pediatrics, renal transplant, and CKD before it is accepted as a routine marker for renal function.

MEASUREMENT OF KIDNEY FUNCTION

The gold standard for the quantitative measure of kidney function is the GFR. However, protein intake such as oral protein loading or an infusion of amino acid solution may increase GFR.¹² As a result, inter- and intrasubject variability must be considered when it is used as a longitudinal marker of renal function. Dietary protein intake has been demonstrated to correlate with GFR in healthy subjects. Brändle and colleagues⁵² evaluated renal function in four groups of healthy volunteers, each ingesting a diet controlled for protein over a 4-month period. The GFR was nonlinearly related to the urine nitrogen excretion, with an observed maximum of 181.7 mL/min at a urinary nitrogen excretion rate of 20 g/day, or 125 g/day protein intake. Subjects who are vegetarian will have a low GFR because of reduced dietary protein intake.

CLINICAL CONTROVERSY

Estimation of creatinine clearance in vegetarians is controversial. Some clinicians advocate use of the 24-hour creatinine clearance in these patients since this method is based on the renal clearance of creatinine. The six-variable Modification of Diet in Renal Disease (MDRD) study equation (see below), which incorporates nutritional parameters such as BUN and albumin, has been suggested as an alternative approach.

When challenged with a protein load, these same subjects are able to increase their GFR to the normal range.¹² Findings from the Nurses' Health Study⁵³ indicate that longitudinal changes in GFR are independent of the source of protein (nondairy animal, dairy, or vegetable) in women with normal renal function. However, women with mild renal insufficiency (GFR 71 ± 7 mL/min) who consumed the highest amount of protein (93 g/day) had a threefold greater risk of a ≥ 15 -mL/min decline in GFR compared to the lowest protein-consuming group (60 g/day), and rates of decline were highest in those consuming nondairy animal protein. The increased GFR following a protein load is the result of renal vasodilation accompanied by increased renal plasma flow. The exact mechanism of the renal response to protein is not known, but it may be related to extrarenal factors such as glucagon, prostaglandins, and angiotensin II, or intrarenal mechanisms such as tubular transport and tubuloglomerular feedback.^{54,55} Despite the evidence of a "renal reserve," standardized evaluation techniques have not been developed. Therefore assessment of the standard GFR measurement must consider the dietary protein status of the patient at the time of the study.

MEASUREMENT OF GLOMERULAR FILTRATION RATE

4 The GFR remains the single best index of functioning renal mass. As renal mass declines in the presence of age-related loss of nephrons or coexisting disease states such as hypertension or diabetes, there is a progressive decline in GFR. The GFR can be used to predict the time to onset of ESKD as well as the risk of complications of chronic kidney disease. Furthermore, accurate assessment of GFR in clinical practice allows proper dosing of drugs excreted renally in order to maximize therapeutic efficacy and avoid potential drug toxicity.

The GFR is expressed as the volume of plasma filtered across the glomerulus per unit time. The most commonly reported range of normal GFR values is 100 to 140 mL/min. For example, if the

normal renal blood flow (RBF) were approximately 1 L/min, plasma volume was 60% of blood volume, and filtration fraction across the glomerulus was 20%, then the normal GFR would be approximately 120 mL/min.

Since GFR cannot be measured directly, clearance methods involving substances that freely diffuse across the glomerulus and into Bowman's capsule without additional clearance by tubular secretion or reduction by reabsorption are required. Additionally, the substance should not be susceptible to metabolism within renal tissues and should not alter renal function. Given these conditions, the GFR is equivalent to the renal clearance of the solute marker:

$$\text{GFR} = \text{renal CL} = (A_e)/\text{AUC}_{0-t}$$

where renal CL is renal clearance of the marker; A_e is the amount of marker excreted in a specified period of time, t ; and AUC_{0-t} is the area under the plasma concentration time curve of the marker.

Under steady-state conditions, the expression simplifies to:

$$\text{GFR} = \text{renal CL} = (A_e)/[(C_{ss}) \times t]$$

where C_{ss} is the steady-state plasma concentration of the marker.

The GFR marker is most often administered as a combination of an IV loading dose and a continuous infusion. Here a loading dose is administered followed by a maintenance infusion designed to achieve the desired target plasma concentration. Following a 60-minute equilibration period, sequential measurements of clearance are made over three periods of 30 to 60 minutes each. Urine is collected, and blood samples bracket each collection period. It is necessary to maintain adequate hydration during the test because GFR is dependent on renal blood flow, and hydration assures adequate urine output during the procedure. A relatively constant urine flow will decrease the variability among repeated measurements, and should be within the range of 1 to 10 mL/min. An initial water load of 10 to 15 mL/kg body weight will usually initiate a diuresis, and additional water equal to 50% to 70% of urine output during the previous interval should be given orally or intravenously to maintain urinary output. It is essential to ensure complete bladder emptying to minimize variability of results. Alternative clearance calculation methods should be employed for patients with benign prostatic hypertrophy and neurogenic bladder.

This continuous infusion method can also be employed without urine collection, and plasma clearance is then calculated as $\text{CL} = \text{infusion rate}/C_{ss}$. Requirements of this method include steady-state plasma concentrations and accurate measurement of infusate concentrations. Plasma clearance can also be determined following a single-dose intravenous injection with multiple samples of blood taken to estimate the area under the curve ($\text{AUC}_{0-\infty}$). Here clearance is calculated as $\text{CL} = \text{dose}/\text{AUC}$. These plasma clearance methods commonly yield clearance values 10% to 15% higher than urine collection methods.^{56,57}

5 Several markers have been used for the measurement of GFR and include both exogenous and endogenous compounds. Those administered as exogenous agents, such as inulin, iothalamate, iohexol, and radioisotopes, require specialized administration techniques and detection methods for the quantitation of function, but generally provide a more accurate measure of GFR. Methods that employ endogenous compounds such as creatinine require less technical expertise, but produce results with greater variability.⁵⁵ The marker of choice depends on the purpose and cost of the test; research protocols will generally use more accurate tests than those used in clinical settings (Table 41-4).

TABLE 41–4. Sensitivity and Clinical Utility of Renal Function Tests

| | Accuracy | Clinical Utility | Cost |
|-----------------------------|----------|------------------|----------|
| Inulin clearance | ++++ | + | \$\$\$\$ |
| Radiolabeled markers | +++ | + | \$\$\$ |
| Nonisotopic contrast agents | +++ | ++ | \$\$\$ |
| Creatinine clearance | ++ | +++ | \$\$ |
| Serum creatinine | + | ++++ | \$ |

+, least acceptable; ++, adequate; +++, better; +++++, best.

INULIN CLEARANCE

Inulin is a relatively large molecule (5200 daltons) and has the necessary characteristics to serve as a marker for the measurement of GFR. Inulin is a fructose polysaccharide obtained from the tubers of the Jerusalem artichoke, dahlia, and chicory plants. It is not bound to plasma proteins, is freely filtered at the glomerulus, is not secreted or reabsorbed, and is not metabolized by the kidney.³⁵ The volume of distribution of inulin approximates extracellular volume, or 20% of ideal body weight. Because it is eliminated by glomerular filtration, its elimination half-life is dependent on renal function and is approximately 1.3 hours in subjects with normal renal function. Measurement of plasma and urine inulin concentrations using high-performance liquid chromatography (HPLC) was recently described. Glucose and drugs commonly administered to patients with renal disease, including corticosteroids, calcitriol, azathioprine, nifedipine, and atenolol, did not interfere with the assay.⁵⁸ Sinistrin, another polyfructosan, is handled in the same fashion as inulin in humans. It is filtered at the glomerulus and not secreted or reabsorbed to any significant extent. It is a naturally occurring substance derived from the root of the North African vegetable red squill, *Urginea maritima*. Its primary difference from inulin is its greater degree of water solubility. Whereas inulin must be boiled to solubilize it, sinistrin is soluble at room temperature. Assay methods for sinistrin have been described using enzymatic procedures, as well as HPLC.^{59–61}

IOTHALAMATE CLEARANCE

Alternatives have been sought for inulin as a marker for GFR because of the problems of intermittent availability, high cost, sample preparation, and assay variability. Iothalamate is an iodine-containing radiocontrast agent that is available in both radiolabeled (¹²⁵I) and nonradiolabeled forms. This agent is handled in a manner similar to that of inulin, and appears to be freely filtered at the glomerulus but does not undergo substantial tubular secretion or reabsorption.²⁵ The nonradiolabeled form is most widely used to measure GFR in ambulatory and research settings, and can safely be administered by IV bolus, continuous infusion, or subcutaneous injection with minimal biohazardous waste.⁶² Plasma and urine iothalamate concentrations can be measured using HPLC methods.⁶³ Plasma iothalamate clearance methods that do not require urine collections have been shown to be highly correlated with iothalamate renal clearance, with a positive bias of approximately 10 mL/min. Here, corrected plasma clearance provided a good estimate of GFR that is well suited for longitudinal evaluations of renal function.⁶⁴

IOHEXOL CLEARANCE

Iohexol, a nonionic, low osmolar, iodinated contrast agent, has also been used for the determination of GFR. It is eliminated almost entirely by glomerular filtration, and plasma and renal clearance values

are similar.⁶⁵ Rocco and associates⁶⁶ compared iohexol plasma clearance with ¹²⁵I-iothalamate renal clearance and demonstrated a strong correlation ($r = 0.95$) between the two tests: CL iohexol = 0.90 CL iothalamate + 6.8 mL/min. The plasma iohexol assay was performed using a reverse-phase HPLC method. Lundqvist and colleagues⁶⁷ evaluated a single-sample plasma clearance calculation method using iohexol compared to ⁵¹Cr-ethylenediaminetetraacetic acid (EDTA) and demonstrated similar results ($r = 0.918$). These data support iohexol as a suitable alternative marker for the measurement of GFR. Following iohexol administration, a single plasma sample can be used to quantify renal function, provided sufficient time has elapsed since injection in patients with a reduced GFR—more than 24 hours if GFR is less than 20 mL/min.⁶⁵ Iohexol has also been assessed for potential renal toxicity in a population of 100 patients, 63 of whom had renal insufficiency. There were no significant changes in renal function as assessed by the serum creatinine concentration and urine protein excretion for up to 1 week after the study.⁶⁸

RADIOLABELED MARKERS

The GFR has also been quantified using radiolabeled markers, such as ¹²⁵I-iothalamate (614 daltons, radioactive half-life of 60 days), ^{99m}Tc-diethylenetriamine pentaacetic acid (DTPA, 393 daltons, radioactive half-life of 6.03 hours), and ⁵¹Cr-EDTA (292 daltons, radioactive half-life of 27 days).⁶⁹ These relatively small molecules are minimally bound to plasma proteins and do not undergo tubular secretion or reabsorption to any significant degree. ¹²⁵I-iothalamate and ^{99m}Tc-DTPA are used in the United States, whereas ⁵¹Cr-EDTA is used extensively in Europe. An advantage of using radiolabeled markers relates to their diagnostic ability to determine the individual contribution to overall renal function of each kidney.⁷⁰ Various protocols exist for the administration of these markers and subsequent determination of GFR using both plasma and renal clearance methods. The nonrenal clearance of these agents appears to be low (3 to 8 mL/min), suggesting that plasma clearance is an acceptable technique except in patients with severe renal insufficiency (GFR <30 mL/min). Indeed, high correlations between renal clearance among radiolabeled markers has been demonstrated.^{63,64} Morton and coworkers⁷¹ recently demonstrated that ^{99m}Tc-DTPA plasma clearance and ¹³¹I-iothalamate renal clearance were highly correlated in patients with clearance values >20 mL/min: CL DTPA = 0.943 CL iothalamate + 1.12 mL/min ($r = 0.983$). Although total radioactive exposure to patients is usually minimal, disadvantages of using radiolabeled markers include the requirement for radiation safety oversight and biohazard waste disposal.

ESTIMATION OF GFR

A series of equations proposed by Levey and associates⁷² may be used to estimate GFR in selected patient populations.

These equations were derived from multiple regression analysis of data obtained from patients enrolled in part of the Modification of Diet in Renal Disease Study (MDRD). Of the 1628 patients enrolled in the baseline phase of the study (mean GFR = 40 mL/min per 1.73 m²), 1070 were randomly assigned to a training sample, with the remaining 558 included in the validation sample. The initial regression model yielded the following six-variable equation:

$$\text{GFR} = 170 \times (\text{Pl}_{\text{cr}})^{-0.999} \times [\text{Age}]^{-0.176} \times [0.762 \text{ if patient is female}] \\ \times [1.180 \text{ if patient is black}] \times [\text{SUN}]^{-0.170} \times [\text{Alb}]^{0.318}$$

where Pl_{cr} = plasma creatinine, SUN = serum urea nitrogen concentration, and Alb = serum albumin concentration. Comparison of various prediction equations showed that the new equation ($r = 0.95$) provided a more precise estimate of GFR than measured CL_{cr} ($r = 0.93$) or the CG method ($r = 0.92$) in the MDRD population. More recent analysis has shown mixed results. In renal transplant patients with severe renal insufficiency ($\text{CL}_{\text{cr}} < 30$ mL/min per 1.73 m²), the MDRD equation was highly correlated with mean CL_{cr} and urea clearances, less biased, and more precise than CG.⁷³ However, this equation was less accurate than CG in healthy subjects, diabetic patients with normal GFRs (88 to 182 mL/min per 1.73 m²), and healthy potential kidney donors.^{74,75} In cirrhotic patients being evaluated for liver transplant (GFR 58 ± 5.1 mL/min per 1.73 m²) both the MDRD and CG equations significantly overestimated GFR by 30% to 50%, and were imprecise estimates of GFR in liver disease patients before and after liver transplantation.^{76,77} In a small study of elderly subjects (age > 68 years) with mild to moderate CKD (GFR 53 ± 18 mL/min per 1.73 m²), the MDRD equation was slightly positively biased compared to CG (8% vs. -10%), but precision was similar between methods relative to measured GFR. Beddhu and associates⁷⁸ reported that the MDRD equation, like the CG method, is dependent on creatinine production and is susceptible to bias in malnourished patients with ESRD.

CLINICAL CONTROVERSY

The MDRD equation was derived from a study evaluating GFR in patients with CKD (GFR <90 mL/min). Some practitioners are advocating the use of this equation in patients without CKD, although it appears to have a weaker correlation with GFR than the Cockcroft-Gault equation. Therefore current evidence suggests that the MDRD equation should be reserved for patients with GFR <90 mL/min.

Recently,²⁴ a modified four-variable version of the original MDRD equation has been proposed for predicting GFR:

$$\text{GFR} = 186 \times (\text{Pl}_{\text{cr}})^{-1.154} \times (\text{Age})^{-0.203} \times (0.742 \text{ if patient is female}) \\ \times (1.210 \text{ if patient is black})$$

This equation, based on plasma creatinine, age, sex, and race, has been validated in the MDRD study sample, and is now recommended by the NKF for estimating GFR in patients with CKD and a GFR <90 mL/min per 1.73 m² in the updated NKF K/DOQI guidelines. The accuracy of these MDRD equations in estimating GFR in individuals with normal renal function; those with diabetes; pediatric, elderly, and obese patients; and for drug dosage adjustment requires further evaluation.

CLINICAL CONTROVERSY

Drug dose individualization is often required in patients with CKD. The drug product label typically includes a dose adjustment table based on the patient's estimated CL_{cr} using the Cockcroft-Gault method. Although some hospital laboratories are now reporting MDRD GFR values (see below), its use for drug dose adjustments for the present time has not been evaluated.

MEASURED CREATININE CLEARANCE

6 Despite the common use of a measured (24-hour) CL_{cr} to estimate GFR, it remains a controversial measurement. Short-duration witnessed CL_{cr} correlates with iothalamate clearance performed using the single-injection technique. In a multicenter study⁷⁹ of 136 patients with type I diabetic nephropathy, GFR was assessed using duplicate serum creatinine and 24-hour urine collection, the mean of four iothalamate clearance periods by single-injection technique during water diuresis, and CL_{cr} . CL_{cr} was also estimated for each patient using the Cockcroft-Gault method,⁸⁰ corrected for weight and gender. The simultaneous iothalamate and CL_{cr} were 78 ± 35 and 86 ± 35 mL/min, respectively, while the separate 24-hour CL_{cr} was 75 ± 33 mL/min. The Cockcroft-Gault estimate was 79 ± 29 mL/min. Using CL iothalamate as the standard, the correlation coefficient values for the simultaneous CL_{cr} , 24-hour CL_{cr} , and Cockcroft-Gault CL_{cr} were 0.90, 0.70, and 0.82, respectively, indicating increased variability with the 24-hour clearance determination. It was not stated whether the 24-hour CL_{cr} measurements were performed as inpatient or ambulatory procedures.⁷⁹ In a selected group of 110 patients, measurement of a 4-hour CL_{cr} during water diuresis provided the best estimate of the GFR as determined by the CL iothalamate. Furthermore, the ratio of CL_{cr} to CL iothalamate did not appear to increase as the GFR decreased. These data suggest that a short collection period with a water diuresis may be the best method for estimation of GFR by creatinine clearance.⁷⁹

Creatinine is eliminated by both glomerular filtration and tubular secretion. Tubular secretion augments the filtered creatinine by about 10% in subjects with normal kidney function. If the nonspecific Jaffé reaction is used, which overestimates the serum creatinine concentration by about 10% because of the noncreatinine chromogens, then the creatinine clearance is a very good measure of GFR in patients with normal kidney function. Tubular secretion, however, increases to as much as 100% in patients with renal insufficiency.³⁴ As renal impairment develops, the remaining nephrons hypertrophy, and the degree of tubular secretion decreases disproportionately (less than) to the decrease in filtration. The result is an overestimation of creatinine clearance as a function of GFR assessed by using inulin clearance. Bauer and associates³⁴ assessed creatinine clearance as a function of inulin clearance in 123 subjects with various degrees of kidney function. Using a specific assay for the measurement of creatinine, the ratio of CL_{cr} exceeded CL inulin by 14%, which suggested that 14% of the creatinine was eliminated by secretion. The $\text{CL}_{\text{cr}}:\text{CL}$ inulin ratio in subjects with mild impairment was 1.20; for moderate impairment, it was 1.87; and for severe impairment, it was 2.32. Thus creatinine clearance is a poor indicator of GFR in patients with moderate to severe renal insufficiency.

Creatinine is secreted via the organic cationic pathway, which can be blocked by the coadministration of drugs that compete for the same secretory path, such as cimetidine and trimethoprim. Shemesh

and colleagues⁸¹ studied the effect of an infusion of cimetidine on the tubular secretion of creatinine. The ratio of $CL_{cr}:CL$ inulin was reduced from 1.67 ± 0.10 to 1.16 ± 0.06 within 80 minutes of the start of the cimetidine infusion with no effect on CL inulin. Roubenoff and coworkers⁸² evaluated the potential role of oral cimetidine to improve the accuracy and precision of creatinine clearance as an indicator of GFR. Thirteen patients with lupus nephritis and 24-hour CL_{cr} ranging from 24 to 115.3 mL/min were given 400 mg of cimetidine orally 4 times daily for 2 days before and during a 24-hour CL_{cr} determination. A simultaneous 4-hour ^{99m}Tc -DTPA and CL_{cr} were also determined. Cimetidine reduced the $CL_{cr}:CL$ DTPA ratio from 1.33 with placebo to 1.07 with cimetidine treatment ($p < .05$). No adverse effects were observed from the 2-day cimetidine treatment. Zaltzman and associates⁸³ administered cimetidine, 800 mg as a single dose, 1 hour prior to a 3-hour timed collection for creatinine and ^{125}I -iothalamate clearances. The $CL_{cr}:CL$ iohalamate ratio was reduced from 1.53 ± 1.02 to 1.12 ± 0.02 , and the authors suggest that this method effectively inhibited the tubular secretion of creatinine. Van Acker and coworkers⁸⁴ demonstrated similar results using multiple doses, although they noted a dose dependency in the effect of cimetidine; subjects with higher renal cimetidine clearance required larger cimetidine doses for complete blockade of creatinine tubular secretion. A single oral dose of cimetidine, 800 mg, should provide adequate blockade of creatinine secretion to improve the use of the creatinine clearance measurement to estimate GFR.

ESTIMATION OF CREATININE CLEARANCE

Several investigators have developed mathematical relationships between various patient factors as a means to estimate CL_{cr} when urine is unavailable (Table 41–5). These factors include age, gender, weight, and serum creatinine concentration. Perhaps the most widely used of these estimators is the one developed by Cockcroft and Gault,⁸⁰ which identified age and body mass as factors that significantly improved the estimate of CL_{cr} . Their relationship was based on

observations of 249 male patients with stable kidney function whose 24-hour creatinine excretion was >10 mg/kg, except for 23 patients who were included because their 24-hour urine volume was >500 mL. Creatinine clearance ranged from 11 mL/min to normal. Creatinine production (P_{cr} , in mg/kg per day) and excretion significantly decreased with increasing age for males ($P_{cr} = 28 - [0.2 \times \text{age}]$) and females ($P_{cr} = 0.8 \times P_{cr}$ males). Based on the usual CL_{cr} formula and the relationship of creatinine excretion to age, they derived the following formula to estimate CL_{cr} :

$$CL_{cr} \text{ (mL/min)} = [(140 - \text{age}) \times \text{ABW}] / (S_{cr} \times 72)$$

where age is expressed in years, S_{cr} is the serum creatinine in mg/dL, and ABW is the actual body weight in kg. For females, the result is multiplied by 0.85. For individuals weighing more than 30% above their ideal body weight (IBW), it is recommended that IBW be used in place of ABW,⁸⁵ where:

$$\text{IBW (kg, males)} = 50 + 2.3 (\text{height in inches} > 60)$$

$$\text{IBW (kg, females)} = 45 + 2.3 (\text{height in inches} > 60)$$

An alternative approach for estimating CL_{cr} (mL/min) in obese patients is the Salazar-Corcoran equation:⁸⁶

$$\text{Men: } CL_{cr} = [(137 - \text{age}) \times [(0.285 \times \text{ABW}) + (12.1 \times \text{height}^2)]] / (51 \times S_{cr})$$

$$\text{Women: } CL_{cr} = [(146 - \text{age}) \times [(0.287 \times \text{ABW}) + (9.74 \times \text{height}^2)]] / (60 \times S_{cr})$$

where ABW is actual body weight in kilograms, and height is the height in meters. This equation has been shown to be unbiased and superior to the CG equation in obese individuals.^{85,86}

Luke and associates⁸⁷ evaluated the ability of the CG method and four other methods to predict CL_{cr} , with inulin clearance being considered the standard measure of GFR. Simultaneous inulin and creatinine clearances, and a 24-hour ambulatory CL_{cr} were conducted in 109 patients. The simultaneously determined inulin and creatinine clearances correlated best ($r = 0.92$), and the CL_{cr} overestimated CL inulin by approximately 15% due to tubular secretion of creatinine. The correlation coefficient between CL inulin and 24-hour ambulatory CL_{cr} was 0.71. For the five calculated clearances, CG and the Mawer⁸⁸ method correlated the best with inulin clearance. The CG method showed a linear relationship with CL inulin equal to 1.121 of CL_{cr} plus 20.6 mL/min ($r = 0.81$), whereas for Mawer the relationship was CL inulin equal to 1.051 of CL_{cr} plus 18.3 mL/min ($r = 0.81$). The calculated CL_{cr} values from CG and Mawer both appeared to correlate well with the ambulatory and 4-hour CL_{cr} , but the regressions were not reported. Based on their findings, Luke and associates⁸⁷ propose continued use of the CG or Mawer method for rapid estimation of CL_{cr} in patients with stable kidney function. The other methods, of Jelliffe^{89,90} and of Hull and colleagues,⁹¹ consistently underestimated the CL_{cr} . As kidney function declined, there was an increase in the fraction of creatinine eliminated by secretion as measured by the $CL_{cr}:CL$ inulin ratio, consistent with earlier reports. This limitation should be taken into consideration when attempting to use CL_{cr} for the estimation of renal function and the individualization of drug dosage regimens. Gault and coworkers⁹² also evaluated the performance of the CG estimator of renal function compared with inulin and ^{99m}Tc -DTPA. Except for conditions of unstable kidney function, it performed similarly to the 24-hour creatinine clearance method.

| Hull et al ⁹¹ | Men: $CL_{cr} = [(145 - \text{age}) / S_{cr}] - 3$ Women: $CL_{cr} \times 0.85$ |
| Levey et al (MDRD) ⁷² | $GFR = 170 \times (S_{cr})^{-0.999} \times [\text{age}]^{-0.176} \times$ $[0.762 \text{ if patient is female}] \times [1.180 \text{ if}$ $\text{patient is black}] \times [\text{SUN}]^{-0.170} \times [\text{Alb}]^{0.318}$ |
| Levey et al (MDRD) ²⁴ | $GFR = 186 \times (S_{cr})^{-1.154} \times (\text{Age})^{-0.203} \times$ $(0.742 \text{ if patient is female}) \times (1.210 \text{ if}$ $\text{patient is black})$ |

Alb, serum albumin concentration (g/dL); CL_{cr} , creatinine clearance in mL/min; IBW, ideal body weight (kg); S_{cr} , serum or plasma creatinine (mg/dL); SUN, serum urea nitrogen concentration (mg/dL).

Patients undergoing screening for participation in the African-American Study of Kidney Disease and Hypertension were evaluated for kidney function based on an estimated CL_{cr} compared with the simultaneous CL_{cr} and ^{125}I -iothalamate, and 24-hour CL_{cr} .⁹³ The simultaneous CL_{cr} provided the best estimate of GFR. The CG method was the preferred method for estimation of GFR, based on performance and ease of use. This method was noted to underestimate the GFR by 9%, perhaps because of the increased excretion rate of creatinine by black patients.^{93,94}

Administration of cimetidine has also resulted in improved performance of CG to predict GFR. Ixkes and associates⁹⁵ gave patients three 800-mg doses of cimetidine in 24 hours, and measured creatinine plasma levels from 3 to 7 hours following the final dose. During this 4-hour period, the CL iothalamate was used to measure the GFR. The CG calculations were performed with the plasma creatinine measurement 3 hours after the last dose of cimetidine. The ratio of the CG-estimated CL_{cr} :CL iothalamate decreased from 1.28 ± 0.21 to 0.98 ± 0.11 in the presence of cimetidine.

SPECIAL POPULATIONS

Assessment of Renal Function In Liver Disease

CL_{cr} estimation in patients with liver disease is problematic. Orlando and coworkers⁹⁶ evaluated 10 healthy subjects, 10 patients with mild liver disease, and 10 with severe liver disease, and observed a measured CL_{cr} :CL inulin ratio of 1.05, 1.03, and 1.04 for each group, respectively. However, when the CL_{cr} of patients with severe liver disease was estimated using the CG equation the resultant ratio (CL_{cr} using CG:CL inulin) was 1.23. Lam and associates⁹⁷ likewise noted an overprediction by CG of the measured CL_{cr} in patients with severe disease, by 40% to 100%.

Studies of renal function in patients with severe hepatic disease and concomitant renal disease confirm the earlier observations of Hull and colleagues⁹¹ and Caregato and associates,⁹⁸ who reported that measured CL_{cr} overestimated GFR by 50% in patients with hepatic disease, likely due to increased tubular secretion of creatinine. DeSanto and coworkers⁹⁹ studied 19 patients with mild liver disease whose inulin and creatinine clearances were 90 ± 4.4 and 122 ± 7 mL/min per 1.73 m^2 , respectively. The degree of overestimation of GFR by creatinine clearance was inversely correlated with GFR ($r = 0.452$; $p < .04$). Thus measurement of renal function in patients with hepatic disease should be performed by using a method that is specific for glomerular filtration, not creatinine clearance.

Other Special Populations

Davis and Chandler¹⁰⁰ confirmed the accuracy of the CG equation to predict CL_{cr} in trauma patients with stable kidney function, and Thakur and colleagues⁴¹ demonstrated its successful utility in 42 paraplegic subjects. Renal transplant recipients are frequently monitored for renal function, as numerous complications may occur during the life of the allograft. Goerdts and associates¹⁰¹ assessed the bias and precision with which several nomographic methods predicted GFR (iohexol clearance) in 127 transplant patients with stable kidney function. The CG method performed poorly, overestimating iohexol clearance. This is expected, as iohexol clearance provides a true measure of GFR, whereas the CG CL_{cr} estimate is falsely high because of the tubular secretion of creatinine. Schuck and coworkers¹⁰² compared the CG method with CL sinistrin, an accurate measure of GFR. The clearance of sinistrin was significantly overestimated by the CG method. These investigators noted significant variability in CG estimates of GFR and concluded that it was an unreliable predictor of

GFR in this patient population. Huang and associates¹⁰³ reported the inability of several CL_{cr} equations to predict renal function in hospitalized patients with advanced human immunodeficiency virus disease. All methods, including CG, Jelliffe, and Mawer, overestimated the measured 24-hour CL_{cr} . The reasons for the poor predictability of these methods is unclear, although 24-hour collection methods often yield highly variable results because of inadequate urine collection.

Renal function assessment during pregnancy is usually performed using a 24-hour creatinine clearance determination. Quadri and colleagues¹⁰⁴ evaluated the CG method during each trimester in 34 pregnant women and compared these estimates with the measured 24-hour CL_{cr} . Prepregnancy weights were used throughout the study for the CG method, and results correlated well with those for the measured clearance ($r^2 = 0.76$). The maximal CL_{cr} occurred during the second trimester for both methods.

Unstable Renal Function

Patients with unstable kidney function present a unique situation because serum creatinine values are changing, and steady state cannot be assumed when estimating CL_{cr} . It can take several days for serum creatinine values to reach steady state in early acute renal failure, but this time can be reduced when renal function is improving. In patients with previously normal renal function, a change in the serum creatinine concentration of more than 50% over a period of 1 day is suggestive of unstable renal function. In patients with preexisting CKD ($S_{cr} > 2$ mg/dL), an increase in serum creatinine of more than 1.0 mg/dL over a 24- to 48-hour period indicates the presence of acute renal failure. Table 41–6 lists several equations that are commonly used to estimate CL_{cr} in patients with acute renal failure.^{105–107} However, a rigorous evaluation of the accuracy and precision of each of these proposed methods is lacking, in part due to the absence of measured creatinine clearance and inability to accurately measure GFR in the acute care setting. The equation proposed by Jelliffe is a revised dynamic model of creatinine kinetics based on theoretical estimates of creatinine production and adjusted for age and changes in serum creatinine. However, its ability to predict changes in drug clearance (and dose adjustments) has not been evaluated. In the acute setting, factors previously discussed that may alter the serum creatinine concentration must be evaluated to avoid misinterpretation. It is ultimately most important to recognize that renal function in patients with acute renal failure is generally markedly lower than one would estimate using steady-state methods.

CLINICAL CONTROVERSY

Serum creatinine values can fluctuate widely in patients with unstable renal function. Although some practitioners advocate use of the Cockcroft-Gault equation using the highest of the two serum creatinine values, most recommend calculation of CL_{cr} using either the Brater or Jelliffe equations.

Inappropriate use of the Cockcroft-Gault equation can significantly overestimate the value of CL_{cr} when compared to equations that are designed to account for changes in serum creatinine in patients with unstable renal function. Table 41–7 illustrates the variability in the CL_{cr} values when three different equations are used to estimate CL_{cr} in patients with decreasing or improving renal function.

Kidney Function in Children

Kidney function in the neonate is difficult to assess because of difficulty in urine and blood collection, the frequent presence of a

TABLE 41–7. Estimation of Creatinine Clearance in Patients with Acute Renal Failure

A patient with worsening renal function:

JR is a 50-year-old male (70 kg, BSA 1.73m²), admitted to the ICU following an automobile accident. His renal function was normal prior to admission; however, his serum creatinine has increased from 0.6 mg/dL to 3 mg/dL in the past 24 hours.

| Authors | CL _{Cr} | Assumptions |
|----------------------------------|------------------------------------|---|
| 1. Jelliffe ¹⁰⁵ | 21.9 mL/min per 1.73m ² | E ^{SS} = 1341.2 mg/day E _{Corr} ^{SS} = 1241 mg/day S _{Cr} = 1.8 mg/dL S _{Cr1} = 0.6 mg/dL S _{Cr2} = 3 mg/dL Δt = 1 day Wt = 70 kg |
| 2. Brater ¹⁰⁷ | 19.1 mL/min | S _{Cr1} = 0.6 mg/dL S _{Cr2} = 3 mg/dL Δt = 1 day Wt = 70 kg |
| 3. Cockcroft-Gault ⁸⁰ | 29.2 mL/min | S _{Cr} = 3 mg/dL Wt = 70 kg |

A patient with improving renal function:

JR has been in the ICU for 1 week, and his status is improving. His serum creatinine has decreased from 3.0 mg/dL to 1.0 mg/dL in the past 24 hours.

| Authors | CL _{Cr} | Assumptions |
|----------------------------------|------------------------------------|---|
| 1. Jelliffe ¹⁰⁵ | 64.5 mL/min per 1.73m ² | E ^{SS} = 1341.2 mg/day E _{Corr} ^{SS} = 1297.7 mg/day S _{Cr} = 2 mg/dL S _{Cr1} = 3 mg/dL S _{Cr2} = 1 mg/dL Δt = 1 day Wt = 70 kg |
| 2. Brater ¹⁰⁷ | 78.7 mL/min | S _{Cr1} = 3 mg/dL S _{Cr2} = 1 mg/dL Δt = 1 day |
| 3. Cockcroft-Gault ⁸⁰ | 87.5 mL/min | S _{Cr} = 1 mg/dL Wt = 70 kg |

non-steady-state serum creatinine, and disparity between development of glomerular and tubular function. Preterm infants demonstrate significantly reduced GFR prior to 34 weeks, which rapidly increases and becomes similar to that of term infants within the first week of life.¹⁰⁸ Evaluation of GFR in preterm infants on day 3 of life, using an inulin infusion, failed to identify a relationship between patient weight and GFR. However, gestational age, which ranged from 23.4 to 36.9 weeks (mean 30.2 weeks), correlated with both GFR and the reciprocal of serum creatinine. The inulin clearance increased from 0.67 to 0.85 mL/min in those with gestational age <28 weeks versus those of 32 to 37 weeks of age, while S_{cr} decreased from 1.05 to 0.73 mg/dL, respectively. Creatinine was measured using a specific enzymatic method to avoid interference from bilirubin or drugs.¹⁰⁹ Creatinine clearance has also been evaluated in infants less than 1 week of age, and values of 17.8 mL/min per 1.73 m² on day 1 increased to 36.4 mL/min per 1.73 m² by day 6.¹¹⁰ In light of these rapid changes in GFR, estimation of GFR is not recommended for infants less than 1 week of age. Kidney function expressed as GFR standardized to body surface area increases with age and stabilizes at approximately 1 year. In older children, GFR is best assessed using standard measurement techniques for GFR. Subcutaneous administration of ¹²⁵I-iothalamate has been effectively used to measure GFR in children ranging in age from 1 to 20 years.¹¹¹

Estimation of CL_{cr} as described by Schwartz and colleagues¹¹² is dependent on the child's age and length:

$$GFR = [\text{length (cm)} \times k] / S_{cr}$$

where k is defined by age group: infant (1 to 52 weeks) = 0.45; child (1 to 13 years) = 0.55; adolescent male = 0.7; and adolescent female = 0.55.

Subsequent studies verified these relationships in children with normal renal function or mild renal impairment. However, variability increases at clearance values <50 mL/min. Al-Harbi and Lireman¹¹³ reported a good correlation of the predicted CL_{cr} with measured 4-hour CL_{cr} and ^{99m}Tc-DTPA ($r = 0.75$) in 48 pediatric renal allograft recipients aged 3 to 19 years. However, predictive performance measures of bias and precision were not reported. Fong and associates¹¹⁴ evaluated the method in critically ill children (mean age 5.6 years; range 0.1 to 20.8 years), and concluded that the method significantly overestimated the measured CL_{cr} (bias = 45%). Pierrat and colleagues recently compared the MDRD, Schwartz, and CG equations in children aged 3 to 19 years. In children <12 years, the Schwartz and MDRD equations were significantly more biased than CG, and CG provided the best prediction of GFR in children >12 years of age.¹¹⁵ Dose adjustments and other therapeutic decisions based on kidney function warrant appropriate measures of renal status to avoid incorrect decisions. The results of these investigations suggest that further studies will be needed to clarify the value of these predictive methods.

Kidney Function in the Elderly

Cross-sectional studies demonstrate decreased GFR as a function of age when GFR is measured as inulin, iothalamate, or creatinine clearance.^{80,116} The Baltimore Longitudinal Study on Aging,¹¹⁷ an evaluation of 254 normal healthy subjects, revealed that creatinine clearance decreases at the rate of approximately 0.75 mL/min per 1.73 m² per year beginning at the fourth decade of life. These subjects were evaluated prospectively for up to 23 years. Interestingly, approximately one-third of the subjects showed no change in renal function from their baseline value, and a small number showed an increased clearance. These changes may be due to normal physio-

logic changes or to subclinical insults to the kidneys that initiate the events leading to chronic progressive loss of renal function. Fliser and coworkers¹¹⁸ studied renal functional reserve in healthy young (23 to 32 years) and elderly (61 to 82 years) volunteers using an amino acid infusion technique. Inulin clearance was used as the measure of GFR, which increased 16% in young and 17% in elderly subjects following the infusion. Renal functional reserve thus appears to be maintained in healthy elderly individuals.

Interpretation of the serum creatinine concentration alone is difficult in the elderly patient because of the decreased muscle mass and resultant lower production rate of creatinine. Thus the serum creatinine often remains within the normal range despite a reduction in the number of functional nephrons. As renal function declines, the kidneys excrete a larger fraction of creatinine. This perpetuates the "normal" serum creatinine. The CG formula⁸⁰ can be used to estimate the CL_{cr} of elderly patients. Smythe and associates¹¹⁹ estimated CL_{cr} in 23 patients >60 years of age using seven different methods, and compared the results to a measured 24-hour CL_{cr} determination. Estimations were performed with the actual serum creatinine concentration and also with the serum creatinine rounded up to 1.0 mg/dL if the actual value was <1 mg/dL. Rounding the serum creatinine to 1 mg/dL resulted in a significantly lower (bias = 28.8 mL/min) estimate of GFR, as compared with the actual clearance, than when the unadjusted serum creatinine (bias = 2.3 mL/min) was used. These data strongly suggest that one should not arbitrarily fix the serum creatinine concentration in elderly patients at 1 mg/dL. An alternative to the estimation of GFR or a 24-hour clearance determination is a 4-hour clearance performed during water diuresis.⁷⁹ This correlated with the inulin clearance as well as an inpatient 24-hour CL_{cr} . However, one must be aware of the potential risk of hyponatremia in the geriatric patient who is unable to tolerate an oral water load, as well as the need for complete bladder emptying to ensure accurate results. O'Connell and associates¹²⁰ assessed the accuracy of 2- and 8-hour urine collections compared with 24-hour creatinine clearance determinations in 45 hospitalized patients >65 years old with indwelling urethral catheters. Single, timed urine collections for CL_{cr} showed minimal bias with the 8-hour collection as compared with the 24-hour value, whereas the 2-hour determination was both biased and imprecise. Unfortunately, the amount of residual urine was not determined, the bladder was not rinsed at each collection period, and the mean urine flow was low at 1.23 mL/min; all of these factors may have negatively affected the results of the 2-hour collection.

ASSESSMENT OF PROGRESSION

8 Chronic kidney disease (see Chap. 43) will eventually lead to ESKD (see Chap. 44), necessitating dialysis or transplantation for survival (see Chaps. 45 and 87). The rate of progression can be slowed and in some cases halted through dietary modification and blood pressure control, angiotensin-converting enzyme (ACE) inhibitor or angiotensin receptor blocker therapy, and improved glucose control in patients with type I diabetes mellitus (see Chap. 43). The efficacy of these interventions is optimally assessed with serial measurements of accurate and sensitive indices of GFR such as iothalamate, or radioisotope clearances.¹²¹

Alternatively, use of newer methods to estimate GFR, such as the MDRD equation, or the linear decline in the reciprocal of the serum creatinine concentration as a function of time, are simple clinical tools that can be used to evaluate the rate of progression of renal disease, and to predict the time when dialysis will be needed.³³ Under

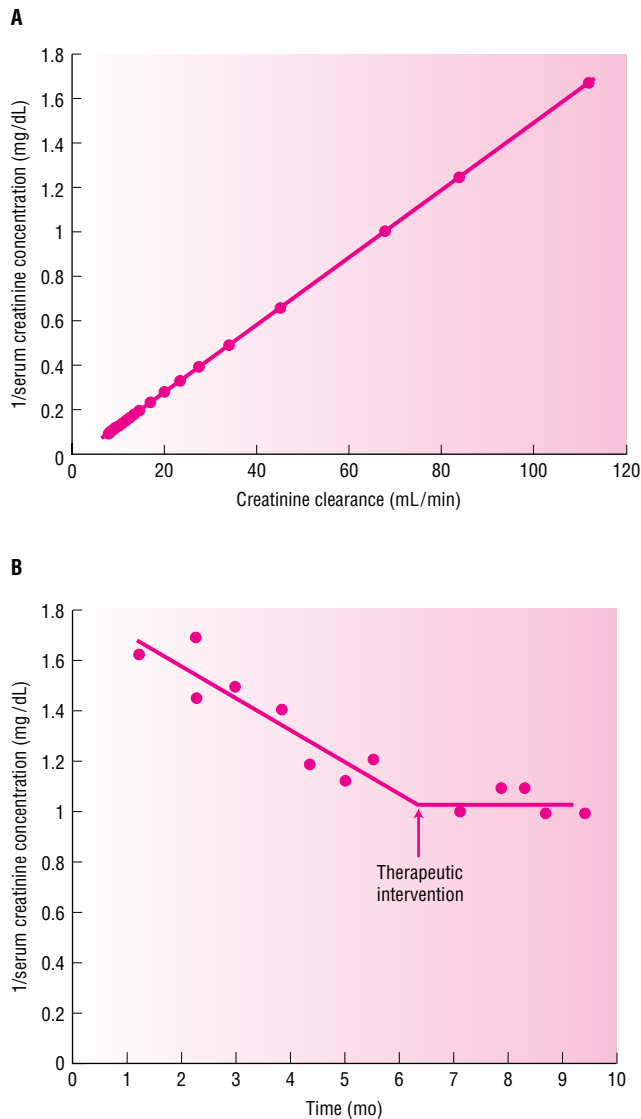

FIGURE 41-3. Linear relationship between 1/serum creatinine concentration and creatinine clearance (A) and 1/serum creatinine concentration as a function of time in a hypothetical patient with progressive renal impairment (B). The arrow indicates a change in the rate of progression, which may be related to a therapeutic intervention.

steady-state conditions, the formation rate of creatinine equals the elimination rate (R), and CL_{cr} is inversely related to S_{cr} as:

$$S_{cr} = R/CL_{cr}$$

The reciprocal relationship between S_{cr} and CL_{cr} is then expressed as:

$$1/S_{cr} = 1/R \times CL_{cr}$$

9 As renal function declines, the reciprocal of the serum creatinine concentration decreases as a linear function of the CL_{cr} , and the slope of the relationship is the reciprocal of the elimination rate of creatinine (Fig. 41-3A). Clinicians can use the reciprocal serum creatinine plotted as a function of time as a prognostic tool to predict when dialysis may be needed (when $1/S_{cr} \sim 0.1$), or as a marker for evaluating the success of therapeutic interventions to alter the rate of decline in renal function (Fig. 41-3B). Several factors, such as changes in

dietary intake of creatinine and decreased muscle mass, which are associated with a reduction in the production of creatinine, may alter the utility of the relationship. Furthermore, if tubular secretion increases in response to nephron hypertrophy disproportionately to filtration, or if nonrenal routes of elimination of creatinine such as metabolism by intestinal bacteria become more important, then changes in the slope of the reciprocal creatinine versus time relationship may be altered. It is most important to be aware of the limitations of serum creatinine measurement and to realize that it is not an adequate test to detect early chronic renal disease or to precisely estimate the rate of progression.

Although not a quantitative measure of renal function, urinary microalbuminuria has been identified as an early marker of renal disease in patients with diabetic nephropathy¹²² and numerous other conditions, such as hypertension and obesity.^{15,123,124} Patients with microalbuminuria (30 to 300 mg/day) on at least two occasions or overt albuminuria (>300 mg/day) should begin to receive pharmacotherapy. For children, microalbuminuria is considered present if albumin excretion exceeds 0.36 mg/kg per day, and overt albuminuria has been defined as an excretion rate that exceeds 4 mg/kg per day. The urinary albumin:creatinine ratio is also an accurate predictor of 24-hour proteinuria, a marker of renal disease. Guidelines for monitoring indicate that a urine albumin:creatinine ratio of >30 mg/g places the patient at increased risk of developing diabetic nephropathy and is an indication for the initiation of pharmacotherapeutic intervention.³⁰ Microalbuminuria has also been suggested as a risk factor for renal dysfunction among patients with essential hypertension.¹²⁵

MEASUREMENT OF RENAL PLASMA AND BLOOD FLOW

Measurement of renal plasma and blood flow is usually reserved for research settings to evaluate hemodynamic changes related to disease or drug therapy. The kidneys receive approximately 20% of cardiac output and representative values of renal blood flow in men and women of about 1200 ± 250 and 1000 ± 180 mL/min per 1.73 m^2 have been reported.¹²⁶ Renal plasma flow (RPF) can be estimated to be 60% of renal blood flow if it is assumed that the average hematocrit is 40%.

PAH is an organic anion that has been used extensively for the quantitation of renal plasma flow. PAH is approximately 17% bound to plasma proteins and is eliminated extensively by active tubular secretion. Because PAH elimination is active, saturation of the transport processes have historically been anticipated, at concentrations of PAH in plasma above 10 to 20 mg/L.⁴⁴ Recently, Dowling and associates¹²⁷ used a sequential infusion technique and only observed concentration-dependent renal clearance of PAH at concentrations above 100 mg/dL. Furthermore, PAH is also metabolized, possibly within the kidney, to *N*-acetyl-PAH, and the analytical method must be able to differentiate the parent compound from the metabolite if one desires to obtain an accurate assessment of RPF.⁶³ Prescott and coworkers¹²⁸ noted that the renal clearance of PAH alone decreases at low plasma concentrations, while the clearance of the acetyl metabolite increases. Further studies are necessary to evaluate the mechanisms and significance of these findings. The extraction ratio (ER) for PAH is 70% to 90% at plasma concentrations of 10 to 20 mg/L, hence the term “effective” renal plasma flow (ERPF) has been used when the clearance of PAH is not corrected for the extraction ratio or if it is assumed to be 1.² Normal values for ERPF are about 650 ± 160 mL/min for men and 600 ± 150 mL/min for women.¹²⁶ Children will reach normalized adult values by 3 years of age, and ERPF will begin to decline as a function of age after 30 years, reaching

about one-half of its peak value by 90 years of age. The method for calculation of ERPF is based on the relationship between organ clearance, ER, and flow:

$$\text{ERPF} = \text{renal PAH CL} = \text{RPF} \times \text{ER}$$

Effective renal blood flow (ERBF) can be estimated from ERPF by assuming the extraction ratio is 1 and correcting for the red blood cell volume of the blood (Hct, hematocrit):

$$\text{ERBF} = \text{ERPF}/(1 - \text{Hct})$$

ERPF can also be measured using the radioisotopes ^{131}I -orthoiodohippurate or $^{99\text{m}}\text{Tc}$ -mercaptoacetyltriglycine.¹²⁹ One important advantage of this method is its ability to measure ERPF in total or for each kidney independently, as well as its ability to produce renal images. Russell and Dubovsky,¹³⁰ using a single-injection technique, compared clearance methods with and without urine collection and showed similar results with each method.

QUANTITATIVE AND SEMIQUANTITATIVE ASSESSMENT OF TUBULAR FUNCTION

Although GFR is perhaps the best overall indicator of renal function, it may not be reflective of tubular function; either secretory capacity or cellular function.¹³¹ Tubular secretory function can be assessed by measuring PAH transport as the prototype marker of the organic anion secretory system. *N*-1-Methylnicotinamide (NMN) and tetraethylammonium (TEA) are prototype compounds secreted by the cationic transport system and may be used as markers of cationic secretory capacity.^{2,132} Studies with NMN suggested its use to assess the effects of selected renal diseases on drug handling by the kidneys.¹³³ Dowling and colleagues¹²⁷ explored the utility of famotidine as a marker for cationic transport, but were unable to demonstrate saturation, perhaps due to contribution from other secretory pathways such as p-glycoprotein. It should be recognized that these transport systems are not necessarily mutually exclusive. Indeed, probenecid, which is secreted by the anionic pathway, inhibits the secretion of cationic compounds. Quantitative measures of tubular transport capacity are currently limited primarily to the research setting.

Other measures of tubular function are less specific and are regarded primarily as indices of damage within the nephron.¹³⁴ Schentag and Plaut¹³¹ demonstrated a delay in the increase of serum creatinine following aminoglycoside toxicity when compared to markers for tubular damage such as the low-molecular-weight protein β_2 -microglobulin (11.8 kDa) and urinary enzymes. The rise in β_2 -microglobulin is related to an early functional defect in the proximal tubular cell. This is followed by a rise in the excretion of enzymes released as a result of structural damage to the cells, and finally, by the formation and excretion of cellular casts. Other low-molecular-weight proteins used as markers of tubular function include retinol-binding protein (21 kDa) and protein HC (also known as α_1 -microglobulin, 27 kDa).¹³⁴ These proteins are normally freely filtered at the glomerulus and then completely reabsorbed by the proximal tubule. Increases in their excretion are thus suggestive of tubular dysfunction but are not diagnostic, as an increased production rate or GFR of less than 30 mL/min may lead to increased excretion. In both cases, the maximal reabsorptive capacity may be exceeded, leading to net excretion of the protein. Retinol-binding protein and protein HC are elevated with tubular damage and may be more appropriate markers than β_2 -microglobulin.

Numerous urinary enzymes such as *N*-acetylglucosaminidase (NAG), alanine aminopeptidase (AAP), alkaline phosphatase (AP),

γ -glutamyltransferase (GGT), pyruvate kinase, glutathione transferase, lysozyme, and pancreatic ribonuclease have been used as diagnostic markers for renal disease. Jung and associates¹³⁵ compared the ability of five enzymes (NAG, AAP, AP, GGT, and lysozyme) to detect early rejection episodes in kidney transplant patients. Only NAG and AAP were early predictors of rejection. NAG is an enzyme contained within the lysosome of the tubular cell and is released when the lysosome is damaged, whereas AAP is an enzyme of the brush border. Both markers were increased approximately 2 days earlier than serum creatinine in patients with transplant rejection.

QUALITATIVE DIAGNOSTIC PROCEDURES

RADIOLOGIC STUDIES

Further evaluation of the etiology of kidney disease can be accomplished using several qualitative diagnostic techniques, including radiography, ultrasound, magnetic resonance imaging (MRI), and biopsy. The standard x-ray of the kidneys, ureters, and bladder (KUB) is useful for a gross estimate of kidney size and to detect the presence of calcifications.⁶⁹ Although an easy test to perform, the useful information achieved is minimal, and more detailed evaluations are often necessary. The intravenous urogram (IVU; formerly known as intravenous pyelogram, or IVP) involves the use of a contrast agent to facilitate visualization of the urinary collecting system. It is primarily used in the assessment of structural changes that may be associated with nonglomerular hematuria, pyuria, or flank pain, resulting from recurrent urinary tract infections, obstruction, or stone formation.⁶⁹ For patients with insufficient renal filtration, retrograde administration of dye into the ureters may be performed to facilitate visualization of the collecting system. Furthermore, local administration may avoid systemic exposure and associated adverse reactions (see Chap. 46). Contrast agents are also employed during renal angiography for the assessment of renovascular disease. As a test for the diagnosis of renovascular hypertension, the captopril (ACE inhibitor) test is a useful adjunct. Under conditions of unilateral renal artery stenosis, the affected kidney produces large quantities of angiotensin II, which vasoconstricts the efferent arteriole to maintain GFR. The administration of an ACE inhibitor results in reduced uptake of the contrast agent because perfusion of the affected kidney decreases. This occurs as a result of decreased efferent arteriolar vasoconstriction. For patients with bilateral disease, a decrease in uptake is observed in both kidneys.¹³⁶ Computed tomography (CT) is a cross-sectional anatomic imaging procedure based on x-ray data. The procedure is frequently performed with contrast to enhance imaging. Spiral, or helical, CT, a more recent technique, provides visual three-dimensional reconstruction of tissues. CT is performed as a test for the evaluation of obstructive uropathy, malignancy, and infections of the kidney.

RENAL ULTRASOUND

Ultrasound uses sound waves to generate a two-dimensional image. The echogenicity of the kidney is compared with that of an adjacent organ—liver on the right and spleen on the left—with an increased echogenicity indicating an abnormal finding. Ultrasonography can distinguish the renal pyramids, medulla, and cortex, and abnormalities in structure, such as occurs with obstruction. Renal ultrasound is also used as a guide for site localization during percutaneous kidney biopsy.

MAGNETIC RESONANCE IMAGING

The MRI is based on aligning hydrogen nuclei in the body with the use of a powerful magnet and applying radiofrequency pulses. The signals emitted by the hydrogen nuclei during realignment on repeated pulses allows for generation of the tissue image. Realignment times can also be altered with the use of contrast agents (e.g., gadolinium or gadopentetate), leading to increased signal intensity and improved imaging. MRI is useful for the assessment of obstruction, malignancy, and renovascular lesions. The relative advantages and limitations of these procedures are discussed in more detail in several recent reviews.^{69,137,138}

BIOPSY

Renal biopsy is used in several conditions to facilitate diagnosis when clinical, laboratory, and imaging findings prove inconclusive. Proteinuria and hematuria are both associated with renal parenchymal disease. When less-invasive studies are unsuccessful in differentiating the cause and the possible causes have different therapeutic approaches, biopsy may be indicated. Functional status of the kidney is not assessed with biopsy, and severity of disease and progression is best measured using the quantitative tests discussed above. Contraindications to renal biopsy include a solitary kidney, severe hypertension, bleeding disorder, severe anemia, cystic kidney, and hydronephrosis, among others. Complications resulting from biopsy primarily include hematuria, which may last for several days, and perirenal hematoma.²⁵

CONCLUSION

The prevalence of kidney disease has increased dramatically over the past decade, indicating a need for early classification and monitoring of renal function in CKD patients. Renal function can be evaluated in clinical settings using estimated or measured creatinine clearance, estimated GFR, and measurement of urinary protein excretion. Accurate measurement of GFR using exogenous administration of inulin, iothalamate, or radioisotope techniques such as ^{99m}Tc-DTPA is required in research settings to assess drug therapy outcomes and progression of disease. Use of qualitative assessments of renal function, such as x-ray, CT, MRI, sonography, and biopsy, can help to determine the underlying cause of kidney disease. The clinical pharmacist can have an important role in the care of CKD patients, including renal function assessment, dose individualization, drug therapy monitoring, and evaluation of therapeutic outcomes.

ABBREVIATIONS

AAP: alanine aminopeptidase
 ABW: actual body weight
 ACE: angiotensin-converting enzyme
 Alb: serum albumin concentration
 AP: alkaline phosphatase
 CG: Cockcroft-Gault (method of calculating CL_{cr})
 CKD: chronic kidney disease
 CL: clearance
 CL_{cr}: creatinine clearance
 DTPA: diethylenetriamine pentaacetic acid
 EDTA: ethylenediaminetetraacetic acid
 EPO: erythropoietin

ER: extraction ratio
 ERBF: effective renal blood flow
 ERPF: effective renal plasma flow
 ESRD: end-stage renal disease
 GFR: glomerular filtration rate
 GGT: γ -glutamyltransferase
 HPLC: high-performance liquid chromatography
 IBW: ideal body weight
 IVU: intravenous urogram
 KUB: kidneys, ureters, and bladder (radiograph)
 MDRD: Modification of Diet in Renal Disease (study)
 MRP: multidrug resistance protein
 NAG: *N*-acetylglucosaminidase
 NKF K/DOQI: National Kidney Foundation Kidney Disease Outcomes Quality Initiative
 NMN: *N*-1-methylnicotinamide
 PAH: *p*-aminohippurate
 P_{cr}: creatinine production rate
 PL_{cr}: plasma creatinine level
 P-gp: P-glycoprotein
 RBF: renal blood flow
 RPF: renal plasma flow
 S_{cr}: serum creatinine concentration
 SNGFR: single nephron glomerular filtration rate
 SUN: serum urea nitrogen (concentration)
 TEA: tetraethylammonium

ACUTE RENAL FAILURE

Bruce A. Mueller

Learning Objectives and other resources can be found at www.pharmacotherapyonline.com.

KEY CONCEPTS

- 1 Identify acute renal failure (ARF) early and eliminate its cause to avoid the spread of damage.
- 2 Prevention is key; little can be done for established acute renal failure.
- 3 In situations in which development of ARF is likely, patients should receive therapy to prevent occurrence or reduce its severity. These situations include: diabetes mellitus, chronic kidney disease, the elderly, radiocontrast dye administration, and ICU patients. Some preventive therapies include: glucose control, sodium loading, and use of L-carnitine.
- 4 Avoid nephrotoxins as much as possible.
- 5 Once the cause of ARF is identified and is eliminated, supportive therapy is the only remaining option, as we cannot hasten recovery of established ARF. Supportive therapies include: renal replacement therapies, nutritional support, avoidance of nephrotoxins, and aggressive fluid management.

The development of acute renal failure (ARF) presents a difficult challenge to the clinician. It has widely varying causes, and unlike other cases of organ failure such as neurologic or cardiovascular failure, the onset of ARF is often silent. In the ambulatory setting, patients may not notice ARF symptoms for days or weeks. Clinical and laboratory markers of its presence can be subtle and are often overlooked. Despite its often insidious presentation, ARF can be one of the most serious consequences that can occur, especially in a hospitalized patient.

Renal replacement therapies (RRTs) like hemodialysis, peritoneal dialysis, and other related treatments have been available for decades, but have not resulted in dramatic improvements in patient outcomes. RRT can help patient management by normalizing blood electrolyte values, augmenting waste product removal, and maintaining fluid balance. Despite the supportive care that RRT offers, development of ARF is frequently a catastrophic event.

DEFINITION OF ARF

A unifying definition of ARF does not exist. Clinicians disagree about when to make the diagnosis and published epidemiologic studies use different definitions in nearly every study.¹ Nonetheless, most use some combination of absolute serum creatinine value and a change in serum creatinine value or daily urine output as criteria for making the diagnosis.^{2,3} In general, these studies typically view ARF as being a condition in which a previously normal serum creatinine rises by 0.5 mg/dL, or an absolute increase in serum creatinine of >1 mg/dL in a patient with previous chronic kidney disease (CKD). Clinicians must recognize that serum creatinine, while simple to measure, is not a very sensitive laboratory test. For example, a patient with an acute event that reduces the glomerular filtration rate (GFR) to zero will have no immediate change in serum creatinine. Depending on the creatinine generation rate and fluid status of the patient,

it may take days before serum creatinine values meet the threshold of a rise of 0.5 mg/dL. This may delay recognizing that ARF has occurred.⁴

ARF CLASSIFICATION

In the clinical setting, ARF is classified in a variety of ways. Classifying ARF by daily urine output can be useful. Anuria is defined as a urine output of <50 mL/d, oliguria is when the daily urine output is 50 to 450 mL/d, and nonoliguria occurs when the patient can make >450 mL of urine per day. This simplistic approach actually is quite useful in determining prognosis. Hospitalized anuric or oliguric patients have significantly higher mortality rates than similar ARF patients with nonoliguria.⁵ Surviving oliguric ARF patients are also less likely to ever fully recover their renal function compared to nonoliguric patients.⁶ Clinically, the nonoliguric patient is easier to manage than the oliguric patient because of reduced concerns about fluid overload. Consequently, knowledge of something as simple as the amount of urine produced per day can yield important information for the clinician.

EPIDEMIOLOGY

ARF is a common condition in the general population, with an annual incidence of approximately 200 cases per million population per year.² The incidence rate is higher in hospitalized patients, 5% of whom may require RRT (Table 42-1).⁷ The highest incidence of ARF is in hospitalized patients in the intensive care unit. Depending on the definition used, ARF develops in 2% to 25% of patients in intensive care units.⁸⁻¹⁰

TABLE 42–1. Incidence and Outcomes of Acute Renal Failure (ARF) Relative to Where It Occurs

| | Community-Acquired | Hospital-Acquired | ICU-Acquired |
|-----------------------|--|--|---|
| Incidence | Low (<1%) | Moderate (2–5%) | High (6–23%) |
| Cause | Single | Single or multiple | Multifactorial |
| Overall survival rate | 70–95% | 30–50% | 10–30% |
| Worsened outcome if: | RRT required Poor preadmission health Other failed organ systems | RRT required Poor preadmission health Ischemic ARF cause Other failed organ systems | Intrinsic renal disease Ischemic cause Septic RRT required Poor preadmission health Other failed organ systems |
| Better outcome if: | Nonoliguric | Nonoliguric Nephrotoxic cause | Prerenal cause Postrenal cause Nonoliguric Nephrotoxic cause Hyperglycemia prevented |

Many patient-specific factors cause a predisposition to the development of ARF. In nonhospitalized patients, ARF is often drug-induced. Common causes of drug-induced ARF include nonprescription nonsteroidal anti-inflammatory drugs (NSAIDs), prompting the FDA to convene an advisory committee to re-examine labeling of these products.¹¹ This drug class alone may be responsible for 500,000 to 2,500,000 cases of nephrotoxicity in the United States per year.¹² More information on drug-induced ARF can be found in Chap. 46.

Preexisting CKD has been associated with a threefold increased risk of ARF in patients requiring intravenous contrast dye during cardiac catheterization.¹³ In patients without preexisting kidney disease who require cardiac catheterization, the development of ARF leads to similarly lethal results. These ARF patients who require dialysis have a ninefold higher 1-year mortality rate and a threefold higher rate of myocardial infarction than cardiac catheterization patients who do not require dialysis.¹⁴ Indeed, it has been suggested that the most important risk factors for development of ARF are present when the patient is admitted to the hospital.⁸ Many studies have reported that hospitalized patients at risk for development of ARF are more likely to have preexisting renal disease, heart failure, or other organ system failure, infection at admission to the hospital, poor nutritional status, and age >65 years than those not developing ARF.^{8,14–15}

Few factors that clinicians can control are associated with ARF development. However, one of these factors that may be under control of prescribers is that of nephrotoxin exposure to the patient. For example, higher cumulative doses of intravenous contrast dye are directly related to the risk of developing ARF in patients receiving cardiac catheterization.¹⁴ This risk can be ameliorated by avoidance of nephrotoxins in patients at high risk of ARF development, or by dosing unavoidable nephrotoxins like aminoglycosides in ways documented to reduce ARF development.¹⁶ Additionally, clinicians can exert tighter control of serum glucose using insulin, and by doing so can reduce the rate of ARF development.¹⁷

One series reported that 5% of all patients admitted to an intensive care unit will require some RRT due to ARF.¹⁰ The mortality rate for these patients is remarkably higher than ICU patients not requiring RRT, even when severity of illness and other factors are controlled for (63% vs. 15%).¹⁰ The cause for this increase in mortality rates due to ARF does not appear to be solely related to the absence of renal function. Patients admitted to the ICU with CKD have significantly lower mortality rates than patients who are admitted to the ICU with ARF or who develop ARF in the ICU.¹⁸

OUTCOMES

The development of ARF is one of the most serious events that can happen to a hospitalized patient, regardless of the reason for hospitalization. In patients admitted for cardiac surgery, the mortality risk is seven- to eightfold higher if the patient develops ARF.¹⁹ Patients who develop ARF following administration of intravenous radiocontrast dye and requiring dialysis have twice the mortality rate of similar patients receiving radiocontrast dye who do not experience an increase in their serum creatinine values.¹³

The outcome of a patient with ARF predominantly depends on the cause of the condition. In general, higher mortality rates are seen in conditions that result in hypoxia to the kidney causing acute tubular necrosis (ATN; 60%) or cortical necrosis (100%) compared to the lower mortality associated with autoimmune ARF causes like glomerulonephritis (9% to 25%), vasculitis (45%), or interstitial nephritis (13%).² Similarly, postrenal causes like obstructive ARF tend to have lower mortality rates (27%), ostensibly because these obstructions can be surgically repaired before permanent damage can be done to the kidney. Other patient factors influence ARF outcomes. Understandably, those patients with higher severity of illness have higher mortality rates than those who do not.¹⁸ Critically ill patients with ARF due to sepsis have mortality rates that are significantly higher than those of patients who develop ARF for other reasons (74% vs. 45%).²⁰

ETIOLOGY

The classification of ARF into broad categories based on the precipitating factors facilitates the diagnosis and management of patients presenting with this disorder (Table 42–2). Traditionally, the causes of ARF have been categorized into prerenal azotemia (resulting from decreased renal perfusion), acute intrinsic renal failure (resulting from structural damage to the kidney), and postrenal obstruction (obstruction of urine flow from the kidney out of the body). The addition of the category “functional ARF” aids in the understanding of the pathophysiology of ARF. This category is the result of hemodynamic changes at the level of the glomerulus without decreased perfusion of the kidney or structural damage to it.

The cause of ARF strongly influences patient outcome.² Kidneys that are not perfused with blood for prolonged periods will develop

TABLE 42–2. Classification of Acute Renal Failure

| Category | Classification of Acute Renal Failure | Differential Diagnosis |
|---------------------------------------|---|--|
| Prerenal renal failure | Systemic hypoperfusion | Intravascular volume depletion Dehydration Hemorrhage CHF Liver disease Nephrotic syndrome Overdiuresis |
| | Isolated renal hypoperfusion | Bilateral renal artery stenosis (unilateral renal artery stenosis in solitary kidney) Emboli Cholesterol Thrombotic |
| Functional acute renal failure | | Medications Cyclosporine ACEIs NSAIDs Hypercalcemia Hepatorenal syndrome |
| Acute intrinsic renal failure | Vascular | Vasculitis Polyarteritis nodosa Thrombotic thrombocytopenic purpura Hemolytic uremic syndrome Emboli Cholesterol Thrombotic |
| | Glomerular | Systemic lupus erythematosus Poststreptococcal glomerulonephritis Antiglomerular basement membrane disease |
| | Acute tubular necrosis | Ischemic Hypotension Vasoconstriction Exogenous toxins Contrast dye Heavy metals Drugs (amphotericin B, aminoglycosides, etc.) Endogenous toxins Myoglobin Hemoglobin |
| | Acute interstitial nephritis | Drugs Penicillins Ciprofloxacin Sulfonamides Infection Streptococcal |
| Postrenal renal failure (obstruction) | Bladder outlet obstruction | Prostatic hypertrophy Improperly placed bladder catheter Cervical cancer |
| | Ureteral (bilateral or unilateral with solitary functioning kidney) | |
| | Renal pelvis or tubules | Retroperitoneal fibrosis Crystal deposition Oxalate Indinavir Sulfonamides Acyclovir Tumor lysis syndrome |

cortical necrosis and this condition is uniformly fatal. In contrast, ARF due to postrenal causes like obstruction have much lower mortality rates.² Consequently, rapid diagnosis of the etiology of ARF is essential so that renal perfusion can be corrected and other causes of ARF eliminated.

PRERENAL AZOTEMIA

Prerenal ARF results from hypoperfusion of the renal parenchyma, with or without systemic arterial hypotension. Renal hypoperfusion with systemic arterial hypotension may be caused by a decline in

intravascular volume (e.g., hemorrhage or dehydration) or a decline in effective blood volume (i.e., the blood volume perceived by the arterial baroreceptors). Examples of disease states in which there is a decline in effective blood volume without a decrease in intravascular volume include congestive heart failure (CHF) and liver failure. Because the kidney is initially undamaged, the urinalysis will be normal. Eventually, the fractional excretion of sodium will be low, reflecting an increase in the concentrations of the sodium-retentive hormones renin, angiotensin, and aldosterone. Urinary solutes will be concentrated as a result of the increased circulating levels of antidiuretic hormone that is released in response to the diminished arterial blood pressure.

Renal hypoperfusion without systemic hypotension most commonly results from bilateral renal artery occlusion, or unilateral occlusion in a patient with a single functioning kidney. In these conditions, the sodium-retentive hormones are activated by the decline in renal parenchymal perfusion. However, systemic arterial blood pressure is usually elevated, leading to an inhibition of antidiuretic hormone release. Consequently, the urinary indices will reflect enhanced sodium reabsorption (i.e., a low fractional excretion of sodium), but the urinary solutes may not be maximally concentrated.

FUNCTIONAL ACUTE RENAL FAILURE

Functional ARF refers to those entities that result in a decline in glomerular ultrafiltrate production secondary to a reduced glomerular hydrostatic pressure without damage to the kidney itself. The decline in glomerular hydrostatic pressure is a direct consequence of changes in glomerular afferent (vasoconstriction) and efferent (vasodilation) arteriolar circumference. These clinical conditions most commonly occur in individuals who have reduced effective blood volume (e.g., CHF, cirrhosis, severe pulmonary disease, or hypoalbuminemia) or renovascular disease (e.g., renal artery stenosis), and cannot compensate for changes in afferent or efferent arteriolar tone. Examples of disorders that result in afferent arteriolar vasoconstriction (and an increase in afferent arteriolar resistance) include hypercalcemia and the administration of certain medications (e.g., Cyclosporine and NSAIDs). A decrease in efferent arteriolar resistance usually results from the administration of an angiotensin-converting enzyme inhibitor (ACEI) or angiotensin II receptor antagonist. With correction of the underlying pathologic process or discontinuation of the responsible medication, renal function rapidly returns to baseline. The hepatorenal syndrome is included in this classification scheme since the kidney itself is not damaged and there is intense afferent arteriolar vasoconstriction leading to a decline in glomerular filtration. In all the above conditions, the urinalysis is no different from its baseline state and the urinary indices suggest prerenal azotemia.

This syndrome of functional ARF is very common in individuals with CHF who receive an ACEI in an attempt to improve left ventricular function. The decline in efferent arteriolar resistance resulting from the inhibition of angiotensin II occurs rapidly. Therefore, if the dose of the ACEI is increased too rapidly, there will be a decline in glomerular ultrafiltrate production with a concomitant rise in the serum creatinine, leading to functional ARF. If the increase in the serum creatinine is not too severe (usually <1 mg/dL) the medication can be continued. Renal function should gradually improve as renal parenchymal perfusion pressure increases with improvement in left ventricular function.

ACUTE INTRINSIC RENAL FAILURE

Acute intrinsic renal failure results from damage to the kidney itself. Conceptually, acute intrinsic renal failure can best be understood in terms of the structures within the kidney: the small blood vessels,

glomeruli, renal tubules, and interstitium. Renal failure secondary to small vessel vasculitis [e.g., polyarteritis nodosa, hemolytic uremic syndrome (HUS), or malignant hypertension] or cholesterol emboli can present with relatively normal urinary sediment since at least initially, the glomerulus and tubules are not damaged. When renal failure results from small vessel vasculitis, the vasculitic process is rarely confined to the kidney. A careful search for diagnostic clues suggesting other organ system involvement usually provides evidence of the diffuse nature of these disease processes.

Acute glomerular inflammation (acute glomerulonephritis) can result from a variety of precipitating causes (systemic lupus erythematosus and antiglomerular basement membrane disease, among others) (see Chap. 47). In these disorders the urinalysis usually reveals the presence of heavy proteinuria (>3 g urinary protein per 24-hour collection period) and hemoglobinuria. Microscopic analysis of the urinary sediment frequently shows numerous red blood cells (RBCs) and RBC casts, the latter being considered diagnostic for glomerulonephritis. In the early stages of the illness, the fractional excretion of sodium is less than 1 because tubular function is still intact. However, as renal failure becomes more established, the fractional excretion of sodium may increase.

The renal tubules are susceptible to a variety of insults. The tubules contained within the medulla of the kidney are particularly at risk from ischemic injury, as this portion of the kidney is very metabolically active, and thus has a high oxygen requirement. Severe hypotension or the administration of vasoconstricting drugs preferentially affects the tubules more than any other portion of the kidney. In addition, exogenous toxic substances (e.g., contrast agents, heavy metals, and pharmacologic agents such as aminoglycosides, amphotericin B, and foscarnet) and endogenous toxins (e.g., myoglobin, hemoglobin, and uric acid) may cause tubular injury. Once tubular cells die, they slough off into the tubular lumen, forming casts causing increased tubular pressures and reduced glomerular filtration.²¹ Regardless of the etiology, tubular injury leads to a loss of urine concentrating ability, defective distal sodium reabsorption, and a reduction in the GFR. The etiology of acute intrinsic renal failure secondary to tubular injury (referred to as acute tubular necrosis or ischemic ARF) is usually discernible by reviewing the patient's history and medication list. The urinalysis suggests tubular injury by the presence of coarse "dirty brown" casts. RBCs and RBC casts are only rarely seen. The urinary indices suggest intrinsic renal dysfunction (i.e., high fractional excretion of sodium, urine osmolality equal to plasma osmolality, and a low urine creatinine:serum creatinine ratio).

▶ The therapeutic approach for the management of ATN secondary to ischemia of the kidneys is changing. Historically, clinicians viewed ischemic ARF as a one-time event that resulted in tubular death. During this time the patient should be supported until renal function recovers. The new model for ischemic ARF is much like that used in treatment of myocardial infarction and stroke. Now, in addition to an initiation phase, when the patient experiences a hypoxic insult, an extension phase has been hypothesized.²² Similar to what is postulated to occur during a myocardial infarction, in the kidney continued hypoxia after the original ischemic event results in an inflammatory response that further damages the kidney. More renal tubular epithelial cells are damaged and die, particularly in the corticomedullary junction. Cytokine release further increases the inflammation. Renal perfusion becomes less organized, as renal vasodilation and vasoconstriction are not occurring efficiently, and the area of injury grows. All of this occurs in the first 24 hours after the initial insult.²² New therapies will address the development of ATN and stop the extension phase as early as possible by blocking the pathways that cause inflammation after the initial insult.²³

The interstitium of the kidney is also susceptible to injury from a variety of causes. Although acute interstitial nephritis is most commonly caused by medications (see Chap. 46), infections (e.g., streptococcal, leptospirosis, hantavirus, and human immunodeficiency virus), selected autoimmune disorders (systemic lupus erythematosus or mixed connective tissue disease) also may produce a similar syndrome. The presence of white blood cells (WBCs), WBC casts, and coarse granular casts in the urine all suggest interstitial inflammation. The presence of eosinophilia and eosinophiluria also strongly suggest the presence of an interstitial nephritis. Occasionally low to moderate proteinuria can be seen on urinalysis.

POSTRENAL OBSTRUCTION

ARF resulting from obstruction may occur at any level within the urinary system from renal tubule to urethra. However, to cause ARF, the obstructing process must involve both kidneys, or one kidney in a patient with a single functioning kidney. Bladder outlet obstruction is the most common cause of obstructive uropathy. Crystal deposition within the tubules (e.g., secondary to uric acid, oxalate, acyclovir, sulfonamide, indinavir, or methotrexate), and ureteral obstruction (e.g., secondary to shed renal papilla or calculi) are infrequent causes of obstructive ARF. Crystal-induced ARF is often seen in patients who have severe volume contraction or who are receiving large doses of a drug with relatively low solubility. In these cases, patients do not have sufficient urine volume to keep the crystals from coming out of solution in the urine.²⁴ The onset of acute anuria in the absence of a catastrophic event should suggest acute urinary tract obstruction. However, the development of ARF in a hospitalized patient admitted with normal renal function is rarely secondary to obstruction unless an indwelling urinary catheter has been misplaced. When the obstructing process (e.g., prostatic hypertrophy or cervical cancer) is gradual and incomplete, the patient may present with complaints of decreased force of the urinary stream and polyuria.

PATHOPHYSIOLOGY

A basic knowledge of renal function facilitates the understanding of how ARF manifests itself clinically. The most logical approach to understanding renal function is to divide the kidney into its four basic component parts: the vasculature, the glomeruli, the tubules, and the interstitium surrounding the other three component parts.

RENAL VASCULATURE

The kidney is a highly vascular organ with blood vessels ranging from the very large (renal arteries) to the very small capillaries providing blood to each individual glomerulus. Obstruction of the renal artery will result in an increase in serum creatinine, hematuria, and proteinuria, but obstruction of smaller vessels will only cause infarction of the downstream parenchyma. If this area is small, no change in serum creatinine will occur.

Smaller vessels may be obstructed with cholesterol emboli, vascular lesions, or platelet plugs, all of which will present as isolated decreased perfusion of the glomeruli. The serum creatinine frequently is increased since the lesions are usually diffuse. However, the urinalysis most commonly will be normal since the kidney itself is not ischemic and the glomeruli are not involved. The urinary indices suggest prerenal azotemia (i.e., a low urine sodium concentration and a low fractional excretion of sodium) in the absence of systemic hypotension or a decrease in effective blood volume. The urine volume may or may not be diminished. However, the onset of oliguria sec-

ondary to diffuse arterial lesions within the kidney, such as that which occurs with hemolytic uremia syndrome, denotes a poor chance for salvage of renal function.

GLOMERULI

The glomerulus consists of an enlargement of the proximal end of the renal tubule to incorporate a vascular tuft connecting the afferent and efferent arterioles (Fig. 42–1). The production of glomerular ultrafiltrate is predominantly dependent on the transcapillary hydrostatic pressure (dictated by the afferent and efferent arteriolar resistance) and the glomerular surface area. Afferent arteriolar tone is determined primarily by the local levels of angiotensin II (which induces vasoconstriction) and prostaglandins (which induce vasodilation). Efferent arteriolar tone is predominantly determined by the local concentration of angiotensin II.

Pathophysiologic processes and medications that result in alterations of the afferent and efferent arteriolar tone (i.e., systemic hypotension, hypercalcemia, or use of ACEIs, angiotensin II receptor blockers, or NSAIDs) reduce glomerular ultrafiltrate production as a result of a decrease in glomerular hydrostatic pressure. Under these conditions, the serum creatinine will rise, the urine sediment will be normal, and the urine indices will suggest prerenal azotemia. However, the urinary solutes may or may not be maximally concentrated, depending on the circulating level of antidiuretic hormone that is necessary to maximally concentrate the urine. Damage to the glomerular capillary tuft (e.g., acute glomerulonephritis) results in a decline in the production of glomerular ultrafiltrate as a result of a decrease in glomerular capillary surface area. Under these conditions the serum creatinine rises and the urinalysis is significant for hematuria and proteinuria because of the increased permeability of the damaged glomerular capillaries. Proteinuria exceeding 3 g/day is often referred to as nephrotic range proteinuria. Prolonged heavy proteinuria secondary to glomerular damage may result in the nephrotic syndrome.

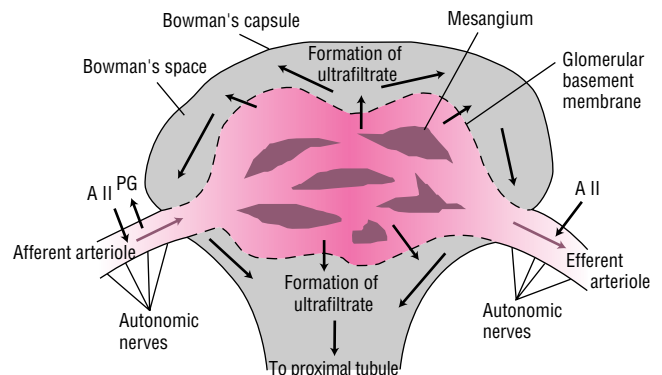

FIGURE 42–1. The formation of glomerular ultrafiltrate is dependent on the surface area of the glomerular capillaries, their permeability, and the net hydrostatic pressure across the capillary wall. As the glomerular capillary surface area increases secondary to mesangial cell relaxation, the formation of glomerular ultrafiltrate is increased. An increase or decrease in glomerular hydrostatic pressure results in either an increase or decrease in glomerular ultrafiltrate production. Afferent arteriolar vasoconstriction (which is primarily mediated by angiotensin II) or vasodilation (primarily mediated by prostaglandins) can result in a decrease or increase, respectively, in hydrostatic pressure across the capillary. Efferent arteriolar vasoconstriction (primarily mediated by angiotensin II) results in an increase in glomerular hydrostatic pressure. Under conditions in which renal blood flow is diminished, the kidney maintains glomerular ultrafiltration by vasodilating the afferent and vasoconstricting the efferent arterioles. Medications that may interfere with these processes might result in an abrupt decline in glomerular filtration.

RENAL TUBULES

Under normal conditions, approximately 180 L of glomerular ultrafiltrate are produced per day, the vast majority of which must be reabsorbed by the renal tubules to maintain homeostasis. Clinically, the renal tubule can be divided into three major sections: the proximal tubule, Henle's loop, and the distal nephron, which includes the distal tubule, the cortical collecting tubule, and the medullary collecting ducts. In the proximal tubule, approximately 60% to 70% of the filtered load of water and solute is isovolemically reabsorbed, as is the vast majority of filtered amino acids, glucose, and bicarbonate.

In addition to its other functions, Henle's loop is responsible for a significant portion of the total reabsorption of potassium, calcium, and magnesium, as well as for generating the osmotic gradient within the kidney that is necessary for the concentration of urinary solutes. Damage to this portion of the nephron results in wasting of potassium and magnesium by the kidney and an inability of the kidney to concentrate the urine. The medullary portions of Henle's loop are very sensitive to ischemia secondary to hypoperfusion. Consequently, in severe prerenal azotemia with renal hypoperfusion, there may be a loss of urinary concentrating ability despite the continued presence of a low urinary sodium concentration and a low fractional excretion of sodium.

Major functions of the distal nephron include the regeneration of bicarbonate, the excretion of acid (hydrogen ion), the secretion of potassium, and the reabsorption of water. Damage to this portion of the nephron may present as significant acidemia and either hypokalemia or hyperkalemia, depending on the mechanism of injury. For example, amphotericin B produces small pores in the luminal membrane of distal tubular cells. These pores allow small molecules such as potassium to leak out; the molecules are then wasted in the urine. Consequently, amphotericin B nephrotoxicity is characterized by hypokalemia secondary to renal potassium wasting. ATN is associated with urinary sediment characterized by the presence of tubular cells, coarse granular casts, and rarely, RBC casts.

INTERSTITIUM

The interstitium of the kidney provides the structural support for the kidney and serves to provide the environment in which concentrating gradients can be established. In addition, the interstitium of the kidney plays a major role in urinary ammonia handling. To facilitate the regeneration of bicarbonate and the excretion of acid by the distal nephron, the kidney utilizes ammonia as a urinary buffer. When the interstitium of the kidney is damaged (e.g., in acute allergic interstitial nephritis), the concentrating gradient within the kidney may be dissipated and ammonia handling disrupted. Consequently, patients presenting with acute interstitial nephritis frequently are unable to concentrate the urinary solutes. The urinalysis may show mild proteinuria and hematuria. However, the striking finding on microscopic examination of the sediment is the presence of numerous WBCs and WBC casts.

Rapid diagnosis is essential in the treatment of ARF in order to prevent extension of renal damage. The cause of most cases of ARF can be diagnosed from relatively few laboratory tests in conjunction with a good history and physical exam.

HISTORY

The diagnostic approach to the patient with ARF differs depending on the clinical setting in which the kidneys fail. For patients who present to the outpatient clinic or hospital with an elevated serum creatinine, the first objective is to determine if the renal failure is acute or

chronic. A past medical history of renal disease or chronic conditions such as poorly controlled hypertension or diabetes mellitus, previous laboratory data documenting the presence of proteinuria or an elevated serum creatinine, and the finding of bilateral small kidneys on renal ultrasonography all suggest the presence of severe and chronic kidney disease.

For patients who do not have the above findings, their renal failure should be considered acute until proven otherwise. In these individuals, a careful review of their recent medications, including nonprescription, complementary, and alternative medications is mandatory. Special attention should be focused on diuretics, NSAIDs, antihypertensives, and any recent additions or changes in the patient's medications.

The patient's recent history can usually provide an indication of when the onset of renal dysfunction began. Frequently, patients may notice a change in their voiding habits with an increase in urinary frequency or nocturia, both suggesting a urinary concentrating defect. A decrease in the force of the urinary stream may suggest an obstruction. The presence of cola-colored urine, indicating the presence of blood in the urine, is common in acute glomerulonephritis. If the accompanying proteinuria is severe, the patient may note excessive foaming of the urine in the toilet. The onset of bilateral flank pain may suggest swelling of the kidneys secondary to either acute glomerulonephritis or acute interstitial nephritis. The onset of severe headaches may suggest the development of hypertension as a result of ARF. A recent increase in the patient's weight or complaints of tight-fitting rings secondary to salt and water retention also may be helpful in defining the onset of renal failure.

For patients who develop ARF while hospitalized, a review of the laboratory data is usually sufficient to define the onset of ARF. However, significant renal injury can occur prior to an increase in the serum creatinine. Consequently, clinicians must pay careful attention to subtle changes in the patient's weight, blood pressure, and urine output if they are to diagnose the onset of ARF. In addition to its prognostic significance, changes in urine output may be helpful in diagnosing the type of renal dysfunction that is present. Acute anuria is secondary to either complete urinary obstruction or a catastrophic event (e.g., shock, HUS, or acute cortical necrosis). Initial presentation with oliguria suggests prerenal azotemia, functional ARF, or acute intrinsic renal failure. Nonoliguric renal failure usually results from acute intrinsic renal failure or incomplete urinary obstruction.

CLINICAL PRESENTATION OF ACUTE RENAL FAILURE

GENERAL

Outpatients often are not in acute distress; hospitalized patients may develop ARF after a catastrophic event

SYMPTOMS

Outpatient: Change in urinary habits, weight gain, or flank pain

Inpatient: Typically ARF is noticed by clinicians before it is noticed by the patient

SIGNS

Patient may have edema; urine may be colored or foamy. Vital signs may indicate orthostatic hypotension in volume-depleted patients

LABORATORY TESTS

Urine and blood chemistries may determine prerenal cause complete blood cell count (CBC) and differential rules out infectious causes

Urine microscopy may reveal casts, WBCs, RBCs, and eosinophils

OTHER DIAGNOSTIC TESTS

Renal ultrasound or cystoscopy may be needed to rule out obstruction; renal biopsy reserved for difficult diagnoses

PHYSICAL EXAMINATION

A physical examination, including assessment of the patient's volume and hemodynamic status, is the next step in evaluating individuals with ARF. Common physical findings in patients with ARF are listed in Table 42–3. The physical exam should be thorough, as clues regarding etiology can come from anywhere from the patient's head (eye exam) to toe (evidence of dependent edema).

LABORATORY TESTS AND INTERPRETATION

Chapter 41 describes the use of serum creatinine as a determinant of renal function. As stated earlier, many clinicians do not agree on the definition of ARF based on specific changes in serum creatinine

values. The difficulty of using serum creatinine as a diagnostic laboratory test for hospitalized patients with ischemic ARF is that it is too insensitive to rapid changes in glomerular filtration rates. An abrupt cessation in glomerular filtration will not yield an immediate measurable change in serum creatinine. Reasons for this include: creatinine generation is relatively slow, lab tests are not very sensitive to small changes, and because fluid retention in renal failure dilutes the retained serum creatinine.⁴ By the time serum creatinine elevates enough to be noticed, the extension phase of ischemic ARF is complete.²² "Correction" of serum creatinine values for hypervolemic patients with ARF has been suggested for earlier detection of ARF in at-risk patients.⁴

Selected blood tests in addition to blood urea nitrogen (BUN) and serum creatinine can have value in the management of the patient with ARF. For example, infectious causes of ARF can be ruled out using a CBC with differential. Serum electrolyte values are likely to be abnormal, and particular attention should be paid to serum potassium and phosphorus values, which can be elevated and cause life-threatening conditions.

Given the limited usefulness of solely using blood markers like creatinine or BUN to diagnose ARF, urinalysis should be performed. Urinalysis is an essential battery of tests when the clinician is attempting to determine the cause of renal failure. The finding of a high urinary

TABLE 42–3. Physical Examination Findings in Acute Renal Failure

| Physical Examination Finding | Possible Diagnosis | Category of Acute Renal Failure |
|---|--|--|
| Vital signs | | |
| Orthostatic hypotension | Volume depletion | Prerenal azotemia |
| Febrile | Sepsis | Acute intrinsic |
| Skin | | |
| Tenting | Volume depletion | Prerenal azotemia |
| Rash | Hypersensitivity reaction | Acute interstitial nephritis |
| Petechiae | Thrombotic thrombocytopenic purpura | Acute intrinsic renal failure—vasculitis |
| | Hemolytic uremic syndrome | |
| | Sepsis | Acute intrinsic |
| Splinter hemorrhages | Endocarditis | Intrinsic renal failure—glomerulonephritis |
| Janeway lesions | | |
| Osler's nodes | | |
| Edema | Total body volume overload | Suggests prerenal azotemia unlikely |
| HEENT | | |
| Hollenhorst plaque | Cholesterol emboli | Acute intrinsic renal failure—vascular |
| Roth spots | Endocarditis | Acute intrinsic renal failure—acute glomerulonephritis |
| Heart | | |
| S ₃ heart sound | Congestive heart failure | Prerenal azotemia |
| New murmur (particularly diastolic murmurs) | Endocarditis | Acute intrinsic renal failure—acute glomerulonephritis |
| Lung | | |
| Rales | Pulmonary edema with volume overload or left ventricular dysfunction | Suggests prerenal azotemia unlikely |
| Abdomen | | |
| Renal artery bruit | Renal artery stenosis | Prerenal azotemia |
| Ascites | Liver failure or right heart failure | Prerenal azotemia |
| Bladder distention | Bladder outlet obstruction | Hepatorenal syndrome Postobstruction renal failure |
| Genitourinary | | |
| Prostatic enlargement | Prostatic hypertrophy or cancer | Postobstruction renal failure |
| Gynecologic | | |
| Abnormal bimanual examination | Possible bilateral ureteral obstruction or cervical cancer | Postobstruction renal failure |

CHF, congestive heart failure; HEENT, head, eyes, ears, nose, and throat.

TABLE 42–4. Diagnostic Parameters for Differentiating Causes of Acute Renal Failure

| Laboratory Test | Prerenal Azotemia | Acute Intrinsic Renal Failure | Postrenal Obstruction |
|------------------------|-------------------|-------------------------------|-----------------------|
| Urine sediment | Normal | Cast, cellular debris | Cellular debris |
| Urinary RBC | None | 2 – 4+ | Variable |
| Urinary WBC | None | 2 – 4+ | 1+ |
| Urine sodium | <20 | >40 | >40 |
| FE _{Na} (%) | <1 | >2 | Variable |
| Urine/serum osmolality | >1.5 | <1.3 | <1.5 |
| Urine/serum creatinine | >40:1 | <20:1 | <20:1 |
| BUN/S _{Cr} | >20 | 15 | 15 |

Common laboratory tests are used to classify the cause of acute renal failure. Functional acute renal failure, which is not included in this table, would have laboratory values similar to those seen in prerenal azotemia. However, the urine osmolality to plasma osmolality ratios may not exceed 1.5 depending on the circulating levels of antidiuretic hormone. The laboratory results listed under acute intrinsic renal failure are those seen in acute tubular necrosis, the most common cause of acute intrinsic renal failure.

BUN, blood urea nitrogen; FE_{Na}, fractional excretion of sodium; S_{Cr}, serum creatinine; RBC, red blood cell; WBC, white blood cell.

specific gravity, in the absence of glucosuria or mannitol administration, suggests an intact urinary concentrating mechanism, and that the cause is likely prerenal azotemia or functional ARF. The presence of proteinuria and hematuria indicate glomerular injury. Microscopic examination of the urine also is helpful in determining the cause of ARF. Benign urine sediment suggests prerenal azotemia, functional ARF, or urinary obstruction. The presence of RBCs and RBC casts indicates a glomerular injury. The finding of WBCs and WBC casts results from interstitial inflammation (i.e., interstitial nephritis), which can be secondary to an allergic, granulomatous, or infectious process.

Simultaneous measurement of serum and urinary chemistries is often helpful in determining the etiology of ARF (Table 42–4). From these values a fractional excretion of sodium from urinary and plasma creatinine and sodium concentrations can be calculated. The equation for the calculation of the fractional excretion of sodium (FE_{Na}) is:

$$\begin{aligned} \text{FE}_{\text{Na}} &= (\text{excreted Na}/\text{filtered Na}) \cdot 100 \\ &= (U_{\text{vol}} \cdot U_{\text{Na}})/(\text{GFR} \cdot P_{\text{Na}}) \cdot 100 \end{aligned}$$

where

$$\text{GFR} = (U_{\text{vol}} \cdot U_{\text{Cr}})/(P_{\text{Cr}} \cdot t)$$

Thus:

$$\text{FE}_{\text{Na}} = (U_{\text{Na}} \cdot P_{\text{Cr}} \cdot 100)/(U_{\text{Cr}} \cdot P_{\text{Na}})$$

where U_{vol} is urine volume; U_{Cr} is urine creatinine; U_{Na} is urine sodium; P_{Cr} is plasma creatinine; P_{Na} is plasma sodium; GFR is the glomerular filtration rate; and t is the time period over which the urine is collected.

The fractional excretion of sodium calculation from plasma and urinary chemistry values is used to differentiate the cause of ARF. A low urinary sodium concentration and low fractional excretion of sodium (<1%) in a patient with oliguria suggest that there is stimulation of the sodium-retentive mechanisms in the kidney and that tubular function is intact. These findings are most characteristic of prerenal azotemia or functional ARF. Inability to concentrate urine results in a high fractional excretion of sodium (>2%), suggesting tubular damage as is seen with ATN. Diagnosing the type of ARF using fractional excretion of sodium is not absolute, as there are some causes that can be associated with a low fractional excretion of sodium (e.g., contrast nephropathy, myoglobinuria, and interstitial nephritis). Highly concentrated urine (>500 mOsm/L) suggests stimulation of antidiuretic hormone and intact tubular function. These findings are consistent with prerenal azotemia. Diuretic use limits the utility of the fractional excretion of sodium calculation by increasing natriuresis, even in hypovolemic patients.

DIAGNOSTIC PROCEDURES

Renal ultrasound is rarely helpful in determining the cause of ARF in a hospitalized patient who previously had normal renal function; however, for the outpatient who presents with renal failure, the renal ultrasound is instrumental in determining whether the renal failure is acute or chronic and whether or not obstruction is present. A plain film radiograph of the abdomen may be useful in documenting the presence of two kidneys and in checking for renal stones. If the possibility of renal artery obstruction exists, a radioisotope scan or renal angiography may be required. Intravenous pyelography is rarely used in the diagnostic work-up of ARF. Cystoscopy with retrograde pyelography may be helpful if the possibility of obstruction exists. If insertion of a urinary catheter into the patient's bladder after the patient has voided does not yield a large volume of urine (>500 mL), then one can usually exclude postrenal obstruction as the cause of ARF. If a large volume of urine remains after the patient has voided, or if the patient is unable to void, urinary catheter placement into the bladder may result in alleviation of symptoms if the obstruction is somewhere between the bladder to the urethral opening.

If the etiology of the ARF is unclear despite a careful history, physical examination, and appropriate diagnostic tests, percutaneous renal biopsy may be indicated. Renal biopsy is associated with some risk (primarily bleeding) and should only be performed in those few patients who meet criteria for biopsy. However, in cases in whom the cause of ARF is not evident, renal biopsies are useful in determining the cause in more than 90% of patients.²⁵

► PREVENTION AND TREATMENT: Acute Renal Failure

■ DESIRED OUTCOME

2 Given the dismal outcomes of patients with ARF, prevention is critical. In many cases, the risk of ARF development is known and is predictable. For example, when patients with risk factors for ARF development are scheduled to receive radiocontrast dye or sur-

gery that will stop blood flow to the kidneys, the clinician knows that ARF may develop. In these cases preventive measures must be taken. Fortunately many therapeutic maneuvers have been identified that can reduce the risk of ARF development in these situations. Consequently the goals of treatment are (1) to prevent ARF, but if ARF develops, (2) avoid or minimize further renal insults that would delay recovery, and (3) provide supportive measures until kidney function returns.

GENERAL APPROACH TO TREATMENT

The general approach to the treatment of established ARF is dependent on the setting in which it develops. In the community setting, the first goal is to remove the causative agent (drugs or nephrotoxins) if possible. If the cause is immune-related, as may be the case with interstitial nephritis or glomerulonephritis, a rapid diagnosis must be made to begin appropriate immunologic therapy (usually corticosteroids). In the hospital setting, nephrotoxic agents should be discontinued and prerenal causes must be ruled out. Renal perfusion should be optimized to stop extension of any ischemic processes. This typically means a fluid challenge with close watch of the patient’s vital signs and urine output. Care must be taken not to fluid overload a patient with absent kidney function. Once renal failure is established and the cause is known, supportive care is all that can be provided. Renal replacement therapy is provided to maintain fluid and electrolyte balance while removing accumulating waste products. All further insults to the kidney must be prevented so the slow process of renal recovery can begin. In the case of ATN, this typically occurs within 10 to 14 days. Longer courses of ARF can occur if the kidney is exposed to repeated insults.

PREVENTION OF ARF

3 The therapies used to prevent ARF are much different than those used to treat established ARF; consequently preventive therapies will be reviewed first and treatment options will follow. Given the dismal outcome of patients with ARF, numerous regimens have been tried to prevent the development of ARF in patients who will be receiving known nephrotoxins. Typically, these interventions are made prior to administration of nephrotoxins like radiocontrast dye, or prior to surgical procedures that will restrict blood flow to the kidneys for extended periods. Because the timing of the renal insult is known, this setting is ideal for conducting clinical studies into ARF prevention. Unfortunately the list of interventions that do not prevent ARF in this setting is longer than the list of those that do. Table 42–5 lists some of the interventions that have been studied to prevent ARF.

NONPHARMACOLOGIC

In situations in which administration of a nephrotoxin cannot be avoided, such as when radiocontrast dye is to be administered, nonpharmacologic therapies can be employed to prevent ARF. The key to nonpharmacologic ARF prevention is the elimination of the patient’s risk factors to the degree that is possible. The best-studied examples of this are the interventions used to maximize renal perfusion when radiocontrast dye is administered. Adequate hydration and sodium loading prior to radiocontrast dye administration have been shown to be beneficial therapies. A trial comparing infusions of 0.9% NaCl or 5% dextrose with 0.45% NaCl administered prior to radiocontrast dye infusion conclusively demonstrated that the normal saline was superior in preventing ARF.²⁶ The intravenous solution infusion rate used in this study was 1 mL/kg per hour beginning the morning that the radiocontrast dye was going to be given, and all subjects were encouraged to drink fluids liberally as well. The benefits of 0.9% NaCl infusions have been found in similar studies,²⁷ suggesting this regimen should be used in all at-risk patients who can tolerate the sodium and fluid load.

Preventive Dialysis

A novel approach to reducing the incidence of nephrotoxicity associated with radiocontrast dye administration is to provide RRT prophylactically to patients at high risk. Hemofiltration provided prior to and 24 hours after dye administration resulted in significantly reduced mortality rates and a reduced need for dialysis.²⁸ In contrast, the use of hemodialysis within an hour of contrast dye infusion did not yield an improvement in nephrotoxicity rates, possibly because the toxicity due to dye occurs within minutes of its administration.²⁹

PHARMACOLOGIC

4 One of the simplest ways to prevent acute nephrotoxicity is to avoid the use of nephrotoxic agents when possible. If

TABLE 42–5. Evidence of Benefit of Prophylactic Therapies for the Prevention of Acute Renal Failure Due to Nephrotoxin Exposure

| Intervention | Evidence for Prevention of Nephrotoxicity | Situations in Which Intervention Documented to be Effective |
|---|---|---|
| Hydration (sodium loading) | Y | Prior to amphotericin or contrast dye administration; tumor lysis syndrome prevention |
| Mannitol | N | |
| Loop diuretics | N | |
| Dopamine | N | |
| Calcium channel blockers | +/- | Recipient should receive drug prior to transplantation and when kidney is stored in solution containing drug. Not useful for preventing contrast dye nephropathy. |
| Theophylline | Y | Prior to contrast dye administration |
| Acetylcysteine | Y | Prior to contrast dye administration |
| Fenoldopam | N | |
| Insulin (to maintain serum glucose of 80–110 mg/dL) | Y | Critically ill patients |

Y, some evidence exists for benefit; +/-, evidence equivocal; N, evidence suggests no benefit.

nephrotoxic agents cannot be avoided, there may be ways to administer them in a manner that reduces their nephrotoxic potential. A good example of this is the use of amphotericin B to treat fungal infections. Amphotericin is a highly nephrotoxic agent, causing ARF in approximately 30% of patients who receive it.³⁰ However, there are many infections for which no good alternative treatment exists. The nephrotoxic potential of amphotericin B deoxycholate can be reduced significantly simply by slowing the infusion rate from a standard 4-hour infusion to a slower 24-hour infusion of the same dose.³¹ In a patient with risk factors for the development of ARF, liposomal forms of amphotericin B can be used. These liposomal formulations are more expensive, but cause a lower incidence of kidney damage.³²

Given the dismal outcome of established ARF, many drugs have been investigated for its prevention. Surprisingly, many of these interventions have been found to be of no benefit. Low doses of dopamine (≤ 2 mcg/kg per minute) increase renal blood flow and might be expected to increase GFR. Theoretically, this might be considered beneficial, as an enhanced GFR might flush nephrotoxins from the tubules, minimizing their toxicity. Furthermore, loop diuretics may decrease tubular oxygen consumption by reducing solute reabsorption.³³ Despite these theoretical suggestions that loop diuretics and dopamine might be useful in ARF prevention, controlled studies do not support these theories. In a blinded and randomized trial conducted in patients undergoing cardiac surgery, dopamine 2 mcg/kg per minute, furosemide 0.5 mcg/kg per minute, and a 0.9% NaCl placebo given at initiation of surgery were compared to determine whether any of these interventions would be beneficial.³⁴ Postoperative increases in serum creatinine occurred significantly more often in the furosemide-treated subjects than in the other two groups. Dopamine afforded no benefit compared to the sodium chloride infusion, and therefore should not be used routinely in this manner.

The use of diuretics to prevent nephrotoxicity may actually result in intravascular depletion, a prerenal state, and an exacerbation of ARF. A trial of forced diuresis, in which mannitol, furosemide, and/or dopamine were given, and resultant urinary losses were replaced with intravenous solutions found that diuretic use resulted in little benefit compared to IV solutions given alone.³⁵ Interestingly, these investigators noted that patients that were unable to produce much urine despite diuretic administration were more likely to develop ARF than patients who did respond to diuretics. While this unresponsiveness to diuretics might simply be an indication of preexisting kidney damage, similar reports have linked diuretic unresponsiveness to increased mortality rates in critically ill patients with ARF.⁶

CLINICAL CONTROVERSIES

Despite the fact that most studies do not show improved patient outcomes with its use, low-dose dopamine continues to be commonly used. The risks associated with dopamine use (extravasation and the potential for significant dosing errors) suggest that it should usually be avoided.

Giving low-dose dopamine infusions (≤ 2 mcg/kg per minute) for the prevention of ARF is a surprisingly common practice given the paucity of data to support its use. While most studies do report an increase in urine output when low-dose dopamine is administered, almost none report that this practice yields a benefit to the patient. A meta-analysis of all low-dose dopamine studies conducted from 1966 to 2000 concluded that low-dose dopamine does not prevent ARF and its use could not be justified.³⁶

Fenoldopam

Fenoldopam is a selective dopamine-1 receptor agonist that has been investigated for its ability to prevent radiocontrast dye nephropathy. Originally approved for use as an intravenous antihypertensive agent, fenoldopam reduces systemic blood pressure while preserving renal blood flow, it appears to have salutary properties for the prevention of drug-induced nephrotoxicity. A large, multicenter, randomized, placebo-controlled trial of fenoldopam use to prevent radiocontrast dye nephropathy in patients with CKD found that fenoldopam provided no benefit.³⁷ The disappointing results of this trial and that of the dopamine studies suggest that dopaminergic manipulation of the kidney is not likely to work as a preventive measure for nephrotoxicity (see Chap. 46).

Acetylcysteine

Pretreatment with oral acetylcysteine, (also called n-acetylcysteine), 600 mg twice daily on the day before and the day of radiocontrast dye administration has been documented to lower the rate of ARF in patients with pre-existing CKD.^{38–39} The mechanism for acetylcysteine's ability to reduce the incidence of radiocontrast dye nephrotoxicity is not fully elucidated, but likely is due to its antioxidant effects. Given the consistent findings of its efficacy and its relatively low cost, acetylcysteine should be given to all patients at risk for radiocontrast dye nephrotoxicity.

Many other drugs have been investigated for the prevention of ARF, with varying degrees of success.³³ A few of these agents bear mentioning. Theophylline 200 mg infused 30 minutes before contrast dye administration resulted in a fivefold decrease in nephropathy compared to a placebo infusion in high-risk patients.⁴⁰ Despite this finding and for reasons that are unclear, most centers typically do not use this intervention to prevent contrast dye nephropathy. Calcium antagonists have shown promise in reducing ATN in kidneys that are transplanted,⁴¹ but their utility is limited in other clinical settings due to their hypotensive effects.

Glycemic Control

Perhaps the most promising agent for the prevention of hospital-acquired ARF is a very old drug, but its use in the prevention of ARF is a very new finding. Van den Berghe and associates randomized patients in a surgical ICU to receive standard control (< 200 mg/dL) or intensive glucose control measures (goal blood glucose concentrations of 80 to 110 mg/dL).⁴² Tight blood glucose resulted in significant improvements in mortality and a 41% reduction in the development of ARF. It appears that while it was blood glucose control that caused the mortality benefit, the reduction in ARF may have been due to the total dose of insulin used to treat the patient, suggesting a direct protective effect of insulin.¹⁷ Strict glycemic control is recognized as an important goal for outpatient diabetics;⁴³ however, intensive insulin therapy will likely also become the standard of care for all critically ill patients to prevent ARF and improve mortality.

TREATMENT OF ESTABLISHED ARF

5 Once the kidney has been damaged by an initial insult (reduced perfusion, nephrotoxins, etc.), initial therapies should be directed to eliminate further harm to the kidney, thus preventing

extension of the injury.²² The time to recovery from ARF is determined from the most recent insult to the kidney, not the first insult. Hospitalized patients with ARF are at risk for repeated episodes of kidney damage through nephrotoxic agents and hypotensive episodes, among other problems. These increased risks coupled with the fact that no drugs have been found to accelerate ARF recovery change the way clinicians approach the ARF patient. Patients with established ARF should be viewed as patients who should be supported and protected through the period of ARF rather than as patients who will respond to therapies designed to hasten renal recovery.

■ NONPHARMACOLOGIC THERAPY

Supportive care goals for the critically ill patient with ARF include aggressive fluid management. Cardiac output and blood pressure must be supported to allow for adequate tissue perfusion. However, a fine balance must be struck in this regard. For example, fluids must be typically restricted in anuric and oliguric patients unless the patient is hypovolemic or is able to achieve fluid balance via renal replacement therapy. If fluid intake is not minimized, edema rapidly occurs, especially in hypoalbuminemic patients. In contrast, vasopressors like dopamine ≥ 2 mcg/kg per minute or norepinephrine are used to maintain adequate tissue perfusion, but may also induce kidney hypoxia via a reduction in renal blood flow. Consequently, Swan-Ganz monitoring is essential for critically ill patients.

Another related supportive care issue is electrolyte management. Hyperkalemia, hypermagnesemia, and hyperphosphatemia are common electrolyte disorders in patients with ARF who are unable to use their kidneys to maintain electrolyte balance. This is generally not a serious concern in patients who are achieving electrolyte control via RRT, but electrolytes should be monitored closely in all patients with ARF.

Renal replacement therapies are the most common nonpharmacologic treatment that patients with ARF receive. Absolute indications for starting RRT in an ARF patient do not exist, but some general guidelines for therapy initiation do exist (Table 42–6). Renal replacement therapies come in two different forms, intermittent therapies like hemodialysis, and continuous RRTs like continuous hemofiltration or peritoneal dialysis. A more detailed explanation of these therapies appears in Chap. 45. The choice of whether continuous therapies or intermittent RRTs are used is a matter of debate and is usually determined by physician preference and the resources available at the hospital.

The merits of intermittent hemodialysis are many. Hemodialysis machines usually are available at hospitals and health care workers are familiar with their use. Hemodialysis treatments usually last 3 to 4 hours, so they can be done during work hours when hospitals are

best staffed. The disadvantages of intermittent hemodialysis are also numerous. Venous dialysis access can be difficult in hypotensive patients with ARF. Because intermittent hemodialysis only runs for a few hours per day, large amounts of fluid must be removed in a relatively short period of time in volume-overloaded patients. This can result in hypotension that may delay the recovery from ARF. If hemodialysis is carefully monitored and hypotension avoided, better patient outcomes can be achieved.⁴⁴ Patients with CKD can achieve adequate solute and volume control with thrice weekly dialysis, but hypercatabolic, fluid-overloaded patients with ARF may require daily hemodialysis treatments.⁴⁵

In contrast, continuous RRTs have a different set of advantages and disadvantages.⁴⁶ Typically peritoneal dialysis does not provide enough solute and fluid control for hypercatabolic patients with ARF. The exception to this rule may be in the treatment of small children, who have a larger peritoneal membrane surface area to body weight ratio than do adults. This larger ratio may allow for enough clearance for peritoneal dialysis to be used in these children. Other than in this pediatric scenario, continuous renal replacement therapy (CRRT) is performed as continuous hemodialysis, continuous hemofiltration, or a combination of the two. Disadvantages of CRRT are that not all hospitals have the special machinery necessary to conduct these treatments, they require intensive nursing care around the clock, they are more expensive because of the custom intravenous and dialysis fluids used, and less is known about drug dosing in these therapies. The main advantage of CRRT is that the continuous nature of these therapies allows for a more gradual removal of solutes and fluid that is better tolerated by critically ill patients. Raw comparisons of patient outcome when treated with intermittent hemodialysis versus CRRT typically show a higher mortality rate with the continuous therapies.⁴⁷ However, patients treated with continuous therapies are almost always more critically ill than those treated by intermittent hemodialysis. The reason for this selection bias is that the sickest patients are unable to tolerate intermittent hemodialysis; consequently comparisons of outcome must control for illness severity. It appears that patient outcome, once adjusted for severity of illness, is no different between intermittent and continuous therapies, and patients who are intolerant of intermittent dialysis may do quite well with continuous therapies.⁴⁸

CLINICAL CONTROVERSY

Some clinicians believe that CRRTs are preferable to intermittent hemodialysis because they provide more consistent fluid and waste product removal. Others suggest that intermittent hemodialysis is preferable because nursing and medical staff are more familiar with its use and round-the-clock nursing is not needed.

Continuous renal replacement therapies are becoming more commonly used for critically ill patients with ARF. Continuous renal replacement therapy operating for 24 hours a day means that more RRT can be given per week than can be accomplished with the thrice-weekly hemodialysis treatments used in patients with CKD. This has influenced how dialysis is prescribed in the ICU for hypercatabolic patients with ARF. Intermittent hemodialysis administered daily has been associated with improved survival and faster resolution of ARF compared to dialysis given every other day.⁴⁹ Daily dosing of dialysis presents challenges to clinicians prescribing drug and nutrition therapy, as most of these dosing guidelines are based on thrice-weekly dialysis, and application of these guidelines may yield inappropriate dosing.

TABLE 42–6. The AEIOUs That Describe the Indications for Renal Replacement Therapy

| Indication for Renal Replacement Therapy | Clinical Setting |
|--|---|
| A Acid-base abnormalities | Metabolic acidosis resulting from the accumulation of organic and inorganic acids |
| E Electrolyte imbalance | Hyperkalemia, hypermagnesemia |
| I Intoxications | Salicylates, lithium, methanol, ethylene glycol, theophylline, phenobarbital |
| O fluid Overload | Postoperative fluid gain |
| U Uremia | High catabolism of acute renal failure |

Modifications to standard intermittent dialysis techniques have been made to try to take advantage of the higher overall doses of renal replacement that can be obtained with CRRT. Some have made a hybrid between intermittent dialysis and continuous therapies. These hybrid therapies have a variety of names, with the two most common being sustained low-efficiency dialysis⁵⁰ and extended daily dialysis.⁵¹ These therapies use standard hemodialysis machines with the blood and dialysate flows slowed down, and they are run for extended periods compared to intermittent hemodialysis. Proposed advantages of these therapies are that no new machinery is needed, and that therapy can be given for 8 to 12 hours per day, allowing for gradual fluid removal. These therapies do not require 24 hour-a-day nursing supervision, yet deliver plenty of urea and waste product removal. The main negative of these hybrid therapies is that while they yield large amounts of urea clearance, drug clearance changes every time the dialysis machine is turned on and off. This makes drug dosing difficult to manage.⁵² Very few pharmacokinetic studies have been conducted with these hybrid therapies.⁵³

One aspect of RRT that is overlooked by most clinicians is which hemodialyzer or hemofilter is used during the treatment. The material used to make the membranes of hemodialyzers (for hemodialysis) and hemofilters (for hemofiltration) varies by manufacturer, and recent evidence suggests that which membrane material is used may influence the outcomes of patients with ARF. When blood comes into contact with these membranes, the complement cascade is activated, resulting in an immune reaction. Each type of membrane induces complement to a different degree. Those that cause less of a complement cascade are termed “biocompatible,” while membranes that induce a large reaction are considered “bioincompatible.” Bio-

compatible membranes tend to be made of newer, more expensive, synthetic materials and usually have larger pores in them. Bioincompatible membranes are usually made of cellulosic materials and have relatively small pores. The use of biocompatible membranes has been associated with slightly better patient outcomes than the use of more complement-activating membranes.^{54–55}

■ PHARMACOLOGIC THERAPY

The use of drug therapy in patients with ARF to accelerate the recovery of renal function has been a dream of clinicians for years. To date, no drug therapy has ever been documented to do this. Many agents have looked promising in animal trials, only to be found ineffective in human trials. The list of drugs that have been investigated and shown no benefit is long.⁵⁶ In recent years thyroxine,⁵⁷ dopamine,⁵⁸ and loop diuretics⁶ have all been documented to either be of no help or to worsen patient outcomes. For example, loop diuretic use in patients with ARF was associated with a 77% increase in mortality or nonrecovery of renal function compared to patients who did not receive loop diuretics.⁶ These findings may be explained by the fact that sicker, fluid-overloaded patients may be more likely to receive diuretics, nonetheless no benefit to loop diuretic use could be found in any subanalysis. Consequently, loop diuretic use should be reserved for fluid-overloaded patients who make adequate urine in response to diuretics to merit their use.

In fluid-overloaded nonoliguric patients, diuretics can facilitate patient management (Fig. 42–2). Prevention of pulmonary edema is an important goal, and it is preferable that this be accomplished

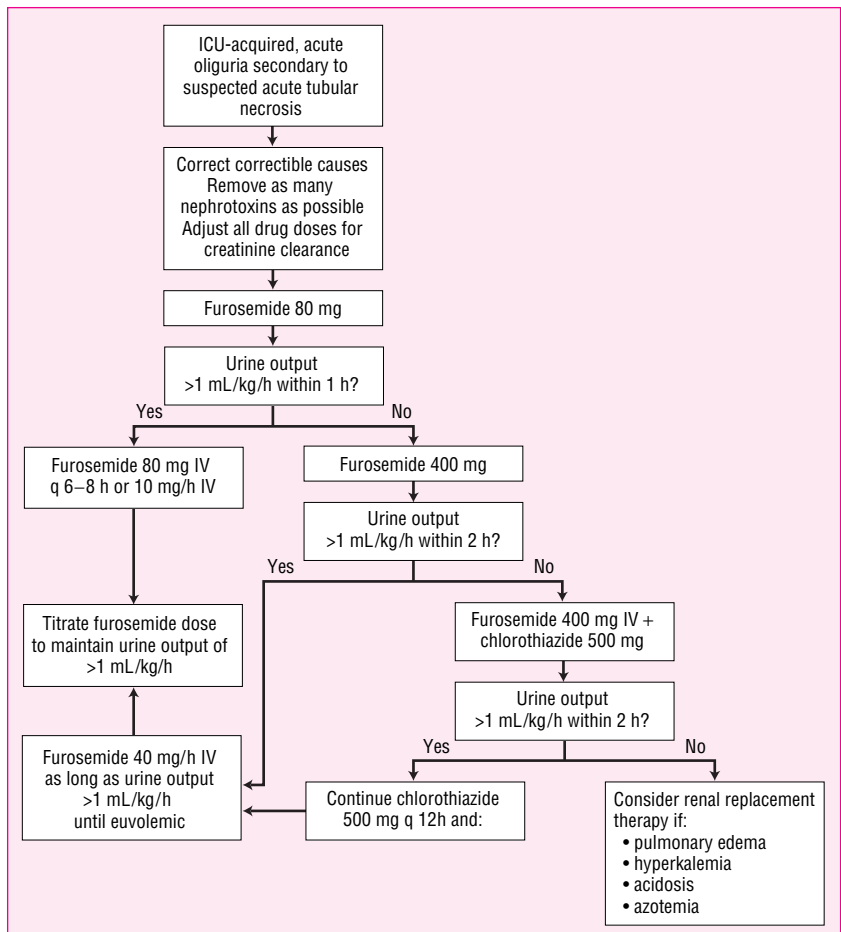

FIGURE 42–2. Suggested treatment algorithm for ICU-acquired oliguric acute renal failure resulting from acute tubular necrosis.

with diuretics instead of more invasive RRTs, despite the previously mentioned finding that diuretic use may be associated with a worse outcome.⁶ The most effective drugs in causing diuresis in the ARF setting are mannitol and the loop diuretics. These two therapies have distinct advantages and disadvantages. Mannitol, which works as an osmotic diuretic, can only be given parenterally. A typical starting dose is mannitol (20%) 12.5 to 25 g infused intravenously over 3 to 5 minutes. It has little nonrenal clearance, so when given to anuric or oliguric patients, mannitol will remain in the patient, potentially causing a hyperosmolar state. Additionally mannitol may cause ARF itself, so its use in ARF must be monitored carefully by measuring urine output and serum electrolytes and osmolality.⁵⁹ Due to these limitations of mannitol, some have recommended that it be reserved for its nondiuretic uses, like management of cerebral edema.⁶⁰

CLINICAL CONTROVERSIES

In edematous patients, occasionally a clinician will suggest infusing albumin to provide intravascular oncotic pressure to mobilize fluid back into the intravascular space, and then administering loop diuretics to remove this fluid. Studies on the merits and costs of this combination have had mixed results.

Furosemide, bumetanide, torsemide, and ethacrynic acid are the most frequently used loop diuretics in patients with ARF. Ethacrynic acid is reserved for patients who are allergic to sulfa compounds. Furosemide is the most commonly used loop diuretic because of its lower cost, availability in oral and parenteral forms, and good safety and efficacy profiles. A disadvantage with furosemide is its variable oral bioavailability in many patients. Consequently, initial furosemide doses (usually 40 to 80 mg) are usually administered intravenously to assess whether the patient will respond. Torsemide and bumetanide have better oral bioavailability than furosemide. Torsemide has a longer duration of activity than the other loop diuretics which allows for less frequent administration but also may make it more difficult to titrate the dose. Loop diuretics should all work equally well in a given patient provided that they are administered in equipotent doses parenterally so that bioavailability issues are obviated. In a patient who is unresponsive to aggressive loop diuretic dosing, switching to another loop diuretic is unlikely to be beneficial. In the outpatient setting, torsemide may be preferred because it can be administered

once daily, and because of its relatively better oral bioavailability than furosemide.

Diuretic Resistance

Inability to respond to administered diuretics is common in ARF and is associated with a poor patient outcome.⁶ An effective technique to overcome diuretic resistance is to give loop diuretics via continuous infusions instead of intermittent boluses. Less natriuresis occurs when equal doses of loop diuretics are given as a bolus instead of as a continuous infusion. Furthermore, adverse reactions from loop diuretics (myalgias and hearing loss) occur less frequently in patients receiving continuous infusion compared to those receiving intermittent boluses, ostensibly because lower serum concentrations are attained. However, these adverse effects still may occur with continuous infusion loop diuretics and should be monitored.⁶¹ The finding that the continuous infusions of loop diuretics have efficacy that is at least as good as intermittent bolus dosing, with fewer adverse effects, appears to be consistent for all agents, including furosemide,⁶² bumetanide,⁶³ and torsemide.⁶⁴ When continuous loop diuretic infusion is used, an initial loading dose is given (equivalent to furosemide 40 to 80 mg) prior to the initiation of the continuous infusion at a dose of 10 to 20 mg/hour of furosemide or its equivalent. Patients with low creatinine clearances have much lower rates of diuretic secretion into the tubular fluid; consequently, higher doses are generally used in patients with renal insufficiency.⁶⁰

Diuretic resistance may occur simply because excessive sodium intake overrides the ability of the diuretics to eliminate sodium. Other reasons exist for diuretic resistance in this population. Patients with ATN have a reduced number of functioning nephrons on which the diuretic may exert its action. Other clinical states like glomerulonephritis are associated with heavy proteinuria. Intraluminal loop diuretics cannot exert their effect in the loop of Henle because they are extensively bound to the protein present in the urine. Still other patients may have reduced bioavailability of oral furosemide. Possible therapeutic options to counteract each form of diuretic resistance are presented in Table 42–7. Combination therapy of loop diuretics plus a diuretic from a different pharmacologic class can be an effective tool in the setting of ARF.⁶⁵ Loop diuretics increase the delivery of sodium chloride to the distal convoluted tubule and collecting duct. With time, these areas of the nephron compensate for the activity of the loop diuretic and increase sodium and chloride resorption. Diuretics that work at the

TABLE 42–7. Common Causes of Diuretic Resistance in Patients with Acute Renal Failure and the Measures Used to Counteract Them

| Causes of Diuretic Resistance | Potential Therapeutic Solutions |
|--|--|
| Excessive sodium intake (sources may be dietary, IV fluids, and drugs) | Remove sodium from nutritional sources and medications |
| Inadequate diuretic dose or inappropriate regimen | Increase dose, use continuous infusion or combination therapy |
| Reduced oral bioavailability (usually furosemide) | Use parenteral therapy; switch to oral torsemide or bumetanide |
| Nephrotic syndrome (loop diuretic protein binding in tubule lumen) | Increase dose, switch diuretics, use combination therapy |
| Reduced renal blood flow | |
| Drugs (NSAIDs ACEIs, vasodilators) | Discontinue these drugs if possible |
| Hypotension | Intravascular volume expansion and/or vasopressors |
| Intravascular depletion | Intravascular volume expansion |
| Increased sodium resorption | |
| Nephron adaptation to chronic diuretic therapy | Combination diuretic therapy, sodium restriction |
| NSAID use | Discontinue NSAID |
| Congestive heart failure | Treat the CHF, increase diuretic dose, switch to better absorbed loop diuretic |
| Cirrhosis | High-volume paracentesis |
| Acute tubular necrosis | Higher dose of diuretic, diuretic combination therapy, add low-dose dopamine |

distal convoluted tubule (thiazides) or the collecting duct (amiloride, triamterene, and spironolactone) may have a synergistic effect when administered with loop diuretics by blocking the compensatory increase in sodium and chloride resorption. The combination of loop diuretics and usual doses of thiazide diuretics may be effective in renal disease despite the accumulation of endogenous organic acids in renal disease that blocks the transport of loop diuretics into the lumen. If oral thiazides cannot be given to the patient, chlorothiazide can be administered parenterally.

Several drug combinations with loop diuretics have been investigated, including the addition of one or more of the following: theophylline, acetazolamide, spironolactone, thiazides, or metolazone.⁶⁵ Of these combinations, metolazone is used most frequently with furosemide. Metolazone, unlike other thiazides, produces effective diuresis at a GFR below 20 mL/minute. This combination of metolazone and a loop diuretic has been used successfully in the management of fluid overload in patients with CHF, cirrhosis, and nephrotic syndrome. Additionally, this combination has been found to be efficacious in pediatric patients as well as adults.⁶⁶ The combination of mannitol plus intravenous loop diuretics is used by some practitioners,⁶⁷ but no convincing evidence of the superiority of this combination regimen to conventional dosing of either diuretic alone exists.

■ NUTRITIONAL INTERVENTIONS

While most drug therapy has yet to show benefit in patients with ARF, certain nutritional interventions may be useful. Pre-existing nutrition status has been shown to be a strong predictor of outcomes in patients with ARF.¹⁵ The use of enteral nutrition in patients with ARF in ICUs has been associated with an improvement in outcomes.¹⁰ Parenteral nutrition did not show the same benefit and some have questioned whether parenteral nutrition should ever be used in this population.⁶⁸

The most common interventions that must be made when treating patients with ARF involve fluid and electrolyte management. Most patients with ARF are fluid overloaded, and fluids must be restricted. This means maximally concentrated drug infusions and nutrition solutions. So-called “keep vein open” or maintenance intravenous infusions should be halted unless the patient is euvolemic or is receiving renal replacement solution that is able to maintain fluid balance.

The most common electrolyte disorder in ARF is hyperkalemia. Life-threatening cardiac arrhythmias may occur from hyperkalemia, so potassium restriction is essential. The treatment of hyperkalemia is discussed in Chap. 50. Typically no potassium should be added to parenteral solutions unless hypokalemia is documented. Patients receiving enteral nutrition should be limited to a 3-g potassium diet. Serum potassium concentrations should be monitored daily, even in patients receiving RRT. Some centers add no potassium to their CRRT solutions and hypokalemia can result with prolonged therapy.

Sodium restriction is also a necessary intervention. A diet with 3 g of sodium per day is usually a reasonable place to start. Ingestion of too much sodium is a common reason diuretic therapy fails. Clinicians should be vigilant about sources of sodium. For example, 1 L of 0.9% NaCl yields 154 mEq of sodium, or 3.5 g. Sodium is usually restricted even in patients who are receiving RRT. In continuous and intermittent RRTs there usually is no worry about hyponatremia developing because these therapies will incorporate isonatremic (135 to 140 mEq/L of sodium) solutions as dialysate or ultrafiltrate replacement solutions. Serum sodium concentrations should be monitored daily.

Other electrolytes that require monitoring include magnesium and phosphorus. Both are eliminated by the kidneys and are not removed efficiently by dialysis. Typically their dietary intake is re-

stricted, but in patients receiving prolonged renal replacement, deficiency states can occur, particularly in pediatric patients due to their reduced body stores. Hypophosphatemia can also occur in these critically ill patients as a result of the refeeding syndrome, in which nutritional supplementation is instituted after the patient goes a long period of time without being fed. Nonetheless, in initial ARF, hyperphosphatemia is more likely. Patients who also have significant tissue destruction (trauma, rhabdomyolysis, tumor lysis syndrome, or sepsis) may have significant phosphorus released from the destroyed tissue. Treatment of the hyperphosphatemic state can include RRT; however, for patients not receiving these therapies, oral phosphate-binding antacids or sevelamer can be administered (see Chap. 44). In hyperphosphatemic patients, calcium-containing antacids are often avoided to prevent precipitation of calcium phosphate in the soft tissues. A common guideline is to maintain the calcium-phosphate product <55 in those with CKD. The calcium-phosphate product is calculated by multiplying the serum calcium (in milligrams per deciliter) by the serum phosphorus (also in milligrams per deciliter). When this product is above 55, sevelamer or aluminum-containing antacids are used, and once the phosphorus is better controlled, calcium-containing antacids can be used.

In contrast to the patient with CKD, the calcium balance is usually not an important issue for the ARF patient due to the limited duration of the illness. One exception to this is in patients receiving continuous RRT that is anticoagulated with citrate. Citrate binds to serum calcium and without calcium, blood cannot form a clot. Citrate is typically infused as blood leaves the body. A calcium infusion must be administered either at the end of the extracorporeal circuit or centrally to provide sufficient unbound calcium to the patient. Insufficient calcium infusions will result in hypocalcemia, arrhythmias, and even death, so frequent monitoring of unbound serum calcium concentrations is essential.

Other nutrition goals for ARF are patient-specific. It may be necessary to limit fluid intake in severely volume-overloaded patients even though this means restricting parenteral or enteral nutrition. Septic patients with ARF usually are hypercatabolic. The net protein catabolism results in rapidly rising BUN and serum creatinine values. The normalized protein catabolic rate has been reported to be 1.75 g/kg per day, but this value varies widely with each patient.⁶⁹ Most patients with ARF cannot tolerate the amount of fluid required to replace catabolized protein unless they are receiving continuous RRT or daily hemodialysis to remove excess volume.

Another nutritional consideration for patients receiving CRRT is the amount of heat each patient loses from the extracorporeal blood circuit and from receipt of room-temperature intravenous ultrafiltrate replacement solutions. Hypothermia occurs in up to half of all patients who receive CRRT, ostensibly because their body heat is radiated away as blood goes through the CRRT circuit.⁷⁰ The energy loss of continuous hemofiltration has been estimated to be almost 800 kcal/day when blood flow is 120 mL/minute and 23 mL/minute of ultrafiltrate is formed.⁷¹ Most of this heat loss can be attenuated by warming the intravenous ultrafiltrate replacement solution.⁷¹ However, most hospitals are unable to heat intravenous solutions as they are infused, so recognition of this large source of energy loss is necessary for the clinician ordering the nutrition prescription.

■ PUBLISHED GUIDELINES OR TREATMENT PROTOCOLS

Standards for the treatment of patients with CKD have been in place for many years as a result of the National Kidney Foundation's Kidney/Dialysis Outcomes Quality Initiative, begun in 1997. Only

recently has a similar initiative been started for patients with ARF. The ADQI (Acute Dialysis Quality Initiative) was started by a group of interested physicians and is officially endorsed by the American Society of Nephrology and the Society of Critical Care Medicine. The goal of this group is to develop evidence-based treatment recommendations for patients with ARF. Seven areas of practice have

been targeted by ADQI. They are (1) Definitions/Nomenclature; (2) Patient Selection; (3) Solute Control (Treatment Dose); (4) Membranes; (5) Operational Characteristics (Convection/Diffusion); (6) Fluid Management/Composition; and (7) Anticoagulation/Access. As these guidelines are developed, they will be published in nephrology journals and at the ADQI website (www.adqi.net).

PHARMACOKINETIC CONSIDERATIONS

Patients with ARF present some interesting pharmacokinetic challenges. Some of these challenges are obvious by simply looking at the patient. Edema is a common finding in patients with ARF, and this can influence the volume of distribution of many drugs, particularly those with relatively small volumes of distribution and those that are water soluble. CRRT can rapidly remove excess fluid from edematous patients, thereby changing the volume of distribution of these drugs fairly rapidly. A dose that provides the desired serum concentration on one day may be inappropriate only a few days later if the patient’s fluid status changes dramatically. Another readily apparent factor that changes drug dosing is the type of RRT used in the patient. Drug clearances attained by intermittent hemodialysis, CRRTs, and hybrid RRTs all differ from each other and must be added to any endogenous drug clearance that the patient generates.⁵²

A pharmacokinetic change in ARF that is not evident by examining the patient is the change in hepatic drug metabolism and drug transport that occurs. Altered cytochrome P450 enzyme activity has been demonstrated in patients with CKD in many instances.⁷² Patients with ARF likely also have changes in nonrenal clearance of drugs, but controlled studies are difficult to conduct in this population. Evidence suggests that vancomycin⁷³ and imipenem⁷⁴ nonrenal clearances are reduced in patients with ARF compared to normal values. As ARF persists, these nonrenal clearances approach those observed in patients with CKD.^{73–74} The nonrenal clearance of these drugs is less than that of normals but higher than that observed in CKD, consequently imipenem and vancomycin doses in patients with ARF likely should fall somewhere in between the doses recommended for patients with normal renal function and doses recommended for CKD. Application of doses derived from studies in patients with CKD will result in underdosing of these agents.

PHARMACOECONOMIC CONSIDERATIONS

ARF is a large burden on the health care system. Much of this cost is due to the fact that many of these patients are in intensive care units where daily costs are high. It has been estimated that the average total hospital cost of a patient with ARF who requires RRT is approximately \$50,000.⁹ Most patients surviving ARF recover life-sustaining renal function, but the 3% that do not recover renal function² continue to incur the costs of a lifetime of dialysis therapy or kidney transplantation. Nonetheless, even in patients who required RRT for their ARF, the quality of life of survivors has been reported to be good.⁹

Medical intervention costs can be normalized to assess total costs using quality-adjusted life years (QALYs) gained by the intervention. The use of a QALY approach to treatment of critically ill patients with ARF indicates that treating these patients is very expensive relative to other common medical interventions.⁷ For example, using 2001 cost values, the treatment of critically ill ARF patients cost per QALY was \$168,711, compared to treatment of acute myocardial infarction cost per QALY of \$45,000, and the routine treatment of hypertension

cost per QALY of \$31,321.³ A typical cost per QALY of <\$100,000 is considered to be cost effective. While nobody is suggesting that serious ARF not be treated, it is clear that research needs to be done to improve the ARF survival rate to reduce this cost per QALY. Furthermore, it underscores the need to prevent the occurrence of ARF in the first place.

EVALUATION OF THERAPEUTIC OUTCOMES

MONITORING OF THE PHARMACEUTICAL CARE PLAN (INCLUDING SPECIFIC PARAMETERS AND FREQUENCY OF MONITORING)

Vigilant monitoring of patients with ARF is essential, particularly in those who are critically ill (Table 42–8). Once the laboratory-based tests (urinalysis, fractional excretion of sodium calculations, etc.) have been conducted to diagnose the cause of ARF, they usually do not have to be repeated. In established ARF, daily measurements

TABLE 42–8. Key Monitoring Parameters for Patients with Established Acute Renal Failure

| Parameter | Frequency |
|---|---|
| Fluid ins/outs | Every shift |
| Patient weight | Daily |
| Vital signs | Every shift |
| Blood cultures and sensitivities | Check for results daily; obtain more when clinical signs of infection present |
| Blood chemistries | |
| Sodium, potassium, chloride, bicarbonate, calcium, phosphate, magnesium | Daily |
| BUN/S _{cr} | Daily |
| Albumin | Once or twice weekly |
| Complete blood cell count with white cell differential | Daily |
| Drugs and their dosing regimens | Daily |
| Nutritional regimen | Daily |
| Blood glucose | Every shift for critically ill patients |
| Serum concentration data for drugs | After regimen changes and after RRT has been instituted |
| Times of administered doses | Daily |
| Doses relative to administration of RRT | Daily |
| Urinalysis | |
| Calculate measured creatinine clearance | Every time measured urine collection performed |
| Calculate fractional excretion of sodium | Every time measured urine collection performed |
| Plans for renal replacement | Daily |
| Invasive monitoring parameters | As indicated |
| Swan-Ganz readings | Every shift |

of urine output, fluid intake, and weight should be performed. Vital signs should be monitored at least daily, more often if patient acuity of illness is high. Daily blood tests for electrolytes, BUN, and serum creatinine, and a CBC should be considered routine for hospitalized patients. Therapeutic drug monitoring should be performed for drugs that can be measured by the hospital laboratory. If results from these serum drug concentrations cannot be turned around in a timely fashion (<24 h) to the patient's care team, then their value is limited. Therapeutic drug monitoring should be conducted more often in patients with ARF than what is done routinely for other patients because of their dynamic status (changing volume status, changing renal function, and RRTs). Swan-Ganz monitoring should be performed in critically ill patients when feasible. Obviously other laboratory tests should be conducted as the patient's status dictates.

ABBREVIATIONS

ACEI: angiotensin-converting enzyme inhibitor
 ADQI: Acute Dialysis Quality Initiative
 ARF: acute renal failure
 ATN: acute tubular necrosis
 BUN: blood urea nitrogen
 CBC: complete blood cell count
 CHF: congestive heart failure
 CKD: chronic kidney disease
 CRRT: continuous renal replacement therapy
 FE_{Na}: fractional excretion of sodium
 GFR: glomerular filtration rate
 HUS: hemolytic uremic syndrome
 NSAID: nonsteroidal anti-inflammatory drug
 QALY: quality-adjusted life year
 RBC: red blood cell
 RRT: renal replacement therapy
 WBC: white blood cell

CHRONIC KIDNEY DISEASE: PROGRESSION-MODIFYING THERAPIES

Melanie S. Joy, Abhijit Kshirsagar, and James Paparello

Learning Objectives and other resources can be found at www.pharmacotherapyonline.com.

KEY CONCEPTS

- 1 The prevalence of chronic kidney disease (CKD) is estimated at nearly 19 million people in the United States.
- 2 Since the development of CKD is a complex phenomenon, the Kidney Disease Outcomes Quality Initiative (K/DOQI) has recommended categorizing risk factors associated with CKD as susceptibility, initiation, and progression factors.
- 3 The most common initiation risk factors are diabetes mellitus, hypertension, glomerulonephritis, and polycystic kidney disease.
- 4 The most important progression risk factors include proteinuria, uncontrolled blood pressure, and for diabetic patients, glycemic control.
- 5 Reduction of kidney mass, development of glomerular hypertension, and intratubular proteinuria are key mechanisms responsible for the progression of chronic kidney disease.
- 6 CKD is classified into five stages based on the presence of proteinuria and/or glomerular filtration rate, with 1 being the mildest form and 5 being the most severe.
- 7 It is critical to determine the glomerular filtration rate rather than just measuring the serum creatinine, since glomerular filtration is a more consistent marker of renal function in most clinical settings.
- 8 The classic symptoms of stage 5 CKD are asterixis, pruritus, dysgeusia, nausea, vomiting, anorexia, and bleeding.
- 9 Optimization of blood glucose and hypertension control are integral in limiting the rate of CKD progression.
- 10 The cornerstones of pharmacologic treatment to limit progressive kidney disease are angiotensin-converting enzyme inhibitors (ACEIs) and angiotensin receptor blockers (ARBs).
- 11 Diabetic patients with or without hypertension who demonstrate persistent microalbuminuria despite intensive insulin therapy should have their ACEI or ARB dose titrated to achieve maximal suppression of urinary albumin excretion to halt or slow CKD progression.
- 12 Supportive therapies that may help to improve the quality of life and slow the rate of progression of CKD include dietary protein restriction, lipid lowering medications, smoking cessation, and anemia management.

Under normal conditions each of the two million nephrons of the kidney work in an organized approach to filter, reabsorb, and excrete various solutes and water. The kidney is a primary regulator of sodium and water as well as acid-base homeostasis. The kidney also produces hormones necessary for red blood cell synthesis and calcium homeostasis. Impairment of normal kidney function is often referred to as renal insufficiency. Based on the time course of development, renal insufficiency has historically been divided into two broad categories. Acute renal failure (ARF) refers to the rapid loss of renal function over days to weeks. Chronic kidney disease (CKD)^a, also called chronic renal insufficiency (CRI) by some, is defined as a progressive loss of function occurring over several months to years, and is characterized by the gradual replacement of normal kidney architecture with interstitial fibrosis. Progressive kidney disease or nephropathy is

generally synonymous with CKD, and the two phrases are often used interchangeably.

The working group of the National Kidney Foundation's Kidney Dialysis Outcomes and Quality Initiative (K/DOQI) has recently developed a new scheme to classify CKD based on the presence of kidney damage, structural or functional, for ≥ 3 months, with or without decreased glomerular filtration rate (GFR) from normal values of ~ 120 mL/min.¹ CKD is further categorized by the level of kidney function (as defined by GFR) into stages 1 through 5.¹ Although these stages are defined later in this chapter, it is necessary to denote at this point that Stage 5 was previously referred to as end-stage renal disease (ESRD) or end-stage kidney disease (ESKD).

EPIDEMIOLOGY OF CKD

The epidemiology of Stage 5 CKD has been well documented through the efforts of the United States Renal Data System (USRDS), a national data system that collects, analyzes, and distributes information

^aThe Executive Committee of the Kidney Dialysis Outcomes Initiative (KDOQI) has recently recommended that CKD replace chronic renal insufficiency (CRI). CRI does not use the word kidney, and thus may be obtuse/obscure to the lay population.

about ESKD in the United States.² Information on the epidemiology of the earlier stages of CKD is less well characterized. In the United States alone, there are several major epidemiologic studies currently in progress or in development to elucidate the natural history of CKD, its progression, and concurrent morbidities. Another study targets individuals with polycystic kidney disease,³ while another study targets African-Americans with hypertensive nephrosclerosis.⁴ The Chronic Renal Insufficiency Cohort study⁵ and an Amgen-sponsored study (Stride Registry) are investigating progressive CKD and its relationship with comorbid cardiovascular disease. The National Kidney Foundation has recognized the importance of early detection and has initiated the Kidney Early Evaluation Program,⁶ to identify, educate, and provide free screening for people at increased risk of developing kidney disease. Furthermore, U.S. governmental agencies have targeted CKD as one of 28 major focus areas for improvement by the year 2010, as set forth in the Healthy People 2010 document.⁷ Over the next decade, as a result of these initiatives our understanding of the epidemiology, pathophysiology, and management of mild (Stage 1) to moderate (Stage 4) CKD will undoubtedly increase.

CKD has been described as a silent epidemic⁸ and is a worldwide public health problem.⁹ Three different national surveys have estimated that the prevalence of CKD is at least 5% of the adult population when using a serum creatinine concentration of greater than 1.2 to 1.5 mg/dL as the definition.^{10–12} The most representative of these studies, the Third National Health and Nutritional Examination Survey (NHANES III)¹⁰ projected that at least 10.9 million people had a decreased level of kidney function as evidenced by serum creatinine concentration (≥ 1.5 mg/dL). The NHANES III analysis also revealed that the prevalence of CKD was significantly associated with age, race, gender, and hypertension; the prevalence of CKD was higher in those of advanced age, black race, male gender, and a diagnosis of hypertension.

Prevalence estimates were revised upwards in 2002 based on the inclusion of the presence of albuminuria in addition to increased serum creatinine in the definition of CKD, and by incorporating adjustments for age, gender, and race into the calculations of GFR.¹ The working group of K/DOQI estimated that CKD affected 10.9% of the adults (≥ 20 years old) population in the United States. This translates into an astonishing 19 million individuals (Fig. 43–1). Worldwide figures on prevalence are not available, but if one extrapolates the prevalence estimates from the U.S. population to the entire world population, it would exceed 100 million individuals. The prevalence

of CKD is thus similar to that of conditions such as hypertension, diabetes mellitus, and cardiovascular disease. However, financial and societal costs of the care of individuals with CKD, especially those individuals with the latter stages, are disproportionately high. ESKD beneficiaries accounted for 0.5% of the total Medicare population, yet received 5% of all Medicare expenditures.¹³ Annualized expenditures per beneficiary ranged from \$36,000 for those 24 years of age and younger to \$51,000 for those 75 years and older.¹³ These costs for the care of advanced CKD are estimated to increase dramatically over the next decade, reaching an estimated \$28 billion dollars by the year 2010 for Medicare alone.¹⁴

Incidence estimates of CKD have generally been extrapolated from the USRDS.² The four most common medical conditions associated with incident Stage 5 CKD are diabetes mellitus, hypertension, glomerulonephritis, and polycystic kidney disease. The respective incidence rates for these conditions are: 150 cases/million, 80 cases/million, 22 cases/million, and 5 cases/million.² Much like the prevalence data, the estimates of incident Stage 5 cases are also greatly increased in the presence of advanced age and black race.² For example, the rate of Stage 5 CKD is fourfold higher for African-Americans as compared to Caucasians.²

It is often assumed that all early stages of CKD progress continuously towards Stage 5. Thus information on risk factors obtained from USRDS data are assumed to be generalizable to all stages of CKD. The validity of this approach to projecting future incidence data has not been tested. Further complicating these issues is the fact that the development and progression of the early stages of CKD is a complex phenomenon.¹⁵ The risk factors associated with CKD are numerous and varied and many of these are not those one would traditionally consider as having a direct influence on the causal pathway. The working group of K/DOQI has recommended categorizing CKD risk factors as *susceptibility* factors, *initiation* factors, or *progression* factors⁹ to help clinicians stratify the overall risks of individual patients (Table 43–1).⁹

ETIOLOGY

SUSCEPTIBILITY FACTORS

Individuals with susceptibility factors have an increased risk for the development of kidney disease, although these risk factors have not been proven to directly cause kidney damage. These factors include

FIGURE 43–1. Prevalence of CKD by stage among those residing in the United States. Adapted from National Kidney Foundation.¹

TABLE 43–1. Risk Factors Associated with Chronic Kidney Disease

| Risk Factor | Key Studies |
|--|--|
| Susceptibility | |
| • Advanced age | Lindeman et al, ¹⁷ Goetz et al ⁷¹ |
| • Reduced kidney mass and low birth weight | Lackland et al ²⁴ |
| • Racial/ethnic minority | Tierney et al, ²¹ Rostand et al, ²² Perry et al ²³ |
| • Family history | Freedman et al, ²⁵ FIND Research Group ²⁶ |
| • Low income or education | Byrne et al ¹⁹ Perneger et al ²⁰ |
| • Systemic inflammation | Kshirsagar et al, ²⁷ Erlinger et al ²⁸ |
| • Dyslipidemia | Muntner et al ²⁹ Schaeffner et al ³⁰ |
| Initiation | |
| • Diabetes mellitus | Hasslacher et al, ³² Brancati et al, ³⁴ Fabre et al ¹⁶⁸ |
| • Hypertension | Coresh et al, ³⁸ Perneger et al, ³⁹ Klag et al ⁴⁰ |
| • Autoimmune disease | Gabow et al ¹⁶⁹ |
| • Polycystic kidney disease | McLaughlin et al, ¹⁷⁰ Walsh et al ¹⁷¹ |
| • Drug toxicity | |
| Progression | |
| • Glycemia (among diabetic patients) | Reichard et al, ⁶⁰ DCCT Research Group ⁶¹ |
| • Elevated blood pressure | Klahr et al, ⁴⁹ Jafar et al, Bakris, ⁵⁶ UKPDS Group, ⁵⁷ UKPDS Group, ⁵⁸ Bakris ⁵⁹ |
| • Proteinuria | Keane et al, ⁴⁸ Klahr, ⁴⁹ Jafar et al ⁵⁰ |
| • Smoking | Orth et al, ⁶³ Orth et al ⁷² |

sociodemographic risk factors, such as advanced age,^{16–18} low income or education,^{19,20} and racial or ethnic minority status,^{21–23} as well as reduction in kidney mass, low birth weight,²⁴ and family history of CKD.^{25,26} Novel susceptibility factors that have been proposed include systemic inflammation^{27,28} and dyslipidemia.^{29,30} Most of these susceptibility factors are not necessarily modifiable by pharmacologic or lifestyle interventions, but rather help to identify potential populations to target screening programs for the presence of CKD.

INITIATION FACTORS

3 Initiation factors are factors or conditions that directly initiate kidney damage, and are modifiable by pharmacologic therapy. These factors include diabetes mellitus, hypertension, autoimmune diseases, polycystic kidney disease, systemic infections, urinary tract infections, urinary stones, lower urinary tract obstructions, and drug toxicity. Since diabetes mellitus, hypertension, and glomerular diseases are respectively the first, second, and third most common causes for CKD in the U.S., the following discussion focuses on these three conditions.

DIABETES MELLITUS

Individuals with type 1 diabetes mellitus have a 40% lifetime risk of developing CKD,³¹ while individuals with type 2 diabetes mellitus have a 50% lifetime risk.³² Given the greater prevalence of type 2 diabetes mellitus compared to type 1, generally a 10:1 ratio in most countries,³³ the majority of CKD from diabetes would be among individuals with type 2 disease. Importantly, although not all individuals with diabetic nephropathy progress to Stage 5 CKD, the lifetime risk is considerable. A recent prospective study of over 300,000 individuals,

screened from the Multiple Risk Factor Intervention Trial (MRFIT), estimated that approximately 3% of individuals with diabetes mellitus will develop Stage 5 CKD during their life.³⁴ Thus diabetics have a 12-fold greater relative risk of developing Stage 5 CKD than someone without diabetes mellitus. The presence of diabetes mellitus also increased the risk of Stage 5 CKD from nondiabetic causes of renal failure as well, suggesting at least an additive effect of concomitant diseases.

HYPERTENSION

The presence of hypertension also increases the risk of CKD. The data are less clear than with diabetes mellitus because the kidney has a fundamental role in the development and modulation of high blood pressure.^{35–37} The interpretation of epidemiologic studies regarding the presence of high blood pressure and the risk of progressive kidney disease may be limited by reverse causation. Hypertension generally develops concomitantly with progressive kidney disease. For example, at a GFR of 90 mL/min per 1.73m², 40% of individuals have hypertension; at a GFR of 60 mL/min per 1.73 m², 55% have hypertension; and at a GFR of 30 mL/min per 1.73m², over 75% have hypertension.¹ Furthermore, an analysis of the NHANES III survey demonstrated that elevated serum creatinine, defined as ≥ 1.6 mg/dL for men and ≥ 1.4 mg/dL for women, was more common in persons with hypertension (9.1%) than in persons without hypertension (1.1%).³⁸ A landmark prospective study of individuals with normal kidney function at baseline³⁹ showed that elevated levels of blood pressure are a risk factor for the development of early CKD. In another analysis of the MRFIT cohort, the overall lifetime risk of developing Stage 5 CKD for individuals with hypertension was 5.6%.⁴⁰ The risk varied dramatically by level of blood pressure, from 0.33% at stage 1 hypertension (systolic blood pressure 140 to 150 mm Hg and/or diastolic blood pressure 90 to 100 mm Hg) to 4.5% for systolic blood pressure levels greater than 180 mm Hg or diastolic blood pressure levels greater than 110 mm Hg⁴⁰ over a follow-up period of approximately 16 years.

GLOMERULONEPHRITIS

Glomerular diseases are another important category of initiation factors for CKD. The epidemiology and pathophysiology of glomerular diseases are variable and thus all diseases cannot be lumped into one disease category. Some conditions, such as Goodpasture's disease or Wegener's granulomatosis, progress rapidly to stage 5 CKD, and thus may best be categorized as causes of ARF. Other conditions, such as IgA nephropathy, membranous nephropathy, focal segmental glomerulosclerosis, lupus nephritis, and others, are more indolent diseases, and are considered causes of CKD (see Chap. 47). The chronic nephritides progress at variable rates, with the loss of GFR ranging from 1.4 to 9.5 mL/min per year.^{41–44}

PROGRESSION FACTORS

4 Progression risk factors are those that cause a worsening of kidney damage, and are associated with a faster decline in kidney function after initiation of kidney damage. The most important predictors of progressive CKD are the persistence of underlying initiation diseases (e.g., diabetes mellitus, hypertension, glomerulonephritis, and polycystic kidney disease), and the progression factors such as proteinuria, elevated blood pressure, and smoking.

PROTEINURIA

Numerous studies have documented the importance of proteinuria in the progression of both diabetic^{45–48} and nondiabetic^{49,50} kidney disease. These studies are not what one would term primary cohort studies, such as the Atherosclerosis Risk in Communities Study,⁵¹ but rather are secondary analyses of intervention trials. Nevertheless, these studies have provided valuable information. In diabetic kidney disease (types 1 and 2), several studies have demonstrated that an albumin excretion rate >30 mg/24 hours strongly predicted the development of overt nephropathy and subsequent loss of kidney function.^{45–47,52} In nondiabetic kidney disease, the Modification of Diet in Renal Disease (MDRD) study, a landmark trial examining the effect of oral protein restriction on the progression of CKD among individuals with advanced CKD, demonstrated that a patient’s baseline level of proteinuria strongly predicted the loss of GFR.⁴⁹ Furthermore, the level of proteinuria significantly altered the effectiveness of blood pressure control with antihypertensive agents; specifically, individuals with the highest levels of baseline proteinuria benefited the most from reduction of blood pressure. Recently, data from a large cohort of over 1800 individuals with varying stages of CKD demonstrated a strong, graded risk for progressive CKD; each 1.0 g/day increase in urinary protein excretion increased the risk of progression fivefold.⁵⁰ Figure 43–2 shows the relationship between systolic blood pressure and relative risk of CKD progression at proteinuria levels of greater than and less than 1 g/day.⁵³ Interestingly, this cohort included individuals with various primary etiologies of kidney disease, including hypertensive nephrosclerosis, polycystic kidney disease, tubulointerstitial disease, and others. Physiologically, the data demonstrating the role of proteinuria in progressive kidney disease makes sense for conditions associated primarily with glomerular damage, such as diabetes mellitus, and a host of traditional glomerulonephritides. Intuitively, it is not clear why proteinuria should predict progressive loss of renal function in conditions under which the primary pathophysiologic insult is vascular (hypertension) or interstitial (polycystic kidney disease or chronic reflux). It is possible that an unknown secondary insult may trigger the development of proteinuria in these conditions, and then lead to the progressive loss of renal function.

HYPERTENSION

The treatment and control of hypertension can delay the progression of CKD.^{49,50,54–58} Bakris and colleagues demonstrated a direct correlation between the level of achieved blood pressure and preservation of

FIGURE 43–2. Relative risk for kidney disease progression based on current level of systolic blood pressure and current urine protein excretion. From Jafar,⁵³ with permission.

FIGURE 43–3. Rates of decline in glomerular filtration rate (GFR) vs the systolic blood pressure (SBP) in studies extending for 3 years or more in patients with type 2 diabetes mellitus nephropathy. From Bakris,⁵⁹ with permission.

kidney function.⁵⁹ The analysis included 10 studies in which patients were treated with various antihypertensive agents. Each study measured the change in GFR during the study period. Bakris demonstrated an inverse linear relationship between the average attained blood pressure at study completion and average GFR—lower mean arterial blood pressure resulted in a lower average decline in GFR. Thus a systolic blood pressure of 180 mm Hg was associated with a decline in GFR of 14 mL/min per year, whereas a systolic blood pressure of 135 mm Hg was associated with a decline of GFR of only 2 mL/min per year (Fig. 43–3).⁵⁹ Though the analysis was conducted among patients with diabetic kidney disease, the results may be extrapolated to individuals with nondiabetic kidney disease.

DIABETES MELLITUS

Hyperglycemia is another initiation and progression risk factor in CKD. Two large prospective studies that showed the benefits of blood glucose control were reported in the early 1990s,^{60,61} and a few years later two British studies^{54,55} confirmed these results. The 1441 patients with type I diabetes mellitus enrolled in the Diabetes Control and Complications Trial (DCCT) were randomized to conventional blood glucose control or to intensive control. Conventional control consisted of up to two insulin injections per day and no goal hemoglobin A_{1c}. However, intensive control consisted of administration of insulin three or more times daily by injection or by external pump to achieve a hemoglobin A_{1c} ≤6.05%. Roughly half of the patients had mild retinopathy, a marker for microvascular complications, at study entry. Primary prevention was defined as a reduction in new occurrence of retinopathy among patients with no baseline retinopathy, and secondary prevention was defined as a reduction of new cases of retinopathy among individuals with retinopathy. A primary risk reduction of 76% and secondary risk reduction of 54% were noted with intensive control. The intensive therapy was associated with a 39% risk reduction for the development of “microalbuminuria” (urinary albumin excretion ≥40 mg/day), and a 54% reduction in the development of “frank albuminuria” (urinary albumin excretion ≥300 mg/day) compared to conventional therapy.

SMOKING

Multiple studies support a relationship between smoking and the initiation and progression of CKD in those with type 1 and type 2 diabetes.^{62–64} Smoking has been suggested to increase the rate of progression in type 1 and type 2 diabetes by approximately twofold.⁶⁵ In diabetics, “cigarette pack years” was an independent predictive factor for progression.⁶⁶ Smoking has also been associated with renal

insufficiency in a study of severe essential hypertension⁶⁷ and in African-American patients with hypertension.⁶⁸ A few prospective studies have demonstrated an association between smoking and microalbuminuria and the development of stage 5 CKD.^{69–71} Smoking has also been identified as a risk factor for progression in patients with IgA nephropathy, polycystic kidney disease, and systemic lupus erythematosus.^{72,73}

HYPERLIPIDEMIA

Although the data are not conclusive, hyperlipidemia has been associated as a susceptibility factor for CKD in both animal and human studies.⁷⁴ The use of lipid-lowering agents in some animal models has been found to decrease the extent of glomerular injury when both underlying renal disease and hyperlipidemia are present.⁷⁵ Therefore the correction of lipid abnormalities in patients with CKD was proposed to have a beneficial effect on the rate of progression of the disease. CKD with or without nephrotic syndrome is frequently accompanied by abnormalities in lipoprotein metabolism. The prevalence of hyperlipidemia appears to increase as kidney function declines and with the presence of the nephrotic syndrome.⁷⁶

In patients with renal insufficiency and urinary protein excretion greater than 3 g/day, the major lipid abnormalities are elevations of plasma total and low density lipoprotein cholesterol (prevalence 85% to 90%), with approximately 50% of patients experiencing a low level (<35 mg/dL) of high density lipoprotein (HDL) cholesterol, and 60% of patients showing triglyceride concentrations greater than 200 mg/dL.⁷⁶

PATHOPHYSIOLOGY

5 The various etiologic factors actually damage the kidney in a heterogeneous manner. For example, the key structural lesion in dia-

betic nephropathy is glomerular mesangial expansion. In hypertensive nephrosclerosis, it is hyalinosis of the kidney's arterioles, and in polycystic kidney disease it is the development and growth of renal cysts. A variety of morphologic glomerular changes have been noted to occur, depending on the primary diagnosis of the glomerulonephritis.

The majority of progressive nephropathies share a final common pathway to irreversible renal parenchymal damage and ESKD^{77,78} (Fig. 43–4). The key elements of this pathway are: (1) loss of nephron mass; (2) glomerular capillary hypertension; and (3) proteinuria.

The presence of or exposure to the initiation risk factors results in loss of nephron mass. The remaining nephrons hypertrophy to compensate for the loss of renal function and nephron mass.⁷⁹ Initially this compensatory hypertrophy may be adaptive. Yet over time the hypertrophy often becomes maladaptive and leads to the development of glomerular hypertension, possibly mediated by angiotensin II.^{80,81} Angiotensin II, a potent vasoconstrictor of both the afferent and efferent arterioles, preferentially affects the efferent arterioles, leading to increased pressure within the glomerular capillaries. The development of intraglomerular hypertension generally correlates with the development of systemic arterial hypertension. Animal studies have demonstrated that high intraglomerular capillary pressure impairs the size-selective function of the glomerular permeability barrier, and results in albuminuria and proteinuria.^{82,83}

The resultant proteinuria is thought to accelerate the progressive loss of nephrons due to direct cellular damage. The filtered proteins consist of albumin, transferrin, complement factors, immunoglobulins, cytokines, and angiotensin II, which have varying molecular weights. Numerous studies have demonstrated that the presence of these proteins in the renal tubule activate tubular cells which leads to the upregulated production of inflammatory and vasoactive cytokines, such as endothelin, monocyte chemoattractant protein (MCP-1), and RANTES (regulated upon activation, normal T-cell expressed and secreted).^{77,84–87} Accumulating evidence now suggests

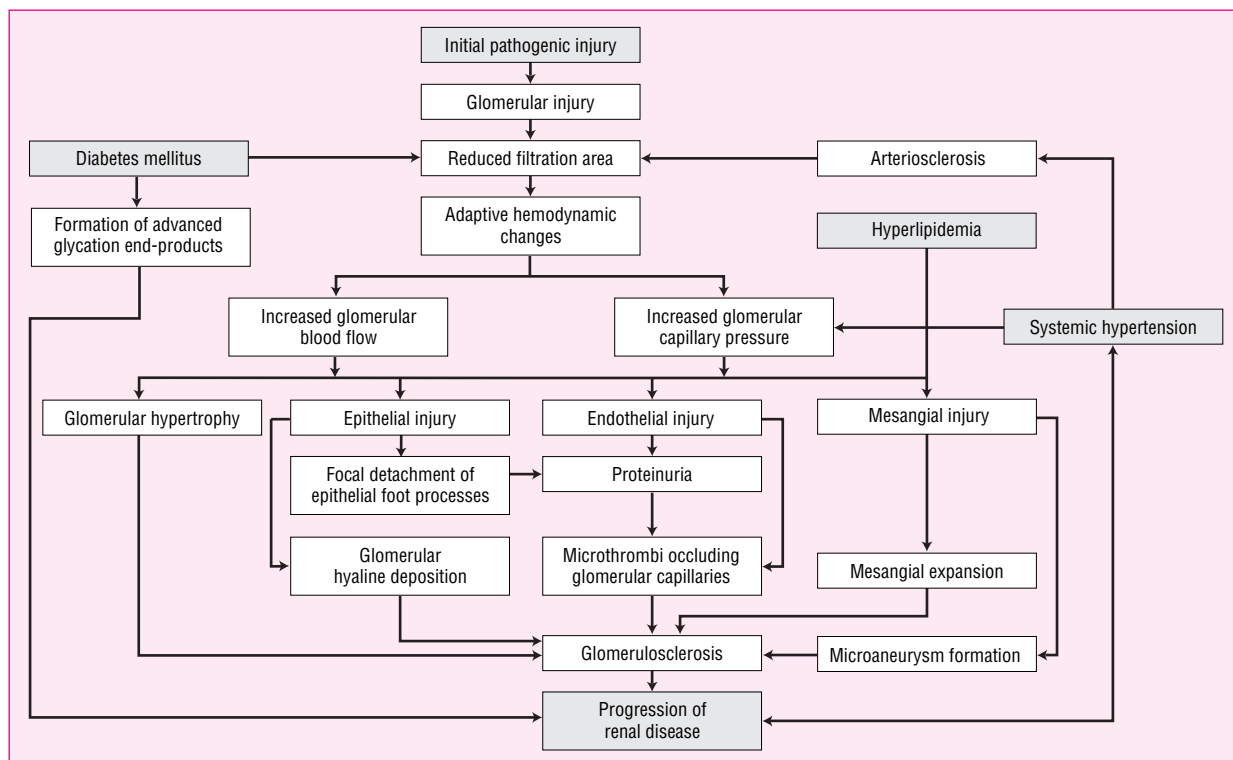

FIGURE 43–4. Proposed mechanisms for progression of renal disease.

that intratubular complement activation may be the key mechanism of damage in the progressive proteinuric nephropathies.^{88–90} Proteinuria is associated with the activation of complement components on the apical membrane of proximal tubules.⁹¹ These events eventually lead to scarring of the interstitium, and the progressive loss of structural nephron units, and ultimately function (reduced GFR).

ASSESSMENT FOR CKD

As CKD presentation is often asymptomatic, recommended screening studies include serum creatinine measurement, urinalysis, and/or imaging studies of the kidneys. Diabetes, hypertension, genitourinary abnormalities, and autoimmune diseases represent some of the more common conditions associated with kidney disease. People who are older or those who have a family history of kidney disease should also be screened. If the serum creatinine is elevated, or more appropriately the GFR decreases, or if there are abnormalities in the urinalysis or imaging studies, an evaluation for CKD should be performed.¹

6 The rate of loss of GFR is difficult to assign to each case of progressive CKD, as this can vary by treatment responsiveness, compliance with therapies, and the underlying disease process. Recognizing the variable course of CKD and the need to denote the particular stage of the disease, the K/DOQI classification system was developed. The classification system divides CKD into five stages, with each increasing number indicating a more advanced stage of the disease, as defined by a declining GFR¹ (Table 43–2). Although the stages are defined functionally by the GFR, the classification system also accounts for structural evidence of kidney damage. The use of GFR versus serum creatinine to define the stages of CKD was chosen since the serum creatinine is an inaccurate index of GFR, and there is marked variability in GFR between subjects with similar serum creatinine values (see Chap. 41). A patient can be diagnosed with CKD despite a GFR of >90 mL/min per 1.73m^2 if there is evidence of structural damage to the kidneys.

Proteinuria was selected as the main structural marker of kidney damage since there were more studies assessing this marker than others, and it could thus be used in the evidence-based assessment.¹ Proteinuria indicates structural renal damage, even in the setting of a normal GFR. The K/DOQI working group defined clinically significant proteinuria as greater than 300 mg of protein excretion per day. Assessment by a spot urine dipstick or urine:creatinine ratio is significant for proteinuria when the former is >30 mg/dL and the latter is >200 mg/g.¹ Microalbuminuria was defined as 30 to 300 mg

TABLE 43–2. Definition and Prevalance of the Stages of Chronic Kidney Disease

| Stage | Glomerular Filtration Rate in mL/min per 1.73m^2 Body Surface Area | Prevalence ^b |
|-------|---|-------------------------|
| 1 | $\geq 90^a$ | 10,500,000 |
| 2 | 60–89 | 7,100,000 |
| 3 | 30–59 | 7,600,000 |
| 4 | 15–29 | 400,000 |
| 5 | <15 (includes patients on dialysis) | 300,000 |

^aChronic kidney disease can be present with a normal or near normal GFR if other markers of kidney disease are present, such as proteinuria, hematuria, biopsy results showing kidney damage, or anatomic abnormalities (e.g., cysts).

^bBased on measurement of an elevated albumin to creatinine ratio.

of albumin in a 24-hour urine collection. Assessment by a spot urine dipstick or urine:creatinine ratio is significant for microalbuminuria when the former is >3 mg/dL and the latter is between 17 and 250 mg/g and 25 to 355 mg/g for men and women, respectively.¹ The spot protein/albumin:creatinine ratio on a random urine sample (preferably a morning sample) allows a clinician to easily screen for microalbuminuria or proteinuria without the cumbersome process of having the patient collect a 24-hour urine collection. Table 43–3 summarizes the clinical tools that are available to detect and interpret protein in the urine. Renal biopsy and/or ultrasound are common assessment tools for specific or gross structural abnormalities associated with kidney dysfunction. Structural abnormalities of the kidney can also be evidenced by pathologic abnormalities in biopsy specimens, abnormal imaging studies, or abnormalities in the urine sediment, such as hematuria.¹ Representative examples of kidney damage found on biopsy from patients with hypertension and diabetes mellitus are depicted in Fig. 43–5.

CLINICAL PRESENTATION OF CHRONIC KIDNEY DISEASE

GENERAL

CKD development and progression is typically insidious in onset, often with the absence of any noticeable symptoms. At a minimum, the diagnosis of CKD requires measurement of serum creatinine, calculation of GFR and assessment of a urinalysis for urinary microalbumin or total protein. The diagnosis of Stages 3, 4, and 5 CKD requires the work-up for other common complications including anemia, cardiovascular risks, metabolic bone disease, malnutrition, and disorders of fluids and electrolytes.

SYMPTOMS

Symptoms are generally absent in CKD Stages 1 and 2, and may be minimal during Stages 3 and 4. Classic symptoms associated with Stage 5 CKD include pruritus, dysgeusia, nausea, vomiting, and bleeding abnormalities. Symptoms associated with anemia include cold intolerance, shortness of breath, and fatigue. The severity of symptoms is related to the rate of anemia development and the degree of hemoglobin reduction.

SIGNS

Cardiovascular: Left ventricular hypertrophy, congestive heart failure, hyperhomocysteinemia, dyslipidemia, palpitations, arrhythmias, electrocardiographic changes, elevated creatine kinase-myocardial bound (CK-MB) and creatine kinase (CK), worsening hypertension, and edema.

Musculoskeletal: Cramping and muscle pain.

Neuropsychiatric: Depression, anxiety, impaired mental cognition, fatigue, and sexual dysfunction.

Gastrointestinal: Gastroesophageal reflux disease, constipation, GI bleeding, nausea, and vomiting.

LABORATORY TESTS

Normal or abnormal GFR with or without documented renal structural abnormalities; presence of urinary albumin or protein; and pathologic assessment of kidney tissue.

Endocrine: Increased sensitivity to insulin, secondary hyperparathyroidism, decreased vitamin D activation, β_2 -microglobulin deposition, and gout.

Hematologic: Anemia, iron deficiency, and bleeding.

TABLE 43-3. Quantification of Proteinuria by Various Methods

| Category | 24-Hour Collection | Spot Collection: Protein: Creatinine Ratio | Spot Collection: Albumin: Creatinine Ratio | Timed Collection |
|-------------------------------------|---|--|--|---|
| | Unit: Milligrams of Protein or Albumin (per 24-Hour Period) | Unit: Milligrams of Protein per Gram of Creatinine | Unit: Micrograms of Albumin per Milligram of Creatinine ^a | Unit: Micrograms of Protein per Minute ^b |
| Normal | <300 mg/day protein or <30 mg/day albumin | <200 mg/g | <30 mcg/mg | <20 mcg/min |
| Microalbuminuria | 30–300 mg/day (of albumin) | Not applicable | 30–299 mcg/mg | 20–199 mcg/min |
| Clinical proteinuria or albuminuria | ≥300 mg/day of protein or albumin | >200 mg/g | ≥300 mcg/mg | ≥200 mcg/min |

^aMicrograms of albumin per milligram of creatinine is equal, as a ratio, to milligrams of albumin per gram of creatinine. The National Kidney Foundation recommendations cite gender differences for values of spot albumin:creatinine ratios that are not included here.

^bIf one converts the rate of micrograms per minute to milligrams per day by multiplying by 1440 minutes in a day, the values obtained are very near those listed under the 24-hour collection column of milligrams per day of albumin, as expected.

B

FIGURE 43-5. **A.** Advanced hypertensive arterionephrosclerosis with global sclerosis of a glomerulus on the left and marked sclerosis in the wall of an artery on the upper right. In the background is interstitial fibrosis, tubular atrophy, and chronic inflammation (PAS stain) **B.** Active (left) and advanced (right) glomerular injury caused by diabetic glomerulosclerosis. The glomerulus on the left shows marked increase in mesangial collagenous matrix, resulting in nodule formation. The glomerulus on the right shows advanced global sclerosis that has obliterated most normal glomerular structures. (PAS stain)

FIGURE 43-6. Staging of CKD.

7 Patients with Stage 1 or 2 kidney disease usually do not have any symptoms, and metabolic derangements such as acidosis, anemia, and bone disease are rarely present. Impairment of kidney function may not be recognized in the early stages of CKD, since in addition to the patient being asymptomatic, there is a lack of concomitant complications from the mildly decreased GFR, and the serum creatinine may be only slightly elevated.

8 The development and early stages of CKD is often clinically silent, and is usually not routinely detected unless the clinician is prudently evaluating for its presence. The classic symptoms of kidney failure are asterixis, pruritus, dysgeusia, nausea, vomiting, anorexia, encephalopathy, and bleeding. Many of these symptoms only appear when the patient has Stage 4 or 5 disease (see Chap. 44) and are therefore not useful in detecting CKD in the earlier stages (Fig. 43-6).

Signs and symptoms associated with CKD become more prevalent in Stages 3, 4, and 5. Anemia, abnormalities of calcium and phosphorus metabolism (and therefore secondary hyperparathyroidism), malnutrition, and fluid and electrolyte abnormalities become more common as kidney function deteriorates (see Chap. 44).

ANEMIA

The kidneys are responsible for secreting 90% of the endogenous hormone erythropoietin, and hence declining kidney function can lead to a reduction in the serum concentration. The consequence of reduced erythropoietin is the development of anemia. The prevalence of anemia at specific stages of CKD is difficult to ascertain, as there are limited data available correlating GFR to anemia, and there are various definitions that are used.¹ Although anemia can appear early in CKD, its prevalence has been estimated to be between 1% and 30% if anemia is defined as a hemoglobin of <12 g/dL in patients with a GFR of >80 mL/min per 1.73 m².⁹² The true prevalence rate estimation is further complicated by the fact that covariates such as ethnicity, age, and gender can also contribute. Anemia, when defined by a hemoglobin of <13 g/dL, was found to increase in prevalence at Stage 3 CKD and become even more prevalent into Stages 4 and 5.¹ Anemia can lead to

symptoms of fatigue, decreased energy level, and shortness of breath. However, mild anemia, especially when present for a prolonged time period, can be asymptomatic. The K/DOQI guidelines recommend evaluating hemoglobin levels in all patients with CKD, noting the increase in anemia prevalence beginning with Stage 3.⁹³ The treatment of anemia can improve or resolve symptoms and may help to stabilize kidney function.⁹⁴ The management of anemia in CKD is discussed in Chap. 44.

CARDIOVASCULAR DISEASE

Monitoring for the presence or development of cardiovascular disease in patients with CKD is of utmost importance due to the recognized high rate of cardiovascular morbidity and mortality in these patients. Patients with CKD have been found to have 16% to 37% of the life expectancy of a matched population without kidney disease.⁹⁵ It has been suggested that a higher proportion of patients with Stages 3 and 4 CKD will actually die from cardiovascular causes than will progress to requiring dialysis therapy. Appropriate traditional and nontraditional cardiovascular risk factor assessments are necessary in the evaluation of the patient with CKD. Guidelines concerning evaluation, monitoring, and treatment for cardiovascular diseases in patients with CKD are currently being written.

METABOLIC BONE DISEASE

There is a high prevalence of abnormalities in calcium and phosphorus metabolism in Stage 5 CKD. However, since these abnormalities can and do occur in Stages 3 and 4, the clinician should monitor all patients. It is often unrecognized that secondary hyperparathyroidism can develop despite normal serum calcium and phosphorus levels, when the GFR is 80 mL/min per 1.73 m² or below.⁹⁶ Thus the clinician should not overlook the possibility of an elevated parathyroid hormone concentration. The calcium, phosphorus, and parathyroid hormone should be evaluated beginning in Stage 3 to evaluate for secondary hyperparathyroidism and serve to limit the manifestations on bone.⁹⁷ Additional systemic benefits such as cardiovascular risk reduction are currently being evaluated. The management of bone disease due to CKD is discussed in Chap. 44.

MALNUTRITION

Anorexia and malnutrition are complications of CKD. Although there are limited data defining at exactly which stage malnutrition develops, the K/DOQI guidelines recommend evaluating for signs of malnutrition when the GFR is <60 mL/min per 1.73 m² (Stages 3, 4, and 5).⁹⁸ An investigation for malnutrition should include a dietary assessment for protein and calorie intake, serum albumin, and/or assessment of protein appearance in the urine (as a marker of protein intake). Proper nutritional counseling in CKD can prevent malnutrition from occurring as patients approach dialysis (Stage 5).¹

FLUID AND ELECTROLYTE DISORDERS

Elevations in sodium and potassium often are associated with Stages 4 and 5 CKD (see Chaps. 49 and 50). Disturbances in volume management due to CKD often occur in those with reduced levels of GFR or if structural damage is present. Other than in nephrotic syndrome, the fluid and electrolyte abnormalities of CKD can occur gradually and therefore without symptoms. Similarly to the other complications of CKD, clinicians must be aware that derangements in volume

and electrolytes can occur at any stage of the disease process. Clinicians should evaluate for electrolyte abnormalities at regular intervals, with the frequency dictated by the stage of CKD and history of these abnormalities. It is common for clinicians to eval-

uate Stage 3 and 4 CKD patients every 3 to 4 months and Stage 5 patients every 1 to 2 months. Evaluation should include an adequate patient history in order to assess for shortness of breath or edema, signs of crackles on lung exam, and increased jugular venous pressure.

► TREATMENT: Diabetic Chronic Kidney Disease

■ DESIRED OUTCOME

The primary goal is to increase the identification of patients at risk so that appropriate interventions can be initiated early in the course of the disease. Nonpharmacologic and pharmacologic interventions are available to slow or halt the rate of CKD progression and thereby decrease the incidence and prevalence of ESKD.

■ NONPHARMACOLOGIC THERAPY

■ DIETARY PROTEIN RESTRICTION

Studies in animals with experimental kidney disease, over 20 years ago suggested that dietary protein restriction may result on a reduction in the rate of progression of renal function decline.⁹⁹ Various deleterious effects of proteinuria on the kidney have been suggested, including damage to the filtration barrier, and increased delivery of iron, complement, and lipids to the tubules. Patients with nephrotic syndrome are likely at high risk for protein-associated kidney damage due to the higher protein content in the filtered urine secondary to glomerular structural damage. The MDRD study was a large, randomized controlled study that showed a benefit to dietary protein restriction.^{49,100} The MDRD study included no type 1 diabetics, and only a few type 2 diabetics who were not receiving insulin. Subjects who were defined as having moderate renal insufficiency (GFR of 25 to 55 mL/min per 1.73 m²) were randomized into one of four groups stratified by a goal dietary protein intake and mean arterial blood pressure (MAP): usual or low-protein diet (1.3 g/kg per day vs. 0.58 g/kg per day) and usual or low MAP goal (107 mm Hg vs. 92 mm Hg). Subjects who were defined as having severe renal insufficiency (GFR 13 to 24 mL/min per 1.73 m²) were also randomized to one of four groups: a low-protein diet (0.58/kg/day) or a very-low-protein diet (0.28 g/kg/day), along with a keto-amino acid supplement with a usual or low MAP goal as defined above. Follow-up measurements included monthly 24-hour urea excretion and blood pressure measurements, dietary records every 3 months, and GFR at months 2, 4, and then every 4 months for the 2- to 3-year study period. Although protein restriction failed to show a statistical benefit after 3 years of follow-up in any of the groups, these results are complicated by the fact that 24% of the subjects had a diagnosis of polycystic kidney disease (a disease that is not glomerular in origin), which may have reduced the ability to see the benefit of dietary protein and blood pressure interventions (interventions hypothesized to result from alterations at the level of the glomerulus).

In order to define the association between dietary protein restriction and CKD progression, two meta-analyses (comprised of several smaller studies) evaluated the effect of dietary protein restriction in diabetic and nondiabetic kidney diseases.^{101,102} The larger study, comprising over 1000 patients (who were predominantly nondiabetic) from 13 randomized controlled trials, found a weak association between dietary protein restriction and reduction in the rate of kidney disease progression.¹⁰² An analysis of the diabetic group from this

study and the diabetic population from the meta-analysis by Pedrini and associates, showed a greater benefit from dietary protein restriction.¹⁰¹ The level of protein restriction ranged from 0.5 to 0.85 g/kg per day in the meta-analysis comprised of diabetics.¹⁰¹ These data suggest a preferential benefit from dietary protein restriction in the diabetic patient population. One recent study employing nutrition counseling in diabetics suggested that patients are generally noncompliant to long-term low-protein diets outside of a regimented study design, and thus this intervention is not likely to be effective long term.¹⁰³

The National Kidney Foundation's K/DOQI guidelines for nutrition in patients with CKD recommend a dietary protein intake of 0.6 g/kg per day for patients with a GFR <25 mL/min.⁹⁸ Titration of protein intake up to 0.75 g/kg per day is suggested for patients who cannot achieve or maintain adequate nutritional status with the lower-protein (0.6 g/kg per day) diet.⁹⁸

■ PHARMACOLOGIC THERAPY

■ Intensive Insulin Therapy

9 The Diabetes Control and Complications Trial (DCCT) is considered to be the landmark study showing the positive long-term benefits of intensive insulin therapy (IIT).⁶¹ IIT was defined as the administration of insulin three or more times daily by injection or by external pump to achieve preprandial and postprandial blood glucose values of 70 to 120 mg/dL and <180 mg/dL, respectively. IIT reduced the incidence of microalbuminuria and albuminuria as compared to standard therapy in both the primary prevention and secondary prevention groups, as described previously.⁶¹ However, IIT was associated with a higher incidence of hypoglycemic reactions (at least one episode of hypoglycemia in 65% of patients, as compared to 35% in the standard treatment group).⁶¹ The positive renal outcomes from this trial may be difficult to reproduce in routine clinical practice since many poorly controlled type 1 diabetic patients may be reluctant to comply with IIT because they fear the risk of hypoglycemia.¹⁰⁴

A meta-analysis of 16 clinical studies showed a benefit of intensive blood glucose control in patients with type 1 diabetes as evidenced by a reduction in the frequency, severity, and a delay in the development or progression of diabetic complications including nephropathy.¹⁰⁵ The Epidemiology of Diabetes Interventions and Complications study, which observed the DCCT subjects for an additional 4 years while they were receiving care from primary physicians, showed a continued benefit of IIT on the risk of nephropathy as defined by the development of microalbuminuria (53% odds ratio reduction in microalbuminuria).¹⁰⁶

■ Optimize Hypertension Control

The Seventh Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure recommends a goal blood pressure of <130/85 mm Hg for patients with kidney

disease and <125/75 mm Hg in patients who have proteinuria.¹⁰⁷ Although these are the goals set forth by the Joint National Committee, any reduction in blood pressure may be deemed beneficial. The UK Prospective Diabetes Study revealed that tight blood pressure control (with captopril or atenolol) to 144/82 mm Hg versus 154/87 mm Hg in the other group conferred reductions of 24% in diabetes-related end points, 32% in deaths related to diabetes, 44% in strokes, and 37% in microvascular end points.⁵⁷ The effect of a rigorous blood pressure goal (MAP of ≤ 92 mm Hg) on proteinuria and progression of kidney disease in type 1 diabetics leads to a decrease in proteinuria.¹⁰⁸ To achieve these goal blood pressures, three or more different blood pressure medications are likely to be required.¹⁰⁹ Figure 43–7 depicts the proposed algorithm for the management of hypertension in people with CKD and diabetes. Chapter 13 reviews the individual agents and proposed doses for optimal management of hypertension.

Elevated blood pressure is more difficult to control in patients with CKD than those with normal kidney function. Patients diagnosed

with both hypertension and diabetes mellitus have been estimated to have up to a sixfold higher risk of developing ESKD than do those patients with diabetes mellitus alone.¹⁰⁹ Adequate blood pressure control can reduce the rate of decline in GFR and the degree of albuminuria in hypertensive type 1 or type 2 diabetics.¹⁰⁹ Although interventions that reduce blood pressure have historically shown reductions in urinary albumin and protein excretion, the angiotensin-converting enzyme inhibitors (ACEIs) were the first agents shown to reduce glomerular capillary pressure and volume, which in animal models and human studies have resulted in preservation of renal function.^{110–112} Table 43–4 summarizes the documented effects of the various available antihypertensive agents on renal blood flow and GFR.^{113,114}

Several studies have confirmed the beneficial effects of ACEIs on renal function in diabetics as well as nondiabetics. The results of the key (>100 evaluated subjects) studies in diabetics are presented in Table 43–5.^{115–121} These studies were conducted over a time frame of 2 to 6 years and thus were likely long enough in duration to

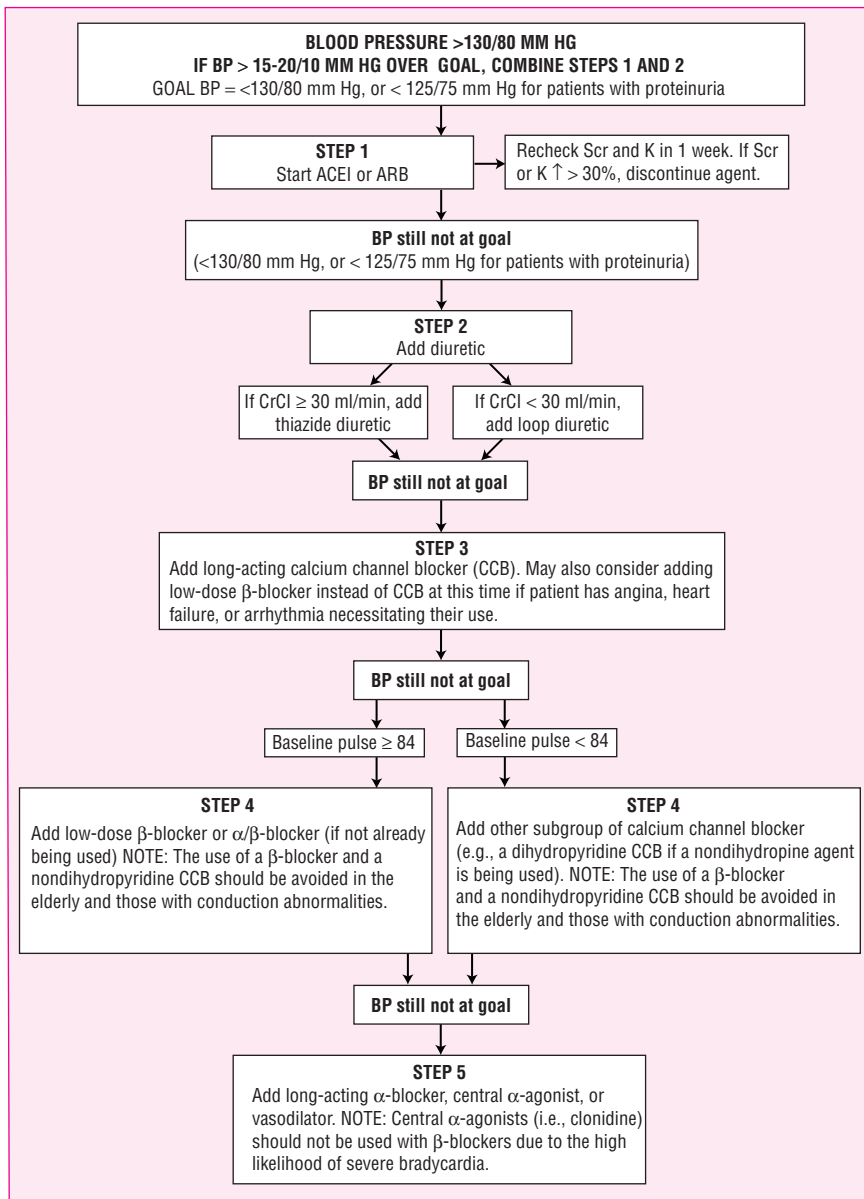

FIGURE 43–7. Hypertension management algorithm for patients with CKD. Dosage adjustments should be made every 2 to 4 weeks as needed. The dose of one agent should be maximized before another is added. Adapted from Bakris,¹⁰⁹ with permission.

TABLE 43–4. Effects of Antihypertensive Agents on Renal Blood Flow (RBF) and Glomerular Filtration Rate (GFR)

| Antihypertensive Agent | Mechanism of Action | Effects on Renal Hemodynamics |
|---|---|--|
| Diuretics | Sodium and volume depletion ↑Vasodilatory prostaglandin levels (IV loop diuretics) Renal vasoconstriction (IV thiazide diuretics) | Decrease in GFR and RBF Increase in RBF |
| β-Adrenergic blockers | ↓ Cardiac output ↑ Renal vascular resistance (nonselective agents) ↓ Renal vascular resistance (β ₁ -selective agents) | Decrease in GFR and RBF Decrease in GFR and RBF No change in GFR and RBF |
| Centrally acting antiadrenergic drugs | ↓ Renal vascular resistance (methyldopa) ↓ Renal perfusion pressure (clonidine, α ₂ -adrenergic agonist) | No change in GFR and RBF Decrease in GFR and RBF |
| Peripherally acting antiadrenergic drugs | Direct vasodilation (postsynaptic α ₁ -adrenoreceptor blocking agents) | No change in GFR and RBF |
| Direct vasodilator agents | ↓ Renal vascular resistance (hydralazine, minoxidil) Arterial vasodilation plus dilatation of venous capacitance vessels (nitroprusside) | Increase in RBF and no effect on GFR Decrease in GFR and RBF (acute effect) |
| Angiotensin-converting enzyme inhibitors/angiotensin-II receptor blockers | Dilation of the efferent arteriole | Decrease in GFR and no change in RBF |
| Calcium channel blockers | ↓ Renal vascular resistance by vasodilation of afferent arterioles (hypertensive patients) | Increase in RBF and no change in GFR |

TABLE 43–5. Summary of Angiotensin-Converting Enzyme Inhibitor Studies in Diabetic Patients

| Drug, Dose and Study Design | Baseline Renal Characteristics | Number of Subjects and Disease | Study Duration | Outcome | Reference and Study Name |
|--|---|--------------------------------|----------------|--|--|
| Captopril 25 mg three times a day; randomized, placebo-controlled trial | UPE ≥ 500 mg/day, S _{Cr} ≤ 2.5 mg/dL | 409 Type 1 DM | 3 years | Risk reduction of doubling S _{Cr} was 48% with captopril treatment; subanalysis showed a larger risk reduction with more elevated S _{Cr} (76% when the S _{Cr} was 2 g/dL) | Lewis et al ¹¹⁵ |
| Enalapril once daily; randomized, placebo-controlled trial | Normotensive, UAE 20–200 mcg/min | 103 Type 2 DM | 5 years | Risk reduction of 66.7% for progression to clinical albuminuria with enalapril | Ahmad et al ¹¹⁶ |
| Enalapril 10 mg once daily; randomized, placebo-controlled trial | Normotensive, UAE ≤ 30 mg/day | 156 Type 2 DM | 6 years | Risk reduction of 12.5% for microalbuminuria with enalapril treatment; GFR reductions were two times greater in the placebo treated patients at 6 years. | Ravid et al ¹¹⁷ |
| Lisinopril 10 mg once daily with titration to BP; placebo-controlled trial | Normotensive patients either normoalbuminuria or microalbuminuria | 530 Type 1 DM | 2 years | 18.8% lower UPE with lisinopril treatment; greater treatment effect in those with baseline microalbuminuria (34.2 mcg/min vs. 1 mcg/min) | EUCLID Study Group ¹¹⁸ |
| Ramipril 10 mg once daily; randomized, placebo-controlled trial | Normoalbuminuria or microalbuminuria | 3577 Type 2 DM | 4.5 years | Ramipril lowered risk of overt nephropathy with and without baseline microalbuminuria (relative risk of 0.8); lower UP:Cr at 1 and 4.5 years with ramipril treatment | HOPE and MICROHOPE ¹¹⁹ |
| Captopril 50 mg twice a day; randomized, placebo-controlled trial | Normotensive patients with microalbuminuria | 143 Type 1 DM | 2 years | Risk reduction of 67.8% for clinical proteinuria with captopril treatment; GFR reductions of 7.9 mL/min per 1.73 m ² per year in placebo while stable in captopril group | North American Microalbuminuria Study Group ¹²⁰ |
| Enalapril 5 mg once daily, titrated to BP; placebo-controlled trial | Hypertensive, GFR of 30–100 mL/min per 1.73 m ² | 121 Type 2 DM | 3 years | Clinical albuminuria progression in 7% of enalapril vs. 21% of placebo group; enalapril therapy preserved GFR, while placebo treatment resulted in a loss of 0.33 mL/min per 1.73 m ² per month | Lebovitz et al ¹²¹ |

adequately assess the proposed outcomes. Various ACEIs and dosages were assessed in both type 1 and type 2 diabetic subjects. Patients with various severity levels of nephropathy were represented, from normoalbuminuria with risk of renal function decline to patients with severe levels of albuminuria/proteinuria and reductions in GFR. The outcomes consistently support the role of ACEI therapy in the management of CKD.

10 The results of a meta-analysis serves to confirm the beneficial effects demonstrated in several of the small and large randomized controlled studies that evaluated the effects of ACEI therapy on diabetic nephropathy. Progression to proteinuria was reduced by 65% in patients with diabetes mellitus and microalbuminuria, and progression of nephropathy (doubling of serum creatinine) was reduced by 40% in patients with overt proteinuria (comprised of 30% diabetics and 70% nondiabetics) (Fig. 43–8).¹²² The meta-analysis, in addition to the available single studies, provide strong support for the use of ACEIs in diabetic patients with or without hypertension.

11 Although a variety of individual ACEIs and doses have been evaluated, there is no consensus regarding the optimal agent, or the starting or maximum dosages to achieve optimal levels of proteinuria reduction. The reason for this lack of consensus is due to the design of the studies, whereby there was assessment of only one ACEI versus a placebo and fixed doses were generally administered. Hence comparative information between the individual ACEIs or variations in proteinuric response relative to dosage titration is sparse. The meta-

analysis referred to previously, however, demonstrated homogeneity among the ACEIs that were included, suggesting that no one agent is superior to the other agents.¹²² In patients with hypertension, the primary goal is to optimally treat the blood pressure to target, and the secondary goal is to minimize proteinuria. For normotensive patients with microalbuminuria, one should titrate the ACEI to reduce the microalbuminuria. The hypertensive ceiling effect noted for ACEI therapy and dosage titration has not been confirmed for treatment to lower urinary protein restriction. However, patients with hypertension and proteinuria can still exhibit side effects associated with blood pressure lowering, and hence dosages should be titrated to the maximal level of proteinuria reduction without reducing the blood pressure to a level associated with adverse events. Patients should be initiated on the lowest possible dose of ACEI and titrated to blood pressure control and proteinuria reduction.

The angiotensin II receptor blockers (ARBs) have been investigated and show favorable results in slowing the progression of diabetic kidney disease. Data from several studies (that included at least 100 patients) evaluating ARB efficacy in type 2 diabetes are summarized in Table 43–6.^{123–126} All patients in these trials had at least a level of proteinuria consistent with microalbuminuria and all were hypertensive. With the exception of one, the studies were of a sufficiently long enough duration to determine the beneficial effects of ARBs on nephropathy. Of note, the beneficial effect of actually delaying the onset of diabetic nephropathy was significant in type 2 patients who received irbesartan 300 mg daily for up to 2 years.¹²⁴ A similar trend (although not statistically significant) was observed in those subjects who received a lower dose of irbesartan (150 mg daily). Although renal benefits of ARBs have been observed in these type 2 diabetic subjects, no differences in death between losartan and placebo-treated subjects were shown. The ELITE study (which assessed losartan versus captopril in diabetics and nondiabetics) showed comparable renal benefits of both ARBs and ACEIs in a population of heart failure patients.¹²⁷ Currently, the data show efficacy of both ACEIs and ARBs in type 2 diabetes, while only ACEIs have been adequately evaluated in patients with type 1 diabetes. Thus, until head-to-head trials with these agents are assessed, they should not be considered interchangeable in all forms of diabetes.¹²⁸

Since ACEIs and ARBs have demonstrated efficacy in patients with diabetes, the possibility of using both agents in type 2 diabetics has been investigated.¹²⁹ This short-term (12 to 24 weeks) study evaluated lisinopril (20 mg once daily) and candesartan (16 mg once daily) versus the combination in 199 patients. The reduction of urinary albumin:creatinine ratios were greater with combination therapy (50%) than either lisinopril (39%) or candesartan (24%) alone. Blood pressure reduction, however, was also significantly greater in the combination therapy patients. Thus it is not clear if the combination produced an enhanced antiproteinuric effect or if the reduction in the albumin: creatinine ratio could be attributable to the greater reduction in blood pressure.¹²⁹

CLINICAL CONTROVERSY

Some clinicians believe that ACEI and ARB medications should be titrated to achieve tight blood pressure control and that this will automatically result in optimal proteinuria reduction.

Some calcium channel blockers have been shown to decrease glomerular injury without negatively changing renal hemodynamics.¹¹¹ The postulated mechanisms for this decrease in renal injury

include suppression of glomerular hypertrophy, inhibition of platelet aggregation, and decreased salt accumulation.¹¹¹ Although the data regarding dihydropyridine calcium channel blockers do not suggest any beneficial effects beyond those attributable to reducing blood pressure, there is some suggestion that the nondihydropyridine agents

(diltiazem and verapamil) may have beneficial effects on proteinuria that are similar to those of ACEIs.^{130–132} A few studies have suggested that the efficacy of combination therapy with ACEIs and nondihydropyridine calcium channel blockers may be superior in terms of proteinuria reduction than the use of either agent alone.¹³³

► TREATMENT: Nondiabetic Chronic Kidney Disease

■ NUTRITIONAL MANAGEMENT

The MDRD study was the largest prospective trial that evaluated the influence of dietary protein and phosphorus restriction on the progression of CKD in a population of patients that consisted mostly of nondiabetics.^{49,100} A secondary analysis of the MDRD study was conducted and revealed that in those patients with a GFR of less than 25 mL/min per 1.73 m², a protein intake of 0.6 g/kg per day was significantly associated with a decreased rate of progressive renal disease.¹⁰⁰ In addition, this analysis showed that the rate of progression to ESKD was significantly reduced by 41% for each 0.2 g/kg per day reduction in dietary protein intake. The discrepancy in results between the primary and secondary analyses can be explained by the different statistical methods used in each of the two analyses, in that the later analysis evaluated participants who were actually compliant with their dietary prescription. Based on these findings, the K/DOQI has advocated a dietary protein intake of 0.6 mg/kg per day in patients with a GFR <25 mL/min per 1.73m².⁹⁸

Two meta-analyses of randomized clinical trials reported that reducing protein intake in nondiabetic patients with CKD could delay

the time to onset and reduce the occurrence of ESKD by approximately 40%.^{108,134} Another meta-analysis reported a reduction in the rate of GFR decline of 0.53 mL/min per year after the addition of a low-protein diet.¹⁰² The suggested benefit of dietary protein restriction in patients without diabetes offers another interventional strategy to reduce the rate of CKD progression. The benefits of dietary protein restriction need to be weighed against the potential adverse event of protein malnutrition and related sequelae including increased morbidity and mortality.

■ PHARMACOLOGIC THERAPY

■ ANTIHYPERTENSIVE AGENTS

Reduction of blood pressure is key to decreasing cardiovascular and renal sequelae. However, antihypertensive agents are not equal in their ability to preserve kidney function despite similar efficacy in terms of blood pressure reduction. As precipitous reductions in blood pressure may be deleterious to kidney function in patients with underlying renal impairment, blood pressure targets in these patients should be

achieved over several weeks to allow the kidney to adapt to reduced perfusion pressures.¹⁰⁷ Typically there is an acute but sustained reduction in GFR of about 25% to 30% within 3 to 7 days after initiation of ACEI therapy, due to a reduction in intraglomerular pressure.¹³⁵ If the serum creatinine increases by more than 0.5 mg/dL and is sustained after ACEI therapy initiation or dosage increase, the patient may require therapy discontinuation due to drug-induced acute renal failure. It is necessary to realize that although ACEI therapy may be effective in reducing the rate of nephropathy, one needs to consider the projected benefit in terms of clinical improvement when the baseline GFR is already too far progressed, propensity for hyperkalemia exists, and potential for acute GFR reduction exists in patients who already have compromised GFR.

CLINICAL CONTROVERSY

Some clinicians fail to prescribe ACEI or ARB medications when the GFR is less than 20 to 30 mL/min per 1.73m² due to fear of the patient developing a further elevation in serum creatinine.

Several short- and long-term clinical trials (that evaluated at least 40 patients) assessed the effect of ACEIs on renal function in patients without diabetes, and these are summarized in Table 43–7.^{136–140} These studies vary in length from 12 weeks to 7 years. Also, the numbers of subjects enrolled in the studies are generally smaller than those studies that evaluated diabetic individuals. Since these patients had forms of nephropathy that are often associated with significant proteinuria, they tended to have more proteinuria and more severe reductions in GFR as compared to the diabetic populations in which ACEI therapy was evaluated. Significant reductions in terms of the risk of doubling serum creatinine or requirement for dialysis or reductions in proteinuria were demonstrated for patients receiving the ACEIs. Ramipril (1.25 to 5 mg daily) reduced proteinuria and the rate of GFR decline to a greater extent than that expected from blood pressure reduction alone.¹³⁷ The proteinuria reduction was greatest in those patients with the highest baseline levels. A limitation of this study was that the additional antihypertensive agents that were administered to study participants were not specified. A subsequent study by the same group of investigators in patients with less proteinuria revealed similar beneficial effects and found that the relative risk of

TABLE 43–8. Summary of Studies with Angiotensin Receptor Blockers in Patients without Diabetes

| Drug, Dose, and Study Design | Baseline Characteristics | Number of Subjects and Disease | Duration | Outcomes | Reference |
|--|---------------------------|--------------------------------|----------|---|------------------------------|
| Losartan 50 mg once daily vs. control | Normotensive, proteinuria | 23 FSGS patients | 1 year | Proteinuria decreased 47% in the losartan group at 1 year, while there was a significant increase in proteinuria in the control group; total serum protein and albumin concentrations also increased in the losartan group; cholesterol levels of the losartan group were significantly reduced | Usta et al ¹⁴² |
| Losartan 25 mg once daily vs. enalapril 10 mg once daily; randomized, controlled trial | GFR 36–93 mL/min | 34 Primary glomerulonephritis | 3 months | Proteinuria reduced 25% vs. 45% in losartan and enalapril groups, respectively; significant decline in GFR in enalapril group and no change in losartan group | Tylicki et al ¹⁴³ |

FSGS, focal segmental glomerulosclerosis; GFR, glomerular filtration rate; UPE, urinary protein excretion.

developing ESKD was 2.3 times higher with conventional therapy plus placebo than for ramipril therapy.¹⁴⁰ The results of these studies and a meta-analysis revealed that ACEIs conferred a 40% reduction in the risk of developing ESKD or doubling of serum creatinine in patients with overt proteinuria (>300 mg protein/24 hours) and renal disease of various etiologies (about 50% diabetic patients; see Fig. 43–8).¹²²

Since the clearance of all ACEIs (with the exception of fosinopril) is reduced in CKD, it is prudent to commence therapy at lower initial doses and then later titrate to achieve the optimal therapeutic effects.¹⁴¹ The antiproteinuric effects of ACEIs are not necessarily attained at the same doses as the antihypertensive effects. Thus patients who have reached their blood pressure goals may require further dosage adjustments to achieve maximal reductions in urinary protein excretion. Serum potassium needs to be monitored when initiating therapy with ACEIs, especially when patients are concurrently receiving drugs that may increase the risk of hyperkalemia, such as nonsteroidal anti-inflammatory agents.

The ARBs, although evaluated to a lesser extent, appear to have similar efficacy in terms of renal protection in patients with several forms of glomerulonephritis (Table 43–8).^{142,143} Proteinuria reduction on the order of 25% to 47% was shown with ARB therapy. It is necessary to note that these studies employed much smaller numbers of patients and follow-up was of shorter duration than many evaluations of diabetic patients. Despite these limitations, most clinicians use either ACEI or ARB therapy as the standard of care in patients with glomerulonephritis and proteinuria. The combination of ARBs with ACEIs has been proposed and preliminary data suggest that this approach is safe and results in a greater decrease in proteinuria than that seen with either agent alone.¹⁴⁴ A recent study prospectively evaluated losartan 100 mg daily or trandolapril 3 mg daily or the combination of the two in 336 patients with nondiabetic kidney diseases. The primary end point, time to doubling of serum creatinine or ESKD was observed in 11% of combination therapy patients and 23% in each of the single-agent treatment groups.¹⁴⁵

The calcium channel blockers also effective treatments for hypertension in patients with CKD but without diabetes. However, as was mentioned previously, only the nondihydropyridine CCBs have data suggesting a reduction in the rate of decline of renal function.^{130,146} There are currently no data to suggest that higher doses of nondihydropyridine CCBs are needed to elicit a reduction in proteinuria as compared to a reduction in blood pressure.

Although diuretics are commonly used to treat fluid overload and hypertension in patients with CKD, there are no compelling data to suggest any renal protection in terms of proteinuria regression or progression. The use of diuretics for managing volume overload is addressed in Chap. 49. Other available antihypertensive agents are used to control blood pressure in patients with kidney disease. The selection of individual agents and dosage to manage blood pressure in patients with CKD is quite similar to that for patients without kidney disease. One must consider the need for dosage reductions due to CKD and/or supplemental doses due to dialysis removal for selected agents such as the hydrophilic β -blockers nadolol, acebutolol, and atenolol.

Regardless of the treatment regimen, hypertension should be treated to the currently accepted targets in patients with CKD. If proteinuria is present, the use of ACEIs, ARBs, and possibly nondihydropyridine CCBs may be superior to conventional agents in decreasing proteinuria and glomerular hypertension.

OTHER INTERVENTIONS TO LIMIT DISEASE PROGRESSION

HYPERLIPIDEMIA TREATMENT

Supportive therapies such as lipid-lowering regimens, smoking cessation, and anemia management may also slow the progression of CKD. Although several drugs are available for lipid lowering, the 3-hydroxy-3-methylglutaryl coenzyme A (HMG-CoA) reductase inhibitors and gemfibrozil have been used most frequently in dyslipidemic patients with CKD with and without proteinuria.⁷⁶ While the primary goal of treatment is to adequately reduce the elevations in lipid parameters in order to decrease one's risk for progressive atherosclerotic cardiovascular disease, a secondary goal of treatment is a reduction in proteinuria and renal function decline. A meta-analysis examined various hypolipidemic modalities including carnitine, fish oil, low-molecular-weight heparins, and exercise, in order to determine their lipid-lowering efficacy in patients with nephrotic syndrome and CKD.¹⁴⁷ These data suggest a consideration of less common therapeutic approaches to lipid lowering in patients in whom contraindications to specific first-line therapies exist. The National Cholesterol Education Program III and K/DOQI

guidelines as well as Chapter 21 should be consulted for a thorough review of lipid reduction and cardiovascular disease in patients with CKD.^{148,149}

A meta-analysis of 13 prospective controlled trials did conclude that lipid-lowering therapies may decrease proteinuria and slow the rate of GFR decline (by a 0.156-mL/min-per-month).¹⁵⁰ It has been suggested that HMG-CoA reductase inhibitors may have some other advantages that may help to reduce kidney disease progression in addition to lipid reduction, such as reduction of monocyte infiltration, mesangial cell proliferation, mesangial matrix expansion, and tubulointerstitial inflammation and fibrosis.¹⁵¹

■ SMOKING CESSATION

Although the adverse cardiovascular disease risks of smoking have been documented, it has only been in the last decade that information has been published regarding the effects of smoking on the progression of CKD. Although the exact physiologic effects of smoking on kidney function have not been fully elucidated, smoking can result in several acute changes, including a drop in GFR and a corresponding increase in heart rate and blood pressure, likely secondary to nicotine.¹⁵² Nicotine has also been shown to cause an increase in urinary albumin excretion.^{65,152} Although the effectiveness of smoking cessation on limiting progressive CKD has not been prospectively evaluated, one recent study suggested that smoking cessation resulted in a protective effect against proteinuria and reduced GFR.¹⁵³ Based on the evolving data concerning the detrimental effects of smoking on the kidney, it is prudent to educate patients regarding this risk, and in-

stitute appropriate therapeutic options institute for smoking cessation as discussed in Chapter 65.

■ ANEMIA TREATMENT

Prolonged anemia has been associated with left ventricular hypertrophy and even heart failure, but only approximately 15% to 23% of anemic CKD patients receive therapy prior to the initiation of dialysis.^{95,154} The cardiovascular sequelae of anemia in patients with kidney disease and a management algorithm is presented in Chapter 44. The presence of anemia may actually be associated with an increased rate of CKD progression.¹⁵⁵ Researchers have coined the phrase “cardio-renal anemia syndrome” to describe the interrelated aspects of anemia, congestive heart failure (CHF), and CKD.¹⁵⁵ It has been hypothesized that by actively treating CHF and anemia, the progression of both CHF and CKD can be reduced.^{156,157} A recent study in renal transplant recipients showed an absence of loss of renal function in newly anemic patients who had erythropoietin therapy initiated, while there was a reduction in the loss of renal function in patients who had anemia for a short time period and subsequently received therapy with erythropoietin.¹⁵⁸ The other finding of this study was that of longer renal graft survival in erythropoietin-treated patients. These data support further study of the potential role of anemia management in reducing renal function decline. Tissue hypoxia associated with anemia may be a stimulus for continued renal injury in those with Stages 3 to 5 CKD. In addition, anemia-related alterations of renal sympathetic nerve activity and related increases in oxidative stress have been reported.¹⁵⁹

PHARMACOECONOMIC CONSIDERATIONS

There have been a few evaluations of the potential pharmacoeconomic impact of screening for microalbuminuria and the subsequent initiation of various pharmacotherapeutic regimens in type 1 diabetic patients.^{160,161} According to one study, the historical standard approach to proteinuria reduction was considered to be treatment with hydrochlorothiazide at the time of hypertension diagnosis, while the newer treatment approach assumed three different screening and treatment strategies with ACEIs. The results from this evaluation suggested that with early screening and treatment of persistent microalbuminuria with ACEIs, it is possible to realize a cost-effectiveness ratio of \$7,900 to \$16,500 per year of life saved. This ratio is similar to the cost effectiveness associated with treating hypertension in the general population. A similar cost-effectiveness analysis using different strategies but the same basic model was also performed,¹⁶¹ and projected that treating all patients with an ACEI 5 years after the diagnosis of diabetes was as cost effective as annual screening for microalbuminuria beginning 5 years after diagnosis, with the initiation of an ACEI when and if persistent microalbuminuria was detected. The DCCT Research Group evaluated the cost effectiveness of intensive insulin therapy as compared with conventional diabetes treatment.¹⁶² The analysis demonstrated that implementing intensive insulin therapy would result in an incremental cost per year of life gained of \$28,661, which represents a good value to the health care system. Overall, it appears that aggressive insulin therapy, as well as treatment with ACEIs when persistent microalbuminuria is identified, reduces complications, improves quality of life by preserving renal function, and ultimately increases length of life at reasonable

costs to society. The results of these simulated analyses remain to be prospectively confirmed.

The UK Prospective Diabetes Study also included a cost-effectiveness study that compared tight blood pressure control (ACEI and β -blocker therapy) with less-tight blood pressure control. The main outcomes included use of health care resources and the time free from diabetes-related end points. The investigators concluded that tight blood pressure control in patients with type 2 diabetes and hypertension produced a positive cost-effectiveness ratio with regard to reducing the cost of complications and increasing the interval without complications.¹⁶³ A recent study concluded that all middle-aged patients with newly diagnosed type 2 diabetes should be treated with an ACEI rather than be screened for microalbuminuria and then treated.¹⁶⁴ They determined that this treatment method would provide additional benefit with only a modest increase in cost.

EVALUATION OF THERAPEUTIC OUTCOMES

DIABETICS

Based on the available clinical and experimental data, pharmacologic interventions can help to limit the progression of CKD in diabetic patients. Figure 43–9 summarizes these interventions in the form of an algorithm.¹⁶⁵ All patients with type 1 diabetes of more than 5 years' duration and all type 2 diabetics should be screened yearly for microalbuminuria (annual urinary albumin excretion or urinary albumin:creatinine ratio).⁵² Blood glucose should be maintained within or close to the normal range by frequent insulin injections or by use

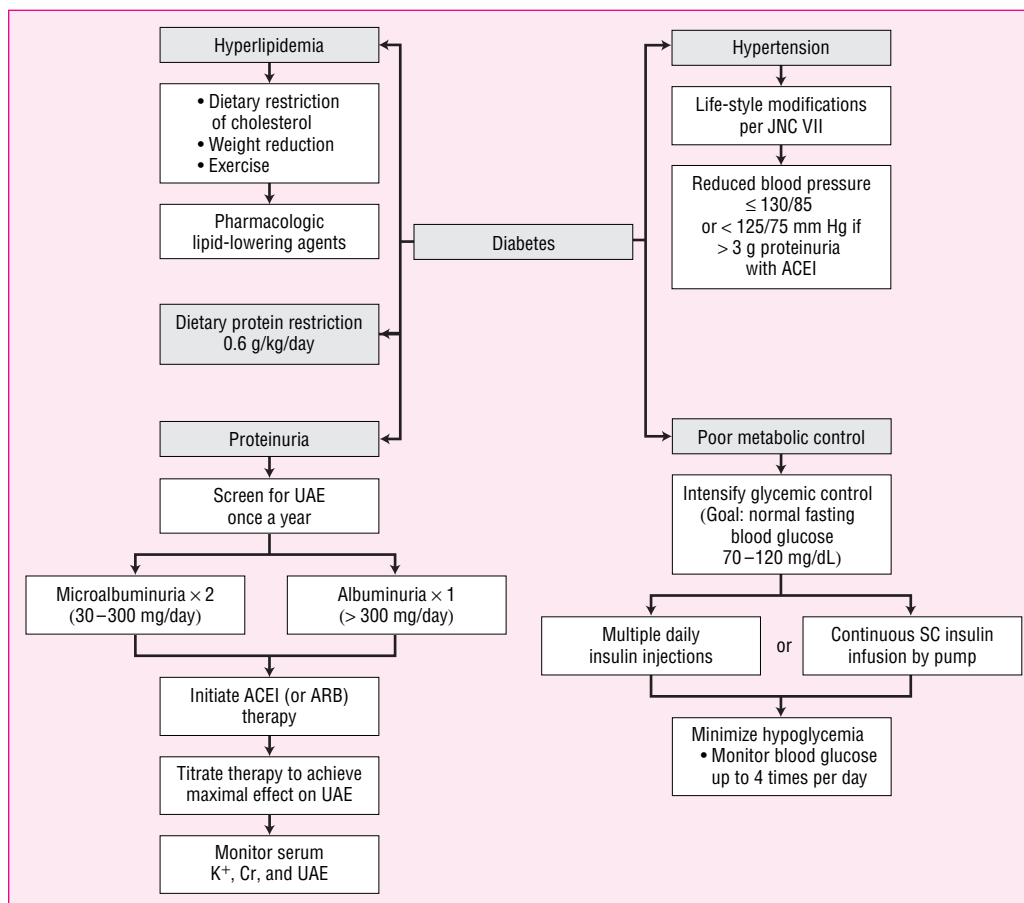

FIGURE 43–9. Therapeutic strategies to prevent progression of renal disease in diabetic individuals. UAE = urinary albumin excretion; SC = subcutaneous; JNC VII = the seventh report of the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure.

of an insulin pump, while minimizing the risk of hypoglycemia by frequent blood glucose monitoring. ACEI therapy should be initiated in normotensive and hypertensive type 1 or type 2 diabetic patients with persistent microalbuminuria (30 to 300 mg/day) or overt albuminuria (>300 mg/day). ACEIs should be titrated every 1 to 3 months to achieve a maximal reduction in urinary albumin excretion. Within 1 week of initiating or increasing the dose of an ACEI, serum creatinine and potassium should be evaluated to detect abrupt reductions in GFR or development of hyperkalemia. ARBs should be considered as another first-line therapy in type 2 diabetic patients for the reduction of persistent proteinuria or albuminuria. A nondihydropyridine CCB may be an effective secondary alternative agent in patients who are unable to tolerate either an ACEI or an ARB. Preliminary data suggest that the combination of an ACEI with an ARB may result in a greater reduction in proteinuria or albuminuria than either agent alone, and thus may be a therapeutic alternative in patients who are not maximally responding to single-agent therapy.

NONDIABETIC PATIENTS

Figure 43–10 summarizes therapeutic interventions for nondiabetic patients with CKD. Nutritional management should be monitored frequently, regardless of the amount of protein intake prescribed, to avoid

malnutrition. Based on the results of the MDRD study, a low-protein diet is of variable benefit in patients with moderate kidney dysfunction (GFR 25 to 55 mL/min per 1.73 m²). Therefore it is probably reasonable to prescribe a standard protein diet unless the patient develops rapid progression of their kidney disease.¹⁶⁵ For patients with moderate kidney dysfunction, as defined by the MDRD study as a GFR of 13 to 24 mL/min per 1.73 m², a low-protein diet of 0.6 g/kg per day may reduce the rate of decline in kidney function, time to reach ESKD, and onset of uremic symptoms.¹⁰⁰

Blood pressure control should target normotensive levels (<130/80 mm Hg in nonproteinuric patients and <125/75 in proteinuric patients).¹⁶⁶ In patients with proteinuria above 3 g/day and CKD, an ACEI or ARB should be considered as first-line therapy. Hyperlipidemia should also be managed due to some studies that have associated lipid abnormalities with CKD progression.

As renal function approaches Stage 4 and the progression-limiting strategies have been or are all being applied, the patient should begin to get prepared for the eventuality of renal replacement therapy. Hemodialysis, peritoneal dialysis, and renal transplantation options need to be discussed (see Chaps. 45 and 87). Early referral to a nephrologist or other clinician specializing in the care of patients with progressive CKD may allow the proper dialysis access to be placed, dialysis to be initiated before adverse effects of uremia develop, and may also enable the identification and treatment of the complications of anemia and of calcium and phosphorus abnormalities.¹⁶⁷

CHRONIC KIDNEY DISEASE: THERAPEUTIC APPROACH FOR THE MANAGEMENT OF COMPLICATIONS

Joanna Q. Hudson and Kunal Chaudhary

Learning Objectives and other resources can be found at www.pharmacotherapyonline.com.

KEY CONCEPTS

- 1 The number of patients with chronic kidney disease (CKD) is increasing, with a doubling in the number of patients with Stage 5 CKD expected by 2010.
- 2 Common complications of Stages 3 to 5 CKD include anemia, hyperphosphatemia, secondary hyperparathyroidism, fluid and electrolyte abnormalities, metabolic acidosis, and malnutrition.
- 3 Cardiovascular complications are prevalent in the chronic kidney disease population and are the leading cause of mortality in patients with Stage 5 disease.
- 4 The management of CKD and the associated secondary complications should be initiated in patients with Stages 1 through 4 CKD, prior to development of end-stage renal disease (Stage 5 CKD).
- 5 Guidelines by the National Kidney Foundation-Kidney Disease Outcomes Quality Initiative (NKF-K/DOQI) should be used as a basis for the work-up of chronic kidney disease and the design of appropriate therapy for associated complications.
- 6 Patient education plays a critical role in the appropriate management of CKD and related complications. A multidisciplinary team structure is a rational approach to provide this education and effectively design and implement the extensive nonpharmacologic and pharmacologic interventions required.
- 7 Anemia is the most common complication of CKD and can lead to cardiovascular disease. It is primarily due to a deficiency in the production of endogenous erythropoietin by the kidney.
- 8 Management of anemia includes administration of erythropoietic agents (epoetin alfa and darbepoetin alfa) and regular iron supplementation (oral and/or intravenous administration) to achieve a target hemoglobin of 11 to 12 g/dL and a hematocrit of 33% to 36%, and to potentially prevent the development of left ventricular hypertrophy.
- 9 Hyperphosphatemia, changes in calcium homeostasis, and secondary hyperparathyroidism are common in patients with CKD and contribute to extravascular calcifications and an increased risk of cardiovascular mortality.
- 10 Management of hyperphosphatemia, calcium balance, and secondary hyperparathyroidism includes dietary phosphorus restriction, use of phosphate binding agents, and vitamin D therapy.

The clinical syndrome that develops insidiously as kidney function declines begins with nonspecific symptoms such as nausea and vomiting, which become progressively worse as the glomerular filtration rate (GFR) drops below 15 mL/min. It is at this stage that renal replacement therapy, either dialysis (see Chap. 45) or transplantation (see Chap. 87), is indicated to remove uremic toxins and to maintain hemodynamic stability. The patient with Stage 5 CKD requiring chronic dialysis or renal transplantation for relief of uremic symptoms is said to have end-stage renal disease (ESRD) or end-stage kidney disease (ESKD). Use of the term ESKD in this chapter will refer specifically to patients receiving chronic dialysis.

The staging system for CKD is designed to trigger implementation of appropriate interventions to delay progression of CKD, as discussed in the previous chapter, and to manage the complications

of CKD, which include anemia and secondary hyperparathyroidism, among others. Comorbidities such as cardiovascular disease are also common in patients with CKD and require early and aggressive intervention.¹ Many of these complications are unrecognized or are inappropriately managed, and for many patients may lead to premature mortality or a poor prognosis by the time they reach ESKD.^{2,3} In this chapter we discuss the pathophysiology and pharmacotherapeutic management of the complications and comorbidities that are frequently seen in patients with Stages 3 through 5 CKD, with a particular focus on the ESKD population. Specifically, the etiology, epidemiology, clinical presentation, treatment, economic considerations, and monitoring parameters for anemia, secondary hyperparathyroidism, renal osteodystrophy, and metabolic acidosis are addressed in this chapter.

EPIDEMIOLOGY

It is estimated that 19 million people in the United States have CKD, 8 million of whom have a GFR <60 mL/min per 1.73 m² (Stage 3, 4, or 5) based on data derived from the third National Health and Nutrition Examination Survey.^{3–5} In 2001 a total of 96,295 new cases of ESKD were reported and the prevalence as of the end of 2001 was 406,081, including 292,215 patients on dialysis and 113,866 with a functioning kidney posttransplant.³ Incidence rates are higher in blacks (fourfold higher), Native Americans (threefold higher), and Hispanics (twofold higher) compared to whites, a trend that has persisted over the last decade. Incidence rates have increased during this time period most notably in patients aged 65 and older. While the overall number of patients with ESKD is already substantial, it is projected that by the year 2010 the number will exceed 660,000, and by 2030 there will be 2.2 million patients with the disease: 1.3 million due to diabetes and 945,000 with other primary causes for their kidney disease.³

Compared to the general Medicare population, CKD patients in the earlier stages of the disease (i.e., Stages 1 through 4 CKD) have twice the risk of death.³ These patients are also 5 to 10 times more likely to die primarily due to cardiovascular disease before they reach ESKD.³ One of the most striking observations is the decreased prevalence between Stage 3 (7.6 million patients) and Stage 4 (400,000 patients) CKD.⁵ While one would like to think that this decrease in prevalence is due to delaying the progression to Stage 4, the data indicate that this difference is due largely to the fact that many patients die before progressing to Stage 4 CKD. Dialysis patients have the highest risk of death, up to four times higher than comparable patients age 65 or older without kidney disease.³ Associated predictors of mortality at the start of dialysis include a lower estimated GFR, decreased serum albumin, and the presence of comorbidities such as diabetes and cardiovascular disease.² Lower hemoglobin levels and body mass index are also associated with increased mortality, although there is some variation in the effect of body mass index according to race.

The incidence of treated ESKD is increasing worldwide; however, the United States has one of the highest incidence rates along with Japan and Taiwan when compared to other countries.³ The United States also has one of the highest prevalence rates of treated ESKD and the highest percentage of ESKD patients with diabetes as the primary cause of their disease. Differences in rates of treated cases of ESKD among countries are dependent to a large extent on the economic conditions and health care delivery systems within each country.

ETIOLOGY

Many clinical conditions and diseases lead to progressive kidney damage and ESKD. A detailed discussion of the pathophysiology and management of progressive CKD is presented in Chap. 43. Diabetes mellitus continues to be the leading cause of CKD and ultimately ESKD in the United States.³ The incidence rate of ESKD attributed to diabetes has doubled while the prevalence has more than tripled in the last 10 years. The incidence of diabetes as the primary cause of ESKD in the year 2001 was 43% in non-Hispanics, 64% in Mexican Hispanics, and 55% in Hispanics of other origin.³ Diabetes is also a common primary and secondary cause of ESKD in Native Americans. Approximately 80% of Native Americans alive 1 year after diagnosis of ESKD had diabetes, classified as either a primary cause of ESKD or a comorbid condition.

Rates of ESKD due to hypertension, the second leading cause of ESKD in the United States, grew almost 50% in the last decade, with

incidence rates in the black population well above those of other racial groups.³ Glomerulonephritis, the third leading cause of ESKD in the United States, includes a wide variety of glomerular lesions caused by immunologic, vascular, and other idiopathic diseases. While other diseases and conditions such as cystic kidney disease, IgA nephropathy, Wegener's granulomatosis, systemic lupus erythematosus, vascular diseases, and acquired immunodeficiency syndrome (AIDS) nephropathy account for fewer cases of ESKD compared to diabetes and hypertension, the number of patients developing ESKD secondary to these conditions has increased dramatically in the last decade.³ The increase in the incidence of AIDS nephropathy was most dramatic between 1991 and 1995, but has since stabilized. While it is encouraging that the incidence has stabilized, it is concerning that the incidence has not dropped in parallel with the decline in incidence of opportunistic infections observed in this population since the introduction of antiretroviral therapy.

PATHOPHYSIOLOGY

Progression of CKD to ESKD occurs over months to years in the majority of cases with the precise mechanism of kidney damage dependent on the etiology of the disease (see Chap. 43). However, the consequences and complications of marked reductions in kidney function are fairly uniform irrespective of the etiology.

No single toxin is responsible for all of the signs and symptoms of uremia observed in patients with Stage 4 or 5 CKD (Table 44–1). Accumulation of these known and potential toxins may be the result of increased secretion of biologically active substances such as parathyroid hormone (PTH) and atrial natriuretic peptide, which are overproduced as part of the adaptation to the loss of renal mass; decreased clearance of endogenous substances normally metabolized by the kidney, such as PTH, gastrin, growth hormone, glucagon, somatostatin, prolactin, calcitonin, and insulin; and/or decreased clearance of metabolic by-products of protein metabolism. The clinical manifestations of a build-up of these uremic toxins ultimately result in altered organ, immune, and other bodily functions and lead to secondary complications.⁶

TABLE 44–1. Potential Uremic Toxins

| | |
|-----------------------------------|-------------------------|
| Acetoin | Indoles |
| Acids | Indoxyl sulfate |
| Aliphatic amines | Insulin |
| α_2 -Glycoprotein | Lipochromes |
| Amino acids | Lysozyme |
| Aromatic amines | Mannitol |
| β_1 -Microglobulin | Methylguanidine |
| β_2 -Microglobulin | Middle molecules |
| 2,3 Butylene | Myoinositol |
| Calcitonin | Natriuretic hormone |
| Chemotaxis-inhibiting protein | Oxalic acid |
| Creatinine | Parathyroid hormone |
| Cyanate | P-cresol |
| Cyclic adenosine monophosphate | Phenols |
| Degranulation-inhibiting proteins | Potassium |
| Gastric inhibitory peptide | Prolactin |
| Gastrin | Pyridine derivatives |
| Glucagon | Renin |
| Glucuronic acid | Retinol-binding protein |
| Growth hormone | Ribonuclease |
| Granulocyte-inhibitory proteins | Urea |
| Guanidines | Uric acid |
| Hippuric acid | |
| Human pancreatic polypeptide | |

2 Anemia of CKD, secondary hyperparathyroidism, altered fluid and electrolyte homeostasis, metabolic acidosis, and nutritional abnormalities are all associated with a substantial decline in GFR. Reduced production of erythropoietin by the progenitor cells of the kidney is the primary cause of anemia of CKD. The decline in hemoglobin is generally observed as GFR falls below 60 mL/min and becomes more severe as GFR decreases further.⁷ Secondary hyperparathyroidism occurs in response to the metabolic abnormalities of CKD; hyperphosphatemia in conjunction with a decrease in conversion of vitamin D to its active form (calcitriol) within the kidney leads to hypocalcemia, the primary stimulus for release of PTH.⁸ If inappropriately managed, secondary hyperparathyroidism can lead to “renal osteodystrophy.” Management of these complications based on the patient’s stage of CKD is discussed later in this chapter.

Fluid and electrolyte disorders and metabolic acidosis are primarily the result of altered transport mechanisms within the kidney and decreased elimination of solutes (see Chaps. 49, 50, and 51). Malnutrition may also occur as dietary changes such as phosphorus restriction are implemented. Foods high in phosphorus are generally also high in protein; therefore restriction of these protein sources contributes to malnutrition. Malnutrition may also develop due to decreased appetite in those with severe kidney disease. The likelihood of developing these secondary complications and comorbidities increases as GFR declines.

3 Patients with CKD are at increased risk of cardiovascular disease, independent of the etiology of their kidney disease. While a clearly unique pathogenesis of cardiovascular disease specific to CKD has not been identified, it is known that manifestations of kidney disease are contributory. Risk factors for cardiovascular disease in this population include hemodynamic and metabolic abnormalities, as well as hypertension, dyslipidemia, elevated homocysteine levels, anemia, hyperparathyroidism, malnutrition, and oxidative stress.⁹ Hypertension induced by volume expansion and increased systemic vascular resistance increases myocardial work and contributes to development of left ventricular hypertrophy (LVH). Hyperlipidemia may enhance atherogenesis, while some uremic toxins can decrease myocardial contractility. In addition, uremic toxins can induce pericarditis, a potentially fatal complication. Currently, measures to screen this high-risk population for cardiovascular risk factors are not routine.^{1,10}

While an understanding of the mechanisms of progression and measures to delay progression is essential and should be a focus of primary care clinicians, those who provide care for patients with Stage 4 and 5 CKD must also have a clear understanding of the pathogenesis and management strategies for secondary complications and comorbidities to improve the quality of care and patient outcomes.

CLINICAL PRESENTATION

Every major organ system is affected by CKD, particularly once patients develop ESKD. At the time of referral to a nephrologist patients may present with some, but rarely all, of the signs and symptoms asso-

ciated with uremia and secondary complications of CKD, unless they are in the more advanced stages of the disease (Stage 4 or 5 CKD).

CLINICAL PRESENTATION OF CHRONIC KIDNEY DISEASE

Patient may appear healthy by observation alone. If in the later stages of CKD, signs and symptoms of uremia and secondary complications may be apparent.

SYMPTOMS

May present with uremic symptoms^a (fatigue, weakness, shortness of breath, mental confusion, nausea and vomiting, bleeding, and loss of appetite), as well as itching, cold intolerance, weight gain, and peripheral neuropathies.

SIGNS

Edema, changes in urine output^a (volume and consistency), “foaming” of urine (indicative of proteinuria), and abdominal distension.

LABORATORY TESTS

Increased serum creatinine, increased BUN, decreased creatinine clearance, hyperkalemia,^a decreased bicarbonate (metabolic acidosis)^b, decreased hemoglobin/hematocrit (anemia),^b low iron stores (iron deficiency),^b elevated phosphorus,^b abnormal calcium^b (low in early stages of CKD; may be elevated in Stage 5 CKD), decreased vitamin D levels, elevated PTH,^b decreased albumin (malnutrition),^b blood pressure may be elevated (hypertension is a common cause and result of CKD), hyperglycemia (uncontrolled diabetes as a cause of CKD), hypoglycemia (from decreased degradation of insulin with impaired kidney function or poor oral intake), increased low-density lipoprotein and triglycerides, may be hemocult-positive if GI bleeding occurs secondary to uremia, and hypothyroidism (increased T₄ levels).

OTHER DIAGNOSTIC TESTS

Left ventricular hypertrophy may be observed, as well as increased homocysteine levels and increased C-reactive protein.

^aMost likely to be seen at more advanced stages of CKD (i.e., Stages 4 and 5).

^bCommon secondary complication of CKD.

The subjective and objective findings of CKD that may be present in an individual are dependent on the severity of disease (i.e., stage of CKD). It is also apparent that management of CKD will likely require the treatment of multiple secondary complications. Damage to the kidney thus has detrimental consequences on many other organ systems, which often go unrecognized or are inappropriately managed.

► TREATMENT: Chronic Kidney Disease

■ DESIRED OUTCOME

Once a patient is diagnosed with CKD, implementation of therapy to address the primary cause (e.g., diabetes, hypertension, or glomerulonephritis) and potentially delay progression is a priority (see

Chap. 43). When patients reach Stage 4, progression to Stage 5 is almost inevitable, although the process may be slowed if appropriate therapy is initiated. It is during Stage 4 CKD that plans for renal replacement therapy (hemodialysis or peritoneal dialysis) need to be made, and patients educated on dialysis modalities and options for transplantation if they are good candidates.

4 Regardless of the stage of CKD at which the patient presents, the management of secondary complications (e.g., anemia and secondary hyperparathyroidism) and comorbid conditions including diabetes and cardiovascular complications is critical. Historically these conditions have not been appropriately managed.^{11,12} Late referral to a nephrologist may account for this poor management; however, even in ideal clinical environments these conditions are not always aggressively treated. Appropriate management of anemia and malnutrition improve the prognosis for Stage 5 patients in their first year on dialysis, the time period historically associated with the highest mortality rate.^{13,14}

GENERAL APPROACH TO PATIENT CARE

5 Interventions to slow or halt progression in patients with Stage 1 through 3 CKD are critically reviewed in Chap. 43. Once a patient reaches Stage 4 or 5 CKD, one of the most important approaches to treatment is early identification of secondary complications and appropriate management based on available guidelines. Guidelines for the work-up and treatment of CKD and its complications are available from the National Kidney Foundation-Kidney Disease Outcomes Quality Initiative (NKF-K/DOQI).^{5,15–19} Unfortunately, laboratory data to diagnose such complications, including anemia and secondary hyperparathyroidism (e.g., iron studies and PTH levels), are often not evaluated until the patient has reached Stage 5 CKD.

Another important consideration in patients with CKD is the avoidance of nephrotoxic agents (see Chap. 46). Chronic use of nonsteroidal anti-inflammatory drugs and cyclooxygenase-2 inhibitors should be minimized or avoided when possible. Patients should be instructed on all brand and generic names of these classes of medications to reduce the risk of exposure. Appropriate measures should also be taken for hospitalized patients to decrease the risk of nephrotoxicity from radiocontrast agents (for procedures requiring such dyes), and antibiotics such as aminoglycosides, as well as from nonsteroidal anti-inflammatory drugs and angiotensin-converting enzyme inhibitors (ACEIs) (see Chaps. 42 and 46). Drug dosing guidelines based on the degree of kidney function should also be implemented, and a complete medication history of prescription and over-the-counter medications as well as herbals and nutritional supplements should be obtained and routinely updated.

6 Appropriate management of secondary complications of CKD usually involves a multidisciplinary approach to manage the nonpharmacologic and pharmacologic interventions, dietary education, and social/financial concerns. The typical team includes physicians (primary care physicians and nephrologists), nurses, dietitians, and social workers in outpatient dialysis facilities. In some outpatient dialysis centers pharmacists are also active members of the care team, although this is more common in institutionalized environments. Patient education for the population with CKD, particularly those with Stage 3, 4, and 5 disease, by all clinicians cannot be overemphasized.

FLUID AND ELECTROLYTE ABNORMALITIES

Maintenance of fluid volume, osmolality, electrolyte balance, and acid-base status are all regulated in large part by the kidney. Homeostasis of sodium, potassium, chloride, calcium, magnesium, and phosphorus is altered due to changes in urinary excretion that occur in patients with impaired kidney function. A comprehensive discussion

of fluid and electrolyte disorders and treatment options is presented in Chaps. 49, 50, and 51; the pathophysiology and therapeutics of these disorders in CKD patients are highlighted here.

ETIOLOGY

Sodium and Water Balance

In persons with normal kidney function, sodium balance is maintained at a sodium intake of 120 to 150 mEq/day. The fractional excretion of sodium (FE_{Na}) is approximately 1% to 3%. Water balance is also maintained, with a normal range of urinary osmolality of 50 to 1200 mOsm/L. In patients with severe CKD (Stages 4 and 5), sodium balance is achieved, but results in a volume-expanded state. FE_{Na} may increase to as much as 10% to 20%, possibly due to increased concentrations of atrial natriuretic peptide.²⁰ An osmotic diuresis occurs with an increase in FE_{Na} leading to obligatory water losses and impairment in the kidney's ability to dilute or concentrate urine (urinary osmolality is often fixed at that of plasma or approximately 300 mOsm/L). Nocturia is present relatively early in the course of CKD (Stage 3) secondary to the defect in urinary concentrating ability. Total renal sodium excretion decreases despite an increase in sodium excretion by remaining nephrons. Volume overload with pulmonary edema can result, but the most common manifestation of increased intravascular volume is systemic hypertension.²⁰

Potassium Homeostasis

The kidneys normally excrete 90% to 95% of the daily potassium dietary load, predominantly via distal tubular secretion. The fractional excretion of potassium (FE_K) is approximately 25%. Normally only 5% to 10% of ingested potassium is excreted through the gut. Potassium homeostasis is also maintained by shifting extracellular potassium intracellularly immediately following ingestion of a potassium load. In patients with CKD, potassium balance is maintained by an increase in distal tubular potassium secretion in which aldosterone plays an important role; FE_K can increase to as high as five times normal. Thus the serum potassium concentration is usually maintained in the normal range until the patient reaches Stage 5 CKD (GFR < 15 mL/min per 1.73 m² body surface area), at which point hyperkalemia is likely to develop. A significant increase in potassium secretion by the colon also contributes to the maintenance of potassium balance, but this adaptation cannot compensate fully for the decrease in renal potassium excretion.

DESIRED OUTCOME

Sodium and Water Balance

The goal in managing sodium and water balance is to maintain a normal serum sodium concentration while preventing fluid overload or volume depletion (i.e., maintaining hemodynamic stability). By achieving these goals, the risk of developing hypertension secondary to volume overload is also reduced, although hypertension is already present in many patients with Stage 3 to 4 CKD.

Potassium Homeostasis

The acute goal is to prevent the adverse consequences of hyperkalemia, particularly cardiac effects, and the chronic goal is to

maintain potassium concentrations of approximately 4.5 to 6 mEq/L. The contribution of dialysis modalities to potassium homeostasis in patients with Stage 5 CKD must also be considered (see Chaps. 45 and 50).

■ PATIENT EVALUATION

■ Sodium and Water Balance

Edema is a common manifestation of volume overload and extracellular fluid volume expansion. Clinicians should evaluate patients for signs and symptoms of volume overload (e.g., pitting edema, rales, ascites, shortness of breath, and increased weight). Blood pressure monitoring in the clinic setting and at home if feasible to detect hypertension is also warranted. As kidney disease progresses dietary intervention and diuretic therapy (based on the degree of kidney function) will likely become necessary.

■ Potassium Homeostasis

In addition to CKD as a risk factor, other contributing factors should also be considered. This includes exposure to potassium-sparing diuretics; β -blockers, which work predominantly via β_2 -antagonistic effects to interfere with the extrarenal translocation of potassium into cells; and ACEIs, which may cause hyperkalemia by reducing aldosterone production. Polycitra, used for the treatment of metabolic acidosis, contains potassium citrate and should not be prescribed for patients with severe CKD. If hyperkalemia develops, management options are based on the degree to which potassium is elevated (see Chap. 50).

■ NONPHARMACOLOGIC THERAPY

■ Sodium and Water Balance

The ability of the kidney to adjust to abrupt changes in sodium intake is greatly diminished in patients with severe CKD. Sodium restriction beyond a no-added-salt diet should not be recommended except in the face of hypertension or edema. The kidney maintains the ability to lower urinary sodium content to essentially zero, but this can only be accomplished by very gradual sodium restriction over a period of several days. Hospitalized patients should not routinely be sodium restricted because they have adapted to their outpatient intake. Negative sodium balance and its resultant volume contraction can result in decreased perfusion to the kidney and a subsequent further decline in GFR. Saline-containing IV solutions should be used cautiously in patients with CKD because the kidney's ability to excrete a salt load is impaired and such patients are prone to volume overload. Sodium retention and volume expansion contribute to hypertension in many patients with severe CKD, and diuretic therapy or dialysis may be necessary for control of edema or blood pressure.

Fluid restriction is generally unnecessary provided sodium intake is controlled, although fluid intake between dialysis sessions is generally limited for hemodialysis patients. An intact thirst mechanism maintains total body water and effective plasma osmolality near normal. Since urine volume is relatively fixed at approximately 2 L/day, fluid restriction below this amount should be avoided. Large amounts of free water administered orally or as IV fluid may induce hyponatremia and volume overload. When the patient develops

ESKD, dialysis (specifically ultrafiltration) or a kidney transplant becomes necessary to maintain normovolemia.

■ Potassium Homeostasis

Hyperkalemia is more common in patients with Stage 5 CKD; therefore the discussion of treatment options focuses on interventions in this population. The majority of patients can be managed with a dietary potassium restriction of 50 to 80 mEq/day and alterations in dialysate potassium concentrations for patients receiving hemodialysis or peritoneal dialysis. Hyperkalemia is less common, however, in the peritoneal dialysis population due to differences in potassium transport. Constipation in patients with CKD can interfere with colonic potassium excretion; therefore a good bowel regimen is important. For severe hyperkalemia hemodialysis is often required using a low-potassium dialysate bath (see Chap. 50).

■ PHARMACOLOGIC THERAPY

■ Sodium and Water Balance

Diuretic therapy is often necessary to prevent edema from volume overload and prevent the associated symptoms. Loop diuretics, particularly when administered by continuous infusion, increase urine volume and renal sodium excretion. A combination of a loop diuretic along with a thiazide diuretic (such as hydrochlorothiazide or metolazone) can result in a profound excretion of sodium and water. Alone, thiazide diuretics are ineffective in patients with a GFR below 30 mL/min (see Chap. 49).

■ Potassium Homeostasis

The definitive treatment of severe hyperkalemia in ESKD is hemodialysis. In reality, there is often a delay between diagnosis of hyperkalemia and institution of dialysis, which necessitates the use of other temporizing measures, such as IV calcium gluconate, insulin and glucose, nebulized albuterol, and sodium polystyrene sulfonate (see Chap. 50). Unfortunately, shifting potassium into the intracellular fluid compartment with insulin and glucose or with albuterol makes removal of potassium via dialysis more difficult. Multiple dialysis sessions may be necessary following potassium redistribution to the extracellular space. Sodium polystyrene sulfonate (with sorbitol), a potassium-sodium exchange resin, can be given orally in doses of 15 to 30 g to increase potassium excretion via the ileum and colon. Lastly, sodium bicarbonate therapy is no longer advocated in the treatment of ESKD hyperkalemia unless severe metabolic acidosis is also present, because the potassium-lowering effect is unreliable. Loop diuretics, a standard pharmacologic treatment option for hyperkalemia, are not effective in patients with severe CKD.

CLINICAL CONTROVERSY

Low-dose spironolactone has been shown to decrease cardiovascular mortality in patients with severe heart failure. However, since spironolactone contributes to hyperkalemia, this agent should not be used in patients with Stage 4 or 5 CKD. New studies will be required before concluding that spironolactone administration is safe in the chronic hemodialysis population to reap the potential cardiovascular benefits.

■ EVALUATION OF THERAPEUTIC OUTCOMES

Monitoring of volume status and serum electrolyte levels should be done at each follow-up visit in patients with Stages 4 or 5 CKD, particularly given the risk and detrimental consequences of volume overload (e.g., hypertension and pulmonary edema) and hyperkalemia (e.g., arrhythmias). Changes in volume status may warrant a change in diuretic therapy or dialysis regimens required to maintain hemodynamic stability. Patients should be educated on modifications in dietary intake and self-evaluation for signs and symptoms of edema.

■ TREATMENT OF ANEMIA OF CKD

7 The primary cause of anemia in CKD patients is a decrease in production of the hormone erythropoietin (EPO) by the progenitor cells of the kidney, where 90% of production typically occurs. Plasma concentrations of EPO increase exponentially in individuals with normal kidney function as hematocrit declines (i.e., in response to decreased oxygenation). In contrast, there is no correlation between the degree of anemia and EPO concentrations in anemic dialysis patients because they are unable to increase production of EPO in response to hypoxia.²¹ The result is a normochromic, normocytic anemia. Additional factors contributing to the development of anemia of CKD are the decreased red cell life span in the presence of uremia (from the normal of 120 days to approximately 60 days in Stage 5 CKD), iron deficiency, blood loss from regular laboratory testing, and blood loss with hemodialysis for patients requiring this modality of renal replacement therapy. Iron deficiency is the primary cause of resistance to therapy with erythropoietic agents (i.e., epoetin alfa or darbepoetin alfa).

Despite the fact that its etiology is well known, anemia of CKD often goes unrecognized and is not appropriately managed in many patients prior to the development of Stage 5 CKD.^{22,23} Lack of attention to the disorder, problems with payment for drug therapy by third-party payers, and the logistics of maintaining the regular follow-up necessary for therapy with erythropoietic agents contribute to this poor management. The effects of anemia and decreased oxygen delivery on other comorbid conditions, including the development of LVH, must also be considered given the burden of cardiovascular complications in this population.²⁴ The negative effects of anemia on quality of life are also important from a patient perspective and a compelling reason for early and aggressive treatment.^{23,25}

■ DESIRED OUTCOME

The desired outcomes are to increase oxygen-carrying capacity and thereby decrease dyspnea, orthopnea, and fatigue,¹⁵ and to prevent long-term consequences such as LVH and associated mortality. The NKF-K/DOQI guidelines include specific targets for hemoglobin/hematocrit; folate, vitamin B₁₂, and iron indices; and recommendations for appropriate use of erythropoietic agents and iron supplements. The hemoglobin concentration (Hgb) is the preferred monitoring parameter since hematocrit (Hct) fluctuates with volume status and may be falsely elevated if a blood sample has been stored for a prolonged period of time. The target Hgb in patients treated for anemia of CKD is 11 to 12 g/dL (Hct 33% to 36%). These values are less than “the normal values” in patients without kidney disease due to the lack of compelling evidence to warrant targeting normal values in the population with CKD and limitations of the existing reimbursement structure for erythropoietic therapy. Although a higher

mortality rate for dialysis patients with Hgb/Hct values above the target ranges has been reported, particularly in patients with cardiac disorders,²⁶ beneficial effects of increasing Hct up to 39% have been shown, including improvements in cardiac function, cognitive ability, and quality of life.²⁷ Thus it is unclear whether the current target ranges for Hgb/Hct are appropriate for all patients with anemia of CKD.²⁸ Until further evidence is available, the current target range recommended in the K/DOQI guidelines should be considered the standard of therapy.¹⁵

Iron indices that should be monitored include the transferrin saturation (TSat), an indicator of iron immediately available for delivery to the bone marrow, and serum ferritin, an indirect measure of storage iron. Transferrin is the carrier protein for iron; therefore the degree of saturation of this protein with iron is a measure of the iron that is most readily available for delivery to the bone marrow. As a protein, transferrin may be affected by nutritional status. Serum ferritin is an acute-phase reactant, and as such may be elevated under certain inflammatory conditions, giving a false indication of storage iron. The reticulocyte hemoglobin content has also proven reliable in assessing iron status and may be evaluated if reliable laboratory methods are available.²⁹ Currently, the TSat and serum ferritin are recommended as the most sensitive and specific indices of iron deficiency in the CKD population.¹⁵ The target levels to achieve prior to initiation of erythropoietic therapy and to maintain during therapy are a TSat of 20% to 50% and a serum ferritin of 100 to 800 ng/mL.¹⁵ These ranges are advocated to maintain adequate iron for red blood cell production (erythropoiesis) yet minimize the risk of iron overload.

The potential benefits of anemia management on cardiovascular risk reduction are currently being investigated in trials such as the Cardiovascular Risk Reduction by Early Anaemia Treatment with Epoetin beta (CREATE) trial, in which different Hgb goals are being targeted in anemic patients with Stages 3 and 4 CKD.³⁰ While retrospective evaluations suggest that active interventions for anemia of CKD are beneficial, if cardiovascular outcomes are improved in prospective trials, earlier and more aggressive therapy will clearly be warranted.¹³

■ PATIENT EVALUATION

Patients with CKD should be evaluated for anemia when the GFR falls below 60 mL/min (Stage 3 CKD). If the Hgb is less than 11 g/dL in premenopausal females or less than 12 g/dL in males and postmenopausal females, a complete work-up for anemia of CKD should be done.¹⁵ This includes evaluation of other causes of anemia such as bleeding, deficiencies in vitamin B₁₂ or folate, or other disease states that contribute to anemia, including human immunodeficiency virus infection and malignancies (see Chap. 99). As the primary cause of resistance to therapy for anemia of CKD, iron deficiency must be considered. Red blood cell indices and iron indices should be measured, including the red blood cell count, reticulocyte count, mean corpuscular volume (MCV), serum iron, total iron binding capacity (TIBC), and serum ferritin. A stool guaiac test should also be performed to rule out GI bleeding. Iron deficiency manifests as a microcytic anemia, as observed by a low MCV, while deficiencies in vitamin B₁₂ and folate appear as a macrocytic anemia, with an increase in MCV. The TSat is calculated as $(\text{serum iron}/\text{TIBC}) \times 100$. If the TSat and serum ferritin values are below the desired range, iron supplementation is warranted prior to starting erythropoietic therapy. If all other causes of anemia are ruled out and the anemia persists despite iron supplementation, patients should be treated with erythropoietic agents, either epoetin alfa or darbepoetin alfa. The need for iron supplementation is based on iron status, but in general is required by most patients

with anemia of CKD due to the increased demand as the result of the stimulation of the production rate of red blood cells.

As CKD worsens, a progressive decline in Hgb/Hct despite erythropoietic therapy may be observed. Therefore regular follow-up of Hgb/Hct and iron status is warranted to ensure the desired outcomes are met and to make necessary dose adjustments in erythropoietic and iron therapy (see section on evaluation of therapeutic outcomes).

■ NONPHARMACOLOGIC THERAPY

Nonpharmacologic therapy for anemia of CKD includes maintaining adequate dietary intake of iron. A relatively small amount of dietary iron, approximately 1 to 2 mg (or approximately 10%), is absorbed each day, primarily in the duodenum. While there is some debate as to whether GI absorption of iron is significantly altered in patients with severe CKD, it is clear that oral intake from dietary sources alone is generally not sufficient to meet the increased iron requirements that are necessitated by the initiation of erythropoietic therapy.^{15,31}

■ PHARMACOLOGIC THERAPY

8 Pharmacologic therapy for anemia of CKD includes chronic erythropoietic therapy to correct erythropoietin deficiency and iron supplementation to correct and prevent iron deficiency caused by ongoing blood loss and increased iron demands associated with the initiation of erythropoietic therapy (Figs. 44–1 and 44–2).

RBC transfusions and androgen therapy are currently third-line treatment options for anemia of CKD. RBC transfusions carry many risks and therefore should only be used in select situations such as acute management of symptomatic anemia, following significant acute blood loss, and prior to surgical procedures that carry a high risk of blood loss. Androgen therapy was used extensively before availability of erythropoietic agents; however, today there is not ample evidence to support use of androgens alone over erythropoietic agents.³² The risks of liver toxicity, malignancy, virilization in females, and hypertriglyceridemia outweigh the benefits of androgen therapy in most individuals.³² L-carnitine supplementation has also been studied as adjunctive treatment of anemia associated with kidney disease.³³ There may in fact be some changes in erythropoiesis that

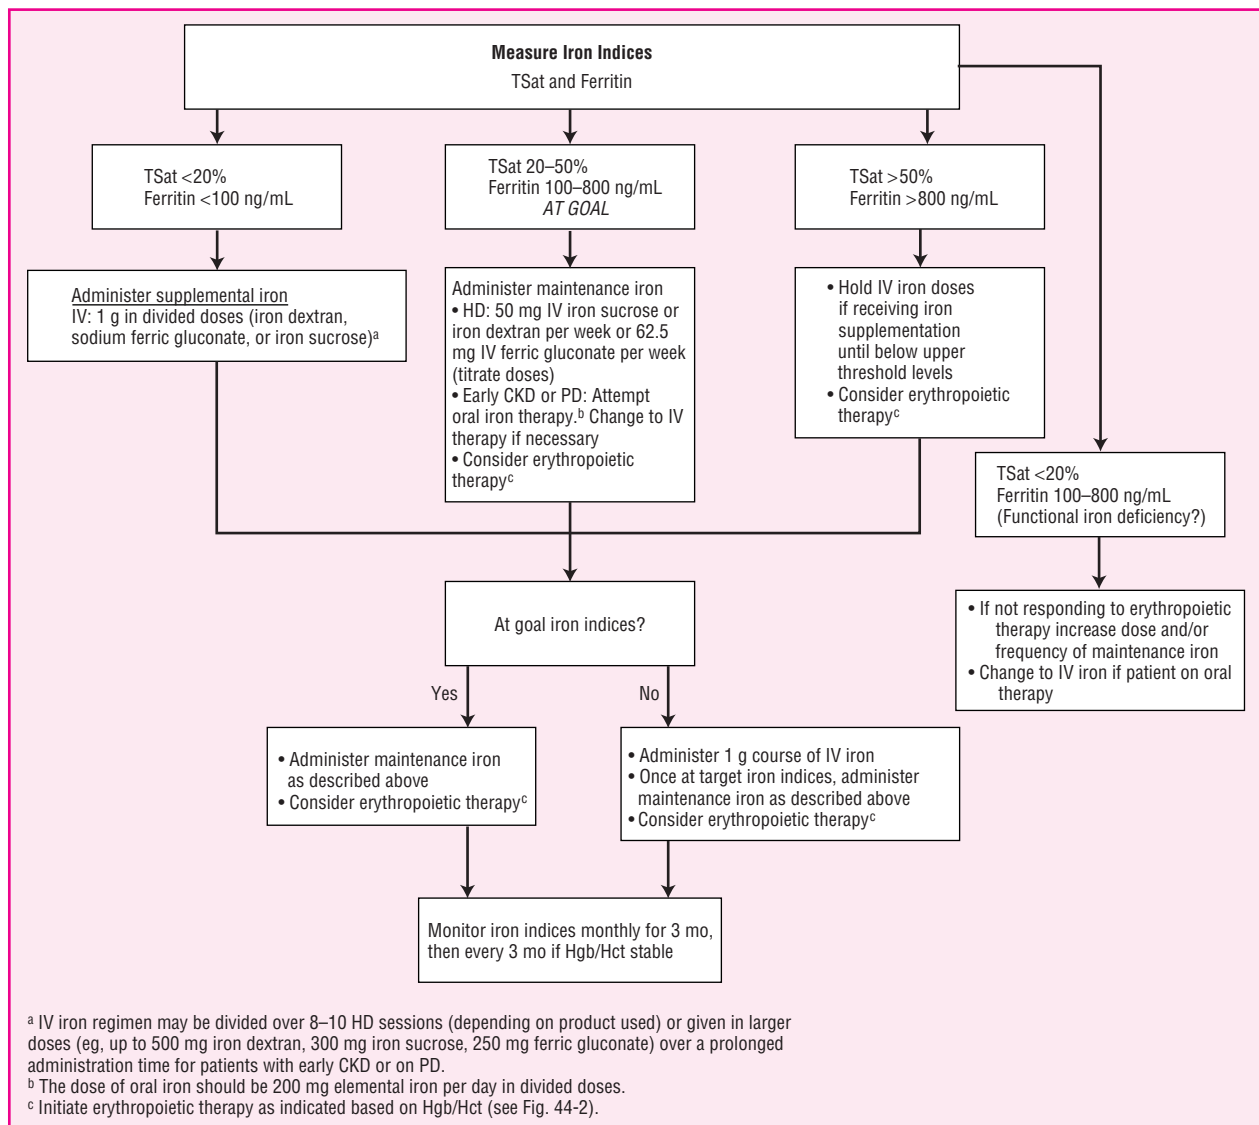

FIGURE 44–1. Guidelines for iron therapy in the management of the anemia of CKD.

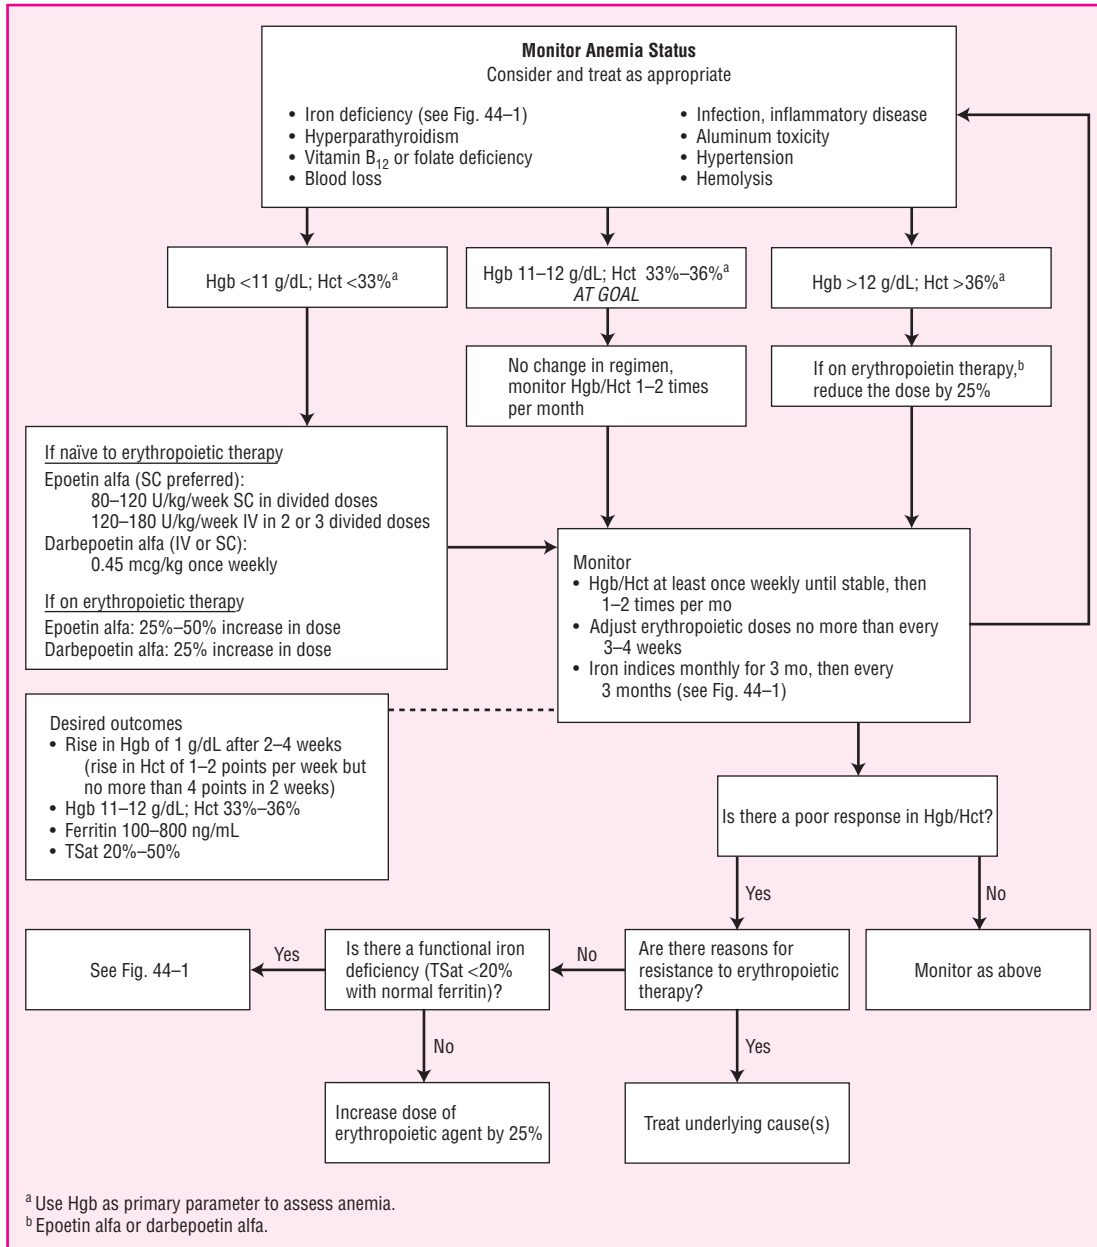

FIGURE 44-2. Guidelines for erythropoietic therapy in the management of the anemia of CKD.

occur in conditions of carnitine deficiency, thus supporting the rationale for regular supplementation. Until this association is confirmed, L-carnitine supplementation is recommended only for treatment of anemia in CKD patients not responding to standard therapy (i.e., erythropoietic agents and iron).^{16,33}

■ Iron Supplementation

If TSat and serum ferritin are below goal indices, iron supplementation is recommended. Options for iron supplementation include oral and intravenous therapy (see Fig. 44-1). Available oral preparations differ in their content of elemental iron (Table 44-2). Products available for oral therapy include ferrous salts (ferrous sulfate, ferrous

fumarate, and ferrous gluconate), polysaccharide iron complex, and most recently a heme iron polypeptide formulation. Four IV iron products are currently available in the United States (Table 44-3): two composed of iron dextran (InFeD, MW 96,000; and DexFerrum, MW 267,000), sodium ferric gluconate (Ferrlecit, MW 350,000), and iron sucrose (Venofer, MW 43,000).

■ *Pharmacology and Mechanism of Action.* Iron supplements provide the elemental iron required for the production of hemoglobin and its subsequent incorporation in red blood cells, the net result of which is an increase in the transportation of oxygen to tissues. Supplementation of iron is necessary to replenish iron stores and for transport to the bone marrow for incorporation immediately into red blood cells.

TABLE 44–2. Oral Iron Preparations

| Iron Product | Common Agents and Available Units | Amount of Elemental Iron per Unit | Number of Units Per Day ^a |
|-----------------------|---|-----------------------------------|--------------------------------------|
| Ferrous sulfate | Fer-In-Sol (75 mg/0.6 mL) | 75 mg | 2–3 |
| | Feosol (200 mg) | 50 mg | 4 |
| | Ferrous sulfate, various preparations (325 mg) | 65 mg | 3–4 |
| Ferrous fumarate | Slow FE (160 mg) | 50 mg | 4 |
| | Ferrous fumarate, various preparations (300 mg) | 99 mg | 2 |
| | Femiron (20 mg) | 20 mg | 10 |
| | Nephro-Fer (350 mg) | 115 mg | 2 |
| Ferrous gluconate | Vitron-C (65–125 mg) | 65 mg | 3 |
| | Ferrous gluconate, various (325 mg) | 36 mg | 6 |
| | Fergon (240 mg) | 27 mg | 6 |
| Polysaccharide iron | Hytinic (150 mg) | 150 | 1–2 |
| | Niferex (50 mg) | 50 mg | 4 |
| Heme iron polypeptide | Proferrin-ES (12 mg) | 12 mg | 17 |

^aNumber of units per day depends on the amount of elemental iron per unit; must give 200 mg elemental iron per day.

■ **Pharmacokinetics.** Approximately 10% of iron administered orally is absorbed in the duodenum and upper jejunum. Absorption of iron is decreased by food and achlorhydria. In patients with iron deficiency GI absorption may be increased, up to 25% to 30%; however, this adaptive response may be impaired in patients with kidney disease.¹⁵ The heme form of oral iron binds to a different receptor in the GI tract than nonheme iron, is absorbed to a greater extent, and may be better tolerated.³⁴ Some oral iron formulations also include ascorbic acid to enhance iron absorption. While there is an association between ascorbic acid intake and oxalate formation, this association is generally not observed at doses of ascorbic acid contained in these iron formulations.³⁵

Intravenous iron preparations differ in the composition of the complex to which elemental iron is bound. These differences affect the rate of dissociation of iron from the complex to the reticuloendothelial system and subsequent storage as ferritin. Iron sucrose is also delivered directly to transferrin. The half-life of these formulations also differ: ferric gluconate 1 hour, iron sucrose 6 hours, and iron dextran 40 to 60 hours. However, there is minimal to no correlation between the pharmacokinetics of these formulations and their pharmacodynamic effects.³⁶

■ **Efficacy.** While supplementation using oral preparations may seem more practical than IV administration, oral iron therapy is lim-

ited by poor absorption and is often inadequate to achieve goal iron indices. This is particularly true for patients with ESKD, who may have higher iron needs due to chronic blood loss associated with hemodialysis.¹⁵ Oral iron supplementation is more convenient for patients who do not have regular IV access, including patients with Stages 3 and 4 CKD and those receiving peritoneal dialysis. Even these patients, however, are likely to require IV iron supplementation periodically to meet iron needs and correct absolute iron deficiency.³¹ Success of oral therapy is also limited by noncompliance due to side effects, primarily GI in nature, and the frequency of administration (up to three times per day).

Intravenous iron therapy is an effective means to prevent iron deficiency and maintain adequate iron status for erythropoiesis. Parenteral iron improves the responsiveness to erythropoietic therapy and reduces the dose required to achieve and maintain the target Hgb/Hct.^{37,38} Iron administration in patients with what is known as a functional iron deficiency is more questionable. Functional iron deficiency is characterized by a low TSat (<20%) in the presence of a normal or elevated serum ferritin. In other words, there may appear to be adequate storage iron, but iron is not being carried by transferrin to the bone marrow for red blood cell production. If the Hgb is less than the target of 11 g/dL, under these conditions a trial of IV iron therapy may be warranted. Iron supplementation alone may improve Hgb/Hct and may

TABLE 44–3. Intravenous Iron Preparations^a

| Iron Compounds | Brand Name | Availability | Warnings | Need for Test Dose | Dose Ranges ^b |
|--------------------------------------|------------|--------------|-----------|--------------------|--------------------------|
| Iron dextran ^c | InFeD | 50 mg/mL | Black box | Yes | 25–1000 mg |
| Sodium ferric gluconate ^d | DexFerrum | 50 mg/mL | Black box | Yes | 25–1000 mg |
| | Ferrlecit | 62.5 mg/5 mL | General | No | 62.5–1000 mg |
| Iron sucrose ^e | Venofer | 100 mg/5 mL | General | No | 25–1000 mg |

^aAll products may be administered IV push (small doses only).

^bMaintenance regimens range from 25–100 mg weekly. Larger doses should be administered in divided doses or over a prolonged dosing interval.

^cSupplied in 2-mL single-dose vials containing 50 mg of elemental iron per milliliter.

^dAvailable in colorless glass ampules containing 62.5 mg elemental iron in 5 mL (12.5 mg/mL). The 125-mg dose may be diluted in 100 mL of 0.9% sodium chloride administered IV over 1 hour, or administered undiluted as an IV injection at a rate of up to 12.5 mg/min.

^eSupplied in 5-mL single-dose vials containing 100 mg elemental iron (20 mg/mL). The 100-mg dose may be diluted in 100 mL of 0.9% sodium chloride administered IV over at least 15 minutes, or administered undiluted by slow IV injection at a rate of 20 mg/min.

lead to improved erythropoiesis at reduced doses of erythropoietic therapy.³⁷

To avoid errors in evaluating iron status, clinicians should wait at least 2 weeks after a loading dose regimen of IV iron to re-assess iron indices; however, iron indices can be evaluated after 1 week if the patient is receiving regular maintenance doses of iron (e.g., 25 to 125 mg/wk).^{37,39}

■ **Adverse Effects.** Adverse effects of oral iron, including constipation, nausea, and abdominal cramping, increase as the dose is escalated and may be present in over 50% of those receiving 200 mg of elemental iron per day. These untoward effects often discourage patients from taking these medications on a chronic basis. Some of these GI side effects can be minimized if oral iron products are taken with food; however, food may decrease absorption of oral iron. Therefore it is generally recommended that iron be taken on an empty stomach.

Adverse effects of IV iron include allergic reactions, hypotension, dizziness, dyspnea, headaches, lower back pain, arthralgia, syncope, and arthritis. Some of these reactions, in particular hypotension, can be minimized by decreasing the dose or rate of infusion of iron. The most concerning potential consequence of IV iron administration is anaphylaxis. Anaphylactoid reactions to iron dextran have been reported in up to 1.8% of patients, with serious reactions including respiratory complications and cardiovascular collapse occurring in approximately 0.6%.⁴⁰ Such reactions are believed to be due in part to antibody formation to the dextran component. Adverse reactions have been reported more frequently in those receiving DexFerrum compared to InFeD; a two- to eightfold increase in the incidence was noted with DexFerrum.⁴¹ Such differences were particularly influential in product selection prior to the availability of sodium ferric gluconate and iron sucrose. These IV iron formulations have a better safety record than either of the iron dextran products, based on their history of use in Europe over the last four decades and recent data in the United States since these products were approved.^{42,43} Sodium ferric gluconate and iron sucrose do not require a test dose prior to administration of the full dose, unlike iron dextran, which requires a 25-mg test dose to reduce the risk of anaphylactic reactions. As a precaution with all IV preparations, patients should be observed during and immediately following administration for any adverse reactions.

Administration of IV iron also introduces a risk of iron overload. Deposition of excess iron may affect several organ systems, leading to hepatic, pancreatic, and cardiac dysfunction. Bone marrow biopsy provides the most definitive diagnosis of iron overload, but since it is an extremely invasive procedure, it is not widely employed in most clinical settings. Maintaining serum ferritin and TSat below the upper threshold values associated with iron overload is the most reasonable approach to minimize the risk of iron toxicity. The challenge is in defining these upper limits, particularly for serum ferritin which may be elevated in inflammatory conditions and not reflective of true iron stores in such situations. Currently the K/DOQI guidelines recommend not to exceed a serum ferritin of 800 ng/mL and a TSat of 50%.¹⁵ If these limits are exceeded, maintenance IV iron therapy should be discontinued, until TSat and serum ferritin levels fall below 50% and 800 ng/mL, respectively. If symptomatic overload does occur, deferoxamine (Desferal) or phlebotomy may be necessary.

The safety and efficacy of high-dose IV iron regimens have been evaluated to determine the most cost-effective and efficacious dosing strategies. Iron dextran has been safely administered in total dose infusions ranging from 400 mg to 2 g to dialysis patients.⁴⁴ Similar high-dose regimens of 500 mg have also been safely administered to

patients with Stages 3 and 4 CKD.⁴⁵ While such iron dextran regimens have been safely administered, it is important to consider that with the information available today on the safety profile of sodium ferric gluconate and iron sucrose, many clinicians would consider these newer agents as first-line therapy. Sodium ferric gluconate has been safely administered at doses of 250 mg infused over 1 hour (4.2 mg/min).⁴⁶ In this same evaluation there were 19 doses of greater than 250 mg administered; one dose of 312.5 mg, fourteen doses of 375 mg, and four doses of 500 mg, with infusion rates varying from 1.22 mg/min to 25 mg/min. No serious adverse events were reported, although nonserious events such as pruritus did occur in 4 of the 144 patients who received the 250-mg dose. Additional studies evaluating higher doses of sodium ferric gluconate are ongoing in the early CKD and dialysis populations. Doses in these higher ranges should not be adopted as standard of care until further safety data become available. If doses higher than those currently approved are used in practice, they should be administered over a prolonged time period (at least 2 hours) and should not exceed 250 mg, based on the limited evidence available. Iron sucrose at doses of up to 500 mg administered over 3 hours on consecutive days has been successful in maintaining iron stores without causing serious adverse events.⁴⁷ When administered over a shorter time period this same dose was associated with dizziness, hypotension, and nausea.⁴⁸ In this same evaluation the administration of lower doses of 200 to 300 mg given over 2 hours resulted in fewer adverse events.

Although there have been conflicting reports, most clinicians believe that exposure to iron may contribute to the risk of bacterial infection since iron is used by microorganisms for metabolic functions.^{49,50} The association of IV iron with oxidative stress, acceleration of atherosclerosis, and other cardiovascular conditions has also been suggested.⁵¹ These potential long-term risks of IV iron therapy are not clearly defined and there are no data that unequivocally confirm that aggressive use of IV iron in CKD patients treated with erythropoietic therapy increases patient morbidity or mortality.³⁷

■ **Drug-Drug and Drug-Food Interactions.** Drugs commonly used in the CKD population that may decrease absorption of oral iron include calcium preparations and antacids. Oral iron may also decrease the absorption of quinolone antibiotics. Medications that increase gastric pH such as H₂-antagonists and proton pump inhibitors may also decrease iron absorption since iron absorption in the duodenum is maximized at an acidic pH.

■ **Dosing and Administration.** If oral therapy is initiated, the recommended dose is 200 mg of elemental iron per day. Patients must generally take two to three pills per day to receive the recommended dose of elemental iron (see Table 44–2). Correction of absolute iron deficiency (TSat <20%, serum ferritin <100 ng/mL) generally requires administration of at least 1 g of IV iron. For the hemodialysis population typical dosing regimens are 100 mg as iron dextran or iron sucrose over 10 dialysis sessions, or 125 mg of sodium ferric gluconate over 8 dialysis sessions (see Table 44–3).^{15,42,43} These regimens are FDA-approved and reduce the risk of adverse reactions to IV iron therapy.

Administration of 1 g of IV iron is reasonable to initially replete patients with an absolute iron deficiency (TSat <20%, serum ferritin <100 ng/mL); however, many patients become iron deficient quickly without ongoing iron supplementation. There is sufficient evidence to support use of maintenance doses of IV iron (e.g., iron sucrose or iron dextran 25 to 100 mg/wk; sodium ferric gluconate 62.5 to 125 mg/wk), particularly in hemodialysis patients.^{15,52}

Erythropoietic Therapy

Pharmacology and Mechanism of Action. Erythropoietic growth factors are required to stimulate division and differentiation of erythroid progenitor cells and induce the release of reticulocytes from the bone marrow to the bloodstream where they mature into erythrocytes (red blood cells). Available erythropoietic agents include epoetin alfa (distributed as Epogen by Amgen, Inc., Thousand Oaks, CA; and Procrit by Ortho Biotech, Johnson & Johnson, Raritan, NJ) and darbepoetin alfa (Aranesp by Amgen, Inc.). Epoetin beta is available outside the United States. These agents are glycoproteins manufactured by recombinant DNA technology that have the same biological activity as endogenous erythropoietin. The amino acid sequence of epoetin alfa is identical to the endogenous protein; however, the carbohydrate structure differs. Since 1989, epoetin alfa has been the mainstay of therapy for anemia of CKD and substantially reduced the percentage of patients dependent on transfusions for management of anemia. Darbepoetin alfa was approved for treatment of anemia of CKD in September 2001.⁵³ Darbepoetin alfa differs from epoetin alfa by the addition of two N-linked carbohydrate side chains. This change in structure increases the sialic acid content of darbepoetin compared with epoetin alfa, resulting in a higher molecular weight (~38,000 daltons for darbepoetin compared with 30,400 daltons for epoetin alfa).⁵⁴

Pharmacokinetics and Pharmacodynamics. Epoetin alfa may be administered by either the IV or subcutaneous (SC) routes. Although bioavailability with SC administration is poor (approximately 20%), the low peak serum concentrations and the prolonged half-life (approximately 24 hours as compared to 8.5 hours IV)^{55,56} yield a Hgb/Hct response that is at least as good or better than that attained with IV administration.⁵⁷ This enhanced efficacy is presumed to be caused by a more prolonged physiologic stimulation of erythroid precursors. Darbepoetin alfa has a longer half-life and prolonged biological activity compared with epoetin alfa (darbepoetin alfa 25.3 h [IV], 48.8 h [SC]) due to the increased sialic acid content.^{55,56}

The pharmacodynamic profile of epoetin and darbepoetin are important to consider when evaluating response to therapy. These erythropoietic agents stimulate erythropoiesis, and therefore increase the red blood cell production rate. Patients with Stages 4 and 5 CKD also have a shorter red blood cell life span compared to patients with normal kidney function (64 days in contrast to 120 days in normal subjects). When the red cell production rate equals the destruction rate, as determined by the red cell life span, steady state is achieved. The challenge is in determining the appropriate dosing regimen of erythropoietic therapy to maintain the target Hgb of 11 to 12 g/dL (Hct 33% to 36%). Figure 44-3 illustrates the Hct response to the pharmacodynamic effect of epoetin (an increase in Hct). Prior to starting epoetin, the baseline Hct is constant, demonstrating that RBC production is at steady state (the rate at which RBCs are being produced equals the rate at which they are leaving the circulation). Although the Hct may begin to rise shortly following epoetin initiation as the result of demargination of reticulocytes, it takes approximately 10 days before erythrocyte progenitor cells mature and begin to be continuously released into the circulation at an increased rate. The Hct continues to increase until the life span of the cells stimulated by epoetin or darbepoetin is reached (mean 2 months; range 1 to 4 months) and a new steady state is achieved. For this reason it is important to evaluate response over several weeks as opposed to making changes to the dosing regimen prematurely.

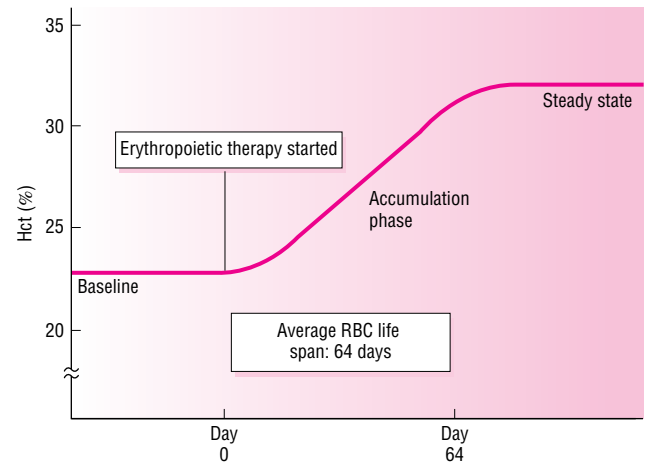

FIGURE 44-3. Pharmacodynamic effect of epoetin or darbepoetin on hematocrit (Hct).

Efficacy. Subcutaneous administration is preferable for chronic ambulatory peritoneal dialysis patients and those in the earlier stages of CKD because these patients do not usually have regular IV access. This route of administration is also recommended for most hemodialysis patients since the dose required to achieve and maintain target Hgb/Hct is lower by 15% to 50% than that associated with the intravenous route of administration.^{15,58} For many hemodialysis patients, however, IV therapy continues to be the predominant method of administration due to convenient IV access during the procedure. Comparison of weekly SC epoetin dosing with dosing three times per week in peritoneal dialysis patients showed weekly dosing to be effective in maintaining Hgb/Hct, albeit at a higher total weekly dose.⁵⁹ Similar evaluations of less frequent dosing of epoetin in the CKD population are ongoing. Figures 44-1 and 44-2 provide an algorithmic approach to management of anemia using erythropoietic agents and iron therapy in patients with CKD.

The prolonged half-life of darbepoetin offers the advantage of less frequent dosing, starting at once-a-week or once-every-other-week when given IV or SC.^{60,61} This is of particular benefit in patients with early CKD and the peritoneal dialysis population, who are not seen in the clinic as often. Prolonged dosing intervals, as infrequent as once every 3 to 4 weeks, have also been effective in maintaining target Hgb/Hct in some dialysis patients.⁶²

Iron deficiency is the most common cause of resistance to erythropoietic therapy.¹⁵ Evaluation and treatment of iron deficiency should occur prior to initiation of erythropoietic therapy as previously discussed (see Figs. 44-1 and 44-2). Inflammation (localized or systemic infection, active inflammatory disease, or surgical trauma) is associated with defective iron utilization known as reticuloendothelial block. Reticuloendothelial block is characterized by a reduction in iron delivery from body stores to the bone marrow, and is generally refractory to iron therapy. Failure to respond to erythropoietic therapy requires evaluation of other factors causing resistance, such as infection, inflammation, chronic blood loss, aluminum toxicity, hemoglobinopathies, malnutrition, and hyperparathyroidism.¹⁵ Erythropoietic therapy may be continued in the infected or postoperative patient, although increased doses are often required to maintain or slow the rate of decline in Hgb/Hct. Deficiencies in folate and vitamin B₁₂ should also be considered as potential causes of resistance to erythropoietic therapy, as both are essential for optimal erythropoiesis. Patients on hemodialysis or peritoneal dialysis should be routinely

supplemented with water-soluble vitamins (including B₁₂ and folate) since these vitamins are often depleted with dialysis therapy.

Hemodialysis may also be associated with subclinical vitamin C deficiency. There are reports in a small number of patients that IV administration of ascorbic acid enhances response to erythropoietic therapy, primarily due to the effects on iron metabolism.⁶³ There is concern, however, that long-term administration of higher doses of vitamin C may cause accumulation of oxalate. A long-term trial that examines the efficacy and safety of vitamin C is needed before this practice can be widely advocated. There is also some evidence to suggest that patients receiving ACEIs may be relatively resistant to erythropoietic therapy, although these findings have not been consistently demonstrated.⁶⁴ An increase in the dosage of erythropoietic agents may be necessary in patients receiving ACEIs who do not maintain a stable Hgb/Hct.

Studies have demonstrated reduced morbidity, increased exercise capacity and tolerance, and enhanced quality of life when erythropoietic therapy was initiated, iron stores maintained, and target Hgb attained.^{15,27} Data also suggest a stabilization or regression of LVH in patients with early kidney disease and in those with ESRD when anemia is successfully treated.^{65,66} Preventing the development of LVH is one of the desired outcomes of anemia management. Thus these findings which demonstrate regression of LVH at increased Hgb levels support more aggressive management of anemia in the early stages of CKD. Whether there is an optimal Hgb target to prevent development of LVH remains to be determined. In a 2-year study no difference in left ventricular mass index was observed for patients with Stages 3 or 4 CKD maintained at a Hgb of 9 to 10 g/dL versus 12 to 13 g/dL.⁶⁷ Given these observations of a relationship between anemia and LVH, additional prospective studies addressing this question will be needed to resolve the controversy.

■ **Adverse Effects.** Epoetin alfa and darbepoetin alfa are generally well tolerated; however, hypertension is the most common adverse event reported.^{15,53} Protocols established in some clinical settings, primarily in outpatient dialysis clinics, sometimes recommend withholding erythropoietic therapy based on the degree of elevation in blood pressure. This practice on a routine basis is not rational given the benefits of maintaining the target Hgb and the availability of more practical measures to control blood pressure. K/DOQI guidelines for anemia recommend withholding erythropoietic therapy only when hypertension is refractory to aggressive blood pressure management approaches such as pharmacologic therapy and dialysis.¹⁵ Of interest is the fact that epoetin doses were 5.5% higher in dialysis patients with hypertension compared to patients without high blood pressure.³ Seizures have occurred in patients treated with epoetin; however, the incidence does not appear to be increased over the baseline levels seen in placebo control groups. Vascular access thrombosis may be more frequent during epoetin therapy, but this finding has not been supported to the extent necessary to advocate increased monitoring for this effect.¹⁵

Neutralizing antibodies to epoetin have been identified in a small number (less than 200) of patients treated with either epoetin alfa or epoetin beta.⁶⁸ These patients developed an absolute resistance to epoetin therapy which relegates them to intermittent blood transfusions as the primary therapeutic option. Cases have been reported, primarily with one epoetin alfa product manufactured outside the United States, Eprex (Johnson & Johnson, Manati, Puerto Rico), and have occurred in parallel with the increase in SC administration. Although the case reports are relatively few in number, clinicians should be aware of this thus far rare phenomenon in patients resistant to erythropoietic

therapy. Patients who develop antierythropoietin antibodies should not receive other erythropoietic agents, as cross-reactivity has been demonstrated.

■ **Drug-Drug Interactions.** No significant drug interactions have been reported with the available erythropoietic agents.

■ **Dosing and Administration.** Starting doses of epoetin alfa are 80 to 120 units/kg per week for SC administration and 120 to 180 units/kg per week for IV administration divided in two to three doses per week (typically three times per week for hemodialysis patients receiving IV therapy). If a patient is converted from IV to SC epoetin and is not at the target Hgb/Hct, the weekly SC dose should remain the same as the IV dose. If they have achieved the target Hgb/Hct a one-third reduction in dose is appropriate.¹⁵ The starting dose of darbepoetin alfa in patients not previously receiving erythropoietic therapy is 0.45 mcg/kg IV or SC administered once weekly.⁵³ A conversion table is available for patients who are to be switched from epoetin alfa (units per week) to darbepoetin alfa (micrograms per week) (Table 44–4).

Currently two formulations of epoetin alfa are available: a single-dose, preservative-free solution (2000-, 3000-, 4000-, 10,000-, and 40,000-unit/mL vials) and a multidose, preserved solution (10,000- and 20,000-unit/mL vials). A clinical trial comparing these two formulations in terms of pain intensity after SC administration found that the multiple-dose formulation was associated with less stinging, although several patients did not experience pain with the single-dose preparation.⁶⁹ Darbepoetin alfa is available in two solutions, a polysorbate solution and an albumin solution, supplied as single-dose vials (25-, 40-, 60-, 100-, and 200-mg/mL vials containing polysorbate) and (25-, 40-, 60-, 100-, 150-, 200-, 300-, and 500-mg/mL vials containing albumin), respectively.⁵³

Generally the response to erythropoietic therapy should be evaluated over at least 2 to 4 weeks before a change in the dose of epoetin alfa or darbepoetin alfa is made. If the change in Hgb is <1 g/dL (Hct less than 2% to 3%), over this time interval the dose of erythropoietic agent should be increased by 50% for epoetin alfa or 25% for darbepoetin alfa. If the change in Hgb is >2 to 3 g/dL (Hct greater than 6% to 8%) the dose of epoetin alfa or darbepoetin alfa should be reduced by 25%.

TABLE 44–4. Estimated Darbepoetin Alfa Starting Doses Based on Previous Epoetin Alfa Dose

| Previous Weekly Epoetin Alfa Dose ^{a,b} (units/week) | Weekly Darbepoetin Alfa Dose (mcg/week) |
|---|---|
| <2,500 | 6.25 |
| 2,500 to 4,999 | 12.50 |
| 5,000 to 10,999 | 25.00 |
| 11,000 to 17,999 | 40.00 |
| 18,000 to 33,999 | 60.00 |
| 34,000 to 89,999 | 100.00 |
| ≥90,000 | 200.00 |

^aDarbepoetin alfa should be administered weekly for patients receiving epoetin alfa two or three times per week and every other week for patients receiving epoetin alfa once per week.

^bFor patients requiring darbepoetin alfa every other week, the weekly dose of epoetin alfa should be multiplied by two and this dose used in the conversion chart to determine the appropriate darbepoetin alfa dose.

From darbepoetin package insert.⁵³

■ PHARMACOECONOMIC CONSIDERATIONS

Pharmacoeconomic considerations in the management of anemia of CKD relate primarily to the costs associated with erythropoietic agents and the increased use of IV iron to sustain erythropoiesis. Over the last decade there has been a steady rise in cost associated with the provision of epoetin and IV iron for the dialysis population: the cost to Medicare has stabilized at just over \$1 billion per year during the last 2 to 3 years.³ Cost advantages can be realized, however, from the benefits associated with appropriate management of anemia, including fewer days of hospitalization, decreased mortality, and increased transplant success.^{3,27} Implementation of maintenance IV iron therapy, as well as SC administration of epoetin, also has the potential to reduce Medicare cost for anemia management. Current Medicare reimbursement rates for epoetin and IV iron produce profits of 12% and 45%, respectively for most dialysis programs, and thus there is little incentive to minimize the use of either agent. In the case of iron therapy, IV iron is reimbursable by Medicare, whereas oral iron is either paid for by the patient out-of-pocket or by secondary insurers (usually with a copayment). Capitation of payments for medications such as erythropoietic agents and IV iron therapy may force the dialysis community to change their clinical practices and thereby optimize their utilization.

Considerations are a bit different in patients with early CKD since Medicare does not cover medication costs for this population. The lack of payment is a deterrent to timely implementation of therapy and likely contributes to the development of secondary complications such as anemia. A recent pharmacoeconomic consideration in the CKD population is whether the addition of darbepoetin alfa offers a financial incentive in addition to advantages of less frequent dosing from a patient's perspective. As use of darbepoetin has become more widespread and the costs more stable, clinicians involved in the care of this patient population are beginning to consider economic factors that influence selection of erythropoietic therapy.⁷⁰

CLINICAL CONTROVERSY

Some clinicians advocate discontinuing IV iron therapy when patients are actively infected. This applies also to erythropoietic therapy if it is believed that the patient will not respond (i.e., they are resistant to therapy because of the inflammatory process).

■ EVALUATION OF THERAPEUTIC OUTCOMES

An algorithmic approach to patient evaluation and treatment with iron and erythropoietic therapies in adults is depicted in Figs. 44–1 and 44–2. Iron status should be assessed every month for patients started on erythropoietic therapy who are not concurrently receiving iron and every 3 months for patients receiving iron until a stable Hgb/Hct has been achieved. Once at the goal Hgb/Hct, iron indices should be measured every 3 months to determine the need for iron supplementation or any adjustments in the current regimen.¹⁵ Hgb/Hct should be monitored every 1 to 2 weeks after initiation of erythropoietic therapy or following a dose change until stable. Once stable, the Hgb should be monitored every 2 to 4 weeks. An inadequate response to epoetin alfa therapy is defined as failure to achieve target Hgb/Hct in iron-replete patients when an adequate dose (usually 450 units/kg per week IV or 300 units/kg per week SC) has been administered for 4 to 6 months, or failure to maintain target Hgb/Hct subsequently at that dose.¹⁵

■ SECONDARY HYPERPARATHYROIDISM AND RENAL OSTEODYSTROPHY

◀ Calcium and phosphorus balance is mediated through the complex interplay of hormones and their effects on bone, the GI tract, kidney, and parathyroid gland. What begins as relatively minor imbalances in phosphorus and calcium homeostasis leads to secondary hyperparathyroidism (sHPT) in the short term and ultimately renal osteodystrophy (ROD) if these metabolic abnormalities are not corrected.

As kidney function declines there is a decrease in phosphorus elimination which results in hyperphosphatemia and a reciprocal decrease in serum calcium concentration. Hypocalcemia is the primary stimulus for release of PTH by the parathyroid glands, the effects of which are mediated by the interaction of ionized calcium with the calcium-sensing receptor on the chief cells of the parathyroid gland. Hyperphosphatemia also increases PTH synthesis and release through its direct effects on the parathyroid gland and production of pre-PTH messenger RNA.⁷¹ In an attempt to normalize ionized calcium, PTH decreases phosphorus reabsorption and increases calcium reabsorption by the proximal tubules of the kidney (at least until the GFR falls to less than approximately 30 mL/min), and also increases calcium mobilization from bone. The result is a correction in calcium and phosphorus, at least in the early stages of CKD; however, this occurs at the expense of an elevated PTH (“the trade-off hypothesis”). The increase in PTH is most notable when GFR is <60 mL/min per 1.73 m² (Stage 3 CKD) and worsens as kidney function declines further.

Active vitamin D (1,25-dihydroxyvitamin D₃ or calcitriol) promotes increased intestinal absorption of calcium which helps to normalize ionized calcium. Calcitriol also works directly on the parathyroid gland to suppress PTH production. The enzyme 1- α -hydroxylase is responsible for the final hydroxylation and conversion of the vitamin D precursor, 25-hydroxyvitamin D, to the active form in the kidney. As kidney disease progresses this conversion is impaired and vitamin D deficiency results. Calcitriol levels have been shown to decrease significantly before there is a perceptible rise in PTH in CKD patients.⁷² Other differences in vitamin D metabolism observed in patients with CKD that lead to deficiencies in the 25-hydroxyvitamin D precursor include decreased dermal synthesis of vitamin D, decreased exposure to sunlight, and reduced dietary intake of vitamin D.¹⁸ Although 1,25-dihydroxyvitamin D₃ is the most potent form, 25-hydroxyvitamin D is the main circulating metabolite and is considered the best functional indicator of vitamin D stores in humans. In patients with Stage 3 or Stage 4 CKD, 25-hydroxyvitamin D levels of <30 ng/mL have been associated with increased PTH.¹⁸ As a result of such findings, evaluation of 25-hydroxyvitamin D levels is warranted in patients with Stage 3 and 4 CKD, with supplementation recommended in patients with observed deficiencies.

A multiplicity of metabolic disorders in patients with CKD contributes to worsening sHPT and the consequences associated with elevated PTH (Fig. 44–4). The continuous production of PTH by the parathyroid glands leads to parathyroid hyperplasia (nodular or diffuse). Nodular tissue demonstrates more rapid growth potential and appears to be associated with fewer vitamin D and calcium-sensing receptors, which results in resistance to the effects of calcium and vitamin D therapy and subsequent development of ROD.⁸ Bone loss can be detected in patients with early stages of kidney disease and multiple types of bone lesions have been identified from bone biopsies of patients on dialysis.⁷³ The skeletal complications associated with ROD

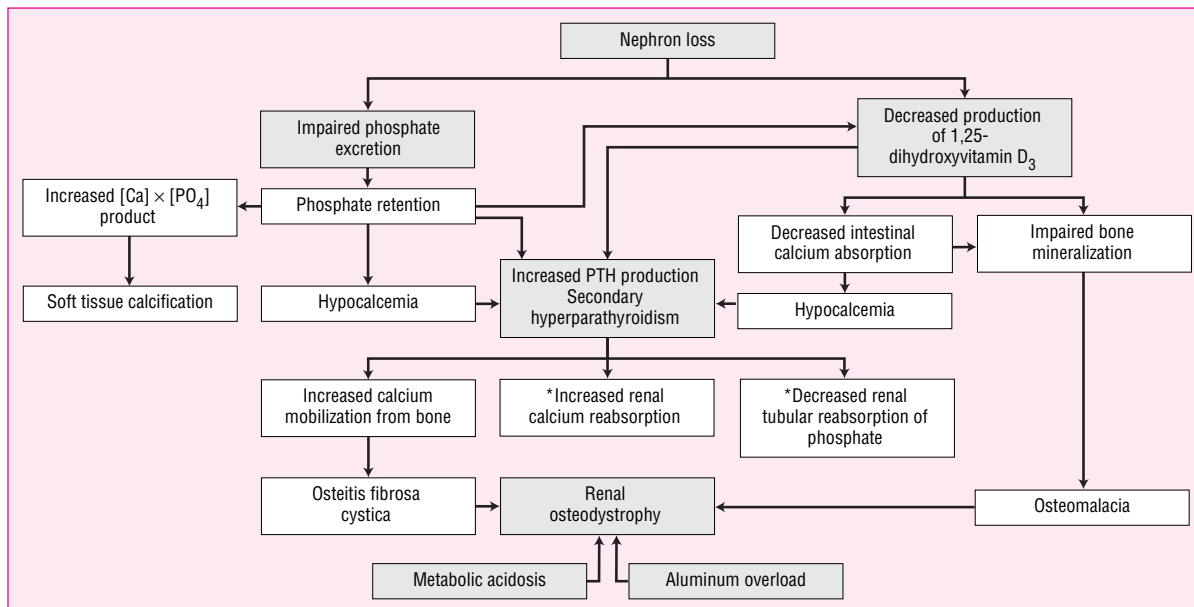

FIGURE 44-4. Pathogenesis of secondary hyperparathyroidism and renal osteodystrophy in patients with CKD. (These adaptations are lost as renal failure progresses.)

include osteitis fibrosa cystica (high bone turnover disease), osteomalacia (low bone turnover disease) and adynamic bone disease. Osteitis fibrosa cystica is characterized by areas of peritrabecular fibrosis. Dynamic measurements show a high bone formation rate, which results from high circulating concentrations of PTH. Osteomalacia was historically caused by aluminum toxicity in hemodialysis patients, a finding less common today with decreased use of aluminum-containing phosphate binders and changes in the processing of dialysate solutions to decrease aluminum absorption. Adynamic lesions are characterized by low amounts of fibrosis or osteoid tissue and low bone formation rates. The incidence of adynamic lesions has increased dramatically over the last 10 years, and may be present in as many as 50% of dialysis patients.⁷⁴ Multiple risk factors for the development of this bone disease have been identified: aluminum toxicity; high concentrations of dialysate calcium along with high doses of calcium-containing phosphate binders; aggressive management with vitamin D therapy; diabetes; and advanced age.⁷⁴ Symptoms often occur late, when significant skeletal damage has developed; therefore prevention is the key to management and controlling long-term complications.

Secondary HPT as evidenced by PTH levels >495 pg/mL in CKD patients has been associated with increased morbidity and mortality and sudden death in hemodialysis patients.⁷⁵ Other adverse consequences of sHPT include alterations in lipid metabolism, insulin secretion, resistance to erythropoietic therapy, and myocardial and skeletal muscle, as well as neurologic and immune functions.⁷⁶ An elevated calcium times phosphorus product ($\text{Ca} \times \text{P}$) is also associated with poor outcomes, including vascular calcification, cardiovascular disease, calciphylaxis, and death.⁷⁷ In two large national cross-sectional samples of hemodialysis patients who had received dialysis for at least 1 year, elevated serum phosphorus levels and $\text{Ca} \times \text{P}$ were associated with increased risk of death.^{77,78} Patients with a $\text{Ca} \times \text{P} > 72$ mg^2/dL^2 were found to have a 34% higher risk of death compared with patients with a $\text{Ca} \times \text{P}$ in the reference range of 43 to 52 mg^2/dL^2 . Calcium scores, as measured by electron beam computed tomography, were significantly higher in hemodialysis patients than patients without kidney disease who had proven coronary artery disease (CAD). Intake of calcium from calcium-based binders also

appears to be a significant contributor to coronary artery calcification, even in young dialysis patients.⁷⁹ These data underscore the need to consider all the consequences of elevated PTH and $\text{Ca} \times \text{P}$, not only ROD.

■ DESIRED OUTCOME

The overall goal of therapy is to prevent sHPT and ROD, and the detrimental consequences of these disorders, including cardiovascular and extravascular calcifications. While clinicians are becoming more aware of such consequences, efforts to improve evaluation and management in patients prior to development of more severe disease are needed. Over 50% of patients with Stage 4 CKD have abnormal bone histology despite having relatively normal PTH levels.⁸⁰ There is also need for improvement in management of metabolic disorders in dialysis patients. In a random sample of 612 hemodialysis patients, 50% had an intact PTH level more than three times the established range.⁸¹ Hyperphosphatemia is present in about 70% of ESKD patients and 40% of these patients had values exceeding 6.5 mg/dL .⁷⁸ Data on medication use in patients with ESKD revealed that only 42% of hemodialysis and 33% of peritoneal dialysis patients were prescribed either oral (8% hemodialysis, 30% peritoneal dialysis patients) or IV (35% hemodialysis, 1% peritoneal dialysis) calcitriol, the only available vitamin D preparation at the time of data collection.⁸² These evaluations show that many patients with CKD are receiving suboptimal management of their disorders of calcium, phosphorus, and PTH homeostasis.

K/DOQI guidelines for the diagnosis and management of bone disease in CKD proposed new criteria for calcium, phosphorus, $\text{Ca} \times \text{P}$, and intact PTH (iPTH) based on the stage of CKD (Table 44-5).¹⁸ The recommended corrected serum calcium for patients with Stage 3 or Stage 4 CKD, is within the normal range while the proposed upper range for patients with Stage 5 CKD is slightly lower than what is considered a normal total calcium. This is based on the observation of an increased risk of soft tissue and vascular calcifications in this population and the exposure to dialysate calcium.

TABLE 44-5. K/DOQI Guidelines for Calcium, Phosphorus, Calcium Phosphorus Product, and Intact Parathyroid Hormone

| Parameter | Stage 3 CKD | Stage 4 CKD | Stage 5 CKD |
|--|-------------|-------------|-------------|
| Corrected calcium (mg/dL) | "Normal" | "Normal" | 8.4–9.5 |
| Phosphorus (mg/dL) | 2.7–4.6 | 2.7–4.6 | 3.5–5.5 |
| Ca × P (mg ² /dL ²) | <55 | <55 | <55 |
| Intact PTH (pg/mL) | 35–70 | 70–110 | 150–300 |

K/DOQI, Kidney Disease Outcomes Quality Initiative.
From Eknoyan et al.¹⁸

It is important to note that these are calcium concentrations corrected for the degree of protein binding (i.e. corrected based on serum albumin concentration). The corrected calcium value should also be used to determine the Ca × P product. Recommended serum phosphorus concentrations are 2.7 to 4.6 mg/dL, with higher concentrations acceptable in Stage 5 CKD. The proposed Ca × P of 55 mg²/dL² is much lower than the historically accepted range of 65 to 70 mg²/dL². The iPTH recommended for patients with Stage 4 or 5 CKD is above the normal range in order to prevent oversuppression of PTH and reduce the risk of adynamic bone disease. Serum aluminum levels should also be maintained below 20 mcg/L to minimize the risk of developing aluminum toxicity, a contributing factor to bone disease.¹⁸

PATIENT EVALUATION

Bone mineral density and serum calcium and calcitriol concentrations decrease progressively, while serum PTH, osteocalcin, bone-specific alkaline phosphatase, and phosphorus concentrations increase as GFR declines.⁷³ Evaluation of bone histology may be warranted in patients with severe sHPT or in Stage 4 or 5 CKD patients who develop symptoms. Bone disease can be diagnosed using iliac crest bone biopsy and bone histomorphometric analysis. Bone-mineral densitometry studies may also be used to detect bone loss in patients with CKD and are useful to follow progress after therapeutic intervention. Coronary artery calcification can be evaluated by noninvasive means using electron beam computed tomography. Invasive procedures such as coronary angiography can also be used to ascertain the degree of damage if the newer technology is not available.

Regular monitoring of serum aluminum levels should be done at least yearly and as frequently as every 3 months in patients receiving aluminum-containing phosphate binders or other aluminum-based medications, although regular use of these agents is not recommended in patients with CKD.¹⁸ If aluminum concentrations are elevated (60 to 200 mcg/L) a deferoxamine (DFO) test should be done. The DFO infusion test is based on the concept that the amount of aluminum mobilized following a single dose of DFO is representative of the total body burden of aluminum. A dose of 5 mg/kg of DFO is administered, generally over the last hour of dialysis for hemodialysis patients. The serum aluminum level predose and 2 days postdose are compared. A change in serum aluminum concentration of ≥50 mcg/L is considered a positive test. A change of this magnitude in conjunction with a iPTH of <150 pg/mL is indicative of aluminum bone disease, which should then be confirmed by bone biopsy.¹⁸

PTH is secreted from the parathyroid gland as intact PTH, an 84-amino-acid peptide chain (1-84 PTH) that is biologically active, and as smaller carboxy-terminal PTH fragments.⁸³ Circulating levels of these fragments (e.g., 7-84 PTH) may increase substantially in patients

with CKD and have activity antagonistic to the effects to 1-84 PTH.⁸³ Available immunoradiometric and immunochemiluminescent assays for measurement of intact PTH such as the Nichols Institute Allegro IRMA measure not only the intact molecule, but also fragments, which may lead to overestimation of biologically active PTH. The goal iPTH based on this assay method in ESKD patients is three to five times the upper limits of normal (approximately 200 to 300 pg/mL). A new assay called the whole PTH or Bio-Intact PTH is now available that detects the full-length PTH molecule.⁸⁴ The predictive power of this newer assay and acceptable target ranges based on the stage of CKD have not been determined. The ratio of the 1-84 PTH to 7-84 PTH has also been evaluated as a tool to assess bone turnover and has been proposed as a better predictor of bone turnover than the other biochemical parameters.⁸⁵ Clinicians involved in the care of patients with CKD should become familiar with the tests used in their facilities in order to provide optimal care for their patients.

GENERAL APPROACH TO TREATMENT

ROD progresses insidiously for several years before patients become symptomatic. When symptoms such as bone pain and skeletal fractures occur, the disease is not easily amenable to treatment. Bone marrow fibrosis and decreased hematopoiesis are also consequences of severe osteitis fibrosa cystica. Therefore preventative measures should be initiated in patients in the early stages of CKD (GFR <60 mL/min).

10 Management of PTH, phosphorus, and calcium balance, and minimization of patient exposure to aluminum are important in preventing the development of sHPT and slowing or preventing the progression of ROD and associated consequences. Control of serum phosphorus is paramount since hyperphosphatemia is an initiating event in the development of other metabolic disturbances. Unfortunately, hyperphosphatemia is difficult to control and hypercalcemia may develop as a result of treatment with calcium-containing phosphate binders.⁷⁹ There are different considerations in management of sHPT based on the stage of CKD. Hyperphosphatemia and sHPT in patients with Stage 3 or Stage 4 CKD are often overlooked. If these patients are not evaluated early in the course of the disease, they have a higher likelihood of developing metabolic abnormalities that contribute to poor outcomes by the time they reach Stage 5 CKD. Patients with Stage 5 CKD usually require a combination of phosphate-binding medication and vitamin D therapy to slow the progression of sHPT, ROD, and cardiovascular and extravascular calcifications. Appropriate management includes all options identified for patients in earlier stages of CKD, with the exception that active vitamin D therapy is generally prescribed for a larger percentage of this population. The risks and benefits of phosphate-binding agents and the risks and benefits of vitamin D therapy must also be considered

when choosing a treatment regimen (see section on pharmacologic therapy).

■ NONPHARMACOLOGIC THERAPY

■ Dietary Phosphorus Restriction

Dietary phosphorus restriction should be a first-line intervention for management of hyperphosphatemia in patients with CKD and should be initiated for most patients with Stage 3 or higher CKD. The K/DOQI guidelines recommend phosphorus restriction to 800 to 1000 mg/day when the upper levels of phosphorus are reached (see Table 44–5).¹⁸ This recommendation also holds true for patients with iPTH levels above the recommended range, given the evidence that lowering phosphorus ingestion directly decreases PTH synthesis and secretion.^{8,18} The challenge with dietary restriction of phosphorus is providing enough protein to prevent malnutrition, a common problem in the CKD population, since foods high in phosphorus are generally high in protein. Examples of foods or beverages that contain high amounts of phosphorus include meats, dairy products, dried beans, nuts, colas, peanut butter, and beer. Nutritional goals must be evaluated on an individual basis, preferably by a dietitian specializing in the care of CKD patients. Dialysis patients require a higher protein intake (1.2 to 1.3 g/kg per day) making restriction of phosphorus even more challenging. Removal of phosphorus does occur with peritoneal dialysis and hemodialysis (approximately 2 to 3 g/wk, dependent on the dialysis prescription); however, dialysis alone does not adequately control hyperphosphatemia for these patients.

One of the most common obstacles to the success of dietary restriction is patient noncompliance due to the poor palatability and inconvenience. Regular counseling by a dietitian is essential to improve patient compliance. As kidney function declines, dietary restriction alone is usually inadequate to control serum phosphorus, and phosphate-binding agents are necessary (see section on pharmacologic therapy).

■ Parathyroidectomy

Parathyroidectomy is the last therapeutic option for patients with sHPT. The K/DOQI guidelines for bone metabolism and disease recommend surgery only for those with persistently elevated iPTH (iPTH >800 pg/mL) associated with hypercalcemia and/or hyperphosphatemia that are refractory to medical therapy.¹⁸ Surgical approaches include either subtotal parathyroidectomy or total parathyroidectomy with autotransplantation of parathyroid tissue to an accessible site, such as the forearm. Postoperative hypocalcemia, hypophosphatemia, and hypomagnesemia may occur because of a marked increase in bone production in relation to bone absorption (“hungry bone syndrome”). Following surgery frequent monitoring of ionized calcium is required (every 4 to 6 hours for the first 48 to 72 hours postsurgery). Ionized calcium should be maintained above 3.6 mg/dL (0.9 mmol/L) using calcium gluconate infusions if necessary. The recommended dose of calcium gluconate is 1 to 2 mg of elemental calcium per kilogram per hour, adjusted to maintain ionized calcium at 4.6 to 5.4 mg/dL (1.15 to 1.36 mmol/L). Once the ionized calcium is stable, oral therapy may be initiated with 1 to 2 g of calcium carbonate in conjunction with calcitriol in doses of up to 2 mcg per day. Adjustments in phosphate binders will also be necessary to maintain target phosphorus levels (see section on pharmacologic

therapy).¹⁸ Treatment with supplemental calcium and vitamin D may be necessary for weeks or months.

■ PHARMACOLOGIC THERAPY

■ Phosphate Binding Agents

■ *Pharmacology and Mechanism of Action.* Drugs that bind dietary phosphorus in the GI tract form insoluble aluminum, calcium, or magnesium phosphate which is excreted in feces, thus reducing phosphorus absorption and serum phosphorus concentrations. A variety of phosphate-binding agents are available including calcium-, aluminum-, or magnesium-containing compounds and the nonelemental agent sevelamer hydrochloride (Table 44–6). Patients must be instructed to take these agents with meals to minimize absorption of phosphorus from dietary sources.

■ *Efficacy.* Oral calcium compounds are well established as first-line agents for control of both serum phosphorus and calcium concentrations, at least in the early stages of CKD when hypocalcemia is more common. Calcium carbonate and calcium acetate are the primary preparations used; calcium citrate is also available, but is not recommended since the citrate component increases aluminum absorption. The chloride salt is also not recommended since it is very astringent and unpalatable, and absorbed chloride may contribute to systemic acidosis. Calcium carbonate is marketed in a variety of dosage forms (see Table 44–6) and is relatively inexpensive. Unfortunately, many calcium carbonate products are considered food supplements and thus are not required by law to meet United States Pharmacopeia (USP) disintegration and dissolution requirements. In general, nationally advertised brands meet USP quality standards for disintegration and dissolution, but it is difficult to determine whether private label or house brands conform to these standards. Variability in gastric pH may also affect disintegration or dissolution, and thus phosphate binding efficacy.⁸⁶ Calcium carbonate is more soluble in an acidic medium, and therefore should be administered prior to meals when stomach acidity is highest. In addition, acid-suppressing agents such as ranitidine or proton pump inhibitors may reduce the phosphate-binding activity of calcium carbonate by increasing gastric pH. Calcium acetate binds approximately twice as much phosphorus as calcium carbonate at comparable doses of elemental calcium.⁸⁷ Increased binding potency limits GI calcium absorption; however, calcium acetate is more soluble, and therefore better absorbed than calcium carbonate in an alkaline pH, which may explain the similar incidence of hypercalcemia. Patients with a corrected calcium of less than 8.4 mg/dL should receive calcium carbonate or calcium acetate as a calcium supplement (with or without vitamin D therapy).

Although calcium-containing phosphate-binding agents continue to be used as first-line therapy, their chronic use may increase the risk for vascular and tissue calcification.⁷⁹ The K/DOQI guidelines now recommend that the total dose of elemental calcium provided by calcium-containing binders not exceed 1500 mg per day and the total daily intake from all sources not exceed 2000 mg.¹⁸ This presents clinicians with a challenge for patients in whom maximum doses do not achieve the goal phosphorus or who have an elevated serum calcium. In such situations, a non-calcium-based binder alone or in combination with a calcium product may be needed. Calcium-containing binders are not recommended in dialysis patients when on two consecutive measurements the serum calcium is >10.2 mg/dL or the iPTH is <150 pg/mL.¹⁸

TABLE 44–6. Phosphate-Binding Agents Used in the Treatment of Hyperphosphatemia in CKD

| Compound | Trade Name | Compound Content (mg) | Elemental Calcium Content (mg) | Starting Doses | Comments |
|---|------------------|---|--------------------------------|--|---|
| Calcium carbonate ^a (40% elemental calcium) | Tums | 500, 750, 1000, 1250 | 200, 300, 400, 500 | 0.5–1 g (elemental calcium) three times a day with meals | First-line agent; dissolution characteristics and phosphate binding affect may vary from product to product; try to limit daily intake of elemental calcium to 1500 mg/day Approximately 39 mg phosphorus bound per 1 g calcium carbonate |
| | Oscal-500 | 1250 | 500 | | |
| | Caltrate 600 | 1500 | 600 | | |
| | Nephro-Calci | 1500 | 600 | | |
| | LiquiCal | 1200 | 480 | | |
| | CalciChew | 1250 | 500 | | |
| Calcium acetate (25% elemental calcium) | PhosLo | 667 | 167 | 0.5–1 g (elemental calcium) three times a day with meals | First-line agent; comparable efficacy to calcium carbonate with half the dose of elemental calcium; do not exceed 1.5 mg of elemental calcium per day Approximately 45 mg phosphorus bound per 1 g calcium acetate By prescription only |
| Sevelamer | Renagel | 400, 800 | — | 800 mg three times a day with meals | First-line agent; lowers LDL cholesterol More expensive than calcium products; preferred in patients at risk for extraskeletal calcification |
| Aluminum hydroxide | Alterna GEL | 600 mg/5 mL | — | 300–600 mg three times a day with meals | Third-line agents; do not use concurrently with citrate-containing products Reserve for short-term use (4 weeks) in patients with hyperphosphatemia not responding to other binders |
| | Amphojel | 300, 600 (tablet) 320 mg/5 mL (suspension) | | | |
| | Alu-Cap | 400 | | | |
| Aluminum carbonate | Basaljel | 500 (tablet, capsule) 400 mg/5 mL (suspension) | — | 450–500 mg three times a day with meals | Same as for aluminum hydroxide |
| Magnesium carbonate | Mag-Carb | 70 mg capsule | — | 70 mg three times a day with meals | Third-line agent; diarrhea common; monitor serum magnesium |
| Magnesium hydroxide | Milk of magnesia | 300, 600 (tablet) 400 mg/5 mL, 800 mg/5 mL (suspension) | — | 300–400 mg three times a day with meals | Same as for magnesium carbonate |
| Magnesium carbonate/ calcium carbonate | MagneBind 200 | 200 mg | 160 | 200 mg three times a day with meals (based on magnesium content) | Same as for calcium carbonate and magnesium carbonate |

^aMultiple preparations available which are not listed.
LDL, low-density lipoprotein.

Sevelamer hydrochloride is a nonabsorbable hydrogel phosphate-binding agent which does not contain aluminum, calcium, or magnesium.⁸⁸ The dosage needed to control serum phosphorus concentrations may be as high as 6.3 g/day.⁸⁸ Sevelamer also significantly lowers low-density lipoprotein (LDL) cholesterol and resulted in an elevation in high-density lipoprotein (HDL) by a mean of 30% and 18%, respectively. This is an added beneficial effect in a population at risk for cardiovascular events. Recent evidence has shown a decreased rate of vascular calcification in hemodialysis patients receiving this agent relative to those prescribed calcium-containing binders.⁸⁹ Sevelamer is now recommended as primary therapy in dialysis patients with severe vascular or soft tissue

calcifications, and may also be used as a first-line phosphate-binding agent in patients with Stage 5 CKD.¹⁸ The cost of sevelamer may be a limiting factor for some patients.

Aluminum salts were widely used in the 1980s as phosphate-binding agents because of their high binding potency. They should be considered as third-line agents now and be reserved for acute treatment of severe hyperphosphatemia or used at low doses in combination with either calcium-containing binding agents or sevelamer hydrochloride in cases of hyperphosphatemia that is not responding to therapy with a single agent. The duration of aluminum therapy should be limited to 4 weeks.¹⁸ Magnesium-containing antacids are also effective phosphate binders and may decrease the amount

of calcium-containing binders necessary for control of phosphorus. Their use may be limited by the frequent occurrence of GI side effects. Other phosphate binders being investigated include lanthanum carbonate, an agent that has demonstrated significant efficacy as measured by decreases in phosphorus, $\text{Ca} \times \text{P}$, and PTH when compared with placebo.⁹⁰ Ferric salts have been shown to bind with intestinal phosphorus in animal and human studies, although the clinical application of these results needs to be confirmed in subsequent clinical trials.⁹¹

■ **Adverse Effects.** Adverse effects of calcium-containing phosphate binders are generally limited to GI side effects including constipation, diarrhea, nausea, vomiting, and abdominal pain. The risk of hypercalcemia is also a concern and may necessitate restriction of calcium intake from the combination of calcium-containing binders and dietary intake. Aluminum binders can no longer be recommended as first-line therapy because of the CNS toxicity and the worsening of anemia associated with aluminum accumulation. While an effective phosphate binder, use of magnesium is often limited by side effects including diarrhea, abdominal cramps, hypermagnesemia, and hyperkalemia.

■ **Drug-Drug and Drug-Food Interactions.** Calcium-containing phosphate-binding agents interfere with the absorption of several other oral medications that are commonly prescribed for CKD patients, including oral iron and zinc and quinolone antibiotics. Data regarding drug interactions with sevelamer are limited; however, in recent evaluations no drug interactions with digoxin, warfarin, metoprolol, or enalapril were observed.^{92,93} Many phosphate binders are marketed as antacids or calcium supplements and often CKD patients do not know why they have been prescribed these agents. Regular patient counseling by a pharmacist is essential to enhance compliance and minimize the potential for drug interactions.

■ **Dosing and Administration.** Starting doses of phosphate binding agents are listed in Table 44–6. Doses should be titrated to achieve the recommended serum phosphorus concentrations yet avoid complications such as hypercalcemia.

■ Vitamin D Therapy

Vitamin D compounds include ergocalciferol (vitamin D_2) and cholecalciferol (vitamin D_3) that must be converted to the active form in the kidney. Calcitriol (1,25-dihydroxyvitamin D_3) is the most active form of vitamin D and is available as an oral formulation (Rocaltrol) as well as an IV formulation (Calcijex). The currently available vitamin D analogs include paricalcitol (19-nor-1,25-dihydroxyvitamin D_2 ; Zemplar), doxercalciferol (1- α -hydroxyvitamin D_2 ; Hectrol) and 1- α -hydroxyvitamin D_3 (alfacalcidol, not available in the United States). Calcitriol or one of the vitamin D analogs is required for patients with severe kidney disease since these agents do not require conversion by the kidney to the most biologically active form.

■ **Pharmacology and Mechanism of Action.** Active vitamin D suppresses PTH secretion by stimulating absorption of serum calcium (and phosphorus) by intestinal cells and through direct activity on the parathyroid gland to decrease PTH synthesis. As a result, the serum calcium concentration is raised and the parathyroid glands decrease the rate of secretion and formation of PTH. The set point for calcium (i.e., the calcium concentration at which PTH secretion is

decreased by 50%), which is generally raised in sHPT, is lowered when active vitamin D therapy is initiated. This indicates that a lower ionized calcium concentration is effective at suppressing secretion of PTH. All of these actions are mediated by the interaction of vitamin D with vitamin D receptors (VDRs) which are located in many organs, including the parathyroid gland, GI tract, and kidney.⁹⁴ Calcitriol also upregulates VDRs, which ultimately may reduce parathyroid hyperplasia. Unfortunately, the enhanced GI absorption of calcium and phosphorus with calcitriol therapy frequently leads to hypercalcemia and hyperphosphatemia. There is also evidence that hyperphosphatemia results in resistance to the PTH-suppressing effects of vitamin D analogs and directly stimulates PTH release. These actions contribute to the increase in the $\text{Ca} \times \text{P}$ product, which can lead to soft-tissue and vascular calcification.^{78,79} Therefore control of calcium and phosphorus must be achieved before vitamin D therapy is initiated.

The unique interactions of vitamin D with the VDRs have been a focus of research and have led to the development of vitamin D analogs, which vary in their affinity for this receptor and thus may result in less hypercalcemia, while retaining the positive physiologic actions on bone and parathyroid tissue.⁹⁴ Paricalcitol and doxercalciferol are D_2 compounds which effectively lower PTH in dialysis patients.^{95,96} Paricalcitol differs from calcitriol by the absence of the exocyclic carbon 19 and the fact that it is a vitamin D_2 derivative. Currently this analog is available only for IV administration; however, an oral formulation is in development. Doxercalciferol, in contrast to calcitriol and paricalcitol, is a prohormone that needs to be hydroxylated in the liver to its active 1,25-dihydroxyvitamin D_2 product. Doxercalciferol is available for both IV and oral administration.

■ **Pharmacokinetics.** Calcitriol can be administered orally as well as by IV injection. Oral absorption occurs rapidly; therefore oral and IV therapies are both reasonable options for treatment of sHPT. While historically a topic of controversy, a review of the available literature has led to the conclusion that intermittent IV administration of calcitriol is more effective than daily oral calcitriol for sHPT.¹⁸ Paricalcitol is administered intravenously and its half-life is similar to that of calcitriol (up to 30 hours). Doxercalciferol as a prodrug has a slightly prolonged half-life of 45 hours, although this difference is not of clinical significance.

■ **Efficacy.** Administration of calcitriol by either the oral or IV route may be based on conventional dosing (usually 0.25 to 0.5 mcg/day) or pulse dosing (0.5 to 2 mcg two to three times per week). Logistically, IV dosing is more practical in hemodialysis patients, while oral therapy is more practical for those with Stage 1 through 4 CKD and peritoneal dialysis patients. Conventional daily oral doses of calcitriol (0.25 mcg) may be more frequently associated with hypercalcemia and hyperphosphatemia, since VDRs are located in intestinal mucosa where direct stimulation can occur. Effects such as this reinforce the importance of regular monitoring of calcium and phosphorus.

When administered at doses ten times that of calcitriol and at a dose equivalent to doxercalciferol, paricalcitol has been less frequently associated with hypercalcemia in animal studies and in human trials.^{97,98} Doxercalciferol has also been associated with a lower incidence of hypercalcemia.⁹⁶ While hypercalcemia is less likely, based on differences in selectivity of these analogs for the VDRs, elevated calcium concentrations have been observed with these agents in patients with ESKD. However, some of these cases were associated with excessive dosing of these agents and oversuppression of PTH, a condition more likely to promote hypercalcemia.⁹⁹ Limited data are available regarding the use of vitamin D analogs in patients with

TABLE 44–7. Dosing Recommendations for Vitamin D in Patients with Stage 3 and 4 CKD

| Definition | Serum 25(OH)D ^a (ng/mL) | Dose of Ergocalciferol ^b |
|-----------------------------|---------------------------------------|---|
| Severe vitamin D deficiency | <5 | 50,000 international units/wk PO × 12 weeks, then monthly × 6 months or 500,000 international units as a single IM dose |
| Mild vitamin D deficiency | 5–15 | 50,000 international units/wk PO × 4 weeks, then monthly × 6 months |
| Vitamin D insufficiency | 16–30 | 50,000 international units/month PO × 6 months |

^a25 (OH) D, 25 hydroxyvitamin D.

^b25 (OH) D levels should be measured following the 6-month course of therapy for patients with mild and severe vitamin D deficiency.

From Eknoyan et al.¹⁸

early CKD; doxercalciferol has been shown to reduce PTH in this population.¹⁰⁰ Clinical trials are ongoing to evaluate an oral formulation of paricalcitol in patients with Stage 3 and 4 CKD.

Although comparisons between vitamin D analogs are relatively limited, fewer cases of hyperphosphatemia have been reported with paricalcitol than calcitriol. While the degree of suppression of PTH was similar with both agents, a trend toward a more rapid suppression of PTH was seen in paricalcitol-treated patients.¹⁰¹ An improvement in 3-year survival in a large dialysis population receiving paricalcitol was also recently noted compared with a historic cohort that received calcitriol.¹⁰² These findings are encouraging, but will require confirmation in prospective randomized trials.

■ **Adverse Effects.** While all agents are effective in suppressing PTH levels, they differ in the degree to which they cause other metabolic abnormalities. Adverse effects of note with vitamin D therapy in patients treated for sHPT include hypercalcemia and hyperphosphatemia. Differences in calcitriol and vitamin D analogs have been demonstrated in animal studies and in clinical trials evaluating the effect on reduction of PTH while minimizing the risk of these adverse consequences.

■ **Drug-Drug and Drug-Food Interactions.** Cholestyramine may reduce the absorption of orally administered calcitriol and doxercalciferol. No other significant interactions have been reported.

■ **Dosing and Administration.** Recommendations for vitamin D therapy differ based on the stage of CKD.¹⁸ Changes in vitamin D metabolism may lead to deficiencies in vitamin D precursors in patients with Stage 3 or 4 CKD. Therefore 25-hydroxyvitamin D levels should be measured in patients with PTH values above the upper recommended ranges of 70 pg/mL or 110 pg/mL for Stage 3 and 4 CKD, respectively (see Table 44–5). If the 25-hydroxyvitamin D level is less than 30 ng/mL, a vitamin D precursor (e.g., ergocalciferol) is recommended (Table 44–7).¹⁸ To prevent vitamin D insufficiency, doses of 600 to 800 units per day of ergocalciferol are recommended. According to the guidelines, active vitamin D or an analog should be administered orally (e.g., as oral calcitriol or doxercalciferol) when PTH remains elevated despite adequate 25-hydroxyvitamin D levels.

Active vitamin D therapy should be initiated in patients with Stage 3 or 4 CKD with oral calcitriol 0.25 mcg per day or oral doxercalciferol 2.5 mcg three times per week. Prior to starting therapy the serum calcium and phosphorus should be well controlled (serum calcium <9.5 mg/dL and phosphorus <4.6 mg/dL) to minimize the risk of hypercalcemia and an elevated Ca × P. In patients with Stage 5 CKD there is a clearly defined role for treatment with active vitamin D or a vitamin D analog since the conversion of precursors to active vitamin D is impaired. Dosing recommendations based on PTH are provided in Table 44–8. Serum calcium and Ca × P should be monitored regularly while the patient is receiving therapy.¹⁸

TABLE 44–8. Dosing Recommendations for Vitamin D in Patients with Stage 5 CKD on Hemodialysis (HD)^a

| PTH (pg/mL) | IV and PO Calcitriol Dose per HD | IV Paricalcitol Dose per HD | PO and IV Doxercalciferol Dose per HD |
|-----------------------|--|--------------------------------|---|
| 300–600 ^b | 0.5–1.5 mcg PO or IV | 2.5–5 mcg | 5 mcg PO 2 mcg IV |
| 600–1000 ^b | 1–4 mcg PO 1–3 mcg IV | 6–10 mcg | 5–10 mcg PO 2–4 mcg IV |
| >1000 ^c | 3–7 mcg PO 3–5 mcg IV | 10–15 mcg | 10–20 mcg PO 4–8 mcg IV |

^aPeritoneal dialysis patients may be treated with PO doses of calcitriol (0.5–1.0 mcg) or doxercalciferol (2.5–5 mcg) two or three times weekly. May also use PO calcitriol at 0.25 mcg daily.

^bIf serum calcium <9.5 mg/dL, phosphorus <5.5 mg/dL, and Ca × P <55 mg²/dL².

^cIf serum calcium <10 mg/dL, phosphorus <5.5 mg/dL, and Ca × P <55 mg²/dL².

PTH, parathyroid hormone.

From Eknoyan et al.¹⁸

The recommended starting dose in patients with ESKD is calcitriol 0.5 to 1.5 mcg IV or paricalcitol 0.04 to 0.08 mcg/kg IV (range, 2.5 to 5 mcg) with each dialysis session, based on the level of PTH.¹⁸ Dose adjustments should be made every 2 to 4 weeks based on PTH concentrations. For patients who need to be converted from calcitriol to paricalcitol, a dosing conversion ratio of 1:4 of IV calcitriol to paricalcitol has been proposed; however, some suggest a ratio of 1:3 to avoid oversuppression of PTH.^{18,103} Starting doses of paricalcitol have also been dosed based on initial PTH levels (PTH/80).¹⁰⁴ The recommended starting dose of doxercalciferol in ESKD patients is 2 mcg IV or 5 mcg administered orally three times per week, with dosing titration based on changes in PTH.¹⁸

■ Calcimimetics

■ **Pharmacology and Mechanism of Action.** Cinacalcet hydrochloride (Sensipar) is a calcimimetic agent recently approved for treatment of sHPT in ESKD patients and for treatment of hypercalcemia in patients with parathyroid carcinoma. Cinacalcet is the first agent in this class to receive FDA approval. This compound acts on the calcium-sensing receptor on the surface of the chief cell of the parathyroid gland to mimic the effect of extracellular ionized calcium and increase the sensitivity of the calcium-sensing receptor to calcium, subsequently reducing PTH secretion.

■ **Pharmacokinetics.** The maximum plasma concentration of cinacalcet is achieved in approximately 2 to 6 hours following oral administration. The half-life is approximately 30 to 40 hours. Cinacalcet has a large volume of distribution (approximately 1000 L), and is 93% to 97% bound to plasma proteins, both characteristics indicating that removal by dialysis is negligible. Cinacalcet is metabolized by the liver, specifically by the cytochrome P450 isoenzymes CYP3A4, CYP2D6, and CYP1A2.¹⁰⁵

■ **Efficacy.** In placebo-controlled clinical trials conducted in dialysis patients (predominantly those receiving hemodialysis) cinacalcet significantly decreased PTH and the Ca × P product within the 6-month study period, regardless of the severity of sHPT.^{106,107} The starting dose of 30 mg per day was titrated every 3 or 4 weeks to a maximum dose of 180 mg per day to achieve the target PTH of ≤ 250 pg/mL and avoid hypocalcemia. Approximately 66% and 93% of patients in the clinical trials were receiving concurrent vitamin D and phosphate binders, respectively. If a patient experienced symptoms of hypocalcemia or had a serum calcium < 8.4 mg/dL, calcium supplements and/or calcium-based phosphate binders could be increased. If ineffective, the vitamin D dose could be increased. The median dose required to achieve the desired PTH by the end of the study period was 90 mg. The challenge to clinicians now that this agent is approved is in deciding how to most effectively use cinacalcet in conjunction with other therapies for hyperphosphatemia and sHPT.

■ **Adverse Effects.** The most frequently reported adverse events with cinacalcet were nausea and vomiting. Although nausea and vomiting occurred more frequently with cinacalcet, these events were generally transient, mild to moderate in nature, and infrequently led to withdrawal from clinical trials.¹⁰⁵

Cinacalcet lowers serum calcium and may cause hypocalcemia; therefore this agent should not be started if the serum calcium is less than the lower limit of normal, approximately 8.4 mg/dL. Serum calcium should be measured within 1 week after initiation or dose adjustment of cinacalcet. Once the maintenance dose has been estab-

lished, serum calcium should be measured approximately monthly. Potential manifestations of hypocalcemia include paresthesias, myalgias, cramping, tetany, and convulsions.

■ **Drug-Drug and Drug-Food Interactions.** Since cinacalcet is metabolized by multiple hepatic enzymes there is potential for drug interactions. Cinacalcet is also a potent inhibitor of the enzyme CYP2D6. As a result, dose adjustments of concomitant medications that are predominantly metabolized by this enzyme and have a narrow therapeutic index such as flecainide, thioridazine, vinblastine, and most tricyclic antidepressants (i.e., amitriptyline) may be required.¹⁰⁵

Several agents commonly used in the CKD population have been evaluated for interactions with cinacalcet.¹⁰⁵ Coadministration of calcium carbonate or sevelamer did not affect the pharmacokinetics of cinacalcet. Pantoprazole did not alter the pharmacokinetics of cinacalcet HCl, an important finding since pantoprazole alters gastric pH, and the solubility of cinacalcet decreases as the gastric pH rises over 5.5. Coadministration of cinacalcet with warfarin also did not affect the pharmacokinetics of warfarin. Coadministration of cinacalcet and ketoconazole, a strong inhibitor of CYP3A4, resulted in an increase in the area under the curve and maximum concentration of 2.3 and 2.2 times, respectively. Concurrent administration of cinacalcet with amitriptyline increased amitriptyline exposure and nortriptyline (active metabolite) exposure by approximately 20% in CYP2D6-extensive metabolizers.

Food has been shown to increase absorption of cinacalcet by up to 81% compared to fasting; therefore this medication should be taken with meals to achieve the maximal effect.

■ **Dosing and Administration.** The recommended starting oral dose of cinacalcet is 30 mg once daily. The dose should be titrated every 2 to 4 weeks to a maximum dose of 180 mg once daily to achieve the desired PTH levels and maintain near normal serum calcium concentrations. Patients with hepatic disease may require lower doses, as studies have shown a decrease in metabolism of cinacalcet in this patient population. Cinacalcet is available as a film-coated tablet containing 30, 60, or 90 mg.

■ PHARMACOECONOMIC CONSIDERATIONS

Pharmacoeconomic considerations in the management of sHPT and ROD include medication costs, the cost associated with laboratory procedures (e.g., monitoring of 25-hydroxyvitamin D and more frequent evaluation of iPTH in patients with Stage 3 or 4 CKD), and the medical expenditures associated with the management of cardiovascular disease and bone fractures. The pattern of vitamin D product use in U.S. dialysis units has been strongly influenced by Medicare reimbursement. Currently, IV vitamin D products are separately reimbursable expenses for dialysis programs. In fact, dialysis programs often generate significant profit from the IV administration of these agents to patients on dialysis. In contrast, oral medications such as calcitriol and doxercalciferol are more convenient for patients with Stage 3 or 4 CKD and the peritoneal dialysis population; however, these agents are not separately reimbursable, and because they must be purchased by the patient, compliance becomes an issue.

The cost:benefit ratio associated with more aggressive management of metabolic disorders (e.g., hyperphosphatemia and hypercalcemia) and sHPT has not been formally evaluated. If the associated complications such as vascular and soft tissue calcifications that may increase morbidity and hospitalizations can be significantly reduced, the additional medication costs may ultimately be of minimal consequence.

CLINICAL CONTROVERSY

Some clinicians advocate use of the Bio-Intact PTH, which detects the full-length 84–amino acid active peptide chain, as opposed to the intact PTH, which also detects active and inactive fragments. The Bio-Intact PTH/Intact PTH ratio, an index of the active fraction of PTH, has also been evaluated as a clinical monitoring tool; however, additional studies are needed to determine how values for the Bio-Intact PTH and this ratio correlate with bone formation and turnover in patients with CKD.

EVALUATION OF THERAPEUTIC OUTCOMES

The goals for treatment with dietary phosphate restriction, phosphate-binding agents, vitamin D therapy, and/or calcimimetic therapy are to prevent sHPT and subsequent ROD without inducing adynamic bone disease from oversuppression of PTH or vascular or extravascular calcifications. Regular monitoring of serum calcium, phosphorus, $\text{Ca} \times \text{P}$, iPTH, and vitamin D status to achieve and maintain target goals is currently the most practical and effective means of achieving these outcomes.

The serum calcium, phosphorus, and iPTH levels should be measured in all patients with a GFR of less than 60 mL/min.¹⁸ Patients with Stage 3 or Stage 4 CKD should have follow-up measurements done at least every 12 months and every 3 months, respectively. More frequent monitoring is required for Stage 5 CKD patients; monitor iPTH every 3 months and calcium and phosphorus every month. More frequent monitoring (monthly for iPTH and every 2 weeks for calcium and phosphorus) may be warranted following any change in the therapeutic interventions to correct these abnormalities.

METABOLIC ACIDOSIS

ETIOLOGY

Individuals with normal kidney function generate enough hydrogen ion to reclaim all filtered bicarbonate and to secrete approximately 1 mEq/kg per day of hydrogen ions, which are generated from the metabolism of dietary proteins (see Chap. 51). As a result they maintain a constant body fluid pH through the buffering of hydrogen ion by proteins, hemoglobin, phosphate, and especially bicarbonate. Renal ammoniogenesis and phosphate excretion buffer the urine and facilitate acid excretion. In severe CKD, all filtered bicarbonate is reclaimed, but the ability of the kidneys to synthesize ammonia is impaired. This decrease in urinary buffer results in decreased net acid excretion and continuous positive hydrogen ion balance; thus metabolic acidosis develops. A clinically significant metabolic acidosis is commonly seen when the GFR drops below 20 to 30 mL/min (Stage 4 CKD). In these patients the plasma bicarbonate concentration tends to stabilize at 15 to 20 mEq/L.

DESIRED OUTCOME

The goals of therapy for patients with CKD are to normalize the pH of the blood (pH of approximately 7.35 to 7.45) and maintain the serum bicarbonate within the normal range (22 to 28 mEq/L). In patients on hemodialysis, the goal of therapy is to maintain a predialysis or stabilized bicarbonate concentration at or above 22 mEq/L.¹⁶

The prevention and treatment of severe metabolic acidosis in patients with kidney disease is also important to prevent the development of renal bone disease, fatigue, decreased exercise tolerance, reduced cardiac contractility, and increased ventricular irritability. Metabolic acidosis also appears to stimulate protein catabolism, which can contribute to a negative nitrogen balance and lower albumin concentrations, as well as cause growth retardation in children.¹⁶ Lower serum bicarbonate levels in peritoneal dialysis patients have also been associated with a higher hospitalization rate and longer hospital stays.¹⁶ Severe acidemia (blood pH <7.1 to 7.2) suppresses myocardial contractility, predisposes patients to cardiac arrhythmias, and may lead to a decrease in total peripheral vascular resistance and blood pressure, reduced hepatic blood flow, and impaired oxygen delivery.¹⁰⁸

GENERAL APPROACH TO EVALUATION AND TREATMENT

Arterial blood gases and serum electrolytes should be measured regularly in patients with CKD. These patients should also have a complete medical history and review of medications to determine if there are other potential causes of acid-base disturbances (e.g., diabetic ketoacidosis, ingestion of toxins, or GI disorders). The anion gap, indicating the differences in unmeasured anions and cations, should also be calculated (see Chap. 51). An elevated anion gap (>17 mEq/L) is often present in those with CKD due to the accumulation of organic anions, phosphates, and sulfates.

Treatment of metabolic acidosis in patients with CKD generally includes administration of bicarbonate to correct acidemia, the time course of which depends on the severity of the acidosis. Asymptomatic patients with mild acidosis (bicarbonate of 12 to 20 mEq/L; pH of 7.2 to 7.4) generally do not require emergent therapy and gradual correction over days to weeks is appropriate.

NONPHARMACOLOGIC THERAPY

Therapy for metabolic acidosis requires pharmacologic intervention to correct the acidemia. Treatment of other underlying disorders that may be contributory is also warranted.

PHARMACOLOGIC THERAPY

In patients with Stage 3 or higher CKD, the use of alkalinizing salts, such as sodium bicarbonate or citrate/citric acid preparations, is useful to replenish depleted body bicarbonate stores. Sodium bicarbonate tablets are manufactured in 325- and 650-mg strengths (a 650-mg tablet contains 7.7 mEq sodium and 7.7 mEq bicarbonate). Shohl's solution and Bicitra contain 1 mEq/mL of sodium and the equivalent of 1 mEq/mL of bicarbonate as sodium citrate/citric acid. Citrate is metabolized in the liver to bicarbonate, and citric acid is metabolized to CO_2 and water. Polycitra, which contains potassium citrate, (1 mEq/mL of sodium, 1 mEq/mL of potassium, and 2 mEq/mL of bicarbonate) should not be used in patients with severe CKD since hyperkalemia may result.

The replacement dose of alkali (base) needed to restore the serum bicarbonate concentration to normal (24 mEq/L) can be approximated by multiplying the volume of distribution of bicarbonate (0.5 L/kg) by the patient's body weight (in kilograms) and their base deficit (difference between the patient's serum bicarbonate value and 24 mEq/L). The calculated amount of bicarbonate replacement therapy (in

milliequivalents) should be administered over several days to prevent volume overload from excessive sodium intake. After the serum bicarbonate has normalized, a maintenance regimen of bicarbonate to neutralize daily acid production may be all that is necessary (12 to 20 mEq/day in divided doses). Doses are subsequently titrated to maintain normal plasma bicarbonate concentrations. Patients with renal tubular acidosis may require higher doses of alkalinizing agents (see Chap. 51). Fluid balance should be monitored carefully because of the sodium content of these agents. Citrate-containing solutions should not be used in combination with aluminum-containing compounds because they can enhance aluminum absorption and increase the risk of aluminum intoxication. Excessive doses of alkalinizing agents may cause metabolic alkalosis, as well as lethargy or cardiac depression secondary to a decrease in ionized serum calcium concentration. Gastrointestinal distress characterized by gastric distention and flatulence is relatively common with high doses of oral sodium bicarbonate. Patients with severe acidosis (serum bicarbonate <8 mEq/L; pH <7.2) may require IV therapy (see Chap. 51).

Metabolic acidosis in both adult and pediatric patients undergoing dialysis can often be managed by using higher concentrations of bicarbonate or acetate in the dialysate (>38 mEq/L bicarbonate is safe and effective). Administration of oral bicarbonate salts as described above may also be necessary for some patients.

Tromethamine (tris-hydroxymethyl aminomethane) and Carbicarb (sodium carbonate and sodium bicarbonate) are alternative alkalinizing agents that have been evaluated for treatment of more severe acidemia. There are extremely limited data regarding their use in patients with CKD, which precludes their use in this population.¹⁰⁸

EVALUATION OF THERAPEUTIC OUTCOMES

Regular monitoring of arterial blood gases and serum electrolytes are necessary to determine the effectiveness of therapy. A gradual correction is appropriate to avoid overcorrection and subsequent complications such as alkalosis and other electrolyte abnormalities (see Chap. 51). Laboratory measurement of serum bicarbonate is associated with several technical problems. Blood collection techniques, transportation, and assay methodology can affect the measured concentrations. Blood samples should not have contact with air; process delays should be avoided; and consistent analytical methods should be used with serial measurements to improve accuracy.¹⁶

TREATMENT OF CARDIOVASCULAR DISEASE IN CKD

Mortality secondary to cardiovascular disease is 10 to 30 times greater in dialysis patients than in the general population.⁹ In addition to traditional cardiac risk factors such as diabetes, hypertension, hyperlipidemia, tobacco use, and physical inactivity, patients with kidney disease have other unique risk factors. Among these are hyperhomocysteinemia, elevated levels of C-reactive protein, increased oxidant stress, and hemodynamic overload.¹⁰⁹ Complications previously discussed such as anemia and metabolic disorders of CKD are also contributory. In particular, arterial vascular disease (i.e., atherosclerosis) and cardiomyopathy are the primary types of cardiovascular disorders present in the CKD population.⁹ These disorders lead to development of ischemic heart disease and its manifestations including myocardial infarction. As a predominant comorbidity, cardiovascular disorders and their sequela are the leading cause of death in the ESKD population.^{3,5}

ETIOLOGY AND EPIDEMIOLOGY

Hypertension

As a primary cause or a consequence of progressive loss of kidney function, hypertension is prevalent in the majority of patients with Stage 3 or 4 CKD (see Chap. 43). Approximately 80% to 90% of patients initiating dialysis are hypertensive.¹¹⁰ The pathogenesis of hypertension in CKD is multifactorial, but in many hypertensive dialysis patients, fluid retention is a major contributor.¹¹⁰ In addition to the general pathophysiologic mechanisms responsible for the development of hypertension, patients with ESKD may also have increased sympathetic activity, the presence of an endogenous digitalis-like substance, elevated levels of endothelin-1, erythropoietin use, hyperparathyroidism, and structural changes in the arteries (e.g., metastatic calcification) as contributing factors.¹¹⁰

Patients with ESKD also display an abnormal diurnal blood pressure rhythm as evidenced by the fact that their blood pressure does not decrease during the nighttime hours.¹¹⁰ It is unclear what causes this disturbance in the diurnal rhythm, but this “nondipping” phenomenon indicates sustained elevations in blood pressure are present over a prolonged period of time when compared to the general population.

Hyperlipidemia

CKD with or without nephrotic syndrome is frequently accompanied by abnormalities in lipoprotein metabolism. It is well established that dyslipidemias cause atherosclerotic cardiovascular disease and there are many compelling reasons to aggressively treat these disorders.¹¹¹ A clear association between hypercholesterolemia, hypertriglyceridemia, or other lipoprotein changes in patients with CKD and the high incidence of cardiovascular disease has not been demonstrated in large prospective studies. However, it is likely that the same lipoprotein abnormalities that confer increased risk of cardiovascular disease in the general population would also be harmful to patients with kidney disease. A low or declining serum cholesterol in patients with ESKD is also indicative of malnutrition and is associated with increased mortality.¹⁶ Thus a fine balance must be struck to optimize patient outcomes.

The few epidemiologic studies in CKD patients with nephrotic syndrome suggest that their relative risk of coronary death or myocardial infarction is higher than that of matched controls.¹¹² Similar analyses have been done in CKD patients without nephrotic syndrome and in patients on dialysis; low HDL, high triglycerides, high apolipoprotein B, and high lipoprotein (a) were all associated with a higher risk of cardiovascular disease.¹¹² The findings are not uniform, as hypertriglyceridemia alone has not been shown to be a strong independent risk factor for coronary heart disease in patients with normal kidney function.¹¹¹ However, hypertriglyceridemia may reduce levels of “protective” HDL, which is now classified as a major risk factor for coronary heart disease. Based on these findings and the high prevalence of atherosclerotic cardiovascular disease in patients with CKD, this population is considered to be in the highest-risk group for such cardiovascular conditions (i.e., equivalent to that of patients with known coronary heart disease).¹¹¹

The prevalence of hyperlipidemia appears to increase as kidney function declines.¹¹² In patients with CKD without nephrotic syndrome, hypertriglyceridemia (plasma concentrations >200 mg/dL) is observed in approximately 40% to 50% of patients. In addition, 20% to 30% of these patients have total cholesterol levels greater than 240 mg/dL, while 10% to 45% have LDL concentrations >130 mg/dL.

Although the concentrations of LDL are not uniformly increased in patients with kidney disease, these patients appear to produce small, dense LDL particles that are more susceptible to oxidation and more atherogenic than larger LDL subfractions. Other lipoprotein abnormalities include a reduction in HDL concentrations in 25% to 30% of patients, as well as changes in apoprotein content of lipoprotein molecules.^{112,113} Peripheral insulin resistance, carnitine deficiency, and hyperparathyroidism may also contribute to lipid abnormalities. For patients with CKD and a urinary protein excretion greater than 3 g/day, the major lipid abnormalities are elevation of plasma total and LDL cholesterol (prevalence 85% to 90%), with approximately 50% of patients experiencing a low HDL cholesterol (<35 mg/dL), while 60% of patients have triglyceride concentrations greater than 200 mg/dL.¹¹² Treatment of proteinuria resolves the hyperlipidemia in most patients with nephrotic syndrome.

■ DESIRED OUTCOME

■ Hypertension

Goals of antihypertensive therapy in patients with CKD are to lower blood pressure to target levels and reduce the risk of cardiovascular disorders. The target blood pressure in patients with ESKD is not well defined. The potential complications of decreasing diastolic blood pressures to below 80 mm Hg, as recommended for patients with Stage 1 through 4 CKD, may outweigh the benefits in this population. Thus different blood pressure goals may need to be set for individual patients based on their clinical status, age, and cardiovascular condition. A target blood pressure in ESKD patients of less than 150/90 mm Hg has been proposed to reduce the risk of associated cardiovascular disorders, yet keep patients hemodynamically stable during dialysis, when hypotension may occur as the result of volume status changes during treatment.¹¹⁰ Hypertension is not adequately controlled in as many as 50% of ESKD patients, especially those with diabetes.¹¹⁰

■ Hyperlipidemia

Based on strong evidence of risk reduction and the benefits of lipid-lowering therapy in the general population, and the high prevalence of atherosclerotic cardiovascular disease in patients with CKD, the consensus is that CKD patients should be treated aggressively for dyslipidemia to an LDL-C goal below 100 mg/dL.^{17,111} Goals for patients with Stage 5 CKD based on lipid abnormality and the appropriate course of therapy are listed in Table 44–9.

■ PATIENT EVALUATION

■ Hypertension

Patients with ESKD should have blood pressure monitored at every scheduled clinic visit (or hemodialysis session) and they should be encouraged to learn how to monitor their blood pressure while at home. These patients should also be evaluated for existing cardiovascular conditions and cardiovascular risk factors. Goals of therapy can be achieved using lifestyle modifications in conjunction with antihypertensive therapy. While these strategies are similar to those used in the general population with hypertension, certain aspects of selection of pharmacologic therapy and dietary instructions are unique to the population with CKD. Recommendations for antihypertensive therapy in patients with CKD are often extrapolated from results of studies conducted in the normal population, as CKD patients are generally excluded from these studies.

■ Hyperlipidemia

A complete fasting lipid profile including total cholesterol, LDL, HDL, and triglycerides should be done in all CKD patients. Lipoprotein levels may be influenced by several factors including GFR and proteinuria. It is recommended that these patients have their lipid profile assessed more frequently than in the general population in order to identify abnormalities and treat them early. In patients on hemodialysis the lipid profile should be done prior to dialysis or on nondialysis days.¹⁷ Patients should also be evaluated for other conditions that are known to cause dyslipidemias (e.g., liver disease and hypothyroidism).

■ NONPHARMACOLOGIC THERAPY

■ Hypertension

The primary intervention for management of hypertension in patients with Stage 1, 2, and 3 CKD is sodium restriction to approximately 2 to 3 g/day. Fluid intake should be restricted in patients with volume overload, and particularly in patients on hemodialysis, who are at risk for substantial fluid accumulation between dialysis sessions. Regular dietary counseling becomes critical to the success of nonpharmacologic interventions, given the large number of lifestyle changes typically required by CKD patients. Other lifestyle modifications

TABLE 44–9. Management of Dyslipidemia in Patients with CKD

| Dyslipidemia | Goal | Initial Therapy | Modification in Therapy ^a | Alternative ^a |
|--------------------------------------|--------------------|-----------------------|--------------------------------------|---------------------------------|
| TG ≥500 mg/dL | TG <500 mg/dL | TLC | TLC + fibrate or niacin | Fibrate or niacin |
| LDL 100–129 mg/dL | LDL <100 mg/dL | TLC | TLC + low-dose statin | Bile acid sequestrant or niacin |
| LDL ≥130 mg/dL | LDL <100 mg/dL | TLC + low-dose statin | TLC + max dose statin | Bile acid sequestrant or niacin |
| TG ≥200 mg/dL and non-HDL ≥130 mg/dL | Non-HDL <130 mg/dL | TLC + low-dose statin | TLC + max dose statin | Fibrate or niacin |

^aDosing of selected agents by class: fibrate (gemfibrozil 600 mg twice a day); niacin (1.5–3 g/day of immediate-release product); statin (simvastatin 10–40 mg/day if glomerular filtration rate [GFR] <30 mL/min, 20–80 mg/day if GFR >30 mL/min); bile acid sequestrant (cholestyramine 4–16 g/day). HDL, high-density lipoprotein; LDL, low-density lipoprotein; Non-HDL, total cholesterol minus HDL cholesterol; TG, triglycerides; TLC, therapeutic lifestyle changes.

See Chap. 21 for more complete dosing information.
From *K/DOQI Clinical Practice Guidelines*.¹⁷

including regular exercise, weight loss, and smoking cessation are also recommended, but difficult to implement.

In hemodialysis patients, achievement of an individual's "dry weight" and control of total-body sodium through the dialytic process may control blood pressure (see Chap. 45). The effects of salt restriction and aggressive ultrafiltration were studied in a small number of hemodialysis patients ($n = 19$) over 12 months.¹¹⁴ After 3 months blood pressure was controlled to $<140/90$ mm Hg and decreases in left ventricular mass index were observed at the end of the study period. Prolonged hemodialysis (8-hour sessions three times per week) has also been shown to maintain normal blood pressures and reduce the need for antihypertensive medications in ESKD patients.¹¹⁰ A lag phenomenon in blood pressure reduction following achievement of "dry weight" was also shown in this population. Blood pressure continued to fall over several months while using the "dry-weight" method of blood pressure control.¹¹⁵ However, the majority of hemodialysis programs in the United States use shorter dialysis methods (3- to 4-hour sessions three times per week).

■ Hyperlipidemia

In patients with elevated triglyceride levels (≥ 500 mg/dL) and/or LDL between 100 and 129 mg/dL, lifestyle changes are recommended (see Chap. 21). Unfortunately, most patients with CKD have already been advised to adhere to difficult dietary regimens, which may include protein, phosphorus, sodium, potassium, and fluid restrictions, as well as diabetic exchanges. Thus although diet therapy is a reasonable first-step approach, it may not be successful in many patients with CKD because of noncompliance. A dietitian who is well versed in the management of kidney disease should be consulted.

■ PHARMACOLOGIC THERAPY

■ Hypertension

Most patients with hypertension and CKD require drug regimens that include three or more antihypertensive agents to achieve target blood pressure.¹¹⁶ Blood pressure reductions can be achieved with agents in all antihypertensive classes, and choice should be guided by the individual patient's concomitant disease states.

Diuretic therapy is beneficial for management of blood pressure in patients with early CKD; however, thiazide diuretics are not generally effective in patients with a GFR of <30 mL/min. Loop diuretics can be used throughout all stages of CKD. In most cases the dose must be increased as kidney function declines, to achieve a similar degree of blood pressure reduction. Patients with ESKD who have minimal to no residual renal function are especially poor responders to these agents.

Angiotensin-converting enzyme inhibitors (ACEIs) or angiotensin receptor blockers (ARBs) are the preferred agents for patients with progressive CKD. They are also effective in patients with ESKD because of the important role the renin-angiotensin axis plays in the etiology of some cases of dialysis-resistant hypertension.^{110,117} ACEIs may also be of benefit since they are associated with substantial reductions in left ventricular mass in patients with ESKD.¹¹⁷ Lower initial doses of these agents may be necessary since the elimination half-lives of the parent compound (captopril and lisinopril) or active metabolite (enalapril, benazepril, or ramipril) are prolonged in ESKD patients. ARBs have not been well studied in patients with ESKD. One notable difference when compared to ACEIs is that ARBs do

not affect bradykinin metabolism, thus they are not expected to cause anaphylactoid reactions when used in conjunction with polyacrylonitrile dialysis membranes. Available ARBs do not require dosage adjustment for decreased kidney function and they are not effectively removed by hemodialysis.

Calcium channel blockers, particularly the dihydropyridines, which selectively lower systemic vascular resistance, also appear to be effective in the treatment of hypertension in patients with ESKD. β -Blockers may be particularly useful in hypertensive CKD patients given the beneficial effects post-myocardial infarction. Agents such as esmolol, timolol, pindolol, metoprolol, or labetalol, which are metabolized and not significantly removed by dialysis, may be easier to dose titrate than agents that are both dialyzable and extensively eliminated unchanged by the kidney (e.g., acebutolol, atenolol, bisoprolol, and nadolol). Agents requiring less frequent dosing may be used to improve patient compliance.

Use of other antihypertensive agents in the patient with CKD should be based on recommendations in the general population (see Chap. 13).¹¹⁶ In the ESKD population there may be some special considerations for use of other antihypertensive therapy. Agents that act on the sympathetic nervous system, such as prazosin, terazosin, doxazosin, clonidine, guanabenz, and guanfacine, may be required in patients unresponsive to ACEIs, calcium channel blockers, or β -blocker therapy used in conjunction with adequate dialysis. Central α_2 -agonists such as clonidine appear to be the safest of these agents; however, adverse effects such as dry mouth may lead to extra fluid consumption in some patients. Postsynaptic α -blockers (e.g., prazosin) are associated with postural hypotension following hemodialysis. Guanethidine and methyldopa should be avoided because of potential complications, including severe postural hypotension, severe dialysis-related hypotension, and impotence. The addition of vasodilators such as minoxidil or hydralazine may prove useful in patients resistant to combinations of the previously mentioned agents. The incidence of systemic lupus erythematosus associated with the use of hydralazine does not appear to be increased by the presence of ESKD. Minoxidil therapy may be associated with pericardial effusion and profound reflex tachycardia, which can be suppressed with either the addition of a β -blocker or a central α -adrenoreceptor agonist.

■ Hyperlipidemia

Management of dyslipidemia in patients with CKD should be based on the report from the National Cholesterol Education Program and the K/DOQI guidelines for dyslipidemia in patients with CKD.^{17,111} If lifestyle changes are not effective in achieving goal triglyceride and LDL levels after a few months, drug therapy is warranted (see Table 44–9). Drug therapy is also recommended for those with more extreme elevations in LDL (≥ 130 mg/dL).

Drug classes that may prove useful in treatment of lipid disorders include: 3-hydroxy-3-methylglutaryl coenzyme A (HMG-CoA) reductase inhibitors (statins); the bile acid sequestrants; nicotinic acid; and fibric acids (gemfibrozil and clofibrate). Statins are the most effective drugs for lowering LDL and total cholesterol in patients with kidney disease (with or without nephrotic syndrome) and should generally be regarded as the drugs of first choice.^{17,112} Drug therapy for hypertriglyceridemia includes a fibrate or nicotinic acid; in general fibrates are better tolerated. Statins are indicated to lower LDL to acceptable levels in CKD patients, based on efficacy and additional benefits observed in the general population, including the reduction in cardiovascular events and all-cause mortality.¹⁷

Several potential drug interactions and/or side effects have been observed in those CKD patients receiving antilipemic therapy. The nonselective binding activity of bile acid sequestrants may reduce absorption of corticosteroids, digoxin, thiazide diuretics, warfarin, and other commonly used medications. Myositis and myalgias, along with increased serum creatine phosphokinase (CPK), may occur in ESKD patients who use clofibrate. Determining the optimal dose of clofibrate in this patient population is difficult, as plasma protein-binding changes markedly affect free concentrations of the active metabolite, clofibric acid, which has a prolonged half-life in patients with Stage 5 CKD. Gemfibrozil may be a safer alternative, as the half-life is not altered with kidney dysfunction. Lower doses of 300 mg twice a day with close monitoring of CPK is recommended by some clinicians, based on an association of standard dose therapy with increases in CPK concentrations in dialysis patients.

Although HMG-CoA reductase inhibitors are remarkably free of adverse effects in otherwise healthy subjects, one should be cognizant of the potential myotoxic effects of these drugs, especially when administered with interacting agents including, but not limited to, azole antibiotics, cyclosporine, gemfibrozil, niacin, and in the presence of hepatic disease.¹⁷ Patients receiving sevelamer as a phosphate binder may reap the benefits of its cholesterol-lowering effects.¹¹⁸

The best approach to the treatment of hyperlipidemia in patients with nephrotic syndrome is to induce remission of the disease (see Chap. 47), or at least to reduce urine protein excretion by aggressive treatment of concurrent hypertension and/or administration of ACEIs or ARBs.¹⁷ Several trials have assessed the effect of L-carnitine supplementation on abnormal lipid metabolism in dialysis patients, but results have been contradictory.¹¹⁹

■ PHARMACOECONOMIC CONSIDERATIONS

■ Hypertension

Compliance and economic factors must be considered in the selection of antihypertensive therapy for CKD patients. Patients with ESKD are prescribed an average of 9 to 12 medications. Choosing agents that can be administered once or twice daily may improve patient compliance. In addition, there are now many options within some antihypertensive classes, such as calcium channel blockers, ACEIs, ARBs, and β -blockers, which allow for less frequent dosing. In most cases, no clear therapeutic advantage has been demonstrated with any particular agent within a class. Therefore selecting the least costly agent that can be administered once or twice daily is reasonable.

As more information becomes available from studies evaluating the effects of long-term therapy of hypertension on cardiovascular events in patients with ESKD, cost benefits from potentially decreasing the occurrence of such events and their comorbidities may be quantified.

■ Hyperlipidemia

Statin therapy for treatment of dyslipidemias has been shown to be cost-effective in patients at high risk for coronary heart disease. While this has not specifically been evaluated in patients with CKD, this population is considered in the highest-risk group for coronary heart disease and cardiovascular events. It may be reasonable at least in theory to extrapolate this information on the cost benefits of therapy to the CKD population.

CLINICAL CONTROVERSY

Currently there is no consensus on the target blood pressure for patients with ESKD. Maintaining a blood pressure of <150/90 mm Hg has been proposed to maintain hemodynamic stability, particularly in the hemodialysis patient, who has frequent shifts in volume status and is thus at high risk for hypotension during and postdialysis.

■ EVALUATION OF THERAPEUTIC OUTCOMES

■ Hypertension

Blood pressure monitoring to determine the effectiveness of therapy should be done at each visit for patients with ESKD, particularly following initiation of therapy (nonpharmacologic or pharmacologic). The importance of home monitoring becomes essential in those patients for whom dose titration and close follow-up is required. Patients on hemodialysis should have blood pressure measured before, during, and after dialysis to determine the effect of changes in their volume status on blood pressure in conjunction with medication therapy. Patients may need to adjust the time of administration of antihypertensive therapy relative to the dialysis session if hypotension during dialysis is problematic. Such decisions should be based on the pharmacokinetic profile of the antihypertensive agent in patients with ESKD. In cases when antihypertensive agents need to be discontinued, they should be withdrawn slowly. Other aspects of monitoring blood pressure and associated complications may be found in Chap. 13.

■ Hyperlipidemia

Patients should have their lipid profile reassessed 2 to 3 months following a change in treatment and at least annually. Periodic evaluations of cardiovascular performance and cardiovascular condition as described in Chap. 21 are also warranted in this patient population.

■ TREATMENT OF OTHER COMPLICATIONS OF CKD

■ NUTRITIONAL STATUS

Protein-energy malnutrition is very common among patients with advanced CKD (Stages 4 and 5; see Chap. 139).¹⁶ Causes of malnutrition in these patients include inadequate food intake secondary to anorexia, altered taste sensation, intercurrent illness, and the unpalatability of prescribed diets. Other factors such as the effect of the dialysis procedure on removal of nutrients, hypercatabolism induced by other inflammatory conditions, and blood loss are also contributory. Protein restriction as an intervention to potentially delay progression of kidney disease in patients with Stage 3 or 4 CKD may also lead to protein malnutrition by the time a patient reaches ESKD; therefore the risks vs. the benefits of this intervention must be considered on an individual basis (see Chap. 43). Hypoalbuminemia and malnutrition have a strong association to mortality in chronic dialysis patients.¹⁶

Patients with ESKD have increased nutritional needs relative to the general population, based on the effect of the disease state and the dialysis procedure on nutritional status. The recommended dietary protein intake in chronic hemodialysis patients is 1.2 g/kg

body weight per day.¹⁶ The recommended intake for chronic peritoneal dialysis patients is at least 1.2 to 1.3 g/kg body weight per day, based on the increased protein loss that occurs with this dialysis modality.¹⁶ Protein requirements are higher in patients who are acutely ill (see Chap. 139). The recommended total daily energy intake in both hemodialysis and peritoneal dialysis patients is 35 kcal/kg body weight per day.¹⁶ For peritoneal dialysis patients, this includes intake from both diet and that obtained from the glucose absorbed from peritoneal dialysate. For patients older than 60 years of age this criterion differs, since increasing age is generally associated with reduced physical activity and lean body mass. Daily energy intake for these patients is 30 to 35 kcal/kg per day.¹⁶ Nutritional support should be considered for those patients who cannot achieve these goals with oral intake alone. Another option for nutritional supplementation in patients on hemodialysis includes interdialytic parenteral nutrition (see Chap. 139).

Vitamin requirements for ESKD patients receiving dialysis differ from those of a healthy person because of dietary modifications, kidney dysfunction, and dialysis therapy.¹²⁰ The plasma concentrations of vitamins A and E are elevated in ESKD, while those of the water-soluble vitamins (B₁, B₂, B₆, B₁₂, niacin, pantothenic acid, folic acid, biotin, and vitamin C) tend to be low in this population, in large part due to the fact that many are dialyzable. The goal for vitamin supplementation in this population should be to prevent subclinical and frank deficiency and to avoid pathology from overdosage. Special vitamin supplements have been formulated for the dialysis population, which primarily include B vitamins with C and folic acid.

Supplementation with L-carnitine has been advocated for its potential benefits in patients with ESKD including management of hypertriglyceridemia, hypercholesterolemia, and anemia.¹¹⁹ In the hemodialysis population L-carnitine may improve complications of dialysis, including intradialytic arrhythmias and hypotension, low cardiac output, interdialytic and postdialytic symptoms of malaise or asthenia, general weakness or fatigue, skeletal muscle cramps, and decreased exercise capacity or low peak oxygen consumption. While some of these benefits have been demonstrated, the evidence does not strongly support routine supplementation with L-carnitine in patients with ESKD. Cost and the addition of yet another medication to the already complex regimen prescribed for many of these patients also mitigates against the routine use of this agent. The K/DOQI nutrition guidelines recommend supplementation with L-carnitine only if the disorders for which L-carnitine has shown some benefit are not responding to standard therapies.¹⁶

■ UREMIC BLEEDING

Bleeding complications in patients with CKD are usually mild, but can result in major hemorrhagic events. The primary mechanisms underlying the hemostatic problem are platelet biochemical abnormalities and alterations in platelet–vessel wall interactions. Decreased platelet aggregation and adhesiveness have been shown in a number of studies.¹²¹ Additionally, there is a decreased plasma concentration and defective binding of the large multimer of von Willebrand factor (vWF), which results in abnormal platelet–blood vessel wall interactions. Patients on hemodialysis are at even greater risk of bleeding due not only to the hemodialysis process itself, but from administration of other medications. Heparin is frequently administered during dialysis procedures to prevent clotting during dialysis. Patients at high risk for bleeding may require alternative anticoagulation procedures rather than traditional hemodialysis with systemic heparinization (see Chap. 45). In addition, dialysis patients often receive systemic anti-

coagulation (warfarin) or antiplatelet therapy (aspirin or clopidogrel) for prevention of access clotting or other cardiovascular disorders.

There are several nondialytic adjunctive therapies that may temporarily shorten the increased bleeding time observed in patients with kidney disease.¹²¹ Cryoprecipitate is rich in factor VIII, fibrinogen, and fibronectin, and shortens bleeding time in 50% of uremic patients within 1 hour.¹²¹ Desmopressin (1-deamino-8-D-arginine vasopressin) has minimal vasoconstrictive effects as compared to vasopressin, but effectively releases autologous factor VIII (vWF) from the endothelial lining of vessel walls. A consistent lowering of bleeding time has been observed with intravenous, subcutaneous, and intranasal routes of administration. A drawback to the use of desmopressin is tachyphylaxis with repeated doses; response may return after 3 to 4 days. This effect is felt to be caused by depletion of vWF stores following the first dose.

Administration of estrogens has also been effective as an intervention to reduce bleeding time in uremic patients, an intervention studied based on the observation that women with von Willebrand's disease improved during pregnancy.¹²¹ The mechanism of action is unknown. Oral conjugated estrogens and low-dose transdermal patches have also been shown to be effective.¹²¹ Side effects, which are uncommon and usually mild, include hot flashes, nausea, vomiting, hypertension, gynecomastia, and loss of libido. An increased risk of thromboembolism may result from estrogen therapy, especially with chronic use.¹²²

■ GASTROINTESTINAL DISORDERS

Anorexia, hiccups, and a metallic taste in the mouth are common as kidney disease becomes more severe. Nausea, vomiting, diarrhea, or abdominal distention may also occur. Gastric and colonic mucosal ulcerations and telangiectasias with resultant gastrointestinal bleeding are common. Ascites may develop secondary to fluid overload or peritoneal serositis.

■ IMMUNE FUNCTION

Infectious diseases are common and result in significant morbidity and mortality in patients with ESKD.³ Although multiple abnormalities in host defenses and an increased susceptibility to infection have been described, the causal link between these observations remains speculative. Absolute lymphopenia and impaired cell-mediated immunity are common in ESKD patients and may be caused by uremic toxins or protein-calorie malnutrition. Although plasma concentrations of IgG, IgM, and IgA are usually normal, antibody responses appear to be significantly depressed.¹²³ Patients requiring dialysis have many problems with vascular access which puts them at higher risk for exposure to infectious sources. The risk of infections in patients with CKD, and particularly ESKD, is an important consideration when reviewing the clinical presentation of a patient, as hospitalization rates for infection and sepsis have increased dramatically in the last 10 years.³

■ PRURITUS

Despite advances in dialysis treatment, pruritus (itching) remains a problem for 60% to 90% of ESKD patients.¹²⁴ The pathogenesis of uremic pruritus is poorly understood, but has been attributed to multiple factors such as inadequate dialysis, skin dryness, secondary

hyperparathyroidism, increased vitamin A and histamine plasma concentrations, and increased sensitivity to histamine. This complication of ESKD is extensively reviewed in Chap. 45.

■ NEUROLOGIC ABNORMALITIES

Uremic encephalopathy occurs as a result of the effects of uremia on the central nervous system and is associated with symptoms including alterations in consciousness, thinking, memory, speech, psychomotor behavior, and emotion. Sensory and motor function may be altered, particularly affecting leg nerves, resulting in leg cramps and restless leg syndrome. Uremic encephalopathy is less common because of earlier initiation of dialysis in patients with Stage 5 CKD.

Peripheral neuropathy is also common with advanced CKD and is typically indistinguishable from other types of neuropathy (e.g., diabetic neuropathy). Symptoms are often uncomfortable for the patient and prompt many clinicians to initiate pharmacologic therapy in an attempt to reduce these symptoms. Tricyclic antidepressants (e.g., amitriptyline) and anticonvulsants (e.g., phenytoin and gabapentin) may have some benefit in alleviating symptoms of neuropathy; however, risks and benefits must be considered for agents

such as gabapentin, which is eliminated exclusively by the kidney and itself may cause neurologic symptoms with accumulation. Abnormalities of the autonomic nervous system that may occur with advanced CKD include postural hypotension, impotence, impaired sweating, and alterations in gastric motility.

■ ENDOCRINE DISORDERS

A variety of endocrine and metabolic abnormalities are common with CKD. Most patients have symptoms of hypothyroidism (low energy, cold intolerance, and constipation), but typically the levothyroxine (T_4) concentration is low and the thyroid-stimulating hormone concentration is normal.¹²⁵ Hypothermia is common; body temperatures are approximately 1°F lower as compared to individuals with normal kidney function. Hyperglycemia secondary to peripheral resistance to insulin can occur. Diabetic patients with CKD may present with more frequent hypoglycemic episodes because the kidney is responsible in large part for the degradation of insulin. Insulin doses often must be adjusted downward as kidney disease progresses. Primary hypogonadism as well as hypothalamic abnormalities contribute to sexual dysfunction and sterility.

ABBREVIATIONS

ACEI: angiotensin-converting enzyme inhibitor
 AIDS: acquired immunodeficiency syndrome
 ARB: angiotensin receptor blocker
 Ca × P: calcium phosphorus product; serum calcium multiplied by serum phosphorus
 CKD: chronic kidney disease
 CPK: creatine phosphokinase
 DFO: deferoxamine
 EPO: erythropoietin
 ESKD: end-stage kidney disease
 ESRD: end-stage renal disease
 FE_K: fractional excretion of potassium
 FE_{Na}: fractional excretion of sodium
 GFR: glomerular filtration rate
 Hct: hematocrit
 HDL: high-density lipoprotein
 Hgb: hemoglobin
 HMG-CoA: 3-hydroxy-3-methylglutaryl coenzyme A (reductase)
 iPTH: intact parathyroid hormone
 LDL: low-density lipoprotein
 LVH: left ventricular hypertrophy
 MCV: mean corpuscular volume
 NKF-K/DOQI: National Kidney Foundation-Kidney Disease Outcomes Quality Initiative
 PTH: parathyroid hormone
 ROD: renal osteodystrophy
 sHPT: secondary hyperparathyroidism
 TIBC: total iron-binding capacity
 TSat: transferrin saturation
 VDR: vitamin D receptor
 vWF: von Willebrand factor

HEMODIALYSIS AND PERITONEAL DIALYSIS

Rowland J. Elwell and Edward F. Foote

Learning Objectives and other resources can be found at www.pharmacotherapyonline.com.

KEY CONCEPTS

- 1 In hemodialysis, blood and dialysate are perfused on opposite sides of a semipermeable membrane. Substances are removed from the blood due to diffusion and ultrafiltration.
- 2 Due to fewer complication and longer survival rates, the native arteriovenous fistula is the preferred access for hemodialysis. Venous catheters are plagued by complications such as infection and thrombosis and often deliver relatively poor blood flow rates.
- 3 The Kt/V and urea reduction ratio are the most commonly used indicators for hemodialysis adequacy. The National Kidney Foundation's Kidney Disease Outcomes Quality Initiative has set a goal Kt/V of greater than 1.2 and a goal urea reduction ratio of greater than 65%.
- 4 Hypotension and cramps are common intradialytic complications. Other serious complications include infection and thrombosis of the access.
- 5 In peritoneal dialysis, dialysate is instilled via a permanent peritoneal catheter into the peritoneal cavity. The peritoneal membrane lines the highly vascularized abdominal viscera and acts as the semipermeable membrane across which diffusion and ultrafiltration occur.
- 6 The most common type of peritoneal dialysis is continuous ambulatory peritoneal dialysis, during which a patient manually instills 2 to 3 L of dialysate four times a day. Other types include a variety of automated systems collectively termed automated peritoneal dialysis in which some of the daily dialysate exchanges (usually the overnight exchanges) are completed using an automated device.
- 7 Peritonitis is a common complication of peritoneal dialysis. Initial empiric therapy for peritonitis should include intraperitoneal administration of agents effective against both gram-positive and gram-negative organisms.
- 8 Nasal carriage of *Staphylococcus aureus* is associated with an increased risk of catheter-related infections and peritonitis. Prophylaxis with intranasal mupirocin (twice a day for 5 days every month) or mupirocin (daily) at the exit site can effectively reduce *S. aureus* infections.

Hemodialysis (HD), peritoneal dialysis (PD), and kidney transplantation are the major treatment options for patients with end-stage kidney disease (ESKD) which has also been referred to as end-stage renal disease (ESRD); or kidney failure. The United States Renal Data System (USRDS)¹ reported in 2003 that there were 406,081 Americans with ESKD. Of these, 65% were treated with HD, 7% were on PD, and 28% had a functioning kidney transplant. During the period between 1997 and 2001, the prevalent HD population grew by 4.5% per year, while the PD population decreased by 4.9% per year. Although the number of kidney transplants performed during this period has risen steadily, transplantation has not kept pace with the growing incidence of ESKD. Although the use of PD has declined, dialysis remains the most common form of chronic renal replacement therapy with 72% of patients receiving either HD or PD. Based on current trends and estimated population growth, it is projected that the number of ESKD patients in the United States may reach 2.24 million by the year 2030.¹ Assuming that the proportion of patients dependent on dialysis remains constant, this population may exceed 1.6 million in 2030. For a more thorough discussion on the epidemiology of chronic kidney disease, see Chap. 43.

This chapter is a primer on the principles and practice of dialysis. The chapter focuses on HD and PD as the dialysis modalities most commonly employed in chronic renal replacement therapy (the reader

is referred to Chap. 42 for a discussion of the use of dialysis in acute renal failure). The pertinent factors involved in the appropriate initiation of dialysis are described. There is discussion and comparison of the morbidity and mortality associated with HD and PD, as these considerations may influence the dialysis method chosen by patients and clinicians. Since dialysis by either method is not a generic procedure, the variants of HD and PD are detailed. The multiple types of vascular and peritoneal access used to provide HD and PD, including various catheters and surgical techniques, are illustrated. The concept of dialysis adequacy for each modality is reviewed, and methodologies to quantify the delivered dose of dialysis are described. Finally, the clinical presentation of the common complications of both dialytic therapies are presented, along with pertinent nonpharmacologic and pharmacologic therapeutic alternatives.

MORBIDITY AND MORTALITY IN DIALYSIS

Morbidity can be grossly assessed by the number of hospitalizations per patient-year, the number of days hospitalized, or the incidence of certain complications such as cardiovascular events. Among dialysis patients, the number of hospital admissions per patient-year has remained fairly constant since 1991. However, average length of stay

has decreased 17% and 21% for HD and PD patients, respectively.¹ Early comparative studies demonstrated more hospitalized days with PD (21.9 vs. 17.3 per year), but the policy at that time was for inpatient treatment of peritonitis. Because many PD infections are now treated on an outpatient basis, the number of hospital days is dramatically lower than for HD patients in some centers.² In fact, admissions for peritonitis have decreased 47% since 1991. Overall, hospitalizations are more frequent for whites than for blacks, and the frequency and duration increase with age in both groups. Although cardiovascular complications and infection are common, the combined category of “other,” which includes vascular access problems, accounts for the greatest number of admissions and days in hospital.¹

In recognition of the high morbidity and mortality of dialysis patients, the Centers for Medicare & Medicaid Services, at that time known as the Health Care Financing Administration, developed a series of health care quality improvement programs in 1993. Now called the ESKD Clinical Performance Measures Project, they examine markers of the quality of dialysis care (anemia management, serum albumin, vascular access for hemodialysis, and adequacy of dialysis). The 2003 report studied a sample population of 8,487 HD and 1354 PD patients.³ The report showed that 79% of HD patients had hemoglobin values at or above the target range (11 to 12 g/dL) in 2002, compared to only 43% in 1997. Similarly, 79% of PD patients had achieved target hemoglobin values in 2002, compared to 55% in 1997. Although less dramatic, improvements in other clinical indicators were also reported. The report concluded that opportunities still exist to improve the care of U.S. dialysis patients in the areas of adequacy of dialysis, vascular access, and anemia management.

Regardless of dialysis modality, the life expectancy of U.S. dialysis patients is markedly lower than that of healthy subjects of the same age and gender. In comparison to the general population, dialysis patients have one-third to one-sixth of the expected remaining lifetime. Nonetheless, improvement has been made and the overall patient mortality rate has fallen 10% among dialysis patients since 1980. The changes in mortality rates are more impressive when dialysis vintage is examined. In patients receiving dialysis for fewer than 2 years and from 2 to 5 years, mortality rates decreased 22% and 15%, respectively, since 1980. However, in those treated for 5 years or more, mortality rates increased 7%. These changes suggest that death is occurring later in the course of dialysis therapy.¹

Life expectancy is reduced for both HD and PD patients, but comparative mortality studies have shown inconsistent results.^{4–9} Bloembergen and colleagues found that there was a 19% increase in the relative risk of death of U.S. peritoneal dialysis patients as compared to those receiving hemodialysis, and that peritoneal dialysis patients had more deaths as a result of infections, acute myocardial infarctions, other cardiac causes, and cerebrovascular diseases.^{4,5} The results of two Canadian studies highlight the extent of the current controversy. Fenton and colleagues retrospectively compared mortality rates of HD and PD patients who started therapy between 1990 and 1994.⁶ They reported that the mortality rate in PD patients was significantly lower than that observed in HD patients; the mortality rate ratio was 0.73 (PD:HD). This effect was most evident in the first 2 years of therapy, as demonstrated by the finding of similar 5-year survival probabilities of approximately 35%. Foley and colleagues prospectively followed a cohort of PD and HD patients who initiated dialysis therapy between 1984 and 1991.⁷ They reported that there was no difference in mortality rate during the first 2 years (17.8% and 16.5% of PD and HD patients, respectively). However, after 2 years the mortality rate in the PD group was significantly greater than in the HD patients (mortality rate ratio = 1.57). These differences in outcome may be related to a wide array of factors, such as the dose of dialysis, physician bias in selection of the initial mode of therapy, patient compliance, and

unmeasured comorbidities, such as hyperlipidemia or degree of diabetic control.⁸ Cardiovascular events account for 25% to 40% of deaths in HD and PD patients, whereas peritonitis is the second most common cause of mortality among peritoneal dialysis patients. Of patients leaving PD, the major reasons are death or transfer to hemodialysis because of inadequate dialysis or frequent episodes of peritonitis.^{7,9} Thus the selection of the optimal therapy for a given patient must be individualized.

CLINICAL CONTROVERSY

There is much debate over which dialysis modality, hemodialysis or PD, is best in terms of morbidity and mortality. Outcomes studies have provided conflicting results. Although only 7% of U.S. patients are treated with PD, surveyed nephrologists report that as many as 45% of prevalent ESKD patients could be treated with PD.

INDICATIONS FOR DIALYSIS

Dialysis should be initiated electively rather than urgently in patients with chronic kidney disease (see Chap. 44). Because of the progressive nature of the disease, the planning for dialysis should begin once the patient’s creatinine clearance (Cl_{cr}) drops below 30 mL/min per 1.73m².¹⁰ Beginning the preparation process at this point allows adequate time for proper education of the patient and family and for the creation of suitable vascular or peritoneal access.

The primary criterion for initiation of dialysis is the patient’s clinical status: the presence of persistent anorexia, nausea, and vomiting, especially if accompanied by weight loss, fatigue, declining serum albumin levels, uncontrolled hypertension or congestive heart failure, and neurologic deficits or pruritus. Some nephrologists use critical lab values of serum creatinine or blood urea nitrogen (BUN) as indicators of when to initiate dialysis. The National Kidney Foundation’s Kidney Disease Outcomes Qualitative Initiative (NKF-K/DOQI) guidelines suggest that nondiabetic patients should be started when their Cl_{cr} is 9 to 14 mL/min per 1.73 m². Diabetics may need to be started earlier.¹¹ Table 45–1 lists the advantages and disadvantages of hemodialysis,

TABLE 45–1. Advantages and Disadvantages of Hemodialysis

Advantages

1. Higher solute clearance allows intermittent treatment.
2. Parameters of adequacy of dialysis are better defined and therefore underdialysis can be detected early.
3. Technique failure rate is low.
4. Even though intermittent heparinization is required, hemostasis parameters are better corrected with hemodialysis than peritoneal dialysis.
5. In-center hemodialysis enables closer monitoring of the patient.

Disadvantages

1. Requires multiple visits each week to the hemodialysis center, which translates into loss of control by the patient.
2. Disequilibrium, dialysis hypotension, and muscle cramps are common. May require months before the patient adjusts to hemodialysis.
3. Infections in hemodialysis patients may be related to the choice of membranes, the complement-activating membranes being more deleterious.
4. Vascular access is frequently associated with infection and thrombosis.
5. Decline of residual renal function is more rapid compared to peritoneal dialysis.

TABLE 45–2. Advantages and Disadvantages of Peritoneal Dialysis**Advantages**

1. More hemodynamic stability (blood pressure) due to slow ultrafiltration rate.
2. Increased clearance of larger solutes, which may explain good clinical status in spite of lower urea clearance.
3. Better preservation of residual renal function.
4. Convenient intraperitoneal route of administration of drugs such as antibiotics and insulin.
5. Suitable for elderly and very young patients who may not tolerate hemodialysis well.
6. Freedom from the “machine” gives the patient a sense of independence (for continuous ambulatory peritoneal dialysis).
7. Less blood loss and iron deficiency, resulting in easier management of anemia or reduced requirements for erythropoietin and parenteral iron.
8. No systemic heparinization requirement.
9. Subcutaneous versus intravenous erythropoietin or darbepoetin is usual, which may reduce overall doses and be more physiologic.

Disadvantages

1. Protein and amino acid losses through peritoneum and reduced appetite owing to continuous glucose load and sense of abdominal fullness predispose to malnutrition.
2. Risk of peritonitis.
3. Catheter malfunction, exit site, and tunnel infection.
4. Inadequate ultrafiltration and solute dialysis in patients with a large body size, unless large volumes and frequent exchanges are employed.
5. Patient burnout and high rate of technique failure.
6. Risk of obesity with excessive glucose absorption.
7. Mechanical problems such as hernias, dialysate leaks, hemorrhoids, or back pain may occur.
8. Extensive abdominal surgery may preclude peritoneal dialysis.
9. No convenient access for intravenous iron administration.

while those for peritoneal dialysis are delineated in Table 45–2. These factors, along with the patient’s concomitant diseases, preferences, and support environments, are the principal determinants of the dialysis mode they will receive. Timely initiation of dialysis in the ambulatory setting before the onset of severe complications such as pericarditis, encephalopathy, or pulmonary edema may result in significant cost savings as compared with the initiation of dialysis in an acute care environment.

HEMODIALYSIS**PRINCIPLES OF HEMODIALYSIS**

1 Hemodialysis consists of the perfusion of blood and a physiologic salt solution on opposite sides of a semipermeable membrane. Multiple substances, such as water, urea, creatinine, uremic toxins, and drugs move from the blood into the dialysate, thus facilitating removal from the blood. Solutes are transported across the membrane by either passive diffusion or ultrafiltration. Diffusion is the movement of substances along a concentration gradient, the rate of diffusion depends on the difference between the concentrations of solute in blood and dialysate, solute characteristics, the dialyzer composition, and flow rates (blood and dialysate). Ultrafiltration is the movement of water across the membrane due to hydrostatic or osmotic pressure, and is the primary means for removal of excess body water. Convection (expressed as mL of plasma water removed per hour per mm of mercury of pressure within the dialyzer) occurs

when dissolved solutes are “dragged” across a membrane with fluid transport (as long as the pores in the dialyzer are large enough to allow them to pass). Convection can be maximized by increasing the hydrostatic pressure gradient across the dialysis membrane, or by changing to a dialyzer that is more permeable to water transport. These two processes can be controlled independently, and thus a patient’s hemodialysis prescription can be individualized to attain the desired degree of solute (urea) removal and fluid balance.

HEMODIALYSIS ACCESS

2 Permanent access to the bloodstream for hemodialysis may be accomplished by several techniques, including creation of an arteriovenous (AV) fistula, the AV graft, and venous catheters^{12,13} (Fig. 45–1). The AV fistula has the longest survival of all blood-access devices and is associated with the lowest rate of complications such as infection and thrombosis, and is therefore considered the preferred access. However, fistulas require 2 months or more for the access to dilate and thicken (“mature”) as the result of the increased arterial pressure. In addition, creation of an AV fistula may be difficult in elderly patients or patients with peripheral vascular disease (particularly common in patients with diabetes). Synthetic AV grafts, usually made of polytetrafluoroethylene, are another option for permanent AV access. Polytetrafluoroethylene grafts require only 2 to 3 weeks to endothelialize before they can be routinely used. The primary disadvantages of this type of access are the shorter survival, and the fact that they have higher rates of infection and thrombosis than do AV fistulas. Cuffed, double-lumen or twin single-lumen venous catheters are now commonly used for patients in whom AV access is not an option. Venous catheters can be placed in the femoral, subclavian, or internal jugular vein. These catheters are often used in small children, diabetic patients with severe vascular disease, the morbidly obese, and those patients who have no viable sites for AV access. The cuff on the catheter stabilizes the catheter placement, reduces the incidence of infection, and prolongs the period of use from several weeks to 6 months or more. The major problem with all venous catheters is they have a shorter life span and are more prone to infection and thrombosis than permanent AV accesses. Furthermore, catheters are generally not able to provide adequate blood flow rates, which can limit the amount of dialysis delivered.

The K/DOQI guidelines suggest that the AV fistula should be the first choice of access for all eligible patients who will become dialysis dependent.¹⁴ If creation of an AV fistula is not possible, a synthetic graft should be constructed. Unless AV access is not possible, cuffed venous catheters should not be used as a permanent dialysis access. Patients who will need dialysis for only a short period of time (i.e., acute kidney failure) generally have a venous catheter (cuffed or non-cuffed) placed. The use of temporary catheters and grafts has declined since 1991, while fistula insertions have shown a modest increase. Of some concern, the most commonly placed access is permanent venous catheters.¹ The extensive use of catheters may be due to the large population of patients who are not candidates for AV access, or they are being used until permanent AV access can be accomplished. Clearly, earlier referral to nephrology and vascular surgery makes it easier to place the most appropriate access.

HEMODIALYSIS PROCEDURES

The HD system consists of an external vascular circuit through which the patient’s blood is transferred in sterile polyethylene tubing to the dialysis filter or membrane (dialyzer) via a mechanical pump (Fig. 45–2). The patient’s blood then passes through the dialyzer on one side of the semipermeable membrane and is returned to the

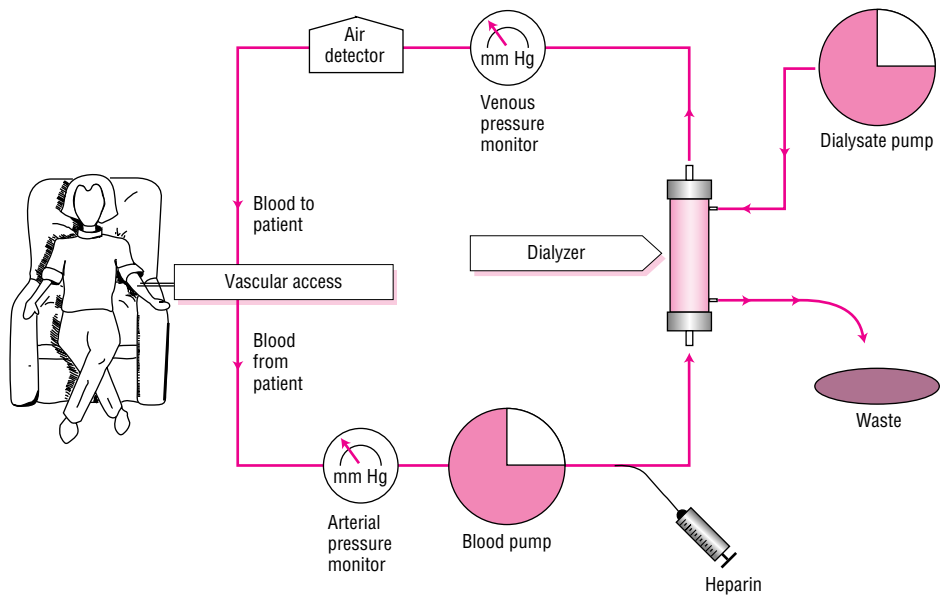

FIGURE 45-1. The predominant types of vascular access for chronic dialysis patients are (A) the arteriovenous fistula and (B) the synthetic arteriovenous forearm graft. The first primary arteriovenous fistula is usually created by the surgical anastomosis of the cephalic vein with the radial artery. The flow of blood from the higher-pressure arterial system results in hypertrophy of the vein. The most common AV graft is between the brachial artery and the basilic or cephalic vein.

patient. The dialysate solution, which consists of purified water and electrolytes, is pumped through the dialyzer countercurrent to the flow of blood on the other side of the semipermeable membrane. The dialysate circuit, unlike the vascular circuit, is not sterile and is a potential source of infection for the patient, particularly if the membrane were to rupture.

Dialysis membranes are classified as conventional (standard), high-efficiency, and high-flux. Conventional dialyzers, mostly made of cuprophane, have small pores that limit clearance to relatively small molecules such as urea and creatinine. High-efficiency membranes have large surface areas and thus have a greater ability to remove water, urea, and other small molecules from the blood. High-flux

FIGURE 45-2. In conventional or high-flux hemodialysis, the patient's blood is pumped to the dialyzer at a rate of 300 to 600 mL/min. Heparin is administered to prevent clotting in the dialyzer. The predominant dialyzers for conventional dialysis are small (0.8 to 1.5 m²), low- to medium-flux dialyzers made of cellulose acetate, cuprophane, or hemophan. High-flux hemodialysis systems incorporate a synthetic dialyzer made of polysulfone, polyacrylonitrile, polymethylmethacrylate, or a high-flux cellulosic-based filter; for example, cellulose triacetate of variable size (0.65 to 2.1 m²). The dialysate, which is usually bicarbonate buffered, is pumped at a rate of 500 to 1000 mL/min through the dialyzer countercurrent to the flow of blood. The rate of fluid removal from the patient is controlled by adjusting the pressure in the dialysate compartment.

membranes have large pores that are capable of removing high-molecular-weight substances such as β_2 -microglobulin and certain drugs, such as vancomycin.^{15,16} The primary reason to use high-efficiency and/or high-flux membranes is that clearance of both low- and high-molecular-weight substances is much greater than with the conventional membranes, so treatment times can be shorter for any set amount of dialysis dose. The use of high-flux and high-efficiency dialysis increased significantly in the United States during the 1990s. High-efficiency and high-flux dialysis require blood flow rates greater than 400 mL/min, dialysate flow rates greater than 500 mL/min, and the use of strict controls on the rate of fluid removal. Typically these dialyzers are composed of polysulfone (PS), polymethylmethacrylate (PMMA), polyamide, cellulose triacetate, and polyacrylonitrile (PAN).¹⁵

Another issue relating to dialysis membranes is their ability to stimulate the immune system. If the dialysis filter membrane does not activate the complement system (C3a and C5a) when it comes in contact with the patient's blood, it is considered biocompatible. In the acute setting, the incidence of hypotension, fever, bronchoconstriction, and thrombocytopenia are lower in patients dialyzed with biocompatible filters. The most biocompatible dialyzers use a synthetic membrane of PS, PAN, or PMMA. Although not definitive, biocompatible membranes may be associated with fewer adverse events during dialysis, lower rates of hospitalization, reduced death rates, and slower declines in residual renal function.¹⁷

ADEQUACY OF HEMODIALYSIS

The objective of hemodialysis dosing is to prescribe and deliver the optimal dose for each individual patient, that is, the amount of therapy above which there is no cost-effective increment in the patient's quality-adjusted life expectancy. The two key goals of the prescription are to achieve the desired dry weight and the adequate removal of endogenous waste products such as urea. Dry weight is the target postdialysis weight at which the patient is normotensive and free of edema.

3 The desired dose of dialysis in terms of solute removal can be expressed as a urea reduction ratio (URR) or the Kt/V (pronounced "K-T-over-V"). The URR is calculated as:

$$URR = \frac{\text{Predialysis BUN} - \text{Postdialysis BUN}}{\text{Predialysis BUN}} \times 100$$

The URR is an easy calculation and thus is frequently used to measure the delivered dialysis dose. However, the URR does not account for the contribution of convective removal of urea. The Kt/V is the dialyzer clearance of urea (K) in L/h multiplied by the duration of dialysis (t) in hours, divided by the urea distribution volume of the patient (V) in liters.¹⁸ Kt/V is a unitless parameter that quantitates the fraction of the patient's total body water that is cleared of urea during a dialysis session. Urea kinetic modeling, using special computer software, is the optimal means to determine the Kt/V . Kt/V can also be calculated by using the following equation.¹⁹

$$Kt/V = \ln(R - 0.008t) + [(4 - 3.5R)(UF/Wt_{\text{post}})]$$

where R is the post-BUN:pre-BUN ratio, t is the duration of dialysis in hours, and UF is the weight loss during dialysis. This equation provides the best estimate of kinetically modeled Kt/V because it considers the effect of the efficiency of the treatment as a function of the treatment time, and the convective removal of urea in the ultrafiltrate (UF/Wt).

With high-efficiency dialysis, urea clearance exceeds 180 mL/min and urea kinetics are best characterized by a two-compartment

model with a central compartment volume that increases during the time between dialysis treatments.¹⁸ As a result of this kinetic behavior, a marked rebound in urea concentrations is seen after dialysis, as has been described for many drugs. Because of the two-compartment behavior of urea, the timing of the posttreatment BUN sample is critical. If the sample is obtained immediately after the end of the treatment, equilibration between the two compartments is incomplete and the sample will overestimate the effect of the treatment administered. The only "true" sample is the one obtained after the two compartments have reached equilibrium. In general, complete equilibration between compartments occurs within 15 to 30 minutes after the end of the treatment; however, this approach is not clinically practical. It is possible to calculate Kt/V using a sample immediately after the treatment if appropriate corrections are made to transform that sample into an equilibrated value (eKt/V). This correction considers the urea clearance of the dialyzer used during the treatment, since the magnitude of the rebound is proportional to the efficiency of the treatment. The eKt/V is typically about 0.2 lower than the standard Kt/V , (often termed the *single pool Kt/V* [$spKt/V$]). Many computer packages, often included in newer dialysis machines, do these calculations automatically.

The K/DOQI recommends that the delivered dose of dialysis be at least a Kt/V of 1.2 (equivalent to an average URR of 65%). To achieve this goal, the recommended *target Kt/V* is 1.3. Many nephrologists believe that even greater doses of dialysis would have positive outcomes in dialysis patients, and so the average dose of dialysis has been increasing in the U.S. In 2001, the median Kt/V was 1.49.³ The HEMO study was designed to determine the effects of high-dose dialysis and the use of high-flux hemodialysis membranes on morbidity and mortality.²⁰ The results of this prospective, randomized trial that assigned patients to either standard (Kt/V 1.25) or high-dose (Kt/V 1.65) dialysis with high- or low-flux membranes, revealed that the risk of death was similar in both the standard and high-dose and the low- and high-flux groups. Thus there does not appear to be any benefit in increasing the amount of dialysis above the current recommendations. As many patients in the U.S. are well above the target Kt/V range, it is unclear if a patient's dose of dialysis should actually be *decreased*. The HEMO study only enrolled patients who were on traditional three-times-weekly dialysis, thus the applicability of these findings to patients on more intensive regimens such as daily or nocturnal HD regimens that provide long, frequent dialysis remain to be determined.^{21,22} Although early data indicate that these intensive HD regimens result in better blood pressure, anemia, and phosphate control,²¹ currently these HD regimens are not widely utilized, in part due to Medicare reimbursement issues.

CLINICAL CONTROVERSY

It remains to be determined what type of hemodialysis is best. Intensive hemodialysis treatments (nocturnal and daily dialysis) may provide better outcomes in hemodialysis patients. Studies on the value of these regimens are currently in development.

A deficiency in delivered hemodialysis therapy may be related to patient compliance with the dialysis prescription (ending dialysis early). Other causes for a low Kt/V include low blood flow rates due to access stenosis or thrombosis, or due to the use of catheters. Adequate dialysis may not be achieved in some patients despite compliance and sufficient blood flow. For these patients there are really only two options to increase urea clearance: use a larger membrane or increase the treatment time.

COMPLICATIONS OF HEMODIALYSIS

INTRADIALYTIC COMPLICATIONS

4 The most common complications that occur during the hemodialysis procedure include hypotension, cramps, nausea and vomiting, headache, chest pain, back pain, and fever or chills. Table 45–3 lists these complications and the etiology with predisposing factors.²³

Hypotension is the most common complication during HD and is primarily related to the large amount of fluid removed during typical treatments, although the other causes listed in Table 45–3 are also important.^{24,25} Intradialytic hypotension is more common in the elderly and patients with diabetes. Other symptoms (nausea and cramping) are often present during acute hypotensive episodes. The replacement of acetate with bicarbonate as the dialysate buffer, the use of volumetric ultrafiltration controllers, as well as individualized dialysate sodium levels has helped reduce the incidence of hypotension. While pruritus may appear worse during the HD treatment, it is actually a complication of ESKD.

OTHER COMPLICATIONS: THROMBOSIS AND INFECTION

Thrombosis of the vascular access is a major problem in chronic HD. Although thrombosis occurs in grafts, and to a lesser extent fistulas, thrombosis associated with catheters is the most problematic and will be the focus of discussion here. Early dysfunction (less than 5 days after placement) of an HD catheter is usually associated with an intracatheter or catheter-tip thrombosis, or a malpositioned catheter. Thrombi that occur after approximately 1 week can be outside the catheter (extrinsic) or within the catheter (intrinsic). Intrinsic throm-

bosis is the major cause of catheter failure and can occur within the lumen of the catheter, at the tip of the catheter, or can present as a fibrin sleeve surrounding the catheter. Fibrin sleeves can obstruct the catheter and be a nidus for infection. Thrombosis is first suspected when blood cannot be aspirated from the catheter yet saline flows in freely. Catheter-related thrombosis can be diagnosed using ultrasonography, venography or computed tomography scans.^{12,26,27}

Infections of the vascular access are a major problem in HD patients. The most common cause of access infection is *Staphylococcus aureus*, although other organisms can be isolated. The type of access is one of the most important risk factors for infection. AV fistulas have the lowest rate of infection followed by grafts, tunneled catheters, and temporary catheters. Catheters in general have more than a sevenfold risk of infection versus fistulas.^{28,29} Catheter-related infections can be exit site, tunnel infection, and catheter-related bacteremia.³⁰ Patients with diabetes, immunosuppression, a history of bacteremia, and those with *S. aureus* nasal carriage are at highest risk for catheter-related bacteremia. Bacteria can seed distant sites and cause endocarditis, osteomyelitis, and septic arthritis.³¹ Clinically, patients present with fever and chills. If fever and chills occur after catheter manipulation, it is highly suggestive of catheter-related bacteremia.^{28,29}

DIALYZER REACTIONS

Dialyzer reactions encompass a broad range of clinical symptoms that include anaphylactic (type A) and nonspecific (type B) events.²³ In the past, these two types of reactions were considered to be part of the “first-use” syndrome because they occurred much more frequently when new, as opposed to reprocessed, dialyzers were used. Although reprocessing may reduce the incidence of type B events, it has little to no benefit for patients who experience a type A reaction.³² The

TABLE 45–3. Common Complications during Hemodialysis

| | Incidence (%) | Etiology/Predisposing Factors |
|---------------------|---------------|---|
| Hypotension | 20–30 | Hypovolemia and excessive ultrafiltration Antihypertensive medications prior to dialysis Target dry weight too low Diastolic dysfunction Autonomic dysfunction Low calcium and sodium in dialysate High dialysate temperature Meal ingestion prior to dialysis |
| Cramps | 5–20 | Muscle hypoperfusion due to ultrafiltration and hypovolemia Hypotension Electrolyte imbalance Acid-base imbalance |
| Nausea and vomiting | 5–15 | Hypotension Dialyzer reaction |
| Headache | 5 | Disequilibrium syndrome Caffeine withdrawal due to dialysis removal |
| Chest and back pain | 2–5 | Unknown |
| Pruritus | 5 | Inadequate dialysis Skin dryness Secondary hyperparathyroidism Abnormal skin levels of electrolytes Histamine release Mast cell proliferation |
| Fever and chills | <1 | Endotoxin release Infection of dialysis catheter |

symptom complex associated with type A reactions is similar to a drug-induced anaphylactic reaction and may be a result of hypersensitivity to ethylene oxide (a common dialyzer sterilant), heparin, or formaldehyde and glutaraldehyde (common reuse sterilants). This type of reaction has also been associated with activation of the bradykinin system by some dialyzer membranes (especially the AN69), particularly in patients receiving angiotensin-converting enzyme inhibitors, because these agents block bradykinin inactivation.²³ A similar reaction has been reported with the use of the angiotensin receptor blocker losartan.³³ However, the mechanism is unclear, as angiotensin receptor blockers do not increase bradykinin levels. In the event of an anaphylactic reaction, the dialysis procedure should

be stopped immediately. The blood in the dialysis circuit should not be returned to the patient, and resuscitative therapy with epinephrine, antihistamines, and steroids is likely to be required.

Type B reactions are more common than type A reactions, but are less severe (3 to 5 per 100 treatments vs. 5 per 100,000 treatments). Chest and back pain are the most frequently reported symptoms and may be noted within minutes of the start of dialysis or delayed (up to 1 to 2 hours). Complement activation has been suggested as the initiating event. Although no specific treatment is warranted and the patient can continue with dialysis treatment, the patient may be switched to a different dialyzer and/or put on a reprocessing program because this may minimize the occurrence of this reaction in the future.²³

▶ TREATMENT: Hemodialysis Complications

■ HYPOTENSION

Acute management of hypotension includes placing the patient in the Trendelenburg position, decreasing the ultrafiltration rate, and/or administering normal or hypertonic saline.^{23,25} Numerous nonpharmacologic and pharmacotherapeutic interventions have been used to prevent or reduce the incidence of symptomatic dialysis hypotension (Table 45-4). Randomized, blinded, prospective trials are rare and thus comparisons between therapeutic alternatives are difficult to quantify. If patients remain symptomatic after nonpharmacologic interventions, oral midodrine, an α_1 -adrenergic agonist prodrug with peripheral vasoconstrictive properties may be considered. Midodrine, when administered in doses ranging from 2.5 to 25 mg prior to dialysis, has been shown to significantly increase the minimal systolic (from 93 to 97 raised to 107 to 114 mm Hg) and diastolic (from 52 to 53 raised to 58 to 59 mm Hg) blood pressures during dialysis.³⁴⁻³⁶ Furthermore, dialysis symptoms of cramps, fatigue, dizziness, and

weakness are reduced with midodrine treatment.³⁴ A long-term study of the benefits of midodrine found that 10 mg given 30 minutes prior to dialysis resulted in correction of hypotension over a 8-month period without any adverse events.³⁷ Some HD patients have chronic hypotension and experience low blood pressure even when not on dialysis. Oral midodrine given 5 mg twice daily can increase blood pressure in these patients as well.³⁸ It is important to note that the effects of midodrine are probably best in patients with hypotension related to autonomic dysfunction as opposed to other causes of hypotension.

Other medications have also been studied in hypotension. The intravenous administration of levocarnitine (20 mg/kg at the end of each dialysis session) reduced the number of hypotensive episodes from 17 to 7 ($p < 0.02$) in a study of 38 patients, while a placebo group demonstrated no significant benefit.³⁹ The high cost and fairly limited data on levocarnitine relegates this agent to a third- to fourth-line alternative. There has been some speculation that caffeine administration may decrease the incidence of dialysis-associated hypotension. Shinzato and colleagues observed a significantly lower frequency of sudden-onset hypotension (1.7 ± 1.5 times per 4 weeks in the caffeine group versus 4.4 ± 1.5 times per 4 weeks in the placebo group), but no effect on gradual-onset hypotension.⁴⁰ However, an earlier trial failed to show an effect of caffeine when patients experienced hypotension due to food ingestion.⁴¹ Caffeine has a minimal likelihood of adverse events and can be easily administered, and thus may be considered if midodrine is ineffective.

Other drugs that may have some benefit include sertraline^{42,43} and fludrocortisone.⁴⁴ These medications may be tried in individual patients with hypotension, but clearly more studies are required before they can be broadly recommended.

TABLE 45-4. Management of Hypotension

| | |
|------------------|--|
| Acute treatment | Place patient in Trendelenburg position Decrease ultrafiltration rate Give a 100- to 200-mL bolus of normal saline Give 10–20 mL of hypertonic saline (23.4%) over 3–5 min Give 12.5 g mannitol |
| Prevention | |
| Nonpharmacologic | Accurately set dry weight Use a constant ultrafiltration rate Keep dialysate sodium greater than serum sodium Use cool dialysate Use bicarbonate dialysate Avoid food before or during hemodialysis |
| Pharmacologic | Midodrine 2.5–10 mg orally 30 min before hemodialysis (start at 2.5 mg and titrate) Other options (not well studied): Caffeine 250 mg orally 2 hours into hemodialysis session Levocarnitine 20 mg/kg IV after hemodialysis Sertraline 50–100 mg daily Fludrocortisone 0.1 mg before hemodialysis |

■ MUSCLE CRAMPS

Skeletal muscle cramps complicate 5% to 20% of hemodialysis treatments.²³ Although the pathogenesis of cramps is multifactorial, plasma volume contraction and decreased muscle perfusion caused by excessive ultrafiltration is frequently the initiating event. Although there are no comparative data regarding the efficacy of nonpharmacologic and pharmacologic therapy, the former should be the first line of treatment because the adverse consequences are minimal (Table 45-5).

Both vitamin E and quinine significantly reduce the incidence of cramps (in one study from 10.4 and 10.9 per month to 3.3 and 3.6 per month, respectively [$p < 0.0005$]).⁴⁵ Quinine is usually well tolerated,

TABLE 45–5. Management of Cramps

| | |
|------------------|---|
| Acute treatment | Give a 100- to 200-mL bolus of normal saline Give 10–20 mL of hypertonic saline (23.4%) over 3–5 min Give 50 mL of 50% glucose (nondiabetic patients) |
| Prevention | |
| Nonpharmacologic | Accurately set dry weight Keep dialysate sodium greater than serum sodium Stretching exercises |
| Pharmacologic | Give vitamin E 400 international units at bedtime Quinine (not recommended) Other options (not well studied): Oxazepam 5–10 mg 2 hours before hemodialysis Prazosin 0.25 mg orally at the start of hemodialysis |

but rarely may cause temporary sight and hearing disturbances, thrombocytopenia, or gastrointestinal distress. Furthermore, it tends to increase plasma digoxin levels and may enhance the effect of warfarin. This constellation of adverse events prompted the withdrawal of quinine from the over-the-counter market in 1995. Prescription quinine can no longer be marketed for leg cramps. A recent randomized double-blind, placebo-controlled trial demonstrated that both vitamin E (400 mg) and vitamin C (250 mg) reduce the frequency of cramps in dialysis patients. The combination of these two drugs had an additive effect. Although these data further strengthen the case for vitamin E, it is unclear what role oral vitamin C would play in the U.S. since many patients are on a renal multiple vitamin that contains vitamin C (the current study restricted all vitamin products for 1 month prior to the study). Furthermore, there is some concern that oxalate, a metabolite of vitamin C, may accumulate in dialysis patients.

There have been other drugs studied in HD-related cramps. Prazosin appears to significantly reduce the incidence of cramps during hemodialysis.⁴⁶ Unfortunately, its use was associated with a significant increase in the incidence of hypotension that required therapeutic intervention during and after dialysis. A recent study by Chang and colleagues suggested that creatine might have some beneficial effects on muscle cramps in dialysis patients.⁴⁷ Ten patients with intradialytic muscle cramps were randomized to either creatine (12 mg before dialysis) or placebo. The frequency of muscle cramps decreased 60% in the creatine group, while there were no differences in the placebo group. Although serum creatinine concentrations rose in the treatment group, no side effects were noted.

Thus vitamin E appears to be the first choice among these therapeutic options due to the accumulated evidence in clinical trials and because of its fairly good safety profile.

■ THROMBOSIS

If a catheter-related thrombus is suspected, a series of saline flushes can be used to try to clear the catheter. Although this would indicate the thrombi has embolized, it is considered safe and frequently effective. Intraluminal thrombolytics are a second option and are widely used in dialysis units.²⁷ The thrombolytic with the most ex-

TABLE 45–6. Management of Hemodialysis Catheter Thrombosis

| Pharmacologic therapy |
| Alteplase: Instill 2 mg/2 mL per catheter port. Attempt to aspirate after 30 minutes. May repeat dose if catheter function not restored in 120 minutes. Longer durations of instillation have been used. |
| Retepase: Instill 0.5 units/2 mL per catheter port |

perience is urokinase, but this was withdrawn from the U.S. market in 1999 due to the risks of transmitting infectious agents. Urokinase was reintroduced in the U.S. market in 2002, but is only available as a 250,000-international unit vial (prior to 1999 there was a 5000-international unit vial specifically designed for catheter clearance). There have been a number of studies published using alteplase^{48–51} and reteplase^{52,53} for thrombosed hemodialysis catheters. Two studies that compared alteplase vs. urokinase suggest that alteplase might be more effective.^{48,50} The initial clearance rate for both alteplase and reteplase is approximately 90%. However, there are no data available that directly compare alteplase and reteplase for management of dialysis catheter thrombosis. Alteplase (but not reteplase) is FDA approved for restoration of function to central venous catheters due to thrombosis, and is commercially available as a 2-mg vial. Therapeutic alternatives for thrombosed venous catheters are presented in Table 45–6.

TABLE 45–7. Guidelines for the Treatment of Hemodialysis Access Infections

| |
|---|
| I. Primary Arteriovenous Fistula |
| A. Treat as subacute bacterial endocarditis for 6 weeks. |
| B. Initial antibiotic choice should always cover gram-positive organisms, e.g., vancomycin 20 mg/kg IV with serum concentration monitoring or cefazolin 20 mg/kg IV 3 times per week. |
| C. Gram-negative coverage is indicated for patients with diabetes, HIV infection, prosthetic valves, or those receiving immunosuppressive agents, gentamicin 2 mg/kg IV with serum concentration monitoring. |
| II. Synthetic Arteriovenous Grafts |
| A. Local infection—empiric antibiotic coverage for gram-positive, gram-negative, and <i>Enterococcus</i> , e.g., gentamicin plus vancomycin then individualized after culture results available. Continue for 2 to 4 weeks. |
| B. Extensive infection—antibiotics as above plus total resection. |
| C. If access is less than 1 month old, antibiotics as above plus remove the graft. |
| III. Tunneled Cuffed Catheters (Internal Jugular, Subclavians) |
| A. Infection localized to catheter exit site. |
| 1. No drainage—topical antibiotics, e.g., mupirocin ointment. |
| 2. Drainage present—gram-positive antibiotic coverage, e.g., cefazolin 20 mg/kg IV 3 times per week. |
| B. Bacteremia with or without systemic signs or symptoms. |
| 1. Gram-positive antibiotic coverage as in III A2. |
| 2. If symptomatic at 36 hours, remove the catheter. |
| 3. If stable and asymptomatic, change catheter and provide culture-specific antibiotic coverage for a minimum of 3 weeks. |

INFECTION

Patients who experience fever during HD should immediately have blood cultures obtained. If a temporary catheter is being used, it should be removed and the tip of the catheter cultured. Commonly used preventive approaches to catheter-related infections include minimizing use and duration of catheters, proper disinfection and sterile technique, and use of exit-site mupirocin or povidone-iodine ointment. Adoption of strict unit protocols that employ universal pre-

cautions, limit manipulation of the catheter, use disinfection with povidone-iodine, and require the use of face masks by the patient and caregiver can significantly reduce the incidence of catheter-related bacteremia.³⁰ Optimal approaches for the treatment of HD access-related infection have been proposed by the K/DOQI, and Table 45–7 outlines these recommendations.¹⁴ Many clinicians also add an aminoglycoside to the regimen for empiric therapy in catheter-related bacteremia. If the isolated organism is methicillin-sensitive *S. aureus*, therapy may be changed to cefazolin (20 mg/kg, rounded to nearest 500 mg) after each dialysis session.^{31,54,55}

PERITONEAL DIALYSIS

Although the concept of peritoneal lavage has been described as far back as 1744, it wasn't until 1923 that PD was first employed as an acute treatment for uremia. It was used infrequently during subsequent years until the concept of PD as a chronic therapy for ESKD was proposed in 1975. In 1978, the results of a cooperative study were published describing the successful management of nine patients with continuous ambulatory peritoneal dialysis (CAPD). Over the ensuing years the number of patients receiving CAPD increased slowly until the early 1980s. At that time, several innovations in PD delivery systems were introduced, such as improved catheters and dialysate bags. These innovations led to improved outcomes, decreased morbidity, and a corresponding increase in the use of CAPD as a viable alternative to HD for the treatment of ESKD.

Although PD use steadily increased through the 1980s and 1990s, it peaked in 1996 and there has been slow but constant decline since then. Between 1997 and 2001 the prevalent PD population has decreased at a rate of 4.9% per year.¹ Reasons for this decline are not well defined. However, it has been shown that certain patient populations may fare better on one dialysis modality compared to the other and this may be a factor.^{4,6,56,57} Some patients—such as those with more hemodynamic instability (angina or hyper- or hypotension) or significant residual renal function, and perhaps patients who desire to maintain a significant degree of self-care may be better suited to PD rather than to HD. Table 45–2 shows the advantages and disadvantages of PD.

PRINCIPLES OF PERITONEAL DIALYSIS

5 The three basic components of dialysis—namely, a blood-filled compartment separated from a dialysate-filled compartment by a semipermeable membrane—are also used for PD. In PD, the dialysate-filled compartment is the peritoneal cavity, into which dialysate is instilled via a permanent peritoneal catheter that traverses the abdominal wall. The contiguous peritoneal membrane surrounds the peritoneal cavity. The cavity, which normally contains about 100 mL of lipid-rich lubricating fluid, can expand to a capacity of several liters. The peritoneal membrane that lines the cavity functions as the semipermeable membrane, across which diffusion and ultrafiltration occur. The membrane is classically described as a monolayer of mesothelial cells. However, the dialyzing membrane is also comprised of the basement membrane and underlying connective and interstitial tissue. The peritoneal membrane has a total area that approximates body surface area (about 1 to 2 m²). Blood vessels supplying and draining the abdominal viscera, musculature, and mesentery constitute the blood-filled compartment.

Metabolic waste products (urea, creatinine, uremic toxins, and water) to be removed from blood during PD are not in intimate con-

tact with the dialysis membrane as they are in hemodialysis, and must therefore travel a considerable distance to the dialysate-filled compartment. Unlike hemodialysis, there is no easy method to regulate blood flow to the surface of the peritoneal membrane, nor is there a countercurrent flow of blood and dialysate to increase diffusion and convection via changes in hydrostatic pressure. For these reasons, PD is a much less efficient process per unit time compared with HD, and must therefore be a virtually continuous procedure to achieve acceptable goals for clearance of metabolic waste products.

During most PD modalities, the metabolic waste clearance profile is markedly different from what is observed in HD patients. In patients treated with intermittent HD, the serum concentrations of metabolic wastes exhibit a “sawtooth” pattern over time. Because CAPD is essentially continuous, a condition similar to a steady state can occur. When the PD dose is well matched to the generation rate of metabolic waste, the serum levels of metabolic waste products fluctuate less over time. Therefore CAPD may represent a more physiologic process that is similar to endogenous renal function. Furthermore, the massive swings in body water content and high peak concentrations of uremic toxins in HD patients are less than optimal. CAPD may therefore be more beneficial for patients with cardiovascular instability.

The peritoneal membrane has different transport characteristics and permits the passage of larger-molecular-weight solutes than the older, low-flux conventional type of HD membranes. However, this difference is less marked for newer, high-flux membranes. These differences not only aid our understanding of the relative efficiency of each system in the removal of endogenous solutes, but also help us to predict the dialyzability of exogenously administered drugs.

PERITONEAL DIALYSIS ACCESS

Access to the peritoneal cavity is via the placement of an indwelling catheter. Many types are available and a typical example is shown in Fig. 45–3. Most catheters are manufactured from Silastic, which is soft, flexible, and biocompatible. A typical adult catheter is about 40 to 45 cm long, 20 to 22 cm of which are inside the peritoneal cavity. Placement of the catheter is such that the distal end lies low in a pelvic gutter. The center section of the catheter has one or two cuffs made of a porous material. This section is tunneled inside the anterior abdominal wall so that the cuffs provide mechanical support and stability to the catheter, a mechanical barrier to skin organisms, and prevent their migration along the catheter into the peritoneal cavity. The cuffs are placed at different sites surrounding the abdominal rectus muscle. The remainder of the central section of the catheter is tunneled subcutaneously before exiting the abdominal surface, usually a few centimeters below and to one side of the umbilicus.

The placement of the exit site of the catheter is one of the factors related to the development or prevention of exit-site infections and peritonitis. Many new catheters and surgical techniques for catheter placement have recently been developed. The driving forces for this

FIGURE 45-3. Diagram of the placement of a peritoneal dialysis catheter through the abdominal wall into the peritoneal cavity.

development are to enhance patient comfort and to reduce infectious risk. The external section of most peritoneal catheters ends with a Luer-lock, which can be connected to a variety of administration sets.⁵⁸ These catheters can be used immediately if necessary, provided small initial volumes are instilled; however, a maturation period of 2 to 6 weeks is preferred.

PERITONEAL DIALYSIS PROCEDURES

6 There are several types of peritoneal dialysis, of which CAPD remains the most common. Others include a variety of automated systems (collectively termed automated peritoneal dialysis [APD]), including continuous cycling PD (CCPD), nocturnal tidal PD (NTPD), and nightly intermittent PD (NIPD) (Fig. 45-4).⁵⁹ In recent years, there has been a substantial increase in the number of PD patients being treated with APD systems. APD may eventually be used to treat more patients than CAPD. The prototypic form of APD is usually a hybrid between CAPD and CCPD, in which some of the daily exchanges (usually the overnight exchanges) are completed using an automated device. All variants of PD require the placement of a dialysis solution in the peritoneal cavity, allowing it to remain in situ for some period of time (called the dwell time), removing the spent dialysate, and then repeating the process.

All forms of PD use the same dialysate solutions, which are commercially available in volumes of 1 to 3 L in flexible polyvinyl chloride plastic bags. Commercial PD solutions include varying concentrations of electrolytes, such as sodium, chloride, lactate, and calcium. In addition, these solutions usually contain dextrose in hyperosmolar concentrations, which induces ultrafiltration (removal of free water) by crystalline osmosis. Dextrose concentrations range from 1.5% to 4.25%, which provides osmolarities of 350 to 480 mOsm/L, as compared to that of serum, which is 280 mOsm/L. It should be recognized that dextrose is not the ideal osmotic agent for peritoneal dialysate because these solutions are not biocompatible with peritoneal mesothelial cells or with peritoneal leukocytes.⁶⁰ The cytotoxic effects on these cells are mediated by the osmolar load and the low pH of the solutions, as well as the presence of glucose degradation products formed during heat sterilization of these products.

Icodextrin is a glucose polymer recently introduced for use as an alternative osmotic agent in PD solutions. Icodextrin PD solution contains 7.5% icodextrin, a starch-derived glucose polymer. It has an osmolality of 282 to 286 mOsm/L, which is iso-osmolar with

FIGURE 45-4. Comparison of peritoneal dialysis modalities. Continuous ambulatory peritoneal dialysis (CAPD). Patients perform three 2.5-L peritoneal dialysate exchanges during waking hours (8 AM to 10 PM), with each dialysate dwell lasting approximately 4 hours. Before bedtime, they perform an exchange and instill 2.5 L of dialysate overnight (10 PM to 8 AM). The following morning, the patient performs an exchange and the process begins again.

Nocturnal intermittent peritoneal dialysis (NIPD). Patients are free from performing dialysate exchanges during their waking hours (8 AM to 10 PM). Prior to bedtime, they attach their catheter to a cycling machine and receive six to eight 2.5-L exchanges of dialysate while they sleep. Each dialysate dwell time is approximately 1–2 hours. The following morning, the patient unhooks their catheters from the cyclor and goes about their normal activities with an empty peritoneum.

Continuous cycling peritoneal dialysis (CCPD). Patients instill 2.5 L of dialysate into their peritoneal cavity upon waking and allow it to dwell for the remainder of their waking hours (8 AM to 10 PM). Prior to bedtime, they drain the daytime dwell and attach their catheter to a cycling machine and receive three to five dialysate exchanges while they sleep. Each dialysate dwell time is approximately 2 hours long. The following morning, a 2.5-L dwell is instilled into the peritoneal cavity and the patient carries it during waking hours (8 AM to 10 PM).

Nocturnal tidal peritoneal dialysis (NTPD). Patients are free from performing dialysate exchanges during their waking hours (8 AM to 10 PM). Prior to bedtime, they attach their catheter to a cycling machine and instill a volume of 2500 mL of dialysate into their peritoneal cavity. Six to eight exchanges of 1250 mL are carried out approximately every hour. Thus the total dialysate volume introduced into the peritoneal cavity ranges from 10–12 L per day. The following morning, the patients unhook their catheters from the cyclor and go about normal activities with an empty peritoneum. (Adapted from Brophy et al.⁵⁹)

serum. Icodextrin produces prolonged ultrafiltration by a mechanism resembling colloid osmosis. Icodextrin produces ultrafiltration volumes similar to those with 4.25% dextrose, but may have fewer of the metabolic effects associated with dextrose, such as hyperglycemia and weight gain. It is indicated for use during the long (8- to 16-hour) dwell of a single daily exchange in CAPD and APD patients.⁶¹ Other osmotic agents have been used in PD solutions, including mannitol, glycerol, and amino acids, but are not in widespread use because of expense or difficulty in manufacture.

In a basic CAPD system, prewarmed dialysate is permitted to flow into the peritoneal cavity under gravity over a period of about 15 minutes. A bag of PD solution is connected to the patient's PD catheter by a length of tubing called a transfer set. The most common transfer set used is the Y transfer set. This consists of a Y-shaped piece of tubing that is attached at its stem to the patient's catheter, leaving the remaining two limbs of the Y attached to dialysate bags, one filled with fresh dialysate and the other empty. The spent dialysate from the previous dwell is drained into the empty bag, and the peritoneum is subsequently refilled from the bag containing fresh dialysate. The Y set is then disconnected and the bag containing the spent fluid, along

with the empty bag that had contained fresh dialysate, is detached and discarded. The Y transfer set with the double-bag system permits both a flush-before-fill procedure and disconnection during the dwell. This minimizes the number of times a patient manipulates the catheter, thereby reducing the risk of peritonitis and catheter-related infections. A typical dwell period for daytime exchanges in CAPD is 4 to 6 hours, using one of the lower-dextrose-concentration dialysate solutions. At the end of the prescribed dwell period a new Y set is attached and the process is repeated. The process of outflow, aseptic manipulation of the administration set and catheter, and inflow requires a total time of about 30 minutes. Thus dialysis actually occurs for about 3.5 hours out of a prescribed 4-hour period. Typically a patient instills 2 to 3 L of dialysate three times during the day, and then a single exchange using a higher-dextrose-concentration dialysate for an overnight, 8 to 12 hour dwell.

The prescribed dose of dialysis may be altered by changing the number of exchanges per day, by altering the volume of each exchange, or by altering the strength of dextrose in the dialysate for some or all exchanges. Increasing any one of these variables increases the effective osmotic gradient across the peritoneum, leading to increased ultrafiltration and diffusion (solute removal). If the dwell time is extended, equilibrium may be reached, after which time there will be no further water or solute removal. Indeed after a critical period, reverse water movement may occur.

Automated PD systems have been designed for patients who are unable or unwilling to perform the necessary aseptic manipulations, and for those who require more dialysis. APD provides an automated cyclor that performs the exchanges. The device is set up in the evening, and the patient attaches the peritoneal catheter to it at bedtime. The machine performs several short-dwell exchanges (usually 1 to 2 hours) during the night. This permits a long cycle-free daytime dwell of up to 12 to 14 hours. Thus APD provides an exchange profile in reverse of that in CAPD. Typical APD regimens involve total 24-hour exchanges of about 12 L, which include one or more daytime dwells.⁶² This type of regimen is sometimes referred to as APD with a “wet” day. The APD variant, NIPD, has a similar theme, except that the peritoneal cavity tends to be dialysate-free during the day. This type of regimen is frequently referred to as APD with a “dry” day. A number of variants exist and depend largely on equipment availability, patient and prescriber preference, and whether the patient retains any residual renal function, which influences the quantity of dialysis prescribed (see Fig. 45–4).⁵⁹

ADEQUACY OF PERITONEAL DIALYSIS

Like HD, the subject of PD adequacy has received considerable attention. The K/DOQI recommends the use of two criteria to assess the dose of dialysis delivered during PD: total weekly Kt/V_{urea} and total weekly Cl_{Cr} (in liters per week) normalized to 1.73 m² body surface area.⁶³ Although K/DOQI recommends target values for these adequacy indices, which are discussed below, the optimal dose of PD remains undefined, and the lower threshold of dialysis dose that constitutes an acceptable risk for patient outcome has been termed “adequate dialysis.”

Unfortunately, it is easier to describe inadequate PD than it is to provide a universally accepted definition of adequate PD. True PD adequacy requires the identification of an optimal dialysis dose that will result in favorable long-term outcomes, such as survival and quality of life. Compared to hemodialysis, which is used by a much larger patient population, there are few data available regarding the optimal dose of dialysis in PD. As a result, much of the work in this area has focused on establishing the minimum acceptable PD

dose, and what constitutes “adequate” versus “optimal” dialysis is controversial.

The Canada-USA cooperative study (CANUSA) evaluated 680 PD patients in 14 centers who began dialysis between 1990 and 1992.⁶⁴ Decreases of 0.1 in weekly Kt/V_{urea} or 5 L/1.73 m² per week in Cl_{Cr} were associated with 5% to 7% increases in the risk for death. No plateau was observed. Based on this finding it would appear that the greater the urea and creatinine clearances, the greater the rate of patient survival. One criticism of the CANUSA study was that it was assumed that the renal and peritoneal contributions to Kt/V were equivalent. Interestingly, the CANUSA data were reanalyzed to assess the contribution of residual renal function to the clinical results reported in CANUSA.⁶⁵ When solute clearance was subdivided into that contributed by residual renal function and that from peritoneal clearance, the former was found to be a more significant predictor of patient survival.

More recently, the Adequacy of Peritoneal Dialysis in Mexico (ADEMEX) study evaluated the effects of increased peritoneal solute clearance on clinical outcomes in 965 CAPD patients.⁶⁶ Despite significantly greater delivered peritoneal Cl_{Cr} (56.9 ± 0.48 vs. 46.1 ± 0.45) and Kt/V (2.13 ± 0.01 vs. 1.62 ± 0.01) in the intervention group compared to controls, respectively, patient 2-year survival was similar in both groups. It has been suggested that the lack of an observed difference in mortality in the ADEMEX study resulted from the inclusion of both incident and prevalent PD patients. Prevalent patients, who represented 58% of the total, have already demonstrated their tendency for better long-term survival on PD.⁶⁷

DIALYSIS DOSE (Kt/V)

As in hemodialysis, the clearance of urea, a product of protein catabolism, is measured with Kt/V . Kt/V is a unitless value that correlates the patient’s peritoneal membrane urea clearance (K) with the duration of dialysis (t) and the volume of distribution (V) of urea. Calculation of Kt/V for PD requires that the total volume of drained effluent per day be determined (this value is the volume instilled plus volume of water ultrafiltered). The dialysate to plasma (D/P) urea concentration is determined, and Kt is estimated as:

$$Kt = D/P \times \text{volume drained (L/d)}$$

The urea distribution volume (V) is determined from a nomogram based on height, weight, age, and gender, or is approximated as 0.6 L/kg. The Kt/V calculated in this way is a value per day and must be multiplied by seven and reported as a weekly value for PD patients.

The K/DOQI clinical practice guidelines recommend that in CAPD patients, weekly Kt/V values should exceed 2. For APD with a dry day and wet day, the Kt/V values should exceed 2.2 and 2.1, respectively.⁶³ This difference may be because of the differences in efficiency of different variants of PD in clearing small- and middle-sized molecules. One problem associated with the determination of Kt/V for PD patients is the impracticality of 24-hour collections of dialysis effluent. Abbreviated collection periods have been used, and calculations based on the first morning exchange after an overnight dwell correlated well ($r = 0.92$) with a 24-hour collection.⁶⁸

CREATININE CLEARANCE

Weekly measured Cl_{Cr} normalized to 1.73 m² is also used to assess adequacy of PD. The Cl_{Cr} measures the removal of a product of muscle metabolism and correlates well ($r = 0.71$) with Kt/V . For CAPD patients, the total Cl_{Cr} should be at least 60 L/wk per 1.73 m², which

is approximately equivalent to a weekly Kt/V_{urea} of 1.96. For APD with a dry day or a wet day, the corresponding values are 66 and 63 L/wk per 1.73 m^2 , respectively. Such values are the sum of both peritoneal and residual renal clearance and are influenced by body muscle mass.⁶³

PERITONEAL EQUILIBRATION TEST

The peritoneal equilibration test (PET) is a diagnostic test designed to determine an individual PD patient's peritoneal membrane clearance and ultrafiltration characteristics. The objective of the PET is to determine which variant of PD is appropriate for an individual patient and to predict the daily dialysis requirement. The PET simultaneously determines the passage of creatinine and urea from blood to dialysate, glucose from dialysate to blood, and free water transfer across the peritoneal membrane. During a PET, simultaneous blood and dialysate samples (for determination of creatinine, urea, and glucose) are obtained at predetermined intervals during a standardized dialysate dwell. The dialysate is drained after 4 hours and the drain volume is recorded. Dialysate to plasma (D:P) ratios of creatinine and urea, and ratios of glucose in the dialysate compared to its initial concentration (D:D₀) are calculated. Based on these ratios, peritoneal membrane transport status is divided into four categories: high, high average, low average, or low. Based on the drain volume, the ultrafiltration rate is categorized as poor, adequate, good, or excellent. Patients with "high" membrane transport will have rapid clearance of creatinine and urea. However, they will also rapidly absorb glucose. Because the glucose concentration in the dialysate is the primary force that results in ultrafiltration, it follows that patients who have a high transport rate often have poor ultrafiltration. Conversely, patients with "low" membrane transport generally have excellent ultrafiltration but inadequate clearance of creatinine and urea. As a result, "low" transporters may be more appropriately treated with HD than PD.

CHANGING THE PD PRESCRIPTION

The K/DOQI clinical practice guidelines suggest that the adequacy of PD be assessed by using measured Kt/V and Cl_{cr} three times in the first 6 months of dialysis (i.e., at months 1, 4, and 6).⁶³ The reasoning behind this frequency is to accurately establish a baseline creatinine and urea excretion rate. Thereafter the Kt/V and Cl_{cr} should be measured every 4 months, at months 10, 14, and so on. The rationale for this is that it is imperative to detect subtle decreases in residual renal function and noncompliance and to make the necessary alterations to the prescribed PD dose to compensate for them. It is recommended that the first PET be conducted within the first month of treatment. Because solute clearance is dependent on peritoneal membrane transport properties, the guidelines also recommend that a PET be conducted within the first month of treatment. Future PET assessment is only recommended for patients with suspected changes in peritoneal membrane transport function, particularly when usual efforts to increase the PD dose are not successful.

It is important to note that residual renal function may provide a significant component of the total Kt/V and Cl_{cr} . Patients may commence PD with a residual $\text{Cl}_{\text{cr,renal}}$ of about 9 to 12 mL/min, which might equate to a Kt/V_{renal} of 0.2 to 0.4. Over a period of 1 to 2 years, residual renal function tends to progressively deteriorate to zero. Because Kt/V_{total} is the sum of Kt/V_{PD} and Kt/V_{renal} , the Kt/V_{total} will progressively diminish unless Kt/V_{PD} is increased (by increasing the prescribed dose of PD) to compensate for the reduced Kt/V_{renal} . Thus

unless Kt/V_{PD} is increased, Kt/V_{total} may diminish from 2 to 1.7 over this period of time.

This progressive loss of residual renal function is the major cause of decreased total clearance in PD patients over time. Unfortunately, the standard regimen of four 2-L exchanges per day in CAPD may provide inadequate clearances in some patients, especially larger patients. In larger patients, clearances might be maximized by adopting larger fill volumes (2.5 to 3 L), more frequent exchanges (5 to 6 per day), and the use of wet days in APD patients.⁶³ A wet day is a regimen that includes a prolonged dwell during the daytime, between the frequent automated nighttime exchanges.

COMPLICATIONS OF PERITONEAL DIALYSIS

Mechanical, medical, and infectious problems complicate peritoneal dialysis therapy. Mechanical complications include kinking of the catheter and inflow and outflow obstruction; excessive catheter motion at the exit site, leading to induration and possible infection and aggravation of tissues; pain from impingement of the catheter tip on the viscera; or inflow pain resulting from a jet effect of too rapid dialysate inflow.

Table 45–8 lists the numerous medical complications of PD. An average PD patient absorbs up to 60% of the dextrose in each exchange. This continuous supply of calories leads to increased adipose tissue deposition, decreased appetite, malnutrition, and altered requirements for insulin in diabetic patients. Fibrin formation in dialysate is common and can lead to obstruction of catheter outflow. Infectious complications of PD are a major cause of morbidity and mortality and are the leading cause of technique failure and transfer from PD to hemodialysis. The two predominant infectious complications are peritonitis and catheter-related infections, which include both exit-site and tunnel infections.

PERITONITIS

Some 40% to 60% of patients develop their first episode of peritonitis within 1 year of starting CAPD, although the incidence is significantly lower in APD patients.⁶⁹ Peritonitis is a major cause of catheter loss in PD patients. A statistically significant correlation between infectious complications and death rates has been reported.⁷⁰ Of patients who had more than 1 peritonitis episode per year, 0.5 to 1 episode per year, or less than 0.5 episode per year, 50% died after 3, 4, and

TABLE 45–8. Medical Complications of Peritoneal Dialysis

| Cause | Complication | Treatment |
|---------------------------|---|---|
| Glucose load | Exacerbation of diabetes mellitus | IP insulin |
| Fluid overload | Exacerbation of CHF Edema Pulmonary congestion | Increase ultrafiltration Diuretics, if the patient has residual renal function |
| Electrolyte abnormalities | Hyper- and hypocalcemia | Alter dialysate calcium content |
| PD additives | Chemical peritonitis | Discontinue PD additives |
| Malnutrition | Albumin loss Loss of amino acids Muscle wasting Increased adipose tissue | Dietary changes, parenteral nutrition, discontinue PD |
| Unknown | Fibrin formation in dialysate | IP heparin |

5 years of therapy, respectively. It is important to note that these relationships are not necessarily cause and effect, because many of these patients succumb to cardiovascular events. The incidence of peritonitis is influenced by connector technology, by the composition of patient populations, and by the use of APD versus CAPD. The incidence of peritonitis for most dialysis centers in the United States is about one episode every 24 patient-months, although it may be as low as one episode every 60 patient-months.⁷¹

CLINICAL PRESENTATION OF PERITONEAL DIALYSIS-RELATED PERITONITIS

GENERAL

Patients generally present with abdominal pain and cloudy effluent.

SYMPTOMS

The patient may complain of abdominal tenderness, abdominal pain, fever, nausea and vomiting, and chills.

SIGNS

Cloudy dialysate effluent may be observed following exchange.

Temperature may or may not be elevated.

LABORATORY TESTS

Dialysate white blood cell count $>100/\text{mm}^3$, of which at least 50% are polymorphonuclear neutrophils.

Gram stain of a centrifuged dialysate specimen.

OTHER DIAGNOSTIC TESTS

Culture and sensitivity of dialysate should be obtained.

Peritonitis has several imprecise definitions, but guidelines suggest that an elevated dialysate white blood cell (WBC) count of less than 100 per microliter with at least 50% polymorphonuclear neutrophils indicates the presence of inflammation, of which peritonitis is the most likely cause.⁷² A patient who presents with abdominal pain and a cloudy effluent is usually given a provisional diagnosis

of peritonitis. Inherent in this definition is a number of false-positive and false-negative diagnoses, because a small percentage of patients with culture-proven peritonitis will have clear dialysate, and some patients, such as menstruating females, may have cloudy PD effluent without clinical infection.⁷¹ Sterile culture peritonitis remains problematic; it is defined as an episode in which there is clinical suspicion of peritonitis, but for which the culture of the dialysate reveals no organisms. There are several postulates for the high incidence (up to 20% of episodes) of culture-negative peritonitis. Many peritonitis-producing organisms are slime producers and may adhere to the peritoneal membrane or to the catheter surface and be protected from exogenous antibiotics.⁷³ Sufficient numbers of these bacteria may proliferate to cause peritoneal membrane inflammation and clinical peritonitis, but an inadequate number may seed into the peritoneal cavity to be recovered by conventional microbiologic techniques. In addition, planktonic bacteria may be rapidly phagocytosed by peritoneal WBCs, thereby rendering them unavailable for culture.

Most of the organisms producing peritonitis adhere to the peritoneal membrane, with a relatively smaller number appearing as free-floating planktonic bacteria in dialysate. There may be as few as 10^4 planktonic organisms per milliliter of effluent. Removal of a small volume of dialysate from the bag may thus result in too few organisms to culture. Contemporary methods have increased the recovery rate of organisms and decreased the culture-negative rate. Centrifugation is currently recommended as the optimum culture method. Centrifugation of a large volume of dialysate (50 mL), resuspension of the sediment in 3 to 5 mL of sterile saline, and subsequent inoculation in culture media produces a culture-negative rate less than 5%. If centrifuge equipment is not available, blood culture bottles can be directly injected with 5 to 10 mL of dialysate effluent. However, this method results in a culture-negative rate up to 20%.⁷²

The majority of infections are caused by gram-positive bacteria in CAPD, of which *Staphylococcus epidermidis* is the predominant organism.⁷⁴ There is no single predominant gram-negative organism. Together, gram-positive and gram-negative organisms account for 80% to 90% of all episodes of peritonitis, and constitute the spectrum against which initial empiric therapy is directed. In APD, there is a relative increase in the percentage of infections caused by polymicrobial and fungal organisms.

► TREATMENT: Peritonitis

7 The International Society of Peritoneal Dialysis (ISPD) Ad Hoc Advisory Committee on Peritoneal Dialysis Related Infections evaluates the diagnostic and therapeutic literature periodically. The most recent report, published in 2005, provides guidelines for the diagnosis and pharmacotherapy of PD-associated infections.⁷² The 2005 ISPD guidelines reflect significant changes from the previous version and specifically address the increasing importance of dialysis center specific antibiotic selection, the effect of residual renal function on the pharmacokinetics of antibiotics, and updated recommendations regarding the use of aminoglycosides and vancomycin.

Intraperitoneal (IP) administration of antibiotics remains the preferred route over IV therapy. The guidelines provide dosing recommendations for intermittent (one large dose into one exchange per day) and continuous therapy (antibiotic addition to each exchange). In addition, dosing recommendations are modified on the basis of the patient's PD modality (CAPD or APD) and whether or not the patient has residual renal function (>100 mL/day urine output). The choice between intermittent and continuous therapies requires careful consideration for several reasons. The dialysate and serum concentra-

tions achieved after these regimens are very different. The pharmacokinetics of intermittent intraperitoneal ceftazidime and cefazolin are well described. Single daily doses of cefazolin and ceftazidime in CAPD are effective in achieving serum concentrations greater than the minimum inhibitory concentration for sensitive organisms over 48 hours. In CAPD, it is usual to add the single daily dose into the exchange with the longest dwell, to ensure maximal bioavailability. Intermittent (once-daily) IP dosing of antibiotics is recommended for CAPD patients with peritonitis.⁷² However, APD dosing strategies are different, because of the increased clearances of solutes in such systems. This appears to be particularly important for first-generation cephalosporins. The ISPD guidelines recommend continuous dosing of first generation cephalosporins due to concerns over inadequate IP drug concentration during the shorter APD dialysate dwells. With regard to residual renal function, in patients with daily urine output greater than 100 mL, the dose should be empirically increased by 25% for drugs that are renally eliminated. The ISPD dosing recommendations for IP antibiotics in CAPD and APD patients are shown in Tables 45-9 and 45-10, respectively.⁷²

TABLE 45–9. Intraperitoneal Antibiotic Dosing Recommendations for CAPD Patients⁷²

| Drug | Intermittent (per exchange, once daily) | Continuous (mg per liter, all exchanges) |
|---------------------------|--|---|
| Aminoglycosides | | |
| Amikacin* | 2 mg/kg | LD 25, MD 12 |
| Gentamicin* | 0.6 mg/kg | LD 8, MD 4 |
| Netilmicin* | 0.6 mg/kg | LD 8, MD 4 |
| Tobramycin* | 0.6 mg/kg | LD 8, MD 4 |
| Cephalosporins | | |
| Cefazolin* | 15 mg/kg | LD 500, MD 125 |
| Cefepime* | 1 g | LD 500, MD 125 |
| Cephalothin* | 15 mg/kg | LD 500, MD 125 |
| Cephadrine* | 15 mg/kg | LD 500, MD 125 |
| Ceftazidime* | 1000–1500 mg | LD 500, MD 125 |
| Ceftizoxime* | 1000 mg | LD 250, MD 125 |
| Penicillins | | |
| Azlocillin* | ND | LD 500, MD 250 |
| Ampicillin* | ND | MD125 |
| Oxacillin* | ND | MD125 |
| Nafcillin* | ND | MD125 |
| Amoxicillin* | ND | LD 250–500, MD 50 |
| Penicillin G* | ND | LD 50,000 units, MD 25,000 units |
| Quinolones | | |
| Ciprofloxacin* | ND | LD 50, MD 25 |
| Others | | |
| Vancomycin* | 15–30 mg/kg Q5-7d | LD 1000, MD 25 |
| Aztreonam* | ND | LD 1000, MD 250 |
| Antifungals | | |
| Amphotericin B | NA | 1.5 |
| Combinations | | |
| Ampicillin/sulbactam* | 2 g Q12h | LD 1000, MD 100 |
| Imipenem/cilastatin* | 1 g BID | LD 500, MD 200 |
| Quinupristin/dalfopristin | 25 mg/L in alternate bags** | |

LD, loading dose in mg; MD, maintenance dose in mg; NA, not applicable; ND, no data; NA, not applicable.

* Dosing of drugs with renal clearance in patients with residual renal function (defined as more than 100 mL/day urine output) dose should be empirically increased by 25%.

** Given in conjunction with 500 mg IV twice daily.

Initial empiric therapy for peritonitis, regardless of whether a Gram stain was performed or organisms were identified, should include agents effective against both gram-positive and gram-negative organisms. Antibiotic selection should be made with consideration given to the dialysis center's and the patient's history of infecting organisms and the antibiotic sensitivity profile of the organisms. In many cases, a first-generation cephalosporin such as cefazolin in combination with a second drug that provides broader gram-negative coverage, such as ceftazidime, cefepime, or an aminoglycoside, will prove suitable. Patients with documented allergy to cephalosporin

TABLE 45–10. Intermittent Intraperitoneal Antibiotic Dosing Recommendations for APD Patients⁷²

| Drug | Intraperitoneal Dose |
|-------------|--|
| Vancomycin | Loading dose 30 mg/kg IP in long dwell, repeat dosing 15 mg/kg IP in long dwell every 3–5 days, following levels |
| Tobramycin | Loading dose 1.5 mg/kg IP in long dwell, then 0.5 mg/kg IP each day in long day dwell |
| Fluconazole | 200 mg IP in one exchange per day every 24–48 h |
| Cefepime | 1 g IP in one exchange per day |

antibiotics can be treated with vancomycin and an aminoglycoside. High rates of methicillin resistance have been reported by many dialysis centers and vancomycin should be used as first-line therapy against gram-positive organisms for patients treated at these centers. Monotherapy with agents providing both gram-positive and gram-negative coverage is an alternative option. Both imipenem/cilastatin and cefepime have been found to be effective in treating CAPD related peritonitis.

After culture and sensitivity results are obtained, antibiotic therapy should be adjusted appropriately (Fig. 45–5). If the patient does not show signs of clinical improvement within 72 hours after antibiotic treatment is initiated, the culture should be repeated and the patient re-evaluated. For streptococcal or enterococcal peritonitis, IP ampicillin (125 mg/L in each exchange) is the preferred treatment. For *Enterococcus*, the addition of an aminoglycoside, depending on sensitivities, may be warranted for synergy. In addition, if the *Enterococcus* is resistant to both ampicillin and vancomycin, linezolid or quinupristin/dalfopristin are recommended. However, quinupristin/dalfopristin is not effective against *E. faecalis*.

The presence of *S. aureus* warrants the use of either cefazolin or vancomycin. If the strain of *S. aureus* is methicillin resistant, then vancomycin should be used. Oral rifampin can be added if there is an inadequate clinical response, defined as continued cloudy dialysate, abdominal pain, and elevated dialysate white blood cells.

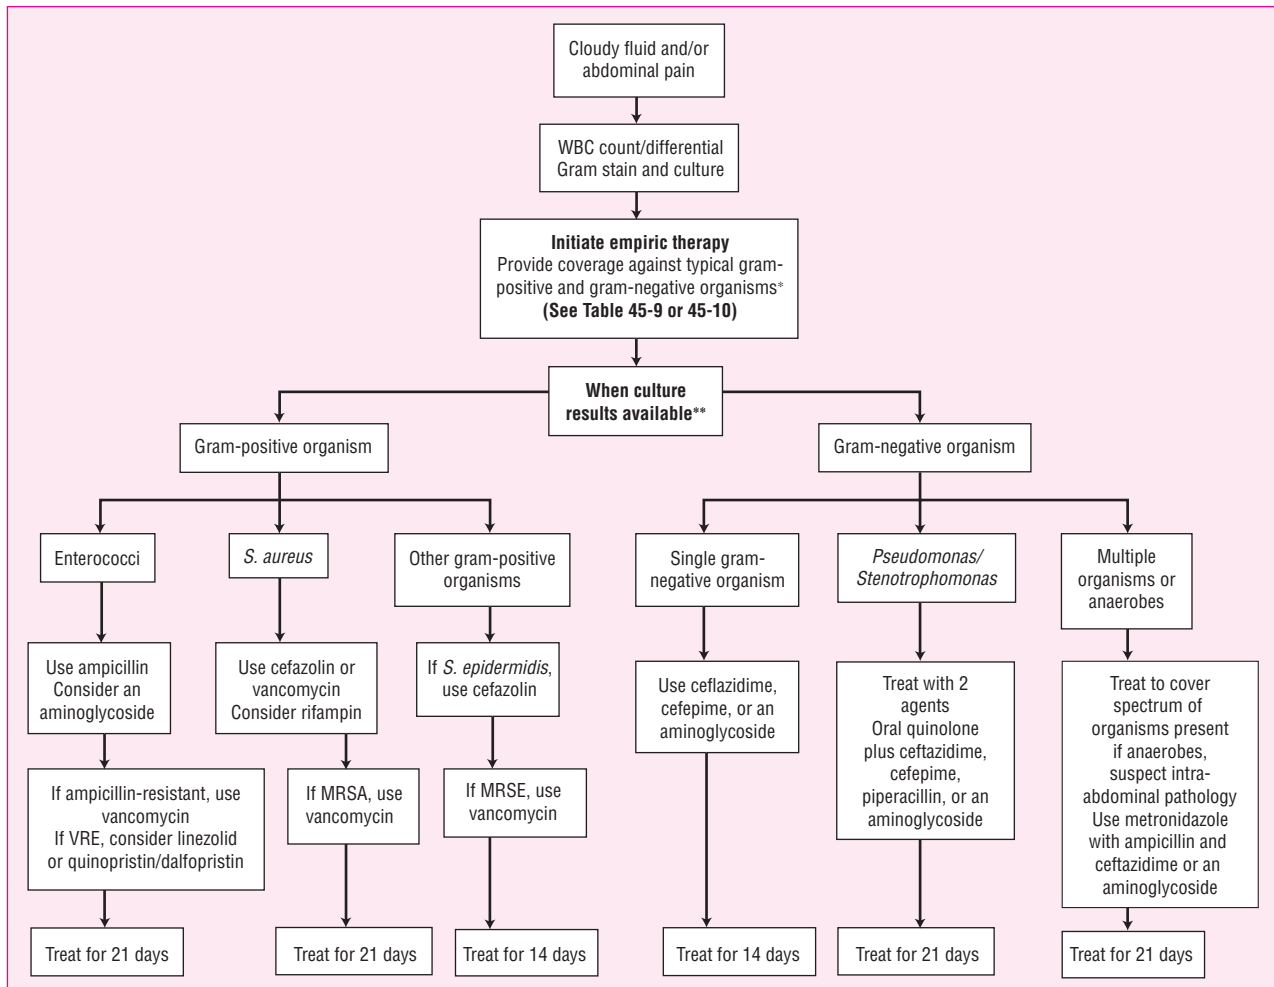

FIGURE 45-5. Pharmacotherapy recommendations for the treatment of bacterial peritonitis in PD patients.

* Choice of empiric treatment should be made based upon the dialysis center's and the patient's history of infecting organisms and their sensitivities.

** Final choice of therapy should always be guided by culture and sensitivity results.

Rifampin therapy should be limited to one week as resistance often develops with extended use. Infections with *S. aureus* or *Enterococcus* are usually more severe than other gram-positive peritonitis episodes and treatment should be continued for at least three weeks. If *S. aureus* peritonitis occurs as a result of an exit site or catheter infection with the same organism the catheter must be removed. Coagulase negative staphylococcus, especially *S. epidermidis*, is very commonly identified as the causative organism and can usually be treated by IP ceftazolin alone. However, *S. epidermidis* is often reported as methicillin-resistant, in which case vancomycin should be used. Treatment should be continued for at least one week after the effluent clears and for at least 14 days total. If a single gram-negative organism, such as *E. coli*, *Klebsiella*, or *Proteus*, is cultured, the antibiotic should be selected based on sensitivities, safety and convenience. Based on sensitivity testing, a cephalosporin, such as ceftazidime or cefepime, or an aminoglycoside may be indicated (see Fig. 45-5). However, isolation of *Pseudomonas* or *Stenotrophomonas* should dictate the use of two concurrent agents with activity against these organisms. For *P. aeruginosa* peritonitis, an oral quinolone can be used as one of the antibiotics. Other alternatives include ceftazidime, cefepime, piperacillin, or an aminoglycoside. If catheter

infection is believed to have caused *P. aeruginosa* peritonitis, the catheter should be removed. Infections with gram-negative organisms are usually severe and treatment should be continued for at least three weeks.

In polymicrobial peritonitis, where multiple organisms are identified, treatment is directed to cover the spectrum of organisms present. If multiple enteric organisms are found, particularly in association with anaerobic bacteria, there should be suspicion of intra-abdominal pathology. When the source is believed to be the intestines, therapy should include metronidazole in combination with ampicillin and ceftazidime or an aminoglycoside. Peritonitis due to multiple gram-positive organisms is more common and can be treated based on microbial sensitivities. Treatment should be continued for at least three weeks.⁷²

Fungal peritonitis is associated with a poor prognosis and high morbidity and mortality. One problem with prospective assessment of antifungal regimens is the infrequency with which these infections occur. This makes it difficult to design and implement comparative studies. Most literature about antifungal treatment is therefore retrospective or limited to reports of local experience.⁷⁵ As a result, the ISPD recommendations for treatment of fungal peritonitis are somewhat

vague and treatment should be based upon culture and sensitivity results. However, one area that has been clarified is the question as to whether the PD catheter should be removed. The ISPD recommendations are to remove the catheter immediately after identifying fungi. If the Gram stain indicates the presence of yeast, treatment may be initiated with amphotericin B and oral flucytosine. Once culture and sensitivity results are available, fluconazole, caspofungin, or voriconazole may replace amphotericin B. Treatment with these agents should be continued orally for an additional ten days after catheter removal.⁷² It remains unclear whether there is any benefit from fungal prophylaxis.⁷⁶ Recommendations are also provided for the treatment of mycobacterial, or tuberculous, peritonitis. While this infection is a rare complication, it can be difficult to diagnose, and treatment requires multiple drugs.

■ TOXICITY OF INTRAPERITONEAL DRUG THERAPY

Although the intraperitoneal administration of antibiotics offers a convenient and effective treatment alternative for PD-related peritonitis, potential toxicities should be considered. Chemical peritonitis is a potential toxicity associated with IP vancomycin therapy. A series of early reports of chemical peritonitis with vancomycin suggested that the problem may be brand-specific or associated with large doses (1 to 2 g). One prospective study suggested the incidence may be as high as 23% with IP doses of 1 g or more.⁷⁷ There may be a hypersensitivity component to the effect, yet patients exhibiting chemical peritonitis have received subsequent doses without adverse effects. The exact etiology of vancomycin-associated chemical peritonitis remains to be clarified. IP amphotericin B also causes pain and chemical peritonitis. However, since IV amphotericin B poorly penetrates into the peritoneal cavity the therapeutic options are limited.⁷²

The systemic toxicities of IP regimens remain unclear, but are likely similar to those associated with IV and oral antibiotic administration. Intermittent (once daily) IP dosing of drugs, such as aminoglycosides, may reduce the risk of systemic toxicity (ototoxicity and nephrotoxicity). In the prior ISPD guidelines (2000) there was a recommendation that routine use of aminoglycosides should be avoided in patients with significant residual renal function if other antibiotic choices are available.⁷¹ This was based on a study that showed rapid loss of residual renal function in PD patients treated with aminoglycosides.⁷⁸ However, a later study concluded that aminoglycosides do not accelerate the decline of residual renal function.⁷⁹ As a result the current ISPD guidelines state that there is not convincing evidence that short courses of aminoglycosides lead to loss of residual renal function. They also state that prolonged or repeated courses are probably not advisable if an alternative approach is possible.⁷² This latter controversial recommendation was based on the opinion of the committee.

CLINICAL CONTROVERSY

The ISPD guidelines for peritonitis treatment state that patients with significant residual renal function should not receive aminoglycosides if other antibiotic choices are available. Aminoglycosides were found to increase the rate of decline in residual renal function in one study. However, another study refuted this claim. It seems reasonable to withhold aminoglycosides if appropriate alternative antibiotics are available.

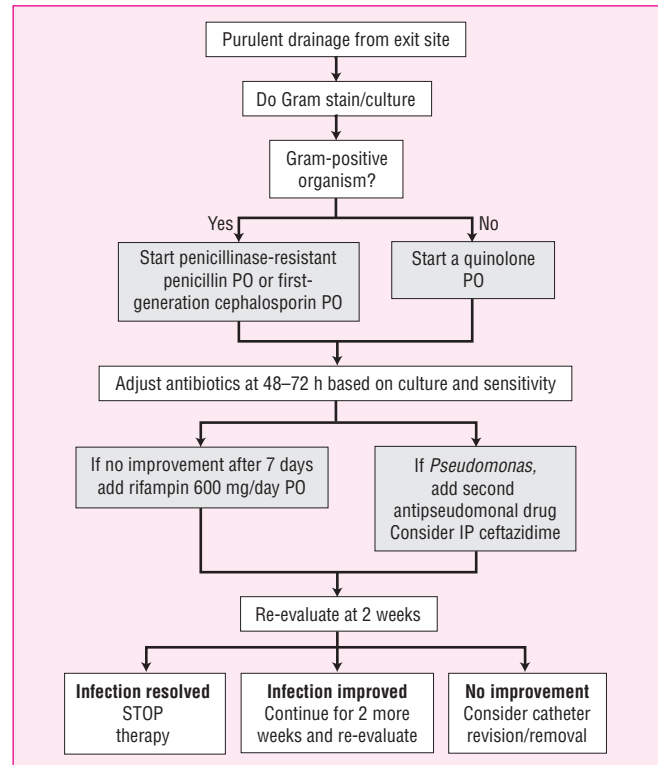

FIGURE 45-6. Management strategy of exit-site infections for peritoneal dialysis patients.

■ CATHETER-RELATED INFECTIONS

PD patients experience exit-site infections with an approximate incidence of one episode every 24 to 48 months. Patients with previous infections tend to have a higher incidence. The majority of exit-site infections are caused by *S. aureus*. In contrast to peritonitis, *S. epidermidis* accounts for less than 20% of exit-site infections. Although gram-negative organisms, such as *Pseudomonas*, are less common, they can result in significant morbidity.⁷⁴ The diagnostic characteristics of these infections are somewhat vague but generally include the presence of purulent drainage, with or without erythema at the catheter exit site. The risk of exit-site infections is increased several-fold in patients who are nasal carriers of *S. aureus*.⁷² The use of topical antibiotics and disinfectants to treat catheter-related infections is controversial and there are few adequately controlled studies to determine the effectiveness of topical antibiotics.^{80,81} Current recommendations suggest that gram-positive organisms should be treated with an oral penicillinase-resistant penicillin or first-generation cephalosporin, such as cephalexin (Fig. 45-6). Rifampin may be added if necessary, in slowly resolving or particularly severe appearing *S. aureus* infections. Vancomycin should be avoided in routine or empiric treatment of gram-positive catheter-related infections, but will be necessary for MRSA. Gram-negative organisms should be treated with oral quinolones. The effectiveness of oral quinolones may be diminished owing to the chelation drug interactions with divalent and trivalent metal ions, which are commonly taken by dialysis patients. Administration of quinolones should occur at least 2 hours prior to these drugs. In cases where *P. aeruginosa* is the pathogen, a second antipseudomonal drug should be added. IP ceftazidime may be considered.

In all cases antibiotics should be continued until the exit site appears normal and 2 to 3 weeks of therapy may be necessary. A patient with

a catheter-related infection that progresses to peritonitis will usually require catheter removal.⁷²

► TREATMENT: Prophylaxis of Peritonitis and Catheter-Related Infections

8 Attempts to prevent peritonitis and catheter-related infections have included refinement of connector system technology and the use of prophylactic antibiotic regimens and vaccines. Several studies have examined the impact of antibacterial agents as prophylaxis against both peritonitis and tunnel-related infections. Intermittent rifampin, 300 mg orally twice a day for 5 days, repeated every 3 months, appears to decrease the number of catheter-related infections, but not peritonitis. The efficacy of other antibiotic prophylaxis for peritonitis and catheter-related infections is limited. Long-term, extended-duration prophylaxis with penicillins or cephalosporins has not been shown to be effective.⁷¹

Nasal carriage of *S. aureus* is associated with an increased risk of catheter-related infections and peritonitis. In addition, diabetic patients and those on immunosuppressive therapy are at increased risk for *S. aureus* catheter infections. Prophylaxis with intranasal mupirocin (twice a day for 5 days every month), mupirocin (daily) at the exit site, or oral rifampin can effectively reduce *S. aureus* exit-site infections. Because of the minimal toxicity of mupirocin and the risk of rifampin resistance, mupirocin regimens are preferred.^{71,72} However, it is important to note that *S. aureus* isolates with a high degree of resistance to mupirocin have been isolated from PD patients using prophylactic mupirocin at the peritoneal catheter exit site.⁸² In addition, gentamicin cream applied daily to the exit site has been found to effectively reduce the incidence of both *S. aureus* and *P. aeruginosa* exit-site infection.⁷²

■ PHARMACOKINETICS OF INTRAPERITONEAL DRUG THERAPY

The pharmacokinetics of intraperitoneal drug therapy have become more clearly defined in recent years.^{83,84} Drugs may be added to dialysate to produce a local effect with limited systemic absorption. Alternatively, high systemic bioavailability may be desired for a systemic effect, or to ensure there is an adequate systemic reservoir, which would produce appropriate dialysate concentrations in subsequent drug-free exchanges (as with intermittent IP antibiotics). The primary pharmacokinetic factor that influences the bidirectional transfer of drugs is the magnitude of the ratio of systemic volume of distribution compared to the dialysate volume. The greater the ratio of the systemic volume to dialysate volume, the more readily a drug molecule will pass into the systemic circulation from the dialysate under the influence of a large concentration gradient. Conversely, drugs will more readily pass from the blood into the dialysate if the ratio of the systemic volume to the dialysate volume is small. Thus drug regimens can be manipulated depending on whether one desires adequate clearance from dialysate into blood, or into dialysate from blood.

Over the past decade, sound pharmacokinetic information has become available for a number of drugs in CAPD patients, and to a lesser extent for APD. Significant systemic bioavailability has been reported for some agents. In addition to their local effects for the management of peritonitis, as a result of their excellent systemic bioavailability, intraperitoneal antibiotics can be used to treat systemic infections.⁸⁵ Potential benefits of the intraperitoneal versus in-

travenous route for the management of systemic infections include use of an already existing access for administration, ability to treat infections on an outpatient basis, avoidance of costs for intravenous lines, possible avoidance of intravenous drug-related toxicities (such as thrombophlebitis and possibly redneck syndrome), and improved patient acceptance. The pharmacoeconomics of this strategy, however, remain to be carefully studied and reported.

■ OTHER INTRAPERITONEAL DRUG THERAPY

Possible advantages of intraperitoneal versus subcutaneous insulin include the avoidance of erratic absorption (both rate and extent of absorption), convenience, avoidance of subcutaneous injection site-related complications, and prevention of peripheral hyperinsulinemia.⁸⁶ Insulin appears to be cleared into the systemic compartment by an active transport process, or via the peritoneal lymphatics. A number of studies have demonstrated the bioavailability of intraperitoneal insulin to be about 25% to 30%, although none clearly compares the clinical effectiveness of intraperitoneal versus subcutaneous insulin in diabetes control. Insulin requirements for PD patients may be greater than in hemodialysis patients because of the continued absorption of dextrose from the peritoneal cavity. Furthermore, because of adsorption of insulin to the polyvinyl chloride bag and administration set, the intraperitoneal dose of insulin often needs to be two to three times the subcutaneous maintenance dose.

Many PD patients secrete large quantities of fibrinogen into the peritoneal cavity, which results in fibrin formation. This can lead to intraperitoneal adhesions and outflow obstruction. Intraperitoneal heparin may prevent this complication as a result of its local antifibrin effect.⁸⁷ Because standard heparin has a molecular weight of 12,000 to 15,000 daltons, it is minimally absorbed and thereby has limited systemic effects. The absorption of intraperitoneal erythropoietin has also been studied. Its bioavailability is low, but may be increased when added into a dry peritoneum.⁸⁸

■ STABILITY OF INTRAPERITONEAL ADDITIVES

There have been relatively few stability studies of drug additives to peritoneal dialysate, and the majority of those completed have been for antibiotics in dextrose-containing PD solutions.⁸⁹ In dextrose solutions, most antibiotic additives appear to be stable (usually defined as retaining at least 90% of initial activity) for about 1 week if refrigerated or 1 to 2 days at room temperature. There are fewer data available regarding drug stability in icodextrin solutions. It is important to note that some studies may not be indicative of stability (i.e., they may assay total concentration of an agent, some of which may be from parent-drug degradation products and which may not therefore maintain the same degree of pharmacologic activity). Thus appropriate studies would be those that also determine the concentrations of known degradation products. Clinicians must recall that chemical stability does not imply microbiologic sterility.

CONCLUSION

Dialysis (HD and PD) remains the most widely available and commonly used means of chronic renal replacement therapy. Despite continual advances in dialysis and transplantation, kidney failure is associated with significant morbidity and mortality. Both HD and PD are associated with complications and are burdensome to affected patients. Given the lack of a true cure for kidney failure, emphasis has recently been placed on the prevention and early detection of kidney disease.¹⁰ In light of the persistent increase in the incidence of ESKD, this approach deserves much effort and should remain a priority for the foreseeable future.

For patients with ESKD, a focus on quality of life and rehabilitation may be a valuable and viable goal toward which the nephrology community should direct its research resources. Efforts to improve the care given to dialysis patients have been admirable, but much remains to be done. The K/DOQI continues to update existing clinical practice guidelines and persists in developing additional guidelines for the treatment of other dialysis-associated disease states. Many of these guidelines offer definitive statements, such as target values for Kt/V , hemoglobin, or serum albumin levels. However, other recommendations remain rather vague. For example, it is suggested that patient quality of life and pediatric growth and development be measured, but no specific goals are cited. This is because of the lack of published literature that might indicate an appropriate goal. Given these circumstances, clinicians are not only encouraged to implement current clinical practice guidelines, but also to become involved in efforts to develop and assess alternative treatment strategies. The ultimate goal of these endeavors is to improve the care that dialysis patients receive.

ABBREVIATIONS

ADEMEX: Adequacy of Peritoneal Dialysis in Mexico (study)
 APD: automated peritoneal dialysis
 AV: arteriovenous
 BUN: blood urea nitrogen

DRUG-INDUCED KIDNEY DISEASE

Thomas D. Nolin, Jonathan Himmelfarb, and Gary R. Matzke

Learning Objectives and other resources can be found at www.pharmacotherapyonline.com.

KEY CONCEPTS

- 1 The initial diagnosis of drug-induced kidney disease typically involves detection of elevated serum creatinine and blood urea nitrogen, for which there is a temporal relationship between the toxicity and use of a potentially nephrotoxic drug.
- 2 Mechanisms of drug-induced kidney disease include immune-mediated toxicities (e.g., glomerulonephritis and allergic interstitial nephritis) and nonimmunologic-mediated toxicities which effect specialized characteristics of normal renal physiology.
- 3 Drug-induced kidney disease is best prevented by avoiding the use of potentially nephrotoxic agents in patients at increased risk for toxicity. However, when exposure to these drugs cannot be avoided, recognition of risk factors and specific techniques such as hydration may be used to reduce potential nephrotoxicity.
- 4 Acute tubular necrosis is the most common presentation of drug-induced kidney disease in hospitalized patients. The primary agents implicated are aminoglycosides, radiocontrast media, cisplatin, amphotericin B, foscarnet, and osmotically active agents.
- 5 Angiotensin-converting enzyme inhibitors and nonsteroidal anti-inflammatory drugs are associated with hemodynamically-mediated renal failure, the pathogenesis of which is a decrease in glomerular capillary hydrostatic pressure.
- 6 Acute allergic interstitial nephritis is the underlying cause for up to 3% of all cases of acute renal failure. Clinical manifestations of AIN typically present about 14 days after initiation of therapy and include fever, maculopapular rash, eosinophilia, pyuria, hematuria, proteinuria, and oliguria.

1 Drug-induced kidney disease or nephrotoxicity (DIN) is a relatively common complication of several diagnostic and therapeutic agents. It is seen in both inpatient and outpatient settings with variable presentations depending on the drug and clinical setting. Manifestations of DIN include acid-base abnormalities, electrolyte imbalances, urine sediment abnormalities, proteinuria, pyuria, and/or hematuria. However, the most common manifestation of DIN is a decline in the glomerular filtration rate (GFR), which results in a rise in the serum creatinine (S_{cr}) and blood urea nitrogen (BUN). Thus initial diagnosis of DIN typically involves detection of elevated S_{cr} and BUN, for which there is a temporal relationship between the toxicity and use of a potentially nephrotoxic drug. This is consistent with the qualitative definition of acute renal failure (ARF) or an “abrupt and sustained decrease in glomerular filtration, urine output, or both.”¹ Unfortunately, numerous quantitative definitions of DIN and/or ARF based primarily on changes in the serum creatinine concentration have been published.^{1,2} Thus it is difficult to ascertain the true incidence of DIN for any drug. As a result, broad ranges of incidence have been reported in various studies of the same agent. DIN is often reversible on discontinuation of the offending agent, but may also lead to acute and/or end-stage renal failure (see Chaps. 42 and 44). Many different mechanisms are involved in the pathogenesis of DIN. The development of drugs with novel mechanisms of action provides the potential for the presentation and identification of new unique nephropathies. This chapter reviews the epidemiology, pathophysiology, risk factors, and basic principles of prevention of drug-induced nephrotoxicity. Detailed discussions of these issues plus management strategies are

presented for widely used agents that have been associated with a moderate to high likelihood of DIN.

EPIDEMIOLOGY

Drug-induced nephrotoxicity occurs in all settings in which drugs are ingested or administered. It is a significant source of morbidity and mortality in the acute care hospital setting. DIN accounts for nearly 7% of all drug toxicity and from 18% to 27% of all cases of acute renal failure in hospitals.^{3–5} Overall, in-hospital drug use may contribute to 35% of all cases of acute tubular necrosis (ATN), most cases of allergic interstitial nephritis (AIN), as well as to nephropathy due to alterations in renal hemodynamics and postrenal obstruction.⁶ Aminoglycoside antibiotics, radiocontrast media, nonsteroidal anti-inflammatory drugs (NSAIDs), amphotericin B, and angiotensin-converting enzyme inhibitors (ACEIs) are frequently implicated.⁵ Computer-guided medication dosing for hospital inpatients may improve the safety of potentially harmful drugs and minimize the occurrence of DIN in this setting.⁷

The incidence and characteristics of outpatient or community-acquired DIN are less well understood since mild toxicity is often unrecognized. However, the pharmacoepidemiology of these effects has become more important as care increasingly shifts to the outpatient setting. Although as many as 3% to 6% of hospital admissions have been attributed to adverse drug effects during outpatient therapy,⁸ 20% of hospital admissions due to acute renal failure have been attributed

specifically to community-acquired DIN.⁹ NSAID nephrotoxicity is common and well defined, with between 1% and 5% of NSAID users developing nephrotoxicity.¹⁰ Prescribed and over-the-counter (OTC) NSAID therapy has been associated with a fourfold-increased risk of hospitalization for acute renal failure during the first month of therapy.¹¹ Since more than 50 million people use NSAIDs in the United States, it is not surprising that 500,000 to 2.5 million people likely develop NSAID nephrotoxicity in this country annually.¹⁰

ASSESSMENT OF KIDNEY TOXICITY

Since the most common manifestation of DIN is a decline in the GFR leading to a rise in the S_{cr} and BUN, the onset of toxicity in hospitalized acutely ill patients is most often recognized by routine laboratory monitoring of the two chemistries. Decreased urine output may also be an early sign of toxicity, particularly with radiographic contrast media, NSAIDs, and ACEIs. In the outpatient setting, nephrotoxicity is often recognized by symptoms such as malaise, anorexia, vomiting, volume overload (shortness of breath or edema) or hypertension. Serum creatinine or BUN concentrations and urine collection for creatinine clearance may subsequently be measured to quantify the degree of loss of glomerular filtration. Marked intrasubject between-day variability of S_{cr} values has been noted ($\pm 20\%$ for values within the normal range; see Chap. 41). Furthermore, they may be altered as the result of dietary changes and initiation of drug therapy, which may interfere with the assay procedure. Thus a change in S_{cr} of at least 0.5 mg/dL for subjects with a baseline $S_{cr} < 2$ mg/dL and an increase of about 30% for those with $S_{cr} > 2$ mg/dL, when correlated temporally with the initiation of drug therapy is a common threshold for the identification of DIN.^{2,5}

Nephrotoxicity may be evidenced by alterations in renal tubular function without loss of glomerular filtration. Indicators of proximal tubular injury include metabolic acidosis with bicarbonaturia; glycosuria in the absence of hyperglycemia; and reductions in serum phosphate, uric acid, potassium, and magnesium due to increased urinary losses. Indicators of distal tubular injury include polyuria from failure to maximally concentrate urine, metabolic acidosis from impaired urinary acidification, and hyperkalemia from impaired potassium excretion. Urinary enzymes and low-molecular-weight proteins are also used as early markers of nephrotoxicity. For example, urinary excretion of the enzymes *N*-acetyl- β D-glucosaminidase, γ -glutamyl transpeptidase and glutathione *S*-transferase are markers of proximal tubular injury and have been used for the early detection of acute kidney damage in critically ill patients.¹² The transmembrane protein kidney injury molecule-1 (KIM-1) is expressed in the proximal tubule and is upregulated in patients with ischemic acute tubular necrosis, appearing in the urine within 12 hours after the ischemic insult. High urinary excretion of KIM-1 is associated with a greater than 12-fold increase in the likelihood of ATN.¹³ In the future, novel biomarkers such as KIM-1 may facilitate the earlier diagnosis of nephrotoxicity and minimize the long-term consequences of this common drug-induced disorder.

PATHOPHYSIOLOGIC MECHANISMS OF NEPHROTOXIC SUSCEPTIBILITY

2 The kidneys are more sensitive than many other organs to drug toxicity. Immune-mediated, drug-induced nephrotoxicities include glomerulonephritis and allergic interstitial nephritis, either with or without nephrotic syndrome. The kidney is highly susceptible in part because of its large vascular surface area for exposure to circu-

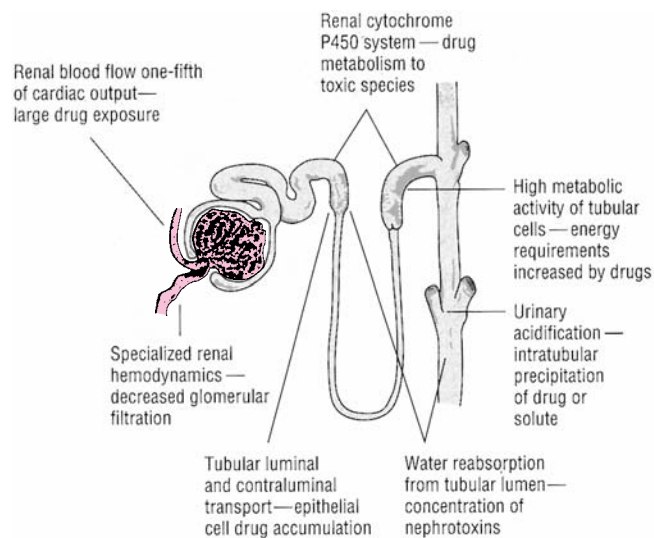

FIGURE 46–1. Mechanisms of renal susceptibility to drug toxicity. See text for discussion.

lating immune mediators and intrinsic immune function of glomerular mesangial cells and renal cytokine activation. Nonimmunologic mechanisms of DIN relate to several specialized characteristics of normal renal physiology, including regulation of blood flow, intrarenal drug metabolism, tubular transport processes, and urine concentration and acidification abilities (Fig. 46–1).

AUTOREGULATION OF RENAL BLOOD FLOW

The kidneys constitute only 0.4% of body weight, but receive 20% to 25% of resting cardiac output. This enhances the kidney's exposure to circulating drugs. Within each nephron, blood flow and pressure are regulated by glomerular afferent and efferent arterioles to maintain capillary hydrostatic pressure and glomerular filtration (Fig. 46–2). This specialized blood flow is precisely regulated by interrelations between arachidonic acid metabolites, natriuretic factors, nitric oxide, the sympathetic nervous system, the renin-angiotensin system, and the macula densa response to distal tubular solute delivery. In this unique vascular setting NSAIDs may reduce total renal blood flow,¹⁰ radiographic contrast media may shunt intrarenal blood flow to the cortex and promote medullary ischemia,¹⁴ osmotic diuresis secondary to mannitol therapy may reduce glomerular blood flow due to tubuloglomerular feedback,¹⁵ and ACEIs dilate glomerular efferent arterioles and result in a decrease in glomerular filtration pressure.¹⁶ Finally, dietary salt restriction can activate neurohumoral renal hemodynamic control systems that increase renal susceptibility to these drug nephrotoxicities.¹⁷

INTRARENAL DRUG METABOLISM

Multiple renal enzymes, including cytochrome P450 (CYP 450), UDP-glucuronyltransferase, and aldehyde dehydrogenase (ALDH) metabolize drugs and either protect the kidney from toxic insults or promote toxicity by transforming a drug to a nephrotoxic metabolite.¹⁸ For instance, the chemotherapeutic agent ifosfamide undergoes hepatic metabolism to form the metabolite chloroacetaldehyde, thought to be responsible for the dose-limiting nephrotoxicity of ifosfamide observed in some patients.¹⁹ Subsequent biotransformation and detoxification of chloroacetaldehyde via ALDH present in the renal tubules appears to play an important role in the

FIGURE 46–2. Normal glomerular autoregulation serves to maintain intraglomerular capillary hydrostatic pressure, glomerular filtration rate (GFR), and ultimately, urine output. This is accomplished by modulation of afferent and efferent arterioles. Afferent and efferent arteriolar vasoconstriction are primarily mediated by angiotensin II, whereas afferent vasodilation is primarily mediated by prostaglandins.

prevention of ifosfamide-induced nephrotoxicity. In contrast, oxidative metabolism of the chemotherapeutic agent cisplatin via CYP 2E1 located in the proximal tubule leads to the development of reactive oxygen intermediates which are responsible for cisplatin-induced nephrotoxicity.²⁰

TUBULAR TRANSPORT PROCESSES

Tubular transport systems within the kidney, including the organic cation transporter 1 (OCT1), organic anion transporter 1 (OAT1), and P-glycoprotein (P-gp), play a vital role in the elimination of drugs and their metabolites from the body.^{21–23} Proximal tubule cells are the primary site of active carrier-mediated transport of organic ions from blood to urine.²³ The concentration of drugs in the proximal tubule can thus be severalfold higher than systemic concentrations, resulting in local cytotoxicity that can eventually manifest as clinical nephrotoxicity. OAT1 has been implicated in the cellular uptake, accumulation, and nephrotoxicity of the acyclic nucleotide antivirals adefovir and cidofovir,²⁴ and some cephalosporin antibiotics.²⁵ Administration of OAT1 inhibitors such as probenecid markedly reduced cytotoxicity induced by these agents. Conversely, P-gp has been called the molecular “vacuum cleaner” due to the varied substrates it is known to pump out of cells, including anticancer agents, calcium channel blockers, steroids, digoxin, cyclosporine, and tacrolimus.^{21,26} Unlike OCT1 and OAT1, overexpression of P-gp in the renal tubular cells has been shown to prevent nephrotoxicity induced by cyclosporine, and inhibition of the protein leads to toxicity.²¹ Elevated intracellular drug concentrations may cause cytotoxicity as the result of impairment of mitochondrial function and decreased adenosine triphosphate synthesis, increased oxidative stress, depletion of reduced glutathione and other antioxidants, inhibition of phospholipid metabolism, or disruption of protein synthesis. Aminoglycosides, cyclosporine, and cisplatin appear to mediate nephrotoxicity by increasing the formation of superoxide ion and hydrogen peroxide, which in the presence of iron may subsequently generate hydroxyl radical, a reactive oxygen species that contributes to cellular oxidative stress and nephrotoxicity.²⁷

CONCENTRATION OF SOLUTE IN THE TUBULAR LUMEN

Ninety-nine percent of the water filtered by the glomerulus is reabsorbed. Normally, 50% to 85% of water reabsorption occurs in the proximal tubule, while the remainder occurs in the descending loop

of Henle and collecting duct. Systemic volume depletion increases the degree of water reabsorption in the proximal tubule. As water reabsorption increases, the concentration of drugs increase within the tubular lumen. Thus the luminal surfaces of cells, particularly in the proximal tubule, can be exposed to higher concentrations of potential toxins and for a longer time than most other tissues in the body. This enhances binding of drugs to tubular epithelial cells and promotes active and passive transport into cells. The enhancement of aminoglycoside nephrotoxicity by systemic volume depletion is an example.²⁸

HIGH ENERGY REQUIREMENTS

Renal tubular epithelial cells have high energy requirements because of active tubular transport and metabolic processes. These high energy needs are precariously supplied to medullary tubular epithelial cells, which function in a state of chronic hypoxia due to their perfusion with venous blood returning from the deep medulla. As a consequence these medullary tubular epithelial cells are especially sensitive to drugs that increase energy demands or decrease oxygen delivery, which can result in ischemic cell death. Amphotericin B–induced medullary tubular cell damage appears to result from an imbalance between increased cellular energy requirements and inadequate oxygen delivery.²⁹

URINE ACIDIFICATION

Urine pH decreases to approximately 4.5 during maximal stimulation of renal tubular hydrogen ion secretion. Certain solutes can precipitate and obstruct the tubular lumen at this acid pH, particularly when urine is concentrated. For example, in the presence of a maximally acidic urine, intratubular precipitation of methotrexate may occur and result in acute renal failure.³⁰

SUSCEPTIBLE PATIENT POPULATIONS

CHRONIC KIDNEY DISEASE

Chronic kidney disease develops as the result of injury to involved glomerular and tubular units while others remain relatively intact. The remaining functional nephron units develop hyperfiltering glomeruli and hyperfunctioning tubules to compensate for the damaged nephrons. These residual nephrons are more susceptible to nephrotoxic injury due to their increased energy requirements and

exposure to elevated concentrations of drugs. The nephrotoxicity of radiographic contrast media in patients with chronic kidney disease is such an example.³¹

ELDERLY

Renal blood flow and GFR decline progressively with age. Progressive sclerosis of glomeruli occurs, and residual glomerular and tubular units increase function in compensation, similarly to patients with chronic kidney disease. This decline in renal function is not accompanied by a rise in the serum creatinine concentration due to the age-related decline in muscle mass and decreased creatinine generation. Older individuals are also more likely to have heart failure and hepatic insufficiency, which also reduce renal blood flow. Together, these processes predispose the elderly to an increased risk of nephrotoxicity.³²

PRINCIPLES FOR PREVENTION OF DRUG NEPHROPATHY

3 The primary principle for prevention of drug-induced nephrotoxicity is to avoid the use of potentially nephrotoxic agents in patients at increased risk for toxicity. However, when exposure to these drugs cannot be avoided, recognition of risk factors and specific techniques may be used to reduce potential nephrotoxicity. No generalizable risk factors are applicable to all drug classes and patient situations, since drug toxicity develops as a result of a wide range of mechanisms, from idiosyncratic hypersensitivity reactions to direct cellular toxicity. An exception is hemodynamically-mediated acute renal failure due to NSAIDs and ACEIs. Their toxicity is frequently preventable by recognizing pre-existing renal insufficiency and decreased effective renal blood flow due to volume depletion, heart failure, or liver disease.¹⁶ Elderly patients with hypertension or heart failure may be especially sensitive to the combined use of ACEIs and NSAIDs, particularly with concurrent diuretic use.

Certain approaches to reduce drug toxicity are prudent and generally effective, for example, careful and adequate hydration to establish high renal tubular urine flow rates. However, other strategies to reduce drug toxicity are still theoretical and/or investigational and relate directly to the nephrotoxic mechanisms of the drug. For example, adefovir is a nucleotide antiviral that is actively transported by OAT1.²⁴ Inhibition of OAT1-mediated transport with NSAIDs minimizes accumulation of adefovir in renal proximal tubule cells and results in a reduction in toxicity.³³ Diflunisal, ketoprofen, flurbiprofen, indomethacin, naproxen, and ibuprofen were at least as effective as probenecid, a known potent inhibitor of OAT1, at preventing cytotoxicity. Antioxidants have also been shown to be protective in gentamicin-, cyclosporine-, and cisplatin-induced nephrotoxicity in experimental models.²⁷ Iron chelators are also protective against gentamicin toxicity.

Specific drug-induced renal structural–functional alterations constitute the remainder of this discussion under the seven broad headings listed in Table 46–1. The general orientation of these topics is in order of decreasing clinical incidence. Pathophysiologic mechanisms of nephrotoxicity will be emphasized, in addition to clinical findings, prevention, and management.

TUBULAR EPITHELIAL CELL DAMAGE

4 Renal tubular epithelial cell damage may be caused by either direct toxic or ischemic effects of drugs. Damage localizes in

the proximal and distal tubular epithelia. This may be seen as cellular degeneration and sloughing from proximal and distal tubular basement membranes in acute tubular necrosis (ATN) or swelling and vacuolization of proximal tubular cells in osmotic nephrosis. ATN is the most common presentation of DIN in the inpatient setting. The primary agents implicated in renal tubular epithelial cell damage are aminoglycosides, radiocontrast media, cisplatin, amphotericin B, foscarnet, and osmotically-active agents such as immunoglobulins, dextrans, and mannitol.^{4,34}

ACUTE TUBULAR NECROSIS

AMINOGLYCOSIDE NEPHROTOXICITY

Incidence

Nephrotoxicity has been reported in 1.7% to 58% of patients receiving aminoglycoside therapy. The large variance is in part due to the use of different definitions of toxicity, variability between agents in the class, as well as the risk factors in the study population.³⁵ The management of nephrotoxicity, a major contributor to the total cost of aminoglycoside therapy, was estimated to be over \$4500 per case in the late 1990s.

Clinical Presentation

A gradual rise in the serum creatinine concentration and decrease in creatinine clearance after 6 to 10 days of therapy are the initial clinical manifestations of toxicity. Increased renal tubular proteinuria (β_2 -microglobulin) and brush border enzymuria precede the creatinine rise by several days, but are not usually detected clinically.²⁸ Patients typically present with nonoliguria, maintaining urine volumes greater than 500 mL/day. Renal magnesium and potassium wasting can occur. Renal failure is usually mild if aminoglycoside therapy is stopped, but may be severe and require dialysis therapy. Aminoglycoside-associated nephropathy must be evaluated carefully since not all renal failure during a course of therapy is due to the aminoglycoside. Dehydration, sepsis, ischemia, and other nephrotoxic drugs frequently contribute.

Pathogenesis

The pathogenesis of reduced GFR in patients receiving aminoglycosides is predominantly the result of proximal tubular epithelial cell damage leading to obstruction of the tubular lumen and backleakage of the glomerular filtrate across the damaged tubular epithelium.³⁶ The toxicity of various aminoglycosides is related to cationic charge, which facilitates binding of filtered aminoglycosides to renal tubular epithelial cell luminal membranes. For instance, neomycin has six cationic amino groups and is the most nephrotoxic aminoglycoside, whereas streptomycin, with three groups, is least toxic. Gentamicin and tobramycin, with five amino groups, have similar and intermediate toxicity, whereas amikacin and netilmicin, with four and three amino groups, respectively, may be less toxic. Binding to tubular epithelial cells is followed by intracellular transport and concentration in lysosomes. Subsequent binding to acidic phospholipids (phosphatidylinositol) causes their aggregation and inhibits phospholipase activity.^{28,36} This presents histopathologically as myeloid bodies within lysosomes of renal tubular epithelial cells. Cellular dysfunction and death may result from release of lysosomal enzymes into the cytosol, generation of reactive oxygen species, altered cellular metabolism, and alterations in cell membrane fluidity, leading to reduced activity of membrane-bound enzymes, including Na^+/K^+ -ATPase, dipeptidyl peptidase IV, and neutral aminopeptidase.²⁸ Although binding of aminoglycosides to tubular epithelial cells is facilitated by the number of cationic groups present, inherent risks of toxicity are also a factor.

Risk Factors

Multiple risk factors for aminoglycoside nephrotoxicity have been identified. These relate to aminoglycoside dosing, synergistic toxicity in combination with other drugs, and predisposing conditions in the patient (Table 46–2). These risk factors have been consistently identified in all investigations and the reader is referred to in-depth reviews on this issue.^{28,36}

Prevention

The prevention of aminoglycoside-induced nephrotoxicity has received considerable attention in recent years. Alternative antibiotics should be used whenever possible and as soon as microbial sensitivities are known. Commonly used alternatives include fluoroquinolones (e.g., ciprofloxacin or levofloxacin) and third-generation cephalosporins (e.g., ceftazidime). When aminoglycosides are necessary, the specific drug used does not appear to significantly affect the risk of nephrotoxicity, and therapy should be selected to optimize antimicrobial efficacy. Furthermore, it is imperative to avoid volume depletion, limit the total aminoglycoside dose administered, and avoid concomitant therapy with other nephrotoxic drugs.

TABLE 46–2. Potential Risk Factors for Aminoglycoside Nephrotoxicity

| Obstructive jaundice |
| Dehydration |
| Potassium or magnesium deficiencies |

Prospective, individualized pharmacokinetic monitoring has been used for over 25 years. Although many have reported a decrease in the incidence of aminoglycoside-induced nephrotoxicity, the studies are often small and statistically underpowered. Recently Streetman and associates estimated that pharmacokinetic monitoring decreased costs associated with aminoglycoside nephrotoxicity by over \$900 per patient.³⁷ High intermittent dosing of aminoglycosides, often called “once-daily dosing,” used in combination with other antibiotics, has been intensively investigated as a practical cost-effective method to maintain antimicrobial efficacy while potentially reducing nephrotoxicity, and vestibular and ototoxicity.^{28,38} Historically, high 1-hour postdose concentrations such as those obtained during once-daily dosing were thought to contribute to the renal and auditory toxicity. Recent data suggest otherwise, and in fact even calls into question the utility of monitoring peak concentrations.^{38,39} Nephrotoxicity may be reduced since proximal tubular aminoglycoside uptake appears to be limited during the transient, high-peak serum concentrations due to saturation of binding sites. The achievement of low aminoglycoside concentrations for a greater proportion of the dosing interval facilitates excretion of the aminoglycoside. A recent meta-analysis suggests greater clinical efficacy and reduced nephrotoxicity with once-daily compared to standard dosing.³⁸ However, seriously ill, immunocompromised, renal-insufficient, and elderly patients are not ideal candidates for this approach. Prevention of nephrotoxicity may be enhanced by more discriminating selection of patients in whom aminoglycosides are used, as well as dosing based on accurate estimates of GFR, such as those provided by the Modification of Diet in Renal Disease (MDRD) equation (see Chap. 41).⁴⁰

Management

Serum creatinine concentrations should be measured frequently (every 2 to 4 days) during therapy. Aminoglycoside use should be discontinued or the dosage regimen revised if the S_{Cr} increases by >0.5 mg/dL during a course of therapy. Other nephrotoxic drugs should be discontinued if possible, and the patient should be maintained adequately hydrated and hemodynamically stable. Dialysis

may be necessary, but renal failure due solely to aminoglycoside toxicity is usually reversible.

RADIOGRAPHIC CONTRAST MEDIA NEPHROTOXICITY

Incidence

Nephrotoxicity induced by radiographic contrast media is the third leading cause of hospital-acquired acute renal failure.¹⁴ The incidence rises from <2% in patients with low risk to 40% to 50% in high-risk patients such as those with pre-existent renal insufficiency or diabetes mellitus.^{14,41} The risk of contrast nephropathy increases as the number of risk factors increases, and diabetic patients with renal insufficiency have the greatest risk.^{42,43}

Clinical Presentation

Toxicity ranges from transient tubular enzymuria to irreversible oliguric (urine volume <500 mL/day) renal failure requiring dialysis therapy.^{31,42} Severe toxicity is most frequent in diabetic patients with pre-existent kidney disease. The typical course is an initial transient osmotic diuresis followed by tubular proteinuria and enzymuria. The serum creatinine rises and peaks between 2 and 5 days after exposure, with recovery after 4 to 10 days. Oliguria is present in about 50% of cases. Urinalysis typically reveals only hyaline and granular casts, but may also be completely bland.⁴³ The urine sodium concentration and fractional excretion of sodium are frequently low. Although toxicity has generally been considered to be mild and reversible, an in-hospital mortality rate of 34% has been reported in patients with contrast media–induced acute renal failure, compared to 7% in those without contrast nephrotoxicity.⁴² Death was attributable to sepsis, respiratory failure, delirium, and bleeding that intensified after the onset of acute renal failure.

Pathogenesis

Contrast nephropathy appears to be due to direct tubular toxicity and renal ischemia.^{31,42} Direct tubular toxicity is suggested by renal tubular enzymuria and biopsy findings of proximal tubular epithelial cell vacuolization and acute tubular necrosis. In addition to the direct toxic effects of contrast media, the nonselective proteinuria induced by contrast media may indirectly damage tubular epithelial cells. In contrast to these findings, the low urine sodium concentration and low fractional excretion of sodium frequently observed suggest preserved renal tubular function and participation of renal ischemia more than tubular toxicity. Renal ischemia may result from systemic hypotension associated with contrast injection, as well as renal vasoconstriction mediated by an imbalance of humoral agents, including prostaglandins, adenosine, atrial natriuretic peptide, nitric oxide, and endothelin.^{31,42,43} Renal ischemia may also result from dehydration due to osmotic diuresis accompanying use of hyperosmolar agents (900 to 1780 mOsm/kg) and increased blood viscosity due to red blood cell crenation and aggregation.

Risk Factors

Pre-existent kidney disease, particularly diabetic nephropathy with renal insufficiency, is the major risk factor. Conditions associated with decreased renal blood flow, including congestive heart failure and dehydration, also confer risk. The presence of multiple myeloma has been considered a relative contraindication for contrast use, but the risk appears to be associated with concomitant dehydration, renal insufficiency, or hypercalcemia rather than the diagnosis itself. Both

larger doses of contrast and use of older hyperosmolar contrast agents promote risk in susceptible patients.³¹

Prevention

The importance of strategies aimed at preventing radiocontrast-induced nephrotoxicity cannot be overemphasized. All patients scheduled to receive radiocontrast media should be assessed for risk factors, and the risk:benefit ratio should be considered.⁴⁴ Nephrotoxicity can be predicted in the majority of patients at risk, which justifies the use of preventative procedures with even minimal benefit.⁴⁵ High-risk patients should be identified, primarily by medical history and indication for the contrast study, but also by prestudy serum creatinine concentrations. Nephrotoxicity is best prevented in high-risk patients by using alternative imaging procedures (e.g., ultrasound, magnetic resonance imaging, and nuclear medicine scans). However, if contrast media must be used, the smallest adequate dose should be administered. Dose reduction proportional to the level of renal insufficiency may be protective, but may limit the adequacy of imaging.⁴⁴

Low-osmolality nonionic (iohexol and iopamidol) and ionic (ioxaglate) contrast agents may be used to prevent nephrotoxicity. Standard contrast media are not reabsorbed in the kidney and cause osmotic diuresis, which contributes to the renal toxicity observed with these agents. The second generation of contrast agents have half the osmolality of standard agents, and have been associated with less toxicity, especially when used in patients with pre-existing kidney disease.⁴³ The incidence of contrast nephropathy in nondiabetic patients with underlying kidney disease is more than twofold higher in those receiving standard contrast agents compared to those receiving low-osmolar agents.¹⁴ However, use of low osmolar agents does not eliminate nephrotoxicity and the preventive measures outlined below should be utilized.

CLINICAL CONTROVERSY

The true cost and benefit of using low-osmolar contrast agents to prevent nephrotoxicity is questionable because they are considerably (three to five times) more expensive than standard higher osmolar ionic agents. A cost-effective strategy may be to use low osmolar contrast agents in patients with pre-existing kidney disease, particularly those with diabetes mellitus, and standard agents in patients with normal renal function. Conversely, the low-osmolar agents cause less histamine release and may be advantageous for hemodynamically unstable patients or those with a history of hypersensitivity to contrast media.

Dehydration should be corrected before contrast administration, other nephrotoxic drugs discontinued if possible, and subsequent contrast studies appropriately timed to avoid cumulative toxicity. Hydration with isotonic saline before and after contrast administration reduces the incidence of toxicity, particularly in high-risk patients.⁴⁶ In addition to the obvious correction of dehydration, saline administration may lessen the impact of contrast-induced osmotic diuresis. Additional beneficial effects of saline prehydration may include dilution of contrast media, prevention of renal vasoconstriction leading to ischemia, and avoidance of tubular obstruction. Acetylcysteine is a thiol-containing antioxidant that may effectively reduce the risk of developing contrast nephropathy in patients with pre-existing kidney disease. Its use should be considered, along with hydration, in all patients at risk of toxicity.^{47,48} Continuous venovenous hemofiltration may be an effective means of preventing contrast nephrotoxicity and is associated with improved outcomes in patients with chronic kidney

disease (CKD).⁴⁹ In contrast, use of mannitol and furosemide to prevent toxicity remains controversial,⁴⁵ and recent evidence indicates that the dopamine₁-receptor agonist fenoldopam may not prevent contrast-induced nephropathy in CKD patients.⁴¹

Management

Currently there is no specific therapy available for managing established contrast nephropathy. Care is supportive with dialysis as needed in selected patients. Careful attention must be given to preventing infection and bleeding and providing respiratory support in view of the high association of these complications with death.

CISPLATIN AND CARBOPLATIN NEPHROTOXICITY

Incidence

Platin-containing compounds are important chemotherapeutic agents that frequently cause renal tubular damage.^{30,50} The incidence of cisplatin nephrotoxicity was 50% to 100% in the 1980s. Subsequently, the incidence of toxicity decreased to 6% to 13%, primarily by limiting the total drug dose and reducing the rate of administration. However, when used in combination with other nephrotoxins, high-dose cisplatin continues to contribute to ARF. A 20% to 40% decline in GFR is frequently observed in patients treated with cisplatin.⁵⁰ Carboplatin, a second-generation platinum analog, is associated with a lower incidence of nephrotoxicity than cisplatin.³⁰

Clinical Presentation

Nephrotoxicity manifests early during therapy as transient proximal tubular cell brush border and lysosomal enzymuria.³⁰ Peak serum creatinine concentrations occur approximately 10 to 12 days after initiation of therapy, with recovery by 21 days. However, renal damage can be cumulative with subsequent cycles of therapy and the serum creatinine concentration may continue to rise. Irreversible kidney disease may result. Renal magnesium wasting is common and can be accompanied by hypocalcemia and hypokalemia. Hypomagnesemia may be severe, causing seizures, neuromuscular irritability, or personality changes, and persist long after chemotherapy has ended. Hypomagnesemia results primarily from urinary losses due to renal tubular damage as well as magnesuric effects of saline hydration and diuretic therapy to prevent toxicity. Anorexia and diarrhea also contribute, due to decreased intake and increased loss of magnesium, respectively.

Pathogenesis

Proximal tubular damage appears acutely after administration of platin-containing compounds, as the result of impairment of cell energy production, possibly by binding to proximal tubular cellular proteins and sulfhydryl groups with disruption of cell enzyme activity and uncoupling of oxidative phosphorylation.³⁰ The initial proximal tubular damage is followed by a progressive loss of glomerular filtration and impaired distal tubular function.⁵⁰ Renal biopsies generally show sparing of glomeruli with necrosis of proximal and distal tubules and collecting ducts.

Risk Factors

Risk factors include increased age, dehydration, renal irradiation, concurrent use of aminoglycoside antibiotics, and alcohol abuse.⁵⁰

Prevention

Toxicity is best prevented by dose reduction and decreased frequency of administration, which usually requires using the platin compounds

in combination with other chemotherapeutic agents. Vigorous saline hydration is important and should be used in all patients; doses range from 1 to 4 L within 24 hours of cisplatin treatment to as high as 3 L/m² within 24 hours for high-dose carboplatin.⁵⁰ Although protective roles per se for furosemide or mannitol diuresis are less clear,³¹ their use is often necessary to maintain volume homeostasis. Amifostine, an organic thiophosphate that is converted to an active metabolite, chelates cisplatin in normal cells and has been shown to reduce the nephrotoxicity, neurotoxicity, ototoxicity, and myelosuppression associated with cisplatin and carboplatin therapy.⁵¹ The renoprotective effect of amifostine administration was recently demonstrated in patients receiving cisplatin/ifosfamide-based chemotherapy.⁵² Amifostine fully preserved GFR in patients with solid tumors after administration of two cycles of chemotherapy compared to a 30% reduction in GFR in controls. In addition, less severe hypomagnesemia and decreased tubular damage were observed in the amifostine group. Pretreatment with amifostine should be considered in patients at risk for renal dysfunction. Promising investigational techniques have included the use of hypertonic saline to reduce tubular cisplatin uptake; reduced renal exposure by use of localized intraperitoneal administration in conjunction with systemic administration of sodium thiosulfate for those with peritoneal tumors; use of *N*-acetylcysteine, a sulfhydryl donor; and disulfiram metabolite diethyldithiocarbamate.^{30,50} Recently the protective effect of melatonin,⁵³ and the ability of cisplatin-incorporated polymeric micelles to maintain antitumor activity while reducing nephrotoxicity have been demonstrated.⁵⁴

Management

Acute renal failure due to cisplatin therapy is usually partially reversible with time and supportive care, including dialysis. Serum magnesium concentrations should be monitored frequently and hypomagnesemia corrected (see Chap. 50). Hypocalcemia and hypokalemia may be difficult to reverse until hypomagnesemia is corrected. Progressive chronic kidney disease due to cumulative toxicity may not be reversible and in some cases may require chronic dialysis support.

AMPHOTERICIN B NEPHROTOXICITY

Incidence

Amphotericin B remains the antifungal drug of choice for most systemic infections, but dose-dependent nephrotoxicity occurs to varying degrees in many patients.⁵⁵ Toxicity is seen initially with cumulative doses as low as 300 to 400 mg, and reaches an incidence of 80% when cumulative doses approach 4 g. Several liposomal amphotericin B formulations are now available. Although numerous studies demonstrate lower rates of nephrotoxicity with liposomal formulations compared to conventional amphotericin B, it is difficult to compare rates of toxicity between products and studies due to varying study populations enrolled, different doses administered, and inconsistent definitions of nephrotoxicity and methods of assessment.⁵⁶

Clinical Presentation

Toxicity is often initially manifest by abnormalities of renal tubular function including potassium, sodium, and magnesium wasting, impaired urine concentrating ability, and distal renal tubular acidosis due to a leak of hydrogen ions back out of the tubular lumen.⁵⁷ Substantial potassium and magnesium replacement may be necessary. Renal blood flow and GFR decreases are common, and result in a rise in serum creatinine and blood urea nitrogen concentrations.

Pathogenesis

Renal pathologic findings include focal vacuolization of small arterial and arteriolar smooth muscle cells, as well as proximal and distal tubular epithelial cell damage. The mechanisms of renal dysfunction include direct tubular epithelial cell toxicity with increased tubular permeability and necrosis, as well as arterial vasoconstriction and ischemic injury.⁵⁸ Tubular membrane permeability to solutes such as sodium and potassium increases when amphotericin binds to membranes and acts as an ionophore. Renal vasoconstriction occurs by unclear mechanisms, possibly including direct effects of amphotericin B on cellular calcium fluxes and activation of vasoconstrictor prostaglandins. Overall, the combined effects of increased cell energy and oxygen requirements due to greater cell membrane permeability, and reduced cellular oxygen delivery due to renal vasoconstriction, results in renal medullary tubular epithelial cell necrosis and renal failure.^{29,57}

Risk Factors

Risk factors include baseline renal insufficiency, higher average daily doses, diuretic use, volume depletion, and concomitant administration of other nephrotoxins (cyclosporine in particular).^{55,57} Rapid infusions of amphotericin B have the potential to increase toxicity. A recent comparison of 24-hour continuous infusions with conventional 4-hour infusions revealed a significant reduction of toxicity, attributed to decreased “pretubular” effects (e.g., effects on renal blood flow and GFR).⁵⁹

Prevention

Nephrotoxicity is best minimized by limiting the cumulative dose and avoiding concomitant administration of other nephrotoxins, particularly cyclosporine.⁶⁰ Additionally, providing hydration with a high sodium diet and 1 L intravenous 0.9% sodium chloride daily appears to reduce toxicity.⁵⁵ Mannitol infusion to induce an osmotic diuresis has not been protective.⁵⁷ Lastly, several liposomal amphotericin B formulations are now available and have been reported to reduce nephrotoxicity by enhancing drug delivery to sites of infection and thereby reducing exposure of mammalian cell membranes.^{61,62}

CLINICAL CONTROVERSY

Many clinicians recommend using liposomal formulations of amphotericin B in all patients with pre-existing kidney disease and those at risk for developing nephrotoxicity, while others maintain that the safety and efficacy of liposomal formulations remains to be unequivocally established and their judicious use is warranted.

Management

Amphotericin nephrotoxicity is best treated by discontinuation of therapy and substitution of alternative antifungal therapy, if possible. Renal tubular dysfunction and glomerular filtration will improve gradually to some degree in most patients, but damage may be irreversible.

PENTAMIDINE NEPHROTOXICITY

Pentamidine therapy for *Pneumocystis carinii* infections is also limited by nephrotoxicity. Prospective studies have shown azotemia in 60% to 90% of treated patients.⁶³ Hyperkalemia, metabolic acidosis, hypomagnesemia, and hypocalcemia may also occur. Toxicity is more frequent in patients with the acquired immunodeficiency syndrome (AIDS) than in patients without this immune deficiency, and may

be accentuated by concomitant amphotericin B therapy. The mechanism of toxicity is unknown, but tubular degeneration has been seen histopathologically. The primary alternative therapy for *P. carinii*, trimethoprim-sulfamethoxazole, may also cause renal dysfunction due to allergic interstitial nephritis and/or inhibition of tubular secretion of creatinine, but the incidence is lower than with pentamidine.⁶³

FOSCARNET NEPHROTOXICITY

Foscarnet, an antiviral pyrophosphate analog used in AIDS and other immunosuppressed patients to treat cytomegalovirus (CMV) retinitis and life-threatening CMV infections, is a highly nephrotoxic agent. As many as 66% of patients treated with foscarnet develop renal insufficiency.⁶⁴ The mechanism appears to be complexation of foscarnet with ionized calcium and precipitation of calcium-foscarnet salt crystals in renal glomeruli causing a crystalline glomerulonephritis. The salt crystals may then secondarily precipitate in the renal tubules causing tubular necrosis. Foscarnet nephrotoxicity can be minimized by administering the appropriate dose after vigorously prehydrating the patient. Intravenous hydration provides better nephroprotection than oral hydration.⁶⁵ In addition, cidofovir and adefovir, potent nucleotide analogs administered for CMV infection in AIDS patients, have been associated with renal proximal tubular cell injury and renal failure.¹⁶ Probenecid blocks renal tubular epithelial cell uptake of cidofovir, and when combined with saline hydration can reduce the incidence of nephrotoxicity.

OSMOTIC NEPHROSIS

Several drugs, including mannitol, low-molecular-weight dextran, and radiographic contrast media, or drug vehicles, including sucrose and propylene glycol, have been associated with vacuolization, swelling, and ultimately necrosis of proximal tubular epithelial cells with a decline in renal function.^{16,66} The decline in renal function may be due to the hypertonic and osmotically active nature of these agents. Intravenous immunoglobulin solutions contain hyperosmolar sucrose and may cause osmotic nephrosis and acute renal failure, which is rapidly reversible on discontinuing therapy. Toxicity may be prevented by diluting the solution and reducing the rate of infusion. Hydroxyethylstarch, used as a plasma volume expander, has also been implicated in the development of osmotic nephrosis.¹⁶

Mannitol may rarely cause oligo-anuric renal failure with proximal tubular cell vacuolization on biopsy. Mechanisms include pinocytosis of mannitol into cells, causing swelling and tubular lumen obstruction.¹⁵ Mannitol can also cause direct renal vasoconstriction or induce an osmotic diuresis with increased solute delivery to the macula densa and subsequent tubuloglomerular feedback, leading to vasoconstriction of the glomerular afferent arteriole and decreased renal blood flow. Risk factors for mannitol DIN include excessive doses, pre-existent renal insufficiency, and concomitant diuretic or cyclosporine therapy. Nephrotoxicity may be prevented by limiting the dose and avoiding dehydration and concomitant diuretic therapy. The serum mannitol concentration should be maintained <1000 mg/dL (as evidenced by an osmolal gap <55 mOsm/kg water). Patients usually recover normal renal function when elevated mannitol concentrations decrease following drug withdrawal or hemodialysis. Mannitol-induced osmotic diuresis and volume depletion could increase the nephrotoxicity of other drugs, particularly NSAIDs, ACEIs, and cyclosporine.

HEMODYNAMICALLY-MEDIATED RENAL FAILURE

▶ Hemodynamically-mediated renal insufficiency results from a decrease in intraglomerular pressure. Mechanisms commonly include a decrease in renal blood flow, vasoconstriction of glomerular afferent arterioles, or vasodilation of glomerular efferent arterioles.

ANGIOTENSIN-CONVERTING ENZYME INHIBITORS AND ANGIOTENSIN II RECEPTOR BLOCKERS

INCIDENCE

The incidence of ACEI- or angiotensin II receptor blocker (ARB)-mediated renal failure has not been established. However, patients with severe atherosclerotic renal artery stenosis, those hospitalized with congestive heart failure, and those with chronic kidney disease, including diabetic nephropathy, are most likely to experience a significant decline in renal function with these agents.

CLINICAL PRESENTATION

Therapy with ACEIs and ARBs can acutely reduce GFR, manifesting as a rise in serum creatinine.¹⁶ Importantly, a distinction must be made between a potentially detrimental reduction in GFR and a normal, predictable rise in serum creatinine. Dose-related changes in serum creatinine should be anticipated in most patients with ACEIs, based

on their pathophysiologic effects.^{67,68} An increase in serum creatinine of up to 30% within 2 to 5 days of initiating therapy is an indication that the drug has begun to exert its desired pharmacologic effect.⁶⁷ The increase in creatinine usually stabilizes within 2 to 3 weeks and is usually reversible upon stopping the drug. Furthermore, an association exists between acute increases in serum creatinine of $\leq 30\%$ from baseline that stabilize within the first 2 months of initiating therapy and preservation of renal function.

A reduction in GFR has been reported in the presence and absence of renal artery stenosis. The rise is often minimal in renovascular disease if only one renal artery is stenotic, but is more apparent in patients with a single kidney with renovascular disease, congestive heart failure, volume depletion, or bilateral renal small vessel disease. Up to one-third of patients with bilateral renal artery stenosis demonstrate a rise in serum creatinine $>30\%$ after starting ACEI therapy.⁶⁹

PATHOGENESIS

The pathogenesis of ACEI- or ARB-mediated renal failure is a decrease in glomerular capillary hydrostatic pressure sufficient to reduce glomerular ultrafiltration.⁴ This often occurs in settings in which glomerular afferent arteriolar blood flow is reduced and the efferent arteriole is vasoconstricted to maintain sufficient glomerular capillary hydrostatic pressure for ultrafiltration (Fig. 46-3A). ACEI or ARB therapy reduces angiotensin II synthesis or activity, respectively, thereby dilating the efferent arteriole and reducing glomerular

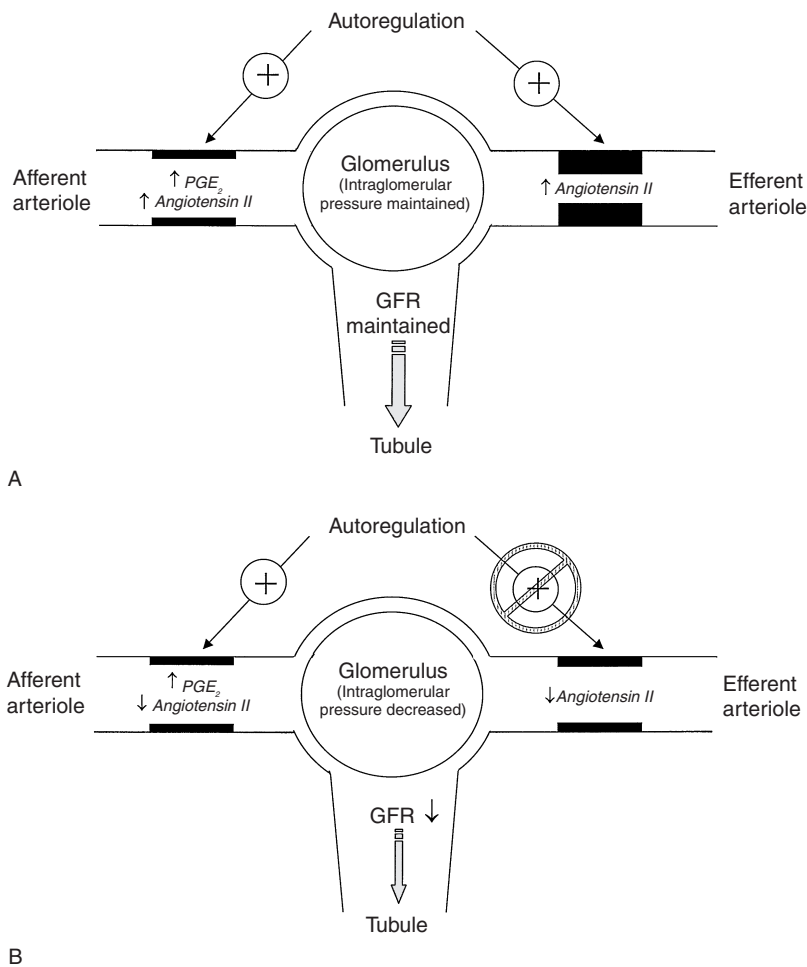

FIGURE 46-3. A. The kidney maintains GFR by dilating the afferent arteriole and constricting the efferent arteriole, specifically in response to a decrease in renal blood flow. During states of reduced blood flow, the juxtaglomerular apparatus increases renin secretion. Plasma renin converts angiotensinogen to angiotensin I, and ultimately angiotensin II (AII) by angiotensin-converting enzyme. AII constricts the afferent and efferent arterioles resulting in a net increase in intraglomerular pressure. Additionally, renal prostaglandins, prostaglandin E_2 (PGE_2) in particular, are released and induce a net dilation of the afferent arteriole, thereby improving blood flow into the glomerulus. Together these processes maintain GFR and urine output. **B.** ACE inhibitor nephropathy often occurs in the setting of reduced blood flow. When ACE inhibitor therapy (e.g., enalapril or ramipril) is initiated, the synthesis of angiotensin II is decreased, thereby preferentially dilating the efferent arteriole. This reduces outflow resistance from the glomerulus and decreases hydrostatic pressure in the glomerular capillaries, which alters Starling's forces across the glomerular capillaries to decrease intraglomerular pressure and GFR.

capillary hydrostatic pressure (Fig. 46–3B). This decreases glomerular ultrafiltration and GFR.

RISK FACTORS

Patients at greatest risk are those dependent on angiotensin II to maintain blood pressure and renal efferent arteriolar constriction. These include patients with hemodynamically significant renal artery stenosis, particularly bilateral stenosis, and those with decreased effective arterial renal blood flow, particularly those with congestive heart failure, volume depletion from excess diuresis or gastrointestinal fluid loss, hepatic cirrhosis with ascites, and the nephrotic syndrome.^{4,69}

PREVENTION

A common strategy for at-risk patients is to initiate therapy with very low doses of a short-acting ACEI, then gradually titrate the dose upward and convert to a longer-acting agent after patient tolerance has been demonstrated. Outpatients may be started on low doses of long-acting ACEIs with gradual dose titration. Renal function and serum potassium concentrations must be monitored carefully, daily for hospitalized patients and every 2 to 3 days for outpatients. Monitoring may need to be more frequent during outpatient initiation of ACEI or ARB therapy for patients with pre-existing renal insufficiency, congestive heart failure, or suspected renovascular disease. Use of concurrent hypotensive agents and diuretics should be discouraged and dehydration avoided.⁶⁹

MANAGEMENT

Acute decreases in renal function and hyperkalemia usually resolve over several days after ACEI or ARB therapy is discontinued. Occasional patients will require management of severe hyperkalemia, usually with sodium polystyrene sulfate (see Chap. 50). ACEI or ARB therapy may frequently be reinitiated, particularly for patients with congestive heart failure, after intravascular volume depletion has been corrected or the diuretic doses reduced. The development of mild renal insufficiency (serum creatinine concentration of 2 to 3 mg/dL) may be an acceptable trade-off for hemodynamic improvement in certain patients with severe congestive heart failure or renovascular disease not amenable to invasive management. Congestive heart failure patients with greater renal insufficiency may be best treated by substitution of hydralazine and nitrates for afterload reduction.

NONSTEROIDAL ANTI-INFLAMMATORY DRUGS

INCIDENCE

NSAIDs have an overall favorable safety profile resulting in OTC availability in the United States of ibuprofen, naproxen, and ketoprofen for short-term therapy. While potential adverse renal effects from OTC NSAIDs have been a concern, activity of vasodilatory prostaglandins is not necessary to maintain renal function in healthy individuals. NSAIDs are unlikely to impair renal function in the absence of renal ischemia or excess renal vasoconstrictor activity. Nevertheless, given the fact that 50 million U.S. citizens report NSAID use, it has been estimated that 500,000 to 2.5 million people will develop NSAID nephrotoxicity in this country annually.¹⁰

CLINICAL PRESENTATION

Renal failure can occur within days of initiating therapy, particularly with a short-acting NSAID such as ibuprofen.¹⁰ Urine volume and sodium concentration are usually low, edema and/or weight gain is noticeable, and BUN, serum creatinine, and potassium are typically elevated. The urine sediment is usually unchanged from baseline, but may show granular casts.

PATHOGENESIS

NSAIDs inhibit cyclooxygenase (COX)-catalyzed prostaglandin production and impair renal function by decreasing synthesis of vasodilatory prostaglandins from arachidonic acid.¹⁰ Renal prostaglandins are synthesized in the renal cortex and medulla by vascular endothelial and glomerular mesangial cells. Their effects are primarily local and result in renal vasodilation (particularly prostacyclin and prostaglandin E₂ [PGE₂]). They have limited activity in states of normal renal blood flow, but in states of decreased renal blood flow their synthesis is increased and they protect against renal ischemia and hypoxia by antagonizing renal vasoconstriction due to angiotensin II, norepinephrine, endothelin, and vasopressin. Administration of NSAIDs in the setting of renal ischemia and compensatory increased prostaglandin activity may thus alter the balance of activity between renal vasoconstrictors and vasodilators. This leaves the activity of renal vasoconstrictors unopposed and promotes renal ischemia with loss of glomerular filtration. This hemodynamically-mediated acute renal failure is the most common adverse renal effect of NSAIDs.

RISK FACTORS

Persons at greatest risk for NSAID hemodynamic nephropathy generally have pre-existing renal insufficiency, medical problems associated with high plasma renin activity (hepatic disease with ascites, decompensated congestive heart failure, or intravascular volume depletion), or systemic lupus erythematosus. Additional risk factors include atherosclerotic cardiovascular disease and diuretic therapy. The elderly are also at higher risk due to interaction of prevalent medical problems, multiple drug therapies, and reduced renal hemodynamics. Advanced age, however, has not been shown to be an independent risk factor for toxicity in limited trials in otherwise healthy elderly subjects.^{10,70} Combined NSAID and ACEI or ARB therapy is also a concern and should be avoided.

PREVENTION

NSAID-induced acute renal failure can be prevented by recognizing high-risk patients and using analgesics with less prostaglandin inhibition, such as acetaminophen, nonacetylated salicylates, aspirin, and possibly nabumetone. Non-narcotic analgesics (e.g., propoxyphene and tramadol) may also be useful but do not provide anti-inflammatory activity.¹⁰ When NSAID therapy is essential for high-risk patients, management of predisposing medical problems should be optimized and renal function monitored. Sulindac may be useful in high-risk patients since it is a potent NSAID that may have lesser effects on renal prostaglandin synthesis and function. The mechanism of renal prostaglandin sparing is unclear, but may involve intrarenal metabolism of the active drug, sulindac sulfide, by cytochrome P450-dependent mixed-function oxidases to an inactive metabolite, sulindac sulfoxide. However, this favorable effect of sulindac has not been consistently observed in patients with hepatic disease, especially at higher therapeutic doses or during prolonged therapy.

Traditional, nonselective NSAIDs inhibit COX-1 and COX-2, while the selective drugs meloxicam, celecoxib, and valdecoxib

preferentially inhibit COX-2.⁷¹ COX-2 inhibitors were anticipated to be beneficial in high-risk patients. However, recent data indicate they affect renal function similarly to nonselective NSAIDs and thus caution is warranted with their use, particularly in high-risk patients.^{71,72}

MANAGEMENT

NSAID-induced acute renal failure is treated by discontinuation of therapy and supportive care. Renal failure may be severe, but recovery is usually rapid and dialysis is rarely necessary. Occasionally the hemodynamic insult is sufficiently severe to cause frank tubular necrosis, which can prolong recovery. The differential diagnosis of NSAID hemodynamically-mediated acute renal failure must include NSAID-induced acute interstitial nephritis, with or without the nephrotic syndrome, because steroid therapy may benefit this type of renal injury.

SULFINPYRAZONE

Sulfinpyrazone, a uricosuric congener of phenylbutazone, also causes hemodynamically-mediated acute renal failure.⁷³ Sulfinpyrazone inhibition of renal prostaglandin synthesis or reduction of renal kallikrein-kinin activity may imbalance renal hemodynamics, causing renal ischemia. Renal insufficiency may be transient despite continued sulfinpyrazone administration or prolonged and oliguric with a low urinary sodium concentration.

CYCLOSPORINE AND TACROLIMUS

Cyclosporine and tacrolimus have dramatically enhanced the success of solid organ transplantation. Nephrotoxicity, however, remains a major dose-limiting adverse effect of both drugs.⁷⁴ Early acute hemodynamically-mediated renal insufficiency and delayed chronic interstitial nephritis have been observed (see section on chronic interstitial nephritis later in this chapter).⁷⁵

INCIDENCE

Historically, reversible acute renal insufficiency occurred frequently in transplant recipients during the first 6 months of cyclosporine therapy. The incidence of chronic kidney disease in nonrenal transplant patients is reported to be from 10% to 83%.⁷⁴ Recent data indicate that the 5-year risk of CKD after transplantation of a nonrenal organ ranges from 7% to 21%, depending on the type of organ transplanted. In addition, the occurrence of CKD in these patients is associated with more than a fourfold increase in the risk of death.

CLINICAL PRESENTATION

Acute renal toxicity may occur within days of initiating therapy. Serum creatinine concentration rises and creatinine clearance decreases. Hypertension, hyperkalemia, sodium avidity, and hypomagnesemia may occur. No urine sediment abnormalities are seen. Urinary enzyme excretions increase, but are not reliable indicators of toxicity. Renal biopsy reveals thickening of arterioles, mild focal glomerular sclerosis, proximal tubular epithelial cell vacuolization and atrophy, and interstitial fibrosis. Biopsy is useful to distinguish acute cyclosporine nephrotoxicity from renal allograft rejection, the latter being evidenced by cellular infiltration.⁷⁵

Chronic toxicity typically becomes apparent after 6 to 12 months of therapy as a slowly rising serum creatinine concentration and decreased creatinine clearance. However, the rise in serum creatinine

concentration and decreased creatinine clearance may be delayed and not reflect the severity of histopathologic changes. Urinalysis reveals few red and white blood cells with low-range proteinuria. Renal biopsy shows progressive renal arteriolar hyalinosis, glomerular sclerosis, and a striped pattern of tubulointerstitial fibrosis. Biopsy cannot easily distinguish chronic cyclosporine toxicity from chronic rejection.⁷⁶

PATHOGENESIS

A dose-related hemodynamic mechanism is likely during the initial months of therapy since renal function improves rapidly following dose reduction. Reversible vasoconstriction and injury to glomerular afferent arterioles occurs, possibly due to increased activity of vasoconstrictors, including thromboxane A₂, endothelin, and the sympathetic nervous system, or diminished activity of vasodilators, nitric oxide, or prostacyclin.^{76,77} Vasoconstriction due to increased renin-angiotensin system activity may also contribute. In contrast renal arteriolar hyalinization and chronic renal ischemia as well as increased extracellular matrix synthesis appear to contribute to cyclosporine-induced chronic kidney disease.^{76,77}

RISK FACTORS

Risk factors include increased age and higher initial cyclosporine dose, as well as renal graft rejection, hypotension, infection, and concomitant therapy with nephrotoxic drugs such as aminoglycosides, amphotericin B, acyclovir, NSAIDs, and radiocontrast agents, as well as drugs that inhibit cyclosporine hepatic metabolism.⁷⁵ (see Chap. 87) The high incidence of acute renal insufficiency with potential progression to chronic nephropathy has decreased with current lower-dose therapy, but concern remains for a slow, dose-dependent decline in glomerular filtration.

PREVENTION

Since acute DIN appears to be dose related, pharmacokinetic and pharmacodynamic monitoring is an important means of preventing toxicity. However, the persistent presence of therapeutic or low cyclosporine concentrations cannot preclude nephrotoxicity. Calcium channel blockers may antagonize the vasoconstrictor effect of cyclosporine by dilating glomerular afferent arterioles and preventing acute decreases in renal blood flow and glomerular filtration.⁷⁵ Lastly, decreased doses of cyclosporine or tacrolimus, primarily when used in combination with other non-nephrotoxic immunosuppressants, may minimize the risk of toxicity, but this may increase the risk of chronic rejection.

MANAGEMENT

Acute renal insufficiency usually improves with dose reduction, and treatment of contributing illness or the discontinuation of interacting drugs. Chronic kidney disease is usually irreversible, but progressive toxicity may be limited by discontinuation of cyclosporine therapy or dose reduction, with the continuation of other immunosuppressants (e.g., prednisone or azathioprine).

TRIAMTERENE

Triamterene, a potassium-sparing diuretic, has been associated with transient decreases in creatinine clearance and abnormal urinary sediment in normal subjects and hypertensive patients.⁷⁸ In combination

with hydrochlorothiazide, triamterene has caused reversible acute renal failure in elderly patients. In combination with indomethacin, triamterene has induced acute renal failure in normal subjects and patients at risk for NSAID nephropathy. A hemodynamic mechanism is most likely, as suggested by the apparent increased risk for nephrotoxicity during combined triamterene and indomethacin therapy. Presumably, triamterene causes renal vasoconstriction that is counterbalanced by increased renal synthesis of vasodilatory prostaglandins. Concomitant NSAID therapy may induce renal ischemia by preventing the compensatory increase in renal prostaglandin synthesis. The implications of these observations are unclear because triamterene and NSAIDs are frequently used together without apparent nephrotoxicity.

OKT3

OKT3 therapy for the prevention and treatment of acute renal and cardiac allograft rejection is often accompanied by a rise in the serum creatinine concentration that returns toward baseline after 3 to 5 days.⁷⁷ Renal biopsy findings of mild interstitial edema or no abnormalities suggest the mechanism is increased vascular permeability due to a renal capillary leak. This renal dysfunction is believed to be part of a cytokine syndrome associated with OKT3 therapy. OKT3 causes lymphocyte activation and release of cytokines, particularly tumor necrosis factor, γ -interferon, and interleukin-2 and interleukin-6, which may induce secretion of group II secretory phospholipase A₂ as a mediator of nephrotoxicity.⁷⁹ Renal function often improves spontaneously despite continued OKT3 therapy.

OBSTRUCTIVE NEPHROPATHY

Obstructive nephropathy is the result of mechanical obstruction to urine flow following glomerular filtration. This may be due to intratubular obstruction from crystal precipitation within the tubules of the kidney or extrarenal obstruction of the ureters or bladder.⁸⁰ Pain, hematuria, and infection may precede a significant rise in serum creatinine.

RENAL TUBULAR OBSTRUCTION

Drug-induced acute renal tubular obstruction can be caused by intratubular precipitation of tissue degradation products as well as by drugs or their metabolites. Acute uric acid nephropathy following chemotherapy is the most common cause of renal failure due to obstruction by tissue degradation products. Acute oliguric or anuric renal failure develops rapidly. The diagnosis is supported by a urine uric acid:creatinine ratio greater than 1. Uric acid precipitation can be prevented by pretreatment hydration, urinary alkalization to pH 7.0, and allopurinol.

Drug-induced rhabdomyolysis leads to intratubular precipitation of myoglobin and if severe, acute renal failure.⁸¹ The most common cause of drug-induced rhabdomyolysis is direct myotoxicity from HMG-CoA reductase inhibitors, including lovastatin and simvastatin.⁸¹ The risk of rhabdomyolysis is increased when this class of drugs is administered concurrently with gemfibrozil, niacin, or inhibitors of the CYP3A4 metabolic pathway (e.g., cyclosporine, erythromycin, or itraconazole). Rhabdomyolysis may also result from pressure necrosis during stupor or coma following ingestion of CNS depressants (e.g., alcohol or narcotics), or extreme neuromuscular agitation and associated metabolic demands with abuse of central

nervous system stimulants (e.g., amphetamines, cocaine, ecstasy, or phencyclidine).⁸¹

Intratubular precipitation of drugs (e.g., sulfonamides) or their metabolites can also cause acute renal failure.⁸⁰ Sulfadiazine when used at high doses,⁸⁰ and methotrexate and its less soluble metabolite, 7-hydroxymethotrexate,³⁰ may also precipitate in acidic urine and can cause oligo-anuric renal failure. Intravenous and high-dose oral acyclovir therapy for acute herpes zoster has also been associated with intratubular precipitation in dehydrated oliguric patients.⁸⁰ This can be diagnosed by the presence of birefringent needle-shaped crystals within leukocytes using polarized light microscopy. Massive administration of ascorbic acid can also result in obstruction of renal tubules with calcium oxalate crystals. Oxalate, a poorly soluble ascorbic acid metabolite, can also precipitate and worsen renal function when ascorbic acid is administered to patients with acute renal failure or the congenital nephrotic syndrome. Low-molecular-weight dextran therapy for volume expansion and rheologic effects has also caused renal failure, possibly by intratubular precipitation of filtered dextran. Triamterene may also precipitate in renal tubules and cause renal failure.⁸⁰ Foscarnet complexation with ionized calcium may result in precipitation of calcium-foscarnet salt crystals in renal glomeruli, causing primarily a crystalline glomerulonephritis. The salt crystals may then secondarily precipitate in the renal tubules causing tubular necrosis.⁶⁴

Renal failure due to intratubular precipitation of most tissue-degradation products or drugs and their metabolites can be largely prevented and possibly treated by administering the appropriate dose after vigorously prehydrating the patient, maintaining a high urine volume and urinary alkalization.

EXTRARENAL URINARY TRACT OBSTRUCTION

Drug therapy may also cause renal insufficiency due to lower urinary tract obstruction. Ureteral obstruction can be caused by calculi or retroperitoneal fibrosis. Bladder dysfunction with urinary outflow obstruction can result, particularly in males with prostatic hypertrophy, from anticholinergic drugs including tricyclic antidepressants and disopyramide. Bladder outlet and ureteral obstruction may result from bladder fibrosis following hemorrhagic cystitis with cyclophosphamide or ifosfamide therapy. Concurrent treatment with mesna can prevent cystitis and this complication.

NEPHROLITHIASIS

Nephrolithiasis (formation of kidney stones) does not present as classic nephrotoxicity since GFR is usually not decreased. Drug-induced nephrolithiasis represents abnormal crystal precipitation in the renal collecting system, potentially causing pain, hematuria, infection, or occasionally urinary tract obstruction with renal insufficiency.

Renal stone formation, possibly also accompanied by intratubular precipitation of crystalline material, has been a rare complication of drug therapy. Until the AIDS era, triamterene had been the drug most frequently associated with renal stone formation, with an incidence approximating 1 in 1500 users of triamterene-hydrochlorothiazide.⁷⁸ However, it has been unclear whether triamterene or its metabolites actually initiated stone formation, or are passively absorbed onto the organic matrix of pre-existing calculi. Sulfadiazine is a poorly soluble sulfonamide that has caused symptomatic acetylsulfadiazine crystalluria with stone formation and flank or back pain, hematuria, or renal insufficiency in up to 29% of patients treated with the drug.¹⁶ A high urine volume and urinary alkalization to

pH >7.15 may be protective. Similarly, the protease inhibitor indinavir has been associated with crystalluria, dysuria, urinary frequency, back and flank pain, or nephrolithiasis in approximately 10% of AIDS patients.⁸² Acute renal failure due to intratubular precipitation of crystalline indinavir and collecting system obstruction from nephrolithiasis have occurred.¹⁶ Since indinavir is more water soluble at acidic pH, urine acidification could be protective, but is not practical. Maintaining a high urine volume may be most protective. Recently, nephrolithiasis has been reported to be a complication of the ingestion of various products containing ephedrine, norephedrine, and pseudoephedrine.⁸³

GLOMERULAR DISEASE

Proteinuria with or without a decline in the GFR is a hallmark sign of glomerular injury (see Chap. 47). Several different glomerular lesions may occur, mostly by immune mechanisms rather than direct toxicity. Although drug-induced glomerular disease is uncommon, a variety of agents have been implicated.

Minimal change glomerular injury with nephrotic range proteinuria (i.e., >3.5 g/day) due to drugs is frequently accompanied by interstitial nephritis and is most common during NSAID therapy.^{10,84} Ampicillin, rifampin, phenytoin, and lithium have also been implicated. The pathogenesis is unknown, but nephrotic-range proteinuria due to NSAID therapy is frequently associated with a T-lymphocytic interstitial infiltrate, suggesting disordered cell-mediated immunity. These cells may release lymphokines that increase glomerular capillary permeability to proteins. Proteinuria usually resolves rapidly after discontinuation of the offending drug, and a 3- to 4-week course of corticosteroids may help resolve the lesion.⁸⁵

Focal segmental glomerulosclerosis (FSGS) is characterized by patchy areas of glomerular sclerosis with interstitial inflammation and fibrosis (see Chap. 47). Chronic heroin abuse is the most common drug cause of this lesion.⁸⁶ The pathogenesis is unknown but may include direct toxicity by heroin or adulterants and injury from bacterial or viral infections accompanying intravenous drug use. End-stage kidney disease (ESKD) develops in most cases. No specific therapy is available, although discontinuation of heroin use may prevent progression. FSGS is the predominant renal lesion in AIDS patients and may result from human immunodeficiency virus (HIV) infection or heroin abuse. Glomerulosclerosis due to HIV infection may be distinguished from heroin nephropathy by tubuloreticular structures in endothelial cells on electron microscopy and a more rapid course and poorer prognosis. The bisphosphonate pamidronate, commonly used to treat malignancy-associated hypercalcemia, is associated with the development of collapsing FSGS. Patients receiving either high doses or prolonged therapy are at highest risk.⁸⁷

Membranous nephropathy, the most common drug-induced glomerular lesion, is characterized by immune complex formation along glomerular capillary loops. Gold therapy is the most common drug-induced cause.^{88,89} The pathogenesis may involve damage to proximal tubule epithelium with antigen release, antibody formation, and glomerular immune complex deposition. Gold has been identified in proximal tubular cells, but not in the glomerular deposits. Genetic factors appear to be important because patients with human leukocyte antigens DR3 or B8 have increased susceptibility. Renal function is preserved and proteinuria resolves 6 to 39 months after discontinuing gold therapy.⁸⁸ Similarly, mercury found in diuretics, topical skin preparations, and industrial vapors causes membranous nephropathy.⁸⁹ NSAIDs have also caused membranous nephrotic

syndrome.⁸⁴ The prognosis appears favorable with resolution after discontinuing NSAID use.

TUBULOINTERSTITIAL DISEASE

These diseases involve the renal tubules and their surrounding interstitial tissue. The presentation may be acute and reversible with interstitial inflammatory cell infiltrates, rapid loss of renal function, and systemic symptoms; or chronic and irreversible with interstitial fibrosis, slow loss of renal function, and no systemic symptoms. Papillary necrosis, a variant of chronic interstitial nephritis, originates deep in the renal medulla and papillae.

ACUTE ALLERGIC INTERSTITIAL NEPHRITIS

INCIDENCE

6 Allergic interstitial nephritis (AIN) is fairly common and the underlying cause for up to 3% of all cases of acute renal failure.⁸⁵ Multiple drugs have been implicated (Table 46–3).

PENICILLINS

Clinical Presentation

Methicillin-induced allergic interstitial nephritis is the prototype for most presentations of AIN.⁸⁵ Clinical signs present approximately

TABLE 46–3. Drugs Associated with Allergic Interstitial Nephritis

| | |
|-------------------------------|---|
| Antimicrobials | Nonsteroidal anti-inflammatory drugs |
| Acyclovir | Aspirin |
| Aminoglycosides | Indomethacin |
| Amphotericin B | Naproxen |
| Aztreonam | Ibuprofen |
| Cephalosporins | Diffunisal |
| Ciprofloxacin | Piroxicam |
| Erythromycin | Ketoprofen |
| Ethambutol | Phenylbutazone |
| Indinavir | Diclofenac |
| Penicillins | Zomepirac |
| Rifampin | Miscellaneous |
| Sulfonamides | Acetaminophen |
| Tetracyclines | Allopurinol |
| Trimethoprim-sulfamethoxazole | Interferon- α |
| Vancomycin | Aspirin |
| Diuretics | Azathioprine |
| Acetazolamide | Captopril |
| Amiloride | Cimetidine |
| Chlorthalidone | Clofibrate |
| Furosemide | Cyclosporine |
| Triamterene | Glyburide |
| Thiazides | Gold |
| Neuropsychiatric | Methyldopa |
| Carbamazepine | Omeprazole |
| Lithium | <i>P</i> -aminosalicylic acid |
| Phenobarbital | Phenylpropanolamine |
| Phenytoin | Propylthiouracil |
| Valproic acid | Radiographic contrast media |
| | Ranitidine |
| | Sulfapyrazone |
| | Warfarin sodium |

14 days after initiation of therapy and include (with their approximate incidence) fever (80%), maculopapular rash (25%), eosinophilia (80%), pyuria and hematuria (90%), low-level proteinuria (90%), and oliguria (20%). Systemic hypersensitivity findings of fever, rash, eosinophilia, and eosinophiluria suggest the diagnosis, but this constellation of findings is not consistently reliable since one or more are frequently absent. Eosinophiluria, an important marker of drug-induced AIN, is frequently absent, possibly due to fragility of eosinophils in urine and inadequate laboratory methodology. Anemia, leukocytosis, and elevated IgE levels may occur. Tubular dysfunction may be manifested by acidosis, hyperkalemia, salt wasting, and concentrating defects.

NSAIDs

Clinical Presentation

NSAID-induced AIN has a different clinical presentation than that seen with most other drugs.⁸⁵ Patients are typically over age 50 (reflecting NSAID use for degenerative joint disease), the onset is delayed a mean of 6 months from initiation of therapy, and extrarenal symptoms are observed in only 10% of patients. Concomitant nephrotic syndrome (proteinuria > 3.5 g/day) occurs in more than 70% of patients. Fenoprofen-allergic interstitial nephritis is considered the prototype for NSAID-induced AIN because it accounts for nearly 50% of cases.⁸⁵

Prompt diagnosis of allergic interstitial nephritis is important since discontinuation of the offending drug may prevent irreversible renal damage. Renal biopsy is the most specific method for diagnosis but is usually not possible in acutely ill patients. Gallium-67 renal imaging is a sensitive diagnostic technique, but is nonspecific and of limited usefulness since glomerulonephritis, minimal change disease, and acute pyelonephritis also give positive scans.⁹⁰

Pathogenesis

The pathology of AIN is a diffuse or focal interstitial infiltrate of lymphocytes, plasma cells, eosinophils, and occasional polymorphonuclear neutrophils.^{85,90} Granulomas and tubular epithelial cell necrosis are relatively common with drug-induced AIN. The pathogenesis is an allergic hypersensitivity response.⁹⁰ Occasionally a humoral antibody-mediated mechanism is implicated by the presence of circulating antibody to a drug haptent-tubular basement membrane complex, low serum complement levels, and deposition of IgG and complement in the tubular basement membrane. More commonly, a cell-mediated immune mechanism is suggested by the absence of these findings and the presence of a predominantly T-lymphocyte infiltrate with an increased helper:suppressor cell ratio. In particular, NSAID interstitial nephritis involves T lymphocytes, possibly in response to altered prostaglandin synthesis.

Risk Factors

No specific risk factors have been identified because these are idiosyncratic hypersensitivity reactions. Individuals with other drug allergies may have increased risk and warrant close monitoring.

Prevention

No specific preventive measures are known due to the idiosyncratic nature of these reactions. Patients must be monitored carefully to recognize the signs and symptoms and discontinue therapy promptly.

Management

No prospective treatment trials have been reported. However, prednisone therapy in a dose of 1 mg/kg daily for 4 weeks has been used and may improve the rate and extent of renal recovery.⁹⁰

CHRONIC INTERSTITIAL NEPHRITIS

Lithium, cyclosporine, and only a few other drugs have been reported to cause chronic interstitial nephritis, which is usually a progressive and irreversible lesion. Streptozotocin and other antineoplastic nitrosoureas also cause dose-dependent chronic interstitial disease.³⁰ In addition, mesalazine, 5-aminosalicylic acid, and ifosfamide may cause chronic interstitial nephritis, which usually resolves promptly when drug use is discontinued.

LITHIUM

Incidence

Several renal tubular lesions have been associated with lithium therapy; an impaired ability to concentrate urine (nephrogenic diabetes insipidus) has been seen in up to 87% of patients.⁹¹ Acute tubular necrosis and chronic tubulointerstitial nephritis are less frequently noted, and incomplete distal renal tubular acidosis is rarely reported. The most important question regarding lithium use is whether long-term lithium therapy, with lithium concentrations maintained in the therapeutic range, causes chronic tubulointerstitial nephritis with renal insufficiency. While mild nonprogressive renal insufficiency has been reported in 10% or more of patients during long-term therapy, the role for lithium has not been established since occurrences have been infrequent and studies suggesting nephrotoxicity were frequently uncontrolled.⁹² Chronic toxicity is also questioned since renal function has not declined during short- and long-term lithium therapy in studies when lithium concentrations have been maintained in the therapeutic range.

Clinical Presentation

Patients with nephrogenic diabetes insipidus often have polydipsia and polyuria (see Chap. 49). They adapt well to their urinary-concentrating defect and these concerns are usually minimal. Acute tubular necrosis is frequent in the setting of acute lithium toxicity. Urinalysis may show moderate proteinuria, a few red and white blood cells, and granular casts. Renal function usually returns to baseline values after lithium concentrations are reduced to the therapeutic range. Nephrotoxicity may develop insidiously and be recognized by rising BUN or creatinine concentrations or the onset of hypertension. The urinalysis may show mild proteinuria and a few red and white blood cells.

Pathogenesis

Impaired ability to concentrate urine is due to a dose-related decrease in collecting duct response to antidiuretic hormone. This results from impaired formation of cellular cyclic adenosine monophosphate in response to antidiuretic hormone. Lithium-induced acute renal failure occurs predominantly during episodes of acute lithium intoxication.⁹² The pathogenesis includes dehydration secondary to nephrogenic diabetes insipidus, as well as direct proximal and distal tubular cell toxicity. Chronic tubulointerstitial nephritis attributed to lithium is evidenced by biopsy findings of interstitial fibrosis, focal tubular atrophy, and glomerular sclerosis.⁹² The pathogenesis may involve cumulative damage from lithium-induced acute tubular necrosis. Alternatively, cumulative direct lithium toxicity may occur since duration

of therapy has correlated with the decline in the GFR. Finally, some patients may have increased susceptibility to lithium toxicity. Although the reason for this is unknown, this could explain the difficulty in characterizing the nephrotoxic effects of chronic lithium therapy.

Risk Factors

The major risk factor for acute renal failure is an elevated lithium concentration, particularly in association with dehydration. Concomitant therapy with neuroleptic agents⁹² may contribute. Chronic nephrotoxicity may result from cumulative damage due to repeated episodes of acute renal injury.

Prevention

Prevention of acute and chronic toxicity includes maintaining lithium concentrations as low as therapeutically possible, avoiding dehydration, and monitoring renal function. It is unknown whether progression to severe renal failure can be prevented by stopping lithium use when mild renal insufficiency is first recognized. This poses a dilemma since lithium is highly effective for affective disorders and the risks and potential benefits of discontinuing such a beneficial drug need to be carefully considered. However, if lithium therapy is continued, renal function must be monitored and therapy discontinued if it continues to decline.

Management

Symptomatic polyuria and polydipsia can be reversed by discontinuation of lithium therapy or ameliorated with amiloride or NSAIDs during continued lithium therapy⁹³ (see Chap. 49). Acute renal failure is usually reversible with supportive care, including dialysis to reduce toxic blood lithium concentrations. Progressive chronic interstitial nephritis is treated by discontinuation of lithium therapy, adequate hydration, and avoidance of other nephrotoxic agents.

CYCLOSPORINE

Cyclosporine causes both acute hemodynamically-mediated renal failure and chronic interstitial nephritis after 6 to 12 months of therapy. This can result in irreversible renal insufficiency and biopsy findings of arteriolar hyalinosis, glomerular sclerosis, and a striped pattern of tubulointerstitial fibrosis.^{75,76} Chronic cyclosporine toxicity has become the more important of these two entities since reduced cyclosporine dosages and monitoring of drug concentrations has decreased acute toxicity. Chronic interstitial nephritis has been a major concern for therapy. The pathogenesis appears to involve sustained renal arteriolar endothelial cell injury causing chronic renal ischemia stemming from increased release of endothelin-1, decreased production of nitric acid, and increased expression of transforming growth factor- β .⁹⁴ Cyclosporine may also induce synthesis and accumulation of interstitial matrix, apparently due to increased activity of cytokines, peptide growth factors, or thromboxane. Nephrotoxicity has been dose dependent in some, but not all analyses, and occurs even following low-dose therapy. The risk of chronic interstitial kidney disease appears to be reduced in those receiving low-dose therapy.⁷⁶

ARISTOLOCHIC ACID (CHINESE HERB NEPHROPATHY)

Incidence

In early the early 1990s, several young women with rapidly progressive kidney failure leading to ESKD were reported in Brussels, Belgium.⁹⁵ The patients had strikingly similar pathologic findings of

interstitial fibrosis with tubular atrophy on renal biopsy. Further investigation revealed that all the women were patients of the same weight loss clinic and had received a weight loss treatment containing Chinese herbs. Subsequent analysis of the herb-based treatment demonstrated significant amounts of *Aristolochia fangchi* (Guang fang ji), known to contain aristolochic acid, the major alkaloid of the botanical species *Aristolochia*.⁹⁵ The term “Chinese herb nephropathy” was established and associated with aristolochic acid exposure after confirmatory renal biopsies were obtained from additional Belgian renal failure patients with prior exposure to the same Chinese herb-based treatment. Approximately 3% to 5% of patients who received the weight loss regimen developed disease, and numerous additional cases of nephropathy and ESKD associated with the use of *Aristolochia* species have been reported from around the globe.⁹⁵

Clinical Presentation

Patients with Chinese herb nephropathy typically present with mild to moderate hypertension, mild proteinuria, glucosuria, and subacute renal failure evidenced by elevated serum creatinine concentrations.^{95,96} Anemia and shrunken kidneys are also common on initial presentation. The overwhelming majority of cases reported to date have been in women. The main pathologic lesions observed in the kidneys of Chinese herb nephropathy patients are interstitial fibrosis with atrophy and destruction of tubules throughout the renal cortex. In general, the glomeruli are not affected. However, collapse of the capillaries, wrinkling of the basement membrane, and thickening of Bowman’s capsule and afferent arteriolar walls are evident. These findings may suggest that the primary lesion is located in the vessel walls, which leads to renal ischemia, tubular necrosis, interstitial nephritis, and ultimately the extensive interstitial fibrosis observed. Atypical urothelial cells are also apparent. Perhaps the most remarkable feature of Chinese herb nephropathy is the rate at which it progresses. In most instances nephropathy progresses to ESKD requiring dialysis or transplantation within 6 to 24 months of exposure to aristolochic acid.⁹⁶ Several cases of malignancy have also been reported in Chinese herb nephropathy patients. An alarming 40% to 46% prevalence of urothelial transitional cell carcinoma has been observed in nephroureterectomy specimens obtained from Belgian patients who underwent renal transplantation.^{97,98}

Pathogenesis

Although the precise mechanism of aristolochic acid–induced nephropathy and urothelial carcinoma is yet to be characterized, recent data indicate direct DNA damage may be the cause. The major components of aristolochic acid are metabolized to mutagenic compounds called aristolactam I and aristolactam II, respectively, which have been demonstrated to form DNA adducts in humans. Direct cellular toxicity is an unlikely mechanism of injury since the onset is delayed and progression of renal failure continues after aristolochic acid exposure.⁹⁶

Risk Factors

Possible risk factors for the development of aristolochic acid–induced toxicity remain speculative. Over 1,700 patients were exposed to aristolochic acid in the Belgian weight loss clinic, yet only 100 patients with nephropathy have been identified.⁹⁷ Furthermore, why is this type of nephropathy not prevalent in China and other Eastern cultures, where use of *Aristolochia* species is commonplace? Possible explanations may include differences in dose and duration of use, since batch-to-batch variability in the composition of herbs in the weight loss regimen was evident. The concurrent use of other medications may also contribute. Many individuals receiving the herbal regimen

were also prescribed the appetite stimulants dexfenfluramine and/or phentermine. It is possible the sympathomimetic agents induced renal ischemia which then potentiated the aristolochic acid toxicity. Lastly, interindividual differences in drug metabolism cannot be ruled out, since the aristolochic acid metabolites have been implicated in the development of toxicity.

Prevention

The primary means of preventing Chinese herb nephropathy appears to be limiting exposure to compounds containing aristolochic acids. Several countries, including the United Kingdom, Canada, Australia, and Germany have banned the use of *Aristolochia*-containing herbs.⁹⁵

PAPILLARY NECROSIS

Papillary necrosis is a form of chronic interstitial nephritis characterized by necrosis of the renal papillae, which are the regions of the kidney where the collecting ducts enter the renal pelvis. Analgesic use is the most common cause of papillary necrosis, accounting for 36% of all cases.⁹⁹

ANALGESIC NEPHROPATHY

Incidence

“Classic” analgesic nephropathy, characterized by chronic tubulointerstitial nephritis with papillary necrosis,¹⁰⁰ was initially reported in 1953 and was subsequently recognized as a worldwide public health concern. Chronic excessive consumption of combination analgesics, particularly those containing phenacetin, was believed to be the major cause and led to the removal of phenacetin and phenacetin mixtures from most world markets. It was subsequently thought, however, that abuse of contemporary analgesics, aspirin, acetaminophen, and NSAIDs, alone or in combinations, also results in analgesic nephropathy regardless of phenacetin content.^{100,101} The incidence of analgesic nephropathy reported among dialysis patients in the United States, Europe, and Australia was 0.8%, 3%, and 9%, respectively.¹⁰¹ This controversial issue is still being scrutinized, and a recent review of the subject suggests that currently there is insufficient evidence to associate nonphenacetin combined analgesics with nephropathy.¹⁰²

Clinical Presentation

Analgesic nephropathy evolves insidiously over years. It is difficult to recognize and may be underdiagnosed as a cause of ESKD. The most sensitive and specific diagnostic criteria include (1) a history of chronic daily habitual analgesic ingestion (classically this equated to daily use for at least 5 years); (2) intravenous pyelography, renal ultrasound, or renal computed tomography imaging, which reveals decreased renal mass and bumpy renal contours; and (3) papillary calcifications.^{101,103} Frequently, however, imaging only demonstrates chronic pyelonephritis and small kidneys with thin renal cortices and blunted calyces. Analgesics are taken most commonly for chronic headaches. Women are affected more than men. Upper gastrointestinal irritation from analgesics with blood loss leading to anemia has been characteristic. Hypertension and atherosclerotic cardiovascular disease are common. Early renal manifestations include impaired maximal urinary concentration, sterile pyuria, microscopic hematuria, and low levels of proteinuria. Urinary tract infection is common. Creatinine clearance declines slowly. Renal biopsy reveals nonspecific chronic interstitial inflammation and scarring. The incidence of lower urinary tract transitional cell carcinoma is increased with heavy phenacetin use.

Pathogenesis

Mechanisms of analgesic nephropathy remain unclear and difficult to study. This is due in part to a lack of diagnostic markers of evolving renal damage in vivo. In addition, animal models of analgesic nephropathy have been difficult to establish. The increased risk with analgesic mixtures containing phenacetin or acetaminophen and salicylates or NSAIDs is based on the following observations.^{103,101} The renal lesion begins in the papillary tip as a result of accumulated toxic metabolites, decreased blood flow, and impaired cellular energy production. The metabolism of phenacetin to acetaminophen, which is then oxidized to toxic free radicals that are concentrated in the papilla, appears to be the initiating factor that causes toxicity by mechanisms analogous to acetaminophen hepatotoxicity. Toxicity is prevented by availability of reduced glutathione. However, salicylates deplete renal glutathione and thereby facilitate phenacetin and acetaminophen toxicity. In addition, renal medullary and papillary ischemia may contribute due to decreased synthesis of vasodilatory renal prostaglandins by salicylates and NSAIDs.

Risk Factors

The epidemiology of analgesic use and analgesic nephropathy continues to evolve.^{102,104} The classic concept persists that risk for ESKD increases with cumulative consumption of combination analgesics, phenacetin, or acetaminophen and aspirin or NSAIDs.¹⁰¹ Caffeine contained in combination analgesics may increase risk, but the role is not clear.¹⁰³ Chronic use of therapeutic doses of NSAIDs alone, but not aspirin or salicylates alone, can cause analgesic nephropathy. Case-control studies have associated high-dose acetaminophen use alone with an increased risk for ESKD. However, these associations remain inconclusive due to study design flaws and the fact that acetaminophen has been the preferentially prescribed analgesic for patients with chronic kidney disease.¹⁰²

Prevention

Prevention has depended primarily on public health efforts to restrict the sale of phenacetin and combination analgesics. This has effectively reduced analgesic nephropathy in Australia and Europe. However, risk continues with continued availability of OTC combination analgesics containing aspirin, acetaminophen, and caffeine in the United States and throughout the world.

Individuals requiring chronic analgesic therapy may reduce risk by limiting the total dose, avoiding combined use of two or more analgesics, and maintaining good hydration to prevent renal ischemia and decrease the papillary concentration of toxic substances. Acetaminophen remains the preferred nonopioid analgesic for renal-insufficient patients.

Management

Treatment of established nephrotoxicity requires cessation of analgesic consumption. This can prevent progression and may improve renal function. Persistent surreptitious analgesic abuse should be considered if renal function continues to decline. Patients should also be monitored for associated transitional cell carcinoma of the renal pelvis, calyces, ureters, and bladder, which may present years after analgesic nephropathy is diagnosed.

RENAL VASCULITIS, THROMBOSIS, AND CHOLESTEROL EMBOLI

Systemic polyarteritis nodosa, a vasculitis with involvement of small- and medium-sized renal arteries, has been described following

methamphetamine abuse.¹⁰⁵ Patients may have hematuria, proteinuria, renal insufficiency, and hypertension. Renal and visceral vascular aneurysms can be demonstrated by angiography. The pathogenesis may be a toxic reaction to methamphetamine or the result of associated hepatitis B infection.

Numerous medications, including mitomycin C, oral contraceptive agents, cyclosporine, tacrolimus, muromonab-CD3, antineoplastic agents, interferon, ticlopidine, clopidogrel, and quinine can cause a thrombotic microangiopathy (hemolytic uremic syndrome or thrombotic thrombocytopenic purpura) manifested by endothelial proliferation and thrombus formation in the renal and central nervous system vasculature.^{106,107} The association with mitomycin C is notable since the pathogenesis appears to be a direct, dose-related toxic effect, rarely occurring in patients who receive doses <30 mg/m². Nephrotoxicity has occurred following chemotherapy with mitomycin C alone or with 5-fluorouracil, cisplatin, bleomycin, a vinca alkaloid, and tamoxifen.¹⁰⁶ Microangiopathic hemolytic anemia and thrombocytopenia are usually present. Systemic endothelial damage with multisystem organ failure has occurred. Renal failure can be severe and irreversible, although corticosteroids, antiplatelet agents, vincristine, plasma exchange, plasmapheresis, and high-dose intravenous IgG have each induced clinical improvement. Gemcitabine is a pyrimidine analog used for the treatment of various solid tumors which was recently associated with the development of hemolytic uremic syndrome, with an estimated incidence of 0.015%.⁵⁰ The drugs hydralazine, propylthiouracil, allopurinol, and penicillamine have been implicated in the development of antineutrophil cytoplasmic antibody (ANCA)-positive vasculitis.¹⁰⁸ Patients exposed to these drugs who subsequently develop ANCA-positive vasculitis appear to exhibit high titers of antimyeloperoxidase antibodies.

Anticoagulants and thrombolytics, particularly warfarin, can systemically embolize cholesterol particles from aortic atherosclerotic plaques to small arteries and arterioles, including renal arterioles. These agents remove or prevent thrombus formation over ulcerative plaques, causing emboli.¹⁰⁹ Cholesterol emboli induce an inflammatory obliterative vascular response, causing renal ischemia. Purple discoloration of the toes and mottled skin over the legs are important clinical clues.

PSEUDO-RENAL FAILURE

Pseudo-renal failure occurs when either the blood urea nitrogen (BUN) or creatinine concentration rises suggesting a decrease in renal function, despite maintenance of the GFR. The BUN concentration commonly increases without an increase in creatinine concentration during corticosteroid or tetracycline therapy. These drugs cause protein catabolism and thereby increase ureagenesis and the BUN concentration as the result of tissue breakdown. The GFR is unchanged and accurately reflected by the creatinine clearance and creatinine concentration.

Similarly, the serum creatinine concentration may rise while the BUN concentration remains unchanged by either of two mechanisms. First, drugs, including trimethoprim, cimetidine, or pyrimethamine, competitively inhibit secretion of creatinine into the proximal tubular lumen (see Chap. 41).¹¹⁰ This effect is minimal during therapy in patients with normal renal function in whom the serum creatinine concentration usually remains in the normal range since tubular secretion of creatinine contributes only 5% to 10% to creatinine excretion. In contrast, in patients with CKD, the rise in serum creatinine is generally greater since tubular secretion of creatinine contributes a proportionately greater amount to urinary creatinine excretion. Ranitidine and famotidine do not inhibit tubular secretion of creatinine

at therapeutic doses.¹¹⁰ Competitive inhibition of creatinine secretion has been considered useful in the evaluation of renal function since creatinine clearance usually overestimates true GFR in the presence of kidney disease. Administration of cimetidine during urine collection decreases creatinine secretion and provides a creatinine clearance value that more closely approximates true glomerular filtration, particularly in patients with renal disease (see Chap. 41). Second, several drugs, particularly cefoxitin and other cephalosporin antibiotics, can increase the serum creatinine concentration by direct interference with the enzymatic measurement of creatinine by the Jaffé method. The incidence of this effect is unknown, but it is uncommon; it is most prevalent among patients with decreased renal function. These drugs do not appear to interfere with determination of creatinine clearance.

COSTS OF DRUG-INDUCED KIDNEY DISEASE

The pharmacoeconomics of drug-induced kidney disease have not been well defined. An analysis of aminoglycoside therapy in the acute care environment for 1984 to 1985 revealed 7.3% of patients experienced nephrotoxicity. The mean additional cost for each episode of toxicity (in 1984 dollars) was \$2501. The average additional cost of toxicity for each individual treated with aminoglycosides was \$183.¹¹¹ Individualized pharmacokinetic monitoring efforts were recently reported to decrease costs associated with aminoglycoside nephrotoxicity by more than \$900 per patient.³⁷ Outpatient care costs of NSAID toxicity have also been evaluated. Costs for hospital care for NSAID-induced acute hemodynamically-mediated renal failure and interstitial nephritis combined have been estimated at \$990 million per year.¹¹² The risk of ESKD stemming from immunosuppressant-induced nephrotoxicity contributes substantially to the cost of heart transplantation.⁷⁵ The estimated cost per transplant patient was \$6700 within 5 years, increasing to \$14,200 within 8 years post-transplantation. Finally, patients who develop ESKD require dialysis, which typically costs more than \$50,000 per year.

ABBREVIATIONS

ACEI: angiotensin-converting enzyme inhibitor
 AIDS: acquired immunodeficiency syndrome
 AIN: allergic interstitial nephritis
 ALDH: aldehyde dehydrogenase
 ANCA: antineutrophil cytoplasmic antibody
 ARB: angiotensin II receptor blocker
 ARF: acute renal failure
 ATN: acute tubular necrosis
 BUN: blood urea nitrogen
 CKD: chronic kidney disease
 CMV: cytomegalovirus
 COX: cyclooxygenase
 CYP 450: cytochrome P450
 DIN: drug-induced nephrotoxicity
 FSGS: focal segmental glomerulosclerosis
 GFR: glomerular filtration rate
 HIV: human immunodeficiency virus
 KIM-1: kidney injury molecule-1
 NSAID: nonsteroidal anti-inflammatory drug
 OAT1: organic anion transporter 1
 OCT1: organic cation transporter 1
 OTC: over-the-counter
 PGE₂: prostaglandin E₂

P-gp: P-glycoprotein
 S_{cr}: serum creatinine

GLOMERULONEPHRITIS

Alan H. Lau

Learning Objectives and other resources can be found at www.pharmacotherapyonline.com.

KEY CONCEPTS

- 1 Glomerulonephritis is a collection of glomerular diseases mediated by different immunologic pathogenic mechanisms, resulting in varied clinical presentation and therapeutic outcomes.
- 2 The signs and symptoms associated with glomerulonephritis can be nephritic in nature, characterized by inflammatory injury, or nephrotic in nature, characterized by proteinuria.
- 3 In the absence of specific and effective therapy for many types of glomerulonephritis, supportive treatments for edema, hypertension, hyperlipidemia, and intravascular thrombosis play important roles in alleviating the complications associated with the disease.
- 4 To maximize therapeutic benefits and minimize drug-induced complications, patients have to be monitored closely to delineate their therapeutic responses as well as the development of any treatment-induced toxicities.
- 5 Among all the types of glomerulonephritis, minimal-change nephropathy is most responsive to treatment. Steroids can induce good responses in most patients during initial treatment as well as relapse.
- 6 Due to the lack of consistently effective treatment for primary focal segmental glomerular sclerosis, angiotensin-converting enzyme inhibitors or angiotensin receptor blockers are commonly used for patients with mild disease to control symptoms. Steroids and immunosuppressive agents are used only for patients with severe disease.
- 7 The optimal treatment for lupus nephritis depends on the underlying lesion and disease activity, as well as the severity and duration of the clinical presentation.
- 8 The treatment of poststreptococcal glomerulonephritis is mainly supportive and symptomatic. Antibiotic therapy does not prevent subsequent diseases, but may reduce the severity.

Clinical and pathologic findings associated with primary glomerular injury were first reported in the nineteenth century. The natural history of many glomerular diseases was not described until the 1950s, when percutaneous diagnostic kidney biopsy became available. The development of immunofluorescence microscopy and advances in immunopathology in the 1960s and 1970s further expanded our understanding of the antibody-related immune mechanisms that are responsible for the different types of glomerular injury. Recent advances in cell and molecular biology afford us a plethora of new information concerning the disease processes. However, the precise pathogenetic mechanisms for many glomerular diseases remain unknown and the available therapeutic regimens are still far from optimal. In the United States in 2001, glomerulonephritis was the third most common cause of end-stage kidney disease (ESKD), which is also referred to as end-stage renal disease (ESRD), accounting for about 15% of all the living ESKD patients. About 8,000 patients (8.3% of all patients) develop ESKD due to glomerulonephritis each year.¹

This chapter provides an overview of the pathophysiologic mechanisms of glomerular injury and the clinical presentations of glomerulonephritis. The treatment approach for the common forms of glomerulonephritis are also discussed. Although diabetes mellitus and amyloidosis are important secondary causes of glomerular diseases, the scope of this chapter is limited to the primary causes of glomerulonephritis.

PATHOPHYSIOLOGY

NORMAL ANATOMY AND FUNCTION

The glomerulus, which is enclosed within the Bowman's capsule, consists of two important components: the filtration barrier and the mesangium (Fig. 47-1). Blood flow in the glomerular capillary bed is supplied by the afferent arteriole, while the efferent arterioles channel the flow leaving the glomerular tuft. The capillary wall, which serves as a filtration barrier, consists of three well-defined layers: fenestrated endothelium, glomerular basement membrane (GBM), and epithelial cells. The epithelial cells, also known as podocytes, have specialized foot processes embedded in the outer layer of the GBM. It is across this barrier that fluid flows and ultimately forms ultrafiltrate. Under normal conditions, the GBM appears to function as a compact hydrated gel of matrix proteins with a pore-like structure. The mesangium provides support for the glomerular capillaries and also modulates blood flow through the capillaries. It consists of mesangial cells embedded in an extracellular matrix.

The unique capillary bed of the glomerulus allows small non-protein plasma constituents up to the size of inulin, which has a molecular weight of 5,200 daltons, to pass freely while excluding macromolecules equal to or larger than albumin, which has a molecular weight of 69,000 daltons (Fig. 47-2). Both the size and charge

FIGURE 47-1. Microanatomy of the glomerulus.

of the molecules affect the ease of passage through the glomerular membrane. Fixed, negatively charged sites are found within the glomeruli in all three layers of the capillary wall: the endothelium, the epithelium, and the GBM. Biochemical and cytochemical studies show that the epithelial cell coat is composed of a negatively charged glycoprotein (podocalyxin), made up largely of sialic acid. The GBM contains an abundance of negatively charged sulfated glycosaminoglycans that can affect the passage of ionic molecules through the capillary wall. The movement of negatively charged molecules is restricted more than that of neutral or positively charged molecules. Different glomerular diseases affect this size- and charge-selective barrier to different extents, and glomerulopathies therefore present with varied clinical features and solute-excretion patterns.

Aside from being a barrier for solute excretion, some of the glomerular cells, such as the epithelial cells, have phagocytic function that can remove macromolecules trapped within the filtration barrier. They are also capable of synthesizing the GBM. In contrast, the mesangial cells regulate glomerular hemodynamics by responding to angiotensin II and producing prostaglandins. They also synthesize and respond to various cytokines and thus play a key role in immune-mediated glomerular diseases. There are also resident phagocytes in the mesangium. They remove macromolecules trapped in the basement membrane and move them into the urinary space. These phagocytes are involved in the development of both immune and nonimmune glomerular injury.

FIGURE 47-2. Movement of various macromolecules across the glomerular capillary. The fractional clearance of each macromolecule decreases as molecular weight (MW) increases. The disproportionately greater restriction of albumin movement indicates importance of factors other than size, such as negative charge of albumin. (Adapted from Hutt MP, Kelleher SP. Proteinuria and the nephrotic syndrome. In: Schrier RW, ed. Renal and Electrolyte Disorders, 3rd ed. Boston, Little, Brown, 1986: p. 568.)

ETIOLOGY

The etiology of most human glomerulonephritides is unknown. However, humoral and cellular immunologic mechanisms are implicated in the pathogenesis. Abnormalities in coagulation and metabolism, as well as hereditary and vascular diseases, also contribute to glomerular damage. The histopathologic manifestations vary substantially among the different types of glomerulonephritis. An overview of the primary pathogenetic mechanisms is presented in this section, and specific abnormalities for each of the primary types of glomerulonephritis are presented in subsequent sections.

PATHOGENESIS OF GLOMERULAR INJURY AND PATHOLOGIC MANIFESTATIONS

1 The glomerular lesion may be diffuse (involving all glomeruli), focal (involving some but not all glomeruli), or segmental, also known as local (involving part of the individual glomerulus). The pathologic manifestations may also be described as proliferative (overgrowth of epithelium, endothelium, or mesangium), membranous (thickening of GBM), and/or sclerotic.

The glomerular capillary wall is particularly susceptible to immune-mediated injury. Antigen and antibody tend to localize in the glomerulus, probably because of its high blood flow and capillary hydrostatic pressure. Parenchymal damage can be induced as a result of humoral- and cell-mediated immune reactions (Table 47-1). Antibodies and sensitized T lymphocytes are the primary mediators of glomerular injury.^{2,3}

Production of antibodies to endogenous or exogenous antigens that are recognized as foreign by the host is the first step in humoral immunologic damage to the glomerulus. Endogenous antigens may be intrinsic glomerular antigens, such as Heymann's antigen on the epithelial cell or Goodpasture's antigen on the GBM, or previously sequestered antigens, such as DNA or thyroglobulin. Exogenous antigens are most often viral, bacterial, parasitic, or fungal in origin (Table 47-2). Antineutrophil cytoplasmic autoantibodies (ANCA), autoantibodies that react to the cytoplasmic components of neutrophils and monocytes, have been found in patients with idiopathic crescentic glomerulonephritis and also in the accompanying vasculitis.

TABLE 47-1. Immunologic Mechanisms of Glomerular Injury

| |

| Circulating immune complexes |
| In situ antigen-antibody interaction |
| Intrinsic glomerular antigen; e.g., GBM antigens |
| Exogenous planted antigens |
| Cell-mediated mechanism |

GBM, glomerular basement membrane.

Classically, it was considered that complexes of antigens and antibodies were formed in the circulation and then passively entrapped in the glomerular capillary or mesangium. However, experimental data show that antibodies may combine with endogenous glomerular antigens or exogenous antigens entrapped in the glomerulus to form complexes locally, or in situ.³ Regardless of the mechanism of formation, these antigen-antibody complexes are often localized along the capillary loop or the mesangium (see Fig. 47-1) and can be detected by immunofluorescence microscopy. The type and extent of glomerular damage is dependent on the location of the immune complex formation and the rate at which it is removed. Impaired removal facilitates the growth of the complex and thus increases the likelihood of glomerular damage.

Subsequent to antigen-antibody formation, a series of biologic events is triggered that ultimately leads to glomerular injury. Both inflammatory and noninflammatory lesions can be induced by antibody deposition. Noninflammatory lesions can be a result of noncomplement-fixing antibody binding to the glomerular epithelial cell (mechanism 1), or activation of the complement system to form the C5b-9 membrane attack complex (mechanism 2).³ Both mechanisms can damage the glomerular epithelial cell and result in capillary wall injury and proteinuria (Fig. 47-3). Inflammatory lesions are induced by glomerular infiltration of circulating inflammatory cells such as neutrophils, monocytes/macrophages, and platelets (mechanism 3), or proliferation of resident glomerular mesangial cells (mechanism 4), resulting in GBM damage.³ The migration of neutrophils and monocytes to the glomerular tufts is promoted by chemoattractants such as complement fragments (C3a and C5a),

TABLE 47-2. Antigens Possibly Involved in Immune-Mediated Glomerular Injury

| Source of Antigen | Clinical Example |
|--|---|
| Endogenous antigens | |
| Released sequestered cellular antigens | DNA, thyroglobulin |
| Endogenous antigens modified by exogenous source | IgG modified by streptococcal neuraminidase |
| Tumor antigens | CEA in bronchial and other solid tumors |
| Intrinsic glomerular antigens | Goodpasture's syndrome |
| Neutrophil granule constituents | ANCA-associated glomerulonephritis |
| Exogenous | |
| Viral | Hepatitis B |
| Bacterial | Streptococcal organisms |
| Parasitic | Malaria |
| Fungal | Candida |

CEA, carcinoembryonic antigen; ANCA, antineutrophil cytoplasmic antibody.

platelet-activating factor, interleukin-8, and monocyte chemoattractic protein-1.⁴ Various cytokines, chemokines, and growth factors are then released to participate in the inflammatory process.²

T cells sensitized to glomerular antigen, macrophages, and resident mesangial cells are important participants in cell-mediated injury. Sensitized T cells can cause glomerular hypercellularity in the absence of antibody deposition.²⁻⁴ Cytotoxic T cells may bind with the target cells and destroy them. Alternatively, a delayed-type hypersensitivity reaction may be initiated by activated T cells through the release of lymphokines, to attract, activate, and transform monocytes into macrophages.³ These humoral and cellular mediators, in conjunction with a host of toxic molecular entities including reactive oxygen species, proteinases, eicosanoids, and procoagulants, which are secreted by neutrophils, macrophages, platelets, and resident glomerular cells can alter the permeability, blood flow, and function of the

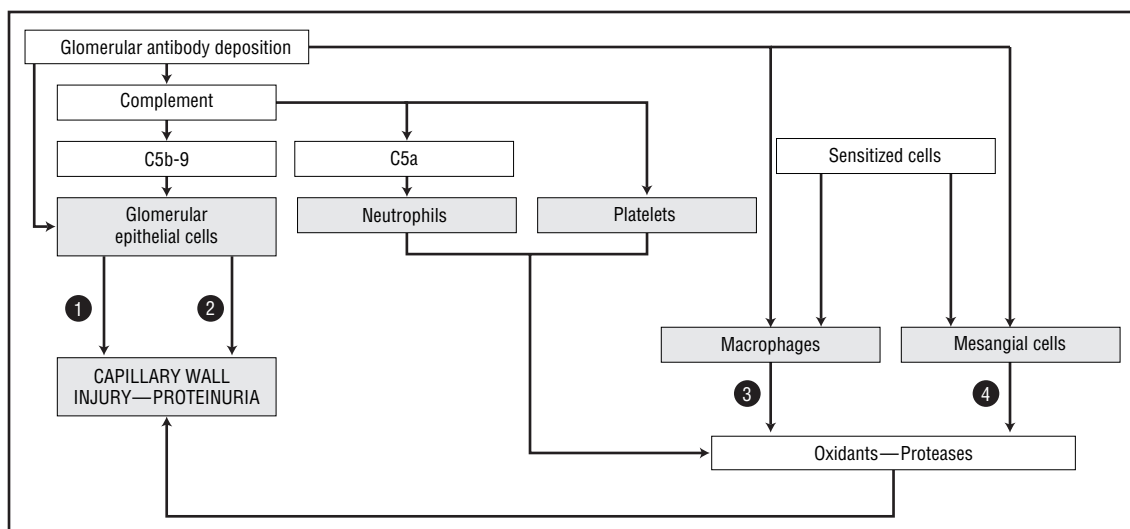

FIGURE 47-3. The major pathways of immune-mediated glomerular injury. Mechanisms 1 and 2 primarily act on the glomerular epithelial cell and result in noninflammatory lesions. Mechanisms 3 and 4 involve participation of effector cells and result in glomerular inflammation and structural damage. (Adapted from Couser.³)

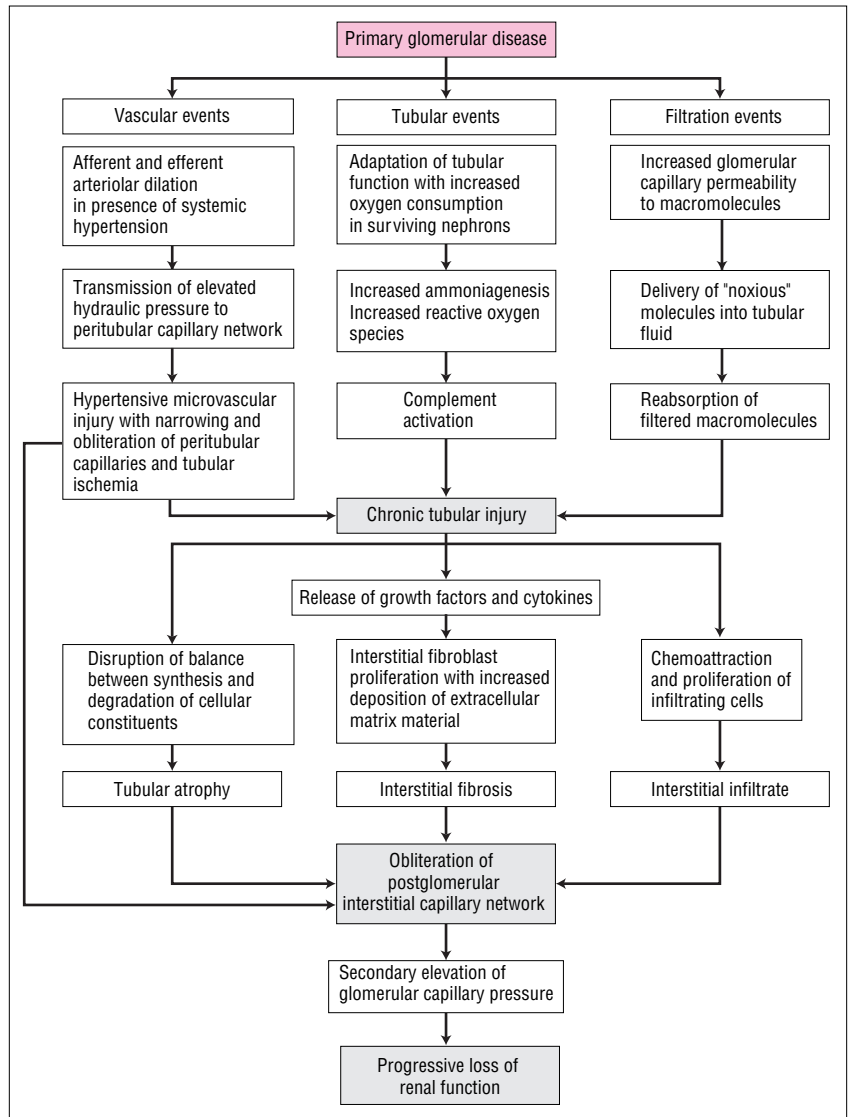

FIGURE 47-4. Proposed sequence of events leading from primary glomerular disease to progressive loss of renal function through tubulointerstitial injury. (Modified from Ong et al,⁷ with permission.)

glomeruli. Vascular constriction and occlusion follow and result in the eventual destruction of the glomeruli.

Acute forms of glomerular injury may frequently lead to chronic and persistent renal dysfunction, even though the original immune factors that induce glomerular injury have resolved. Progression to ESKD may be inevitable. Experimental and clinical investigations suggest that a variety of factors may participate in the progression of renal injury. These factors include systemic and glomerular hypertension;⁵ high dietary protein intake; proteinuria;^{6–8} glomerular hypertrophy; hyperlipidemia;⁹ activation of the coagulation system;⁵ abnormalities of calcium and phosphorus balance;⁵ and tubulointerstitial injury.⁷ Tubulointerstitial injury is an important factor in the progression of glomerular disease (Fig. 47-4). Much interest has been focused on the role of proteinuria in causing glomerular and tubulointerstitial damage. The degree of proteinuria not only is an index of the severity of glomerular disease, but also provides a measure of the rate of progression of renal injury. Heavy proteinuria is an indicator of poor prognosis in various glomerular diseases.⁸ Although there is no direct evidence to substantiate that proteinuria per se results in progression of renal impairment,^{6,7} there are many possible mechanisms through which proteinuria directly or indirectly causes renal damage.

Proximal tubular uptake and metabolism of albumin may lead to unregulated intracellular release of potentially toxic fatty acids, which may provoke secretion of a lipid macrophage chemotactic factor, resulting in interstitial inflammation.⁸ Tubular hypermetabolism may lead to increased production of reactive oxygen species and renal ammoniogenesis, resulting in complement activation and consequent tubular injury.⁷ Proteinuria is also accompanied by an increased flux of macromolecules across the mesangium. The mesangial overload may then lead to structural damage. The passage of serum components, such as complement, across the GBM may have a pathophysiologic effect on the glomerular epithelial cells and alter the integrity of the glomerular filtration barrier.⁶ The damaging effects of macromolecules other than albumin, such as immunoglobulins, lipoproteins, transferrin, and complement, remain to be characterized.⁷

CLINICAL PRESENTATION

2 Patients with glomerular disease may present with a nephritic or a nephrotic syndrome (Table 47-3). Nephritic syndrome reflects glomerular inflammation and frequently results in hematuria. White

TABLE 47–3. Tendencies of Glomerular Diseases to Manifest Nephrotic and Nephritic Features

cells and cellular and granular casts are commonly found in the urine. In contrast, nephrotic syndrome reflects noninflammatory injury to the glomerular structures, and results in few cells or cellular casts in the urine. Initially, there may be limited or no reduction in renal excretory function.

Hematuria occurs when red blood cells leak through the openings of the GBM. The presence of red cell casts is highly indicative of glomerulonephritis or vasculitis. The presence of dysmorphic red blood cells in the urine is suggestive of glomerular disease. The red blood cells are damaged as they pass through the openings in the GBM or the cells may sustain osmotic injury as they travel through the different osmotic environments within the lumen of the kidney tubules.

The presence of proteinuria indicates a defect of the size- and/or charge-selective barriers within the GBM. Normal urinary protein excretion is between 40 and 80 mg/day, with a maximum of 150 mg. Fewer than 20 mg of the excreted proteins are albumin. Most of the albumin that enters the glomerular filtrate is either reabsorbed or catabolized by the tubular epithelium. The dipsticks that are commonly used to identify proteinuria detect only albumin; they become positive when protein excretion is more than 300 to 500 mg/day. They are therefore unable to detect the early stages of renal injury secondary to diabetes mellitus or hypertension, which often result in microalbuminuria with urinary albumin excretion ranges between 30 and 300 mg/day. Chemstrip Micral-Test II (Boehringer Mannheim Diagnostics), a simple immunoassay on a dipstick, permits specific and semiquantitative determination of urinary albumin concentrations at five levels: 0, 10, 20, 50, and 100 mg/L. It shows no cross-reactivity with other human proteins that may possibly be present in urine. The test may be used reliably for a urine specimen that has been stored for up to 7 days at 4°C (39.2°F), and even in the presence of bacterial contamination. Another qualitative test, Micro-Bumintest (Ames), registers a positive reading when the urine albumin concentration is greater than 40 mg/L.¹⁰

Hypertension is a common feature in patients with glomerular diseases. Expansion of plasma volume as a result of renal salt retention is frequently the cause of hypertension, especially during acute disease. In contrast, increased activity of vasoconstrictors such as angiotensin II is often the cause in patients with chronic glomerular diseases. Scarring of the glomerulus resulting in regional ischemia is thought to be responsible for the hypertension. Activation of the sympathetic nervous system and the release of vasoconstrictor substances may also contribute.

TABLE 47–4. Evaluation of Patients Suspected of Having Glomerular Disease

Medical history

To identify symptoms of medical conditions that may cause glomerular disease:

- Diabetes mellitus
- Amyloidosis
- Systemic lupus erythematosus
- Other familial conditions associated with renal disease

To identify symptoms suggestive of nephrotic syndrome:

- Reduced appetite
- Fatigue
- Weight gain
- Edema

Medication, environmental and occupational histories

To identify possible exposure to potentially nephrotoxic drugs, toxins, or chemicals

Physical examination

To identify signs and symptoms associated with systemic diseases

- Hypertension
- Rash
- Arthritis
- Retinopathy
- Neuropathy
- Lymphadenopathy
- Hepatomegaly
- Malignancy

Laboratory evaluation

Urinalysis

- To determine nephrotic nature of glomerular disease:
 - Heavy proteinuria (usually >3 g/day), or
 - Lipiduria, to determine nephritic nature of glomerular disease
- Hematuria
- Pyuria
- Cellular, granular casts

Glomerular filtration rate

- To determine extent of glomerular damage

Other tests

- To identify type and etiology of glomerular disease
- Serum complement concentration
- Antinuclear and anti-DNA antibodies
- Antistreptolysin antibodies
- Circulating anti-GBM antibodies
- Cryoglobulins

Percutaneous renal biopsy

- To provide definitive diagnosis of glomerular disease

GBM, glomerular basement membrane.

NEPHRITIC SYNDROME

Glomerular bleeding resulting in hematuria is a typical finding in nephritic syndrome. Dysmorphic red cells, especially acanthocytes, are a sensitive and specific marker of glomerular bleeding. The presence of pus and cellular and granular casts in the urine is common. The extent of proteinuria is variable, typically about 1 to 3 g/day, but it may be in the nephrotic range (>3 g/day). Patients with severe nephritic glomerular injury have renal function impairment because of the reduced glomerular surface area available for filtration. The latter is a result of constriction of the capillary lumen by proliferating mesangial cells or inflammatory cells. As renal function declines, hypertension and edema may develop or pre-existing conditions may worsen.

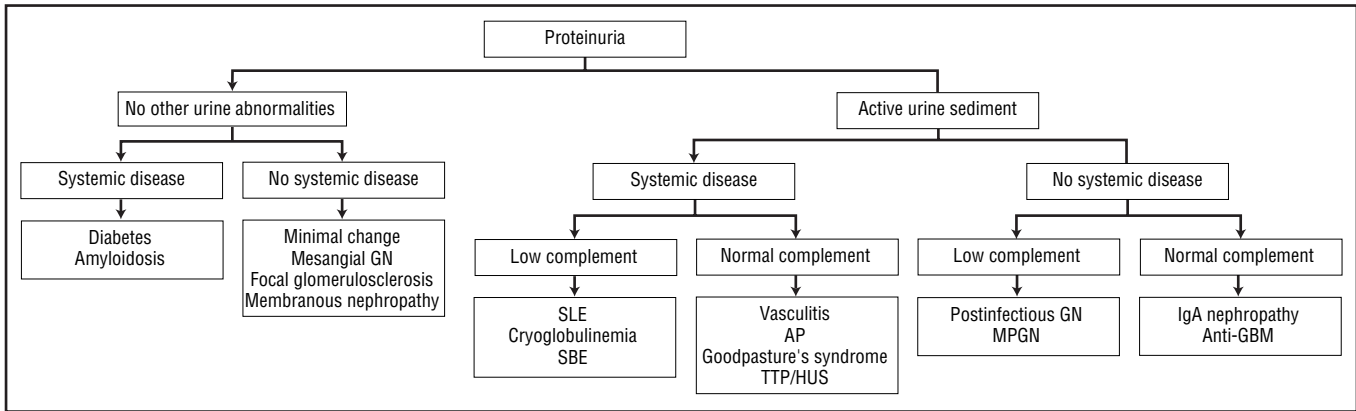

FIGURE 47–5. Clinical presentations of glomerulonephritis. AP, anaphylactoid purpura; GBM, glomerular basement membrane; GN, glomerulonephritis; HUS, hemolytic uremic syndrome; MPGN, membranoproliferative glomerulonephritis; SBE, subacute bacterial endocarditis; SLE, systemic lupus erythematosus; TTP, thrombotic thrombocytopenic purpura.

NEPHROTIC SYNDROME

Nephrotic syndrome is characterized by proteinuria greater than 3.5 g/day per 1.73 m², hypoproteinemia, edema, and hyperlipidemia. A hypercoagulable state may also be present in some patients. The syndrome may be the result of primary diseases of the glomerulus, or be associated with systemic diseases such as diabetes mellitus, lupus, amyloidosis, and preeclampsia. Hypoproteinemia, especially hypoalbuminemia, results from increased urinary loss of albumin and an increased rate of catabolism of filtered albumin by proximal tubular cells. The compensatory increase in hepatic synthesis of albumin is insufficient to replenish the protein loss, probably because of malnutrition.

Edema formation in patients with nephrotic syndrome was traditionally thought to be driven by the reduced plasma oncotic pressure secondary to hypoalbuminemia. If the oncotic pressure is low, the movement of fluid from the vascular space to the interstitial compartment results in a reduction of the plasma volume, which can trigger compensatory renal sodium and water retention through the activation of the renin-angiotensin-aldosterone axis, vasopressin, and the sympathetic nervous system (the “underfill” mechanism). However, experimental data suggest that the plasma volume is actually normal or elevated. Hypoalbuminemia may not cause edema until the serum albumin concentration is less than 2 g/dL. In addition, the transcapillary oncotic pressure gradient is not as high as previously thought because increased lymphatic flow reduces the interstitial oncotic pressure by removing protein and fluid from the interstitium, thereby reducing the transcapillary oncotic pressure gradient.¹¹ Thus fluid retention is likely mediated by a primary increase in sodium reabsorption at the distal nephron, which is probably caused by tubular resistance to the action of atrial natriuretic peptide (the “overflow” mechanism).¹² It is likely that both mechanisms may contribute to nephrotic edema in different patients.¹²

Although albuminuria below the nephrotic range appears to have a minor influence on serum cholesterol in patients with primary glomerular disease, daily urinary albumin excretion of greater than 3 g is associated with a significant increase in serum cholesterol concentrations.¹³ Hyperlipidemia in nephrotic syndrome is characterized by elevated serum total cholesterol and triglyceride concentrations, with increased very-low-density lipoprotein (VLDL) and low-density lipoprotein (LDL) cholesterol concentrations. Although high-density lipoprotein (HDL) cholesterol concentrations are nor-

mally distributed, there is a maldistribution of HDL subtypes, with a reduction in HDL₂ and an increase in HDL₃.^{14,15} Furthermore, lipoprotein (a) levels may also be increased. Oval fat bodies and fatty casts are also found in the urine. The mechanisms for nephrotic hyperlipidemia are not well defined. A reduction in plasma oncotic pressure as a result of hypoalbuminemia may stimulate hepatic synthesis of lipids and lipoproteins. The increased VLDL production and increased liver cholesterol synthesis along with a decrease in LDL receptor activity can then lead to an increase in LDL cholesterol concentrations. In addition, reduced serum albumin or the loss of a liporegulatory substance may result in reduced VLDL clearance.^{14,15} Nephrotic patients with hyperlipidemia, especially those with concomitant hypertension, are presumed to have an increased risk for atherosclerotic vascular disease. Hyperlipidemia also promotes the progression of glomerular injury, as evidenced by glomerulosclerosis, mesangial expansion, and hyalinosis.^{9,14}

Many patients with nephrotic syndrome have a hypercoagulable state caused by defects of several control proteins in the coagulation cascade. The concentration of the coagulation inhibitor antithrombin III is reduced because of increased loss in the urine. A reduced amount of the coagulation inhibitors proteins C and S, along with increased concentrations of factors V and VIII, increased fibrinogen concentrations, and abnormal platelet function, may also contribute to the hypercoagulable state. The net result of these alterations in coagulation is an increased risk for arterial and venous thrombosis, especially in the deep veins and renal veins. As many as 25% of patients with membranous nephropathy may have renal vein thrombosis.

DIAGNOSIS

Patients with suspected glomerular disease should have an extensive medical history obtained to identify potential systemic causes (Table 47–4). Medication, environmental, and occupational histories may also help identify possible exposure to potentially nephrotoxic agents. A carefully conducted physical examination and laboratory evaluation may reveal the presence of systemic diseases (Fig. 47–5; Table 47–5) that may contribute to the development of glomerular disease. In addition, the patient’s age, gender, and ethnic background may be helpful in pinpointing the specific type of glomerular disease. Many of the conditions are more prevalent in certain age groups, although they

TABLE 47-5. Categorization of Renal Diseases Based on Serum Complement Levels

| Low Serum Complement Level | Normal Serum Complement Level |
|--|---|
| Systemic diseases Systemic lupus erythematosus Infection-related glomerulonephritis Subacute bacterial endocarditis "Shunt" nephritis Cryoglobulinemia | Systemic diseases Vasculitis group Polyarteritis nodosa Hypersensitivity vasculitis Wegener's granulomatosis Henoch-Schönlein purpura Goodpasture's syndrome |

may occur at any age. Figure 47-6 indicates the distribution of different causes of nephrotic-range proteinuria relative to the age of patients who had undergone renal biopsy.

Laboratory evaluation such as urinalysis can help differentiate the nephrotic or nephritic nature of the disease. The glomerular filtration rate (GFR) may be used to determine the extent of glomerular damage. In the early stages of the disease, the GFR may remain normal. Initial injury to the glomerulus primarily lowers the permeability coefficient (K_f) of the GBM, by reducing the surface area available for filtration and/or the unit permeability of the membrane. The reduced permeability is compensated by an elevation in the glomerular capillary hydrostatic pressure through afferent arteriolar dilation and efferent arteriolar constriction. Extensive glomerular damage may

FIGURE 47-6. Frequency of various causes for nephrotic-range proteinuria (>3 g/day) relative to age in patients undergoing renal biopsy evaluation at the University of North Carolina Nephropathology Laboratory. The full vertical height of the bar represents 100% of the patients. The patients with proliferative glomerulonephritis generally presented with nephritic features in addition to the proteinuria, and included patients with lupus nephritis, IgA nephropathy, and postinfectious glomerulonephritis. (Used with permission from Jennette et al.⁴⁰)

therefore be present before a substantial reduction of total GFR is evident (Table 47-5).

Although the cause of glomerular disease may be established from clinical and laboratory evaluation, sometimes percutaneous renal biopsy may be needed to provide a definitive diagnosis.

▶ TREATMENT: Glomerulonephritis

■ GENERAL APPROACH TO TREATMENT

The management of patients with glomerulonephritis involves specific pharmacologic therapy for the glomerular disease, and supportive measures to prevent and/or treat the pathophysiologic sequelae, namely hypertension, edema, and progression of renal disease. In patients with nephrotic syndrome, supportive therapy should also address the management of extrarenal complications of heavy proteinuria, namely hypoalbuminemia, hyperlipidemia, and thromboembolism. Patients with significant proteinuria tend to have a more rapid decline of renal function. Thus reduction of proteinuria becomes critical in delaying the rate of progression towards end-stage renal disease.

Immunosuppressive agents, alone or in combination, are commonly used to alter the immune processes that are responsible for the glomerulonephritides. Corticosteroids, in addition to their immunosuppressive effect, also possess anti-inflammatory activities. They reduce the production and/or release of many substances that mediate the inflammatory process, such as prostaglandins, leukotrienes, platelet-activating factors, tumor necrosis factors (TNFs), and interleukin-1 (IL-1). Movement of leukocytes and macrophages to the site of inflammation is also inhibited. The immunosuppressive effects of corticosteroids are mediated through the inhibition of the release

of IL-1 and TNF by activated macrophages, and IL-2 by activated T cells. In addition, the actions of migration-inhibiting factor and γ -interferon are inhibited. Processing of antigens is thus affected by the presence of corticosteroids. Cytotoxic agents, such as cyclophosphamide, chlorambucil, or azathioprine, are used occasionally to treat glomerular diseases. Cyclosporine is also used to treat certain types of glomerulonephritis. It can reduce lymphokine production by activated T lymphocytes and it can decrease proteinuria by improving the permselectivity of the GBM.

Because many immune factors are implicated in the pathogenesis of glomerulonephritis, plasmapheresis may be used to remove these mediators. During the procedure, whole blood is removed from the body and centrifugation is used to separate the cellular elements from the plasma. The cells are then infused back to the patient after resuspension in saline or plasma substitute. The plasma proteins, presumably including the pathogenic immune factors, are thereby removed from the patient.

Various new experimental agents, such as etanercept and alemtuzumab, have also been used to treat glomerulonephritis.¹⁶ Sufficient experiences are not yet available to determine their role in therapy. However, as we acquire further understanding of the pathogenic processes, innovative therapy can be developed to improve patient outcome.

■ SUPPORTIVE THERAPY

3 In patients with nephrotic syndrome, dietary measures involve restriction of sodium intake to 50 to 100 mEq/day,^{11,17} protein intake of 0.8 to 1 g/day,^{17,18} and a low-lipid diet of less than 200 mg cholesterol. Total fat should account for less than 30% of daily total calories.¹⁷ Sodium restriction is important not only in the control of edema, but also in the control of hypertension and proteinuria. Similarly, protein restriction not only helps to reduce proteinuria, but also has a potential role in retarding the progression of renal disease. Patients should also stop smoking because a dose-dependent increase in risk for developing ESKD was observed in men with primary inflammatory (IgA glomerulonephritis) or noninflammatory (polycystic kidney disease) renal diseases.¹⁹

■ EDEMA

Management of nephrotic edema involves salt restriction, bedrest, and use of support stockings and diuretics. However, severe salt restriction is difficult to achieve in patients who are sodium-avid, and prolonged bedrest could predispose nephrotic patients to thromboembolism. Hence the use of a loop diuretic such as furosemide is frequently required. Although the delivery of diuretic to the kidney tubules is normal, the presence of large amounts of protein in the urine promotes drug binding, and thereby reduces the availability of the diuretic to the luminal receptor sites. In addition, reduced sodium delivery to the distal tubule secondary to decreased glomerular perfusion may also alter diuretic effectiveness. Large doses of the loop diuretic, such as 160 to 480 mg of furosemide, may be needed for patients with moderate edema (see Chap. 49). In some patients, a thiazide diuretic or metolazone may be added to enhance natriuresis.^{17,20} Alternatively, continuous intravenous infusion of a loop diuretic, such as furosemide 160 to 480 mg/day, may be employed and is more effective than intermittent bolus injections in inducing urinary sodium excretion.²¹ In patients with morbid edema, albumin infusion may be used to expand plasma volume and to increase diuretic delivery to the renal tubules, thus enhancing diuretic effect. However, it may precipitate congestive heart failure and may also reduce therapeutic response to steroid in minimal-change nephropathy. In patients with significant edema, the goal of treatment should be a daily loss of 1 to 2 lb of fluid until a reasonable weight has been obtained.

■ HYPERTENSION

Optimal control of hypertension in patients with glomerular disease is important in reducing both the progression of renal disease and the risk for cardiovascular disease^{18,22} (see Chaps. 13 and 43). The Seventh Report of the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure report recommended the target blood pressure to be 130/80 mm Hg in patients with chronic renal insufficiency defined by GFR <60 mL/min or albuminuria >300 mg/d.²³ Angiotensin-converting enzyme inhibitors (ACEIs) or angiotensin II receptor blockers (ARBs) have been shown to delay the loss of renal function in patients with diabetic and nondiabetic (primarily glomerulonephritis) renal diseases.²⁴ They reduce renal protein excretion and exert renoprotection through mechanisms independent of their blood pressure-lowering effects. Alternatively, nondihydropyridine calcium channel blockers (e.g., diltiazem) may have proteinuria-reduction properties and could be used as an

additional agent. The dihydropyridine calcium channel blockers (e.g., nifedipine, amlodipine, or nisoldipine) can also be used to lower blood pressure, but without the benefit of urinary protein reduction.²⁵

■ PROTEINURIA

Dietary protein restriction reduces proteinuria and may retard renal function deterioration. The intent-to-treat analysis of the Modification of Diet in Renal Disease study in patients with moderate renal insufficiency (GFR of 25 to 55 mL/min per 1.73 m²), did not show that a low-protein diet was able to slow renal disease progression. However, the secondary analysis revealed that protein intake of 0.66 g/kg per day reduced the rate of GFR deterioration in patients with severe renal insufficiency, GFR of 13 to 24 mL/min per 1.73 m².²⁶ In view of the lack of definitive proof about the benefit of protein restriction on disease progression, modest protein restriction of 0.8 g/kg per day is reasonable for patients with moderate renal insufficiency. Decreasing dietary protein will also reduce the intake of phosphorus and potassium. In many instances, the potential benefits of protein restriction have to be balanced against the need for protein intake to overcome nutritional deficiencies. The patient's protein and energy intake as well as the nutritional status therefore have to be monitored adequately. For nondialyzed patients who have GFRs of less than 25 mL/min per 1.73 m², dietary protein intake should be reduced to 0.6 g/kg per day because it can retard the rate of renal function loss and also the time to reach end-stage renal disease.¹⁸

It is now recognized that patients with significant proteinuria may experience a rapid decline of GFR. In both patients with diabetic nephropathy and nondiabetic chronic renal disease, reducing proteinuria is associated with slowing of renal function loss and delaying the progression to end-stage renal failure.^{27,28} The antiproteinuric effect of ACEIs is associated with a fall in filtration fraction, suggesting a reduction in intraglomerular pressure. However, an improvement of GBM permselectivity may be responsible for the long-term effect of ACEIs.²⁹ Such beneficial effects on proteinuria and reduction of glomerular hyperfiltration secondary to nephron loss are beyond what can be attributed by the drug's antihypertensive effects (see Chap. 43).^{30,31}

Recent studies indicate that combined use of an ACEI and an ARB reduced the rate of renal function decline more than either treatment alone.^{24,32} Such combination maximizes blockade of the renin-angiotensin system by counteracting the effects of angiotensin II produced by non-ACE pathways. In addition, with the blockade of the angiotensin II type 1 receptor, the angiotensin II produced by the non-ACE pathways may still act on the angiotensin II type 2 receptors, further facilitating vasodilatation.³³ Patients with IgA nephropathy seem to respond the best when they receive such combination therapy.³² An angiotensin II receptor antagonist should therefore be added to the regimen for those patients who do not attain full and persistent remission of proteinuria with an ACEI alone.⁴⁴

NSAIDs probably reduce proteinuria through prostaglandin E₂ inhibition, resulting in a reduction of intraglomerular pressure, a decrease in GFR, and also restoration of the barrier size-selectivity of the GBM.^{17,29} Indomethacin and meclofenamate are the two NSAIDs that have been evaluated the most. Their antiproteinuric effect is comparable to those attained with ACEIs, and combined treatment with an ACEI results in additional proteinuria reduction.³⁴ However, adherence to a low-sodium diet or concurrent use of a diuretic is needed to maximize the antiproteinuric effect. Due to their potential for nephrotoxicity, especially in patients with poor renal function, long-term use of an NSAID for renoprotection is not preferred.³⁰

Recently, cyclooxygenase-2 inhibitors have been shown to have proteinuria-lowering and renoprotective effects in animal models. If such beneficial effects are confirmed in humans, cyclooxygenase-2 inhibitors may become useful renoprotective agents for those patients whose low blood pressure preclude further use of drugs for ACE inhibition.³⁰

■ HYPERLIPIDEMIA

An abnormal lipoprotein profile increases the risk of atherosclerosis and coronary heart disease in patients with nephrotic syndrome. It is therefore prudent to treat patients with persistent nephrotic syndrome and sustained dyslipidemia, especially those with high VLDL and LDL cholesterol levels in the presence of a normal or low HDL cholesterol level (see Chaps. 21 and 43). Therapy is especially needed for those with concurrent atherosclerotic cardiovascular disease, or with additional risk factors for atherosclerosis, such as smoking and hypertension.¹⁴ Whether correction of lipoprotein abnormalities will slow the progression of renal disease as demonstrated in animal studies requires clinical confirmation.¹⁴

A low-fat diet is usually not sufficient to correct hyperlipoproteinemia.^{9,17,35} Lipid-lowering agents are usually required. Probucol, bile acid resins, fibric acid derivatives, and hydroxymethylglutaryl coenzyme A (HMG-CoA) reductase inhibitors have been evaluated in patients with nephrotic syndrome.¹⁴ HMG-CoA reductase inhibitors, also known as the statins such as lovastatin, pravastatin, simvastatin, and fluvastatin, are considered the treatment of choice.^{9,14,17} In short-term studies, they reduce total plasma cholesterol concentration, LDL cholesterol, and total plasma triglyceride concentrations.¹⁴ The increase in HDL cholesterol and/or decrease in atherogenic lipoprotein (a) is variable.²² Meta-analysis showed that use of HMG-CoA reductase inhibitors resulted in the greatest and most consistent decrease in LDL cholesterol levels.³⁵ Recent experimental data reveal that the statins may modulate intracellular signaling systems that involve in cell proliferation, inflammation, and fibrogenic responses. As such, the statins may also have beneficial effects on the progression of renal disease.³⁶

When ACEIs are used to reduce proteinuria, it is common to see an accompanying decrease in total plasma cholesterol and the lipoprotein (a) level.²⁶ Combined use of an ACEI with an HMG-CoA reductase inhibitor may therefore offer additional benefits in controlling nephrotic hyperlipidemia.

■ ANTICOAGULATION

Intravascular thrombosis is a serious and common complication of nephrotic syndrome, particularly in membranous nephropathy. Patients are at risk for developing renal vein thrombosis, pulmonary emboli, or other thromboembolic events. Although it is generally agreed that patients who have documented thromboembolic episodes should be anticoagulated with warfarin until remission of nephrotic syndrome, the use of prophylactic anticoagulation is controversial. A decision analysis study suggested that prophylactic anticoagulation is beneficial in patients with membranous nephropathy.³⁷ However, prospective controlled studies should be conducted to confirm these findings. Anticoagulation should also be considered in patients with increased risks for thrombosis, such as prolonged bedrest, surgery, episodes of dehydration, or use of high-dose intravenous steroids.¹⁷ As an example, low-dose subcutaneous heparin may be given prophylactically for a limited duration in patients with severe nephrotic syndrome who are placed on bedrest. For patients with a history of

a thromboembolic episode, warfarin should be given after an initial course of standard or low-molecular-weight heparin, for as long as heavy proteinuria and hypoalbuminemia are present. The role of low-molecular-weight heparin in preventing thromboembolism is uncertain, but preliminary results are encouraging.³⁸

■ DISEASE PROGRESSION AND TREATMENT CONSIDERATIONS

The course and prognosis of the different glomerular diseases are extremely variable and depend on the underlying etiology. In glomerular diseases with a secondary cause, such as poststreptococcal glomerulonephritis, after the initiating factor is removed, the prognosis of the renal disease is often good. In contrast, the rates of renal function deterioration among the primary glomerulonephritides vary according to the form of glomerulonephritis. The majority of patients with minimal-change disease, IgA nephropathy, and membranous nephropathy have a fairly good prognosis. However, those with focal segmental glomerulosclerosis who are resistant to therapy, as well as those with rapidly progressive glomerulonephritis who are untreated, are likely to experience rapid loss of renal function. In some instances, half of the renal function may be lost within a 3-month period. Certain glomerulonephritides, such as minimal-change nephropathy, are very responsive to treatment. In contrast, for some other types of glomerulonephritis, such as membranous proliferative glomerulonephritis, consistently effective therapy has yet to be found.

Because of the variable courses exhibited by the different glomerulonephritides, specific treatment approaches have been developed for each disease. The natural history of the glomerulonephritis has to be well delineated before a promising regimen can be evaluated, from both therapeutic and economic perspectives. Otherwise patients will be exposed to unnecessary treatment-related toxicities if they have a type of glomerulonephritis that is likely to undergo spontaneous remission. The potential therapeutic benefits of treatment regimens should always be weighed against the risks to which the patients are being exposed. It is therefore imperative to identify patients who are most likely to benefit from treatment, especially those who have other risk factors that may contribute to the deterioration of their renal function. In those instances in which satisfactory regimens are not available to treat the primary disease, appropriate supportive measures should be employed. Optimization of systemic and glomerular pressure, reducing proteinuria, and possibly controlling hyperlipidemia may all improve the long-term outcome as well as the quality of life of these patients.

■ TREATMENT MONITORING

4 Patients should be monitored closely for therapeutic response as well as the development of treatment-related toxicities. While the rate of renal function deterioration is an important indicator of the long-term success of treatment, resolution of nephrotic and nephritic signs and symptoms associated with the glomerulopathies are important short-term therapeutic targets.

Serum creatinine concentration as well as creatinine clearance should be evaluated prior to and during treatment; 24-hour urine outflow should be collected to determine the extent of proteinuria. Alternatively, the daily urine protein excretion may be estimated by the urinary total protein:creatinine concentration ratio. After establishing the correlation between the 24-hour urinary protein excretion and the protein:creatinine ratio, single random urine specimens may be

used in place of a 24-hour urine collection. Blood pressure should be monitored periodically to assess the need for and also the adequacy of antihypertensive therapy. The pressures should also be evaluated in conjunction with clinical signs and symptoms of edema and fluid overload to gauge the need for volume control as well as diuretic use. For patients with nephrotic syndrome, serum lipid concentrations should be monitored. If the patient has hematuria, urinalysis and a complete blood count should be obtained. The clinician should also be aware of the patient's appetite and energy level, because these are indicators of the patient's overall state of well-being. At times, renal biopsy is needed to assess response to treatment and disease progression, to determine future treatment strategy, and to confirm the initial diagnosis.

Patients receiving cytotoxic drug treatment should be evaluated for drug-related toxicities every week during the initial treatment period. After 1 month of treatment, the frequency of monitoring may be reduced. When the patient is on long-term steroid treatment, monthly visits are often required for assessment of both efficacy and toxicities. If a favorable response is obtained after a course of treatment, the patient may be evaluated every 3 to 4 months. The patient's renal function, proteinuria, urinalysis, blood pressure, lipid profile,

and the overall state of health should be assessed during these regular follow-up visits.

■ OUTCOME AND ECONOMIC EVALUATION

Prospective, randomized, controlled comparative trials need to be conducted in a sizable patient population before the efficacy and economic implications of a new regimen can be established. This type of large-scale study is potentially feasible for the more common forms of glomerulonephritis, such as minimal-change disease, IgA nephropathy, and membranous nephropathy. In contrast, prospective controlled trials are difficult to conduct for the relatively uncommon glomerulonephritides such as membranous proliferative glomerulonephritis. After defining the natural history and the optimal drug regimen for each glomerulonephritis, in conjunction with the incidence of drug-induced complications, the economic implications of the individual treatment approach can be assessed. However, the optimal approaches for treating most types of glomerulonephritis have not been identified and the economic implications of the individual treatment regimens have yet to be established.

PATHOPHYSIOLOGY AND PHARMACOTHERAPY OF INDIVIDUAL GLOMERULOPATHIES

MINIMAL-CHANGE NEPHROPATHY

Minimal-change nephropathy (also termed minimal-change disease) is commonly found in children between 3 months and 6 years of age. It is one of the most common chronic diseases in childhood. In children between 1 and 4 years of age, minimal-change disease accounts for more than 90% of all cases of nephrotic syndrome. The percentage drops gradually to less than 50% after age 10 years, and only accounts for 10% to 15% of all cases of idiopathic nephrotic syndrome in adults. Secondary causes of minimal-change nephropathy have been reported with NSAIDs, lymphoproliferative disorders, lupus, and interferon- β treatment of malignant melanoma. They are responsible for up to 13% of all cases of minimal-change nephropathy in adults.

PATHOPHYSIOLOGY

Minimal-change disease is also known as "nil" disease, primarily because of the absence of definitive pathologic changes observed under light and immunofluorescence microscopy. The characteristic lesion in patients with minimal-change disease, as visualized under electron microscopy, is the spreading and fusion of the foot processes of epithelial cells over an unchanged GBM. *Lipoid nephrosis* is another term that has been used to describe this type of glomerular disease because lipids, as well as renal tubular cells, are found in the urine.

The pathogenesis of minimal-change disease is still unknown. Altered cell-mediated immunologic response, specifically T-cell dysfunction or changes in the T-cell subpopulations, is suspected to be responsible. The activated lymphocytes are thought to secrete lymphokines that reduce the production of anions in the GBM. The permeability of the GBM to plasma albumin is therefore increased through a reduction of electrostatic repulsion. The loss of anionic charges also results in fusion of the foot processes of the epithelial cells. Other conditions that involve T-cell abnormalities, such as Hodgkin's disease, T-cell lymphoma, and nephritis induced by NSAIDs, are also associated with minimal-change disease.

CLINICAL PRESENTATION

Most patients present initially with edema, frequently acute in onset, following a nonspecific upper respiratory tract infection, allergic reaction, or vaccinations, which might have activated the T lymphocytes. Nephrotic syndrome with massive proteinuria (substantially more than 40 mg/m² per hour for children and 3 g/day for adults), edema, hypoalbuminemia, and hyperlipidemia is common. The patient's weight may be increased dramatically because of sodium and fluid retention. Nephrotic features such as gross hematuria are uncommon. However, microscopic hematuria may be seen in up to 20% to 25% of patients. Hypertension and decreased renal function are uncommon in children but are more common in older adults.³⁹ In some patients, volume depletion may result in mild to moderate azotemia.

■ PHARMACOLOGIC THERAPY

■ STEROIDS

5 Minimal-change disease is the most responsive to initial treatment with corticosteroids. In children, steroid therapy is expected to reduce proteinuria in about 90% of the patients. The 10-year renal survival is greater than 95%.⁴⁰ Because of the excellent response to initial therapy with steroids and the prevalence of this

glomerular disease in children, reduction of proteinuria secondary to steroid treatment is considered diagnostic for minimal-change disease without the need for biopsy. In the International Study of Kidney Disease in Children, remission was induced, as evidenced by diuresis, loss of edema, and resolution of proteinuria, within 8 weeks of therapy in more than 93% of the 363 children.⁴¹ Prednisone was administered at a dose of 60 mg/m² per day, with a maximum of 80 to 100 mg daily, in divided doses during the first 4 weeks. The dose was then reduced to 40 mg/m² per day, or a maximum of 60 mg daily, in divided doses for

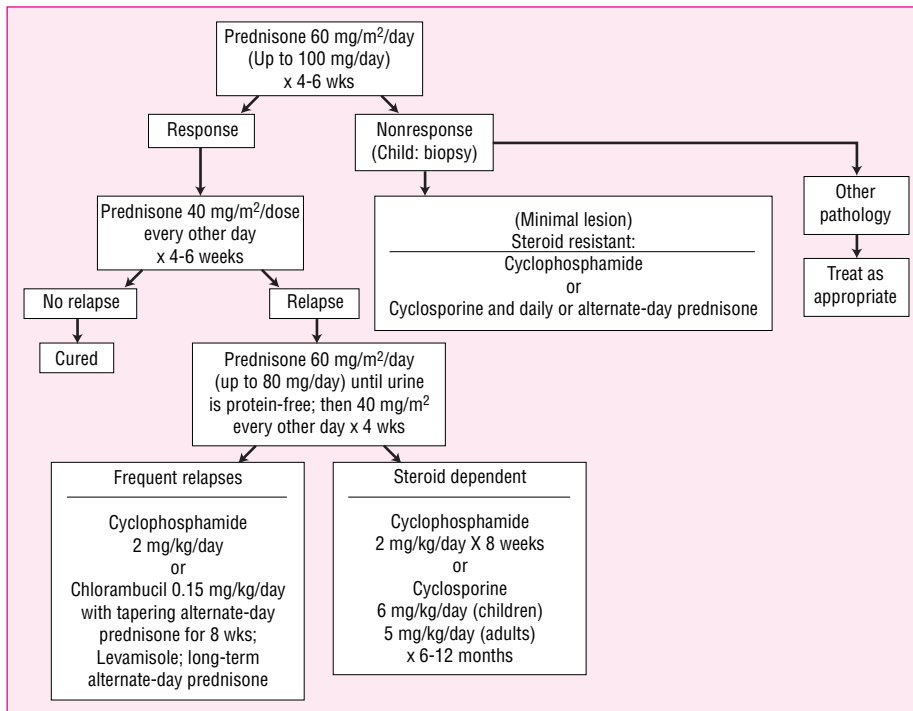

FIGURE 47-7. Treatment algorithm for minimal-change nephropathy. (Modified from Bargman.⁴²)

3 consecutive days every 7 days for another 4 weeks. An alternate-day dosage regimen can be used instead in the second 4 weeks, after which the prednisone dosage is tapered over several months (Fig. 47-7).^{40,42} Single daily doses of prednisone, instead of multiple daily doses, may result in faster and more sustained response with less-frequent and less-severe side effects.⁴⁰ Proteinuria will disappear in 50% of patients after 1 week and in 90% of patients after 4 weeks of treatment. Studies conducted to evaluate the effectiveness of longer and shorter courses of steroid therapy for initial treatment, as well as recurrences,⁴² showed that longer therapy (6 weeks of daily prednisone followed by 6 weeks of alternate-day treatment) results in lower incidence of relapse (36%) than both standard-course (4 weeks; 61%) and short-course (3 weeks; 81%) therapy. However, the cumulative doses of steroid received for the initial treatment and subsequent relapses during the entire follow-up period were no different between the long and standard courses. As a result, long-course therapy is commonly used for the initial episode, followed by short-course treatment for relapses.⁴³

For adults, the dose of prednisone is 1 mg/kg per day during the initial 4 weeks with a reduction to 0.75 mg/kg per day every other day for the next 4 weeks. Proteinuria will disappear in 50% to 60% of patients after 8 weeks of treatment, and complete remission will be attained in 80% of patients after 28 weeks of therapy.³⁹ In some patients, 16 weeks of therapy may be needed before remission is induced.^{39,41} Use of lower doses of steroids may increase relapse rate and alternate-day high-dose steroid therapy may reduce the rate of total remission.

Relapse

As many as 75% to 85% of the patients who respond to initial steroid therapy (steroid sensitive) will experience a relapse of proteinuria, mostly within 6 to 12 months after disease onset. However, some patients may not have the first relapse until 24 to 30 months later. The risk of relapse is affected by the duration of initial steroid therapy.^{17,42}

Children who were asymptomatic with proteinuria diagnosed on a urinary screening program tend to have less frequent relapses and a more favorable clinical course.⁴⁴ In those who relapse, 50% to 65% may have steroid-responsive relapse episodes over the subsequent 3- to 5-year period. The dose and duration of steroid treatment for the relapse do not influence the subsequent rate of relapse.^{17,42} The current regimen for relapse consists of 60 mg/m² per day, up to 80 mg/day of prednisone, until the urine is free of protein for 3 days. Four weeks of alternate-day prednisone at 40 mg/m² per dose will then be used.⁴² Giving the initial daily doses of prednisone for 4 weeks, instead of until the urine is clear of protein may induce a more prolonged remission; however, the cumulative dose of prednisone will be doubled. Because most patients will relapse soon, it is preferred to treat until the urine is free of protein for 3 days and then proceed with the tapering regimen as described earlier.⁴²

Frequent Relapse

About 10% to 20% of children experience three or four relapses that are responsive to steroid. However, half of these patients will relapse frequently and become steroid dependent, requiring continuous low-dose alternate-day prednisone to maintain an extended relapse-free period.⁴² A small number of patients eventually develop resistance to steroids, and a biopsy done at that time often reveals another pathology such as focal segmental glomerulosclerosis. It is controversial whether minimal-change disease progresses into focal segmental glomerulosclerosis or whether the glomerulosclerosis that was present at the time of initial diagnosis was inadvertently diagnosed as minimal-change nephropathy because of tissue-sampling error during the renal biopsy.

CYTOTOXIC AGENTS

For patients who are steroid resistant, as well as for those patients who require large doses of steroids to sustain remission (steroid

dependent), alternative therapy should be considered. Furthermore, in pediatric patients the growth inhibition associated with long-term steroid use often necessitates the use of alternative agents. Cyclophosphamide at 2 mg/kg per day for 12 weeks given alone or with prednisone (50 to 75 mg/m²) is very effective in inducing remission and restoring steroid responsiveness in patients who were previously steroid dependent and then became steroid resistant. Alternatively, chlorambucil at 0.1 to 0.2 mg/kg per day may be used. This agent, however, is associated with more adverse effects than cyclophosphamide. Azathioprine has also been used; however, treatment for 6 to 12 months is often needed before any favorable response is apparent. Because of the risk for adverse reactions, use of these cytotoxic agents should be reserved for patients who are clearly steroid resistant, or who are steroid dependent (two consecutive relapses during therapy or relapse within 14 days after dosage reduction or termination of steroid treatment) with significant adverse effects; or for those patients who have two or more relapses within 6 months after the first episode, or who had three or more relapses within 12 months.¹⁷

The immunosuppressive effect of cytotoxic agents, with or without the concurrent use of steroids, can result in serious infections, which are the primary cause of death in patients with minimal-change nephropathy. Other toxicities associated with cyclophosphamide include gonadal fibrosis, which results in sterility, hemorrhagic cystitis, alopecia, and a potential to develop malignancy in those on long-term treatment. Patients on chronic steroid therapy often develop growth retardation, osteoporosis, obesity, and cataracts.⁴²

■ CYCLOSPORINE

Cyclosporine has been used in adult and pediatric patients. The drug decreases lymphokine production by activated T lymphocytes and thereby reduces proteinuria by reversing the lymphokine-induced alterations in the anionic charge and permeability of the GBM to albumin. Cyclosporine can also reduce proteinuria by improving the permselectivity of the GBM.

In patients with steroid-sensitive or steroid-dependent minimal-change disease, cyclosporine induces remission in 80% to 85% of patients. However, the disease-free period is not often sustained, and relapse, which is usually not as responsive to cyclosporine retreatment, may occur as soon as the drug is tapered or discontinued.⁴⁵ The rate of relapse is also reduced when the dose tapering is gradual or when the cyclosporine treatment period is prolonged.⁴⁶ Although only 10% to 20% of patients who have steroid-resistant disease respond to cyclosporine, combination treatment with low-dose steroid may increase the effectiveness.⁴⁵ A 2-month trial treatment with cyclosporine may therefore be warranted in steroid-resistant patients. The steroid-sparing effect of cyclosporine is also useful in steroid-dependent patients, especially those who have experienced significant adverse effects.

The usual starting daily dose of cyclosporine for remission induction is 5 mg/kg for adults and 100 to 150 mg/m² for children. Similar dosages are used to maintain remission long term. The need to monitor cyclosporine blood concentrations is controversial. No correlation has been found between the severity of the cyclosporine-induced tubulointerstitial lesions and mean dose or trough drug concentration. The incidence of these lesions increases with the duration of treatment and cyclosporine should therefore not be given for more than 4 months in the absence of any beneficial effect.⁴⁵ Results from a recent study of

37 children being treated with cyclosporine for over 18 months indicate that 35% of the patients developed chronic tubulointerstitial lesions consistent with cyclosporine nephrotoxicity. Currently cyclosporine is indicated for patients (1) who relapse frequently or are steroid dependent, after failing to respond to a course of cyclophosphamide; (2) for whom cyclophosphamide is contraindicated or when gonadal toxicity is a concern; (3) who are steroid dependent when a “steroid holiday” is needed for catch-up growth and puberty; or (4) who have steroid-resistant disease.⁴²

■ LEVAMISOLE

Levamisole, an immunostimulant, can promote the maturation of young T cells and restore the function of T cells and phagocytes when the immune system is depressed. It may also inhibit the production of an immunosuppressive lymphokine. Levamisole was found in a placebo-controlled study to have a steroid-sparing effect in children who had steroid-responsive and steroid-dependent nephrotic syndrome.⁴⁷ However, two other controlled studies with a longer period of follow-up did not reveal any significant beneficial effect.^{48,49} The most serious adverse effect of levamisole is neutropenia, which is generally reversible. At present the drug is no longer available in the U.S.; however, it is still used elsewhere in the world for selected steroid-dependent patients.

■ MYCOPHENOLATE MOFETIL

Mycophenolate mofetil is an immunosuppressant that can suppress lymphocyte proliferation. It inhibits inosine monophosphate dehydrogenase, which is pivotal in de novo purine synthesis in lymphocytes. Mycophenolate mofetil, 1 to 3 g/day, has been reported to have steroid-sparing effects in patients with minimal-change disease as well as other forms of glomerulonephritis.^{50,51}

■ THERAPEUTIC OUTCOMES

The long-term prognosis of most patients with minimal-change disease is good. The majority of pediatric patients will not experience any relapse of the disease 10 years after the initial onset, and most will be free of the proteinuria after puberty. In adults, an 85% to 90% survival rate is seen 10 years after disease onset. Although this condition may spontaneously remit in up to 70% of untreated adults, life-threatening complications may be associated with untreated nephrotic syndrome. Development of renal failure is uncommon in both adult and pediatric patients. Significant deterioration of renal function is observed only in those patients who are steroid resistant or steroid dependent. Because of the overall favorable outcome of the disease and the relatively uncommon progression into chronic renal failure, aggressive use of cytotoxic agents is not indicated even in most patients with frequent relapses. Toxicities associated with aggressive therapy do not justify the need to induce remission in those patients who fail to respond to steroids and the nonaggressive use of cytotoxic agents. Symptomatic therapy with diuretics to control edema, in conjunction with a low-salt diet and albumin infusion as needed for acute development of anasarca, is often a more rewarding therapeutic approach. NSAIDs and ACEIs may also be used to reduce the proteinuria.

FOCAL SEGMENTAL GLOMERULOSCLEROSIS

Focal segmental glomerulosclerosis (FSGS) is a histologic lesion that can be idiopathic (primary) or secondary to a variety of causes. Conditions such as sickle cell disease, cyanotic congenital heart disease, and morbid obesity can induce hemodynamic stress on an initially normal nephron population and result in FSGS.⁵² Severe glomerular injury can also be seen in patients with nephropathy associated with heroin abuse, human immunodeficiency virus (HIV) infection and genetic mutations involving the podocin and WTI genes.^{52,53} The primary and secondary sclerotic lesions may be morphologically similar, but they represent diseases with different courses and responses to therapy.

PATHOPHYSIOLOGY

Sclerotic lesions are characteristically found in some of the glomeruli (focal) and usually involve only a portion of the glomeruli (segmental).⁵⁴ Similar to minimal-change disease, fusion of foot processes is commonly seen in those glomeruli that are not sclerotic. It is thought that both minimal-change disease and FSGS share similar pathogenetic mechanisms, with FSGS resulting in severe injury to the glomerular epithelial cells. During the early stage of FSGS, only a small number of glomeruli may have the segmental sclerotic lesion and the disease may be confined to the juxtamedullary region. If an inadequate number of glomeruli are sampled during renal biopsy, the diagnosis of FSGS may be missed, or the patient may be thought to have minimal-change disease. Resistance to steroid therapy may thus

be one of the first clues that the patient indeed has FSGS rather than minimal-change disease. Alternatively, a patient may have the steroid-sensitive minimal-change disease initially, which subsequently progresses to steroid-resistant FSGS. In those patients who have cellular lesions, such as collapse of glomerular capillaries, or hypertrophy and hyperplasia of surrounding glomeruli epithelial cells, the risk for developing renal failure is increased.⁵⁵

CLINICAL PRESENTATION

FSGS accounts for less than 15% of the cases of idiopathic nephrotic syndrome in children and about 15% to 20% in adults; however, it may account for 36% to 80% of the cases in African-Americans.⁵³ Almost all the patients present with proteinuria, and many of them have all the features of nephrotic syndrome.⁵⁶ The proteinuria is nonselective, containing albumin and other higher-molecular-weight proteins, and is usually less severe when compared to patients who have minimal-change disease. Hypertension, microscopic hematuria, and renal dysfunction may be seen in up to half of the patients. Reduced renal function becomes more prevalent as the disease progresses.

The presenting clinical features in nephrotic adults with minimal-change nephropathy can be indistinguishable from that of FSGS, and renal biopsy is therefore critical in the treatment of adults with nephrotic syndrome. FSGS is two to four times more common in black patients than in white patients. They tend to present with proteinuria more frequently in the nephrotic range and are more likely to experience a rapid decline in renal function.

▶ TREATMENT: Focal Segmental Glomerulosclerosis

■ PHARMACOLOGIC THERAPY

■ STEROIDS

6 Because the pathophysiology of primary FSGS is unknown, it is impossible to direct pharmacologic treatment against any specific pathologic processes. Furthermore, the treatment of FSGS remains controversial because of the lack of data from randomized, prospective, controlled trials. A course of prednisone (1 to 2 mg/kg per day) with tapering after 3 to 4 months of treatment is first used for nephrotic patients.^{53,54} Urinary protein excretion and serum albumin concentration should be monitored to assess efficacy. The median time to induce complete remission is 3 months, although 5 to 9 months may be needed in some patients.⁵³ Of all patients 30% to 40% can be expected to attain complete remission; however, fewer patients will respond with regimens of shorter duration.⁵³ In general, treatment should be continued for 6 months before the patient is considered steroid resistant.^{46,57}

For patients who relapse after an adequate response to the initial treatment, a second course of steroids is generally sufficient.⁵³ However, for those who relapse frequently, cytotoxic agents or cyclosporine are indicated.

The relatively favorable prognosis of patients who are not nephrotic does not support the use of steroids or other immunosuppressive agents. However, close follow-up and good blood pressure control with ACEIs are necessary to minimize disease progression.⁵⁴

■ CYTOTOXIC AGENTS

Cytotoxic agents such as cyclophosphamide, chlorambucil, and azathioprine historically have been ineffective in the treatment of FSGS. However, Ponticelli and associates recently reported that treatment with the immunosuppressive agents chlorambucil and cyclophosphamide for more than 1 year was successful in inducing remission in those patients receiving their first treatment, as well as in those patients who did not respond initially.⁵⁸ Cyclophosphamide (2 mg/kg per day) or chlorambucil (0.1 to 0.2 mg/kg per day), when used with steroids, results in remission in more than 70% of patients.⁵³ The rate of relapse is also reduced. When combined with pulse methylprednisolone, these alkylating agents were reported in some trials to be effective in inducing remission in steroid-resistant patients.⁴³

■ CYCLOSPORINE

Short-term cyclosporine therapy reduces proteinuria in many steroid-responsive patients and in some patients who are resistant to corticosteroid and cytotoxic agents.^{56,57} However, more than 75% of the patients have relapse of proteinuria occurring within 2 months of tapering or drug discontinuation.⁵⁶ A prolonged period of treatment with slow tapering may result in longer periods of remission.⁴⁶ Long-term cyclosporine therapy was evaluated in 21 black and Hispanic children (who tend to have more rapid renal function deterioration than

do white children) who had steroid-resistant FSGS.⁵⁹ This aggressive regimen (4 to 20 mg/kg per day for 3 to 97 months) reduced proteinuria from 6.2 to 2 g/day and the percentage of patients who developed ESKD.⁵⁹ Although histologic evidence of cyclosporine nephrotoxicity was not seen in this study, the drug was found by others to be more nephrotoxic in steroid-resistant than in steroid-responsive disease.⁴³ When cyclosporine was combined with low-dose prednisone for 26 weeks, the regimen was found to induce partial or complete remission of proteinuria in 70% of steroid-resistant patients. Renal function was also better preserved than treatment with steroids alone. However, the relapse rate was still high upon treatment discontinuation.⁶⁰ In a recent study, once-daily low-dose cyclosporine (mean, 4.6 mg/kg per day) was effective in inducing total and partial remission in 76% of children with minimal side effects.⁶¹

■ MYCOPHENOLATE MOFETIL

Mycophenolate mofetil, 1 to 3 g daily, has been used effectively in a small number of patients to reduce proteinuria and induce remission.⁵⁰ Further studies are needed to further define its role among the various treatment options.

■ SYMPTOMATIC THERAPY

Because of the lack of a consistently effective regimen for primary FSGS, many patients with mild disease are treated conservatively for symptomatic control. ACEIs and ARBs are effective in reducing proteinuria and in stabilizing renal function in patients with primary or secondary FSGS.⁵³ They should be used in all patients with primary glomerular diseases. The dilation of efferent arterioles by these agents reduces intraglomerular pressure, which may diminish the potential effect of glomerular hypertension on the development of FSGS.³² The driving force for proteinuria may also be reduced without necessarily correcting the primary defect in glomerular wall permselectivity.⁵² The NSAID meclufenamate is effective in reducing proteinuria in patients with steroid-resistant

FSGS.³³ These favorable results have, however, not been confirmed in studies using a larger number of patients. Thus their role in the overall scheme of therapy remains to be defined. For patients with more severe disease, corticosteroids with or without immunosuppressive agents should be considered. Treatment should not be continued for more than 3 to 4 months unless the patient experiences a remission. In this case, therapy may be continued for 12 to 24 months to maintain the therapeutic response.

■ THERAPEUTIC OUTCOMES

Patients with primary FSGS are at risk for developing ESKD. For the 30% to 50% of adults and children who had attained complete remission, ESKD develops in about 10% or less of these patients at 10 years.^{56,61} For those patients who are resistant to therapy, the rate of renal function deterioration to ESKD may be rapid, within 1 year, or slow, over as long as 10 to 20 years. About 50% of them develop ESKD in 10 years.⁶¹ Those patients with severe proteinuria (>10 to 15 g/day), high serum creatinine concentration at diagnosis, initial steroid resistance, or interstitial fibrosis on renal biopsy are likely to have a more rapid decline in renal function.⁵⁴ African-American patients may also have a higher risk. Kidney transplantation is often indicated for those patients who develop ESKD; however, FSGS has recurred in 20% to 50% of the renal allografts soon after transplantation. Children and those with severe disease or rapid progression to ESKD prior to transplantation are more likely to experience a recurrence. The proteinuria may reappear within hours after transplantation and graft failure may occur in one-third to one-half of the patients. The median time to recurrence was reported to be 14 days in one study. Although cyclosporine is ineffective in preventing the recurrence of nephrotic syndrome after transplantation, a high dose of the agent (up to 35 mg/kg per day) induces a remission of the recurrent disease. ACEIs and plasmapheresis are also used to prolong graft survival. The effectiveness of these therapies and the rapid recurrence of the disease in the transplanted kidney substantiate the possibility that a circulating humoral mediator is responsible for the nephropathy.

MEMBRANOUS NEPHROPATHY

Membranous nephropathy is the most common disorder responsible for idiopathic nephrotic syndrome in adults, accounting for about 20% to 25% of cases.⁶² It is also a frequent cause of renal failure secondary to glomerulonephritis. The hallmark histologic features of membranous nephropathy are glomerular capillary wall thickening with subepithelial deposits under light and electron microscopy. Most cases are idiopathic, but about 25% of adults and 80% of children have secondary causes.^{62,63} In the United States, the most common etiologies are autoimmune diseases (e.g., lupus), infection (e.g., hepatitis B), syphilis, neoplasm (e.g., carcinoma of the lung, breast, gastrointestinal tract, or kidney), and medications (e.g., organic gold, penicillamine, mercury, or captopril). Malaria and schistosomiasis are common causes in other parts of the world. De novo membranous nephropathy can also occur in the allografts of renal transplant patients. Because the response to therapy as well as the prognosis for idiopathic and secondary membranous nephropathy are different, it is important to identify any potential underlying causes for the nephropathy prior to treatment. Although this glomerular disease can occur at any age,

the peak incidence is between 30 and 50 years and is especially likely in patients over 50 years old who present with nephrotic syndrome.⁶²

PATHOPHYSIOLOGY

Examination of kidney tissue under light microscopy reveals normal mesangium and normocellularity. The glomerular capillary wall may be thickened in well-developed lesions. In the advanced stage, the capillary wall is markedly thickened and intramembranous deposits are found. Progressive changes in capillary lumen patency parallel those in the GBM, resulting in glomerulosclerosis with capillary collapse and tubular atrophy in end-stage membranous nephropathy. Immunofluorescence microscopy shows strong capillary wall staining of IgG and C3 on the epithelial side of the basement membrane. Antibody-mediated immune injury appears to be the main pathogenetic mechanism. The immune complex can be formed in situ or deposited from circulating immune complexes.

CLINICAL PRESENTATION

Most patients with membranous nephropathy present with heavy proteinuria exceeding 3.5 g/day. Those excreting large amounts of IgG and α_1 -microglobulin, indicating more significant tubulointerstitial damage, have a lower remission rate and are more likely to progress towards renal failure.⁶⁴

The signs and symptoms are usually insidious in onset and may consist of anorexia, malaise, edema, anasarca, or ascites, and pericardial and pleural effusions may also be present. As a result of a hypercoagulable state, pulmonary embolism may develop, but rarely results in death.⁶⁴ The incidence of renal vein thrombosis varies from 5% to 62%,^{63,64} and membranous nephropathy should be suspected when there is a sudden onset of hematuria; loin pain; pulmonary embolus; fluctuating or worsening proteinuria or glomerular filtration rate; renal tubular acidosis; or an increase in leg edema. Hypertension is found in about 30% of patients and is more common in the presence of renal insufficiency or until the disease is advanced.

In addition to heavy proteinuria, urinalysis often reveals lipiduria and oval fat bodies. Microhematuria is seen in fewer than 25% of patients, and gross hematuria and red cell casts are rare. In idiopathic membranous nephropathy, the serum complement concentrations are normal. Low levels of complement should alert one to search for secondary causes, such as lupus, hepatitis B infection, or an alterna-

tive diagnosis. Similarly, antinuclear antibodies, anti-DNA antibodies, rheumatoid factor, hepatitis B serologies, and serum cryoglobulins are generally negative in idiopathic membranous nephropathy. Occult malignancy has been found in as many as 10% of elderly patients with membranous nephropathy.

The natural course of idiopathic membranous nephropathy is variable. About 25% of patients experience spontaneous remission of the disease over a mean of 5.5 years.⁶³ Less than 10% of the non-nephrotic patients and about one-third to one-half of the nephrotic patients will progress to end-stage renal failure over 10 to 15 years.⁶² Some other patients have various degrees of renal insufficiency and persistent proteinuria. Heavy proteinuria (>10 g/day); male gender; elevated serum creatinine concentration at the time of presentation; poorly controlled hypertension; advanced age at onset of disease; non-Asian race; certain human leukocyte antigen phenotypes; and tubulointerstitial fibrosis on initial renal biopsy are associated with progressive renal disease.^{62,63} Overall, patients with idiopathic membranous nephropathy have a relatively benign course. The mean 10-year survival is about 70%. Those who present with persistent non-nephrotic proteinuria seldom develop renal insufficiency and have a normal life expectancy. Fewer than 10% of patients develop a remitting and relapsing course.⁶³ The prognosis for secondary membranous nephropathy depends on the underlying cause. Remission occurs when the infection resolves or when the causative medication is withdrawn.

► TREATMENT: Membranous Nephropathy

The treatment of idiopathic membranous nephropathy is controversial and ranges from supportive therapy to immunosuppression with steroids alone, or in combination with alkylating agents. Conservative management of membranous nephropathy includes the control of edema with salt restriction and diuretics¹¹ and reduction of proteinuria with protein restriction and ACEIs (Fig. 47–8).⁶⁵ Management of hypertension and hyperlipidemia is required for most patients, whereas prophylactic anticoagulation, despite having benefits shown to out-

weigh the risks, is usually given only for patients with renal vein thrombosis or documented pulmonary embolus.^{37,63}

CLINICAL CONTROVERSY

The optimal treatment for membranous nephropathy is controversial since there is no consistently effective drug regimen.

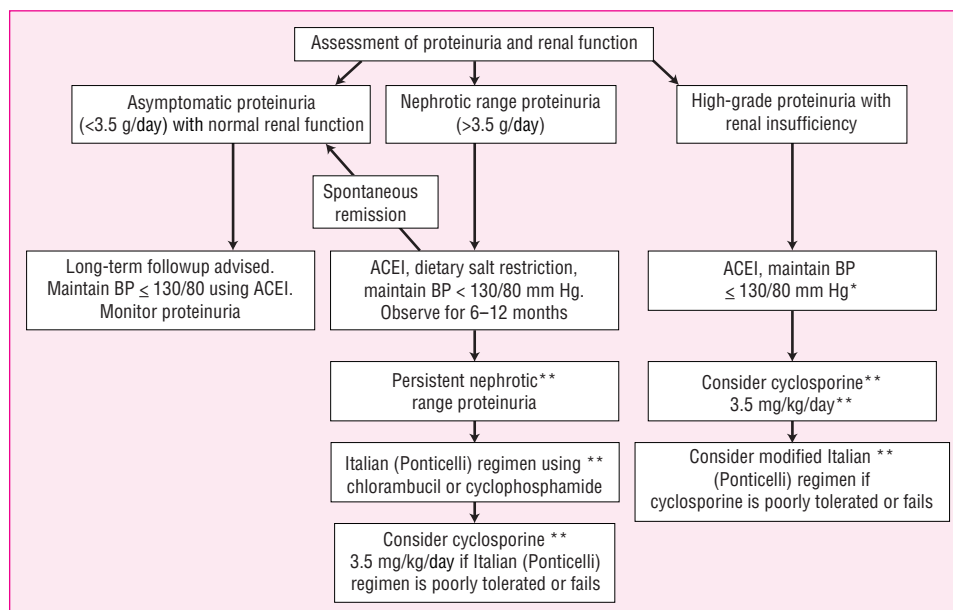

FIGURE 47–8. Treatment algorithm for idiopathic membranous nephropathy. Patients may change from one category to another during the course of follow-up. *, supported by evidence from controlled trials; ACEI, angiotensin-converting enzyme inhibitor; **, introduction of risk reduction strategies for both secondary effects of disease and adverse effects of immunotherapy. (Modified from Geddes et al.⁶³)

■ PHARMACOLOGIC THERAPY

■ STEROIDS

Remission of proteinuria, whether spontaneously or treatment related, may confer a good prognosis. Corticosteroids alone were ineffective in increasing the remission rate of proteinuria in all controlled trials and in preventing progression in all but one study.⁶³ The result of a meta-analysis also confirmed the lack of efficacy of steroids alone.

■ CYTOTOXIC AGENTS

Cytotoxic agents, when used in conjunction with corticosteroids, are effective in increasing the remission rate of nephrotic syndrome and reducing the frequency of ESKD at 10 years.^{63,66} Ponticelli and colleagues devised such a regimen by combining intravenous methylprednisolone (1 g) for 3 days followed by oral methylprednisolone (0.4 mg/kg) for the subsequent 27 days of months 1, 3, and 5. Oral chlorambucil (0.2 mg/kg) is to be given daily in months 2, 4, and 6.⁶⁶ They also substituted cyclophosphamide (2.5 mg/kg per day) for chlorambucil, which resulted in similar rates of proteinuria remission and relapse, but with fewer serious side effects in those who received cyclophosphamide.⁶⁷

A meta-analysis was conducted to evaluate the data from prospective trials using steroids and cytotoxic agents. The cytotoxic agents, but not steroids, were found to be effective in reducing nephrotic-range proteinuria as well as increasing the likelihood of complete or partial remission.⁶⁸

■ CYCLOSPORINE

For patients with severe nephrotic syndrome who did not respond to cytotoxic therapy, cyclosporine may offer some benefits; however, the risk for cyclosporine nephrotoxicity is of concern, especially during long-term therapy. A 12-month course of cyclosporine (mean dose of 3.8 mg/kg per day) was found to reduce proteinuria as well as the rate of renal deterioration.⁶⁹ In a recent study of 41 patients who received cyclosporine, many with concurrent steroid and ACE inhibitor therapy, the median treatment time to complete remission was 225 days among the 34% of patients who attained complete remission.⁷⁰ At present, the beneficial effects of cyclosporine are not well substantiated and the optimal duration of treatment is also not known. For many patients, hypertension may be exacerbated and the serum creatinine concentration may be increased due to nephrotoxicity. When the renal function declines, the dose of cyclosporine should be reduced. In addition, proteinuria may recur when the cyclosporine treatment is stopped.

■ THERAPEUTIC OUTCOMES

Because spontaneous remission is common and only about 25% of patients with new-onset idiopathic membranous nephropathy ulti-

mately develop ESKD in 20 to 30 years, it is prudent not to aggressively treat all patients at the onset of the disease.⁷¹ Patients who have a low likelihood for renal disease progression can be managed with observation and symptomatic therapy. Normalizing the blood pressure and reducing proteinuria with ACEIs is reasonable because both hypertension and proteinuria are independent risk factors for the progression of renal failure.⁶³ Patients with low risk for renal disease progression include children 2 to 16 years of age, adult males with proteinuria less than 2 g/day, or adult females with proteinuria less than 5 g/day and normal renal function.⁷² In contrast, patients who have a high risk of developing renal failure, including those with proteinuria greater than 10 g/day with or without impaired renal function, and patients with symptomatic nephrotic syndrome with a plasma albumin of less than 2 g/dL, should be aggressively treated to induce remission.⁷¹ An alkylating agent such as chlorambucil or cyclophosphamide, combined with steroids^{71,72} or the high-dose steroid regimen used in the study by Ponticelli,⁷² can be given to induce remission after considering the benefits and risks of treatment.^{17,72} Recently, mycophenolate mofetil and rituximab have been shown separately to be effective in treating a small number of patients.^{50,73}

When a slightly modified version of the regimen by Ponticelli (methylprednisolone plus chlorambucil) was used in patients with renal insufficiency, improvement in renal function was reported in some small, uncontrolled studies.⁶³ However, more than half of the patients experienced significant myelosuppression secondary to chlorambucil. When cyclophosphamide was used with steroid, beneficial effects were observed in a small case series, but not in a randomized, controlled trial.^{63–68,71–74} Although the therapeutic effects of cytotoxic agents for these patients have yet to be confirmed, patients with renal insufficiency are more susceptible to immunosuppression by cytotoxic agents. Cytotoxic therapy should thus be avoided when the serum creatinine concentration at diagnosis is greater than 3 mg/dL.⁷² The dose of cytotoxic agents should also be reduced in patients with renal impairment to minimize side effects.

Because aggressive treatment is not warranted for patients with mild disease and the risk of immunosuppression by cytotoxic agents is high, there has been attempt to identify, early in the course of disease, patients at high risk for progressing to ESKD. A model to predict the probability of progression to renal insufficiency has been developed which incorporates the level of proteinuria and the creatinine clearance at the beginning of observation, as well as the slope of renal function decline over a 6-month period.⁷⁵ Although the model was validated retrospectively using patient data from Italy and Finland, the applicability of this model in clinical practice remains to be confirmed prospectively.

The treatment of secondary membranous nephropathy is directed at removing the underlying cause. For instance, membranous nephropathy secondary to syphilis can be treated with penicillin. α -Interferon is beneficial for hepatitis B–induced membranous nephropathy.⁷⁶ Corticosteroids should be avoided because they may induce transient viral replication.⁷⁷

Both de novo and recurrent membranous nephropathy may occur in the renal allograft. Patients with primary membranous nephropathy are more at risk. Recurrence is typically associated with nephrotic syndrome and a high risk of allograft failure from disease and/or rejection.

MEMBRANOPROLIFERATIVE GLOMERULONEPHRITIS

Membranoproliferative glomerulonephritis (MPGN) is one of the least-common renal morphologic entities that occurs in older children and adults. Although whites are more frequently affected,

there is no gender difference in incidence. Many diseases and disorders, such as infections and neoplasms, may result in secondary MPGN.

The several types of MPGN are classified according to the pathologic features. Type I MPGN, also known as mesangiocapillary

glomerulonephritis, is characterized by diffuse thickening of glomerular capillary walls and mesangial hypercellularity. Subendothelial dense deposits that frequently contain immunoglobulins and C3 of the complement system are responsible for the capillary wall thickening. Immune complexes are therefore presumed to have a major role in the pathogenesis of type I MPGN, which is the most common type of primary, idiopathic MPGN. Hepatitis C is the most common cause of type I MPGN; other secondary etiologies may include systemic immune-complex-mediated disease (lupus), chronic infection (HIV, infected ventriculoatrial shunt, endocarditis, and malaria), chronic liver disease (hepatitis B and cirrhosis), and malignancy (lymphoma and leukemia).⁷⁸

Type II MPGN is also known as dense-deposit disease because of the presence of dense deposits of C3 within the glomerular basement membrane, which gives rise to a ribbon-like appearance. The deposit contains C3, but without immunoglobulins. Other variants of the disease include type III MPGN, which is seen rarely and consists of subendothelial and subepithelial de-

posits with lamination and disruption of the lamina densa of the GBM.⁷⁹

Type I MPGN is a slowly progressive disease that accounts for 80% of all cases of MPGN, but only 5% to 15% of all cases of nephrotic syndrome seen in pediatric and adult patients. It occurs most frequently in patients between 5 and 30 years of age, and because remissions are rare, many patients eventually develop ESKD. The renal survival is 60% to 65% at 10 years, and the presence of nephrotic syndrome, interstitial disease, and hypertension are poor prognostic indicators.⁸⁰ Type II MPGN is a more aggressive disease that constitutes about 15% of all patients with MPGN. Only 20% of patients remain stable for more than a few years and the median time before the development of ESRD is 7 years. There is an impression that the incidence of idiopathic MPGN has declined recently worldwide.

Nephrotic syndrome is the most common presenting condition and some patients may also have a nephritic component (hematuria), hypertension, and renal insufficiency. Hypocomplementemia is commonly seen.

► TREATMENT: Membranoproliferative Glomerulonephritis

The efficacy of corticosteroids, cyclophosphamide, antiplatelet drugs, and anticoagulants has been evaluated in patients with MPGN. In children, prednisone 40 mg/m² given on alternate days is effective, when compared with placebo, in reducing the decline in GFR.⁸¹ This observation was confirmed by other uncontrolled studies.⁸⁰ Prednisone should therefore be given for 6 to 12 months to children with MPGN, proteinuria (more than 3 g/day), and/or impaired renal function.⁸⁰ Other studies suggest that this regimen may also be beneficial in children with mild proteinuria.

While the effect of steroids has not been proven in adults, antiplatelet drugs, such as dipyridamole and aspirin, as well as warfarin, were found in randomized controlled trials to reduce proteinuria, but had no effect on GFR.⁸⁰ However, an increased incidence of bleeding was observed in the treatment groups.⁸² Adult patients with idiopathic MPGN, heavy proteinuria, and/or impaired renal function should be given dipyridamole or aspirin. Unfortunately, no controlled

study comparing the effect of steroids with antiplatelet agents is yet available.

Cyclophosphamide and azathioprine were found to have no beneficial effect. Cyclosporine was evaluated in a limited number of patients with MPGN with some beneficial effect; however, the trials were not controlled or randomized.⁸³ In addition, the risks for developing adverse effects were high. Figure 47–9 presents an algorithm for treatment and follow-up.

It is difficult to conduct large-scale controlled trials for MPGN because of the low incidence of the disease. Based on the available studies, many of the drugs evaluated do not have any consistent, beneficial effect on renal function and proteinuria. Renal transplantation is an alternative; however, the recurrence rate is close to 100% for type II MPGN and is about 20% to 30% for type I MPGN. Nonetheless, fewer than 10% of the transplanted patients have graft failure as a result of recurrence.

IMMUNOGLOBULIN A NEPHROPATHY

Immunoglobulin A nephropathy, also known as Berger's disease, was first described by Berger and Hinglais in France in 1968. It is now recognized to be the most common primary glomerulonephritis in the world and accounts for 10% of patients with ESRD in many countries. The prevalence among patients with glomerulonephritis or patients who had kidney biopsy varies around the world from as high as 50% in Japan and East Asia to 10% to 30% in Europe. In the United States, the overall prevalence is about 10% to 15%, but is as high as 35% among Native Americans living in New Mexico.⁸⁴ These differences in prevalence may reflect the more conservative diagnostic approach used for U.S. patients with isolated hematuria or mild proteinuria, who are generally not referred for kidney biopsy in the United States.

IgA nephropathy has a male predominance, and the disease is two to six times more common than in females, and it is more frequently seen in younger adults. It is uncommon in blacks both in the United States and in Africa.⁸⁴ IgA nephropathy was once thought to be a benign disease presenting with asymptomatic hematuria; however, it is now recognized that IgA nephropathy can present with any clinical syndrome associated with glomerular disease, and some of the patients will develop ESRD over variable periods of time.

PATHOPHYSIOLOGY

Primary IgA nephropathy an immune-complex-mediated disease in which IgA deposits and other pathologic lesions are found in kidney tissues. In contrast, Henoch-Schönlein purpura is a systemic disease that is believed to be closely linked to IgA nephropathy because they share similar immunohistologic features. Only the joints, skin, and gastrointestinal tract are affected in Henoch-Schönlein purpura. Mesangial deposition of IgA immune complex is also seen in patients with celiac disease and dermatitis herpetiformis, possibly due to an increased exposure to antigens. Patients with chronic liver disease may have IgA nephropathy because of reduced clearance of IgA immune complexes. Secondary IgA nephropathy may be present in patients with different connective tissue diseases, carcinomas, and HIV infection.

The diagnosis of IgA nephropathy can be established by immunofluorescence examination of the kidney biopsy. The hallmark feature is the dominance or codominance of IgA deposition in the mesangium. The IgA immune complex, composed of IgA antibody

bound with an environmental antigen, such as a virus, bacteria, or food substances, is presumed to be deposited from the systemic circulation. Alternately, the complex may be formed in situ, with the IgA antibody bound with an endogenous antigen in the mesangium. Another theory postulates that abnormal IgA, produced in excess by B cells during upper respiratory infection, self-aggregates or causes production of autoantibodies and immune complexes, which deposit in the mesangium. In the mesangium, IgA can bind with receptors on the mesangial cells to induce proliferation and cytokine production. In addition, it can activate complement through the alternate pathway to induce glomerular damage.⁸⁵

Conditions that stimulate the release of IgA are believed to cause IgA deposition in the mesangium. In fact, infections of the upper respiratory tract or intestinal mucosa are known to correlate with the onset or exacerbation of IgA nephropathy. IgA production is likely to be increased through antigenic stimulation of IgA-producing mucosal lymphoid tissue by microorganisms as well as ingested or inhaled substances.

CLINICAL PRESENTATION

IgA nephropathy commonly presents in the second and third decades of life, but it can occur at any age. Many of the patients have gross hematuria concurrent with an infection, most commonly pharyngitis or tonsillitis, and less often pneumonia, gastroenteritis, or urinary tract infection.⁸⁴ In contrast to the 10- to 14-day delay after the pharyngitis in poststreptococcal glomerulonephritis, the hematuria of IgA nephropathy occurs 1 to 2 days after the onset of infection symptoms. The hematuria lasts from 24 hours to a few days, and it may recur with a febrile illness months or years later. Frequently, there is persistent microscopic hematuria between episodes of gross hematuria. Proteinuria is common and sometimes it can be in the nephrotic range. In contrast, hypertension and edema that are frequent in poststreptococcal glomerulonephritis are infrequent in IgA nephropathy. Renal dysfunction is uncommon at the initial presentation; however, about 10% to 20% of the patients develop ESKD within 10 years, and 30% develop it after 20 years.⁸⁶ Hypertension, severe proteinuria, renal function impairment, old age, and the severity of histologic lesions are all predictive factors for poor long-term outcome.^{85,86} The alternative, but less common, clinical presentations are asymptomatic, microscopic hematuria with variable degrees of proteinuria or nephrotic syndrome.

► TREATMENT: Immunoglobulin A Nephropathy

CLINICAL CONTROVERSY

The role of specific therapies for IgA nephropathy is not known since no conclusive data are available for each treatment option.

Spontaneous remission is seen in only 10% to 25% of children and 5% to 7.5% of adults. Unfortunately, no therapy is known to be consistently effective for the treatment of IgA nephropathy. Because of the slow progression of the disease to ESKD, it is very difficult to conduct trials to evaluate the long-term effectiveness of specific treatments. The lack of understanding of the pathogenetic mechanisms and the unavailability of appropriate animal models severely limit the development of rational treatment regimens. This section discusses the several therapeutic approaches that have been used to treat IgA nephropathy (Fig. 47-10).

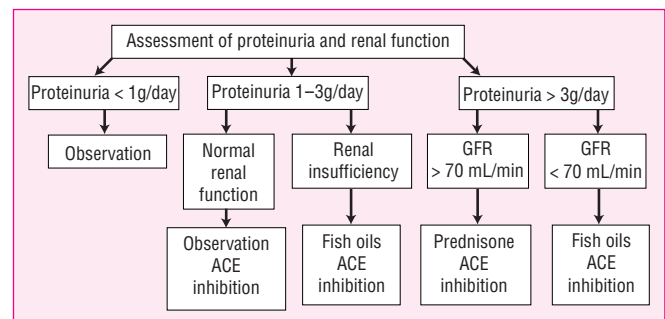

FIGURE 47-10. Treatment algorithm for biopsy-proven IgA nephropathy. (Modified from Nolin et al.⁸⁶)

■ REDUCTION OF IgA IMMUNE COMPLEX: LOW-GLUTEN DIET, PHENYTOIN, AND TONSILLECTOMY

Restriction of dietary gluten is effective in patients with celiac disease, but not in patients with no identifiable nephritogenic antigens. Phenytoin was evaluated because of its ability to reduce the amount of polymeric IgA in the circulation.⁸⁷ Although phenytoin reduced serum IgA concentrations and frequency of macroscopic hematuria, the glomerular lesions deteriorated in some of the patients despite treatment. Removal of the tonsils, which produce IgA₁ and may contribute to IgA nephropathy, may reduce proteinuria and hematuria; however, the beneficial effect of tonsillectomy on renal function long-term has not yet been substantiated.⁸⁸

■ REDUCTION OF IgA PRODUCTION: CORTICOSTEROIDS AND IMMUNOSUPPRESSANTS

The second approach is to reduce IgA production. Corticosteroids with or without immunosuppressive agents have been evaluated in several studies. Low-dose, short-term (<3 months) therapy is not expected to yield favorable results. Patients with progressive renal failure will not generally benefit from steroid therapy. Early treatment of proteinuric patients using an intensive and prolonged regimen (IV methylprednisolone and oral prednisolone combination for 6 months) reduces proteinuria and may preserve renal function.^{86,89} A meta-analysis of randomized trials reveals that heavy proteinuria (greater than 3 g/day) may be reduced by steroids and/or cytotoxic drugs in 66.7% of the patients.⁹⁰ Prednisone and azathioprine, when used together, has been found retrospectively to preserve renal function for up to 10 years in patients with significant proteinuria who had mild renal dysfunction initially.⁹¹ The combination of cyclophosphamide, dipyridamole, and warfarin was shown to reduce proteinuria; however, renal function continued to decline on long-term follow-up.⁸⁶ Another study showed that the azathioprine, prednisolone, heparin, and warfarin combination was better than heparin and warfarin alone in preserving renal function and reducing proteinuria at 2 years.⁹² However, long-term follow-up data are not yet available.

■ REDUCTION OF GLOMERULAR INFLAMMATION: FISH OIL

The third approach is to reduce glomerular inflammation and glomerulosclerosis induced by IgA deposits. Anti-inflammatory agents, antiplatelet drugs, and anticoagulants have been tried without success to decrease the production or action of mediators responsible for IgA immune complex–induced glomerular damage. However, the *n*-3 fatty acids in fish oil, which limit the production or action of cytokines and eicosanoids, delay the progression of renal failure and reduce proteinuria slightly in patients with marked proteinuria and serum creatinine concentrations less than 3 mg/dL prior to study enrollment. A meta-analysis of five controlled studies indicated that a minor, but not statistically significant, beneficial effect on renal function may be observed.⁹³ Donadio and colleagues recently reported that fish oil was effective in reducing renal function deterioration over a 2-year period in patients with severe disease.⁹⁴ However, reduction in proteinuria, a key cause for renal injury, was only modest. Some of the fish oil preparations are rich in cholesterol; it is therefore appropriate

to monitor the low-density lipoprotein cholesterol levels in patients receiving fish oil therapy.

■ ACE INHIBITION

ACE inhibitors can reduce proteinuria in patients with IgA nephropathy through their effect on the filtration barrier in the glomerular membrane.⁹⁴ Several randomized trials and a large retrospective trial demonstrated that ACEIs moderately reduced proteinuria without improving renal function.⁹⁵ Combined use of ACEIs and ARBs may have an additive effect on proteinuria reduction.^{84,96} However, their effects on renal function preservation is not known.^{84,97} Because hypertension is a negative prognostic indicator of IgA nephropathy and many of these patients already have left ventricular diastolic malfunction, despite being normotensive, early antihypertensive intervention with ACEIs or ARBs should be instituted.^{84,85}

■ OTHER THERAPEUTIC APPROACHES

Patients with IgA nephropathy have abnormal production of IgA and several different immunoglobulins. High-dose immunoglobulins, initially administered intravenously followed by the intramuscular route, for over 9 months arrested the decline of renal function and reduced hematuria and proteinuria in all of the 11 patients evaluated.⁹⁷ The efficacy of this regimen must be confirmed in a larger number of patients before it is used as primary therapy.

Urokinase, danazol, dapsone, sodium cromoglycate, and plasma exchange have also been evaluated, but none is consistently effective nor shown to affect renal function.⁸⁶ Cyclosporine treatment for 12 weeks was evaluated in nine patients. Proteinuria was reduced and plasma albumin concentrations increased. However, the creatinine clearance decreased during treatment and did not return to baseline after termination of cyclosporine therapy.⁹⁸ Cyclosporine is not, therefore, indicated for patients with IgA nephropathy.

Recently, the HMG-CoA reductase inhibitor fluvastatin was reported to reduce urinary protein excretion in moderately proteinuric (0.6 to 1.6 g/day) patients who had IgA nephropathy with normal renal function.⁹⁹ Creatinine clearance remained stable during the 6-month study. Longer-term evaluation in a larger patient population will be needed to confirm the effect of this class of agents.

Mycophenolate mofetil and several new strategies are being evaluated as experimental treatments for IgA nephropathy on the premise that they may reduce IgA synthesis and mesangial uptake and/or suppress the effects of proinflammatory or profibrogenic mediators.¹⁰⁰

■ THERAPEUTIC OUTCOMES

Normotensive patients with normal renal function, isolated microhematuria, and proteinuria less than 1 g/day should be observed closely without specific treatment.⁸⁵ Because corticosteroids reduce proteinuria, a course of alternate-day prednisone (1 mg/kg per day) with subsequent tapering is indicated for patients with proteinuria greater than 3 g/d who have good renal function (>70 mL/min).⁸⁶ The more aggressive IV or oral steroid regimen described above may also be considered, even though its efficacy has not been definitively established. For patients with a slow progressive decline in creatinine

clearance (<70 mL/min), fish oil should be given. Azathioprine, mycophenolate mofetil, or dipyridamole/warfarin therapy may also be used, although the efficacy of these agents has not been established. If the patient experiences rapid GFR decline of more than 2 mL/min per month, immunoglobulin therapy may be considered despite the fact that only limited data are available. Other therapies that may be considered for these patients include pulse steroids, a cyclophosphamide/steroid combination, mycophenolate mofetil, and plasmapheresis.^{85,86,98}

If the patient is hypertensive, ACEIs or ARBs should be used to control the blood pressure as well as the proteinuria. The target blood pressure should be <125/75 mm Hg. Some clinicians recommend using ACEIs or ARBs for all patients with >1 g/day proteinuria.⁹⁷ In patients with recurrent macroscopic hematuria in conjunction with tonsillitis, tonsillectomy should be considered.⁸⁶ In all of the patients,

smoking should be avoided because of the dose-dependent increase in risk for developing ESKD.¹⁹

Urinary protein excretion and the mean arterial blood pressure at follow-up correlate well with the progression of disease. The risk of developing end-stage renal disease is proportional to the amount of proteinuria, under the influence of ACEI and ARB therapy, after 1 year of follow-up.¹⁰¹ For those patients who develop end-stage renal failure, transplantation is appropriate, especially for young adults. Recurrence of IgA mesangial deposits in the renal allograft may occur in up to 50% of patients in 5 years and be universally present at 10 years or more posttransplant, but the recurrence of clinical disease is only about 10% to 15%.^{84,85} There is also no correlation between the aggressiveness of the primary disease and the rate of recurrence.⁸⁴ Immunosuppression using corticosteroids, azathioprine, and/or cyclosporine is not expected to prevent the recurrent nephropathy.

LUPUS NEPHRITIS

Glomerulonephritis is one of the most serious complications of systemic lupus erythematosus (SLE) and accounts for much of the morbidity and mortality of patients afflicted with the disease. The renal manifestations of lupus nephritis are variable and encompass a wide spectrum of histopathologic lesions.^{102,103} The underlying histopathology is associated with different prognoses and responses to therapy, which cannot be predicted solely based on clinical manifestations. A renal biopsy is therefore required to assess the severity of the disease and to predict the short-term and long-term outcomes associated with therapy. Drugs, such as hydralazine and procainamide, are known to precipitate a lupus syndrome; however, they are unlikely to cause disease that affects the kidney.

PATHOPHYSIOLOGY

Immune complex deposits, whether formed in the circulation or in situ, can be found in various regions of the glomerulus, as well as the peritubular interstitium and vasculature outside the glomerulus.¹⁰³ Based on light, immunofluorescence, and electron microscopy findings, lupus nephritis can be categorized into six World Health Organization (WHO) classes: I—normal; II—mesangial; III—focal proliferative; IV—diffuse proliferative; V—membranous; and VI—advanced sclerosing.¹⁰⁴ In an attempt to enhance the predictive values of the histologic findings, semiquantitative assessment of active lesions and sclerotic changes are used to determine activity index and chronicity index, respectively.¹⁰³ The hallmark feature in the pathogenesis of SLE is the dysregulated production of antibodies against multiple antigens in the body.¹⁰² The size and location of the immune complexes in the glomerulus correlate with the nature and severity

of renal injury.¹⁰³ Deposition of small numbers of stable immune complexes of intermediate size in the mesangium tends to produce less-severe inflammation in the glomerulus. The sequestration of the immune complexes in the mesangium prevents them from activating inflammatory mediators. Hence the lesion is noninflammatory in nature. In contrast, large numbers of intermediate-sized or large immune complexes results in infiltration of inflammatory cells and release of necrotizing enzymes.

CLINICAL PRESENTATION

Females have a higher risk for developing lupus, especially in the adult years. Nephritis is usually seen within the first 4 years of diagnosis of SLE, but may also be the first manifestation of the disease. The clinical presentation ranges from minimal hematuria and proteinuria to severe, rapidly progressive diffuse glomerulonephritis. Proteinuria is very common and nephrotic syndrome is seen in most patients with membranous lesions. Microscopic hematuria is almost always present, while macroscopic hematuria is rare.¹⁰⁴ Active urinary sediments (red cell casts, dysmorphic red cells, and hematuria) are suggestive of the diffuse proliferative lesion.¹⁰² Hypertension is present in 25% to 45% of patients, and is associated with a worse prognosis. Other conditions found to be associated with poor prognosis include elevated serum creatinine concentration, heavy proteinuria, anemia (hematocrit <26%), black race, and disease onset during childhood or in those >60 years of age. Most patients have hypocomplementemia and increased antibody titers for anti-double-stranded DNA, particularly those with focal or diffuse proliferative lesions.⁶² Serum creatinine concentration at the time of diagnosis is most predictive of short-term outcome.¹⁰³

► TREATMENT: Lupus Nephritis

7 The treatment of lupus nephritis has evolved over the past several decades. The choice of therapy depends on the underlying lesion and the activity, as well as the chronicity indices. Acute life-threatening disease involving multiple organs requires induction treatment that can suppress the disease promptly. In contrast, long-term management of chronic indolent disease requires therapy with more acceptable side-effect profiles. Corticosteroids are the cornerstone of therapy. However, for severe lupus nephritis, primarily the diffuse proliferative type, alkylating agents may be needed to reduce or prevent the progression to ESKD.

Patients with normal renal function and less than 2 g of proteinuria usually do not require therapy, except for the management

of extrarenal lupus manifestations. The prognosis of these patients is generally good and renal biopsy can be delayed. However, close follow-up of renal function and urinalysis is required.

■ ACUTE INDUCTION TREATMENT

Patients with more than 2 g of proteinuria, deteriorating renal function, and/or active urinary sediments require a renal biopsy to define the underlying lesion and determine the activity and chronicity of disease. Those with class III or V lesions can be treated with oral steroids

for 12 to 16 weeks with subsequent tapering to low doses to maintain remission. The concurrent use of an immunosuppressive agent was found in meta-analysis to be more effective in reducing the incidence of ESKD than steroid alone.¹⁰⁵ Patients with class IV lesions and those with class III lesions associated with subendothelial deposits and signs of severe disease activity, should be treated with pulse intravenous methylprednisolone followed by low-dose oral steroids. Cyclophosphamide is used concurrently because it is a powerful B-cell inhibitor and can suppress the resynthesis of autoantibodies to normal levels.¹⁰⁴ Combined use of intravenous cyclophosphamide and methylprednisolone is more effective than either agent alone in inducing remission.¹⁰⁶ However, the risk for adverse events, such as infection, amenorrhea, and cervical dysplasia, is increased with the cytotoxic regimens.¹⁰⁷

Investigators at the National Institutes of Health have used fludarabine, which targets lymphoid cells, with cyclophosphamide.¹⁰⁸ Favorable results have been obtained thus far with respect to proteinuria reduction. Also being investigated is the use of immunoblative high-dose cyclophosphamide with reinfusion of autologous stem cells. Alternately, granulocyte-stimulating factor may be used without stem-cell rescue.¹⁰⁸

■ CHRONIC MAINTENANCE TREATMENT

Oral steroid is most frequently used for maintenance treatment (prednisolone 5 to 15 mg/day or equivalent).¹⁰⁴ Alternate-day regimens, although not evaluated, are often used in children to minimize growth retardation. Monthly pulse IV steroids in conjunction with cyclophosphamide resulted in more sustained remission, fewer relapses, and no significant increase in side effects.¹⁰⁹ This combination has also been shown by meta-analysis to be more beneficial than steroid or cyclophosphamide alone.¹⁰⁵ Cyclophosphamide, because of its bladder and gonadal toxicity, has been given as monthly and then bimonthly intravenous injection, instead of daily administration, for up to 2 or more years. However, toxicity is still a concern. A recent trial in Europe showed that after initial lower pulse doses of IV cyclophosphamide, oral azathioprine was able to attain remission rates similar to those of higher initial pulse doses of cyclophosphamide with quarterly follow-up doses.¹¹⁰

Cyclosporine has been evaluated in a few studies with varied results. There are recent data to suggest that it may reduce proteinuria and lupus activity, stabilize renal function, and improve kidney morphology. A randomized trial is currently underway at the National Institutes of Health to evaluate its effectiveness.

■ RAPIDLY PROGRESSIVE GLOMERULONEPHRITIS

Rapidly progressive glomerulonephritis (RPGN) describes a clinicopathologic syndrome of rapid loss of renal function—usually a greater than 50% decrement of the glomerular filtration rate within 3 months. The predominant histologic finding of RPGN is extensive crescent formation, usually in more than 50% of the glomeruli. Hence, it is also known as crescentic glomerulonephritis. RPGN accounts for 2% to 7% of all renal biopsy findings, and is responsible for up to 5% of patients with ESKD. Although a rare disease, RPGN usually leads to renal demise within weeks or months if left untreated.

RPGN is not a single disease entity. A variety of glomerulonephritides with or without systemic diseases may present as RPGN, including anti-GBM glomerulonephritis; Goodpasture's syndrome; lupus nephritis; poststreptococcal glomerulonephritis; mem-

branoproliferative glomerulonephritis; IgA nephropathy; polyarteritis nodosa; Wegener's granulomatosis; and idiopathic crescentic glomerulonephritis.¹¹⁸ RPGN may also be found superimposed on an underlying primary glomerulopathy such as membranous nephropathy.

Mycophenolate mofetil has been used for patients resistant to or intolerant of cyclophosphamide with good efficacy and limited side effects.^{108,111} A recent controlled study indicates that it may be a better maintenance therapy option than cyclophosphamide.¹¹² Other therapeutic measures that have been used for lupus nephritis include plasmapheresis, intravenous γ -globulin, fish oil, total lymphoid irradiation, and intravenous thromboxane antagonists.¹¹³ None of these modalities was effective in controlled trials. However, plasmapheresis, in place of cyclophosphamide, was found to be effective when used with steroids in a small number of patients.¹¹⁴ LJP-394, composed of four double-stranded oligodeoxynucleotides, can reduce anti-DNA antibody production and render specific B-lymphocytes unresponsive to immunogen. It may reduce renal and systemic SLE flares in a subgroup of patients whose anti-DNA antibodies are bound avidly to the compound. However, whether such beneficial effect is reproducible in other settings is questionable.¹¹⁵ Anti-C5A is a monoclonal antibody that is being evaluated for membranous nephropathy and is potentially beneficial for lupus nephritis. Anti-CD40 ligand, which exerts immunosuppression by blocking communication between B and T cells, was not found to be useful because of thromboembolic complications.¹¹⁶ Also being investigated is bindarit, which blocks the production of monocyte chemoattractant protein MCP-1. As a result, the inflammation in the glomeruli is reduced.¹⁰⁷

■ TREATMENT OUTCOME

The prognosis of patients with class II disease is generally good and no specific treatment is commonly needed. In patients with class V disease, steroids alone commonly induce partial or complete remission. Immunosuppressive agents can be used for those who are not responsive to steroids. The survival of patients with class III and IV disease has improved during the last two to three decades to about 74% to 80% at 10 years.¹⁰² Besides the judicious use of cytotoxic agents, the lower steroid dosage and better management of complications such as hypertension, infections, hyperlipidemia, and other metabolic complications of the disease have all likely contributed to the more favorable long-term outcome. Lupus patients with ESKD on dialysis fare as well as those with non-lupus-related renal disease. In those patients who received a renal transplant, the allograft outcome of patients with lupus nephritis is favorable.¹¹⁷ Recurrence of lupus in the renal allograft can occur, but is usually of minor clinical importance.

Besides the hallmark feature of extensive crescents, severe endocapillary proliferation and segmental necrosis can also be seen on light microscopy. Based on immunofluorescence microscopic findings, three types of primary RPGN can be identified. Type I RPGN is characterized by the linear localization of immunoglobulins, mainly IgG, along the GBM, signifying anti-GBM antibody-induced injury. Type II is defined by the coarse granular deposition of immunoglobulins and complement within the capillary walls and mesangium, denoting immune-complex-mediated injury. Type III is characterized by scanty or complete lack of immune complex deposits; therefore it

is also known as pauci-immune RPGN. Circulating ANCA are often detected in type III RPGN. This immunohistologic classification of RPGN reflects the immunopathogenesis of the different types of crescentic glomerulonephritis.

PATHOPHYSIOLOGY

Several etiologic factors are implicated as the cause of RPGN: toxins, drugs, viral and bacterial infections, neoplasms, autoimmune mechanisms, and various immunogenetic factors.¹¹⁸

Regardless of the etiology and type of RPGN, the disruption in the glomerular capillary wall seems to be the common lesion in crescentic glomerulonephritis.¹¹⁸ Both humoral and cellular pathways of inflammation are responsible for the severe damage to the capillary wall. Activation of the terminal C5b-9 (membrane-attacking complex) of the complement system produces severe capillary wall injury. Both neutrophils and macrophages release proteinases and reactive oxygen species and may thereby produce severe glomerular injury. Platelets and the coagulation system are activated and result in capillary thrombosis. Fibrinogen and procoagulants that are released from ruptured capillaries may come into contact with thrombogenic tissue debris and lead to fibrinoid changes. In anti-GBM glomerulonephritis, the direct attack of the anti-GBM antibody on the noncollagenous region of the type IV collagen molecule of the GBM, is responsible for the capillary wall injury.¹¹⁸ ANCA may also play an important role in mediating the vascular injury in patients with ANCA-associated disease. The interaction of ANCA with neutrophils and monocytes, which have been primed by concurrent infections or inflammatory processes, can lead to activation of these leukocytes and release of toxic oxygen species and lytic enzymes, resulting in vascular injury.

The disruption of the capillary wall allows movement of macrophages and other plasma constituents into Bowman's space and stimulates the formation of crescents, which are composed mainly of parietal epithelial cells, as well as macrophages and fibroblasts. Crescent formation indicates the severity of the glomerular capillary disease but not its pathogenesis. The age of crescents can serve as a marker for disease duration and the likelihood of successful therapeutic intervention.¹¹⁸

CLINICAL PRESENTATION

Among the crescentic glomerulonephritides, the pauci-immune RPGN is the most frequent, accounting for more than 50% of cases, whereas the anti-GBM antibody-mediated RPGN is the least fre-

quent, occurring in roughly 10% to 20% of patients. Of patients with type I RPGN, 60% to 70% may have concurrent pulmonary hemorrhage and Goodpasture's syndrome, which is caused by antibodies directed against the pulmonary alveolar basement membrane. Most patients with immune complex-mediated RPGN have collagen vascular disease, systemic infections, or a severe form of primary glomerular disease. Approximately 70% of patients with type III RPGN also present with evidence of systemic vasculitis, such as Wegener's granulomatosis and polyarteritis nodosa. They often have insidious onset with initial symptoms such as fatigue, fever, night sweats, and arthralgias. Other patients have only renal manifestations, and they are said to have idiopathic crescentic glomerulonephritis or renal vasculitis.¹¹⁸

The clinical presentation is dominated by progressive renal insufficiency with complaints of tea-colored urine, malaise, anorexia, low-grade fever, and migratory polyarthropathy. Mild hypertension is usually present. Uremic signs and symptoms may develop as renal function worsens. Type I RPGN is more commonly found in the third and sixth decades of life, while patients with ANCA-mediated disease tend to be older, with peak incidence occurring between 50 and 60 years of age. The age-related incidence varies among the immune complex-mediated RPGN; for example, poststreptococcal glomerulonephritis and Henoch-Schönlein purpura nephritis are more common in young children, whereas membranoproliferative glomerulonephritis is more frequently seen in older children. Urinalysis commonly shows nephritic sediments with hematuria, erythrocyte casts, and proteinuria. However, overt nephrotic syndrome is rare.

Serologic analysis is very useful in distinguishing the different types of RPGN. The detection of serum anti-GBM antibodies with the appropriate clinical presentation confirms the diagnosis of anti-GBM glomerulonephritis. More than 80% of patients with pauci-immune or idiopathic crescentic glomerulonephritis have circulating ANCA. ANCA are autoantibodies specific for the cytoplasmic constituents of neutrophil granules and monocyte lysosomes. Patients with ANCA-associated disease limited to renal involvement often have P-ANCA (perinuclear staining), whereas patients with Wegener's granulomatosis tend to have C-ANCA (cytoplasmic staining). Both the anti-GBM antibody and the ANCA are absent in patients with type II RPGN. Measurements of circulating immune complexes are not useful for making a specific diagnosis, but detection of specific serum antibodies known to mediate immune complex-associated nephritis is helpful: anti-DNA antibody as a marker for lupus nephritis and elevated anti-streptolysin-O titers for poststreptococcal glomerulonephritis. The serum complement levels are normal in RPGN, although they can be low in the immune complex-mediated category.

► TREATMENT: Rapidly Progressive Glomerulonephritis

CLINICAL CONTROVERSY

The optimal treatment of many types of rapidly progressive glomerulonephritis is not known since it is difficult to find sufficient number of patients to conduct well designed and credible clinical trials.

Early aggressive therapy has improved the renal prognosis of patients with crescentic glomerulonephritis. The rapid deterioration of renal function and the paucity of a large number of patients make randomized controlled studies very difficult to conduct. Based on the available data, immunosuppressive therapy alone appears to be ineffective for type I RPGN, while types II and III RPGN respond well to high-dose steroid therapy.^{118,119} Regardless of the type of

RPGN, poor response to therapy and an ominous renal survival are expected if the patient presents with oliguria, has a serum creatinine concentration greater than 6 or 7 mg/dL, is dialysis dependent, or has a renal biopsy showing advanced chronic parenchymal disease.¹²⁰

■ ANTI-GBM GLOMERULONEPHRITIS (TYPE I)

Pulse intravenous administration of corticosteroids has been used successfully to alleviate pulmonary hemorrhage, but the results are not as convincing for glomerulonephritis.^{118,119} When used, the immunosuppression should be maintained for 8 weeks to prevent antibody rebound.¹¹⁸ Plasmapheresis, in combination with steroids and

cytotoxic agents, was found to be more beneficial than immunosuppression alone.^{98,119} Plasmapheresis may confer its benefits by removing the circulating pathogenetic anti-GBM antibody, and is therefore used for 2 weeks or until the antibody disappears.^{119,121} The treatment was found to be useful in treating pulmonary hemorrhage; however, the long-term benefits on renal function are unknown. Because of the rapid decline in renal function, diagnosis should be established early so that therapy can proceed without delay. When the serum creatinine concentration is 6 mg/dL or above, or the patient is oliguric or requires dialysis, the response to therapy is usually poor and the patient should be treated conservatively.^{118,119} Poor response should also be expected when crescents are found in more than 85% of the glomeruli.

■ IMMUNE COMPLEX-MEDIATED GLOMERULONEPHRITIS (TYPE II)

The treatment of this type of RPGN varies with the underlying glomerulonephritis. Patients with postinfectious RPGN generally have a favorable prognosis even without treatment. Complete spontaneous recovery occurs in 50% of cases, whereas chronic renal failure develops in 32%.¹¹⁸ Pulse doses of methylprednisolone, followed by oral prednisone and then tapering, have been shown to be beneficial in type II RPGN, with a response rate of 85% in patients with acute disease and 70% in those with more chronic disease.¹¹⁹ Plasmapheresis does not appear to provide any additional benefit.¹¹⁹

■ ANTINEUTROPHIL CYTOPLASMIC AUTOANTIBODY (ANCA)-ASSOCIATED GLOMERULONEPHRITIS (TYPE III)

Type III RPGN has been treated successfully with pulse doses of intravenous methylprednisolone, followed by oral prednisone for 1 month and then tapering over the next 6 to 12 months.^{118,119} The recognition that pauci-immune necrotizing crescentic glomerulonephritis is part of the spectrum of necrotizing vasculitides, especially with the detection of ANCAs in these patients, has led to the use of cyclophosphamide with steroids.¹¹⁹ Cyclophosphamide should be given for

6 to 12 months, either orally (2 mg/kg per day) adjusted to maintain the leukocyte count between 3000 and 5000/mL, or intravenously starting at 0.5 g/m² per month and increased monthly by 0.25 g to a maximum of 1 g/m² per month.^{119,122} Vigilant monitoring of the white cell count is necessary to prevent severe leukopenia. The combined use of cyclophosphamide and steroids resulted in a higher remission rate and less risk for relapse than steroids alone. This regimen is indicated even for patients with advanced disease or dialysis dependence as well as for relapse. During treatment the serum ANCA levels can be monitored to determine the efficacy of therapy. However, the precise role of ANCA monitoring is not clear.

At present, plasmapheresis is not expected to have any additional benefits for patients with mild to moderate disease who are receiving immunosuppressive therapy.¹²¹ However, recently completed randomized studies and meta-analyses of controlled trials strongly suggest that, when used as an adjunct to immunosuppressive therapy, plasmapheresis is beneficial for patients with severe disease presenting with acute renal failure.⁹⁸ In those patients presenting with pulmonary hemorrhage, early and aggressive use of plasmapheresis has reduced substantially the nearly 50% mortality rate.¹²²

Several other agents have been used to prevent recurrence of ANCA-associated diseases.^{120,122} Mycophenolate mofetil has been used anecdotally with favorable results for remission maintenance. Methotrexate has also been used; however, it should not be given when the creatinine clearance is <50 mL/min. Trimethoprim-sulfamethoxazole was found to reduce ANCA-associated vasculitis, especially in the upper respiratory tract.

■ RENAL TRANSPLANTATION

Anti-GBM nephritis may recur in up to 55% of patients who received a renal transplant. However, only 25% of these patients showed clinical disease activity, with rare allograft failure. Because the frequency of recurrence and its severity are related to the presence of circulating anti-GBM antibody, it is recommended that transplantation should not be performed until the anti-GBM antibody is undetectable for at least 6 to 12 months.¹²³ The recurrence rate of ANCA-associated nephritis is 17%, with the average time to relapse from transplantation of 31 months.¹²⁴

POSTSTREPTOCOCCAL GLOMERULONEPHRITIS

Poststreptococcal glomerulonephritis (PSGN) and glomerulonephritis caused by other infectious agents, such as bacteria, viruses, and parasites, were once common. Improved sanitation, personal hygiene, medical care, and public health measures helped to decrease the incidence of group A streptococcal infection both in the United States and other developed countries, resulting in a decline of PSGN. However, PSGN is still common in developing countries. In contrast, glomerulonephritis secondary to other infectious agents, such as hepatitis C and HIV, is seen with increasing frequency in developed countries.

It was more than 200 years ago when hematuria and proteinuria were found to be associated with epidemics of scarlet fever. Certain strains of group A streptococci were identified in the 1950s to be responsible for the glomerular disease. PSGN is now the most common form of glomerulonephritis in children, but is less common than the other types of glomerulonephritis in adults. It normally follows pharyngeal or skin infection caused by the nephritogenic strains of

group A streptococci; however, other strains of streptococci, such as group C and G, have also been reported to cause PSGN. Streptococcal pharyngitis is more common in winter and early spring, whereas skin infection is frequently found in the summer. The risk for developing acute glomerulonephritis secondary to the nephritogenic strains of bacteria is about 10% to 15% in infected patients. However, three to four times more patients may experience a subclinical form of the disease.

PATHOPHYSIOLOGY

Despite decades of research, the characteristics of the antigens responsible for the production of the nephritogenic immune complexes remain unclear. It has been postulated that the streptococcal antigens may induce changes in the glomerular components so that they become immunogenic or that autologous IgG may be altered to become antigenic. Alternately, the streptococcal antigens may induce antibodies that react with glomerular antigens. In situ immune complexes

are then formed and result in a complement-mediated inflammatory response. The kinin and coagulation cascades are activated and chemotactic factors are released to recruit neutrophils and monocytes, resulting in acute glomerular lesions.

Examination of the acute PSGN kidneys reveals hypercellular glomeruli with proliferation of mesangial and endothelial cells. Infiltration of neutrophils, monocytes, and eosinophils is apparent within the capillary lumen and also in the mesangial areas. Crescent formation may be seen in patients with severe disease, and if found in more than 30% of the glomeruli, RPGN may be present concurrently.¹²⁵ The prognosis is generally poor for these patients and complete recovery is unlikely. When the tissue is examined under electron microscope, “humps,” which are multiple large, discrete, electron-dense, dome-shaped deposits can be found beneath the epithelial foot processes. Immunofluorescence examination reveals diffuse granular deposits of IgG and C3 along the glomerular basement membrane and also in the mesangium.

CLINICAL PRESENTATION

PSGN is seen mostly in children aged between 5 and 15 years, with a peak incidence between ages 6 and 7 years. It is uncommon in children younger than 2 years of age and in adults older than 50 years of age. Males are twice as likely to be affected as females. The nephritis is preceded by a latent period following a streptococcal infection. The latent period is commonly 7 to 14 days for pharyngitis and 14 to 28 days for skin infection. In patients with pre-existing nephritis such as IgA nephropathy and membranoproliferative glomerulonephritis, the streptococcal infection may exacerbate the nephritis and result in hematuria.

Following the latent period, an acute nephritic syndrome develops with hematuria and edema being the most common characteristics. Gross hematuria is seen in 70% of patients, and microscopic hematuria can be found in all patients. Edema, which is often worse in the morning, is found commonly in the periorbital area and around the eyelids. Hypertension is usually mild to moderate and results from sodium and water retention; at times, it may be severe enough to cause hypertensive encephalopathy. Many patients have signs and symptoms associated with volume overload, which include dyspnea, orthopnea, and cough. In some instances, progression to overt con-

gestive heart failure may be seen. Severe hypertension may also result in neurologic abnormalities.

Urinalysis of patients with PSGN reveals hematuria, dysmorphic red blood cells, and red cell casts. Proteinuria is common, but often not in the nephrotic range. Renal function is frequently mildly impaired, and serum creatinine concentration is often normal. However, blood urea concentration may be disproportionately high.

Throat or skin culture may be positive for group A streptococci, despite the latent period following the initial infection. However, antibiotic therapy may render the culture result negative. Serologic measurements of antibodies to different streptococcal antigens can confirm recent exposure to the infection. Titers that can be measured include the antistreptolysin (ASO), antistreptokinase, antihyaluronidase (AHase), antideoxyribonuclease B (ADNase B), and antinicotinadenine dinucleotidase (NADase).¹²⁶ In most patients with streptococcal pharyngitis, the ASO titers begin to rise about 10 to 14 days later, peak at 3 to 4 weeks, and persist for several months before decreasing. The rise in ASO titers can be reduced by antibiotic treatment and may not be seen in patients with streptococcal skin infection in whom the streptolysin may be bound to skin lipids. ADNase B and AHase titers should be used instead because they are specific and are positive in the majority of patients. The streptozyme test is a combined assay for ASO, ADNase B, NADase, and AHase. It has a high rate of false-positive and false-negative results, and the antibody levels do not correlate with nephritogenicity or disease severity. Recently, antizymogen titers were found to be the best marker to diagnose streptococcal-associated nephritis.¹²⁷ Increased availability of this test may facilitate early and accurate diagnosis of nephritis.

Serum complement levels are often decreased in patients with PSGN in whom hemolytic complement activity and C3 levels are reduced in more than 90% of the patients for 4 to 6 weeks. If the C3 level is depressed for more than 6 to 8 weeks, MPGN, lupus nephritis, or glomerulonephritis related to endocarditis or occult visceral abscess should be suspected.

Renal biopsy is not normally indicated for PSGN unless the patient has severe renal dysfunction, severe proteinuria, significant hypertension, and/or prolonged oliguria, which are not typical for PSGN. If the hematuria is prolonged or proteinuria or depressed C3 level persists, renal biopsy is needed to detect other types of glomerulonephritis such as lupus, RPGN, or MPGN.

► TREATMENT: Poststreptococcal Glomerulonephritis

8 The treatment of PSGN is mainly supportive and symptomatic. Early antibiotic therapy does not prevent subsequent PSGN, but it may reduce the severity of the disease. It can, however, prevent the spread of the streptococcal infection to other family members. Antibiotic prophylaxis is not recommended because infected patients will develop long-lasting, often lifelong immunity against the strain of streptococci. Exposure to another nephritogenic strain of streptococci is possible, but unlikely.

Supportive measures, as discussed earlier in this chapter, should be used to control fluid volume and blood pressure. Because the hypertension is of the low-renin type, ACEIs and β -blockers are not expected to be useful. If the patient has crescentic disease, use of pulse steroids and/or immunosuppressive agents can be considered;¹¹⁸ however, the efficacy and safety of these agents have not been established for this condition.

The acute manifestations of PSGN are normally self-limited, and more than 95% of the patients have renal function restored within 3 to 6 weeks. Diuresis usually begins 7 to 10 days after onset of the acute episode, whereas hypertension and azotemia resolve in 1 to 2 weeks. Gross hematuria lasts for 1 to 2 weeks and proteinuria usually resolves within 6 months in more than 90% of children. However, microscopic hematuria may persist for up to 2 years. In general, children have more rapid recovery than adults. Prognosis is often better when PSGN occurs during an epidemic than in cases found sporadically. Most of the children will recover fully and be free from chronic complications of PSGN if they have no pre-existing renal disorder, heavy proteinuria, or crescentic glomerular lesions, or did not require hospitalization during the acute episode.¹²⁸ In contrast, adult patients have a less favorable long-term outcome. As many as 50% of the patients had persistent proteinuria, hypertension, and renal insufficiency.¹²⁹ Some of the patients may develop end-stage renal failure.

CONCLUSIONS

A better understanding of the pathogenetic mechanisms leading to glomerular injury has improved the treatment of glomerulonephritis. However, the glomerulonephritides are a heterogeneous group of immune disorders with different clinical courses, prognoses, and responses to current immunologic and nonimmunologic therapies. The clinician should understand the natural history and prognosis of each subgroup of glomerulonephritis, the efficacy of different immunomodulating regimens in inducing disease remission and preserving renal function, and the characteristics of at-risk patients who warrant aggressive therapy. Judicious use of immunosuppressive agents with careful monitoring of their adverse effects cannot be overemphasized. In addition, treatment of the disease complications and control of factors that lead to progression of renal disease are important in reducing the morbidity and mortality of patients with glomerulonephritis.

ABBREVIATIONS

ACE: angiotensin-converting enzyme
 ADNase B: antideoxyribonuclease B
 AHase: antihyaluronidase
 ANCA: antineutrophil cytoplasmic autoantibody
 ARB: angiotensin II receptor blocker
 ASO: antistreptolysin
 ESRD: end-stage renal disease
 GBM: glomerular basement membrane
 GFR: glomerular filtration rate
 FSGS: focal segmental glomerulosclerosis
 HDL: high-density lipoprotein (cholesterol)
 HIV: human immunodeficiency virus
 HMG-CoA: hydroxymethylglutaryl coenzyme A (reductase)
 IL-1: interleukin-1
 IL-2: interleukin-2
 LDL: low-density lipoprotein (cholesterol)
 MPGN: membranoproliferative glomerulonephritis
 NADase: antinicotinadenine dinucleotidase
 PSGN: poststreptococcal glomerulonephritis
 RPGN: rapidly progressive glomerulonephritis
 SLE: systemic lupus erythematosus
 TNF: tumor necrosis factor
 VLDL: very-low-density lipoprotein (cholesterol)
 WHO: World Health Organization

DRUG THERAPY INDIVIDUALIZATION FOR PATIENTS WITH RENAL INSUFFICIENCY

Reginald F. Frye and Gary R. Matzke

Learning Objectives and other resources can be found at www.pharmacotherapyonline.com.

KEY CONCEPTS

- 1 Chronic kidney disease can affect all aspects of drug disposition, including absorption, distribution, metabolism, and elimination.
- 2 Changes in protein binding induced by renal failure can alter the relationship between total drug concentration and response.
- 3 In addition to the expected changes in renal drug elimination, nonrenal drug clearance (i.e., hepatic drug

metabolism) may also be decreased in patients with chronic kidney disease.

- 4 Individualization of a drug dosage regimen in a patient with renal disease is based on the pharmacokinetic characteristics of the drug and the patient's level of renal function.
- 5 The effect of hemodialysis or chronic renal replacement therapy on drug elimination is dependent on the characteristics of the drug and the dialysis conditions.

Patients with renal insufficiency are commonly encountered in clinical practice. Indeed, it is estimated that nearly 11 million people in the United States have serum creatinine values of 1.5 mg/dL or greater and another 0.8 million have serum creatinine values of 2.0 mg/dL or greater.¹ Reductions in renal function can be associated with disease states, drug effects (e.g., drug-induced nephrotoxicity), or the result of the known age-related maturation or diminution of renal function. In children, renal function does not mature to adult values until approximately 1 year of age.² In older adults, age-related declines in renal function combined with the increased use of medications make this patient group particularly susceptible to adverse effects secondary to inappropriate pharmacotherapy.³ The presence of compromised renal function in any patient age group, ranging from pediatric to geriatric, requires that the clinician understand the aspects of drug disposition that are altered in the presence of renal insufficiency and the appropriate methods to individualize drug therapy.^{4,5}

Acute renal failure (ARF) and chronic kidney disease (CKD) are often accompanied by alterations in several other organ systems and results in the development of anemia, hyperparathyroidism, bleeding abnormalities, hyperlipidemia, hypertension, and changes in gastrointestinal tract integrity (see Chaps. 42 and 44). There are now many reports that document changes in the disposition of some drugs in patients with renal insufficiency as the result of changes in bioavailability,⁶ protein binding,⁷ distribution volume,⁸ and metabolic activity.⁹

Drug therapy individualization for patients with renal insufficiency may require only a simple dose adjustment based on the fractional reduction in creatinine clearance.¹⁰ However, the use of medications that are extensively metabolized or for which dramatic changes in protein binding and/or distribution volume have been noted may require a more complex adjustment.^{8,10} Furthermore, because of the physiologic and biochemical changes associated with progressive

renal insufficiency, patients may respond to a given dose or serum concentration of a drug differently than patients with normal renal function.¹¹

Knowledge of basic pharmacokinetic principles combined with the drug disposition properties of a particular compound and the degree and type of pathophysiologic alterations associated with renal insufficiency makes it possible for the clinician to design an individualized therapeutic regimen. This chapter describes the influence of renal insufficiency on drug absorption, distribution, metabolism, and elimination, and provides a practical approach for drug dosage individualization for patients with ARF or CKD as well as those receiving continuous renal replacement therapy, continuous ambulatory peritoneal dialysis, or hemodialysis.

EFFECT ON DRUG ABSORPTION

- 1 There is little quantitative information regarding the influence of impaired renal function on drug absorption and bioavailability. Drug bioavailability in ARF or CKD patients may be altered by several factors, including changes in gastrointestinal transit time and gastric pH; edema of the gastrointestinal tract; vomiting and diarrhea (frequent complications of severe renal insufficiency); and antacid administration. Evaluations of bioavailability are generally conducted in those with severe stable renal insufficiency, i.e. stage 5 CKD also called end-stage kidney disease (ESKD). The assessment of bioavailability in this patient population is further complicated, because most patients with severe CKD receive multiple medications, many of which cannot be discontinued during the course of a bioavailability study.

Some of the drug absorption “bioavailability” studies in ESKD patients have not provided an assessment of absolute bioavailability

(i.e., they have not included intravenous administration of the drug). Rather, they have documented alterations in the peak concentration (C_{max}), time at which the peak concentration was attained (t_{max}), or in the fractional amount of drug recovered in the urine in a finite time period. Unfortunately, this limited information has been extrapolated to suggest that drug absorption is slowed and/or that the extent of absorption is reduced.⁶

The absolute bioavailability of only a few drug compounds is affected by ESKD. An increase in bioavailability as the result of a decrease in metabolism during the drug's first pass through the gastrointestinal tract and liver has been noted for some β -blockers (i.e., bufuralol, oxprenolol, propranolol, and tolamolol), dextropropoxyphene, and dihydrocodeine.^{6,8} Although the bioavailability of these compounds is increased, clinical consequences (development of excessive or unexpected adverse effects) have only been demonstrated with dextropropoxyphene and dihydrocodeine. The lack of association between the pharmacokinetic profile and clinical consequences of the β -blockers may result from an alteration in the responsiveness of patients with renal disease to these agents, as has been reported with propranolol in the elderly.³

EFFECT ON DRUG DISTRIBUTION

The volume of distribution of many drugs may be significantly increased or decreased in patients with renal insufficiency (Table 48–1).^{8,12,13} Alterations in distribution volume may result from increased or decreased protein binding; altered tissue binding; or pathophysio-

logic alterations in body composition (e.g., the fractional contribution of total body water to total body weight; or they may be an artifact of the volume term used in the comparison).

Generally, the plasma protein binding of acidic drugs (e.g., warfarin and phenytoin) is decreased in those with ESKD^{7,14} (Table 48–2), whereas the binding of basic drugs (e.g., quinidine and lidocaine) is usually normal or slightly decreased or increased^{7,15,16} (Table 48–3). The decrease in binding of acidic drugs has been attributed to qualitative changes in the binding sites, accumulation of endogenous inhibitors of binding, and decreased concentrations of albumin. The first two of these mechanisms appear to account for most of the observed changes in binding. In addition, the high concentrations of metabolites of some compounds that accumulate in patients with ESKD may interfere with the protein binding of the parent compound.

Although the fraction of unbound drug increases in patients with renal insufficiency, a new equilibrium is established as a result of increased drug elimination/distribution such that the free concentrations remain comparable. However, total concentrations are reduced because of an increase in drug clearance. Thus the net effect of changes in protein binding is an alteration in the relationship between total drug concentration and effect. This can be illustrated with the anticonvulsant phenytoin. The protein binding of this acidic drug, which binds to albumin, is significantly reduced as a result of endogenous substances that accumulate in renal failure and compete for binding, as well as by conformational changes in albumin in CKD patients.¹⁷ This change in protein binding alters the relationship between total phenytoin concentration and effect or toxicity. The resulting increase in unbound fraction, from the normal of 0.1 to 0.2 or more, results in increased hepatic clearance and decreased total concentrations. Thus in patients with CKD, the therapeutic range based on total phenytoin

TABLE 48–3. Change in Percent Unbound of Basic Drugs in Patients with Normal Renal Function and End-Stage Kidney Disease (ESKD)

concentration (normal, 10 to 20 mcg/mL) shifts downward as the degree of renal impairment increases. The unbound concentration therapeutic range is however unchanged in the presence of renal failure.

Unbound concentration measurements provide the best means for individualizing phenytoin therapy in patients with renal insufficiency. They are however not widely available nor routinely utilized. Therefore methods have been presented to equate an observed total concentration in patients with ESKD receiving hemodialysis treatment to what would be expected in patients with normal renal function. Liponi and associates¹⁷ suggested a method by which the total phenytoin concentration (C_m^{total}) in patients with creatinine clearance values of 10 to 24 mL/min or less than 10 mL/min can be equated to the concentration that would be observed if plasma protein concentrations and phenytoin-binding characteristics were normal. A patient's "equated" total phenytoin concentration (C_e^{total}) would thus equal:

$$C_e^{\text{total}} = \left(\frac{1}{[1] + [(nK_a)(p)]} \right) (C_m^{\text{total}}(10))$$

where nK_a is the binding parameter based on the patient's renal function (10 to 24 mL/min = 1.5, and <10 mL/min = 1.0), and p is the measured serum albumin concentration. This methodology allows one to approximate the equivalent "total" phenytoin concentration in a patient with reduced renal function and can be used to predict dosage requirements via a standard nonlinear approach (see Chap. 5).

The principal binding protein for several basic drug compounds is α_1 -acid glycoprotein, which is an acute-phase reactant with increased plasma concentrations in a wide variety of patients, including renal transplant patients and hemodialysis patients.⁸ The fraction of those drugs principally bound to α_1 -acid glycoprotein may be significantly increased in ESKD patients.⁷ Thus patients with renal insufficiency may experience increased or decreased protein binding, depending on the principal binding protein for the drug in question.

Altered tissue binding may also affect the apparent volume of distribution of a drug. For example, the distribution volume of digoxin has been reported to be reduced by 30% to 50% from normal values in patients with renal disease.¹⁸ It has been postulated that this reduction in the distribution volume is secondary to a decrease in tissue

binding as a result of competitive inhibition by endogenous or exogenous substances. This factor must therefore be considered when designing individualized dosage regimens. Multiple methods have been proposed to estimate the degree of reduction in digoxin's distribution volume.¹⁸ The volume of distribution (V_D) of digoxin can be estimated as follows:

$$V_{D(\text{liters})} = [226] + \left[\frac{(298)(\text{CLcr})}{29.1 + \text{CLcr}} \right]$$

For a patient weighing 60 kg with a creatinine clearance (CLcr) of approximately 15 mL/min per 1.73 m², the volume of distribution for digoxin would be:

$$V_{D(\text{liters})} = [226] + \left[\frac{(298)(15)}{29.1 + 15} \right] = 327 \text{ L or } 5.5 \text{ L/kg}$$

This represents a 30% reduction from the volume of distribution that would have been anticipated in a patient with normal renal function. Acidosis or the presence of digoxin-like immunoreactive substances that bind to and inhibit membrane ATPase may also contribute to this phenomenon.¹⁹ In this situation, the absolute amount of digoxin bound to the receptor is reduced and the resultant serum digoxin concentration from any dose would be greater.

Knowledge of protein and tissue binding changes in patients with renal insufficiency is critically important in the interpretation of serum drug concentrations. Numerous investigations show that the unbound concentration of several drugs in plasma correlates more closely with the concentration of drug at the receptor site, and therefore with the pharmacologic effect, than does the total concentration of drug in plasma.²⁰ Because an alteration in plasma protein or tissue binding of a drug will likely alter the total drug concentration, the usual expected relationship between total drug concentration and pharmacologic response will be perturbed, but the relationship to unbound drug should not be affected.

Thus in patients with renal insufficiency, particularly those with ESKD a "normal" total drug concentration may be associated with either serious adverse reactions secondary to elevated unbound drug concentrations, or subtherapeutic responses because of an altered plasma:tissue drug concentration ratio. Therefore the monitoring of unbound drug concentrations in this patient population is suggested for those drugs that have a narrow therapeutic range, are highly protein bound (free fraction of <20%), and for which marked variability in the free fraction has been reported (e.g., phenytoin and disopyramide).

Finally, the method used to calculate the volume of distribution may be influenced by renal insufficiency. The three most commonly used volume of distribution terms are volume of the central compartment (V_c), volume of the terminal phase (V_β , V_{area}), and volume of distribution at steady state (V_{ss}). The central compartment volume is calculated as the intravenous bolus dose divided by the initial plasma concentration. V_c for many drugs approximates extracellular fluid volume and thus may be increased or decreased by shifts in this physiologic volume. Renal insufficiency, especially oliguric acute renal failure, is often accompanied by fluid overload and a resultant increased V_c due to reduced renal elimination of water and sodium. V_{area} or V_β is calculated as the total body clearance divided by the terminal elimination rate constant (k or β). This volume term represents the proportionality constant between plasma concentrations in the terminal elimination phase and the amount of drug remaining in the body. V_β is affected by both distribution characteristics, as well as by the elimination rate constant. The third volume term, the steady-state volume of distribution (V_{ss}), is calculated as $(\text{AUMC} \times \text{dose})/\text{AUC}^2$, where AUMC is the area under the first moment of the concentration-time curve and AUC is the area under the concentration-time curve

(see Chap. 5). V_β and V_{ss} will often be similar in magnitude, with V_β being slightly larger. In situations in which V_β is much larger than V_{ss} , V_β may reflect the elimination rate more than the distribution volume. Because V_{ss} has the advantage of being independent of drug elimination, it may be the most appropriate volume term to use when one desires to compare drug distribution volumes between patients with renal insufficiency and those with normal renal function.²¹

EFFECT ON METABOLISM

3 A decrease in the renal elimination of drugs in patients with renal insufficiency is well appreciated and rational methods for adjusting treatment regimens on the basis of renal function are presented in this chapter. However, in addition to the expected decrease in renal drug elimination, there is increasing evidence that CKD also alters other elimination pathways, most notably cytochrome P450 (CYP450)-mediated metabolism in the liver and other organs.⁹

Initial clinical evidence supporting the notion that kidney disease affects hepatic drug metabolism included observations of reduced nonrenal clearance for several drugs in patients with renal insufficiency.^{9,11} The observed reductions in nonrenal clearance were generally proportional to the reductions in glomerular filtration rate (GFR). However, the effect(s) of renal failure on nonrenal drug clearance may also depend on whether the renal failure is acute or chronic in nature. Effects observed in ARF do not appear to be as great as those observed in ESKD patients, potentially due to less accumulation of/or exposure to metabolic inhibitors.¹¹ The nonrenal clearance of a drug may be increased, decreased, or unaffected by renal failure, depending on the metabolic pathway(s) involved and the drug and the species (animals versus humans) investigated^{22–24} (Table 48–4). In general, these studies should be interpreted with caution since concurrent drug intake, age, smoking status, and alcohol intake were often not controlled. Furthermore, the possibility of pharmacogenetic variation in drug-metabolizing enzymes (e.g., CYP450 enzymes) must be considered. Prediction of the effect of renal insufficiency on the metabolism of a particular drug is thus difficult and a general quantitative strategy to adjust treatment regimens is not available. However, some insight can be gained if one knows what particular enzyme is involved in the

metabolism of the drug of interest and how the enzyme(s) is affected in the presence of renal insufficiency.

CYP450 enzymes are widely distributed throughout the body with the most abundant expression being found in the liver and intestine. CYP450 enzymes in the kidney catalyze the metabolism of a variety of chemicals and drugs with activity similar to that in the liver on an activity-per-gram-of-tissue basis, but the contribution to total metabolic activity is generally low since total kidney weight is far less than total liver weight.

Investigations of the effect of chronic renal failure on hepatic enzyme activity in animals have demonstrated reductions in some, but not all, pathways of drug metabolism.^{9,25} The mechanism(s) by which chronic renal failure affects hepatic drug metabolism is not clearly known, but may relate to accumulation of endogenous inhibitors (e.g., uremic toxins) or to the fact that CKD patients exist in a chronic inflammatory state and have increased levels of oxidative stress,²⁶ factors known to downregulate CYP450 enzymes.²⁷ It has been shown in rat models of chronic renal failure that protein expression of several CYP450 enzymes, including CYP450 3A1 and CYP450 3A2 (corresponding to human CYP450 3A4), is reduced in the liver by as much as 75%. The mechanism of this decrease in protein content is reduced mRNA expression, indicating transcriptionally mediated downregulation.²⁵ The *in vivo* relevance of these effects was demonstrated in rats with chronic renal failure using enzyme-selective breath tests; the results showed that chronic renal failure has differential effects on enzyme activity with CYP450 2C11 and CYP450 3A2 being significantly reduced (by 35%), while CYP450 1A2 activity was no different from that in control animals.²⁸ Consistent with these observations in animals, CYP450 3A activity as measured by the erythromycin breath test was 28% lower in ESKD patients as compared to healthy controls.²⁹ While baseline CYP450 3A activity was lower in these patients, the increase in CYP450 3A activity observed following enzyme induction with rifampin was similar.²⁹ Collectively, these data indicate that chronic renal impairment has a detrimental effect on some important pathways of hepatic drug metabolism.

In addition to changes in hepatic metabolism, chronic renal failure has also been shown in animals to affect the expression and activity of CYP450 enzymes in the intestine.³⁰ CYP450 1A1 and CYP450 3A2 enzyme content was reduced by 43% and 71%, respectively, and corresponding mRNA levels were decreased by 32% and 36%, respectively. Although this has not been specifically evaluated in humans, an effect on intestinal metabolism may be clinically relevant for those drugs for which intestinal metabolism is known to be important (e.g., CYP450 3A substrates with low bioavailability).

Unfortunately, the effect of renal insufficiency on CYP450 enzymes has not been fully evaluated, but current data suggest a differential effect on the individual enzymes with the activity of some enzymes (e.g., CYP450 3A4 and CYP450 2C9) being reduced,^{29,31} while others (e.g., CYP450 2E1) are not affected.³² This differential effect on individual enzymes may help to explain some of the conflicting reports of whether drug metabolism is altered in the presence of renal disease. If the metabolism of a drug is known to be increased or decreased in patients with renal failure, then the dose will need to be adjusted appropriately to achieve the desired effect. If the effect of renal failure on metabolism is unknown, then the agent should be used with extreme caution.

EFFECT OF RENAL INSUFFICIENCY ON METABOLITE ELIMINATION

Patients with severe renal insufficiency receiving chronic treatment with some agents may experience accumulation of metabolite(s) as

TABLE 48–4. Effect of End-Stage Kidney Disease on Nonrenal Clearance

| Decreased | | | |
|----------------|-----------------|----------------------|--------------------|
| Acyclovir | Aztreonam | Bufuralol | Captopril |
| Cefmenoxime | Cefmetazole | Cefonicid | Cefotaxime |
| Cefotiam | Cefsulodin | Ceftizoxime | Cilastatin |
| Cimetidine | Ciprofloxacin | Cortisol | Encainide |
| Erythromycin | Imipenem | Isoniazid | Methylprednisolone |
| Metoclopramide | Moxalactam | Nicardipine | Nimodipine |
| Nitrendipine | Procainamide | Quinapril | Repaglinide |
| Verapamil | Zidovudine | | |
| Unchanged | | | |
| Acetaminophen | Chloramphenicol | Clonidine | Codeine |
| Diflunisal | Indomethacin | Insulin ^a | Isradipine |
| Lidocaine | Morphine | Metoprolol | Nisoldipine |
| Nortriptyline | Pentobarbital | Propafenone | Quinidine |
| Theophylline | Tocainide | Tolbutamide | |
| Increased | | | |
| Bumetanide | Cefpiramide | Fosinopril | Nifedipine |
| Phenytoin | Rosiglitazone | Sulfadimidine | |

^aMay be unchanged or decreased.

TABLE 48–5. Pharmacologic Activity of Selected Drug Metabolites

| Parent Drug | Metabolite | Pharmacologic Activity of Metabolites |
|-------------------|--|--|
| Acetaminophen | <i>N</i> -acetyl- <i>p</i> -benzo-quinoneimine | Responsible for hepatotoxicity |
| Allopurinol | Oxipurinol | Metabolite primarily responsible for suppression of xanthine oxidase |
| Azathioprine | Mercaptopurine | All of the immunosuppressive activity resides in the metabolite |
| Cefotaxime | Desacetyl cefotaxime | Similar antimicrobial spectrum, but one-fourth to one-tenth as potent |
| Chlorpropamide | 2-Hydroxychlorpropamide | Similar in vitro insulin-releasing activity |
| Clofibrate | Chlorophenoxyisobutyric acid | Primarily responsible for hypolipidemic effect and direct muscle toxicity |
| Codeine | Morphine-6-glucuronide | Possibly more active than parent compound; may contribute to prolonged narcotic effect in renal failure patients |
| Imipramine | Desmethylimipramine | Similar antidepressant activity |
| Ketoprofen | Ketoprofen glucuronide | Accumulation of acyl glucuronide may worsen toxic effects (gastrointestinal disturbances and impairment of renal function) |
| Meperidine | Normeperidine | Less analgesic activity than parent, but more CNS-stimulatory effects |
| Morphine | Morphine-6-glucuronide | Possibly more active than parent compound; may contribute to prolonged narcotic effect in renal failure patients |
| Mycophenolic acid | Mycophenolic acid glucuronide | Lacks pharmacological activity but may be associated with dose-limiting (gastrointestinal) side effects |
| Procainamide | <i>N</i> -acetyl procainamide | Distinct antiarrhythmic activity, the mechanism of which is different from that of the parent compound |
| Sulfonamides | Acetylated metabolites | Devoid of antibacterial activity, but elevated concentrations are associated with increased toxicity |
| Theophylline | 1,3-Dimethyl uric acid | Cardiotoxicity has been demonstrated |
| Zidovudine | Zidovudine triphosphate | Primarily responsible for antiretroviral activity |

well as parent compound. Metabolites of several drugs have been reported to have significant pharmacologic and/or toxicologic activity. However, the pharmacokinetics and pharmacology of metabolites are not often fully elucidated in humans. In a sense, the patient with severe renal impairment is being exposed to a new pharmacologic entity if the serum concentrations of the metabolite exceed those reported in patients with normal renal function.

The metabolite may have pharmacologic activity similar to that of the parent drug and thus contribute significantly to clinical response; for example, oxypurinol and desacetyl cefotaxime.³³ Alternatively, the metabolite may have qualitatively dissimilar pharmacologic action; for example, normeperidine has central nervous system (CNS)-stimulatory activity that reportedly produces seizures, whereas meperidine has CNS-depressant actions.³⁴ Because of the multiplicity of potential interactions of compounds that are primarily metabolized, the practical consequences of metabolite accumulation are difficult to predict and are most often identified in those patients at risk by trial and error (Table 48–5).

EFFECT ON RENAL EXCRETION

Net renal clearance (CL_R) of a drug is the composite of GFR, tubular secretion, and reabsorption ($CL_R = (GFR \times f_u) + CL_{\text{secretion}} - CL_{\text{reabsorption}}$), where f_u is the fraction of the drug unbound to plasma proteins. Drug elimination by filtration occurs by a diffusion process, but tubular secretion and reabsorption are bidirectional processes that involve carrier-mediated renal transport systems.³⁵ Renal transport systems have been broadly classified on the basis of substrate selectivity into the anionic and cationic renal transport systems, which are responsible for the transport of a number of organic acidic and basic drugs, respectively. Renal organic anion transport is mediated by organic anion transporters, organic anion transporting polypeptides, and multidrug resistance-associated protein transporters.³⁵ Several drugs including β -lactam antibiotics, diuretics, and nonsteroidal

anti-inflammatory drugs are eliminated by members of these transporter families. These transporters also have an essential role in the elimination of glucuronide metabolites. Organic cation transport systems mediate the reabsorption and excretion of endogenous cationic compounds and cationic drugs (e.g., cimetidine, famotidine, and quinidine). The P-glycoprotein transport system in the kidney is also involved in the secretion of cationic and hydrophobic drugs (e.g., digoxin and vinca alkaloids).³⁵

Other important renal transport systems include the peptide transporters, which are involved in the uptake of peptide-like drugs including β -lactam antibiotics and angiotensin-converting enzyme inhibitors, and nucleoside transporter proteins, which are involved in uptake of nucleosides and nucleoside analogs (e.g., zidovudine and dideoxyinosine).³⁵

Alterations in one or more of the three renal processes (filtration, secretion, or reabsorption) secondary to reductions in functional nephron mass may have a dramatic effect on the pharmacokinetics of a drug. A reduction in glomerular filtration rate results in a decrease in renal drug clearance. For drugs that are extensively renally secreted ($CL_R > 300$ mL/min), the loss of filtration clearance (up to 120 mL/min) will have less of an impact than for those primarily dependent on GFR.

Although it was once thought that the mechanisms of renal elimination declined in a parallel manner in the presence of renal disease, it is now known that this may not be a valid assumption. Kamiya and associates³⁶ and Hori and colleagues³⁷ demonstrated that the type of renal disease may explain in part the differences in pharmacokinetic parameters observed among patients with similar reductions in GFR. The disposition of antibiotic agents extensively secreted by the proximal renal tubules (e.g., ampicillin and cephalixin) was altered to a greater degree in patients with tubulointerstitial disease as compared to those with primary glomerular disease. Quantitative investigations of renal handling of new drugs will be required to elucidate the relative contribution of tubular and glomerular function to renal drug clearance. The availability of these

data should provide a more rational approach to dosage regimen design for those agents that undergo extensive tubular secretion or reabsorption.

In the absence of data delineating the contribution of tubular function to renal elimination, the clinical measurement or estimation of creatinine clearance remains the guiding factor for drug-dosage regimen design.^{8,10} Although several methods have been proposed to estimate GFR from routinely available clinical data (see Chap. 41) the utility of a calculated GFR to guide drug dosing has not been extensively evaluated. The importance of an alteration in renal function on drug elimination thus depends on two factors: the fraction of drug normally eliminated by the kidney unchanged and the degree of renal insufficiency.

Quantitation of the patient's renal function can be accomplished by measurement of creatinine clearance or estimation based on the stable serum creatinine (see Chap. 41). Because of the time delay involved and problems in obtaining complete urine collections, measured creatinine clearance values are infrequently used for initial drug-dosage regimen design. Therefore the calculation of initial drug dosage regimens relies on the estimation of creatinine clearance (CL_{cr}) in adults and children from such routinely available clinical data as age, gender, height, weight, and serum creatinine. These relationships are most accurate for individuals of average muscle mass for their age, weight, and height. The creatinine clearance of emaciated and obese adult patients is difficult to predict, and incorrect estimates have been obtained with most methods.

Several methods are also available for estimating creatinine clearance in adults with ARF using age, height, weight, serum creatinine, and time data (see Chap. 41). These methods have not been as rigorously validated as the equations for patients with stable renal function. However, they are one of the few methods we have to approximate renal function in this complex patient situation.

DRUG-DOSAGE REGIMEN DESIGNS

PATIENTS WITH RENAL INSUFFICIENCY

The typical steps involved in designing a dosage regimen in a patient with renal insufficiency as the result of an acute insult or CKD are listed in Table 48–6. Most dosage adjustment guidelines have proposed the use of a fixed dose or interval for patients with broad ranges of renal function.^{12,38,39} For example, moderate renal insufficiency may encompass a creatinine clearance range of 30 to

50 mL/min, severe renal insufficiency is often defined as a creatinine clearance of 15 to 29 mL/min, and ESKD is defined by a creatinine clearance <15 mL/min. These categories encompass up to a 10-fold range in renal function, and thus the drug regimen may not be optimal for all patients whose renal function lies within the range.

4 The design of the optimal dosage regimen for patients with renal insufficiency requires an individualized assessment and is dependent on the availability of an accurate characterization of the relationship between the pharmacokinetic parameters of the drug and renal function, and an accurate assessment of the patient's renal function, CL_{cr}. Secondary references such as the American Hospital Formulary Service Drug Information book,³⁸ and textbooks^{13,40} and computer databases (e.g., Micromedex or Clinical Pharmacology) are excellent sources of information about a drug's pharmacokinetic characteristics in subjects with normal renal function. However, they often do not provide the explicit relationships of the kinetic parameters of interest (total body clearance, elimination rate constant, and distribution volume) with a continuous index of renal function, such as CL_{cr}. To find this information, one may need to identify the original research study that assessed the drug's disposition, or a comprehensive review article on the class of drugs of interest. Ideally, one should be able to identify a relationship between total body clearance (CL), elimination rate constant (*k*), or distribution volume (*V*_D) with CL_{cr} (Table 48–7). This information, along with the patient's CL_{cr}, will enable prediction of the patient's kinetic parameters and then formulation of a therapeutic regimen to attain the desired therapeutic outcome (see Chap. 5).

If specific literature recommendations and/or the relationship of kinetic parameters to CL_{cr} are not available, then one can estimate the kinetic parameters of the patient with the method of Rowland and Tozer,¹⁰ provided you know the fraction of the drug that is eliminated renally unchanged (*f*_e) in subjects with normal renal function.¹³ This approach assumes that the change in CL and *k* are proportional to CL_{cr}, that renal disease does not alter the drug's metabolism, that the metabolites if formed are inactive and nontoxic, that the drug obeys first-order (linear) kinetic principles, and that it is adequately described by a one-compartment model. If these assumptions are true, then the kinetic parameter/dosage adjustment factor (*Q*) can be calculated as:

$$Q = 1 - [f_e(1 - KF)]$$

where *KF* is the ratio of the patient's CL_{cr} to the assumed normal value of 120 mL/min. Thus for a drug that is 85% eliminated renally

TABLE 48–6. Steps to Adjust Drug Dosages for Patients with Renal Insufficiency

| | | |
|--------|--|--|
| Step 1 | Obtain history and relevant demographic/clinical information | Record demographic information, obtain past medical history including history of renal disease, and record current laboratory information (e.g., serum creatinine) |
| Step 2 | Estimate creatinine clearance | Use equation (e.g., Cockcroft-Gault) to estimate creatinine clearance, or calculate creatinine clearance from timed urine collection |
| Step 3 | Review current medications | Identify drugs for which individualization of the treatment regimen will be necessary |
| Step 4 | Calculate individualized treatment regimen | Determine treatment goals (see text); calculate dosage regimen based on pharmacokinetic characteristics of the drug and the patient's renal function |
| Step 5 | Monitoring | Monitor parameters of drug response and toxicity; monitor drugs levels if available/applicable |
| Step 6 | Revise regimen | Adjust regimen based on drug response or change in patient status (including renal function) as warranted |

TABLE 48-7. Relationship between Renal Function and Pharmacokinetic Parameters of Selected Drugs

| Drug | Total Body Clearance |
|---------------|-------------------------|
| Acyclovir | CL = 3.37 (CLcr) + 0.41 |
| Amikacin | CL = 0.6 (CLcr) + 9.6 |
| Cefmetazole | CL = 1.18 (CLcr) - 0.29 |
| Ceftazidime | CL = 1.15 (CLcr) + 10.6 |
| Ciprofloxacin | CL = 2.83 (CLcr) + 363 |
| Digoxin | CL = 0.88 (CLcr) + 23 |
| Gentamicin | CL = 0.983 (CLcr) |
| Lithium | CL = 0.235 (CLcr) |
| Netilmicin | CL = 0.65 (CLcr) + 3.72 |
| Ofloxacin | CL = 1.04 (CLcr) + 38.7 |
| Piperacillin | CL = 1.36 (CLcr) + 1.50 |
| Teicoplanin | CL = 7.09 (CLcr) - 16.2 |
| Tobramycin | CL = 0.801 (CLcr) |
| Vancomycin | CL = 0.69 (CLcr) + 3.7 |

ABW, average body weight; CL, total body clearance; CLcr, creatinine clearance. Compiled from St. Peter et al,¹² Thummel et al,¹³ and Murphy.⁴²

unchanged in a patient who has a CLcr of 10 mL/min, the Q factor would be:

$$\begin{aligned} Q &= 1 - [0.85(1 - (10/120))] \\ &= 1 - [0.85(0.92)] \\ &= 1 - 0.78 \\ &= 0.22 \end{aligned}$$

The estimated total body clearance for this patient would then be calculated as $CL_{PT} = CL_{norm} \times Q$, where CL_{norm} is the mean value in patients with normal renal function as reported in the literature.

After the kinetic parameters for the patient are estimated, the best method for dosage regimen adjustment should be selected. Specifically, one must determine whether the desired goal is the maintenance of a similar peak, trough, or average steady-state drug concentration. If there is a significant relationship between peak concentration and clinical response⁴¹ (e.g., aminoglycosides) or toxicity⁴² (e.g., quinidine, phenobarbital, and phenytoin), then attainment of the specific target values is critical. If, however, no specific target values for peak or trough concentrations have been reported (e.g., antihypertensive agents, benzodiazepines, and cephalosporins), then a regimen goal of attaining the same average steady-state concentration may be appropriate.

Although several methods have been proposed to attain the desired average steady-state concentration profile, the principal choices are to decrease the dose or prolong the dosing interval. If the size of the dose is reduced while the dosing interval remains unchanged, the desired average steady-state concentration will be similar; however, the peak will be lower and the trough higher (Fig. 48-1). Alternatively, if the dosing interval is increased and the dose size remains unchanged, the peak and trough concentrations in the patient with reduced renal function will be similar to those in the patient with normal renal function. This dosage adjustment method is often preferred because it is likely to yield significant cost savings as a result of a reduction in nursing and pharmacy time, as well as a reduction in the supplies associated with frequent drug administration. Finally, the dose and dosing interval may both need to be changed to attain a desired peak or trough serum concentration time profile.

Regardless of the approach chosen to adjust the dosage regimen, the first step in the process, if the relationship between the pharma-

| Scenario | Dose | τ | Cmax | Cmin | Cave |
|----------|------|--------|------|------|------|
| A | 5.0 | 12 | 27.0 | 19.6 | 22.6 |
| B | 0.67 | 12 | 3.6 | 2.6 | 3.0 |
| C | 5.0 | 90 | 8.1 | 0.7 | 3.0 |
| D | 1.33 | 24 | 4.2 | 2.2 | 3.0 |

FIGURE 48-1. Without a change in dosage regimen, this patient would achieve excessive steady-state serum concentrations (Scenario A). Although the average steady-state concentrations (Cave) are identical, the concentration-time profile will be markedly different if one changes the dose and maintains the dosing interval (τ) constant (Scenario B), versus changing the dosing interval and maintaining the dose constant (Scenario C) or changing both (Scenario D).

kinetic parameters of the drug and renal function are known, is to estimate the drug disposition parameters in the patient with renal insufficiency. The ratio (Q) of the estimated elimination rate constant or total body clearance of the patient relative to subjects with normal renal function ($CLcr > 120$ mL/min) may then be calculated. This parameter may be used to determine the dose or dosing interval alterations necessary for the patient.

For example, the following relationship between total clearance (CL) and creatinine clearance has been reported for ganciclovir:⁴³

$$CL(\text{mL/min}/1.8 \text{ m}^2) = 1.25(CLcr) + 8.57$$

Thus CL for a subject with normal renal function (CL_{norm}) would be calculated as:

$$\begin{aligned} CL_{norm} &= [1.25(120)] + 8.57 \\ CL_{mean} &= 158.6 \text{ mL/min per } 1.8 \text{ m}^2 \end{aligned}$$

Clearance (CL_{fail}) for a patient with a creatinine clearance of 10 mL/min would be:

$$\begin{aligned} CL_{fail} &= [1.25(10)] + 8.57 \\ CL_{fail} &= 21.1 \text{ mL/min per } 1.8 \text{ m}^2 \end{aligned}$$

Ganciclovir is commonly used in solid organ transplant patients as prophylaxis against or treatment for cytomegalovirus infection.⁴⁴ The inhibitory concentration of 50% (IC_{50}) of ganciclovir against most clinical isolates of cytomegalovirus is between 0.1 and 2.8 mcg/mL (approximately 0.4 to 11 mcmol/L).⁴³ Therefore trough concentrations should exceed these values, but caution is warranted since neutropenia has been associated with the attainment of ganciclovir trough concentrations exceeding 2.6 mcg/mL (10 mcmol/L).⁴⁵ Although a definitive relationship between ganciclovir concentration and either efficacy or toxicity has not been established,⁴³ it is standard practice to adjust the dose based on renal function. If a patient with reduced renal function received the typical ganciclovir dose for a patient with

normal renal function, the predicted trough concentrations would approach 20 mcmol/L. Therefore a dosage modification in this patient is necessary to avoid potential toxicity. The dosing regimen can be modified using the ratio of the predicted clearance values. Therefore the quotient or Q for this patient is calculated as:

$$\begin{aligned} Q &= CL_{\text{fail}}/CL_{\text{norm}} \\ Q &= 21.1/158.6 \\ Q &= 0.133 \end{aligned}$$

where CL_{norm} is the clearance in a patient with normal renal function and CL_{fail} is the clearance of the patient with impaired renal function.

The maintenance dose (D_f) for the patient or the adjusted dosing interval (τ_f) may then be calculated from the following relationships, where D_n is the normal dose and τ_n is the normal dosing interval:

$$\begin{aligned} D_f &= D_n \times Q \\ \tau_f &= \tau_n/Q \end{aligned}$$

For this patient situation, the normal dose and dosing interval of ganciclovir would be 5 mg/kg and 12 hours, respectively. If we wanted to maintain the dosing interval at 12 hours, then D_f would be calculated as:

$$D_f = (5 \text{ mg/kg}) \times (0.133) = 0.67 \text{ mg/kg}$$

This regimen would result in decreased peak and trough concentrations compared to a patient with this degree of renal insufficiency who received a normal dosage regimen (see Fig. 48–1, Scenario B). The peak concentrations would however be lower and the trough concentrations higher than those observed when a patient with normal renal function received a standard regimen.

If we want to maintain D_n and extend the dosing interval, τ_f would be calculated as:

$$\tau_f = \tau_n/Q = 12/0.133 = 90 \text{ hours}$$

This regimen would yield similar peak and trough concentrations in the renally impaired patient as in the patient with normal renal function, but there is a risk of missed doses with such an unorthodox interval (see Fig. 48–1, Scenario C). In addition, the prolonged period below the C_{ss} average concentration may be less than optimal.

Finally, a practical dosing interval (τ_p) may be selected and then a dose based on that interval can be calculated (see Fig. 48–1, Scenario D). If a dosage interval τ_f of 24 hours were selected, because in many institutions there is an increased risk of missed doses with longer dosing intervals, then the D_f would be calculated as follows:

$$\begin{aligned} D_f &= [D_n \times Q \times \tau_f]/\tau_p \\ &= [(5 \text{ mg/kg}) \times (0.133) \times (24)]/12 \\ &= 1.33 \text{ mg/kg} \end{aligned}$$

This method would likely be most appropriate in this case; prolonged subtherapeutic concentrations are avoided and troughs are reduced from the first method. The selection of which dosage adjustment method to use to calculate an optimal regimen depends on the drug characteristics and the patient care situation. This dosage adjustment method assumes that the protein binding and volume of distribution of the drug are not significantly altered by renal insufficiency. Thus this approach cannot be used with accuracy for those drugs with demonstrated differences in these pharmacokinetic parameters.

If the volume of distribution (V_D) of a drug is significantly altered in patients with renal insufficiency or in whom one desires to attain a specific maximum or minimum concentration, the estimation of a dosage regimen becomes more complex. If the relationship between

V_D and creatinine clearance has been characterized, then V_D may be estimated. If one assumes that a one-compartment linear model can describe the drug, the predicted V_D may then be used with the predicted elimination rate constant (k) of the drug to yield an adjusted dosing interval and intravenous or oral dose.

For orally administered drugs, the τ_f can be calculated as:

$$\tau_f = [(-1/k_f)(\ln[C_{\text{min}}/C_{\text{max}}])] + t_{\text{peak}}$$

and the dose can be approximated as:

$$\text{Dose}_{\text{po}} = [\text{SFC}_p^t V_D(k_a - k)]/[k_a(e^{-k_f t}/1 - e^{-k_f \tau})(e^{-k_a t}/1 - e^{-k_a \tau})]$$

where, S equals the salt fraction, F equals bioavailability, C_p^t equals the desired plasma concentration at time t , and k_a is the absorption rate constant. This approach allows for the individualization of a dosage regimen for attainment of specific peak and trough serum concentrations. If the drug is absorbed extremely rapidly, one can approximate the τ_f as:

$$\tau_f = (-1/k_f)(\ln[C_{\text{min}}/C_{\text{max}}])$$

and the dose as:

$$\text{Dose}_{\text{po}} = V_D \times (C_{\text{max}} - C_{\text{min}})$$

Digoxin is a frequently used oral medication for which the V_D is decreased in patients with renal insufficiency, and for which one usually desires to closely control the plasma concentration time profile. The V_D and CL_{fail} of digoxin can be estimated for a 70-kg patient with a CLcr of 12 mL/min per 1.73 m² as summarized by Job¹⁸:

$$\begin{aligned} V_D &= 226 + [(298(\text{CLcr}))/(29.1 + \text{CLcr})] \\ &= 226 + [(298(12))/(29.1 + 12)] \\ &= 226 + 87.0 \\ &= 313 \text{ L} \\ CL_{\text{fail}} &= (0.88 \times \text{CLcr}) + 23 \text{ mL/min} \\ &= 10.6 + 23 \\ &= 33.6 \text{ mL/min} \\ k_f &= CL_{\text{fail}}/V_D \\ &= (33.6 \text{ mL/min} \times 1440 \text{ min/d})/313 \text{ L} \\ &= (48.3 \text{ L/d})/313 \text{ L} \\ &= 0.154 \text{ day}^{-1} \end{aligned}$$

The t_{peak} is generally at 2 hours, and the k_a from the literature is about 0.76 hour⁻¹ or 18 day⁻¹.¹³ Thus one now has all the information needed to calculate the τ_f and dose for this patient:

$$\begin{aligned} \tau_f &= [(-1/k_f)(\ln[C_{\text{min}}/C_{\text{max}}])] + t_{\text{peak}} \\ &= [(-1/0.154)(\ln[0.8/1.4])] + 2 \text{ hours} \\ &= [(-6.49)(-0.56)] + 2 \text{ hours} \\ &= 3.6 \text{ days} + 2 \text{ hours} \\ &\approx 4 \text{ days} \end{aligned}$$

$$\begin{aligned} \text{Dose}_{\text{po}} &= [(1.4)(313)(18 - 0.154)]/[18(e^{-0.154(0.083)}/1 - e^{-0.154(4)}) \\ &\quad - (e^{-18(0.083)}/1 - e^{-18(4)})] \\ &= 0.226 \text{ mg or one } 0.25 \text{ mg oral capsule every } 4 \text{ days} \end{aligned}$$

Alternately, the predicted volume of distribution and elimination rate constant or the total body clearance may be used to calculate a dose

regimen that will maintain the desired average steady-state concentration of the drug (C_{ss}).

$$\text{Dose (mg/h)} = C_{ss}[(k_f \times V_D) \text{ or } (CL_f)]$$

Depending on how much variance above and below the average steady state one desires, the dosing interval may range from hourly to as infrequently as every 48 hours or longer. For example, if the calculated dose were 10 mg/h, the desired average steady-state concentration would be maintained with a dosing interval of 60 mg every 6 hours or 480 mg every 48 hours.

PATIENTS RECEIVING CONTINUOUS RENAL REPLACEMENT THERAPY

Continuous renal replacement therapy (CRRT) is used for the management of fluid overload and the removal of uremic toxins in patients with ARF and other conditions.⁴⁶ The several forms of CRRT are extensively described in Chap. 42. Which of these therapies will be optimal for a given patient is dependent on several factors, including bleeding risk, degree of hypercatabolism, acid-base balance, and experience of the health care provider.

Drug therapy individualization for the patient receiving CRRT is complicated by the fact that patients with ARF may have a higher residual nonrenal clearance of some drugs than patients with CKD who have a similar CL_{cr}.^{33,47–49} For example, the nonrenal clearance of imipenem in patients with ARF (91 mL/min) is between the values observed in CKD patients (50 mL/min) and those with normal renal function (130 mL/min).⁴⁸ This may occur because of less exposure to or accumulation of uremic by-products that may alter hepatic function. A nonrenal clearance value in a patient with ARF that is higher than anticipated based on chronic renal failure data would result in lower than expected, possibly subtherapeutic, serum concentrations. For example, in order to maintain comparable serum concentration, the imipenem dose requirement in patients with ARF would be 2,000 mg/24 hours as compared to the recommended dosage for patients with ESKD of 1,000 mg/24 hours.⁴⁸

In addition to patient-specific differences, there are marked differences between intermittent hemodialysis and the three primary types of CRRT: continuous arteriovenous or venovenous hemofiltration (CAVH/CVVH), continuous arteriovenous or venovenous hemodialysis (CAVHD/CVVHD), and continuous arteriovenous or venovenous hemodiafiltration (CAVHDF/CVVHDF) with regard to drug removal.^{46,50,51}

During CAVH/CVVH, drug removal primarily occurs via convection/ultrafiltration (the passive transport of drug molecules at the concentration at which they exist in plasma water into the ultrafiltrate). The clearance of a drug by either of these methods is thus a function of the membrane permeability for the drug, which is called the sieving coefficient (SC) and the rate of ultrafiltrate formation (UFR). The SC can be calculated as:

$$SC = (2C_{UF}) / [(C_a / 1 - \theta) + (C_v / 1 - \theta)]$$

where C_a and C_v are the concentration of the drug in the plasma going into and returning from the filter, respectively; C_{UF} is the concentration in the ultrafiltrate; and θ is 0.0107 times the total protein concentration in plasma. The SC is often approximated by the fraction unbound (f_u) because this information may be more readily available. Thus the clearance by these two modes of CRRT can be calculated as:

$$CL_{CVVH} = UFR \times SC$$

or approximated as:

$$CL_{CVVH} = UFR \times f_u$$

Clearance of a drug by CAVHDF/CVVHDF (CL_{CAVHDF}/CL_{CVVHDF}) is generally greater than that by CAVH/CVVH, because in addition to the convection/ultrafiltration process, drug is removed by diffusion from the plasma water into the dialysate. The CL_{CVVHDF} can be mathematically approximated providing the blood flow rate is greater than 100 mL/min and the dialysate flow rate (DFR) is between 8 and 33 mL/min as:

$$CL_{CVVHDF} = (UFR \times f_u) + CL_{\text{diffusion}}$$

where $CL_{\text{diffusion}}$ is the clearance via diffusion from plasma water to the dialysate. In the clinical setting, it is not possible to separate these two components (blood flow rate and DFR) of CL_{CVVHDF} . In essence the CL_{CVVHDF} is calculated as the product of the combined ultrafiltrate and dialysate volume (V_{df}) and the concentration of the drug in this fluid (C_{df}) divided by the plasma concentration (C_p^{mid}) at the midpoint of the V_{df} collection period.

There are differences in the rate of drug removal, not only between the three primary modes of CRRT, but also within each mode.^{46,49,50,52} This is a result of differences in the filter membrane composition, variable degrees of drug binding to the membrane and the permeability characteristics of the membrane.^{53–56} The primary factors that influence drug clearance during CRRT are thus ultrafiltration rate, blood flow rate, and dialysate flow rate. For example, clearance in CAVH/CVVH is directly proportional to the ultrafiltration rate, whereas clearance during CAVHDF/CVVHDF, which depends on both the ultrafiltration rate and the dialysate flow rate, increases as either flow rate increases. Changes in blood flow rate generally have only a minor effect on drug clearance by any mode of CRRT. An increase in ultrafiltration flow rate (5 to 45 mL/min) and dialysate flow rate (8.3 to 33.3 mL/min) however have dramatic effects on ceftazidime clearance during CVVH and CVVHD respectively.⁵⁵ (Fig. 48–2)

An algorithmic approach for drug dosage adjustment in patients undergoing CRRT has been proposed.⁴⁶ Individualization of therapy for a patient receiving CRRT therapy is dependent on the patient's residual renal function and the clearance of the drug by the mode of

FIGURE 48–2. The effect of increasing ultrafiltration rate (UFR in milliliters per minute) and dialysate flow rate (DFR in milliliters per minute) on the clearance of ceftazidime.

CRRT they are receiving. The patient’s residual drug clearance can be predicted as described in the previous section of this chapter. The CRRT clearance can also be ascertained from published reports.^{46,57,58} The SCs of frequently used drugs are summarized in Table 48–8, and the clearance of selected drugs by CAVH/CVVH or CAVHD/CVVHD is listed in Table 48–9. These data can be used to design initial dosage regimens for patients receiving CRRT.^{50,52}

For example, WT is a 48-year-old, 60-kg male in ARF with a serum creatinine that has increased from 2.3 mg/dL to 7.2 mg/dL over 3 days. The residual CL_{Cr} value in this patient, calculated using the Jelliffe and Jelliffe equation for changing serum creatinine levels (see Chap. 41) is 4.8 mL/min. The consulting nephrologist recommends that CVVHDF be initiated using a Fresenius F-40 filter at blood and dialysate flow rates of 100 and 33.3 mL/min, respectively. The patient is to receive ceftazidime while on CVVHDF. The patient’s residual ceftazidime clearance can be estimated using the regression equation in Table 48–7 relating CL_{Cr} and drug clearance:

$$CL_{RES} \text{ (mL/min)} = [1.15 \times (CL_{Cr})] + 10.6$$

$$CL_{RES} = [1.15 \times (4.8)] + 10.6 = 16.1 \text{ mL/min}$$

The total clearance while on CVVHDF would be the sum of the patient’s residual clearance and the ceftazidime clearance associated with CVVHDF (see Table 48–9) as follows:

$$CL_T = CL_{RES} + CL_{CVVHDF}$$

$$CL_T = 16.1 \text{ mL/min} + 15.2 \text{ mL/min} = 31.3 \text{ mL/min}$$

This patient’s clearance value can be used to adjust the ceftazidime dose as described earlier. The ceftazidime clearance in a patient with normal renal function would be calculated as:

$$CL_{norm} \text{ (mL/min)} = [1.15 \times (CL_{Cr})] + 10.6$$

$$CL_{norm} = [1.15 \times (120)] + 10.6 = 148.6 \text{ mL/min}$$

The dosage adjustment factor would then be:

$$Q = CL_{fail} / CL_{norm}$$

$$Q = 31.3 / 148.6 = 0.21$$

For this patient’s situation, the normal regimen of ceftazidime would be 1,000 mg (D_n) every 8 hours (τ_n). If one wanted to maintain D_n and extend the dosing interval, then τ_f would be calculated as:

$$\tau_f = \tau_n / Q$$

$$\tau_f = 8 \text{ hours} / 0.21$$

$$\tau_f = 38 \text{ hours, or a more practical value of 36 hours}$$

TABLE 48–9. Clearance of Selected Drugs by CAVH/CVVH and/or CAVHD/CVVHD

| Drug | CAVH/CVVH | | CAVHD/CVVHD | |
|---------------|-------------|------------|-------------|------------|
| | SC | Clearance | SC | Clearance |
| Amikacin | 0.93 ± 0.16 | 10.1 | | |
| Amrinone | 0.80–1.4 | 2.4–14.4 | | |
| Cefuroxime | | 11.0 ± 5.2 | 0.90 ± 0.30 | 14.0 ± 2.2 |
| Ceftazidime | | | 0.86 ± 0.07 | 13.1 ± 1.3 |
| Cilastatin | 0.77 | 4.0 ± 2.3 | 0.68 ± 0.08 | 10.0 ± 3.0 |
| Ciprofloxacin | | | | 16.3 |
| Digoxin | | | | 6.4–10.0 |
| Gentamicin | | 3.5 ± 1.9 | | 5.2 ± 1.8 |

| Phenytoin | 0.37 ± 0.08 | 1.0 | | 6.5 |
| Theophylline | | | | 14.8 |
| Tobramycin | | 3.5 ± 1.9 | | 11.1–29 |
| Vancomycin | 0.80 | 6.7–13.3 | 0.66 ± 0.08 | 12.1 ± 5.7 |

Clearance is in milliliters per minute.
DFR, dialysate flow rate; SC, sieving coefficient.
From Joy et al,⁴⁶ Mueller et al,⁴⁹ and Bugge.⁵⁰

Therefore, this patient should receive 1,000 mg every 36 hours. If the additional clearance associated with CVVHDF (15.2 mL/min) was not considered, the calculated dosing interval would have been considerably longer, at approximately 72 hours.

PATIENTS RECEIVING CHRONIC AMBULATORY PERITONEAL DIALYSIS

Although the majority of patients with ESKD receive treatment with hemodialysis, approximately 15% of dialysis patients receive one of the multiple variants of continuous peritoneal dialysis. Peritoneal dialysis, like other dialysis modalities, has the potential to affect drug disposition; however, drug therapy individualization is often less complicated in these patients owing to the continuous nature of the procedure (see Chap. 45).

Many of the factors that are important in determining drug dialyzability for other treatment modalities pertain to peritoneal dialysis as well.^{59,60} Peritoneal dialysis involves the instillation of 1 to 3 L of dialysis solution into the peritoneal cavity. Waste products and other substances, including drugs, move from the blood and surrounding tissues into the dialysis solution by means of diffusion and ultrafiltration. Factors that influence drug dialyzability in peritoneal dialysis include drug-specific characteristics such as molecular weight, solubility, degree of ionization, protein binding, and volume of distribution. The intrinsic properties of the peritoneal membrane that affect drug removal include blood flow, pore size, and peritoneal membrane surface area, which is approximately equal to the body surface area. There is an inverse relationship between peritoneal drug clearance and molecular weight, protein binding, and volume of distribution. Also, drug compounds that are ionized at physiologic pH will diffuse across the membrane more slowly than un-ionized compounds. In general, hemodialysis is more effective in removing drug substances than peritoneal dialysis such that if a drug is not removed by hemodialysis, it is not likely to be removed by peritoneal dialysis. As shown in Table 48–10, the contribution of peritoneal dialysis to total body clearance is often low, and for most drugs, markedly less than the contribution of hemodialysis. Detailed reviews of the disposition of other drugs in chronic ambulatory peritoneal dialysis patients are reported elsewhere.^{8,59,60} Anti-infective agents are the most commonly studied drugs due to their primary role in the treatment of peritonitis.⁶¹ Most other drugs can generally be dosed according to the residual renal function of the patient because additional clearance by peritoneal dialysis is so small.

TABLE 48–10. Comparison for Selected Drugs of Residual Drug Clearance in End-Stage Kidney Disease (CL_{ESKD}) to Clearance by Continuous Ambulatory Peritoneal Dialysis (CL_{CAPD}), Intermittent Peritoneal Dialysis (CL_{IPD}), and Hemodialysis (CL_{HD})^a

CHRONIC HEMODIALYSIS PATIENTS

The number of patients with ESKD who receive chronic hemodialysis has steadily increased since the early 1970s and currently over 260,000 patients receive this life-sustaining therapy.⁶² Although many new hemodialyzers have been introduced in the past 20 years and the efficiency of the hemodialysis procedure has been increased, the effect of hemodialysis on drug disposition is rarely re-evaluated after it is initially reported. Thus most of the literature probably represents an underestimation of the impact of hemodialysis on drug disposition.

5 The impact of hemodialysis on a patient's drug therapy is dependent on several factors, including the characteristics of each drug, the dialysis conditions, and the clinical situation for which dialysis is performed. Drug-related factors that affect dialyzability include the molecular weight, protein binding, and distribution volume of each drug.⁸ The impact of distribution volume (V_D) on drug removal by dialysis is evident in the following example, in which drug A has a 10-L V_D , but drug B has a V_D of 80 L. Neither drug is bound to plasma proteins. They are exclusively eliminated unchanged by the kidney and both drugs have a molecular weight of 300 and a dialyzer clearance of 40 mL/min (2.4 L/h). The half-life in an anuric patient during dialysis [$t_{1/2} = (V_D \times 0.693)/CL$] will be markedly different for these two drugs (2.9 hours vs. 23 hours), and thus approximately 50% of drug A but only 10% of drug B will be removed during 3 hours of dialysis as a direct result of the larger distribution volume.

Prior to the mid-1980s these were the primary factors that needed to be known to assess the degree of dialyzability of a given drug, because the vast majority of dialysis filters were composed of cellulose, cellulose acetate, or regenerated cellulose (cuprophane) (see Chap. 45). These "conventional" filter materials were generally impermeable to drugs with a molecular weight over 1,000 daltons, and the clearance by hemodialysis tended to decline dramatically (by up to 60%) as molecular weight increased from 100 to 500 daltons.⁶³ Drugs that are small but highly protein bound are also not well dialyzed because both of the principal binding proteins, α_1 -acid glycoprotein and albumin, have a very high molecular weight. Finally, those drugs that are widely distributed throughout the body are poorly removed by hemodialysis.

The dialysis prescription for the patient can also dramatically affect the degree of drug removal. The primary factors that can vary between patients are the type of hemodialysis they are prescribed, which is primarily reflected in the composition of the dialysis membrane; the filter surface area; blood and dialysate flow rates; and whether or not the dialysis unit reuses the dialysis filter. Dialysis membranes are composed of cellulose-based, semisynthetic, or synthetic materials (e.g., polysulfone, polymethylmethacrylate, or acrylonitrile). The synthetic filter materials are now available for low-, medium-, and high-flux modes of dialysis (see Chap. 45), with the principal difference between modes being in the filter pore size, which can range from 25 to greater than 60 angstroms, and the degree of water transport (ultrafiltration coefficient). The dialysis membranes used in high-flux hemodialysis have the greatest pore sizes and more closely mimic the filtration characteristics of the human kidney than the filters used to deliver conventional hemodialysis. This allows the passage of most solutes, including drugs, that have a molecular weight of 20,000 daltons or less.⁶³ Thus high-molecular-weight drugs such as vancomycin are likely to be removed by this mode of dialysis, although they are not by conventional dialysis.

An increase in removal has also been reported with several other drugs that have lower molecular weights (Table 48–11).^{64–71} Figure 48–3 shows the plasma concentration–time profile of gentamicin in patients receiving dialysis using either a low-flux conventional

TABLE 48–11. Drug Disposition during Dialysis Depends on Filter Characteristics

| Drug | Hemodialysis Clearance (mL/min) | | Half-Life during Dialysis (h) | |

[cellulose acetate (CA170)] or a high-flux [polysulfone (F80)] dialyzer. The net result is that the patient receiving high-flux dialysis will require larger postdialysis doses relative to the patient receiving low-flux dialysis to maintain similar concentrations.

The final component of the dialysis prescription that may affect drug clearance by dialysis is whether or not the patient has authorized the unit to reuse his or her dialyzer. Currently, more than 75% of all dialysis units in the United States use this procedure to reduce the cost of chronic hemodialysis.⁷² The effect of dialysis filter reuse on the clearance of endogenous molecules such as urea, creatinine, and β_2 -microglobulin has been evaluated for many dialyzers.⁷³ A decrease in urea and creatinine clearances and an increase in β_2 -microglobulin clearance was observed with some, but not all, dialyzers. Only one center has evaluated the effect of reuse on drug clearance (cefazolin, ceftazidime, tobramycin, and vancomycin) following the first and tenth use of cellulose acetate, cellulose triacetate, and polysulfone

dialyzers.⁷⁴ No change was noted with the cellulose acetate dialyzer. Ceftazidime and vancomycin clearance decreased by up to 13% with the polysulfone filter. In contrast, significant decreases in clearance were observed with the cellulose triacetate dialyzer (24% to 43%) for all four drugs.

The impact of hemodialysis on drug therapy should thus not be viewed as a generic procedure such that a certain percentage of drug in the body is removed with each dialysis session; neither should simple “yes-no” answers on the dialyzability of drug compounds be considered sufficient information to make therapeutic decisions. Reference materials that indicate “yes-no” status regarding the dialyzability of drug compounds provide no quantification of the impact of hemodialysis, and are thus of little value to the clinician who needs to design a rational dosing regimen for a patient. Compounds considered nondialyzable with low-flux dialyzers may in fact be significantly removed by high-flux hemodialyzers. Characteristics of the dialysis prescription such as membrane composition and surface area, and blood and dialysis flow rates, are thus critical data for the design of drug dosing regimens for chronic hemodialysis patients.

The effect of hemodialysis on drug disposition can be estimated in several ways.⁸ The determination of drug concentrations at the start and end of dialysis, with the subsequent calculation of the half-life during dialysis ($t_{1/2, \text{onHD}}$), has frequently been used as an index of drug removal by dialysis. Unfortunately, the $t_{1/2, \text{onHD}}$ may not be interpretable because declining plasma drug concentrations during dialysis represent elimination by the body as well as by dialysis. Furthermore, if significant rebound in drug concentrations after dialysis has been reported, the removal of drug by the dialysis procedure may be artificially high, depending on when after dialysis the concentration is determined.^{75–79}

An alternative and more accurate means of assessing the effect of hemodialysis is to calculate the dialyzer clearance of the drug.⁸ The dialyzer clearance (CL_D) can be calculated by several approaches. The CL_D from blood can be calculated as $CL_D = Q_b [(A_b - V_b)/A_b]$, where Q_b is blood flow through the dialyzer, A_b is the concentration of drug in blood going into the dialyzer, and V_b is the blood concentration of drug leaving the dialyzer. This equation is valid only if the drug concentrations are measured in whole blood and if the drug rapidly and completely distributes into red blood cells. Because drug concentrations are generally determined in plasma, the previous equation is usually modified to $CL_D^p = Q_p [(A_p - V_p)/A_p]$ where p represents plasma and Q_p is plasma flow, which equals $Q_b (1 - \text{hematocrit})$. This clearance calculation accurately reflects dialysis drug clearance only if the drug does not penetrate red blood cells or bind to formed blood elements.

Because of potential problems in accurately determining Q_b or Q_p , the dialysate recovery method is widely used. In addition, venous plasma concentrations may be concentrated, because plasma water is generally removed from the blood at a faster rate than drug when ultrafiltration is performed simultaneously with diffusion during dialysis.

The recovery clearance approach, the benchmark for the determination of dialyzer clearance, can be calculated as:⁸

$$CL_D^r = R/AUC_{0-t}$$

where R is the total amount of drug recovered unchanged in the dialysate and AUC_{0-t} is the area under the predialysis plasma concentration-time curve during the period of time that the dialysate was collected. To determine the AUC_{0-t} , at least two, and preferably three to four plasma concentrations should be obtained during dialysis.

The hemodialysis clearance values reported in the literature may vary significantly depending on which of the previous methods was

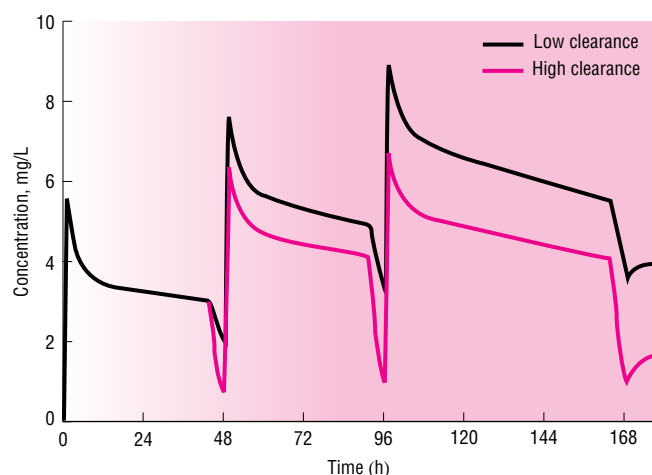

FIGURE 48–3. Clearance of gentamicin by low- and high-clearance dialyzers in patients given the same gentamicin dose after each dialysis treatment. Concentrations in the patient receiving dialysis with a low-clearance dialyzer will continue to increase, whereas concentrations in the patient receiving dialysis with the high-clearance dialyzer will be maintained at the same peak and predialysis concentrations observed after the third dose.

used to calculate CL_D . The principal reason for this is that for most medications we do not know the degree and rapidity with which the drug crosses the red blood cell membrane. Because the CL^r_D method incorporates no assumption of the degree of red blood cell permeability, it can be reliably used as the benchmark value. Comparisons of CL^p_D and CL^b_D values to the CL^r_D benchmark thus provide valuable insight to a drug's dialyzability.

The following principles may be applied to drug dosage regimen design for hemodialysis patients by using a value of CL_D that is reported in the literature.^{8,12,80} Because clearance terms are additive, the total clearance during dialysis can be calculated as the sum of the patient's residual clearance during the interdialytic period (CL_{RES}) and dialyzer clearance (CL_D):

$$CL_T = CL_{RES} + CL_D$$

The half-life during the period between dialysis treatments and during dialysis can then be calculated from the following relationships using an estimate of the drug's distribution volume (V_D), which can be obtained from review articles:^{8,12,80}

$$t_{1/2, \text{offHD}} = 0.693 [V_D / CL_{RES}]$$

$$t_{1/2, \text{onHD}} = 0.693 [V_D / (CL_{RES} + CL_D)]$$

Once the key pharmacokinetic parameters have been estimated/calculated, they may be used to simulate the plasma concentration-time profile of the drug for the individual patient and ascertain how much drug to administer and when. This approach to drug therapy individualization can be accomplished in a stepwise fashion assuming first-order elimination of the drug and a one-compartment model. For example, a 34-year-old male with ESKD was admitted to a hospital from the outpatient hemodialysis unit, where he experienced shaking and chills and had a temperature of 40°C (104°F). He weighed 70 kg and was 69 inches tall, had a residual CL_{CR} of 3 mL/min, and received conventional low flux dialysis for 4 hours three times a week on a CA210 cellulose acetate dialyzer. He received 140 mg of tobramycin at the end of his most recent hemodialysis treatment which end less than an hour prior to admission.

The first step is to estimate this patient's pharmacokinetic parameters of tobramycin on the basis of published population data.¹² The volume of distribution in this patient is 23.1 L (0.33 L/kg × 70 kg), and his residual total body clearance (CL_{RES}) estimated from the relationship between CL and creatinine clearance [$CL_{RES} = CL_{CR} \times 0.98$] is 3 mL/min or 0.176 L/h. The elimination rate constant can be approximated as:

$$k = CL_{RES} \div V_D$$

$$= 0.176 \text{ L/h} \div 23.1 \text{ L}$$

$$= 0.0076 \text{ hr}^{-1}$$

The hemodialysis clearance of tobramycin is dependent on the dialyzer, and a value of 73 mL/min has recently been reported by Matzke and associates⁶⁷ for the CA210 dialyzer.

One now can predict what the plasma concentrations of tobramycin will be over the next 24 to 48 hours, assuming the infusion time for the drug (t') was 30 minutes. The concentration at the end of the 30-minute infusion (C_{max}) would be:

$$C_{max} = \frac{(\text{Dose}/t')1 - e^{-kt'}}{CL_{RES}}$$

$$C_{max} = \frac{(280 \text{ mg/h})1 - e^{-(0.0076)0.5}}{0.176 \text{ L/h}}$$

$$C_{max} = (1944 \text{ mg/L}) (0.003) = 6.0 \text{ mg/L}$$

The plasma concentration prior to the next dialysis session (C_{bD}), which is 44 hours away, and the concentration after dialysis (C_{aD}) can be calculated as:

$$C_{bD} = C_{max} \times e^{-(CL_{RES}/V_D) \times t}$$

$$= 6.0 \times e^{-0.0076 \times 44}$$

$$= 4.3 \text{ mg/L}$$

$$C_{aD} = C_{bD} \times e^{-((CL_{RES} + CL_D)/V_D) \times t}$$

$$= 4.3 \times e^{-((0.176 + 4.38)/23.1) \times 4}$$

$$= 4.3 \times e^{-0.197 \times 4}$$

$$= 1.9 \text{ mg/L}$$

On the basis of these data, no further therapy will likely be required until after the next dialysis treatment since one generally desires to have tobramycin concentrations fall below 2 mg/L before administering another dose.

During this interdialytic interval, however, several blood samples should be collected to characterize this patient's residual tobramycin clearance, distribution volume, and then the clearance of tobramycin during dialysis. Blood samples were therefore collected at the following times after the first dose:

| | | |
|-------|--|----------|
| DAY 1 | 7 PM (2 hours after dose) | 6.5 mg/L |
| DAY 2 | 8 AM (39 hours after dose; just before dialysis) | 4.1 mg/L |
| DAY 3 | 12 noon (immediately after dialysis) | 2.0 mg/L |

The C_{max} can be calculated by back-extrapolation to the end of the infusion as described in Chap. 5. The elimination rate during the interdialytic period (k_{ID}) and during dialysis (k_{DD}), and the V_D can be calculated as:

$$k_{ID} = (\ln C_1 / C_2) / \Delta t$$

$$k_{ID} = (\ln 6.5 / 4.1) / 37 = 0.0125 / \text{h}$$

$$k_{DD} = (\ln C_2 / C_3) / \Delta t$$

$$k_{DD} = (\ln 4.1 / 2.0) / 4 = 0.179 / \text{h}$$

$$V_D = \frac{\text{Dose}/t'}{k_{ID}} \frac{1 - e^{-k_{ID}t'}}{(C_{max} - C_{min}e^{-k_{ID}t'})}$$

$$V_D = \frac{140/0.5}{0.0125} \frac{1 - e^{-(0.0125)0.5}}{(6.7 - 0.0 e^{-(0.0125)0.5})}$$

$$V_D = \frac{134.4}{6.7} = 20 \text{ L}$$

where Δt is the time in hours between the two measured concentrations and C_{min} is the tobramycin concentration in plasma prior to the administration of this dose.

The patient's residual clearance (CL_{RES}) of tobramycin can then be calculated as:

$$CL_{RES} = V_D \times k_{ID}$$

$$CL_{RES} = 20.0 \text{ L} \times 0.0125 = 0.25 \text{ L/h or } 4.2 \text{ mL/min}$$

The dialyzer clearance (CL_D) can be calculated since one knows the total clearance during dialysis (CL_T) and CL_{RES} as:

$$CL_D = CL_T - CL_{RES}$$

$$CL_D = (k_{DD} \times V_D) - 4.2 \text{ mL/min}$$

$$CL_D = (0.179 / \text{h} \times 20.0 \text{ L}) - 4.2 \text{ mL/min}$$

$$CL_D = (3.6 \text{ L/h or } 59.6 \text{ mL/min}) - 4.2 \text{ mL/min}$$

$$CL_D = 55.4 \text{ mL/min}$$

This case illustrates the need for individualizing drug therapy for hemodialysis patients since this patient's V_D was 13% smaller, CL_{RES} was 42% greater, and CL_D was 25% less than the estimates based on population parameters.

The ultimate reason for measuring the plasma concentrations of aminoglycosides and several other agents is to individualize the patient's dosage regimen. Thus there remains one important step in our evaluation: the calculation of the dose this patient should receive next. The two factors that enter into this decision are the desired peak and trough concentrations and the degree of rebound in drug concentrations, after the end of dialysis. Because tobramycin concentrations have been noted to increase by about 20% within 1.5 to 2 hours after the end of hemodialysis, the trough concentration of this patient can be considered to be 2.4 mg/L ($2.0 \text{ mg/L} \times 1.2$). Although this value is higher than one might like to maintain in an individual with normal renal function, a prolonged period of almost 24 hours would be required just to have the concentration drop below 2.0 mg/L. It is frequently necessary in critically ill individuals with ESKD to redose the patient even though the postdialysis trough serum concentration is between 2 and 3 mg/L. Assuming the desired peak concentration was 7.0 mg/L, the postdialysis dose this patient would need can then be calculated using the simplified approach below, because the elimination half-life is extremely prolonged relative to the infusion time, and thus minimal drug is eliminated during the infusion period:

$$\begin{aligned} \text{Dose} &= V_D \times (C_{\max} - C_{\min}) \\ &= 20.0 \text{ L} \times (7.0 - 2.4) = 92 \text{ mg} \end{aligned}$$

Combination antibiotic therapy with aminoglycosides and extended-spectrum penicillins are frequently prescribed for ESKD patients to provide wider antibacterial coverage against gram-negative bacilli through a synergistic effect. The combined use may result in *in vitro* chemical inactivation of the aminoglycoside, leading to a loss in antibiologic activity. The rate of inactivation is related to the incubation period, temperature, presence of solutes, and β -lactam concentration.

The extent of aminoglycoside inactivation *in vivo* may not be clinically significant in patients with normal or slightly impaired renal function due to the short contact time. However, in patients with ESKD, subtherapeutic aminoglycoside concentrations and a decreased aminoglycoside elimination half-life have been reported. Patients will require appropriate dosage modification to maintain the desired serum concentrations. Inactivation of gentamicin and tobramycin by ticarcillin^{81,82} and piperacillin^{83,84} has been reported in patients receiving chronic dialysis therapy. The disposition of netilmicin and isepamicin, however, is unaffected by piperacillin administration.^{83,84} No significant changes in V_D were noted for any of the aminoglycosides, and thus the inactivation clearances of netilmicin and isepamicin were significantly less than those of tobramycin and gentamicin. From these data tobramycin appears to be affected to the greatest degree, followed by gentamicin, netilmicin, and isepamicin, in descending order.

Thus the elimination of aminoglycosides in ESKD patients also receiving antipseudomonal penicillins will be increased; therefore frequent serum concentration monitoring should be performed. To minimize any *in vitro* inactivation of aminoglycosides that would complicate assessment of the *in vivo* effects, serum samples should be assayed as soon as possible after collection. If this is not possible, serum samples should be frozen (preferably at -70°C , or -94°F) until they can be assayed.

CONCLUSIONS

Subtherapeutic or supratherapeutic responses to drugs in patients with renal insufficiency are often misinterpreted and not recognized as such. The adverse outcomes associated with inappropriate drug use and dosing have not been quantified but do warrant future investigations. Sound pharmacokinetic principles as illustrated in this chapter, used in concert with reliable population pharmacokinetic estimates, should ultimately yield the optimal approach to drug dosage regimen design for patients with renal insufficiency. Individualization of therapy should be undertaken whenever clinical therapeutic monitoring tools are available.

ABBREVIATIONS

- A_b : concentration of drug in blood going into the dialyzer (arterial side)
- A_p : concentration of drug in plasma going into the dialyzer (arterial side)
- AUC: area under the concentration-time curve
- AUC_{0-t} : the area under the predialyzer plasma concentration-time curve during hemodialysis
- AUMC: the area under the first moment of the concentration-time curve
- C_a : concentration of the drug in the plasma going into a filter
- C_{ad} : plasma concentration after dialysis
- C_{ave} : average plasma concentration
- CAVH: continuous arteriovenous hemofiltration
- CAVHD: continuous arteriovenous hemodialysis
- CAVHDF: continuous arteriovenous hemodiafiltration
- C_{bd} : plasma concentration prior to the next dialysis session
- C_{df} : concentration of drug in the dialysis fluid
- C_e^{total} : equated total phenytoin concentration
- C_m^{total} : total drug concentration measured in a patient with altered protein binding
- C_{ss} : average steady-state plasma concentration
- C_f : concentration of the drug in the plasma returning from a filter
- CVVH: continuous venovenous hemofiltration
- CVVHD: continuous venovenous hemodialysis
- CVVHDF: continuous venovenous hemodiafiltration
- CL: total body clearance
- CL_D^b : dialyzer clearance from blood
- CL_{CAVHDF} : clearance of a drug by CAVHDF
- CL_{CAVH} : clearance of a drug by CAVH
- CL_{cr}: creatinine clearance
- CL_{CVVHDF} : clearance of a drug by CVVHDF
- CL_{CVVH} : clearance of a drug by CVVH
- CL_D : dialyzer clearance
- $CL_{\text{diffusion}}$: clearance via diffusion from plasma water to the dialysate
- CL_{fail} : clearance of a drug in a patient with impaired renal function
- CL_{norm} : clearance of a drug in patients with normal renal function
- CL_D^p : dialyzer clearance from plasma
- CL_{PT} : estimated total body clearance for a given patient
- CL_R : net renal excretion
- $CL_{\text{reabsorption}}$: tubular reabsorption
- CL_{RES} : residual drug clearance in a dialysis patient
- $CL_{\text{secretion}}$: tubular secretion
- CL_T : total clearance while on CVVHDF
- C_{\max} : peak drug concentration
- C_p^{mid} : plasma drug concentration at the midpoint of the dialysis session

CNS: central nervous system
 CRRT: continuous renal replacement therapy
 C_p : desired plasma concentration at time t
 CYP450: cytochrome P450 enzymes
 D_f : maintenance dose for a patient with renal insufficiency
 DFR: dialysate flow rate
 D_n : dose for a patient with normal renal function
 ESKD: end-stage kidney disease
 F: bioavailability
 f_e : fraction of drug eliminated unchanged in the urine
 f_u : fraction of drug unbound to plasma proteins
 GFR: glomerular filtration rate
 IC_{50} : inhibitory concentration of 50%
 k_a : absorption rate constant
 k : elimination rate constant
 k_{DD} : elimination rate constant during dialysis
 KF : ratio of the patient's creatinine clearance to the assumed normal value of 120 mL/min
 k_{ID} : elimination rate constant between dialysis sessions (interdialytic)
 Q : kinetic parameter/dosage adjustment factor
 Q_b : blood flow through the dialyzer
 Q_p : plasma flow through the dialyzer = $Q_b(1 - HCT)$
 R : the total amount of drug recovered unchanged in the dialysate
 S: salt form
 SC: sieving coefficient
 τ_f : dosing interval in a patient with renal failure
 τ_p : practical dosing interval for a patient with renal failure
 τ_n : dosing interval in a patient with normal renal function
 θ : 0.0107 times the total protein concentration in plasma
 t_{max} : time to peak drug concentration
 $t_{1/2}$: half-life
 $t_{1/2, onHD}$: half-life during dialysis
 $t_{1/2, offHD}$: half-life off dialysis
 UFR: ultrafiltrate formation
 V_{area} : volume of distribution area
 V_β : volume of distribution beta
 V_c : volume of the central compartment
 V_D : volume of distribution
 V_{df} : volume of dialysate/ultrafiltrate fluid
 V_{ss} : volume of distribution at steady state

DISORDERS OF SODIUM, WATER, CALCIUM, AND PHOSPHORUS HOMEOSTASIS

Melanie S. Joy and Gerald A. Hladik

Learning Objectives and other resources can be found at www.pharmacotherapyonline.com.

KEY CONCEPTS

- 1 Patients with symptomatic hyponatremia are at high risk of neurologic complications, and the serum sodium concentration in these patients should be raised 1.5 to 2 mEq/L per hour for the first 3 to 4 hours, but no more than 12 mEq/L per day to avoid cerebral demyelination.
- 2 In patients with the syndrome of inappropriate secretion of antidiuretic hormone and symptomatic hypotonic hyponatremia, the most efficient means of correcting the hyponatremia involves the administration of 3% saline in conjunction with a loop diuretic.
- 3 Patients with hypotonic hyponatremia caused by volume depletion should initially receive normal saline followed by 0.45% saline once signs of extracellular fluid volume depletion abate in order to avoid overly rapid correction of the serum sodium concentration.
- 4 The serum sodium concentration should be corrected at a rate of approximately 0.5 mEq/L per hour in patients with hypernatremia. The serum sodium concentration in patients who develop hypernatremia over the course of several hours (such as following hypertonic saline infusion) should be corrected at approximately 1 mEq/L per hour.
- 5 Patients with central diabetes insipidus should be treated with intranasal desmopressin acetate, with goals of decreasing urine volume to less than 2 L/day while maintaining the serum sodium concentration between 137 and 142 mEq/L.
- 6 Patients with nephrogenic diabetes insipidus should be treated by correcting the underlying cause when possible, and sodium chloride restriction in conjunction with a thiazide diuretic to decrease the extracellular fluid volume by approximately 1 to 1.5 L.
- 7 Patients with nephrotic syndrome commonly develop diuretic resistance. It is suggested that the impaired natriuretic response may be overcome by using higher doses to increase the delivery of free drug to the secretory site in the proximal nephron. Another approach is to use the combination of a loop diuretic with a distal diuretic.
- 8 Patients with cirrhosis should initially be treated with spironolactone in the absence of impaired glomerular filtration rate and hyperkalemia. Thiazides may then be added for patients with a creatinine clearance >50 mL/min. For those patients who remain diuretic resistant, a loop diuretic may replace the thiazide.
- 9 The fluid and electrolyte complications of diuretic therapy usually occur within the first 2 weeks of diuretic therapy, and repeated monitoring of serum chemistries is generally not necessary in the absence of a change in clinical status, diuretic dose, or dietary intake.
- 10 The correction of hypercalcemia includes multiple treatment modalities including hydration, diuretics, bisphosphonates, and steroids.
- 11 Hypophosphatemia can result from decreased gastrointestinal absorption, increased urinary excretion, and intracellular redistribution.
- 12 The treatment for hypophosphatemia consists of intravenous phosphate salts in doses of 0.08 to 0.64 mmol/kg for acute therapy and oral doses of 50 to 60 mmol/d for maintenance therapy.

Homeostasis of fluid and electrolytes is necessary for the body's normal physiologic functions. Disorders of sodium, water, calcium, and phosphorus are common complications of multiple acute and chronic diseases. These disorders are frequently associated with the acute care setting; however, they are clearly present in a less-severe state in the ambulatory care environment. The consequences of electrolyte disorders can range from asymptomatic to life-threatening requiring hospitalization. The maintenance of fluid and electrolyte homeostasis

requires adequate functioning of feedback mechanisms, hormones, and multiple organ systems. It is necessary to understand the pathophysiology of these disorders in order to develop appropriate treatment plans.

From a pharmaceutical care perspective, disorders of electrolyte homeostasis can result from drug therapy. In addition, with some drug therapies, toxicity can be enhanced when underlying electrolyte disorders are present. Drug-induced disorders respond well to

discontinuation of the offending agent(s); however, additional therapies are sometimes required to correct the disorder. This chapter reviews the etiology, classification, clinical presentation, and therapy for disorders of sodium, water, calcium, and phosphorus homeostasis.

SODIUM AND WATER HOMEOSTASIS

Two-thirds of total body water is distributed intracellularly while one-third is contained in the extracellular space.¹ Sodium and its accompanying anions, chloride and bicarbonate, comprise more than 90% of the total osmolality of the extracellular fluid (ECF), while intracellular osmolality is primarily dependent on the concentration of potassium and its accompanying anions (mostly organic and inorganic phosphates). The differential concentrations of sodium and potassium in the intra- and extracellular fluid is maintained by the Na⁺-K⁺-ATPase pump.² Most cell membranes are freely permeable to water, and thus the osmolality of intra- and extracellular body fluids is the same. Symptoms in patients with hypo- and hypernatremia are primarily related to alterations in cell volume.³ It is therefore essential to understand the factors that cause changes in cell volume.

Solutes that cannot freely cross cell membranes, such as sodium, are referred to as effective osmoles. The concentration of effective osmoles in the ECF determines the tonicity of the ECF, which directly affects the distribution of water between the extra- and intracellular compartments.⁴ Addition of an isotonic solution to the ECF will result in no change in intracellular volume because there will be no change in the effective osmolality of the ECF. Addition of a hypertonic solution to the ECF, however, will result in a decrease in cell volume, whereas addition of a hypotonic solution to the ECF will result in an increase in cell volume. Table 49–1 summarizes the composition of commonly used intravenous solutions and their respective distribution into extracellular and intracellular compartments following infusion.

Hypo- and hypernatremia are syndromes of altered tonicity and cell volume caused by changes in water balance. Thus an understanding of factors that affect tonicity and water balance is essential in order to understand the pathogenesis and evaluation of these syndromes. The serum sodium concentration is tightly regulated, and usually varies by no more than 2% to 3%. The kidney regulates water excretion through a feedback mechanism with the hypothalamus, such that the serum osmolality remains relatively constant (275 to 290 mOsm/kg) despite day-to-day variations in water intake. The serum osmolality is comprised primarily of sodium and the accompanying anions chloride and bicarbonate, and may be estimated by:

$$\text{Sosm} = (2 \times S_{\text{Na}}) + (\text{B}_{\text{glucose}}/18) + (\text{BUN}/2.8)$$

where Sosm = serum osmolality in milliosmoles per kilogram; S_{Na} = serum sodium concentration in mEq/L; B_{glucose} = glucose concen-

tration in mg/dL; and BUN = blood urea nitrogen concentration in mg/dL.⁵

Antidiuretic hormone (ADH) is released from the posterior pituitary when the plasma osmolality rises by 1% to 2% or more.⁶ ADH binds to the vasopressin-2 (V2) receptors on the basolateral surface of renal tubular epithelial cells, and through a series of second messenger reactions, a water channel (aquaporin-2) is inserted into the apical tubular lumen surface of the cell.⁷ Water may then pass through the cell into the peritubular capillary space, and is then reabsorbed into the systemic circulation. A rise in serum osmolality sensed in the hypothalamus results not only in ADH release, but also in stimulation of thirst. The combination of an increase in water intake and a decrease in water excretion results in a decrease in the serum osmolality and inhibition of ADH secretion once the plasma osmolality is restored to normal.

Nonosmotic release of ADH occurs when the effective arterial blood volume (EABV) decreases by approximately 5% to 10%.⁸ The EABV is the vascular component of the ECF that is responsible for organ perfusion.⁹ A change in the EABV promotes an afferent response from baroreceptors in the chest and neck and activation of the renin-angiotensin system, leading to synthesis of angiotensin II. Angiotensin II then stimulates both nonosmotic release of ADH and thirst. The volume stimulus overrides osmotic inhibition of ADH release, and conservation of water fosters restoration of blood pressure and EABV at the expense of hypo-osmolality.

The proper assessment of a patient with an abnormal serum sodium concentration requires recognition that the serum sodium level may bear no relationship to the ECF volume and sodium content. Hypernatremia and hyponatremia may be associated with conditions of high, low, or normal ECF sodium and volume. Abnormalities in the serum sodium concentration are thus a result of an alteration in the normal ratio between the total sodium and water content in the ECF.

HYPONATREMIA

EPIDEMIOLOGY AND ETIOLOGY

Hyponatremia (serum sodium <135 mEq/L) is the most common electrolyte abnormality in hospitalized patients, with a reported incidence of about 2.5%.¹⁰ Brain injury results from either the acute effects of hypo-osmolality or from too rapid correction of hypo-osmolality in patients with symptomatic hyponatremia, and is associated with a 20% incidence of significant morbidity and a mortality rate as high as 25%.¹¹ Hyponatremia is predominantly the result of an excess of extracellular water relative to sodium because of impaired water excretion. The kidney normally has the capacity to excrete large volumes of dilute urine after ingestion of a water load. Nonosmotic

TABLE 49–1. Composition of Intravenous Replacement Solutions

| Solution | Dextrose g/dL | [Na ⁺] (mEq/L) | [C ⁻] (mEq/L) | Tonicity | Distribution | | |
|---|------------------|-------------------------------|------------------------------|------------|------------------|-------|--------------|
| | | | | | % ECF | % ICF | Free Water/L |
| 5% dextrose in water (D ₅ W) | 5 | 0 | 0 | Hypotonic | 40 | 60 | 1,000 mL |
| 0.45% saline (1/2 normal saline) | 0 | 77 | 77 | Hypotonic | 73 | 37 | 500 mL |
| 0.9% saline (normal saline) | 0 | 154 | 154 | Isotonic | 100 | 0 | 0 mL |
| 3% saline (hypertonic saline) | 0 | 513 | 513 | Hypertonic | 100 ^a | 0 | –2,331 mL |

^aThis solution will result in osmotic removal of water from the intracellular space.

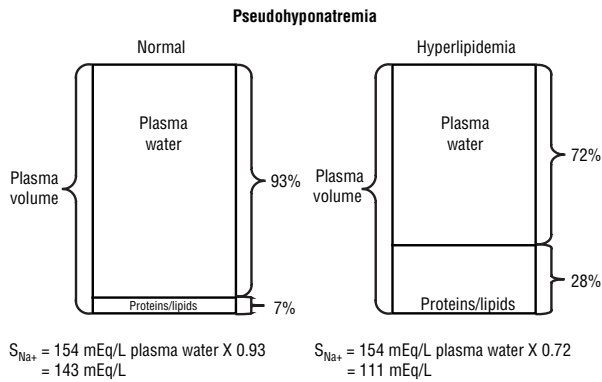

FIGURE 49-1. Elevated lipids or proteins result in a larger discrepancy between the volume of the sample and plasma water, leading to a falsely low measurement of the serum sodium concentration when using the method of flame photometry.

release of ADH, however, can lead to retention of water and to a drop in serum sodium concentration, despite a fall in both serum and intracellular osmolality. The causes of nonosmotic release of ADH include hypovolemia; decreased EABV as seen in patients with CHF, nephrosis, and cirrhosis; and the syndrome of inappropriate secretion of ADH (SIADH). The pathophysiology, clinical features, and management of hyponatremia are detailed below.

PATHOPHYSIOLOGY

Hyponatremia in patients with normal serum osmolality may be caused by hyperlipidemia or hyperproteinemia. If serum sodium concentration is measured by flame photometry, the volume of serum is overestimated because the elevated lipids or proteins account for a greater proportion of the total volume of the sample (Fig. 49-1).¹² Because the sodium is distributed in only the water component of

serum, the measured serum sodium concentration is falsely decreased. The measurement of serum osmolality, however, is not significantly affected, leading to a discrepancy between the calculated and measured serum osmolality. Because the serum sodium level is falsely decreased, this condition has been termed *pseudohyponatremia*. This laboratory artifact is uncommon today and has been overcome with the use of ion-specific electrodes to measure the serum sodium concentration.¹³

Hyponatremia in the presence of an elevated serum osmolality suggests the presence of excess effective osmoles in the ECF. This is most frequently encountered in patients with hyperglycemia, but is also seen in patients who have received irrigation with glycine during surgery, or in patients who have been treated with osmotic diuretics such as mannitol.^{14,15} The presence of glucose, glycine, or mannitol leads to diffusion of water from the cells into the extracellular compartment resulting in hyponatremia. For every 100-mg/dL rise in the serum glucose concentration, the serum sodium level decreases by 1.7 mEq/L¹⁶ and the serum osmolality rises by 2 mOsm/kg.¹⁷ Unmeasured osmoles should be suspected in patients with hypertonic hyponatremia when the difference between the measured and calculated osmolality, the “osmolal gap,” exceeds 15 mOsm/kg.¹⁸

In patients with a low plasma osmolality (hypotonicity), the most important step in the diagnostic evaluation of hyponatremia is the clinical assessment of the extracellular fluid volume.¹⁹ Categorization of patients with hypotonic hyponatremia into one of three groups (decreased, increased, or clinically normal ECF volume) is crucial in order to identify the pathophysiologic mechanisms responsible for the hyponatremia and thereby propose an appropriate treatment regimen (Fig. 49-2).

HYPOVOLEMIC HYPOTONIC HYPONATREMIA

Most patients with ECF volume contraction lose fluids that are hypotonic relative to plasma and thus may be transiently hypernatremic.

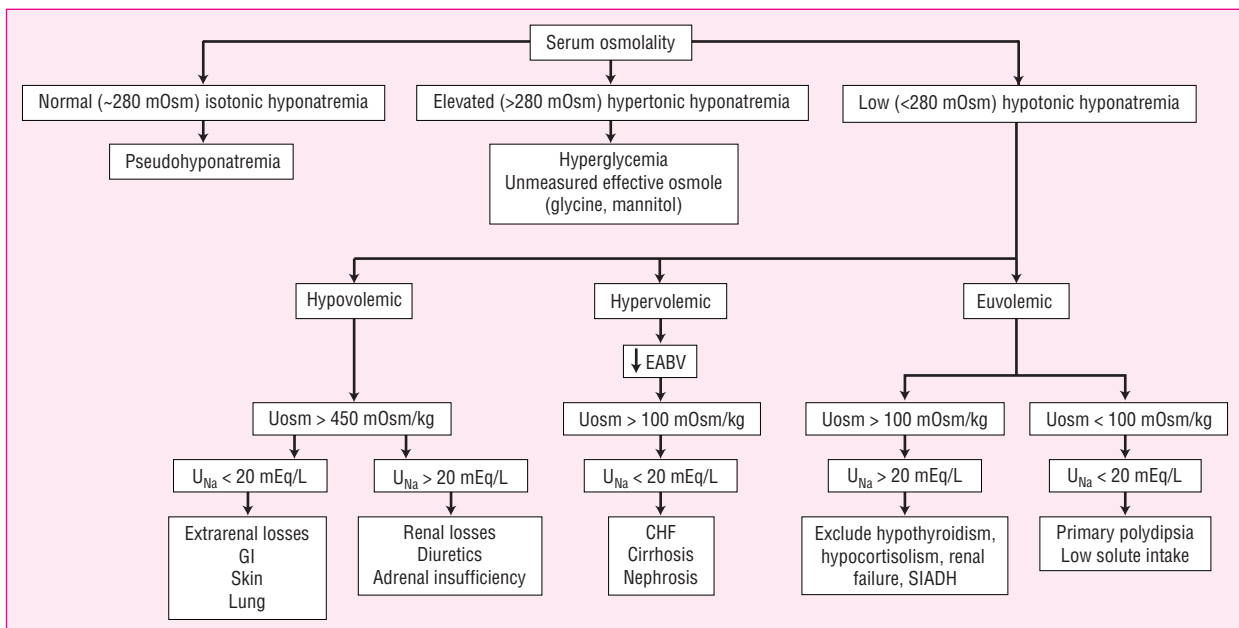

FIGURE 49-2. Diagnostic algorithm for the evaluation of hyponatremia. CHF, congestive heart failure; SIADH, syndrome of inappropriate secretion of antidiuretic hormone; U_{Na} , urine sodium concentration; U_{osm} , urine osmolality.

This includes patients with fluid losses caused by diarrhea, excessive sweating, and diuretics. This “transient” hypernatremic hyperosmolality results in osmotic release of ADH and stimulation of thirst. If sodium and water losses continue, more ADH is released as a result of hypovolemia. Patients who then drink water or who are given hypotonic fluids intravenously retain water and develop hyponatremia. Urine osmolality is generally greater than 450 mOsm/kg, reflecting the presence of ADH and formation of a concentrated urine.¹⁹ The urine sodium concentration is <20 mEq/L when sodium losses are extrarenal, as in patients with diarrhea, and >20 mEq/L in patients with renal sodium losses, as occurs in the setting of diuretic use or adrenal insufficiency.²⁰

Diuretic-induced hyponatremia occurs more frequently in patients treated with thiazide diuretics than in patients who are receiving loop diuretics.²¹ In addition to causing extracellular volume depletion and nonosmotic stimulation of ADH, thiazides interfere with urinary dilution and water excretion by blocking tubular sodium and potassium reabsorption in the distal tubule. Water is then retained in excess of sodium by virtue of nonosmotic release of ADH and excretion of urine with a concentration of sodium and potassium that exceeds that of the plasma.

Hyponatremia occurs less commonly with loop diuretics for several reasons. First, most loop diuretics have a shorter half-life than that of thiazides, and patients can therefore replete the urinary sodium and water losses prior to taking the next dose, thereby minimizing the degree of nonosmotic ADH stimulation. Loop diuretics also interfere with both urinary dilution and concentration. The latter is disrupted through inhibition of solute transport into the medulla, which interferes with creation of the medullary osmotic gradient. Thus relatively less water is retained in the presence of ADH.

EUVOLEMIC HYPOTONIC HYPONATREMIA

Euvolemic hyponatremia is associated with a normal or slightly decreased ECF sodium content and increased total body water and ECF volume. The increase in ECF volume is usually not sufficient to cause peripheral or pulmonary edema, and thus patients appear clinically euvolemic. Euvolemic hyponatremia is most commonly caused by SIADH secretion. In this syndrome, water intake exceeds the capacity of the kidneys to excrete water, either because of enhanced renal sensitivity to ADH, or because of an increased release of ADH via nonosmotic and/or nonphysiologic processes.²² The urine osmolality in SIADH is generally greater than 100 mOsm/kg, and the urine sodium concentration is greater than 20 mEq/L as a result of the ECF volume expansion. The most common causes of SIADH include tumors such as oat cell cancer of the lung, central nervous system (CNS) disorders (e.g., head trauma, stroke, meningitis, and pituitary surgery), as well as pulmonary disease. Drugs such as chlorpropamide, carbamazepine, cyclophosphamide, and nonsteroidal anti-inflammatory drugs (NSAIDs) induce SIADH by enhancing the sensitivity of the kidney to ADH.^{23–26} Selective serotonin reuptake inhibitors and methylenedioxymethamphetamine, a drug of abuse commonly known as “ecstasy,” also induce nonosmotic release of ADH.^{27,28} Patients with renal insufficiency, adrenal insufficiency, and hypothyroidism may also present with euvolemic hyponatremia, and the evaluation of patients with suspected SIADH should always include exclusion of these disorders.

The differential diagnosis of euvolemic hypotonic hyponatremia also includes primary or psychogenic polydipsia. Patients with this

disorder drink more water (usually >20 L/day) than the kidneys can excrete as solute-free water. Unlike SIADH, however, ADH is suppressed, resulting in a urine osmolality that is less than 100 mOsm/kg. The urine sodium is typically low (<15 mEq/L) as a result of urinary dilution.²⁹ Hyponatremia may develop with more modest water intake in patients on a very-low-solute diet, such as a sodium-free vegetarian diet.

HYPERVOLEMIC HYPOTONIC HYPONATREMIA

Hyponatremia associated with an increase in ECF volume occurs in conditions in which renal sodium and water excretion are impaired. Patients with cirrhosis, congestive heart failure, and nephrotic syndrome have an expanded ECF volume and edema, but a decreased EABV. The decreased EABV results in renal sodium retention, and eventually ECF volume expansion and edema. At the same time, there is nonosmotic release of ADH and retention of water in excess of sodium, thus perpetuating the hyponatremia.

CLINICAL PRESENTATION

Most patients with hyponatremia are asymptomatic, and the laboratory finding is often uncovered in the routine evaluation of patients presenting with symptoms attributable to another medical condition such as volume depletion or congestive heart failure.⁵ Hyponatremic patients with a decreased ECF volume present with decreased skin turgor, orthostatic hypotension, and dry mucous membranes as the result of excessive losses or inadequate intake of sodium and water. Both total body water and extracellular sodium are decreased, but the sodium deficit exceeds that of water, thus accounting for the decrease in the serum sodium concentration. Patients with serum sodium values greater than 125 mEq/L are generally asymptomatic except when hyponatremia develops in less than 24 hours. The symptoms of acute hypotonic hyponatremia usually result from an increase in neuronal cell volume and consequent cerebral edema. Symptoms may range from nausea, malaise, and headache in milder cases, to coma and seizures in severe cases.⁵ Respiratory arrest secondary to neurogenic pulmonary edema, presumably as a consequence of cerebral edema, has also been described.³⁰

Decreases in plasma tonicity result in movement of water into cells until the osmolality of the cells equals that of the extracellular fluid. Neurons have the capacity to adapt to increases in cell volume by actively transporting potassium and other osmotically active solutes (called organic osmolytes) such as taurine, glutamine, and inositol out of cells. Water will then redistribute into the extracellular space until osmotic equilibrium is achieved, resulting in decreased brain water and edema.³¹ Cerebral adaptation requires several hours to days, and thus patients who develop hyponatremia slowly, or patients who have chronic hyponatremia, may be asymptomatic or experience less-severe symptoms such as lethargy, nausea, headache, confusion, and disorientation. Recent studies suggest that patients with concurrent respiratory failure and hypoxemia are at greater risk for adverse neurologic outcomes because hypoxemia diminishes the capacity of the brain to actively transport solute out of cells, leading to a higher incidence of cerebral edema.³²

If hyponatremia is corrected too rapidly (i.e., >12 mEq/L per day), patients may experience an acute decrease in brain cell volume, which contributes to the pathogenesis of demyelinating brain injury.³³ Patients with this complication may develop paralysis or coma 5 to 7 days after treatment.³⁴ Patients who have a significant degree of

cerebral adaptation are at highest risk for this complication, presumably because rapid increases in plasma tonicity will result in larger decrements in cell volume.

CLINICAL PRESENTATION OF HYPONATREMIA

GENERAL

Hyponatremia is asymptomatic in most patients. The symptoms that may be seen with hyponatremia are primarily associated with concomitant volume depletion or congestive heart failure. Neurologic symptoms are related both to the severity and in particular to the rapidity of onset of the change in the plasma sodium concentration.

SYMPTOMS

The symptoms directly attributable to hyponatremia primarily occur with acute and marked reductions in the plasma sodium

concentration and reflect neurologic dysfunction induced by cerebral edema.

Nausea and malaise are the earliest findings, followed by headache, lethargy, and obtundation, and eventually seizures, coma, and respiratory arrest if the plasma sodium concentration falls below 115 to 120 mEq/L.

SIGNS

Pulmonary: Noncardiogenic pulmonary edema has been described.

Neurologic: Rapid correction of hyponatremia may result in an acute decrease in brain cell volume resulting in demyelinating brain injury.

LABORATORY TESTS

Serum sodium values lower than 135 mmol/L are present.

► TREATMENT: Hyponatremia

■ DESIRED OUTCOME

The goal of treating patients with hypovolemic hypotonic hyponatremia is to correct the ECF volume deficit, which will then lead to correction of the hyponatremia and restoration of organ perfusion. The treatment goals for hypervolemic and euvolemic hypotonic patients depend on the underlying cause of the hyponatremia and whether the patient is symptomatic. Patients who develop hyponatremia rapidly have the highest risk for cerebral edema, and thus require more aggressive therapy to correct the hypotonicity. The goal for these patients is to increase the tonicity at a rate appropriate to restore and maintain cell volume as close to normal as possible. Asymptomatic patients do not require rapid correction of the serum sodium, and the treatment is dictated by the underlying etiology. In all cases the goal is to avoid a rise in the serum sodium concentration greater than 12 mEq/L in 24 hours.

■ ACUTE SYMPTOMATIC HYPOTONIC HYPONATREMIA

1 The patient with symptoms attributable to hypotonicity regardless of fluid status should initially be treated with either a 0.9% or a 3% concentrated solution of sodium chloride until symptoms resolve, which generally requires that the serum sodium be increased to approximately 120 mEq/L.³⁵ The relative concentrations of urine sodium and potassium (osmotically effective urine cations) must be compared with those of the infusate in planning a treatment regimen for patients with hypotonic hyponatremia. For the serum sodium to rise after infusion of a solution of sodium chloride, the concentration of sodium in the infusate must exceed the sum of the sodium and potassium concentration in the urine in order to effect net free water excretion.

2 Patients with SIADH often have urinary concentrations of osmotically effective urine cations that exceed the sodium concentration of 0.9% saline (154 mEq/L), and thus patients should be preferentially treated with 3% saline (513 mEq/L). In this case use of isotonic saline carries the potential hazard of actually worsening hyponatremia.³⁵ The relatively high concentration of urinary sodium

in patients with SIADH stems from the fact that the ECF is expanded, thus minimizing reabsorption of sodium along the nephron. When the urine osmolality exceeds 300 mOsm/kg, it is generally advisable to add an intravenous loop diuretic, not only to increase the excretion of solute-free water, but also to prevent volume overload, which may result from infusion of hypertonic saline. Intravenous furosemide, initially at a dose of 40 mg every 6 hours, is generally sufficient to prevent volume overload and to decrease the concentration of osmotically active urine cations to less than 150 mEq/L.

Patients with hypovolemic hypotonic hyponatremia, on the other hand, should be treated with normal saline because the concentration of osmotically effective urine cations is invariably less than that of isotonic saline. In contrast to patients with SIADH, sodium is avidly reabsorbed throughout the nephron when the effective circulating blood volume is decreased. Thus the urine osmolality is primarily comprised of urea, and the concentration of urine sodium is often less than 20 mEq/L.

Hypervolemic patients are particularly problematic to manage acutely because the sodium and volume required to minimize the risk of cerebral edema or seizures may worsen their already compensated hepatic, cardiac, or renal function. It is generally agreed that these patients should be treated with hypertonic saline and prompt initiation of fluid restriction. Loop diuretic therapy will also likely be required to facilitate urinary excretion of free water.

■ DETERMINATION OF THE HYPERTONIC SALINE REGIMEN

Several methods have been developed to determine the correct volume of 3% saline to administer, but it is important to keep in mind that these formulas do not account for ongoing solute and water excretion, and only provide a rough estimate of the correct dose. The formula below is valid only for estimating the change in S_{Na} that will result from the infusion of 3% or 0.9% saline. The change in plasma sodium resulting from the infusion of 3% saline can be estimated as:⁵

$$\begin{aligned} \text{Change in } S_{Na} \text{ with 1 liter of infusate} \\ = [IV_{Na} - S_{Na}^I] \div (BW + IV_{vol}) \end{aligned}$$

where S_{Na}^1 = initial patient serum sodium concentration; IV_{Na} = sodium concentration of infusate; IV_{vol} = 1L of infusate; and BW = total body water (in liters), which may be estimated as a fraction of total body weight (kilograms) as follows:³⁶

$$0.6 \times \text{Body weight for children and men } <70 \text{ years old}$$

$$0.5 \times \text{Body weight for men } \geq 70 \text{ years old and females } <70 \text{ years old}$$

$$0.45 \times \text{Body weight for women } \geq 70 \text{ years old}$$

The serum sodium of a 50-kg 80-year-old female with SIADH presenting with confusion and a serum sodium level of 108 mEq/L, for example, should be corrected to approximately 120 mEq/L over the first 24 hours of hospitalization. The change in serum sodium of 12 mEq/L may be calculated as follows:

$$\begin{aligned} \text{Change in } S_{Na}^1 \text{ with 1L of infusate} &= (513 \text{ mEq/L} - 108 \text{ mEq/L}) \\ &\div [(0.45 \text{ kg} \times 50 \text{ kg}) + 1.0 \text{ L}] \\ &= [405 \text{ mEq/L}] \div 23.5 \text{ L} \end{aligned}$$

$$\text{Change in } S_{Na}^1 \text{ with 1L of infusate} = 17 \text{ mEq/L}$$

Because 1 L of 3% saline results in a 17 mEq/L rise in the serum sodium, one can extrapolate that each 100 mL would increase the serum sodium by 1.7 mEq/L. Thus the total dose required to achieve a change of 12 mEq/L in 24 hours will be approximately 705 mL. In the presence of symptoms, the serum sodium should be raised by approximately 1.5 mEq/L per hour over the first 2 to 4 hours (for a total of 6 mEq/L) or until the symptoms have resolved. Thus an initial infusion rate of 88 mL/h [1.5 mEq/L per hour \div 1.7 mEq/L per 100 mL] for the first 2 to 4 hours, followed by an infusion rate of approximately 17.5 to 22 mL/h for the next 20 to 22 hours, respectively, would be a reasonable initial treatment plan.

CLINICAL CONTROVERSY

Clinicians are often in disagreement regarding administration of 0.9% versus 3% saline in patients with symptomatic hyponatremia.

EVALUATION OF THERAPEUTIC OUTCOMES

Patients with symptomatic hyponatremia should be admitted to the intensive care unit or to a highly monitored setting for close monitoring of neurologic and volume status. Serial physical examinations of the heart, lungs, and neurologic status should be performed several times over the initial 12 hours of hospitalization. The serum sodium concentration should be measured every 2 to 4 hours, and the urine osmolality, sodium, and potassium should be measured every 4 to 6 hours over the first day of therapy. The rate of administration of the infusate should then be adjusted to avoid exceeding a rise in the serum sodium greater than 12 mEq/L per day.

HYPOVOLEMIC HYPOTONIC HYPONATREMIA

Because this condition is rarely associated with symptoms, the desired outcomes can generally be achieved with restoration of the blood pressure to the normal range, and absence of postural changes in blood pressure or increases in the central venous pressure or pulmonary cap-

illary wedge pressure to greater than 10 cm H₂O as assessed by central venous or pulmonary artery catheter. A 0.9% solution of sodium chloride, which has a tonicity that approximates that of the ECF, should be infused to correct the volume deficit, because all of the infused solution will remain in the ECF.

ECF volume deficit (ECFVd) is dependent on the patient's weight, age, and the degree of volume depletion, and is difficult to precisely estimate. An ECFVd loss that is equal to a 10% to 15% decrease in body weight is associated with the development of postural hypotension. An ECFVd loss as low as 5%, however, can result in hyponatremia caused by nonosmotic ADH release as a result of stimulation of baroreceptors located in the chest and neck. The ECFVd of patients can be estimated as illustrated in this case: a 42-year-old male weighs 70 kg on initial examination and presents with postural hypotension and has a serum sodium of 125 mEq/L.³⁷

$$\begin{aligned} \text{ECFVd} &= \text{ECFV}_{\text{norm}} - \text{ECFV}_{\text{current}} \\ \text{ECFVd} &= [\text{TBW}_{\text{norm}} \times 0.6 \text{ L/kg} \times 0.33] \\ &\quad - [\text{TBW}_{\text{current}} \times 0.6 \text{ L/kg} \times 0.33] \end{aligned}$$

where TBW_{norm} is 15% greater than $\text{TBW}_{\text{current}}$:

$$\begin{aligned} \text{ECFVd} &= [80.5 \text{ kg} \times 0.6 \text{ L/kg} \times 0.33] \\ &\quad - [70 \text{ kg} \times 0.6 \text{ L/kg} \times 0.33] \\ \text{ECFVd} &= 15.9 \text{ L} - 13.9 \text{ L} \\ \text{ECFVd} &= 2 \text{ L} \end{aligned}$$

A 0.9% solution of sodium chloride is considered to be isotonic and thus is optimal to correct the volume deficit because it will remain in the ECF space (see Table 49–1).

The expected rise in the serum sodium concentration following infusion of 1 L 0.9% saline (154 mEq/L) may be estimated as:

$$\begin{aligned} \text{Change in } S_{Na} \text{ with 1 liter of infusate} &= [IV_{Na} - S_{Na}^1] \div (BW + IV_{vol}) \\ &= [154 \text{ mEq/L} - 125 \text{ mEq/L}] \\ &\quad \div \{(0.6 \times 70 \text{ kg}) + 1.0 \text{ L}\} \\ &= [29 \text{ mEq/L}] \div 43 \text{ L} \\ &= 0.67 \text{ mEq/L} \end{aligned}$$

Thus the infusion of 2L of 0.9% saline will result in an increase of serum sodium of 1.34 mEq/L (2×0.67 mEq/L). The patient's sodium serum concentrations can thus be approximated to be 126.3 mEq/L (125 mEq/L + 1.34 mEq/L).

3 Because the overriding initial treatment goal is to restore vital organ perfusion, it is generally necessary to infuse 0.9% saline at 200 to 400 mL/h until hemodynamic stability is restored. The infusion rate can then be decreased to 100 to 150 mL/h such that the serum sodium level rises no more than 12 mEq/L over the initial 24 hours. Infusion of 0.9% saline at rates greater than 250 mL/h, however, should be used cautiously in patients with a history of left ventricular dysfunction or renal insufficiency. Once the ECF volume is restored, ADH secretion will cease, and a rapid water diuresis may ensue, which may potentially result in a rise in the serum sodium at a rate greater than 12 mEq/L per day. If this occurs, the infusate should be changed to 0.45% saline at a rate that approximates urine output (approximately 1.5 to 2 mL/kg per hour is a reasonable initial rate), in order to decrease the rate of rise in the serum sodium concentration.⁵

EVALUATION OF THERAPEUTIC OUTCOMES

Patients presenting with evidence of volume depletion should be re-examined frequently during the initial few hours of the resuscitation phase until hemodynamic stability is restored. Intravenous 0.9% saline should be administered judiciously in patients with a history of congestive heart failure or renal insufficiency, with frequent assessments of the cardiopulmonary examination so the infusion rate may be appropriately decreased when pulmonary congestion is detected. The serum sodium concentration should be measured every 2 to 4 hours to allow timely adjustment of the rate and composition of intravenous fluids in order to avoid a rise in the serum sodium greater than 12 mEq/L per day.

ASYMPTOMATIC EUVOLEMIC HYPOTONIC HYPONATREMIA

The treatment of SIADH always involves water restriction and correction of the underlying cause. Drugs that could be contributing should be identified and discontinued when possible. The goal is to induce negative water balance by restricting water intake to approximately 1,000 to 1,200 mL/day, such that water losses from insensible sources (skin and lung) and from obligate urine and fecal losses exceed intake. Daily insensible water losses via skin and lungs are approximately 700 mL/day, while approximately 100 to 200 mL and 1,500 mL/day is lost in stool and in urine output, respectively. Because approximately 850 mL of water per day is ingested in food, and an additional 350 mL are generated from oxidative processes, the water intake reduction should result in a negative water balance of several hundred milliliters per day.³⁸ Other goals include maintenance of the serum sodium level above 125 mEq/L to prevent symptoms of hyponatremia, and avoidance of iatrogenic hypo- or hypervolemia.

Patients with chronic SIADH who are unable to restrict water sufficiently to maintain the serum sodium greater than 120 to 125 mEq/L may be treated by increasing solute intake with either urea or sodium chloride and/or loop diuretics.³⁹ Sodium chloride or urea tablets increase the obligatory daily solute excretion, which augments the capacity for renal water excretion. The goal is to increase the daily solute intake and excretion to approximately 900 mOsm per day. Because an average diet contains approximately 600 mOsm, 9 g of sodium chloride would be required to increase the osmolar excretion to 900 mOsm/day (each 1-g sodium chloride tablet contains 17 mmol of sodium and 17 mmol of chloride). Because extracellular volume expansion is an expected adverse effect, a loop diuretic should be administered concurrently to avoid pulmonary congestion and peripheral edema. Loop diuretics also enhance water excretion by limiting the formation of the medullary concentration gradient.⁴⁰

Other treatment options include demeclocycline therapy and investigational ADH receptor antagonists. Demeclocycline (initially 900 to 1,200 mg/day, then decreased to 600 to 900 mg/day total daily dose given in three to four divided doses), interferes with tubular ADH activity, and is yet another option for patients with chronic SIADH.⁴¹ Because of its delayed onset of action (3 to 6 days), this agent has no role in the acute management of severe hyponatremia. It should not, however, be used in patients with liver disease or compromised fluid intake, who are at high risk for demeclocycline-induced renal tubular toxicity and acute renal failure.⁴² Recently several V2 receptor antagonists of ADH have been developed. These agents competitively bind to the V2 receptor on the basolateral surface of epithelial cells

in the collecting duct. Blockade of ADH binding to the V2 receptor prevents aquaporin transport to the apical surface, thereby precluding water reabsorption. Several antagonists are under investigation, and show promise for the treatment of chronic hypo-osmolar syndromes such as chronic SIADH.⁴³

EVALUATION OF THERAPEUTIC OUTCOMES

The serum sodium level should be measured every 24 to 48 hours after the water restriction is initiated until it stabilizes at a concentration of greater than 125 mEq/L. A continued decline in the serum sodium level would indicate either noncompliance with the prescribed restriction or the need for a more stringent restriction. Once the serum sodium level has stabilized above 125 mEq/L, patients should then be seen every 2 to 4 weeks to assess neurologic status and to obtain serum and urine for sodium, potassium, and osmolality. Again attention should be given to volume status (i.e., blood pressure, skin turgor, and heart and lung exam), particularly in patients who are being treated with sodium chloride tablets and loop diuretics.

ASYMPTOMATIC HYPERVOLEMIC HYPOTONIC HYPONATREMIA

The goals of treatment of asymptomatic hyponatremic patients with an expanded ECF volume include minimizing rapid changes in cell volume and effecting negative water balance until the serum sodium is greater than 125 mEq/L. This entails correction of the underlying cause when possible, as well as restriction of water intake to a volume less than 1,000 to 1,200 mL/day. Dietary intake of sodium chloride should be restricted to 1,000 to 2,000 mg/day, depending on the degree of ECF volume expansion and edema.

Patients with hypervolemic hyponatremia caused by congestive heart failure should be treated with measures that can potentially improve cardiac contractility and improve the EABV, thereby limiting the nonosmotic release of ADH. Therapeutic options include digitalis or afterload reduction with angiotensin-converting enzyme inhibitors (ACEIs) or angiotensin II receptor blockers (ARBs). Of these, only ACEIs have been shown in clinical trials to be of benefit in partially correcting hyponatremia in patients with congestive heart failure.⁴⁴ No specific ACE inhibitor offers any particular advantage for this indication, and the dose should be titrated to keep the systolic blood pressure in the 110 to 130 mm Hg range. Dose-limiting adverse effects include hyperkalemia (serum potassium >5.5 mEq/L), as well as a decline in renal function. The benefits and risks of continuing ACE inhibition must be weighed carefully in each case, but in general, an acute increase in the serum creatinine greater than 30% would require either a decrease in dose or discontinuation of the ACE inhibitor.

CLINICAL CONTROVERSY

Some clinicians regard any increase in serum creatinine in patients on ACEIs as a reason to decrease dosage or discontinue the medication.

Other potentially treatable causes of asymptomatic hyponatremia associated with an expanded ECF volume include nephrotic syndrome and cirrhosis. ACEIs may be used to decrease proteinuria

in patients with nephrotic syndrome, leading to partial correction of hypoalbuminemia and to a decrease in nonosmotic release of ADH. Patients with advanced cirrhosis may benefit from placement of a transjugular intrahepatic portosystemic shunt, which can increase the EABV and thus reduce the nonosmotic release of ADH. This procedure can potentially exacerbate or precipitate hepatic encephalopathy, and should be avoided in patients with a history of encephalopathy. V2 receptor antagonists also show promise for treating hyponatremia in the setting of cirrhosis.⁴⁵

HYPERNATREMIA

EPIDEMIOLOGY AND ETIOLOGY

Hypernatremia (serum sodium >145 mEq/L) is always associated with hypertonicity and results from a deficit of water relative to ECF sodium content. Hyperosmolar states are a potent stimulus for thirst, and therefore hypernatremia is most commonly observed in patients with an impaired thirst response or in those without access to water. Infants and comatose patients, as well as elderly or disabled patients with an impaired sensorium or functional status are therefore at highest risk for this disorder.⁴⁶ Hypernatremia occurs in approximately 0.3% to 1% of hospitalized patients.⁴⁷ Outcome generally depends on the rapidity with which the hypernatremia developed. Mortality from acute hypernatremia in children, which develops in less than 72 hours, ranges from 10% to 70%. In contrast, chronic hypernatremia in children, defined as that which develops over three or more days, has a mortality rate of 10%.⁴⁸ An acute increase in serum sodium in adults to greater than 160 mEq/L is associated with a 75% mortality rate. Adults in whom the hypernatremia developed chronically also have a high mortality in the 60% range.⁴⁹ Hypernatremia in adults is often associated with a serious underlying illness, which may contribute to the high mortality rates.

PATHOPHYSIOLOGY

Hypernatremia may result from either loss of water or hypotonic fluids, or less commonly from administration of hypertonic fluids or ingestion of sodium (Fig. 49–3). Water loss commonly occurs as a result of insensible losses (evaporative losses of water through the skin and lungs) in patients deprived of water. Hospitalized patients who are febrile or receiving mechanical ventilation are often treated with intravenous fluids containing insufficient free water to replace insensible losses. Hypernatremia may be observed in patients with hypotonic gastrointestinal losses (diarrhea or vomiting) or in patients who have been exposed to high temperatures who suffer large water losses from both sweat and insensible losses.

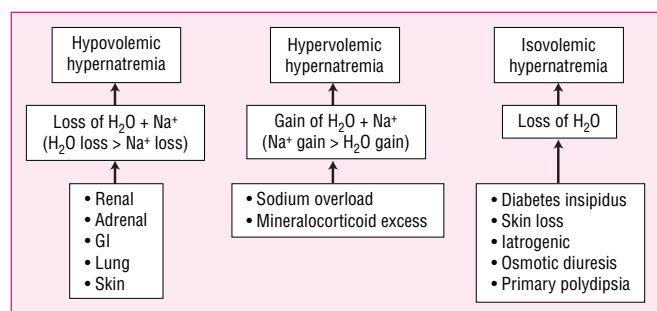

FIGURE 49–3. Common etiologies of hypernatremia.

EVALUATION OF TREATMENT OUTCOMES

Patients should initially be evaluated on a daily basis with a thorough physical exam to assess for lung congestion, ascites, and peripheral edema. The serum sodium concentration should be measured daily until it stabilizes above 125 mEq/L following initiation of water restriction. Patients should then be assessed 1 week following discharge, and then every 2 to 4 weeks to assess compliance with the water restriction and to reassess volume status.

Patients with diabetes insipidus (DI), or those undergoing an osmotic diuresis, may also have large urinary losses of water. DI is classified as either central (characterized by deficient secretion of ADH) or nephrogenic (characterized by resistance to ADH activity). Table 49–2 summarizes the causes of DI. Patients with central DI often present with sudden onset of polyuria, whereas patients with nephrogenic DI develop polyuria more gradually.

Administration of hypertonic saline can result in hypernatremia and an expanded ECF volume. This is typically iatrogenic, and may follow administration of sodium bicarbonate, use of hypertonic saline enemas, or intrauterine injection of hypertonic saline. Rarely, patients with hyperaldosteronism spontaneously present with an expanded ECF and mild hypernatremia.⁵⁰

CLINICAL PRESENTATION

The symptoms of hypernatremia are primarily caused by a decrease in neuronal cell volume, and may include weakness, restlessness, confusion, and coma. Hypernatremia results in movement of water from the intracellular space to the extracellular fluid. Neurons can adapt to hypertonicity in the ECF by generating intracellular organic osmolytes within 24 hours of onset. This increase in intracellular fluid tonicity then draws water into the neurons, thus limiting the decrease in cell volume. Patients with chronic hypernatremia are less likely to present with symptoms caused by this cerebral adaptation.

Hypernatremia is often associated with serious underlying illness, and thus symptoms may also be due to coexisting disorders. Patients with a history of severe diarrhea or vomiting may present with ECF volume depletion. Elderly patients deprived of water after sustaining a stroke or hip fracture often present with mental status changes and signs of ECF volume depletion. Clinically detectable extracellular fluid volume depletion, however, may not be evident until the serum sodium concentration exceeds 160 mEq/L, because these patients primarily have water loss, two-thirds of which is derived from the intracellular space. The urine is concentrated with an osmolality greater than 450 mOsm/kg as a result of both osmotic and nonosmotic release of ADH. The first step in evaluating patients with

TABLE 49–2. Causes of Diabetes Insipidus

ADH, antidiuretic hormone; CNS, central nervous system.

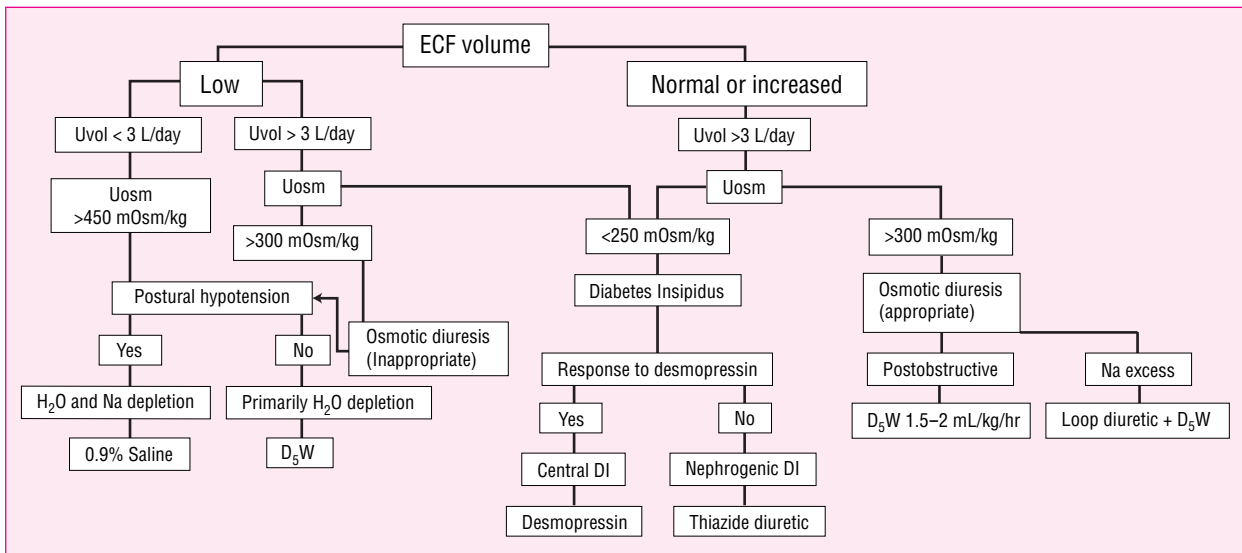

FIGURE 49-4. Diagnostic and treatment algorithm for hypernatremia. D₅W, 5% dextrose in water; ECF, extracellular fluid; H₂O, water; Na, sodium; Uosm, urine osmolality; Uvol, daily urine volume. See text for guidelines regarding calculations of infusion rates for intravenous solutions.

hypernatremia is the clinical assessment of the ECF volume, urine volume, and urine osmolality (Fig. 49-4).

Patients with a contracted ECF volume and a low urine output include those who have sustained insensible water losses that exceed intake, as well as those with extrarenal losses of hypotonic fluids. On physical exam, one should search for postural hypotension, diminished skin turgor, and delayed capillary refill. The daily urine output is typically less than 1 L.

CLINICAL PRESENTATION OF HYPERNATREMIA

GENERAL

The rise in the plasma sodium concentration and osmolality causes acute water movement from the intracellular to the extracellular fluid. In the brain this decrease in volume can cause rupture of the cerebral veins, leading to focal intracerebral and subarachnoid hemorrhages and possible irreversible neurologic damage.

SYMPTOMS

The clinical manifestations of this disorder begin with lethargy, weakness, confusion, restlessness, and irritability, and can progress to twitching, seizures, and coma. Severe symptoms usually require an acute elevation in the plasma sodium concentration to above 160 mEq/L. Values above 180 mEq/L are associated with a high mortality rate.

SIGNS

Signs of hypernatremia may include postural hypotension, diminished skin turgor, and reduced urine output. Signs associated with chronic hypernatremia are often difficult to detect because most affected adults have underlying neurologic disease.

LABORATORY TESTS

Serum sodium levels are generally higher than 145 mEq/L.

OSMOTIC DIURESIS

Patients undergoing an osmotic diuresis generally have urine volumes greater than 3 L/day. Excessive urinary excretion of glucose, sodium, urea, or an exogenously administered solute such as mannitol, are identified either by history or by direct measurement of serum and urinary concentrations of the suspected solute. Patients with postobstructive diuresis, such as those with bladder outlet obstruction due to prostatic hypertrophy, are usually volume expanded as a result of retained excess solute due to a decline in the glomerular filtration rate (GFR).⁵¹ The osmotic diuresis that follows alleviation of the obstruction is appropriate in that it promotes excretion of the excess retained solute. Patients with severe hyperglycemia, on the other hand, present with signs of volume depletion, and the diuresis is therefore inappropriate, further exacerbating the degree of ECF volume contraction.

Diabetes Insipidus

Patients with diabetes insipidus tend to maintain a normal ECF volume as long as they are conscious and have free access to water.

FIGURE 49-5. Water deprivation test. The change in plasma osmolality is plotted against the change in urine osmolality following water deprivation and subcutaneous administration of 5 mcg of desmopressin acetate. DI, diabetes insipidus; P_{osc}, plasma osmolality; Uosc, urine osmolality. (Adapted from Rose et al.⁵¹)

Patients typically have only a slight elevation in the serum sodium concentration (usually in the 141 to 145 mEq/L range), and a daily urine volume greater than 3 L.⁵² The type of DI may be diagnosed by performing the water deprivation test. This consists of depriving patients of water for 8 to 12 hours. Urine osmolality, urine volume, and body weight, are then measured before and after subcutaneous administration of 5 mcg of desmopressin acetate. Patients with central DI will show a prompt increase in urine osmolality to approximately 600 mOsm/kg and a decrease in urine volume after desmopressin administration. Those with nephrogenic DI will be unable to increase the urine osmolality above 300 mOsm/kg.⁵¹ Figure 49–5 depicts the changes in plasma and urine osmolality observed in the water deprivation test. Direct measurement of vasopressin levels after infusion of 5% saline at a rate of 0.05 mL/kg/min for no more than 2 hours

improves the accuracy of diagnosis, but carries a high risk of ECF volume overload.⁵³ Furthermore, measurement of serum vasopressin levels, is complicated by the fact that the molecule is unstable, and inappropriate specimen handling and processing often results in falsely low values.

Sodium Overload

Patients who have ingested large amounts of sodium [>4 tablespoons (1,400 mEq Na^+) of sodium chloride] or who have received greater than 5 L of hypertonic fluids are volume expanded, although this may not always be clinically evident as edema. This results in an osmotic diuresis, polyuria, and a urine osmolality greater than 300 mOsm/kg. The excess sodium will be excreted in the urine in patients with normal renal function.

► TREATMENT: Hyponatremia

■ DESIRED OUTCOME

The goals in treating patients with hyponatremia include correction of the serum sodium concentration at a rate that restores and maintains cell volume as close to normal as possible, as well as normalizing the ECF volume in states of ECF volume depletion and expansion. Adequate treatment should result in the resolution of symptoms associated with hypovolemia. Careful titration of fluids and medications should minimize the adverse effects from too rapid correction. Modulation of dietary sodium intake and sodium replacement may be necessary to prevent recurrence of hyponatremia.

■ PHARMACOLOGIC THERAPY

■ HYPOVOLEMIC HYPONATREMIA

4 Hypovolemic hyponatremia (postural hypotension, tachycardia, and decreased skin turgor) should initially be treated with 0.9% saline until hemodynamic stability is restored. An initial infusion rate of 200 to 300 mL/h will likely be appropriate for many patients. Once intravascular volume is restored, 0.45% saline or 5% dextrose in water (D_5W) can then be infused to correct the water deficit,³⁷ the volume of which may be estimated as:

$$\text{Water Deficit} = \text{Present TBW} \times \left[\left(\frac{S_{\text{Na}}^1}{140} \right) - 1 \right]$$

where TBW = total body water; S_{Na}^1 = initial patient serum sodium concentration (in mEq/L); and 140 = normal or goal S_{Na} (in mEq/L).

The rate of correction depends on the rapidity with which the hyponatremia developed. Hyponatremia that has developed over a few hours may be corrected at a rate of approximately 1 mEq/L per hour, whereas a rate of 0.5 mEq/L per hour should be used when it has developed more slowly.⁵⁰

Treatment of hyperglycemia-induced osmotic diuresis consists of correcting the hyperglycemia with insulin, as well as administering 0.9% saline until signs of ECF volume depletion resolve. Once hemodynamic stability is restored, the water deficit should be corrected in a manner analogous to that described for patients with hypovolemic hyponatremia above. The corrected serum sodium level should be calculated by adding 1.7 mEq/L for every 100-mg/dL rise in the serum glucose concentration before estimating the water deficit.⁵

Hyponatremia in patients undergoing a postobstructive diuresis should be treated with infusion of hypotonic fluids such as 0.45% saline at maintenance rates of approximately 1.5 mL/kg per hour. It is important to avoid the temptation to administer fluids to replace urine output on a 1 mL:1 mL volume basis, because this tends to perpetuate the diuresis.

The serum sodium concentration and fluid status should be monitored every 2 to 3 hours over the first 24 hours of admission in patients with symptomatic hyponatremia to permit appropriate adjustment in the rate of infusion of hypotonic fluids. After symptoms resolve and the serum sodium is less than 148 mEq/L, serum sodium determinations every 6 to 12 hours and fluid status assessment every 8 to 24 hours are generally sufficient to follow the course of therapy.

■ CENTRAL DIABETES INSIPIDUS

5 The beginning dose of intranasal desmopressin should be 10 mcg once daily. Ultimately the dose may need to be titrated up to 10 mcg twice daily for most adults. Because of variable absorption of oral desmopressin, DI is best treated with the intranasal formulation 1-deamino-8-D-arginine vasopressin (DDAVP). Each insufflation of intranasal DDAVP delivers 10 mcg of desmopressin acetate at a concentration of 100 mcg/mL.⁵⁴ Drugs with antidiuretic properties have been successful in the management of central and nephrogenic DI (Table 49–3). They may be used as an alternative to DDAVP or adjunctively.

The desmopressin dose should be adjusted to achieve adequate urinary concentration during sleep to prevent nocturia, to result in a daily urine volume of approximately 1.5 to 2 L, and to maintain the serum sodium concentration in the 137 to 142 mEq/L range. The serum sodium concentration should be measured every 3 to 4 days during the initial dose titration period, and then every 2 to 4 months.

■ NEPHROGENIC DIABETES INSIPIDUS

6 Hypercalcemia and hypokalemia should be corrected and medications that may contribute to the pathogenesis should be discontinued. One key goal in treating nephrogenic DI is to induce a mild ECFvD (1 to 1.5 L) with a thiazide diuretic and dietary sodium restriction (85 mEq Na^+ or 2,000 mg sodium chloride per day), which

TABLE 49–3. Drugs Used to Manage Central and Nephrogenic Diabetes Insipidus

| Drug | Indication | Dose |
|------------------------------|--------------------------------|-------------------------------------|
| Desmopressin acetate (DDAVP) | Central and nephrogenic DI | 5–20 mcg intranasally every 12–24 h |
| Chlorpropamide | Central DI | 125–250 mg orally daily |
| Carbamazepine | Central DI | 100–300 mg orally twice a day |
| Clofibrate | Central DI | 500 mg orally four times a day |
| Hydrochlorothiazide | Central and nephrogenic DI | 25 mg orally every 12–24 h |
| Amiloride | Lithium-related nephrogenic DI | 5–10 mg orally daily |
| Indomethacin | Central and nephrogenic DI | 50 mg orally every 8–12 h |

often can decrease urine volume by as much as 50% (see Table 49–3). This will increase proximal water reabsorption and therefore decrease the volume of filtrate delivered to the distal nephron, thus resulting in decreased urine volume. NSAIDs such as indomethacin at a dose of 50 mg three times a day may be used as adjunctive therapy by potentiating the activity of ADH.⁵⁵ Patients with lithium-induced nephrogenic DI may derive particular benefit from amiloride at a dose of 5 to 10 mg daily, which directly inhibits uptake of lithium from the tubular lumen into principal cells in the cortical collecting duct.⁵⁶

CLINICAL CONTROVERSY

The use of NSAIDs or amiloride to produce mild extracellular volume depletion needs to be evaluated in terms of the risks of an increase in serum creatinine concentration.

EVALUATION OF TREATMENT OUTCOMES

Physical examination with attention to volume status and measurement of serum and urine sodium concentration and osmolality should

be assessed every 2 to 3 months. A 24-hour urine collection to measure urine volume and sodium excretion will help guide therapy with diuretics and determine compliance with sodium restriction.

SODIUM OVERLOAD

Treatment of sodium overload consists of administration of loop diuretics to facilitate excretion of the excess sodium, as well as intravenous D₅W. The latter should be infused at a rate that will decrease the serum sodium at approximately 0.5 mEq/L per hour, or 1 mEq/L per hour in cases in which the hyponatremia developed rapidly over several hours.⁵⁰ The volume of infusate may be estimated as described previously. Furosemide should be administered at a dose of 20 to 40 mg intravenously every 6 hours.

The serum sodium should initially be measured every 2 to 4 hours, and the diuretic continued until signs of ECF volume overload (pulmonary congestion and edema) resolve. The serum sodium concentration can be determined every 6 to 12 hours once the serum sodium level is less than 148 mEq/L and symptoms of hypertonicity resolve.

EDEMA

The kidney responds to changes in the EABV, rather than directly sensing or measuring the sodium content of the ECF. A decline in the EABV results in decreased sodium and water excretion.⁹ Under these conditions, the kidneys retain all of the water and sodium ingested until the EABV is restored to normal. An increase in dietary sodium is accompanied by an increase in water intake caused by the initial increase in serum osmolality and stimulation of thirst. The resultant increase in ECF volume augments renal perfusion, effecting a transient increase in GFR which leads to enhanced sodium filtration and excretion.⁵⁷ These homeostatic mechanisms are crucial in maintaining sodium balance, as retention of just a few milliequivalents of sodium per day can eventually lead to an expanded ECF volume and edema formation.

PATHOPHYSIOLOGY

Edema is clinically detectable in adults when the interstitial volume increases by approximately 2.5 to 3 L, which correlates with a 4- to 4.5-L increase in ECF volume, and a 500 to 600 mEq increase in ECF sodium.⁵⁸ Edema develops when excess sodium is retained either as a primary defect in renal sodium excretion, or as a response to a decrease in the EABV despite an already expanded or normal ECF volume. An increase in the capillary hydrostatic pressure because of

an expansion of the ECF volume, or an increase in central venous pressure may lead to edema formation. Edema may also occur when there is an alteration in Starling forces within the capillary.⁵⁹ The Starling equation denotes the relationship between factors affecting the movement of fluid between the capillary and interstitium and is discussed in detail in Chap. 24.

An acute decompensation in myocardial contractility leads to an elevation in pulmonary venous pressure that is transmitted back to the pulmonary capillaries resulting in pulmonary edema. On a chronic basis, renal sodium and water retention due to diminished EABV leads to a rise in the ECF volume and edema formation in both peripheral and pulmonary interstitial tissues.

Edema formation in patients with nephrotic syndrome is primarily related to renal sodium and water retention. A decrease in capillary oncotic pressure does not appear to play a major role until the serum albumin concentration falls to less than 2 g/dL. This is explained by the fact that both capillary and interstitial oncotic pressure decrease proportionately above a serum albumin concentration of 2 g/dL, and thus the transcapillary oncotic gradient is not significantly altered.⁶⁰

Patients with cirrhosis initially develop ascites as a result of an increase in the pressure in the portal circulation proximal to the diseased liver. Sequestration of fluid in the abdominal cavity (ascites) and peripheral vasodilation as a consequence of increased levels of circulating cytokines, result in a decrease in the effective circulating volume, activation of the sympathetic nervous system and secondary

hyperaldosteronism. Therefore renal sodium retention leads to worsened ascites and edema.

CLINICAL PRESENTATION

Edema is usually first detected in the feet or pretibial area of ambulatory patients and in the presacral area of bed-bound individuals. Edema is described as “pitting” when a depression created by exerting pressure for several seconds over a bony prominence such as the tibia

does not rapidly refill. The severity of the edema may be quantified based on the depth of the pit thusly: 1+ = 2 mm, 2+ = 4 mm, 3+ = 6 mm, and 4+ = 8 mm.

The extent of the edema should also be quantified according to the area of involvement. Pretibial edema, for example, should be quantified according to how far it extends up the lower leg (e.g., one-third up the lower leg). Pulmonary edema, defined as an increase in lung interstitial and alveolar water, is manifest as end-inspiratory rales, initially localized to the dependent portions of the lungs.

► TREATMENT: Edema

■ GENERAL APPROACH TO TREATMENT

The goals of diuretic therapy are to minimize tissue edema and thus improve organ function, as well as to relieve symptoms of edema such as dyspnea in patients with congestive heart failure (CHF) or abdominal distention in patients with ascites. It is important to emphasize that the presence of edema does not always dictate the need for instituting pharmacologic (diuretic) therapy. Only pulmonary edema requires immediate pharmacologic treatment because it is life-threatening. Other forms of edema may be treated gradually, with a comprehensive approach that includes not only diuretics, but also sodium restriction and treatment of the underlying disease state. Sodium chloride intake should generally be restricted to 1,000 to 2,000 mg/day. A slow, more judicious approach in non-life-threatening situations will help to minimize complications of diuretic therapy and excessive fluid removal. These may include impaired vital organ perfusion, azotemia, and impaired cardiac output due to a fall in the left ventricular end-diastolic filling pressure.

■ PHARMACOLOGIC THERAPY

Diuretics are the primary pharmacologic therapy for the management of edema. Patients with expanded ECF volume and edema often require therapy with diuretics when treatment of the underlying disease and daily sodium restriction are insufficient to relieve the edema. Diuretics can be categorized according to the site in the nephron where sodium reabsorption is inhibited. Loop diuretics inhibit the $\text{Na}^+ - \text{K}^+ - 2\text{Cl}^-$ carrier in the loop of Henle. Thiazide diuretics inhibit the Na^+

Cl^- carrier in the distal tubule. Finally, potassium-sparing diuretics inhibit the sodium channel in the cortical collecting duct either directly (triamterene and amiloride), or by interfering with aldosterone activity (spironolactone and eplerenone). The efficacy of a diuretic depends on the presence of several factors, including the amount of filtered solute normally reabsorbed at the site of action, the amount of solute reabsorbed distal to the site of action, and adequate delivery of drug to the site of action in the nephron.

Loop diuretics are the most potent diuretics, as evidenced by the fact that they increase peak fractional excretion of sodium (Fe_{Na}) to 20% to 25%. Thiazide- and potassium-sparing diuretics are less potent and increase peak Fe_{Na} to 3% to 5% and 1% to 2%, respectively.⁶¹ Although a large portion of the filtered sodium is reabsorbed in the proximal nephron, the efficacy of proximal-acting diuretics such as acetazolamide are limited by reabsorption of the excess fluid and sodium in the loop of Henle.

The effectiveness of thiazide and loop diuretics is dependent on the concentration of the drug in the tubular lumen. Diuretics are delivered to the tubular lumen of the kidney by active transport by the proximal tubular cells. Osmotic diuretics, on the other hand, are freely filtered into the tubular lumen in the proximal tubule, whereas spironolactone gains access to mineralocorticoid receptors in the cortical collecting duct through diffusion from the systemic circulation.

A threshold concentration of loop or thiazide diuretic must be delivered to the active site (e.g., loop of Henle or distal tubule) in order to achieve a natriuresis.⁶² Once this concentration is achieved, further increases in diuretic dose will not elicit an increase in diuretic response. Thus a ceiling dose of diuretic is recognized. Administration of 40 mg of intravenous furosemide to a normal subject will result in excretion of 200 to 250 mEq of sodium in 3 to 4 L of urine over a 3- to 4-hour period.⁶² Table 49–4 summarizes the maximal effective

TABLE 49–4. Maximal Effective Dose and Dosing Interval for Edema Management with Loop Diuretics

| Diuretic | Dosing Interval | Normal | Cirrhosis | CHF | Nephrotic Syndrome | GFR 10–50 mL/min | GFR <10 mL/min |
|------------|-----------------|----------|-----------|-----------|--------------------|------------------|----------------|
| Furosemide | | | | | | | |
| IV | 6–8 h | 10–40 mg | 40 mg | 40–80 mg | 120 mg | 80 mg | 200 mg |
| Oral | 6–8 h | 20–80 mg | 80 mg | 80–160 mg | 240 mg | 160 mg | 320–400 mg |
| Bumetanide | | | | | | | |
| IV/Oral | 6–8 h | 1 mg | 1 mg | 2–3 mg | 3 mg | 2–3 mg | 8–10 mg |
| Torsemide | | | | | | | |
| IV/Oral | 24 h | 15–20 mg | 10–20 mg | 20–50 mg | 50 mg | 20–50 mg | 50–100 mg |

CHF, congestive heart failure; GFR, glomerular filtration rate.

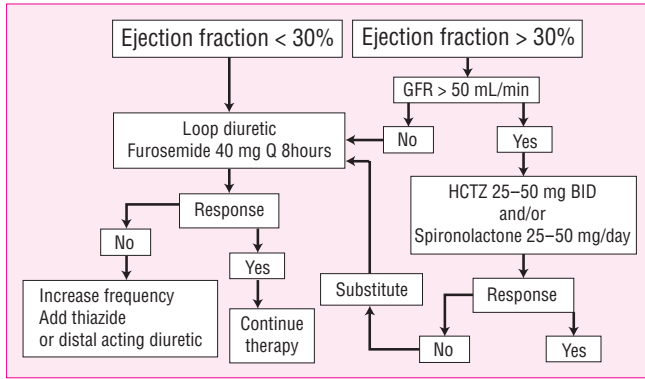

FIGURE 49-6. Therapeutic algorithm for diuretic use in patients with congestive heart failure. GFR, glomerular filtration rate; HCTZ, hydrochlorothiazide.

doses and dosing intervals for loop diuretics in patients with cirrhosis, CHF, and nephrotic syndrome, with normal and decreased glomerular filtration rates. Patients with renal insufficiency require larger doses of diuretics to achieve adequate concentration of the drug to the active site (see Chap. 42). The natriuretic response is decreased in patients with renal insufficiency because the filtered load of sodium falls proportionately as GFR declines. This may be partially overcome by dosing diuretics more frequently, as well as by using continuous infusions in critically ill hospitalized patients.⁶³ The latter will maintain more consistent levels of the diuretic above the threshold concentration. Patients that are diuretic resistant should be treated with both a loop and a thiazide-type diuretic. Patients with CHF and a normal GFR have impaired oral absorption of furosemide. An adequate diuresis is most readily sustained by increasing the frequency of diuretic administration (Fig. 49-6).

7 Diuretic resistance may be due to increased uptake of sodium in the distal tubule, impaired delivery of diuretics to the site of action, or decreased intrinsic diuretic activity. Animal studies have demonstrated binding of furosemide to albumin in the tubular lumen, which decreases the availability of the drug to the active site.⁶⁴ Human studies, however, have demonstrated that when albumin binding is inhibited by concurrent administration of sulfasoxazole, diuretic resistance persists, suggesting a decrease in intrinsic tubular sensitivity to loop diuretics.⁶⁵ This impaired natriuretic response may be overcome by using higher diuretic doses to increase the delivery of free drug to the secretory site in the nephron.⁶³ Combinations of loop diuretics with distally-acting diuretics are generally necessary

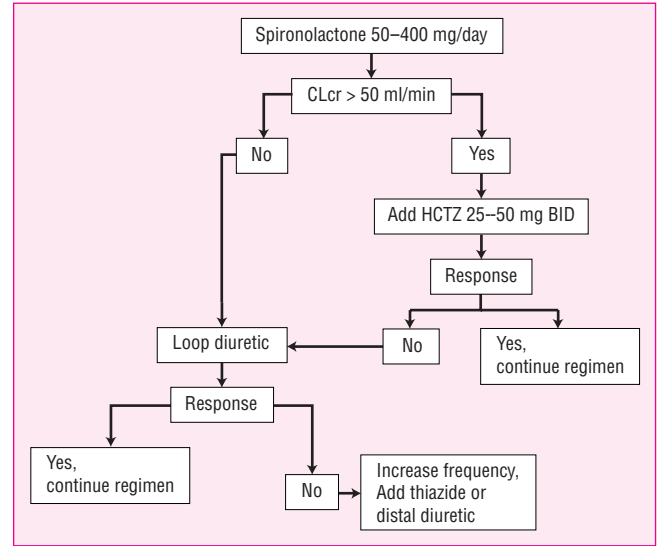

FIGURE 49-8. Therapeutic algorithm for diuretic use in patients with cirrhosis. CLcr, creatinine clearance; HCTZ, hydrochlorothiazide.

to promote a natriuresis that exceeds tubular sodium reabsorption (Fig. 49-7).

CLINICAL CONTROVERSY

Some clinicians advocate using combinations of diuretics in cases of diuretic resistance associated with nephrotic syndrome, while others prefer to use larger-than-average doses to overcome enhanced protein binding in the tubular lumen associated with proteinuria.

8 Secondary hyperaldosteronism plays a major role in the pathogenesis of edema in patients with cirrhosis. Therefore these patients should initially be treated with spironolactone in the absence of impaired GFR and hyperkalemia. Thiazides may then be added for patients with a creatinine clearance >50 mL/min. For those patients who remain diuretic resistant, a loop diuretic may replace the thiazide. Patients with impaired GFR (creatinine clearance of <30 mL/min) generally will require a loop diuretic, with addition of a thiazide in those who do not achieve adequate diuresis.⁶³ Care should be taken to avoid hypokalemia, which may precipitate hepatic encephalopathy by increasing ammoniogenesis (Fig. 49-8).⁶⁶

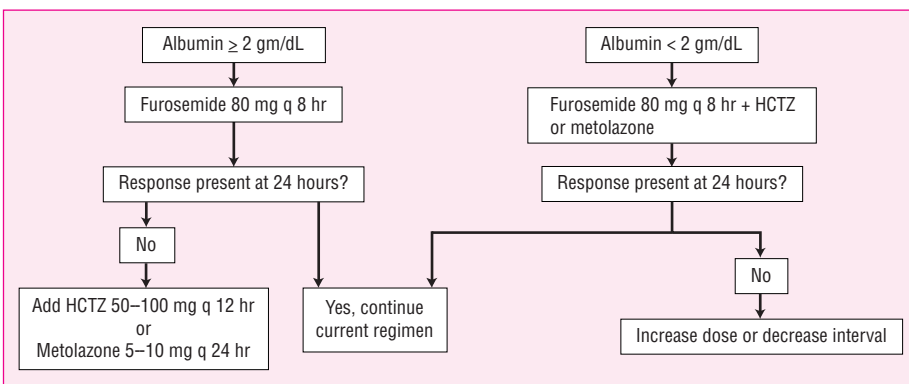

FIGURE 49-7. Therapeutic algorithm for diuretic therapy in patients with nephrotic syndrome. HCTZ, hydrochlorothiazide.

EVALUATION OF THERAPEUTIC OUTCOMES

9 Patients should be monitored by serial physical examinations, including measurement of blood pressure and pulse in either supine or seated positions and after standing for 2 to 3 minutes. ECF volume may be estimated based on the height of the jugular venous pressure, extent of edema, auscultation of the heart and lungs, and skin turgor. Follow-up monitoring (10 to 14 days after initiation of therapy) should include determinations of serum sodium, potassium, chloride, bicarbonate, magnesium, calcium, blood urea nitrogen, serum creatinine, and uric acid. A new steady state will have developed over that time period and further fluctuations in ECF volume and electrolyte balance should not occur in the absence of a change in clinical status, diuretic dose, or dietary intake. Repeated blood tests are not neces-

sary at every visit unless there is a change in the patient’s clinical status.

Complications of loop and thiazide diuretic therapy include hypokalemia, excess depletion of ECF volume, hyponatremia, hypomagnesemia, metabolic alkalosis, and hyperuricemia. Thiazides can also cause hypercalcemia, particularly in patients with mild subclinical hyperparathyroidism. Chronic therapy with potassium-sparing diuretics, including triamterene, amiloride, and spironolactone, may cause a mild metabolic acidosis and can precipitate hyperkalemia. Patients with renal insufficiency or those receiving NSAIDs, ACEIs, or ARBs are at highest risk for this complication. In addition, spironolactone may cause reversible gynecomastia in patients receiving therapy for more than several weeks. This side effect, however, has not been associated with eplerenone, a newly available aldosterone antagonist.⁶⁷

DISORDERS OF CALCIUM HOMEOSTASIS

The maintenance of physiologic calcium concentrations in the intracellular and extracellular spaces is vital for the preservation and function of cell membranes; propagation of neuromuscular activity; regulation of endocrine and exocrine secretory functions; blood coagulation cascade; platelet adhesion process; bone metabolism; muscle cell excitation/contraction coupling; and mediation of the electrophysiologic slow-channel response in cardiac and smooth-muscle tissue.

The disorders of calcium homeostasis are related to the calcium content of the extracellular fluid, which contains less than 0.5% of the total body stores of calcium. Skeletal bone contains more than 99% of total body stores of calcium.⁶⁸ ECF calcium is moderately bound to plasma proteins (46%), primarily albumin.⁶⁹ Unbound or ionized calcium is the physiologically active form and is the fraction that is homeostatically regulated.⁷⁰ Extracellular calcium, however, is most commonly measured as the total serum calcium level, which includes both bound and unbound calcium.⁶⁹ The normal total calcium serum concentration range is 8.5 to 10.5 mg/dL.⁷⁰

The concentration of ionized calcium is closely regulated by the interactions of parathyroid hormone (PTH), phosphorus, vitamin D, and calcitonin (Fig. 49–9). Parathyroid hormone increases serum calcium concentrations by stimulating calcium release from bone, reducing renal excretion, and enhancing absorption in the gastrointestinal tract secondary to increased renal production of 1,25-

dihydroxyvitamin D₃. Vitamin D directly increases serum calcium, as well as phosphorus concentrations, by increasing gastrointestinal absorption. Indirectly, it can also lead to calcium release from bone and reduced renal excretion. Calcitonin inhibits osteoclastic bone resorption. Its plasma concentrations are increased when ionized calcium concentrations are high as the body attempts to return the calcium level to the normal range. Disruption of these homeostatic mechanisms results in the clinical manifestations of hypercalcemia or hypocalcemia.

Any factor that alters the concentration of albumin or its binding of calcium may be expected to change the fraction of total serum calcium in the ionized form. The most significant cause of changes in calcium binding to albumin is a change in extracellular fluid pH. In the presence of metabolic alkalosis the fraction of calcium bound to albumin is increased, thus reducing the plasma concentration of ionized calcium. This may result in symptomatic hypocalcemia; that is, paresthesias, muscle cramping and spasms, memory loss, and seizures.⁶⁸ Conversely, metabolic acidosis decreases calcium binding to albumin and results in increased ionized calcium. Hypoalbuminemic states are probably the most common cause of “laboratory hypocalcemia.” When the albumin level is decreased, ionized calcium concentration may be normal even though total concentration is reduced. Each 1 g/dL drop in the serum albumin concentration below 4 g/dL will result in a decrease of total serum calcium concentration by 0.8 mg/dL.^{68,69} This approach of calculating an albumin-adjusted calcium concentration has been found to overestimate

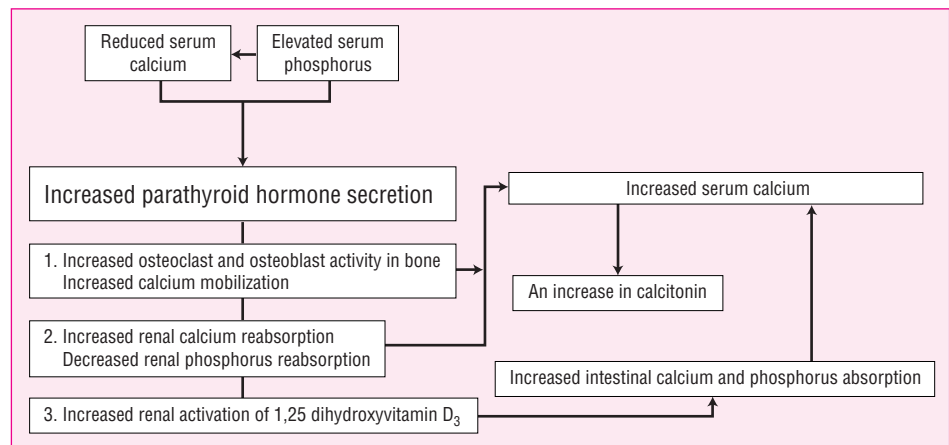

FIGURE 49–9. Homeostatic mechanisms to maintain serum calcium concentrations.

TABLE 49–5. Etiologies of Hypercalcemia

| Neoplasms | Medications |
|--------------------------------------|------------------------------|
| Bone metastasis | Thiazides |
| Breast | Lithium |
| Multiple myeloma | Vitamin D |
| Lymphoma | Vitamin A |
| Leukemia | Calcium |
| Humoral induced | Aluminum/magnesium |
| Ovary | antacids |
| Kidney | Theophylline |
| Pheochromocytoma | Tamoxifene |
| Multiple endocrine neoplasia | Gancyclovir |
| Lung | Granulomatous disease |
| Head and neck | Sarcoidosis |
| Esophagus | Tuberculosis |
| Cervix | Cryptococcus |
| Lymphoproliferative disease | Berylliosis |
| | Histoplasmosis |
| Hyperparathyroidism | Coccidioidomycosis |
| Primary | Leprosy |
| Tertiary | Endocrine disease |
| Miscellaneous | Adrenal insufficiency |
| Immobilization | Hyperthyroidism |
| Paget's disease | Acromegaly |
| Familial hypocalciuric hypercalcemia | |
| Adolescence | |
| Rhabdomyolysis | |

hypercalcemia and usually fails to identify hypocalcemia in critically ill patients.⁷¹

HYPERCALCEMIA

Hypercalcemia (total serum calcium >10.5 mg/dL) may be induced by a multitude of causes (Table 49–5). The most common causes of hypercalcemia are cancer and primary hyperparathyroidism. The incidence of primary hyperparathyroidism is approximately 270 new cases per million persons per year.⁷² Hypercalcemia of cancer occurs in approximately 20% to 40% of cancer patients at some time during the course of their disease.⁷³ Cancer-associated hypercalcemia is predominantly encountered in hospitalized patients, while primary hyperparathyroidism accounts for the vast majority of cases in the outpatient setting.^{74,75}

PATHOPHYSIOLOGY

Hypercalcemia is the result of one of three primary mechanisms: increased bone resorption, increased gastrointestinal absorption, or decreased elimination by the kidneys (see Fig. 49–9). Many tumors secrete parathyroid hormone–related protein which binds to the parathyroid hormone receptors in bone and renal tissues, leading to increased bone resorption and renal tubular reabsorption.⁷⁶ Tumors may also secrete substances such as vitamin D, transforming growth factor, interleukins, prostaglandins, interferon, tumor necrosis factor, and granulocyte-macrophage colony stimulating factor, which are associated with the development of hypercalcemia.⁷³ Hypercalcemia of malignancy is a common complication of squamous cell carcinomas of the lung, head, and neck, hematologic malignancies such as multiple myeloma and T-cell lymphomas, and carcinomas of ovary, kidney, bladder, and breast. The most frequent types of malignancy associated with hypercalcemia are carcinomas of the lung and breast.⁶⁹ Further-

more, up to 40% of patients with multiple myeloma may develop hypercalcemia.⁷⁵ Primary hyperparathyroidism is the most common cause of hypercalcemia in the general population. Benign parathyroid adenomas account for 80% to 85% of these cases of hyperparathyroidism, parathyroid hyperplasia accounts for 15%, and parathyroid carcinoma is the cause in less than 1% of cases.^{73,74}

Other causes of hypercalcemia include medications, endocrine and granulomatous disorders, immobilization, high bone-turnover states (adolescence and Paget's disease), and rhabdomyolysis. Increased gastrointestinal absorption may be the result of excessive ingestion of vitamin D analogs, calcium supplements, and lithium. Lithium and vitamin A therapy can increase bone resorption, while increased renal tubular reabsorption of calcium can occur with thiazide and lithium therapy. Aluminum antacids prevent calcium deposition, thereby increasing serum concentrations.⁷⁷ Addison's disease, acromegaly, and thyrotoxicosis are endocrine disorders that may lead to hypercalcemia due to increased renal tubular reabsorption and increased bone resorption. Finally, the granulomatous disorders (sarcoidosis, tuberculosis, histoplasmosis, and leprosy) are associated with hypercalcemia caused by an increase in gastrointestinal absorption.⁷⁸

CLINICAL PRESENTATION

Patients with mild to moderate hypercalcemia, that is, serum calcium concentrations of less than 13 mg/dL, may often be asymptomatic. This is usually the case in drug-induced hypercalcemia and the vast majority of patients with primary hyperparathyroidism.^{74,79–80} In fact, one study noted nearly normocalcemia in approximately 20% of patients with a diagnosis of primary hyperparathyroidism, suggesting target tissue resistance to parathyroid hormone.⁸⁰ The signs and symptoms of hypercalcemia that are usually present if the total serum calcium concentration is >13 mg/dL may differ depending on the acuity of onset.⁶⁹ Hypercalcemia of malignancy usually develops quickly and is accompanied by a classic symptom complex of anorexia, nausea and vomiting, constipation, polyuria, polydipsia, and nocturia.⁷⁹ Polyuria and nocturia secondary to a urinary-concentrating defect constitute some of the most frequent renal effects of hypercalcemia.⁷⁹ Hypercalcemic crisis is characterized by an acute elevation of serum calcium to a value >15 mg/dL, acute renal insufficiency, and obtundation (inability to arouse).⁷⁹ If untreated, hypercalcemic crisis may progress to oliguric renal failure, coma, and life-threatening ventricular arrhythmias that may lead to death.⁷⁹ Complications associated with chronic hypercalcemia (hyperparathyroidism) include metastatic calcification, nephrolithiasis, and chronic renal insufficiency.⁷⁹

Calcium and/or calcium-phosphorus complex deposition in blood vessels and multiple organs is a complication of chronic hypercalcemia and/or concomitant hyperphosphatemia and hyperparathyroidism (see Chap. 44). Calcium deposits in atherosclerotic lesions contribute to cardiac disease. Patients with renal insufficiency are especially vulnerable due to the use of calcium products as phosphate-binding agents and their higher overall risk of developing cardiovascular disease. The rate of coronary artery calcification progression was found to be 50% greater in young hemodialysis patients versus normal middle-aged adults.⁸¹ Furthermore, patients with calcifications had higher serum phosphorus concentrations, higher calcium-phosphorus product, and higher intake of calcium-based phosphate-binding agents.^{81,82} Another study showed that the intake of calcium-containing phosphate binders was solely associated with vascular calcification score.⁸³ Intracardiac and arterial calcifications have been found in patients with Paget's disease who have normal renal function. These calcifications were found to be five times more

common than in the general population. Although usually asymptomatic, these lesions can result in heart block and valvular disease.⁸⁴

The electrocardiographic changes associated with hypercalcemia include shortening of the QT interval and coving of the ST-T wave.⁷⁹ Very high serum calcium concentrations may cause T-wave widening, indicating a repolarization defect that may be associated with spontaneous ventricular tachyarrhythmias.⁷⁹ Hypertension and arrhythmias have occurred in the setting of hypercalcemia. Sensitivity to the pharmacologic and toxic actions of digitalis may be enhanced in the setting of hypercalcemia.⁷³

Nephrolithiasis (kidney stones) and nephrocalcinosis (calcium deposits in the kidney) are the primary renal complications arising from long-standing hypercalcemia, as the result of primary hyperparathyroidism. It is estimated that hyperparathyroidism accounts for 2% to 8% of all patients with calcium stones.^{85,86} Of note, in those patients with low glomerular filtration rates, the 24-hour urinary calcium will actually diminish secondary to the reduced urine flow. However, the fractional excretion of calcium may increase.⁸⁶ Sarcoidosis is the other hypercalcemic condition frequently associated with calcium stones.⁸⁵ Other causes of nephrolithiasis with calcium-containing stones include hypocitraturia, renal tubular acidosis, hyperoxaluria, and hyperuricosuria.^{87,88} Stone formers who have primary hyperparathyroidism are more likely to be female, over age 50 years, and have a family history of multiple endocrine disorders.⁸⁵ High dietary sodium intake can also raise urinary calcium concentrations, thus predisposing patients to calcium stones. The proposed mechanism is a reduction in calcium reabsorption in the kidney. Although chronic renal failure can be the ultimate result of persistent stones, it is the primary cause of renal disease in <2% of the end-stage renal disease population.⁸⁹ A patient's first renal symptom is a loss of medullary concentrating ability.⁸⁵

CLINICAL PRESENTATION OF HYPERCALCEMIA

GENERAL

The signs and symptoms of hypercalcemia depend on its level, and also on the rapidity of the onset.

SYMPTOMS

Symptoms include fatigue, weakness, anorexia, depression, anxiety, cognitive dysfunction, vague abdominal pain, and constipation. Renal symptoms can include polyuria, polydipsia, and nocturia. The extent of symptoms is related to both the degree of hypercalcemia and the rate of onset of the elevation in the serum calcium concentration. Rarely, severe hypercalcemia leads to acute pancreatitis.

SIGNS

Renal: The most important renal manifestations of hypercalcemia are nephrolithiasis; renal tubular dysfunction, particularly decreased concentrating ability; and acute and chronic renal insufficiency.

Cardiovascular: Long-standing hypercalcemia can lead to the deposition of calcium in heart valves, coronary arteries, and myocardial fibers. Hypercalcemia also directly shortens the myocardial action potential, which is reflected in a shortened QT interval and coving of the ST-T wave. Spontaneous ventricular tachyarrhythmias and elevations in blood pressure have also been reported.

Musculoskeletal: A number of rheumatologic complaints have been described in hyperparathyroidism, including gout, pseudogout, and chondrocalcinosis. The relative roles of hypercalcemia and PTH excess in these problems are not known.

Other signs: Band keratopathy, a reflection of subepithelial calcium phosphate deposits in the cornea, is a very rare finding associated with hypercalcemia. It extends as a horizontal band across the cornea in the area that is exposed between the eyelids.

LABORATORY TESTS

Serum calcium concentrations of more than 10.5 mg/dL are considered to represent hypercalcemia. Values up to 13 mg/dL suggest mild or moderate hypercalcemia, while values greater than this indicate severe hypercalcemia.

► TREATMENT: Hypercalcemia

■ DESIRED OUTCOME

The indications for the treatment of acute hypercalcemia are dependent on the degree of hypercalcemia, acuity of its development, and presence or absence of symptoms. The objectives of treatment are reversal of signs and symptoms, restoration of normocalcemia, treatment of the underlying cause of hypercalcemia, and prevention of long-term consequences. Chronic hypercalcemia is usually caused by an underlying medical condition or prescribed therapies. The treatment of malignancies may help mitigate acute hypercalcemic episodes. The goals of treatment of hyperparathyroidism are to reduce serum calcium concentrations as well as to reduce long-term complications such as vascular complications, chronic renal insufficiency, and kidney stones. Medications including thiazides, lithium, antacids, and vitamins A and D need to be recognized as potential reversible causes of hypercalcemia.

■ NONPHARMACOLOGIC THERAPY

Hypercalcemic crisis and acute symptomatic severe hypercalcemia should be considered medical emergencies and treated immediately (Fig. 49–10). These patients may require immediate-acting interventions to promptly reduce the serum calcium concentration. Hemodialysis against a zero- or low-calcium dialysate solution is considered the treatment of choice, especially in patients with impaired renal function or life-threatening hypercalcemia.⁷⁷ However, because there may be considerable delays in initiating dialysis due to the need for evaluation by a nephrologist and placement of a vascular access device, pharmacologic therapy consisting of volume expansion and enhancement of urinary calcium excretion (when not contraindicated by renal dysfunction) and/or calcitonin is usually initiated in the interim. Effective treatment of moderate to severe hypercalcemia in the absence of life-threatening symptoms begins with attention to the underlying

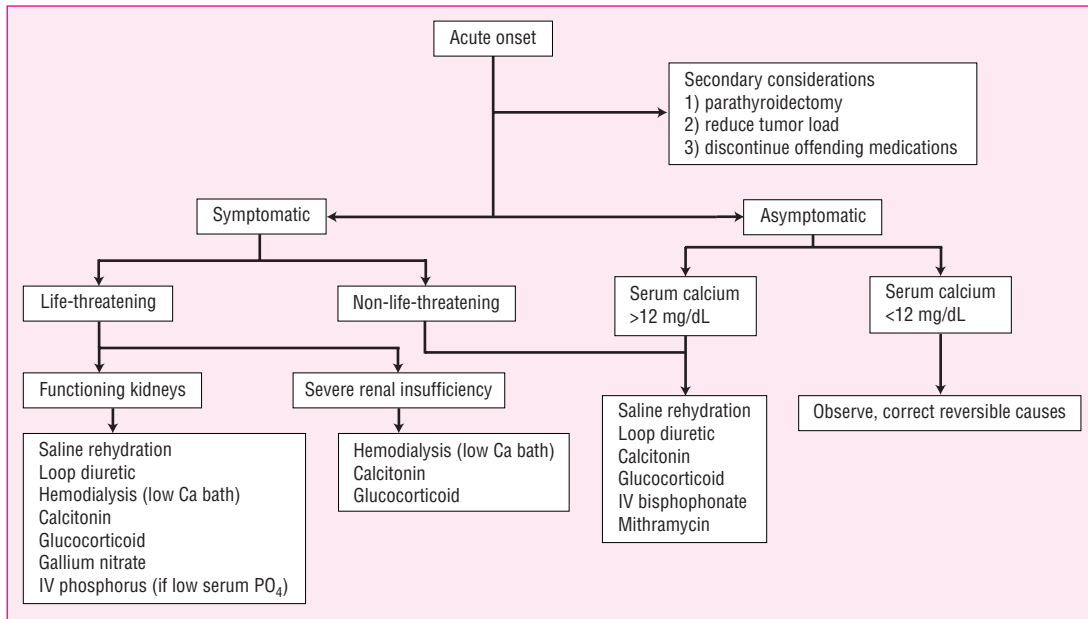

FIGURE 49-10. Pharmacotherapeutic options for the acutely hypercalcemic patient. Ca, calcium; PO₄, phosphorus.

disorder and correction of associated fluid and electrolyte abnormalities. Patients with primary hyperparathyroidism may ultimately need surgery, particularly if they have had calcium nephrolithiasis. Patients with malignancy often require reduction of tumor load to control the exogenous supply of cytokines and hormones that cause the hypercalcemia. In contrast, patients with drug-induced hypercalcemia generally respond to discontinuation of the offending agent.

CLINICAL CONTROVERSY

Although dialysis is the best method for rapidly reducing a highly elevated serum calcium, many clinicians choose a pharmacologic approach as the initial therapy.

PHARMACOLOGIC THERAPY

For those patients with normal to moderately impaired renal function, the cornerstone of initial treatment of hypercalcemia is volume expansion to increase urinary calcium excretion (see Table 49-6). Patients with severe renal insufficiency usually do not tolerate volume expansion; they may be initiated on therapy with calcitonin. Patients with symptomatic hypercalcemia are often dehydrated secondary to vomiting and polyuria; thus rehydration with saline-containing fluids is necessary to interrupt the stimulus for sodium and calcium reabsorption in the renal tubule.⁹⁰ Rehydration can be accomplished by the infusion of normal saline at rates of 200 to 300 mL/h, depending on concomitant conditions (primarily cardiovascular and renal) and extent of hypercalcemia. Adequacy of hydration is assessed by measuring fluid intake and output or by central venous pressure monitoring.^{75,76} Loop diuretics such as furosemide (40 to 80 mg IV every 1 to 4 hours) or ethacrynic acid (for patients with sulfa allergies) may also be instituted to increase urinary calcium excretion and to minimize the development of volume overload from the administration of saline⁷⁵ (see Table 49-6). Loop diuretics such as furosemide

block calcium (and sodium) reabsorption in the thick ascending limb of the loop of Henle and augment the calciuric effect of saline alone. The importance of rehydration prior to loop diuretic use is reiterated because dehydration may lead to increased serum calcium because of enhanced proximal tubule calcium reabsorption.⁶⁹ Potassium chloride should be added to the saline solution after rehydration is accomplished to maintain normokalemia in the presence of diuretic therapy. Serum magnesium levels should also be monitored, and magnesium replacement instituted if magnesium levels begin to trend downward. Rehydration with saline and administration of furosemide can result in a decrease of 2 to 3 mg/dL in total serum calcium within 24 to 48 hours.⁷⁵

In those patients in whom saline hydration therapy may be contraindicated (e.g., those with CHF or moderate to severe renal dysfunction), short-term therapy with calcitonin is effective in reducing serum calcium levels within hours. Calcitonin decreases serum calcium concentrations, primarily by inhibiting bone resorption. It may also reduce renal tubular reabsorption of calcium, thus promoting calciuresis. Calcitonin may be administered subcutaneously or intramuscularly (for larger volumes) in a starting dose of 4 units/kg every 12 hours, or intravenously at a rate of 10 to 12 units/h. The side effects from intravenously administered calcitonin (facial flushing, nausea, and vomiting) limit patient acceptability. Allergic reactions, although rare, do occur; therefore a test dose (intradermal injection of 0.1 mL of a 10-units/mL solution) is recommended prior to starting therapy. If marked erythema and/or wheal formation does not occur within 15 minutes after administration, therapy can begin. Calcitonin has a rapid onset of action (within 1 to 2 hours); however, the degree and extent of serum calcium level reduction are often unpredictable.⁶⁹ Calcitonin therapy is frequently associated with tachyphylaxis caused by antibody formation to foreign proteins or molecules resembling the calcitonin polypeptide.⁹¹ The addition of corticosteroid therapy or conversion to human calcitonin increases effectiveness.⁶⁹ Subcutaneous administration of salmon calcitonin in doses of 50 to 100 international units daily or three times weekly have been prescribed in patients with Paget's disease. The intranasal formulation of calcitonin has been used in the treatment of Paget's disease, in

TABLE 49-6. Drug Therapy Used to Treat Hypercalcemia

| Drug | Starting Dosage | Time Frame to Initial Response | Contraindications | Adverse Effects |
|----------------------------|---|--------------------------------|---|---|
| 0.9% saline ± electrolytes | 200–300 mL/h | 24–48 hours | Renal insufficiency; congestive heart failure | Electrolyte abnormalities; fluid overload |
| Loop diuretics | 40–80 mg IV every 1–4 hours | n/a | Allergy to sulfas (use ethacrynic acid) | Electrolyte abnormalities |
| Calcitonin | 4 units/kg every 12 h SQ/IM 10–12 units/h IV | 1–2 hours | Allergy to calcitonin | Facial flushing nausea/vomiting allergic reaction |
| Pamidronate | 30–90 mg IV over 2–24 hours | 2 days | Renal insufficiency | Fever |
| Etidronate | 7.5 mg/kg per day IV over 2 hours | 2 days | Renal insufficiency | Fever |
| Zoledronate | 4–8 mg IV over 15 minutes | 1–2 days | Renal insufficiency | Fever, fatigue, skeletal pain |
| Gallium nitrate | 200 mg/m ² per day | ? | Severe renal insufficiency | Nephrotoxicity; hypophosphatemia; nausea/vomiting/diarrhea; metallic taste |
| Mithramycin | 25 mcg/kg IV over 4–6 hours | 12 hours | Decreased liver function; renal insufficiency; thrombocytopenia | Nausea/vomiting; stomatitis; thrombocytopenia; nephrotoxicity; hepatotoxicity; |
| Glucocorticoids | 40–60 mg oral prednisone equivalents | ? | Serious infections; hypersensitivity | Diabetes; osteoporosis; infection |

doses of 200 to 400 international units daily; unfortunately this has resulted in only mild decreases in serum calcium. The lack of significant efficacy of the synthetic intranasal formulation is a result of the lower potency and shorter duration of action as compared to salmon calcitonin.

Bisphosphonates block bone resorption very efficiently, render the hydroxyapatite crystal of bone mineral resistant to hydrolysis by phosphatases, and also inhibit osteoclast precursors from attaching to the mineralized matrix, thus blocking their transformation into mature functioning osteoclasts.^{75,79,92} Pamidronate is very effective in controlling hypercalcemia associated with malignancy and slightly more effective than etidronate.⁷³ The usual dose of pamidronate is 30 to 90 mg as an IV infusion given over 2 to 24 hours. Pamidronate also has the advantage of single-day therapy.⁷⁵ Etidronate, when administered in doses of 7.5 mg/kg per day by slow intravenous infusion over at least 2 hours for 3 days, is effective in the therapy of hypercalcemia of malignancy.⁷⁵ Zoledronate and ibandronate are the newest high-potency bisphosphonates with demonstrated effectiveness in the treatment of hypercalcemia of malignancy. Complete response has been reported in 88.4% to 86.7% of zoledronate-versus 69.7% of pamidronate-treated patients.^{93,94} Zoledronate intravenous doses of 4 to 8 mg given over 5 minutes have resulted in normalization of serum calcium concentrations.⁹⁴ Intravenous infusions of 0.02 or 0.04 mg/kg diluted in 5% dextrose (given over 20 to 50 minutes) have also been effective.⁹⁵ A similar hypocalcemic response has been noted with ibandronate in comparison to pamidronate (76.5% versus 75.8%); however, the time period to a relapse of hypercalcemia was longer with ibandronate (14 days versus 4 days), suggesting a therapeutic advantage.⁹⁶ Ibandronate is administered (diluted in 500 mL 0.9% sodium chloride) by intravenous infusion in doses of 2 mg up to 6 mg.

The onset of serum calcium concentration decline is slower with bisphosphonate therapy (concentrations begin to decline in 2 days

and reach a nadir in 7 days); thus calcitonin therapy may be necessary if rapid serum level reduction is required.^{75,97} Duration of normocalcemia varies, but usually does not exceed 2 to 3 weeks, depending on the severity and treatment response of the underlying malignancy.⁶⁹ The duration of response has been suggested to be longer with zoledronate (4 to 5 weeks).⁹⁵ Fever is a common side effect of intravenous bisphosphonate therapy. Data on the use of these agents for maintenance intravenous therapy are limited; however, pamidronate has demonstrated more promise than etidronate. Although oral bisphosphonates are useful for the treatment of bone turnover in Paget's disease, there are insufficient data to suggest their use for the initial treatment of hypercalcemia. The use of oral bisphosphonates for maintenance therapy in patients predisposed to hypercalcemia (malignancy) has been successful in some cases.⁹⁸ The safety of continuous bisphosphonate therapy in patients with moderate to severe renal insufficiency is currently unknown. Renal function monitoring (serum creatinine) is advised with the use of bisphosphonates, as cases of acute tubular necrosis have been reported.^{99,100} Although there are no published guidelines for frequency of serum creatinine monitoring, it is advisable to evaluate serum creatinine within a week after the infusion and just prior to the next scheduled dose.

CLINICAL CONTROVERSY

Although some clinicians administer bisphosphonates to patients regardless of their degree of renal function, the FDA approved labeling states that they are contraindicated when GFR is less than 30 mL/min.

Gallium nitrate is indicated for the treatment of symptomatic hypercalcemia of malignancy not responsive to hydration therapy.¹⁰¹ However, because of its adverse side-effect profile, it is generally reserved for those who fail to respond to less toxic agents. Gallium

nitrate inhibits bone resorption, and may be superior to calcitonin in inducing normocalcemia. It may provide a longer duration of normocalcemia as compared to etidronate. The initial dose is usually a continuous IV infusion of 200 mg/m² per day for 5 consecutive days. Because gallium nitrate is nephrotoxic, use caution if it is coadministered with other nephrotoxic drugs. Other common adverse effects include hypophosphatemia, nausea, vomiting, diarrhea, hypocalcemia, and metallic taste.

Mithramycin (plicamycin) is a potent cytotoxic antibiotic that inhibits osteoclast-mediated bone resorption and thereby reduces hypercalcemia. Mithramycin may be administered at a dose of 25 mcg/kg via intravenous infusion over 4 to 6 hours in saline or 5% dextrose solutions. This therapy may be repeated daily for 3 to 4 days or on alternating days for 3 to 8 doses.^{75,102} Serum calcium levels begin to fall within 12 hours of a mithramycin dose, with the peak effect generally occurring within 48 to 96 hours.^{69,75} Single doses are usually well tolerated.¹⁰² Adverse effects of mithramycin include nausea, vomiting, stomatitis, thrombocytopenia, inhibition of platelet function, and renal and hepatotoxicity.⁶⁹ Because these adverse effects are more commonly associated with multiple doses, mithramycin is usually limited to short-term therapy in patients who have not responded to alternative therapies. Monitoring parameters include complete blood count, liver function, and renal function. Mithramycin should be avoided in patients with thrombocytopenia and liver and renal insufficiency.⁷⁵

Glucocorticoids are usually effective in the treatment of hypercalcemia resulting from multiple myeloma, leukemia, lymphoma, sarcoidosis, and hypervitaminoses A and D.^{69,92,102} The mechanisms of glucocorticoid-induced reductions in serum calcium include reduced gastrointestinal absorption, defective vitamin D metabolism causing hypercalciuria, increased bone resorption, decreased osteoblast proliferation, and reduction in sex hormone (estrogen and testosterone) concentrations.¹⁰³ Daily doses of 40 to 60 mg of prednisone or the equivalent is effective.⁶⁹ The disadvantages of glucocorticoid therapy

are its relatively slow onset of action and the potential for diabetes mellitus, osteoporosis, and increased susceptibility to infection.^{72,91}

Finally, intravenous phosphate may rapidly reduce ionized calcium concentrations through the formation of insoluble calcium-phosphate salts. However, intravenous phosphate is extremely hazardous because extraskeletal precipitation of calcium-phosphate may result in metastatic calcification, hypotension, acute renal failure, or death.^{69,81} Therefore intravenous phosphates should be reserved for the extraordinary patient with severe hypercalcemia and concomitant hypophosphatemia.⁶⁹ Oral phosphorus is not used chronically for the treatment of hypercalcemia because calcium-phosphate crystals may precipitate in the kidneys or other major organs when the calcium-phosphorus product is >50 to 60 mg²/dL².¹⁰⁴ Serum calcium, phosphorus, and creatinine should be monitored closely. Oral phosphorus treatment is only indicated when there is concomitant hypophosphatemia (<2 mg/dL).

Inhibitors of prostaglandin synthesis such as indomethacin are rarely effective and thus not currently recommended. Asymptomatic patients with mild hypercalcemia may be carefully observed, especially if treatment for the underlying condition (malignancy) is initiated. The calcimimetic agent cinacalcet HCl was recently approved for the treatment of secondary hyperparathyroidism in patients with chronic kidney disease and for its calcium-lowering effect in the management of parathyroid carcinoma.^{105,106} These agents bind to the calcium-sensing receptor, albeit at a different location than calcium, and increase the sensitivity for receptor activation by extracellular calcium. This results in reduced parathyroid hormone and serum calcium concentrations.^{105,106}

A review of the use of cinacalcet HCl for secondary hyperparathyroidism is provided in Chap. 44. Cinacalcet HCl is administered at a starting dose of 30 mg given orally twice daily for the treatment of parathyroid carcinoma. The dosage is titrated every 2 to 4 weeks in 30-mg increments twice daily. The maximum approved dosage is 90 mg three to four times daily.

HYPOCALCEMIA

The incidence of hypocalcemia (total serum calcium less than 8.5 mg/dL) in intensive care unit patients ranges from 70% to 90% based on total, to 15% to 50% based on ionized calcium concentrations.⁷⁰ Hypocalcemia is more commonly seen in hospitalized patients than in outpatients.

PATHOPHYSIOLOGY

Hypocalcemia is the result of alterations in the effect of parathyroid hormone and vitamin D on the bone, gut, and kidney (see Fig. 49–9). The primary causes of hypocalcemia are postoperative hypoparathyroidism and vitamin D deficiency. Other causes include magnesium deficiency, thyroid surgery, medications, hypoalbuminemia, blood transfusions, peripheral blood progenitor cell harvesting, tumor lysis syndrome, and mutations in the calcium-sensing receptor.^{107–112} Parathyroid hormone concentrations are elevated in conditions of hypocalcemia, with the exception of hypoparathyroidism and hypomagnesemia (Fig. 49–11).¹¹³

A symptomatic rapid fall in serum calcium concentrations (often to values <7 mg/dL) is common in patients who have had a parathyroidectomy or thyroidectomy. Hypocalcemia in these postsurgical patients is generally transient in nature.¹¹⁴ The “hungry bone syndrome” is a condition of profound hypocalcemia whereby the bone avidly in-

corporates calcium and phosphorus from the blood in an attempt to recalcify bone. This is common after correction (usually surgery) of prolonged states of hyperparathyroidism and/or hyperthyroidism. Serum calcium concentrations should be monitored every 6 hours during the 24 to 48 hours following such surgeries, and pharmacologic doses of calcium may be necessary to prevent or minimize the drop in serum calcium (see the treatment discussion).

Vitamin D and its metabolites play an important role in the maintenance of extracellular calcium concentrations and in normal skeletal structure and mineralization. Vitamin D is necessary for the optimal absorption of calcium and phosphorus. On a worldwide basis, the most common cause of hypocalcemia is nutritional vitamin D deficiency. In malnourished populations, manifestations include rickets and osteomalacia. Nutritional vitamin D deficiency is uncommon in Western societies because of the fortification of milk with ergocalciferol.¹¹⁴ The most common cause of vitamin D deficiency in Western societies is gastrointestinal disease.⁷⁹ Gastric surgery, chronic pancreatitis, small-bowel disease, intestinal resection, and bypass surgery are associated with decreased concentrations of vitamin D and its metabolites.⁷⁹ Vitamin D replacement therapy may need to be administered by the intravenous route if poor oral bioavailability is noted. Decreased production of 1,25-dihydroxyvitamin D₃ may occur as a result of a hereditary defect resulting in vitamin D–dependent rickets. It also can occur secondary to chronic renal insufficiency if there is insufficient production of the 1- α -hydroxylase enzyme for the

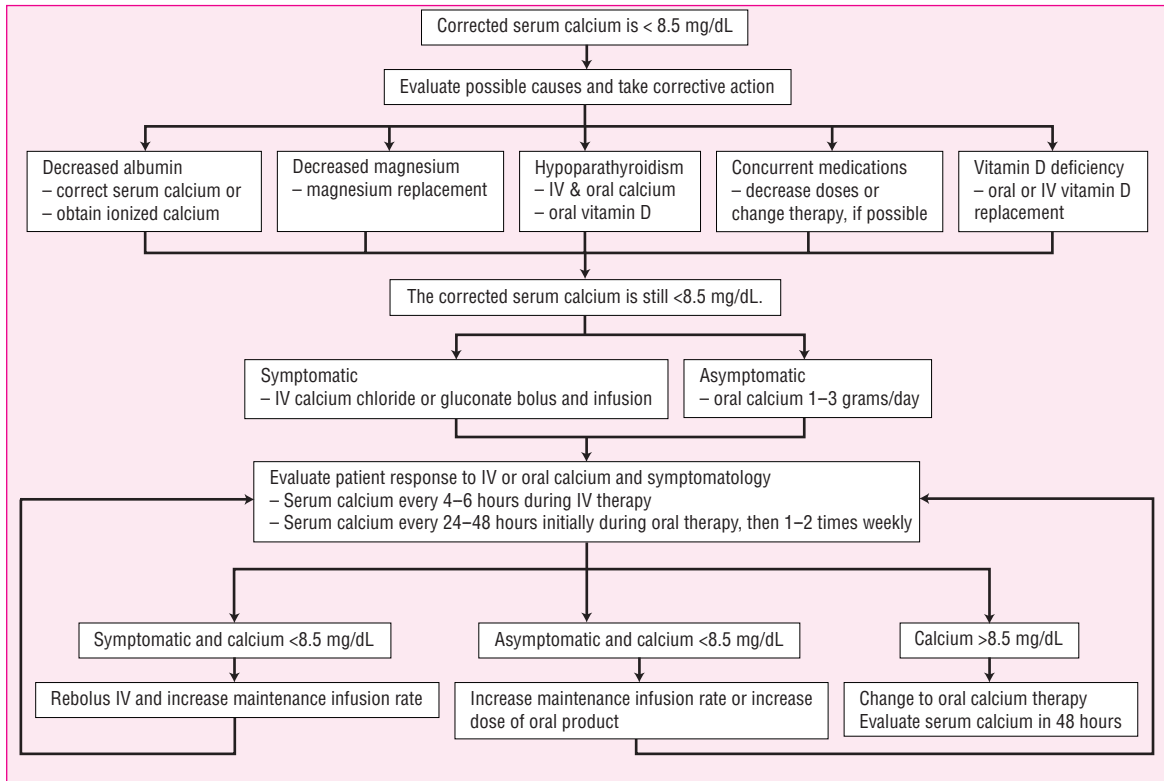

FIGURE 49-11. Hypocalcemia diagnostic and treatment algorithm.

production of the most active metabolite, 1,25-dihydroxyvitamin D₃.¹¹⁵ Treatment of hypocalcemia associated with chronic kidney disease is reviewed in Chap. 44.

Hypomagnesemia of any cause may be associated with severe symptomatic hypocalcemia that is unresponsive to calcium replacement therapy (see Chap. 50). Reduced serum magnesium concentrations can impair PTH secretion and induce resistance of target organs to the actions of PTH.¹⁰⁷ Normalization of serum calcium concentrations in these patients is thus dependent on appropriate replacement of magnesium.

Drug-induced hypocalcemia has been reported with furosemide, calcitonin, bisphosphonates, gallium nitrate, and mithramycin. Oral phosphorus therapy, commonly used to treat patients with malabsorption syndromes caused by gastrointestinal diseases, can also result in hypocalcemia, necessitating calcium-concentration monitoring. The anticonvulsants phenobarbital and phenytoin cause hypocalcemia by increasing catabolism of vitamin D and thereby impairing calcium release from bone and reducing intestinal calcium absorption.¹⁰⁷ Drugs that cause hypomagnesemia (aminoglycosides, amphotericin B, cyclosporine, diuretics, foscarnet, and cisplatin) are associated with an increased risk of hypocalcemia. Chelating agents in blood (citrate) and in radiographic contrast media (ethylenediamine tetraacetate) can also cause transient hypocalcemia.^{108,109,116} Other agents associated with hypocalcemia include fluoride, ketoconazole, calcimimetics, and pentamidine.¹⁰⁷

Proper assessment of total serum calcium concentrations includes measurement of serum albumin concentrations. Hypoalbuminemia, which may be associated with many chronic disease states, is probably the most common cause of “laboratory hypocalcemia.” Patients remain asymptomatic because the ionized fraction of serum calcium remains normal (reference range 4.4 to 5.4 mg/dL). A

corrected total serum calcium concentration can be calculated based on the measured total serum calcium and the difference between a patient’s measured albumin concentration and the normative value of 4 g/dL by the following equation:

$$\text{Corrected } S_{\text{Ca}}(\text{mg/dL}) = \text{measured } S_{\text{Ca}}(\text{mg/dL}) + [0.8 \times (4.0 \text{ g/dL} - \text{measured albumin (g/dL)})]$$

CLINICAL PRESENTATION

The clinical manifestations of hypocalcemia are quite variable. The acuteness of the development of hypocalcemia plays a large role in whether or not symptoms will occur.¹¹⁴ The more acute the drop in ionized calcium concentration, the more likely the patient will develop symptoms. Thus acid-base balance plays a significant role in the likelihood of the development of hypocalcemic symptoms, with alkalosis predisposing to symptom development. Concomitant hypomagnesemia, hypokalemia, hyponatremia, and additive side effects from prescribed medications also increase the likelihood of symptomatic presentation.

Hypocalcemia may manifest as neuromuscular, CNS, dermatologic, and cardiac sequelae.⁷⁹ Acute hypocalcemia is more likely to manifest as neuromuscular (paresthesias, muscle cramps, tetany, and laryngeal spasm) and cardiovascular symptoms, whereas chronic hypocalcemia often presents as CNS (depression, anxiety, memory loss, confusion, hallucinations, and tonic-clonic seizures) and dermatologic symptoms (hair loss, grooved and brittle nails, and eczema).¹⁰⁷ The hallmark sign of acute hypocalcemia is tetany caused by enhanced peripheral neuromuscular irritability.⁷⁹ Tetany manifests as paresthesias around the mouth and in the extremities, muscle spasms and cramps, carpedal (hands and feet) spasms, and rarely as

laryngospasm and bronchospasm.⁷⁹ Chvostek's and/or Trousseau's sign may be elicited during physical examination.¹⁰⁷ Chvostek's sign is elicited as twitching of facial muscles when the facial nerve is tapped anterior to the ear. Trousseau's sign is elicited by carpal spasm when a blood pressure cuff is inflated above systolic blood pressure for 3 minutes.

The cardiovascular manifestations of hypocalcemia result in electrocardiographic changes characterized by a prolonged QT interval and symptoms of decreased myocardial contractility often associated with congestive heart failure.¹⁰⁷ Both acute and chronic hypocalcemia may result in a reversible syndrome characterized by acute myocardial failure or refractory congestive heart failure. Other cardiovascular manifestations include arrhythmias, bradycardia, and hypotension that is unresponsive to fluid and pressor administration.¹⁰⁷

CLINICAL PRESENTATION OF HYPOCALCEMIA

GENERAL

Hypocalcemia is caused in part by disorders of vitamin D or parathyroid hormone. Other causes of hypocalcemia include sepsis and disorders that result in a decrease in serum ionized calcium concentration by either binding of calcium within the vascular space or its deposition in tissues, or drug-induced causes. Parathyroidectomy or thyroidectomy are also associated with a rapid reduction in serum calcium. Malnutrition associated with vitamin D deficiency should not be overlooked as an etiology of hypocalcemia.

SYMPTOMS

The symptoms of hypocalcemia, usually associated with an acute decrease in serum calcium, include tetany, paresthesias, muscle cramps, and laryngeal spasms. Chronic hypocalcemia is usually associated with the symptoms of depression, anxiety, memory loss, confusion, seizures, hair loss, grooved and brittle nails, and eczema. Associated hypomagnesemia, hypokalemia, and hyponatremia can increase the likelihood of symptoms.

SIGNS

Neurologic: Chvostek's and/or Trousseau's signs can be elicited during physical examination. The hallmark of acute hypocalcemia is tetany, which is characterized by neuromuscular irritability including seizure potential. Extraparathyroidal disorders, mainly parkinsonism but also dystonia, hemiballismus, choreoathetosis, and oculogyric crises, occur in 5% to 10% of patients with idiopathic hypoparathyroidism.

Dermatologic: The skin can be dry, puffy, and coarse. Other dermatologic manifestations may include hyperpigmentation, dermatitis and eczema, and psoriasis. Hair and skin signs including coarse, brittle, and sparse hair with patchy alopecia and brittle nails can also appear.

Ophthalmologic: Cataract development has been reported to occur with hypocalcemia.

Dental manifestations: These are usually associated with the presence of hypocalcemia in early development. Signs include dental hypoplasia, failure of tooth eruption, defective enamel and root formation, and abraded carious teeth.

Cardiovascular: Hypotension, decreased myocardial performance, and congestive heart failure have been reported. A prolonged QT interval, arrhythmias, and bradycardia may also occur.

Gastrointestinal: Steatorrhea may be associated with hypocalcemia.

Musculoskeletal: While patients with several hypocalcemic disorders have skeletal abnormalities, such findings do not appear to be direct consequences of hypocalcemia. Some patients with hypocalcemia have myopathy.

Endocrine: Hypocalcemia alone may impair insulin release. In addition, idiopathic hypoparathyroidism may be associated with polyglandular autoimmune syndromes.

LABORATORY TESTS

Serum calcium levels of less than 8.5 mg/dL are considered to represent hypocalcemia.

► TREATMENT: Hypocalcemia

■ DESIRED OUTCOME

The goals of therapy for patients with normal renal function are the resolution of signs and symptoms of hypocalcemia, restoration of normocalcemia, management of associated electrolyte abnormalities, and treatment of the underlying cause of hypocalcemia. The goals for patients with chronic renal insufficiency are different and are discussed in detail in Chap. 44. Asymptomatic hypocalcemia associated with hypoalbuminemia requires no treatment because ionized (physiologically active) plasma calcium concentrations are normal. Treatment of hypocalcemia is dependent on identification of the pathogenesis of the underlying disorder, acuteness of onset, and presence and severity of symptoms. Acute symptomatic hypocalcemia requires parenteral administration of soluble calcium salts (see Fig. 49–11).

■ PHARMACOLOGIC THERAPY

The initial therapeutic intervention for patients with acute symptomatic hypocalcemia is to administer 100 to 300 mg of elemental calcium intravenously over 5 to 10 minutes.¹¹⁷ This may be provided by the administration of 1 g of calcium chloride (27% elemental calcium) or 2 to 3 g of calcium gluconate (9% elemental calcium). Calcium gluconate is generally preferred over calcium chloride for peripheral venous administration because calcium gluconate is less irritating to veins. Disadvantages to the use of calcium gluconate are the lower percentage of elemental calcium per volume and the less predictable, slightly smaller increase in plasma ionic calcium compared with calcium chloride. Calcium should not be infused at a rate greater than 60 mg of elemental calcium per minute because severe cardiac dysfunction may result.¹¹⁷ Intravenous calcium administration should be

used with caution in patients receiving digitalis glycosides, because of the possibility of cardiac arrhythmias.⁷⁰ Calcium should not be added to bicarbonate- or phosphate-containing solutions because of the possibility of precipitation. The bolus dose of calcium is only effective for 1 to 2 hours and should be followed by a continuous infusion of elemental calcium at a rate of 0.5 to 2 mg/kg per hour.⁷⁰ The calcium concentrations should be monitored every 4 to 6 hours during the intravenous infusions. The ionized calcium concentration usually normalizes within 4 hours, and the maintenance infusion rate of elemental calcium can then be decreased to 0.3 to 0.5 mg/kg per hour.⁶⁹ The maintenance infusion can be adjusted to maintain the desired concentration of calcium.

Once acute hypocalcemia is corrected by parenteral administration, further treatment modalities should be individualized according to the cause of hypocalcemia. If hypomagnesemia is present, magnesium supplementation is indicated (see Chap. 50). Asymptomatic and chronic hypocalcemia associated with hypoparathyroidism and vitamin D–deficient states may be managed by oral calcium and vitamin D supplementation (see Tables 44–6 and 44–7). Therapy is begun with 1 to 3 g/day of elemental calcium.⁶⁸ Average maintenance doses range from 2 to 8 g of elemental calcium per day in divided doses. If serum calcium does not normalize, a vitamin D preparation may need to be added.

Treatment of hypocalcemia associated with vitamin D–deficient states should be individualized. In patients with malabsorption, vitamin D requirements vary markedly, and large doses may be required. In contrast, vitamin D deficiency associated with anticonvulsant med-

ication may be corrected with smaller doses of vitamin D. Oral doses of 1,25-dihydroxyvitamin D₃ usually range from 0.5 to 3 mcg daily. The usual initial oral dose of ergocalciferol is 50,000 international units daily.¹¹⁷ Vitamin D doses are usually adjusted approximately every 4 weeks. The treatment of vitamin D deficiency associated with chronic renal failure generally requires the administration of 1,25-dihydroxyvitamin D₃ or another synthetic analog, such as paricalcitol or doxercalciferol. Situations in which 25-hydroxylase activity is reduced (e.g., hepatic disease) may also require treatment with calcitriol (1,25-dihydroxyvitamin D). The newer vitamin D analogs (paricalcitol and doxercalciferol) were developed to preferentially suppress PTH secretion with less effect on serum calcium concentration. Their efficacy in treating hypocalcemia may thus be less apparent. In selected cases, calcium supplementation may be required if vitamin D replacement alone is ineffective in returning calcium concentrations to normal.

Adverse effects of oral calcium and vitamin D supplementation include hypercalcemia and hypercalciuria, especially in the hypoparathyroid patient, in whom the renal calcium-sparing effect of parathyroid hormone is absent. Hypercalciuria may increase the risk of calcium stone formation and nephrolithiasis in susceptible patients. One maneuver to help prevent calcium stones is to maintain the calcium at a low normal concentration. Monitoring 24-hour urine collections for total calcium concentrations (goal <300 mg/24 h) may also minimize the occurrence of hypercalciuria. The addition of thiazide diuretics for patients at risk for stone formation may result in a reduction of both urinary calcium excretion and vitamin D requirements.¹¹⁷

DISORDERS OF PHOSPHORUS HOMEOSTASIS

Phosphorus is an essential element in phospholipid cell membranes, nucleic acids, and phosphoproteins required for mitochondrial function.¹¹⁸ Phosphorus regulates the intermediary metabolism of carbohydrates, fats, and proteins. Phosphorus also regulates enzymatic reactions including glycolysis, ammoniogenesis, and the 1-hydroxylation of 25-hydroxyvitamin D₃.¹¹⁸ In addition, phosphorus is required for the generation of 2,3-diphosphoglycerate (2,3-DPG) in red blood cells, which is required for normal oxygen-hemoglobin dissociation and delivery of oxygen to the tissues.¹¹⁹ Phosphorus is the source of the high-energy bonds of adenosine triphosphate (ATP), thus fueling a wide variety of physiologic processes, including muscle contractility, electrolyte transport, neurologic function, and other important biochemical reactions.¹¹⁸ Considering its diverse biologic importance, it is not difficult to appreciate the clinical implications of disorders of phosphorus homeostasis.

Phosphorus is present in living organisms mainly as inorganic phosphate and organic phosphate esters. Phosphorus is the major intracellular anion. The majority of intracellular phosphorus exists as organic esters, mainly 2,3-DPG, adenosine and guanosine triphosphate, and fructose 1,6-diphosphate.¹¹⁸ Only a small fraction of intracellular phosphorus exists as inorganic phosphate; however, this fraction is critical because it is the source from which ATP is resynthesized.¹¹⁸ The majority of inorganic phosphate is located in the extracellular space. Normal serum phosphorus concentration in the adult is 2.5 to 4.5 mg/dL. Extracellular inorganic phosphate is the prime determinant of intracellular phosphate; thus small increments in the organic phosphate pool can profoundly alter both the extracellular and intracellular phosphate pools. Metabolic disturbances (acidosis, alkalosis, and ketoacidosis), hydrogen ion shifts, and hormones (PTH, calcitonin, cortisol, and vitamin D) all can cause shifts in phosphorus concentrations. Because of these phenomena, the serum phosphorus level does not accurately reflect total body stores.¹¹⁹

The typical western diet provides a daily intake of 800 to 1,600 mg of phosphorus. Approximately 60% to 80% of this is absorbed in the gastrointestinal tract by passive and active transport (vitamin D–mediated). PTH, 1,25-dihydroxyvitamin D₃, and low-phosphate diets mediate increased absorption. Decreased absorption occurs under conditions of increased dietary intake of phosphorus and magnesium, glucocorticoid therapy, and hypothyroidism. Excretion by the kidney is the single most important regulator of steady-state serum phosphorus concentrations. Renal excretion of phosphorus is regulated by glomerular filtration and proximal tubular reabsorption by passive transport coupled to sodium (sodium-phosphate cotransport). Under normal conditions, 85% to 90% of filtered phosphate is reabsorbed, the majority in the early proximal tubule. Renal tubular reabsorption of phosphorus is inhibited by parathyroid hormone and 1,25-dihydroxyvitamin D₃.¹¹⁸ Conversely, phosphorus reabsorption in the renal tubule is increased by growth hormone.¹¹⁸ Internal phosphorus balance (transcellular phosphate distribution) is also of importance in the maintenance of normal serum phosphorus. The serum phosphorus level may vary by as much as 2 mg/dL throughout the day, as the result of acute changes in transcellular distribution of phosphate influenced primarily by carbohydrate intake, insulin secretion, and diurnal variation.¹¹⁹

HYPERPHOSPHATEMIA

Serum phosphorus concentration is so closely regulated by the kidneys that it is unusual for hyperphosphatemia (serum phosphorus concentration >4.5 mg/dL) to develop in patients with normal renal function. The most frequent causes of hyperphosphatemia are decreases in urinary phosphorus excretion, and increases in phosphate entrance into the extracellular fluid via either exogenous administration or endogenous intracellular phosphate release.

PATHOPHYSIOLOGY

The most common cause of hyperphosphatemia is a decrease in urinary phosphorus excretion secondary to decreased glomerular filtration rate.¹²⁰ Retention of phosphorus decreases vitamin D synthesis and induces hypocalcemia, which leads to an increase in PTH. This physiologic response inhibits further tubular reabsorption of phosphorus to correct hyperphosphatemia and normalize serum calcium concentrations. Patients with excessive exogenous phosphorus administration or endogenous intracellular phosphorus release in the setting of acute renal failure may develop profound hyperphosphatemia.¹¹⁸ Severe hyperphosphatemia is commonly encountered in patients with chronic kidney disease, especially those with GFRs less than 15 mL/min per 1.73 m² (see Chap. 44).

Hypoparathyroidism results in increased renal tubular reabsorption of phosphorus and may result in hyperphosphatemia. Hyperphosphatemia associated with hypoparathyroidism is usually less severe than that associated with severe renal failure or excessive exogenous or endogenous introduction of phosphorus into the ECF. Hypoparathyroidism is the most important cause of increased tubular phosphorus reabsorption. Acromegaly and thyrotoxicosis may also cause hyperphosphatemia by reducing urinary phosphorus excretion.

Iatrogenic causes of hyperphosphatemia have been widely reported, and awareness of the phosphorus content of intravenous, oral, and rectally administered phosphorus-containing products can aid in its prevention. It is often recognized that large doses of phosphorus administered intravenously to treat hypercalcemia can result in severe life-threatening hyperphosphatemia. Although less-well recognized, oral and rectal administration of phosphate-containing solutions can also result in severe and life-threatening hyperphosphatemia, especially in patients with moderate and severe renal insufficiency.¹²⁰ The risk of mortality (because of sudden hypocalcemia with tetany and hyperphosphatemia) is dependent on the amount of phosphorus absorbed from the administered product; a 25% mortality rate has been observed with serum phosphorus concentrations ≥ 33 mg/dL.¹²⁰

Any disorder that results in necrosis of skeletal muscle cells (i.e., rhabdomyolysis) can result in the release of large amounts of intracellular phosphorus into the systemic circulation. This condition is frequently associated with acute renal failure and thus severe hyperphosphatemia may develop due to increased endogenous phosphorus release coupled with decreased renal phosphorus excretion. Bowel infarction, malignant hyperthermia, and severe hemolysis are also conditions that may increase endogenous release of phosphorus.

Hyperphosphatemia is not uncommonly observed in patients undergoing treatment for acute leukemia and lymphomas.¹²¹ Chemotherapeutic treatment of acute lymphoblastic leukemia may result in the release of large amounts of phosphorus into the systemic circulation secondary to lysis of lymphoblasts. Initiation of chemotherapy for Burkitt's lymphoma results in a rapid lysis of malignant cells, resulting in hyperphosphatemia, hyperuricemia, hyperkalemia, and hypocalcemia. This syndrome is commonly referred to as tumor lysis syndrome.¹²¹

Acid-base disorders such as lactic acidosis and diabetic ketoacidosis can release endogenous intracellular phosphorus and cause

hyperphosphatemia. In one study, hyperphosphatemia was present in 94.7% of patients with diabetic ketoacidosis prior to the initiation of treatment.¹²² After the institution of treatment, serum phosphorus levels decrease and patients may ultimately develop hypophosphatemia.

Medications are another cause of hyperphosphatemia. Excessive intravenous or oral administration of phosphorus is an obvious potential cause of elevated serum phosphate concentrations. Phosphate-containing enemas increase concentrations, especially in those with renal insufficiency. Intravenous or oral vitamin D therapy can increase absorption of phosphorus in the gastrointestinal tract by up to 50%. Bisphosphonate therapy is associated with increased serum phosphate concentrations. Acute phosphorus poisoning as a result of ingestion of laundry detergents is a rare and often unrecognized cause of elevated phosphate concentrations.

CLINICAL PRESENTATION

The major effects of hyperphosphatemia are related to the development of hypocalcemia (caused by phosphate inhibition of renal 1α -hydroxylase) and its related consequences, as well as vascular and organ damage resulting from the deposition of calcium-phosphate crystals. Extravascular calcification can result in band keratopathy, "red eye," pruritus, and periarticular calcification, especially in renal failure patients (see Chap. 44). In addition, soft-tissue calcifications in the conjunctiva, skin, heart, cornea, lung, gastric mucosa, and kidney have been observed, primarily in chronic renal failure patients.¹¹⁸ Hyperphosphatemia associated with chronic renal disease may result in renal osteodystrophy because of overproduction of parathyroid hormone. This condition is discussed in detail in Chap. 44.

CLINICAL PRESENTATION OF HYPERPHOSPHATEMIA

GENERAL

Since the serum phosphate concentration is primarily determined by the ability of the kidneys to excrete dietary phosphate, hyperphosphatemia is uncommon in patients with normal kidney function.

SYMPTOMS

Symptoms associated with hyperphosphatemia are associated with deposition of calcium-phosphate crystals and include "red eye" and pruritus. Other symptoms are attributable to hypercalcemia.

SIGNS

The elevated calcium-phosphate product results in precipitation in arteries, joints, soft tissues, and the viscera. This can result in tissue ischemia, termed *calciphylaxis*.

LABORATORY TESTS

Serum phosphate levels higher than 4.5 mg/dL represent hyperphosphatemia.

► TREATMENT: Hyperphosphatemia

■ DESIRED OUTCOME

The treatment of hyperphosphatemia should be directed at the correction of reversible factors, treatment of the disease states associated

with its development, the management of associated signs and symptoms, management of associated electrolyte abnormalities, return of serum phosphate concentrations to the normal range, and minimize the long-term cardiovascular consequences of calcium-phosphorus deposition. It has been estimated that calcium-phosphate crystals are

likely to form in vivo when the product of the serum calcium and phosphate concentrations exceeds 50 to 60 mg²/dL².¹⁰⁴ Recent evidence suggests that the calcium-phosphorus product should be maintained at less than 55 mg²/dL² to reduce cardiovascular morbidity and mortality secondary to arterial calcification.^{81,104} The recently published National Kidney Foundation's Dialysis Outcomes Quality Initiative guidelines for bone metabolism and disease defines the goal calcium-phosphorus product as less than 55 mg²/dL².¹²³ Furthermore, serum phosphorus concentrations greater than 6.5 mg/dL, but not serum calcium concentrations, are associated with increased morbidity and mortality.¹⁰⁴ Serum phosphorus concentrations should be maintained in the 2.7 to 4.6 mg/dL range for those with Stage 3 and 4 chronic kidney disease, while for patients in Stage 5 chronic kidney disease the goal is to maintain values between 3.5 and 5.5 mg/dL.¹²³

PHARMACOLOGIC THERAPY

Severe symptomatic hyperphosphatemia manifesting as hypocalcemia and tetany should be treated by the intravenous administration of calcium salts (see the discussion of hypocalcemia). Although this may seem counterintuitive in a patient with a phosphorus of 16 mg/dL and a calcium of 7 mg/dL (the calcium-phosphorus product is 112 mg²/dL²), correction of severe hypocalcemia is of primary importance because of the critical nature of this disorder. In general, the

most effective way to treat asymptomatic chronic hyperphosphatemia is to decrease phosphate absorption in the lumen of the GI tract by the use of phosphate-binding agents.¹¹⁸ Antacids containing divalent and trivalent cations (calcium, magnesium, and aluminum) or sevelamer are the agents most frequently used in the prevention and treatment of hyperphosphatemia (see Table 44–6). The recently approved phosphate binder lanthanum carbonate is another non-calcium-based product that has demonstrated efficacy and safety.^{124,125} Long-term treatment with aluminum hydroxide and aluminum carbonate should be discouraged because of the association with anemia, CNS disorders, and bone disease. Short-term therapy with these agents is effective and safe. The most frequent adverse effect from phosphate-binding agents (especially calcium) is constipation. Calcium salts are the preferred phosphate-binding agents except when there is concomitant hypercalcemia. Therapy with the polymer agent (sevelamer) or lanthanum carbonate may avoid the detrimental effects associated with aluminum, magnesium, or calcium therapy. A thorough review of phosphate-binding agents is provided in Chap. 44.

CLINICAL CONTROVERSY

The selection of a phosphate binding agent is often arbitrary although it should be based on limiting the total daily intake of calcium and avoiding drug-related adverse events. The optimal therapeutic regimen may involve a combination of agents.

HYPOPHOSPHATEMIA

Mild to moderate hypophosphatemia is defined as a serum phosphorus concentration of 1 to 2 mg/dL, whereas severe hypophosphatemia is defined as a serum phosphorus concentration of less than 1 mg/dL.¹²⁶ Hypophosphatemia is found in approximately 1% to 3% of hospital admissions.¹¹⁹ The incidence in hospitalized critically ill patients is 18% to 28%.¹²⁶ Unlike its severe form, mild or moderate hypophosphatemia seldom causes recognizable signs and symptoms.¹²¹

PATHOPHYSIOLOGY

Hypophosphatemia may be the result of decreased gastrointestinal absorption, increased urinary excretion, or extracellular to intracellular redistribution.¹¹⁸ Although mild to moderate hypophosphatemia is common and can occur in inpatients and outpatients, severe hypophosphatemia is predominantly encountered in the acute care setting and can be associated with life-threatening symptoms (Table 49–7).

Phosphate-binding substances such as sucralofate, calcium carbonate, sevelamer, lanthanum carbonate and aluminum- or magnesium-containing antacids have the potential to bind large amounts of phosphorus in the gut, thereby preventing absorption. If phosphate-binding agents are ingested on a chronic basis in conjunction with a dietary phosphorus deficiency, hypophosphatemia may result.¹²¹ Patients who are receiving long-term phosphate-binding agents, those with peptic ulcer disease or chronic renal insufficiency, and those who may be predisposed to moderate hypophosphatemia (alcoholics) are at highest risk for the development of severe hypophosphatemia. Hyperparathyroidism may cause hypophosphatemia as a result of decreased gastrointestinal absorption of dietary phosphorus.

Increased renal losses of phosphorus can occur in hyperparathyroid (primary and secondary) patients with normal renal function and

those with vitamin D deficiency. Elevated parathyroid hormone levels lead to an increase in serum calcium concentrations and decreased serum phosphorus concentrations. Serum phosphorus is decreased as the result of a reduction in renal tubular reabsorption.¹²⁷ Recovery from extensive third-degree burns is associated with a marked diuretic phase associated with an impressive renal loss of phosphate.¹²¹ This recovery may also be associated with the development of an anabolic state as stress levels decrease and nutritional therapies take effect. Because phosphorus is rapidly incorporated into the new cells, this may contribute to the severity of the hypophosphatemia. Drugs that cause increased renal elimination of phosphorus include diuretics (acetazolamide and osmotic diuretics), glucocorticoids, and sodium bicarbonate.

Rapid refeeding of malnourished patients with high-carbohydrate, high-calorie nutritional diets with inadequate amounts of supplemental phosphorus may result in severe symptomatic hypophosphatemia. This phenomenon is especially prevalent in patients with other underlying risk factors for the development of hypophosphatemia, such as alcoholism.¹²⁷ The etiology of severe hypophosphatemia associated with hyperalimentation and nutritional recovery may be separated into two phases: acute, rapid hypophosphatemia secondary to intracellular shifts of phosphorus resulting from glucose-induced insulin secretion; and the gradual decrease in serum phosphorus concentration over 5 to 10 days secondary to tissue repair in the presence of phosphorus deprivation.¹²⁸ The development of severe hypophosphatemia secondary to hyperalimentation can be prevented by the administration of 12 to 15 mmol of phosphorus per liter of hyperalimentation solution or 15 mmol per 1,000 calories of dextrose.¹²⁹ Transcellular shifts in phosphorus also occur after parathyroidectomy, causing severe hypocalcemia and hypophosphatemia because of hungry bone syndrome (deposition of phosphorus and calcium in the bone).

 Alcoholism
 Respiratory alkalosis
 Diabetic ketoacidosis (correction)
 Dextrose solutions
 Insulin
 Catecholamines
 Anabolic steroids
 Glucagon
 Calcitonin
 Erythropoietin

Severe and prolonged respiratory alkalosis (a result of hyperventilation, pain, anxiety, and sepsis) can cause hypophosphatemia.¹¹⁹ Respiratory alkalosis is thought to contribute significantly to the hypophosphatemia observed during alcohol withdrawal.¹¹⁹ Although patients with diabetic ketoacidosis may present with hyperphosphatemia, the institution of therapy to correct it may cause serum phosphorus concentrations to decrease rapidly as phosphorus shifts back into the intracellular compartment. In addition, the acidosis associated with the diabetic ketoacidotic state can cause a decomposition of organic compounds inside the cell and a release of inorganic phosphorus into the plasma and subsequently into the urine.¹²⁸ The combination of intracellular phosphorus breakdown and the shift of phosphorus into cells on initiation of treatment may lead to severe hypophosphatemia. Drugs associated with transcellular shifts in phosphorus include dextrose solutions, glucagon, insulin, catecholamines, calcitonin, erythropoietic agents, and anabolic steroids.

❖ Chronic ethanol abusers are prone to a variety of serum electrolyte disorders including hypocalcemia, hypomagnesemia,

hypokalemia, and hypophosphatemia. The etiology of hypophosphatemia in the alcoholic patient is multifactorial. Malnutrition, poor dietary intake, diarrhea, vomiting, and the use of phosphate-binding antacids may all contribute to the hypophosphatemia of alcoholism.¹²⁸ In addition, serum phosphorus concentrations may decrease after hospitalization in the alcoholic patient with the institution of dextrose-containing intravenous fluids, as a result of an intracellular shift of phosphorus.^{129,130} Hyperventilation associated with the alcohol withdrawal syndrome may also contribute to the development of hypophosphatemia.¹²¹ Alcoholic patients are particularly susceptible to the complications of hypophosphatemia such as rhabdomyolysis, which is often seen during withdrawal or refeeding.^{121,130} Thus serum phosphorus concentrations should be routinely monitored in alcoholic patients.

CLINICAL PRESENTATION

The clinical manifestations of severe hypophosphatemia are diverse and may affect many organ systems (Table 49–8). It is likely that two primary biochemical abnormalities are responsible for most of the clinical manifestations of severe hypophosphatemia.¹¹⁸ First, intracellular energy stores may be decreased secondary to depletion of intracellular ATP, which is dependent on inorganic intracellular phosphate. This can result in disruptions in cellular function. Second, reduced red blood cell 2,3-DPG concentrations are associated with a shift to the left of the oxyhemoglobin saturation curve. This shift is associated with a decrease in the release of oxygen to peripheral tissues (increased oxygen affinity for hemoglobin) and may result in tissue hypoxia.¹¹⁸ These metabolic disorders can be seen in a wide variety of organ systems.

Neurologic (CNS) manifestations of severe hypophosphatemia result in a metabolic encephalopathy syndrome.¹²⁸ This progressive syndrome of irritability, apprehension, weakness, numbness, paresthesias, dysarthria, confusion, obtundation, seizures, and coma has been described in patients with severe hypophosphatemia.^{121,127} Neuropsychiatric disturbances include apathy, delirium, hallucinations,

TABLE 49–8. Manifestations of Severe Hypophosphatemia

| | |
|-----------------------|---|

| Rhabdomyolysis | |
| Dysphagia | |
| Ileus | |

and paranoia. Peripheral neuropathy and symptoms resembling Guillain-Barré syndrome have also been reported.¹²⁷

Severe hypophosphatemia may result in significant dysfunction of skeletal muscle ranging from myalgia, bone pain, and weakness, with chronic hypophosphatemia, to potentially fatal rhabdomyolysis with severe acute hypophosphatemia.¹²⁷ Laboratory evaluations can help to distinguish between chronic and acute or chronic hypophosphatemia. Elevated alkaline phosphatase, normal creatine phosphokinase, and normal to low phosphorus and calcium are present in cases of chronic hypophosphatemia. In contrast, hyperkalemia, hyperuricemia, elevated blood urea nitrogen and creatinine, hypercalcemia, and myoglobinuria are present in cases in which rhabdomyolysis complicates the acute or chronic hypophosphatemia.¹²⁷ Hypophosphatemia can result in acute respiratory failure secondary to respiratory muscle weakness and diaphragmatic contractile dysfunction. Thus frequent assessment of serum phosphorus concentration is indicated in patients at risk for respiratory failure. Likewise, adequate treatment of hypophosphatemia in respiratory failure may aid in successful weaning from the ventilator.¹¹⁹ Dysphagia and ileus have also been attributed to hypophosphatemia.¹¹⁹

Cardiac muscle function has been reported to be impaired in the setting of hypophosphatemia and has resulted in congestive cardiomyopathy.¹³¹ This has been reported in alcoholics, and postoperative and intensive care patients. A depletion in cardiac ATP stores has been hypothesized as the cause of this syndrome.¹²⁷ Arrhythmias have also been reported in patients with hypophosphatemia. Because hypophosphatemia is a potentially reversible cause of heart failure, it should be considered in patients who experience an acute deterioration in ventricular function.

Hematologic manifestations of hypophosphatemia include decreased levels of 2,3-DPG, decreased red blood cell ATP, and membrane rigidity.¹¹⁸ When red blood cell ATP decreases to below 15% of normal, cells become spherocytic and rigid, and are trapped and destroyed in the spleen.¹²⁸ Therefore hemolysis may be a manifestation of severe hypophosphatemia. Reduction in ATP content of white blood cells may result in mobility, chemotaxis, phagocytosis, and bactericidal dysfunction.¹²¹ These changes may contribute to an increased risk of infection in hypophosphatemic patients. Animal studies also demonstrate platelet abnormalities in the setting of hypophosphatemia.¹²⁷ The implications of hypophosphatemia for human platelet function, however, have not been determined.

Finally, prolonged hypophosphatemia may result in osteopenia and osteomalacia because of enhanced osteoclastic resorption of bone. Glucose intolerance from hypophosphatemia caused by tissue insensitivity to insulin has also been described.

CLINICAL PRESENTATION OF HYPOPHOSPHATEMIA

GENERAL

The manifestations of hypophosphatemia depend on the chronicity and severity of the phosphate depletion. The major conditions associated with symptomatic hypophosphatemia are chronic alcoholism, intravenous hyperalimentation without adequate phosphate supplementation, and the chronic ingestion of antacids. Severe hypophosphatemia can also be seen during treatment of diabetic ketoacidosis and with prolonged hyperventilation.

SYMPTOMS

Except for the effects on mineral metabolism, the symptoms of hypophosphatemia are due to two consequences (reduction of red cell 2,3-DPG and reduction of intracellular ATP levels), and can impact virtually all organ systems. Resulting symptoms can include irritability, apprehension, weakness, numbness, paresthesias, confusion, seizures, and coma.

SIGNS

The initial response of bone to hypophosphatemia is increased resorption and the associated release of bone calcium, contributing to hypercalciuria. Prolonged hypophosphatemia can result in rickets and osteomalacia due to decreased bone mineralization.

Neurologic: Severe hypophosphatemia can lead to a metabolic encephalopathy.

Cardiopulmonary: Impaired myocardial contractility and respiratory failure secondary to ATP depletion has been described. The reduction in cardiac output may become clinically significant, leading to congestive heart failure.

Musculoskeletal: Proximal myopathy, dysphagia, and ileus have been reported. Acute hypophosphatemia superimposed upon pre-existing severe phosphate depletion can lead to rhabdomyolysis.

Hematologic: Alterations in the hematopoietic system can also occur, resulting in hemolysis, reduction in phagocytotic and granulocyte chemotactic ability, as well as defective clot retraction and thrombocytopenia.

LABORATORY TESTS

Serum phosphate levels below 2.4 mg/dL represent hypophosphatemia.

► TREATMENT: Hypophosphatemia

■ DESIRED OUTCOME

The goals of therapy are the reversal of signs and symptoms of hypophosphatemia, normalization of serum phosphorus concentrations, and management of underlying conditions. Awareness of the clinical situations in which hypophosphatemia may be anticipated (alcoholism, diabetic ketoacidosis, and parenteral nutrition) is of vital importance in preventing iatrogenic hypophosphatemia. The routine addition of phosphorus in concentrations of 12 to 15 mmol/L to intra-

venous hyperalimentation solutions is of utmost importance for the prevention of severe hypophosphatemia in hospitalized patients.

■ PHARMACOLOGIC THERAPY

Severe (<1 mg/dL) or symptomatic hypophosphatemia should be treated with parenteral phosphorus replacement. Oral phosphorus supplementation is usually reserved for patients who are asymptomatic

or who exhibit mild to moderate hypophosphatemia. Estimation of total body phosphorus deficit is difficult because phosphorus is an intracellular electrolyte. Dosage and infusion recommendations, as well as response to parenteral phosphorus replacement, are highly variable.¹²⁶ The infusion of 15 mmol of phosphorus in 250 mL 5% dextrose or 0.9% sodium chloride over 3 hours is a safe and effective treatment for severe hypophosphatemia.¹²⁶ Mean increases in serum phosphate of 0.5 to 0.8 mg/dL have been reported. Doses of 15 to 30 mmol of phosphorus can be given over 1 to 3 hours in patients without hypercalcemia (serum calcium >10.5 mg/dL).^{126,132} Other authors recommend a wider dosage range of 0.08 to 0.64 mmol/kg body weight (5 to 45 mmol in a 70-kg patient) given over 4 to 12 hours.^{132–134} Intravenous phosphate therapy produces the desired increase in serum phosphorus at 24 hours in 20% to 80% of patients. Response is dependent on the degree of phosphate depletion and replacement dose administered.¹¹⁸ Furthermore, the initial success is often followed in 48 to 72 hours by recurrent hypophosphatemia, necessitating close monitoring of serum phosphorus and repeated administration of phosphorus products as warranted.

CLINICAL CONTROVERSY

The recommended dosage of intravenous phosphorus in conditions of severe hypophosphatemia is not well established and may range from 5 to 45 mmol of phosphorus.

Parenteral phosphorus supplementation is associated with risks of hyperphosphatemia, metastatic soft tissue deposition of calcium-phosphate product, hypomagnesemia, hypocalcemia, and hyperkalemia or hypernatremia (caused by intravenous phosphorus salt) (Table 49–9). Inappropriate administration of large doses of parenteral phosphorus over relatively short time periods has resulted in symptomatic hypocalcemia and soft-tissue calcification.¹¹⁸ The rate of infusion and choice of initial dosage should therefore be based on severity of hypophosphatemia, presence of symptoms, and coexistent medical conditions. Patients should be closely monitored with frequent (every 6 hours) serum phosphorus determinations for 48 to 72 hours after starting intravenous therapy. It may be necessary to continue administration of intravenous phosphorus for several days in some patients, while other patients may be able to tolerate an

TABLE 49–9. Phosphorus Replacement Therapy

| Product (Salt) | Phosphate Content |
|---|------------------------|
| Oral therapy | |
| Neutra-Phos (7 mEq/packet each of Na and K) | 250 mg (8 mmol)/packet |

| Intravenous therapy | |
| Sodium PO ₄ (4.0 mEq/mL Na) | 3 mmol/mL |
| Potassium PO ₄ (4.4 mEq/mL K) | 3 mmol/mL |

oral maintenance regimen. Monitoring should also include assessment of serum potassium, calcium, and magnesium concentrations. Hypomagnesemia secondary to intracellular shifts occurs frequently (27% to 80%) in severely hypophosphatemic patients.¹²⁶ Therapy with parenteral phosphorus should be undertaken with great caution and at reduced dosage for patients with hypercalcemia or renal dysfunction.^{121,130}

2 Mild to moderate or asymptomatic hypophosphatemia can be treated by the administration of oral phosphorus salts in doses of 1.5 to 2 g (50 to 60 mmol) daily in divided doses (see Table 49–9). Phosphorus concentrations should be monitored daily, with the goal of correcting the reduced phosphorus concentration in approximately 7 to 10 days. The primary dose-limiting adverse effect associated with oral phosphorus replacement is the development of osmotic diarrhea. Patients with mild to moderate hypophosphatemia and moderate to severe renal insufficiency should receive reduced daily oral doses (i.e., 1 g or approximately 30 mmol of phosphorus) with careful monitoring of serum phosphorus concentration, because they are predisposed to phosphorus retention. In addition to phosphorus supplementation for hypophosphatemia, dipyridamole may decrease renal phosphate leaking and increase serum phosphorus. Doses of 75 mg four times daily have resulted in increases in serum 1,25-dihydroxyvitamin D₃ and decreases in serum calcium and urolithiasis events.¹³⁵

CONCLUSIONS

Clinicians play an integral part in the management of fluid and electrolyte abnormalities; initially they should review the patient's medication history to determine if any of the patient's current drug therapy may have contributed to the existing abnormalities. They should also carefully evaluate all drug therapy options to reduce the risk of developing new electrolyte problems and to optimize the outcome of the current management plan. This proactive interventional approach will facilitate the management of mild disorders in the community and may reduce the need for hospitalization.

ABBREVIATIONS

ACEI: angiotensin-converting enzyme inhibitor
ADH: antidiuretic hormone
ATP: adenosine triphosphate
BUN: blood urea nitrogen

CHF: congestive heart failure
CNS: central nervous system
DDAVP: 1-deamino-8-D-arginine vasopressin
2,3-DPG: 2,3-diphosphoglycerate
D₅W: 5% dextrose in water
DI: diabetes insipidus
EABV: effective arterial blood volume
ECF: extracellular fluid
ECFVd: extracellular fluid volume deficit
ECFV_{current}: current extracellular fluid volume
ECFV_{norm}: normal extracellular fluid volume
FeNa: fractional excretion of sodium
GFR: glomerular filtration rate
IV_{Na}: sodium concentration of infusate
IV_{vol}: volume of infusate
NSAID: nonsteroidal anti-inflammatory drug
PTH: parathyroid hormone
S_{ca}: serum calcium
S_{Na}ⁱ: initial patient serum sodium concentration

SIADH: syndrome of inappropriate secretion of antidiuretic hormone

TBW: total body water

TBW_{current}: current total body water

TBW_{norm}: normal total body water

V2: vasopressin-2

KEY CONCEPTS

- 1 Potassium is the primary intracellular ion in the human body.
- 2 The normal plasma potassium concentration range is 3.5 to 5 mEq/L (3.5 mmol/L).
- 3 Potassium regulates many biochemical processes in the body, and is a key ion for electrical action potentials across cellular membranes.
- 4 Potassium chloride is the preferred potassium supplement for the most common causes of hypokalemia.
- 5 In patients with concomitant hypokalemia and hypomagnesemia, it is imperative to correct the hypomagnesemia before the hypokalemia.
- 6 Hyperkalemia commonly results in patients with acute or chronic kidney disease.
- 7 Magnesium is an important cofactor for many cellular functions.
- 8 The normal plasma magnesium concentration range is 1.4 to 1.8 mEq/L (0.85 to 1.15 mmol/L).
- 9 Hypomagnesemia is commonly caused by excessive gastrointestinal or renal magnesium wasting.
- 10 Hypermagnesemia is commonly observed in patients with acute or chronic kidney disease.

Potassium and magnesium are electrolytes that are responsible for numerous metabolic activities. Disorders of these electrolytes are frequently seen in both the acute care and community ambulatory care settings. Clinicians should have a firm understanding of the etiology, pathophysiology, symptoms, pharmacotherapy, and monitoring of these disorders. This chapter describes the homeostatic mechanisms that are responsible for the maintenance of normal potassium and magnesium serum concentrations. The clinical disorders responsible for the development of hyperkalemia, hypermagnesemia, hypokalemia, and hypomagnesemia are also reviewed.

POTASSIUM

- 1 Potassium is the most abundant cation in the body, with estimated total body stores of 3,000 to 4,000 mEq.¹ Ninety-eight percent of this amount is contained within the intracellular compartment, and the remaining 2% is distributed within the extracellular compartment. The Na⁺-K⁺-ATPase pump located in the cell membrane is responsible for the compartmentalization of potassium. This pump is an active transport system that maintains increased intracellular stores of potassium by transporting sodium out of the cell and potassium into the cell at a ratio of 3:2. Consequently the pump maintains a higher concentration of potassium inside the cell.
- 2 The normal serum concentration range for potassium is 3.5 to 5.0 mEq/L, whereas the intracellular potassium concentration

is usually about 140 mEq/L.² Approximately 70% of the intracellular potassium is located in skeletal muscle; the remaining 30% is located in the liver and red blood cells. Extracellular potassium is distributed throughout the serum and interstitial space. Potassium is dynamic in that it is constantly moving between the intracellular and extracellular compartments according to the body's needs.³ Thus the serum potassium concentration alone does not accurately reflect the total body potassium content.

- 3 Potassium has many physiologic functions within cells, including protein and glycogen synthesis and cellular metabolism and growth. It is also a determinant of the electrical action potential across the cell membrane.¹ The ratio of the intracellular to extracellular potassium concentration is the major determinant of the resting membrane potential across the cell membrane. Thus the resting membrane potential is greatly affected by variations in extracellular potassium concentration. Serum potassium concentrations outside the normal range can have disastrous effects on neuromuscular activity, in particular cardiac conduction. Hypo- and hyperkalemia are both associated with potentially fatal cardiac arrhythmias, along with other neuromuscular disturbances.

CONTROL OF POTASSIUM HOMEOSTASIS

Potassium homeostasis and the maintenance of serum potassium within the normal range are regulated by dietary intake,

gastrointestinal and urinary excretion, hormones, acid-base balance, and body fluid tonicity.⁴

The recommended daily allowance for dietary potassium intake is approximately 50 mEq/day.² Potassium is found in abundance in fruits, vegetables, and meats. The typical American ingests approximately 50 to 150 mEq of potassium daily.⁴ Nearly all of this is absorbed, with only 10 to 20 mEq eliminated in feces. The amount eliminated in the feces increases, however, in patients with diarrhea, and perhaps in those with underlying chronic kidney disease (CKD).⁵

The kidney is the primary route of potassium elimination. Potassium is freely filtered with almost all of it being reabsorbed passively in the proximal tubule and the thick ascending limb of the loop of Henle.⁶ Therefore urinary potassium excretion is primarily determined by potassium secretion from the luminal cells of the distal tubule and collecting duct. The normal daily amount of potassium excreted in the urine is generally 40 to 90 mEq/L,² but it can vary based on dietary intake, serum potassium concentration, and aldosterone activity.

Hormones such as insulin, catecholamines, and aldosterone dramatically affect potassium homeostasis. Insulin may be the most important hormonal mediator of potassium balance because it stimulates the cellular $\text{Na}^+ - \text{K}^+ - \text{ATPase}$ pump to increase cellular potassium uptake in the liver, muscle, and adipose tissue.⁴ Evidence suggests that a complex negative feedback loop exists in which insulin secretion tightly regulates potassium concentrations.¹ Indeed, serum potassium increases of only a few tenths of a milliequivalent stimulate pancreatic insulin secretion into the portal circulation in an attempt to prevent hyperkalemia from occurring.^{1,2} If hyperkalemia occurs, glucagon is released from the liver to protect against insulin-induced hypoglycemia. Conversely, hypokalemia inhibits insulin secretion, which explains why some patients receiving diuretics develop hyperglycemia.⁷

Circulating catecholamines such as epinephrine also result in an intracellular movement of potassium by two mechanisms.⁸ They stimulate the β -receptor, which directly activates the $\text{Na}^+ - \text{K}^+ - \text{ATPase}$ pump. Secondly, they stimulate glycogenolysis, which raises blood glucose levels, thereby increasing insulin secretion. This dual mechanism is often used therapeutically in patients with hyperkalemia to normalize serum potassium concentrations.

Aldosterone is a mineralocorticoid that is secreted from the adrenal glands in response to high serum potassium concentrations. Aldosterone promotes potassium excretion through the kidneys. Aldosterone works at the distal tubule and collecting duct to promote the reabsorption of sodium and water in exchange for potassium. The net result is potassium secretion into the urine. Aldosterone may also have extrarenal activity by stimulating cellular $\text{Na}^+ - \text{K}^+ - \text{ATPase}$ pump activity.⁸

Changes in acid-base status significantly affect the serum potassium concentration. For example, in an acidotic state, the body compensates for excessive hydrogen ions by moving them from the serum into the cell, in exchange for intracellular potassium, to maintain electroneutrality. However, the process by which this occurs is complex, and a cellular $\text{H}^+ - \text{K}^+ - \text{ATPase}$ pump has been identified. The efflux of potassium into the serum can result in hyperkalemia. A commonly quoted approximation of the pH effect is that for every 0.1 unit decrease in pH, there is a corresponding increase in serum potassium of 0.6 to 0.8 mEq/L (with a wide range of 0.2 to 1.7).⁶ This is often referred to as *false hyperkalemia* because there isn't a true excess of total body potassium. Only metabolic inorganic acids, such as hydrochloric acid, result in an increase in serum potassium. Metabolic acidosis caused by organic acids, such as lactic acidosis and ketoacidosis, do not result in hyperkalemia, because both cation

and anion enter the cell, thus maintaining electroneutrality.¹ Respiratory acidosis does not significantly affect the serum potassium concentration.⁸

Conversely, metabolic alkalosis results in hypokalemia as a result of a net loss of hydrogen ion in the serum. In response, the body releases intracellular hydrogen ion into the serum to increase the acidity of the blood in exchange for extracellular potassium ions. This creates a relative deficiency of serum potassium. Serum potassium falls approximately 0.6 mEq/L for each 0.1 unit rise in blood pH. Similarly, this is frequently termed *false hypokalemia* because there isn't a true deficiency in total body potassium.

Finally, hyperosmolality results in enhanced movement of potassium from the cell into the extracellular fluid. This occurs most likely because of the associated cell shrinkage and water loss, which increases the intracellular-to-extracellular potassium gradient.⁴ This is seen most commonly in conditions such as diabetic ketoacidosis. Conversely, hypo-osmolality does not seem to affect potassium distribution.

HYPOKALEMIA

EPIDEMIOLOGY

Hypokalemia (defined as a plasma potassium concentration < 3.5 mEq/L) is one of the most commonly encountered electrolyte abnormalities in clinical practice.^{9,10} However, it is virtually nonexistent in otherwise healthy adults not receiving medication. This is partly explained by the high potassium content in the typical Western diet as well as the effective potassium-sparing mechanisms in the body to autoregulate the plasma potassium concentration. Hypokalemia usually occurs in patients who are receiving diuretic therapy. It has been estimated that as many as 50% of patients who receive diuretics have plasma potassium concentrations less than 3.5 mEq/L.¹⁰ Hypokalemia can be described as mild (serum potassium 3 to 3.5 mEq/L), moderate (serum potassium 2.5 to 3 mEq/L), or severe (< 2.5 mEq/L). When hypokalemia is detected, a diagnostic work-up that evaluates the patient's comorbid disease states and concomitant medications should be initiated.

ETIOLOGY AND PATHOPHYSIOLOGY

Hypokalemia results when there is a total body potassium deficit, or when serum potassium is shifted into the intracellular compartment. Total body deficits occur in the setting of poor dietary intake of potassium, or when there are excessive renal and gastrointestinal losses of potassium from the body.

Maintaining a consistent dietary intake of potassium is important because the body has no effective method for storing potassium. At steady state, potassium excretion matches potassium intake; approximately 90% of ingested potassium is renally excreted whereas 10% is excreted in feces.¹¹ This underscores the importance of eating a well-balanced diet. Elderly patients with chronic diseases, and patients undergoing surgery are at increased risk for developing hypokalemia because of insufficient intake or losses resulting from surgery.

Many drugs may cause hypokalemia by a variety of mechanisms. These mechanisms include intracellular potassium shifting and increased renal or stool losses (Table 50-1). Non-potassium-sparing diuretic administration is the most common cause of drug-induced hypokalemia.⁹ Loop and thiazide diuretics inhibit renal sodium reabsorption, which results in increased sodium delivery to the distal tubule. Consequently, hypokalemia develops because the distal

TABLE 50–1. Mechanism of Drug-Induced Hypokalemia

Adapted from Gennari.⁹

tubule selectively reabsorbs sodium, and excretes potassium down its concentration gradient. Secondly, because diuretics result in volume contraction, aldosterone is secreted which further promotes the renal excretion of potassium. If concomitant potassium supplements are not provided to patients receiving loop and thiazide diuretics, hypokalemia is inevitable.

The second most common etiology of hypokalemia is loss of potassium-rich GI fluid through diarrhea and vomiting. The typical potassium loss in feces is approximately 10 mEq per day.⁹ In diarrheal states, this amount increases proportionally with the volume of stool output. Vomiting also accounts for substantial potassium losses, which have been estimated to be as high as 30 to 50 mEq/L.² Metabolic alkalosis can also occur in cases of severe diarrhea and vomiting due to loss of bicarbonate-rich fluids. As discussed above, this causes an intracellular shifting of potassium, which lowers the serum concentration of potassium even further. Prolonged diarrhea and vomiting can significantly affect children and elderly patients because their kidneys are unable to effectively maintain an adequate fluid status.

Hypomagnesemia can also contribute to the development of hypokalemia because it reduces the intracellular potassium concentration and promotes renal potassium wasting.¹² The intracellular potassium concentration falls because hypomagnesemia impairs the function of the $\text{Na}^+ - \text{K}^+ - \text{ATPase}$ pump. The mechanism of the accelerated renal loss of potassium is unknown.¹² It is unclear whether hypomagnesemia directly causes hypokalemia, because the two are often found together as a result of drugs (diuretic administration) or disease states (diarrhea). When concomitant hypokalemia and hypomagnesemia occur, the magnesium deficiency must be corrected first, otherwise full repletion of the potassium deficit is difficult.¹²

► TREATMENT: Hypokalemia

■ DESIRED OUTCOME

The goals of hypokalemia management are to prevent and to treat serious life-threatening complications, to normalize the serum potas-

CLINICAL PRESENTATION OF HYPOKALEMIA^{9,13–24}

GENERAL

The presence of signs and symptoms with hypokalemia are usually nonspecific and highly variable between patients.

SYMPTOMS

Symptoms are highly dependent on the degree of hypokalemia and its rapidity of onset. Mild hypokalemia is often asymptomatic. Moderate hypokalemia is associated with cramping, weakness, malaise, and myalgias. Severe hypokalemia is associated with cardiac arrhythmias.

SIGNS

Cardiovascular: Essential hypertension and electrocardiographic changes are present (ST-segment depression or flattening, T-wave inversion, and U-wave elevation). Clinical arrhythmias include heart block, atrial flutter, paroxysmal atrial tachycardia, ventricular fibrillation, and digitalis-induced arrhythmias.

Musculoskeletal: Cramping and impaired muscle contraction are seen.

LABORATORY TESTS

Serum potassium concentration less than 3.5 mEq/L is diagnostic. Hypomagnesemia (serum magnesium concentration <1.7 mg/dL) may also be present.

sium concentration, to identify and correct the underlying cause of hypokalemia, and to prevent overcorrection of the potassium concentration.

■ GENERAL APPROACH TO THERAPY

The general approach to therapy depends on the degree and rapidity of hypokalemia, and the presence of symptoms. Serum potassium concentrations between 3.5 and 4 mEq/L are a sign of early potassium depletion. No pharmacologic therapy is recommended at this point; however, these patients should be encouraged to increase their dietary intake of potassium-rich foods. When the serum potassium concentration is between 3 and 3.5 mEq/L, it is still debatable whether pharmacologic therapy should be initiated for all patients. Oral potassium supplementation should be initiated in patients with underlying cardiac conditions that predispose them to cardiac arrhythmias. This includes patients receiving concomitant digoxin therapy.²² Patients with serum potassium concentrations below 3 mEq/L should always be treated to achieve values >4 mEq/L. In asymptomatic patients, oral therapy is the preferred route of administration. Intravenous potassium may be necessary in symptomatic patients with severe depletion, or in patients who are intolerant to oral supplementation. In patients with concomitant hypomagnesemia, the magnesium deficit should be corrected before potassium supplementation, to prevent refractory hypokalemia.²¹

■ NONPHARMACOLOGIC THERAPY

Various nonpharmacologic therapies exist to prevent and treat hypokalemia. Probably the best and most abundant source of potassium comes from dietary sources, in particular, fresh fruits and vegetables, fruit juices, and meats.²¹ Table 50–2 lists foods that are excellent sources of potassium. Salt substitutes are another effective, inexpensive source of potassium. Increased dietary intake of foods with high potassium content is not recommended long-term because it may add unwanted calories to the patient's diet. Moreover, dietary potassium is almost entirely coupled with phosphate, rather than chloride, so it isn't as effective in correcting potassium loss associated with hypochloremic conditions such as vomiting, nasogastric suctioning, and diuretic therapy.²¹

PHARMACOLOGIC THERAPY

Guidelines for potassium supplementation have been published by the National Council on Potassium in Clinical Practice (Table 50–3).²¹ These guidelines provide a comprehensive framework for potassium prophylaxis and replacement in many distinct patient populations. When deciding on appropriate pharmacotherapy to replete potassium, five factors must be considered: (1) the patient's normal baseline potassium concentration; (2) underlying medical conditions that may affect potassium balance; (3) concomitant medications that may affect potassium balance; (4) the patient's dietary and salt intake; and (5) the patient's ability to comply with the therapeutic regimen.²¹

A general rule for potassium replacement is that for every 1-mEq/L fall of potassium below 3.5 mEq/L, there is a corresponding total body potassium deficit of 100 to 400 mEq. Due to the wide variance in projected deficits each patient's therapy must be individualized and adjustments made on the basis of the patient's signs, symptoms, and frequent measurements of serum potassium. In patients receiving loop or thiazide diuretics, 40 to 100 mEq of potassium is generally needed to correct mild deficits. Doses up to 120 mEq may be required in more severe deficiencies. The total daily dose should be divided

into three to four doses to prevent GI side effects. Patients receiving diuretics may become chronically hypokalemic and may benefit from combination potassium-sparing diuretic therapy.

CLINICAL CONTROVERSY

The replacement of potassium IV may be accomplished by way of IV piggyback or by buretrol. A pharmacist usually prepares the potassium IV piggyback, double checks the concentration and fluid, then dispenses the final product to the medical unit. However, with buretrol administration, essentially any clinician (e.g., nurse or physician) can prepare the solution on the medical unit, and infuse the potassium solution into the patient.

4 Whenever possible, potassium supplementation should be administered by mouth. Three salts are available for oral potassium supplementation: chloride, phosphate, and bicarbonate. Potassium phosphate should be used when patients are both hypokalemic and hypophosphatemic; potassium bicarbonate is most commonly used when potassium depletion occurs in the setting of metabolic acidosis. Potassium chloride, however, is the primary salt form used because it is the most effective treatment for the common causes of potassium depletion (i.e., diuretic-induced and diarrhea-induced hypokalemia). Because diarrhea and diuretics such as hydrochlorothiazide and furosemide promote net potassium and chloride losses, supplementation with potassium chloride repletes both electrolytes. Potassium chloride can be administered in either tablet or liquid formulations (Table 50–4). The liquid forms are generally less expensive; however,

TABLE 50–3. General Consensus Guidelines for Potassium Replacement

| Guideline | Comment |
|--|--|
| Potassium replacement therapy should accompany dietary consumption of potassium-rich foods. | Potassium-rich foods often cannot completely replace potassium associated with chloride losses (vomiting, diuretics, or nasogastric suction) because it is almost entirely coupled to phosphate. Furthermore, increasing dietary intake of these foods may lead to unwanted weight gain. |
| Potassium replacement is recommended in patients who are sodium sensitive, and in hypertensive patients. | A high-sodium diet often results in excessive urinary potassium excretion. |
| Potassium replacement is recommended in patients who are subject to vomiting, diarrhea, or diuretic/laxative abuse. | These conditions promote excessive renal and GI potassium loss. |
| Potassium supplementation is best administered orally in divided doses over several days to achieve full repletion. | |
| Laboratory measurement of serum potassium is convenient, but not always accurate. | Clinicians should be aware of the factors that result in transcellular potassium shifts. Monitoring 24-hour urinary potassium excretion may be necessary in high-risk patients. |
| Patient adherence to potassium replacement may be increased with compliance-enhancing regimens. | Microencapsulated products have no bitter smell or aftertaste and have much better GI tolerance. Regimens should be made as simple as possible to follow. |
| A potassium dosage of 20 mEq/day is usually sufficient to prevent hypokalemia from occurring. Doses of 40–100 mEq are usually sufficient to treat hypokalemia. | |

Adapted from Cohn et al.²¹

patient compliance may be low because of their strong, unpleasant taste.²¹ Two sustained-release preparations are currently available in the United States: a wax-matrix formulation, and a microencapsulated formulation. The microencapsulated tablet disintegrates better in the stomach as compared to the wax-matrix preparation, and is associated with less GI erosion.^{9,21} Regardless of the preparation used, the potassium is generally well absorbed.

Intravenous potassium use should be limited to (1) severe cases of hypokalemia (serum concentration <2.5 mEq/L); (2) patients exhibiting signs and symptoms of hypokalemia such as electrocardiogram (ECG) changes or muscle spasms; or (3) patients unable to tolerate oral therapy. Intravenous supplementation is more dangerous than oral therapy because it is more likely to result in hyperkalemia, thrombophlebitis, and pain at the site of infusion.

The vehicle in which intravenous potassium is administered is important. Whenever possible, potassium should be mixed in saline-containing solutions (e.g., 0.9% or 0.45% NaCl), and not dextrose-containing solutions. Dextrose-containing solutions stimulate insulin secretion, which causes further intracellular shifting of potassium. Indeed, there are reports of enhanced hypokalemia in patients being repleted with potassium in dextrose infusions.²⁵ Generally, 10 to

20 mEq of potassium is diluted in 100 mL 0.9% NaCl for intravenous administration. These concentrations are generally safe when administered through a peripheral vein over 1 hour. When infusion rates exceed 10 mEq/h, ECG monitoring should be performed to detect cardiac signs of hyperkalemia. The serum potassium concentration should be evaluated following the infusion of each 30 to 40 mEq, to direct further potassium replacement requirements. Multiple doses of potassium can be repeated as needed until the serum potassium concentration normalizes.

In cases of severe potassium depletion, patients may require as much as 300 to 400 mEq/day. In this instance, it is common practice to dilute 40 to 60 mEq in 1,000 mL 0.45% NaCl and infuse at a rate not exceeding 40 mEq/h. If possible, this should be performed in an intensive care unit under continuous ECG monitoring. Because of the high potassium concentration, and the risk for burning pain and peripheral venous sclerosis, the infusion should be through a central intravenous line into a large vein (e.g., superior vena cava). Frequent serum potassium monitoring should be performed to avoid the development of hyperkalemia.

ALTERNATIVE THERAPIES

Potassium-sparing diuretics are an alternative to exogenous potassium supplementation, especially when patients are concomitantly receiving drugs that are known to deplete potassium (e.g., diuretics or amphotericin B). Spironolactone inhibits the effect of aldosterone in the distal convoluted tubule, thereby decreasing potassium elimination in the urine. Spironolactone is especially effective as a potassium-sparing agent in patients with primary or secondary hyperaldosteronism. Amiloride and triamterene act by an aldosterone-independent mechanism; however, the complete mechanism of their potassium sparing is unknown.

Spironolactone is available as 25-mg, 50-mg, and 100-mg tablets. The usual starting dose is 25 to 50 mg daily, and can be titrated to a maximum dose of 400 mg/day. The potassium-retaining effects generally take about 48 hours to occur. Important side effects

TABLE 50–4. Differentiation of Available Potassium Supplements

| Supplement | Comment |
|---|---|
| Controlled-release microencapsulated tablet | Disintegrates better in GI tract; fewer GI erosions as compared to wax-matrix tablets |
| Encapsulated controlled-release microencapsulated particles | Fewer erosions as compared to wax-matrix tablets |
| Potassium chloride elixir | Inexpensive, poor taste, poor compliance, immediate effect |
| Potassium chloride effervescent tablets for solution | More expensive than elixir, convenient |
| Wax-matrix extended-release tablets | Easier to swallow; more GI erosions as compared to other therapies |

include hyperkalemia, gynecomastia, breast tenderness, and impotence in men.²³

Triamterene is available as 50-mg and 100-mg capsules. The usual starting dose is 50 mg twice daily, which can be titrated to 100 mg twice daily. Triamterene 50 mg is available as a combination product with hydrochlorothiazide 25 mg and is commonly used for the treatment of stage I and II hypertension. Common side effects include hyperkalemia, sodium depletion, and metabolic acidosis.²²

Amiloride is available as a 5-mg tablet. The usual starting dose is 5 mg daily; however, 10 mg can be given in those with severe hypokalemia. This is also available as a combination product with hydrochlorothiazide 50 mg. The most common side effects are hyperkalemia and metabolic acidosis.²³

Generally, concomitant use of potassium supplementation with potassium-sparing diuretics is not necessary. However, conditions that result in excessive urinary potassium wasting, such as congestive heart failure, cirrhosis, or the nephrotic syndrome, may require dual therapy.²³ There is a significant risk of hyperkalemia during combination therapy, especially in patients with underlying renal insufficiency or diabetes mellitus.

■ PHARMACOECONOMIC CONSIDERATIONS

To date, there have been no pharmacoeconomic evaluations of the different pharmacotherapeutic alternatives to manage hypokalemia. The most economical source of potassium is from the diet. Thus patients receiving diuretic therapy should be instructed to increase their dietary intake of potassium-rich foods. By doing so, they may avert the need for exogenous potassium therapy. Additionally, oral potassium supplementation is much less expensive than intravenous supplementation by virtue of its ease of administration and lack of need

for ECG monitoring. The pharmacoeconomic difference between the oral products is dependent on several variables, including patient tolerance and compliance.

CLINICAL CONTROVERSY

Oral replacement is usually preferred. However, patients who are hospitalized often have intravenous access, and hence IV potassium is frequently ordered. Clinicians should make every effort to promote oral potassium replacement, as it is less expensive to the health care system and the patient, and it obviates potential adverse effects such as thrombophlebitis.

■ EVALUATION OF THERAPEUTIC OUTCOMES

5 Serum potassium concentrations should be monitored regularly while the patient is receiving potassium supplementation. For patients receiving long-term prophylactic potassium supplementation during diuretic therapy, the serum potassium and magnesium concentrations, as well as renal function should be monitored during each clinic visit. In hospitalized patients receiving therapy for mild hypokalemia, the potassium concentration should be monitored every 2 to 3 days. This usually isn't a problem because of the frequent laboratory monitoring performed in hospitalized patients. Generally, the potassium concentration begins to rise within 72 hours. If it doesn't rise appreciably within 96 hours, the clinician should suspect concomitant magnesium depletion.²³ If present, correcting the magnesium deficit generally results in normalization of potassium. Patients receiving IV potassium supplementation require close ECG monitoring if the infusion rate is greater than 10 mEq/h. In addition the patient should be assessed for adverse effects such as burning pain at the infusion site or thrombophlebitis.

HYPERKALEMIA

Hyperkalemia is defined as a serum potassium concentration greater than 5.5 mEq/L. It can be further classified according to its severity: mild hyperkalemia (serum potassium 5.5 to 6 mEq/L); moderate hyperkalemia (6.1 to 6.9 mEq/L); and severe hyperkalemia (>7 mEq/L).²²

EPIDEMIOLOGY

Hyperkalemia is much less common than hypokalemia. In fact, if all patients with acute and chronic kidney disease were excluded, the true prevalence of hyperkalemia would be insignificant.^{23,26} Indeed, the incidence of hyperkalemia in hospitalized patients has been estimated to be 1.4% to 10%.²⁷ Most cases of hypokalemia are the result of overcorrection of hypokalemia with potassium supplements. Severe hyperkalemia occurs more commonly in elderly patients with renal insufficiency who receive potassium supplementation.²⁷

ETIOLOGY AND PATHOPHYSIOLOGY

Hyperkalemia develops when potassium intake exceeds excretion (i.e., elevated total body stores), or when the transcellular distribution of potassium is disturbed (i.e., normal total body stores). Generally, there are four primary causes of true hyperkalemia: (1) increased

potassium intake; (2) decreased potassium excretion; (3) tubular unresponsiveness to aldosterone; and (4) redistribution of potassium into the extracellular space. The four major causes of true hyperkalemia are discussed below.

Hyperkalemia Associated with Increased Potassium Intake

Hyperkalemia in this setting is almost always associated with renal insufficiency. Predialysis and dialysis patients that are noncompliant with dietary potassium restrictions often present with life-threatening hyperkalemia. Many of these patients don't realize that fresh fruits and vegetables contain large amounts of potassium. Anecdotally, in many dialysis centers the incidence of hyperkalemia peaks during the summer months, when fresh garden produce is available. Another common dietary source of hyperkalemia is potassium chloride salt substitutes. Many dialysis patients are instructed to use salt substitutes to avoid excessive sodium intake in an attempt to control volume overload. These patients unwittingly become hyperkalemic because these products contain approximately 10 to 15 mEq potassium per gram, or 200 mEq per tablespoon. Finally, many over-the-counter herbal products may contain unknown concentrations of potassium in their dosage forms. A case of hyperkalemia was recently reported in a patient ingesting noni juice, an herbal product purported to increase energy levels.²⁸

It is essential for patients with CKD to receive education regarding dietary sources of potassium as well as information on the

potassium content of herbal products, since the ingestion of these may lead to hyperkalemia.

Hyperkalemia Associated with Decreased Renal Potassium Excretion

6 The kidneys excrete 80% of the daily potassium intake. Therefore when the kidney is unable to excrete potassium appropriately, as in acute renal failure and CKD, potassium is retained and often results in hyperkalemia. Moreover, many drugs can inhibit the kidney's ability to excrete potassium by inhibiting aldosterone and thus contribute to an increase in serum potassium levels.

Severe hyperkalemia is more common in acute renal failure (ARF) than in CKD because ARF patients are often hypercatabolic and can have underlying disorders, such as rhabdomyolysis or tumor lysis syndrome, which result in release of potassium from injured or lysed cells.²⁹ Severe hyperkalemia is rare in stable CKD, perhaps because of enhanced GI and renal potassium excretion.^{23,30} A recent study suggests that hyperkalemia actually functions in a homeostatic fashion, directly stimulating renal K^+ excretion through an effect that is independent of, and additive to, aldosterone.³⁰ Renal excretion of potassium is also inhibited by various endocrinologic disorders, including adrenal insufficiency, Addison's disease, and selective hypoaldosteronism. All of these disorders involve a decreased production of aldosterone, which results in the retention of potassium. In addition, several drugs have profound effects on the kidney's ability to secrete potassium. Four drug classes in particular have specific effects at the kidney: angiotensin-converting enzyme inhibitors (ACEIs), angiotensin receptor blockers (ARBs), potassium-sparing diuretics, and

prostaglandin inhibitors such as nonsteroidal anti-inflammatory drugs (NSAIDs). Other miscellaneous drugs that cause hyperkalemia are trimethoprim-sulfamethoxazole, heparin, and pentamidine.

Tubular Unresponsiveness to Aldosterone

Certain medical conditions, such as sickle cell anemia, systemic lupus erythematosus, and amyloidosis, can produce a defect in tubular potassium secretion, possibly as the result of an alteration in the aldosterone-binding site. The exact mechanism of the tubular unresponsiveness is unknown.

Redistribution of Potassium into the Extracellular Space

The efflux of potassium into the extracellular fluid is to be expected in the presence of metabolic acidosis, secondary to diabetes mellitus, chronic renal failure, or lactic acidosis. β -Blockers can also result in a transcellular potassium shift.

The serum potassium concentration may also be falsely elevated in some conditions, and not reflect the actual *in vivo* potassium concentration. This is termed *pseudohyperkalemia*. Pseudohyperkalemia occurs most commonly in the setting of extravascular hemolysis of red blood cells.²⁶ When a blood specimen is not processed promptly and cellular destruction occurs, intracellular potassium is released into the serum. Pseudohyperkalemia can also occur in conditions of thrombocytosis or leukocytosis. If severe hyperkalemia is found in a patient who is asymptomatic with an otherwise normal laboratory report, the hyperkalemia is most likely pseudohyperkalemia,²³ and a repeat blood sample should be evaluated. Elevated potassium concentrations are normally associated with other laboratory abnormalities,

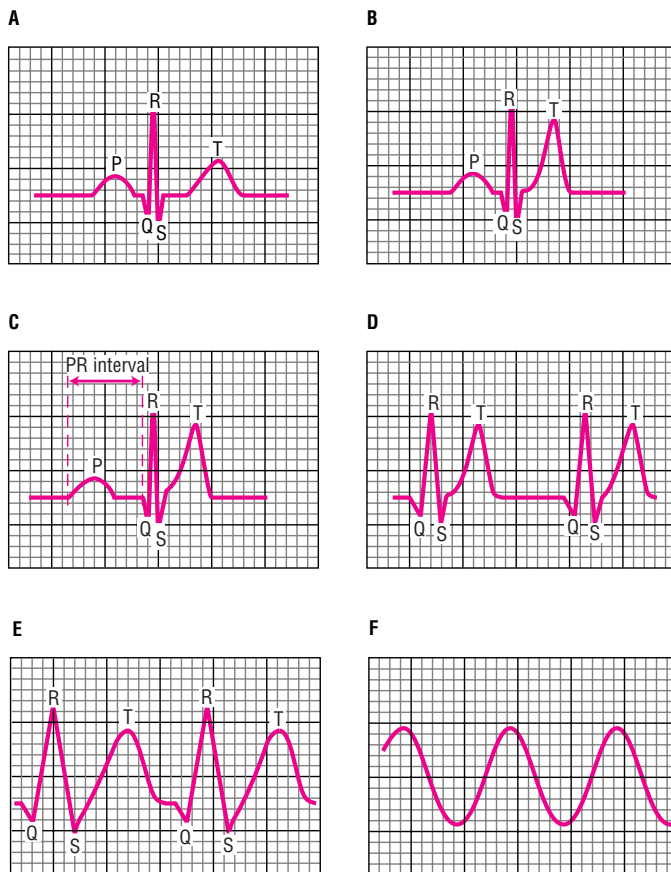

FIGURE 50-1. The earliest electrocardiographic manifestation of hyperkalemia is an increase in the rate of ventricular repolarization, which results in a peaking of the T wave at serum potassium concentrations of ≈ 5.5 to 6 mEq/L (B), relative to the normal ECG presentation (A). Further increases in the serum potassium concentration above 6 mEq/L result in conduction delays through the His-Purkinje system, the atrial myocardium, and the ventricular myocardium. The ECG manifestations of these conduction delays and the sequence in which they occur are a widening of the PR interval (C), delay through the His-Purkinje system, a loss of the P wave (D), delay through the atrial myocardium, a widening of the QRS complex (E), and delay through the ventricular myocardium. Finally, there is a merging of the QRS complex with the T wave (F), which results in a sine-wave appearance to the tracing.

such as low carbon dioxide (acidosis) or elevated blood urea nitrogen and creatinine concentrations (indicating renal insufficiency).

CLINICAL PRESENTATION OF HYPERKALEMIA

GENERAL

Related to the effects of excessive potassium on neuromuscular, cardiac, and smooth muscle cell function.

► TREATMENT: Hyperkalemia

■ DESIRED OUTCOME

The goals of therapy for the treatment of hyperkalemia are to antagonize adverse cardiac effects, reverse any symptoms that may be present, and to return the serum and total body stores of potassium to normal. Severe hyperkalemia (>7 mEq/L) or moderate hyperkalemia (6.1 to 6.9 mEq/L), when associated with clinical symptoms or electrocardiographic changes, requires immediate treatment. Initial treatment of hyperkalemia is focused on antagonism of the membrane actions of hyperkalemia (calcium). Secondarily, one should attempt to decrease extracellular potassium concentration by promoting its intracellular movement (e.g., with glucose, insulin, β_2 -receptor agonists, or sodium bicarbonate). Finally, removal of potassium from the body by hemodialysis and/or cation-exchange resins may need to be implemented.²⁶ The underlying cause of hyperkalemia should be identified and reversed, and exogenous potassium must be withheld.

■ GENERAL APPROACH TO TREATMENT

The general treatment approach for patients with hyperkalemia is outlined in Fig. 50–2. In patients who are symptomatic, calcium should be administered to prevent or treat any cardiac manifestations of hyperkalemia. Once the patient is hemodynamically stabilized, the serum potassium concentration should be rapidly decreased within minutes by administering drugs that result in an intracellular shift. If the patient is asymptomatic, rapid correction is not necessary. The clinician can administer an ion exchange resin (e.g., sodium polystyrene sulfonate; SPS) that results in removal of potassium from the body over several hours.

■ NONPHARMACOLOGIC THERAPY

End-stage renal disease (ESRD) patients who present with severe hyperkalemia, or with cardiac manifestations of hyperkalemia, should undergo immediate hemodialysis. Dialysis is the most rapid means of lowering potassium compared to bicarbonate, epinephrine, or insulin plus glucose therapy.^{31,32} Other forms of dialysis can be performed (e.g., peritoneal dialysis or continuous renal replacement therapy), although they appear to be less effective means to acutely lower an elevated serum potassium.³¹

SYMPTOMS

Frequently asymptomatic; however, the patient may complain of heart palpitations or skipped heartbeats.

SIGNS

ECG changes (see Fig. 50–1 for description).

LABORATORY TESTS

Serum potassium concentration >5.5 mEq/L.

■ PHARMACOLOGIC THERAPY

Various drug therapies exist for lowering the serum potassium concentration. The optimal regimen for a given patient is dependent on the rapidity and degree of lowering that is necessary. Table 50–5

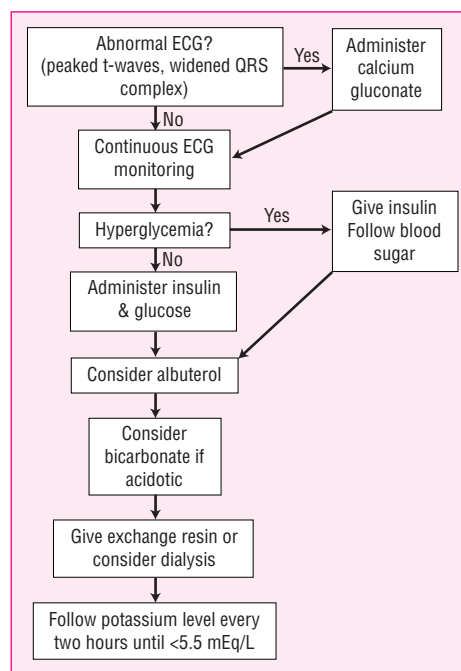

FIGURE 50–2. Treatment algorithm for hyperkalemia. The first step is to evaluate the patient's electrocardiogram. If peaked T waves or widened QRS complexes are present, administer 1 ampule IV calcium gluconate 10% and repeat every 30 to 60 minutes until the ECG normalizes. If the ECG is normal, continue to monitor for cardiac complications. Next, decide on the best therapeutic approach based on the underlying patient symptoms; for example, underlying diabetes or acid-base status, and need for immediate correction. For nonacidotic conditions, IV insulin and glucose is preferred for nondiabetic patients with normal blood glucose. If the patient is diabetic with elevated blood glucose, only IV insulin is required. If the patient is unresponsive to this therapy after 30 to 60 minutes, albuterol via nebulizer is considered adjunctive second-line therapy. Sodium bicarbonate should only be administered when the hyperkalemia is secondary to metabolic acidosis. Potassium exchange resins or dialysis should be used last line for acute situations. If the patient has end-stage renal disease, dialysis may be the preferred first-line therapy. In nonacute situations in which rapid onset is not required, potassium exchange resins are considered a first-line therapy. The patient should be monitored every 2 hours until the serum potassium concentration falls below 5.5 mEq/L.

TABLE 50-5. Therapeutic Alternatives for the Management of Hyperkalemia

| Medication | Dose | Route of Administration | Onset/Duration of Action | Acuity | Mechanism of Action | Expected Result |
|------------------------------|------------------|-------------------------|--------------------------|----------|--|---|
| Calcium | 1 g (1 ampule) | IV over 5–10 min | 1–2 min/10–30 min | Acute | Raises cardiac threshold potential | Reverses electrocardiographic effects |
| Furosemide | 20–40 mg | IV | 5–15 min/4–6 hours | Acute | Inhibits renal Na ⁺ reabsorption | Increased urinary K ⁺ loss |
| Regular insulin | 5–10 units | IV or SC | 30 min/2–6 hours | Acute | Stimulates intracellular K ⁺ uptake | Intracellular K ⁺ redistribution |
| Dextrose 10% | 1,000 mL (100 g) | IV over 1–2 hours | 30 min/2–6 hours | Acute | Stimulates insulin release | Intracellular K ⁺ redistribution |
| Dextrose 50% | 50 mL (25 g) | IV over 5 min | 30 min/2–6 hours | Acute | Stimulates insulin release | Intracellular K ⁺ redistribution |
| Sodium bicarbonate | 50–100 mEq | IV over 2–5 min | 30 min/2–6 hours | Acute | Raises serum pH | Intracellular K ⁺ redistribution |
| Albuterol | 10–20 mg | Nebulized over 10 min | 30 min/1–2 hours | Acute | Stimulates intracellular K ⁺ uptake | Intracellular K ⁺ redistribution |
| Hemodialysis | 4 hours | N/A | Immediate/variable | Acute | Removal from plasma | Increased K ⁺ elimination |
| Sodium polystyrene sulfonate | 15–60 g | Oral or rectal | 1 hour/variable | Nonacute | Resin exchanges Na ⁺ for K ⁺ | Increased K ⁺ elimination |

provides an overview of the available therapies, and their respective onset and the degree of change one can expect.

In asymptomatic patients with mild to moderate hyperkalemia (serum concentration 5.5 to 6.9 mEq/L), aggressive therapy is usually not indicated. In patients with normal renal function, loop diuretics can be administered in the short term to promote urinary potassium excretion. Furosemide 20 to 40 mg orally is a common starting dose, and this can be titrated to response. Its onset of activity is within minutes, and its duration of activity is approximately 4 to 6 hours. Close monitoring of the patient's volume status and other electrolyte concentrations is required while the patient is receiving loop diuretic therapy. Alternatively, SPS (Kayexalate), a cation-exchange resin, can be administered orally or rectally by enema. SPS is available in powder form or prepackaged as 70% sorbitol suspension. The oral route is more effective than the enema and is better tolerated by the patient. As the resin passes through the intestines, each gram of SPS exchanges 1 mEq of sodium for 1 mEq of potassium ions, which are in a relatively higher concentration in the large intestine. The onset of action of SPS is within 1 hour, and it can be repeated every 4 hours as needed. The sorbitol component of the suspension promotes the excretion of the cationically modified potassium exchange resin by inducing diarrhea.²³ The usual oral dose of SPS is 15 to 60 g in 70% sorbitol suspension. A retention enema prepared by mixing 60 to 100 g SPS in 100 to 200 mL 30% sorbitol or 10% dextrose warmed to body temperature will usually remove 0.5 mEq of potassium per gram of SPS.²³ The enema may be retained in the rectum for several hours as tolerated by the patient.

In symptomatic patients, or in those with severe hyperkalemia (serum potassium >7 mEq/L), emergency care is indicated. Initial therapy in this setting is the administration of intravenous calcium to protect the heart from life-threatening arrhythmias.^{11,27,31} Calcium antagonizes the cardiac membrane effect of hyperkalemia and reverses ECG changes within minutes. Its duration of action is 30 to 60 minutes, and it can be repeated as needed based on ECG findings.

Intravenous calcium can be given as either the chloride or gluconate salt; each is available as a 10% solution by weight. Calcium chloride provides approximately three times more calcium than equal volumes of the gluconate salt; however, it can cause tissue necrosis if extravasation occurs. For this reason, calcium gluconate is more commonly administered, with the standard dose being one 10-mL ampule IV bolus over 5 to 10 minutes.

Rapid correction of hyperkalemia may necessitate the administration of drugs that result in an intracellular shift of potassium, such as insulin and dextrose, sodium bicarbonate, and the β_2 -receptor agonist albuterol. The treatment of choice depends on the underlying medical disorders accompanying hyperkalemia. For example, in patients with concomitant metabolic acidosis, a sodium bicarbonate bolus or infusion of 50 to 100 mEq is the preferred therapy (see Chap. 51 for additional information). Sodium bicarbonate helps to correct the metabolic acidosis by raising the extracellular pH, in addition to causing a rapid intracellular potassium shift. It should be noted that sodium bicarbonate is much less effective when hyperkalemia is not related to metabolic acidosis.²⁹ Sodium bicarbonate is also less effective in patients with ESRD, in whom a decrease in serum potassium may not be seen for as long as 4 hours.³² Sodium bicarbonate can also lead to sodium and volume overload in ESRD patients. Administration of insulin (5 to 10 units IV) and dextrose (dextrose 10% or 50%) is an effective method of reducing potassium. Insulin increases the activity of the Na⁺-K⁺-ATPase pump, thereby intracellularly shifting potassium. Glucose should be given with insulin unless the serum glucose is greater than 250 mg/dL because hypoglycemia can develop with unopposed insulin therapy. Albuterol is a β_2 -adrenergic agonist that has a dual mechanism for lowering serum potassium. First, it stimulates the Na⁺-K⁺-ATPase pump to promote intracellular potassium uptake. Second, it stimulates pancreatic β receptors to increase insulin secretion. Albuterol can be administered intravenously (0.5 mg given over 15 minutes) or via nebulizer (10 to 20 mg nebulized over 10 minutes); however, it should be noted that injectable albuterol

is not available in the United States. The problems with nebulized albuterol therapy are frequent underdosing, and subsequently poor response in as many as 33% of patients.³³ Moreover, cardiac side effects such as tachycardia may be undesirable in patients who already have abnormal ECGs. In summary, albuterol should be reserved as adjunctive therapy in patients already receiving insulin and dextrose therapy, due to its synergistic activity on the Na⁺-K⁺-ATPase pump.

EVALUATION OF THERAPEUTIC OUTCOMES

In patients who have acute symptomatic hyperkalemia (e.g., ECG changes), frequent potassium concentration and ECG monitoring is warranted. The patient should receive continuous ECG telemetry monitoring until the serum potassium concentration falls below 5 mEq/L, and the ECG abnormalities resolve. Similarly, while the

patient is receiving emergent therapy, serial serum potassium concentrations should be obtained every hour until the potassium concentration falls below 5 mEq/L. The patient's medication records should be reviewed to assure the patient is not receiving drug therapy that increases the serum potassium concentration. For patients who receive insulin and dextrose therapy for hyperkalemia, blood glucose monitoring should be performed hourly, or more frequently if patients demonstrate signs and symptoms of hypoglycemia. For patients who receive large doses of sodium bicarbonate therapy for hyperkalemia, an arterial blood gas or serum chemistry profile should be obtained to assess blood acid-base status. Furthermore, the patient should be evaluated for signs of fluid overload secondary to the high sodium load. Patients receiving albuterol therapy should be questioned regularly regarding the development of palpitations and tachycardia. In asymptomatic patients receiving SPS, serum potassium concentrations can be obtained within 4 hours, and the dose repeated as necessary. Furthermore, the patient should be questioned regarding the occurrence of diarrheal stool output.

DISORDERS OF MAGNESIUM HOMEOSTASIS

7 Magnesium plays a central role in cellular function and is an important cofactor in more than 300 biochemical reactions in the body, especially those systems that are dependent on adenosine triphosphate.^{34,35} Mitochondrial function, protein synthesis, cell membrane function, and parathyroid hormone (PTH) secretion are just a few important functions affected by magnesium. It is the fourth most abundant extracellular cation and second most abundant intracellular cation. Disorders of magnesium homeostasis are commonly encountered in clinical situations and most frequently are manifested as alterations in cardiovascular and neuromuscular function. Life-threatening conditions such as paralysis and cardiac arrhythmias may occur, making the proper recognition and treatment of these problems of paramount importance.

8 Magnesium is distributed in three major compartments: extracellular, 1.3%; intracellular, 13%; and bone, 67%.^{36,37} Because of its predominantly intracellular distribution, measurement of magnesium in the extracellular compartment may not accurately reflect the total body magnesium content. The majority of magnesium in the extracellular fluid is in the ionized form; only 20% to 30% is protein bound. The normal range for serum magnesium is 1.4 to 1.8 mEq/L, which equals 1.7 to 2.3 mg/dL or 0.85 to 1.15 mmol/L.

The maintenance of magnesium homeostasis depends on the balance between intake and output. Thirty to forty percent of ingested magnesium is absorbed in the small bowel. A small amount is present in intestinal secretions and reabsorbed in the sigmoid colon. The kidneys play a major role in maintaining magnesium balance. Renal magnesium handling is unique in that only 15% to 25% of the filtered magnesium is reabsorbed in the proximal tubule; the majority of reabsorption occurs in the loop of Henle.³⁶ This explains why loop diuretics often cause profound urinary magnesium wasting. Unlike most other important electrolytes, there is no hormonal regulation of the distribution of magnesium between bone and circulating or intracellular magnesium pools. Because of this, both hypomagnesemia and hypermagnesemia commonly occur.

HYPOMAGNESEMIA

EPIDEMIOLOGY

The prevalence of hypomagnesemia in outpatients and hospitalized patients is approximately 6% to 12%.³⁸ In patients with concomitant

hypokalemia, the incidence rises to nearly 42%.³⁸ The incidence in critically ill patients may be as high as 65%, principally because of the concomitant use of diuretics and aminoglycosides.³⁹ Although serum magnesium concentrations are not a reliable index of total body magnesium content, they remain the primary diagnostic tool to evaluate body stores.

ETIOLOGY AND PATHOPHYSIOLOGY

9 Hypomagnesemia is usually associated with disorders of the intestinal tract or kidney. Drugs or conditions that interfere with intestinal absorption or increase renal excretion of magnesium can result in hypomagnesemia (Table 50–6). Decreased intestinal absorption as a result of small bowel disease is the most common cause of hypomagnesemia worldwide.⁴⁰ These disorders include regional enteritis; radiation enteritis; ulcerative colitis; acute and chronic diarrhea; pancreatic insufficiency and other malabsorptive syndromes; small-bowel bypass surgery; and chronic laxative abuse.⁴⁰

Hypomagnesemia is commonly associated with alcoholism, and occurs in as many as 30% of hospitalized patients.⁴¹ The etiology is often multifactorial, including reduced intake, pancreatic insufficiency, chronic vomiting and diarrhea, and urinary magnesium wasting. In addition, patients who are hospitalized for acute alcohol withdrawal often receive IV glucose and may experience even greater reductions in the serum magnesium concentration.⁴² Because hypomagnesemia may contribute to the development of delirium tremens associated with alcohol withdrawal, frequent monitoring and aggressive magnesium replacement is indicated for these patients, especially those with tachyarrhythmias, hypocalcemia, or hypokalemia.

Primary renal magnesium wasting may be due to a defect in renal tubular magnesium reabsorption, or inhibition of sodium reabsorption in those segments in which magnesium transport follows passively. The former condition is associated with hypercalciuria, nephrolithiasis, and progressive renal disease.⁴⁰ The latter is associated with Gitelman's and Bartter's syndromes.⁴⁰ Much more common than these is renal magnesium wasting secondary to diuretics. Hypomagnesemia occurs with both thiazide and loop diuretics, and may be present in as many as 37% of diuretic users.⁴³ Other commonly used drugs which may cause renal magnesium wasting include aminoglycosides, amphotericin B, cyclosporine, tacrolimus, cisplatin, pentamidine, and foscarnet.⁴³

TABLE 50–6. Causes of Hypomagnesemia**Gastrointestinal**

Reduced intake
 Protein-calorie malnutrition
 Total parenteral nutrition without magnesium
 Prolonged parenteral fluid administration without magnesium
 Alcoholism

Reduced absorption
 Primary hypomagnesemia
 Malabsorption syndromes (e.g., tropical sprue, celiac disease, radiation enteritis or intestinal lymphectasia)
 Short-bowel syndrome (e.g., small-bowel resection or ileal bypass)
 Pancreatic insufficiency

Increased loss
 Excessive vomiting
 Prolonged nasogastric suction
 Excessive laxative use
 Intestinal and biliary fistulas
 Prolonged diarrhea (ulcerative colitis, Crohn's disease, or cancer of the colon)

Renal

Primary tubular disorders
 Primary renal magnesium wasting
 Bartter's syndrome
 Renal tubular acidosis
 Diuretic phase of acute tubular necrosis
 Postobstructive diuresis
 Postrenal transplant diuresis

Renal (continued)

Glomerulonephritis
 Pyelonephritis
 Nephrotic syndrome
 Drug-induced renal losses
 Aminoglycosides
 Amphotericin B
 Cyclosporine
 Diuretics
 Digitalis
 Cisplatin
 Hormone-induced renal losses
 Primary hyperparathyroidism
 Hyperthyroidism
 Aldosteronism
 "Hungry bone syndrome" after parathyroidectomy

Internal redistribution

Diabetic ketoacidosis
 Glucose, amino acid, or insulin administration
 Massive blood transfusion (citrate)
 Pancreatitis with lipidemia (magnesium soap)

Other

Excessive sweating and lactation
 Hypercalcemia and hypercalciuria
 Phosphate depletion
 Chronic alcoholism
 Extracellular fluid volume expansion

CLINICAL PRESENTATION

Because hypomagnesemia is often associated with a variety of other electrolyte abnormalities such as hypokalemia and hypocalcemia, it is difficult to ascribe specific clinical manifestations solely to magnesium deficiency. Hypocalcemia is one of the most prominent symptoms of hypomagnesemia.⁴⁰ Hypocalcemia is usually detected first because it is more commonly measured in clinical practice. The etiology of hypocalcemia is not entirely clear, but it is probably caused by decreased secretion of PTH, low 1,25-(OH)₂ vitamin D concentrations, and skeletal resistance to PTH.⁴⁰ As with hypokalemia, hypocalcemia accompanied by hypomagnesemia is most effectively treated with magnesium administration.

CLINICAL PRESENTATION OF HYPOMAGNESEMIA^{40,43,44}**GENERAL**

The dominant organ systems involved in hypomagnesemia include the neuromuscular and cardiovascular systems.

SYMPTOMS

The patient may complain of neuromuscular symptoms such as tetany, twitching, and generalized convulsions. Cardiac symptoms include heart palpitations.

SIGNS

Neuromuscular: Presence of Chvostek's sign, Trousseau's sign (see description below), tremor, and tetany.
 Cardiovascular: Cardiac arrhythmias (ventricular fibrillation, torsades de pointes, or digoxin-induced arrhythmias), sudden cardiac death, and hypertension may be present. ECG abnormalities include widened QRS complex and peaked T waves with mild hypomagnesemia; and prolonged PR interval, progressive widening of QRS complex, and flattened T waves with moderate to severe hypomagnesemia.

LABORATORY TESTS

Serum magnesium concentration less than 1.4 mEq/L. Serum potassium and calcium concentrations may also be low.

► TREATMENT: Hypomagnesemia**■ DESIRED OUTCOME**

The treatment goals in the management of hypomagnesemia are: (1) resolution of the corresponding signs and symptoms; (2) restoration of normal magnesium concentrations; (3) correction of concomitant electrolyte abnormalities; and (4) identifying and correcting the underlying cause of magnesium depletion.

■ GENERAL APPROACH TO TREATMENT

Magnesium supplementation can be given by the oral, intramuscular (IM), or IV route. Table 50–7 outlines one approach to the hypomagnesemic patient. The severity of the magnesium depletion and the presence of severe signs and symptoms should dictate the route of administration. Because IM administration is painful, it should be

TABLE 50–7. Guidelines for Treatment of Magnesium Deficiency in Adults

- 1. Serum magnesium <1 mEq/L (1.2 mg/dL) with life-threatening symptoms (seizure or arrhythmia)**

Day 1
2 g MgSO₄ (1 g MgSO₄ = 8.1 mEq Mg²⁺) mixed with 6 mL 0.9% NaCl in 10-mL syringe and administer IV push over 1 min
Follow with 0.5 mEq Mg²⁺/kg lean body weight IV infusion over 5–6 h, then 0.5 mEq Mg²⁺/kg lean body weight IV infusion over 17–18 h

Days 2–5
0.5 mEq Mg²⁺/kg lean body weight per day divided in maintenance IV fluids
- 2. Serum magnesium <1 mEq/L (1.2 mg/dL) without life-threatening symptoms**

Day 1
Total of 1 mEq Mg²⁺/kg lean body weight per day as continuous IV infusion, or divided and given IM every 4 h for five doses

Days 2–5
Total of 0.5 mEq Mg²⁺/kg lean body weight IV infusion per day as continuous IV infusion or divided and given IM every 6–8 h
- 3. Serum magnesium >1 mEq/L (1.2 mg/dL) and <1.5 mEq/L (1.8 mg/dL) without symptoms**

As in no. 2, above, or
Milk of magnesia 5 mL four times daily as tolerated, or
Magnesium-containing antacid 15 mL three times daily as tolerated, or
Magnesium oxide tablets 300 mg four times daily; increase to two tablets four times daily as tolerated

reserved for those patients with severe hypomagnesemia and limited venous access. IV bolus administration is associated with flushing, sweating, and a sensation of warmth; thus bolus administration should be avoided if possible. Even if severe magnesium depletion is present, approximately 50% of the administered dose is excreted in the urine. Consequently, magnesium replacement should be performed over 3 to 5 days, and continued supplementation should be provided for patients unable to eat and for those patients with continued magnesium wasting.

■ PHARMACOLOGIC THERAPY

Asymptomatic patients, or those patients with serum magnesium concentrations greater than 1 mEq/L (1.2 mg/dL), can be treated with oral supplements, such as magnesium-containing antacids or laxatives. However, as expected, diarrhea is the most common dose-limiting side effect of oral therapy, which may greatly reduce patient compliance. Moreover, many oral products contain very little magnesium, which necessitates frequent dosing, resulting in the increased risk of side effects.⁴⁵

In cases of severe magnesium depletion (serum levels <1 mEq/L), or if signs and symptoms are present regardless of the

serum level, IV magnesium should be administered. A 50% solution of MgSO₄ is available for injection in 2-mL or 10-mL ampules (4 mEq/mL). The 50% solution should be diluted to 20% before injection to prevent venous sclerosis and pain. Therapy should be continued until the signs and symptoms have completely resolved. In patients with renal insufficiency, the dose should be reduced by 50%.

■ EVALUATION OF THERAPEUTIC ENDPOINTS

Patients being treated for symptomatic severe hypomagnesemia should have their serum magnesium concentration monitored hourly until the serum concentration reaches 1.5 mEq/L and the symptoms resolve. At that point the serum magnesium concentration can be monitored every 6 to 12 hours for the first 24 hours while receiving magnesium supplementation. Once the magnesium concentration is stable in the normal range, a level can be obtained daily. It should be reiterated that it typically takes 3 to 5 days to fully replete total body magnesium stores. Patients receiving oral magnesium-containing antacids or supplements should be asked regularly about the occurrence of diarrhea.

HYPERMAGNESEMIA

EPIDEMIOLOGY

▶ **10** Hypermagnesemia (serum magnesium >2 mEq/L) is a rare occurrence. It is generally seen in the setting of advanced renal failure when magnesium intake exceeds the excretory capacity of the kidneys. The prevalence of hypermagnesemia in hospitalized patients has been estimated to range from approximately 6% to 9%.^{46,47} Elderly patients are prone to hypermagnesemia because of their reduced GFR

and because of their consumption of magnesium-containing antacids and vitamins.³⁷

ETIOLOGY AND PATHOPHYSIOLOGY

Because absolute magnesium excretion falls as GFR declines, serum magnesium concentrations rise in patients with moderate to severe renal insufficiency. Indeed, magnesium concentrations steadily rise as the GFR falls below 30 mL/min.⁴⁸ As long as the patient maintains

TABLE 50–8. Causes of Hypermagnesemia**Decreased renal excretion**

Lithium therapy
Hypothyroidism
Milk-alkali syndrome
Addison's disease
Viral hepatitis
Acute diabetic ketoacidosis

a normal diet, the serum magnesium concentration typically stabilizes at approximately 2.5 mEq/L. If patients with renal insufficiency are taking concomitant magnesium-containing antacids, the serum level can approach 6 mEq/L, a value associated with signs and symptoms of toxicity.³⁷ Critically ill patients with multiorgan system failure receiving enteral or parenteral nutrition are also prone to develop hypermagnesemia. Finally, the parenteral treatment of eclampsia with magnesium sulfate can lead to hypermagnesemia. Table 50–8 lists other causes of hypermagnesemia.

CLINICAL PRESENTATION

The signs and symptoms of hypermagnesemia reflect magnesium's action on the neuromuscular and cardiovascular systems.^{34,48,49} Although there is wide interpatient variability between magnesium concentration and symptoms, they are rare when the serum concentration is less than 4 mEq/L. Figure 50–3 provides a general guide to the clinical findings associated with hypermagnesemia.

**FIGURE 50–3.** Clinical findings associated with hypermagnesemia.**► TREATMENT: Hypermagnesemia****■ DESIRED OUTCOME**

The goals of therapy are to (1) reverse the neuromuscular and cardiovascular manifestations of hypermagnesemia; (2) decrease the magnesium concentration toward normal values; and (3) diagnose and reverse the underlying cause of hypermagnesemia.

■ PHARMACOLOGIC THERAPY

The treatment of hypermagnesemia depends on the presence of signs and symptoms, and degree of serum concentration elevation. Intravenous calcium in doses of 100 to 200 mg of elemental calcium directly antagonizes the neuromuscular and cardiovascular effects of hypermagnesemia. The clinical effect of calcium is immediate but the effect is transient; hence repeated intravenous doses of 100 to

200 mg elemental calcium can be administered hourly until the hypermagnesemic symptoms abate and the magnesium concentration is normalized. Supportive care with cardiac pacing, vasopressors, and mechanical ventilation may be necessary in life-threatening situations. In patients with adequate renal function, forced diuresis with saline and loop diuretics can promote magnesium elimination. An initial loop diuretic bolus of furosemide 40 mg intravenously can be used for immediate effects. Subsequent dosing can be determined based on the patient's clinical response. Patients with CKD may require long-term loop diuretic therapy to maintain adequate fluid and electrolyte balance. In patients with ESRD, hemodialysis with a magnesium-free dialysate should be emergently undertaken.

■ EVALUATION OF THERAPEUTIC ENDPOINTS

Patients who are receiving intravenous calcium salts for the treatment of severe, symptomatic hypermagnesemia should have their

serum magnesium concentration evaluated hourly until symptoms abate and the magnesium concentration falls below 4 mg/dL. Furthermore the patient should be observed on continuous ECG telemetry. In CKD patients who can produce urine, forced diuresis with saline and furosemide should reduce the serum magnesium concentration within 6 to 12 hours. Close monitoring of the urine output and physical exam

for signs of volume overload are important. For patients who have end-stage renal disease and receive dialysis, emergency hemodialysis will usually correct the hypermagnesemia within 4 hours. To prevent further episodes of hypermagnesemia, the patient should receive dietary education regarding foods and beverages that contain large quantities of magnesium.

ABBREVIATIONS

ACEI: angiotensin-converting enzyme inhibitor
 ARB: angiotensin receptor blocker
 ARF: acute renal failure
 CKD: chronic kidney disease
 ECG: electrocardiogram
 ESRD: end-stage renal disease
 NSAID: nonsteroidal anti-inflammatory drug
 PTH: parathyroid hormone
 SPS: sodium polystyrene sulfonate

ACID-BASE DISORDERS

Gary R. Matzke and Paul M. Palevsky

Learning Objectives and other resources can be found at www.pharmacotherapyonline.com.

KEY CONCEPTS

- 1 The kidney plays a central role in the regulation of acid-base homeostasis through the excretion or reabsorption of filtered HCO_3^- , the excretion of metabolic fixed acids and generation of new HCO_3^- .
- 2 Arterial blood gases, along with serum electrolytes, physical findings, medical and medication history, and the clinical condition of the patient, are the primary tools to determine the cause of an acid-base disorder and to design and monitor a course of therapy.
- 3 Metabolic acidosis and metabolic alkalosis are generated by a primary change in the serum bicarbonate concentration. In metabolic acidosis, bicarbonate is lost or a non-volatile acid is gained, whereas metabolic alkalosis is characterized by a gain in bicarbonate or a loss of nonvolatile acid.
- 4 Renal tubular acidosis refers to a group of disorders characterized by impaired tubular renal acid handling despite normal or near-normal glomerular filtration rates. These patients often present with hyperchloremic metabolic acidosis.
- 5 Respiratory compensation for a primary metabolic acidosis begins rapidly (within 15 to 30 minutes) but does not reach a steady state for 12 to 24 hours after the onset of metabolic acidosis.
- 6 Primary therapy of most acid-base disorders must include treatment or elimination of the underlying cause, not just correction of the pH and electrolyte disturbances.
- 7 Potassium supplementation is always necessary for patients with chronic metabolic acidosis, as the bicarbonaturia resulting from alkali therapy increases the renal potassium wasting.
- 8 Effective treatment of the underlying cause of some organic acidoses (e.g., ketoacidosis) can result in the regeneration of bicarbonate within hours, thus mitigating the need for alkali therapy.
- 9 Loss of gastric acid from vomiting or nasogastric suctioning is often responsible for the development of a metabolic alkalosis, characterized by hypochloremia and hyperbicarbonatemia.
- 10 Aggressive diuretic therapy may produce a metabolic alkalosis, and the accompanying hypokalemia may be serious.
- 11 The patient's response to volume replacement may be predicted by the urine chloride concentration, and permits the differential diagnosis of metabolic alkalosis.
- 12 Management of these disorders usually consists of treatment of the underlying cause of mineralocorticoid excess. In patients in whom the mineralocorticoid excess cannot be corrected, chronic pharmacologic therapy may be required.
- 13 In most cases of acute respiratory acidosis, such as following cardiopulmonary arrest, sodium bicarbonate therapy is not indicated and may be detrimental. Blood gas analysis should guide therapy.

Acid-base disorders are common, and often serious, disturbances that may result in significant morbidity and mortality. This chapter reviews the mechanisms responsible for the maintenance of acid-base balance and the laboratory analyses that aid clinicians in their assessment of acid-base disorders. The pathophysiology of the four primary acid-base disturbances is presented, the therapeutic options are critiqued, and guidelines for the achievement of the desired therapeutic outcomes are presented. Because many drugs affect acid-base homeostasis and many acid-base abnormalities are potentially preventable, clinicians must anticipate drug-related problems in order to avoid or minimize the clinical consequences, and when necessary design appropriate treatment regimens.

ACID-BASE CHEMISTRY

An acid is a substance that can donate protons (hydrogen ions, H^+):

A base is a substance that can accept protons (hydrogen ions):

The acid-base pairs commonly encountered in clinical practice are listed in Table 51-1.

The acidity of body fluids is quantified in terms of the hydrogen ion concentration. By convention, the degree of acidity is expressed

TABLE 51–1. Acid-Base Pairs

| | |
|-----------------------------|---|
| Carbonic acid/bicarbonate | $\text{H}_2\text{CO}_3/\text{HCO}_3^-$ |
| Monobasic/dibasic phosphate | $\text{H}_2\text{PO}_4/\text{HPO}_4^-$ |
| Ammonium/ammonia | $\text{NH}_4^+/\text{NH}_3$ |
| Lactic acid/lactate | $\text{H}_6\text{C}_3\text{O}_2/\text{H}_5\text{C}_3\text{O}_2^-$ |

as pH, or the negative logarithm (base 10) of the hydrogen ion concentration. Thus hydrogen ion concentration and pH are inversely related. Normally, the pH of blood is maintained at 7.40 ($[\text{H}^+]$ of 4×10^{-8} M) with a range of 7.35 to 7.45. A pH of less than 6.7 ($[\text{H}^+]$ of 2×10^{-7} M), representing a fivefold increase in hydrogen ion concentration, or greater than 7.7 ($[\text{H}^+]$ of 2×10^{-8} M), representing a 50% decrease in hydrogen ion concentration, are considered incompatible with life.

The hydrogen ion concentration in blood may not be indicative of that in other body compartments. For example, the pH within cells, within the cerebrospinal fluid, or on the surface of bone may all be altered without causing an alteration in blood pH.¹ Recognizing this caveat, the acid-base status of the body is usually analyzed based on measurement of blood pH. Alterations in blood pH serve as the basis for the diagnosis of acid-base disorders.

Because the dissociation of acid-base pairs is an equilibrium reaction, the relationship between hydrogen ion concentration or pH and the relative concentrations of the acid and base can be described mathematically in terms of the dissociation constant for the acid-base buffer pair. When expressed as a logarithmic relationship, where pK is the negative logarithm of the dissociation constant *K*, this is known as the Henderson-Hasselbalch equation:

$$\text{pH} = \text{pK} + \log ([\text{base}]/[\text{acid}])$$

BUFFERS

The ability of a weak acid and its corresponding anion (base) to resist change in the pH of a solution upon the addition of a strong acid or base is referred to as *buffering*. An acid-base pair is most efficient in functioning as a buffer at a pH close to its pK. The principal extracellular buffer is the carbonic acid/bicarbonate ($\text{H}_2\text{CO}_3/\text{HCO}_3^-$) system. Other physiologic buffers include plasma proteins, hemoglobin, and phosphates. Because the isohydric principle requires that all buffer systems remain in chemical equilibrium, the complex buffering of biologic fluids can be analyzed based on a single buffer pair.

The carbonic acid/bicarbonate buffer system plays a unique role in acid-base homeostasis. In addition to being the most abundant extracellular buffer, the components of this buffer pair are under dynamic regulation by the body. In the presence of carbonic anhydrase, carbonic acid, $[\text{H}_2\text{CO}_3]$ is in equilibrium with carbon dioxide (CO_2) gas. Changes in ventilation that alter the partial pressure of CO_2 (PCO_2) in the blood regulates the carbonic acid level in the blood. The bicarbonate concentration is independently regulated by the kidney. Because the pK for the carbonic acid/bicarbonate system is 6.1, the relationship between pH, carbonic acid, and bicarbonate concentrations can be described by the Henderson-Hasselbalch equation. The concentration of carbonic acid is directly proportional to the amount of CO_2 dissolved in blood, which is equal to the product of PCO_2 and its solubility in physiologic fluids, ($\text{PCO}_2 \times 0.03$). This term can therefore be substituted into the equation below in place of $[\text{H}_2\text{CO}_3]$.

$$\text{pH} = 6.1 + \log ([\text{HCO}_3^-]/[\text{H}_2\text{CO}_3])$$

$$\text{pH} = 6.1 + \log ([\text{HCO}_3^-]/(\text{PCO}_2 \times 0.03))$$

Thus, hydrogen ion concentration and pH are determined not by the absolute amounts of bicarbonate and PCO_2 , but by their ratio.¹ Under normal physiologic conditions, the kidneys maintain the serum bicarbonate at about 24 mEq/L, while the lungs maintain the PCO_2 at approximately 40 mm Hg. The normal physiologic pH is thus 7.4:

$$\text{pH} = 6.1 + \log [24/(0.03 \times 40)]$$

$$\text{pH} = 6.1 + 1.3 = 7.4$$

If, in response to an acid load, the serum bicarbonate concentration were to fall to 12 mEq/L, the predicted pH would be:

$$[\text{HCO}_3^-] = 12 \text{ mEq/L}$$

$$\text{PCO}_2 = 40 \text{ mm Hg}$$

$$\text{pH} = 6.1 + \log [12/(0.03 \times 40)]$$

$$\text{pH} = 6.1 + 1.0 = 7.1$$

However, the normal respiratory response to an acid load is hyperventilation. As a result, if the PCO_2 fell to approximately 26 mm Hg, the change in pH would be less:

$$[\text{HCO}_3^-] = 12 \text{ mEq/L}$$

$$\text{PCO}_2 = 26 \text{ mm Hg}$$

$$\text{pH} = 6.1 + \log [12/(0.03 \times 26)]$$

$$\text{pH} = 6.1 + 1.19 = 7.29$$

Thus, the physiologic regulation of both PCO_2 and $[\text{HCO}_3^-]$ permit the carbonic acid/bicarbonate system to provide more effective buffering of the extracellular fluids than could be achieved on the basis of chemical buffering alone.

REGULATION OF ACID-BASE HOMEOSTASIS

Cellular metabolism results in the production of large quantities of hydrogen that need to be excreted in order to maintain acid-base balance. In addition, small amounts of acid and alkali are also presented to the body through the diet. The bulk of acid production is in the form of CO_2 , from the metabolism of carbohydrates, proteins, and lipids. When respiratory function is normal, the amount of CO_2 produced metabolically is equal to the amount lost by respiration, and the blood CO_2 concentration remains constant. The average adult produces approximately 15,000 mmol of CO_2 each day from the catabolism of carbohydrate, protein, and fat.²

Digestion of dietary substances and tissue metabolism also results in the production of nonvolatile acids. These acids are derived primarily from the sulfur-containing amino acids cysteine and methionine, as well as from ingested sulfur. In addition, phosphates are generated from the metabolism of proteins and phospholipids. Neutral substances such as glucose may also be incompletely metabolized to intermediates, such as lactic and pyruvic acid, and fatty acids may be incompletely metabolized to acetoacetic acid and β -hydroxybutyric acid. These dietary and metabolic fixed acids are excreted, primarily by the kidney, to maintain acid-base homeostasis. On average, daily fixed acid excretion is approximately 0.8 mEq/kg per day.³

Three mechanisms collectively maintain acid-base balance: extracellular buffering, ventilatory regulation of carbon dioxide elimination, and renal regulation of hydrogen ion and bicarbonate excretion. Extracellular buffering is the body's first and fastest defense against a sudden increase in hydrogen ion concentration. Hyperventilation will then result in a decrease in PCO_2 , returning blood pH toward normal. Finally, the kidney will excrete the excess hydrogen ion, and return acid-base balance to normal.

EXTRACELLULAR BUFFERING

The body's buffering system can be divided into three components: bicarbonate/carbonic acid, proteins, and phosphates. The bicarbonate buffer is the most important of the body's buffers, because (1) there is more bicarbonate present in the extracellular fluid (ECF) than any other buffer component; (2) the supply of carbon dioxide is unlimited; and (3) the acidity of ECF can be regulated by controlling either the bicarbonate concentration or the PCO_2 .

Carbonic acid represents the respiratory component of the buffer pair because its concentration is directly proportional to the PCO_2 , which is determined by ventilation. Bicarbonate represents the metabolic component because the kidney may alter its concentration by reabsorption, generating new bicarbonate, or altering elimination.⁴ The bicarbonate buffer system easily adapts to changes in acid-base status by alterations in ventilatory elimination of acid (PCO_2) and/or renal elimination of base (HCO_3^-).

The phosphate buffer system consists of serum inorganic phosphate (3.5 to 5 mg/dL), intracellular organic phosphate, and calcium phosphate in bone. Extracellular phosphate is present only in low concentrations, so its usefulness as a buffer is limited; however, as an intracellular buffer, phosphate is more useful. Calcium phosphate in bone is relatively inaccessible as a buffer, but prolonged metabolic acidosis will result in the release of phosphate from bone.

Intracellular and extracellular proteins also act as buffering systems. The charged side chains of amino acids provide the buffering action. Because the concentration of protein is much greater intracellularly than extracellularly, protein is much more important as an intracellular buffer.

RESPIRATORY REGULATION

The second mechanism for maintenance of acid-base homeostasis is control of ventilation. Both the rate and depth of ventilation can be varied to allow for excretion of CO_2 generated by diet and tissue metabolism. Medullary chemoreceptors in the brain stem sense changes in PCO_2 and in pH and modulate the control of breathing. Increasing minute ventilation, by increasing either or both respiratory rate or tidal volume, will increase CO_2 excretion and decrease the blood PCO_2 . Conversely, decreasing minute ventilation decreases CO_2 excretion and increases blood PCO_2 . This system rapidly adjusts, within minutes, to changes in acid-base balance.²

RENAL REGULATION

Because bicarbonate is a small ion, it is freely filtered at the glomerulus. The bicarbonate load delivered to the nephron is approximately 4,500 mEq/day. To maintain acid-base balance, this entire filtered load must be reabsorbed. Bicarbonate reabsorption occurs primarily in the proximal tubule (Fig. 51-1). In the tubular lumen, filtered bicarbonate combines with hydrogen ion secreted by the apical $Na^+ - H^+$ -exchanger to form carbonic acid. The carbonic acid is rapidly broken down to CO_2 and water by carbonic anhydrase located on the luminal surface of the brush border membrane. The CO_2 then diffuses into the proximal tubular cell, where it reforms carbonic acid in the presence of intracellular carbonic anhydrase. The carbonic acid dissociates to form hydrogen ion, that can again be secreted into the tubular lumen, and bicarbonate that exits the cell across the basolateral membrane and enters the peritubular capillary.

Excretion of metabolic fixed acids and generation of new HCO_3^- is achieved through renal ammoniogenesis and distal tubular hydrogen ion secretion. Ammoniogenesis plays a critical role in acid-base homeostasis, with ammonium (NH_4^+) excretion comprising approxi-

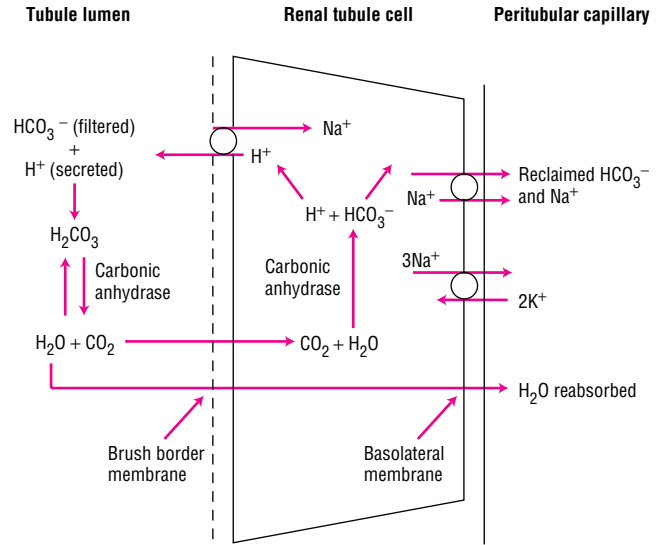

FIGURE 51-1. Proximal tubular bicarbonate reabsorption. In the tubular lumen, filtered bicarbonate combines with hydrogen ion secreted by an apical $Na^+ - H^+$ -exchanger to form carbonic acid. The carbonic acid is rapidly broken down to CO_2 and water by carbonic anhydrase located on the luminal surface of the brush border membrane. The CO_2 then diffuses into the proximal tubular cell, where it reforms carbonic acid in the presence of intracellular carbonic anhydrase. The carbonic acid dissociates to form hydrogen ion, that can again be secreted into the tubular lumen, and bicarbonate that exits the cell across the basolateral membrane and enters the peritubular capillary.

mately 50% of renal net acid excretion. Ammonium is generated from the deamination of glutamine in the proximal tubule. For each ammonium ion excreted in the urine, one bicarbonate ion is regenerated and returned to the circulation.⁵

Distal tubular hydrogen ion secretion accounts for the remaining 50% of net acid excretion (Fig. 51-2). In the distal tubular cell, CO_2 combines with water in the presence of intracellular carbonic anhydrase to form carbonic acid, which dissociates to H^+ and HCO_3^- . The

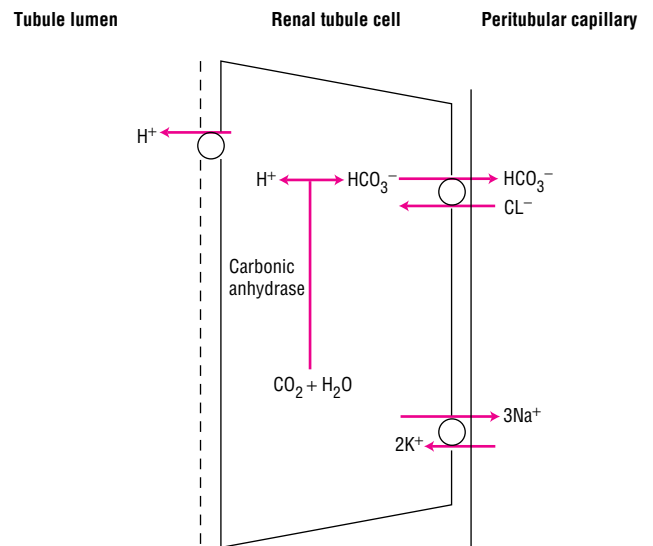

FIGURE 51-2. Collecting duct acid excretion. Hydrogen ion and bicarbonate are generated intracellularly from CO_2 and water, in the presence of intracellular carbonic anhydrase. The hydrogen ion is actively secreted into the tubular lumen by H^+ -ATPases located in the apical (luminal) membrane. Bicarbonate exits the cell across the basolateral membrane and enters the peritubular capillary.

TABLE 51–2. Interpretation of Simple Acid-Base Disorders

| Acid-Base Disorder | pH | Primary Disturbances | Compensation |
|--------------------|----------|---------------------------|---------------------------|
| Acidosis | | | |
| Respiratory | Decrease | Increase PaCO_2 | Increase HCO_3^- |
| Metabolic | Decrease | Decrease HCO_3^- | Decrease PaCO_2 |
| Alkalosis | | | |
| Respiratory | Increase | Decrease PaCO_2 | Decrease HCO_3^- |
| Metabolic | Increase | Increase HCO_3^- | Increase PaCO_2 |

H^+ is actively transported into the tubular lumen by a H^+ -ATPase. The bicarbonate exits the cell across the basolateral membrane and enters the circulation.⁵

ACID-BASE DISTURBANCES

Alterations in blood pH are designated by the suffix “-emia”; *acidemia* is an arterial blood pH <7.35 and *alkalemia* is an arterial blood pH >7.45 . The pathophysiologic processes that result in alterations in blood pH are designated by the suffix “-osis.” These disturbances are classified as either metabolic or respiratory in origin. In metabolic acid-base disorders, the primary disturbance is in the plasma bicarbonate concentration. Metabolic acidosis is characterized by a decrease in the plasma bicarbonate concentration while in metabolic alkalosis the plasma bicarbonate concentration is increased. Respiratory acid-base disorders are caused by alterations in alveolar ventilation that produce corresponding changes in the arterial carbon dioxide tension (PaCO_2). In respiratory acidosis, the PaCO_2 is elevated; in respiratory alkalosis it is decreased. Each disturbance has a compensatory (secondary) response which attempts to correct the $[\text{HCO}_3^-]:\text{PaCO}_2$ ratio toward normal and mitigate the change in pH (Table 51–2). Although the time course of the respiratory compensatory responses to metabolic disturbances is rapid, the metabolic compensation for respiratory disturbances is slow. As a result, respiratory disturbances are characterized as acute (minutes to hours in duration), indicating that there has not been sufficient time for metabolic compensation, or chronic (days), indicating sufficient time for metabolic compensation has elapsed.

CLINICAL ASSESSMENT OF ACID-BASE STATUS

2 Blood gases are measured to determine the patient’s oxygenation and acid-base status. Under normal circumstances, there is

TABLE 51–3. Normal Blood Gas Values

| | Arterial Blood | Mixed Venous Blood |
|------------------|------------------|--------------------|
| pH | 7.40 (7.35–7.45) | 7.38 (7.33–7.43) |
| PO_2 | 80–100 mm Hg | 35–40 mm Hg |
| Sao_2 | 95% | 70%–75% |
| PCO_2 | 35–45 mm Hg | 45–51 mm Hg |
| HCO_3^- | 22–26 mEq/L | 24–28 mEq/L |

HCO_3^- , bicarbonate; PCO_2 : partial pressure of carbon dioxide; PO_2 : partial pressure of oxygen; Sao_2 , saturation of arterial oxygen.

no clinically significant difference in pH between arterial and mixed venous blood. Arterial samples are designated with the letter “a” (e.g., PaO_2 and PaCO_2), while mixed venous samples are labeled with the letter “v” or not labeled (e.g., PvO_2 and PvCO_2). The normal values for arterial and venous blood gases are shown in Table 51–3. Arterial blood provides the added information of how well the lungs are oxygenating the blood (an accurate measurement of partial oxygen pressure [PaO_2]). Arterial blood rather than venous blood should be used whenever possible because venous blood obtained from an extremity may provide misleading information. If metabolism in the extremity is altered by hypoperfusion, exercise, infection, or some other cause, the differences between arterial and venous blood can be dramatic. The venous pH and PCO_2 during cardiopulmonary resuscitation, may be significantly lower and higher, respectively than the arterial pH and arterial PCO_2 . This indicates a severe tissue acidosis from CO_2 accumulation due to hypoperfusion.

ANALYSIS OF ARTERIAL BLOOD GAS DATA

Arterial blood gases provide an assessment of the patient’s acid-base status. Low pH values (<7.35) indicate an acidemia, whereas high pH values (>7.45) indicate an alkalemia (Fig. 51–3). In a metabolic acidosis, the pH is decreased in association with a decreased serum bicarbonate concentration and a compensatory fall in PaCO_2 . In a respiratory acidosis, the pH is decreased; the PaCO_2 , however, is elevated. The serum bicarbonate concentration is variable, depending on whether it is an acute disturbance (minimal increase in serum bicarbonate) or a chronic respiratory acidosis (substantial increase in serum bicarbonate). In a metabolic alkalosis, the pH is elevated in association with an increased bicarbonate concentration and a compensatory rise in PaCO_2 . In respiratory alkalosis, the pH is also elevated; the PaCO_2 , however, is decreased. As with respiratory acidosis, the metabolic compensation is variable, with a minimal decrease in serum bicarbonate in acute respiratory alkalosis and a larger decrease in $[\text{HCO}_3^-]$ in chronic respiratory alkalosis.

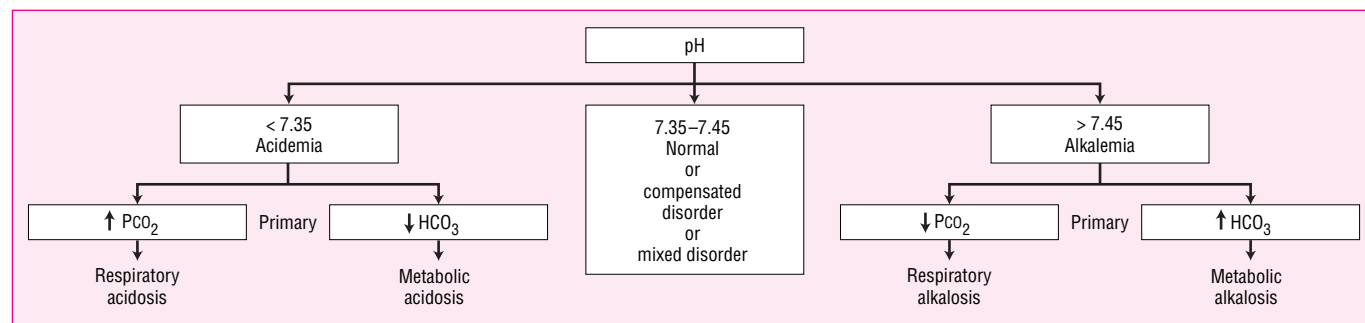

**FIGURE 51–3.** Analysis of arterial blood gases.

TABLE 51-4. Guidelines for Initial Interpretation of Acid-Base Disorders

| | |
|-------------------------------|---|
| Metabolic acidosis | P_{aCO_2} (in mm Hg) should fall by 1–1.5 times the fall in plasma $[HCO_3^-]$ (in mEq/L) |
| Metabolic alkalosis | P_{aCO_2} (in mm Hg) should increase by 0.25–1 times the rise in plasma $[HCO_3^-]$ (in mEq/L) |
| Acute respiratory acidosis | The plasma $[HCO_3^-]$ should rise by 0.1 times the increase in $P_{aCO_2} \pm 3$ |
| Acute respiratory alkalosis | The plasma $[HCO_3^-]$ should fall by 0.1–0.3 times the decrease in P_{aCO_2} but usually not to less than 18 mEq/L |
| Chronic respiratory acidosis | The plasma $[HCO_3^-]$ should rise by 0.4 times the increase in $P_{aCO_2} \pm 4$ |
| Chronic respiratory alkalosis | The plasma $[HCO_3^-]$ should fall by 0.2–0.5 times the decrease in P_{aCO_2} but usually not to less than 14 mEq/L |

Adapted from Shapiro and Kaehny⁴.

The degree of expected compensatory response for each primary disturbance is depicted in Table 51-4. If the observed compensatory response is substantially different than that predicted by these empiric relationships, a mixed acid-base disturbance (i.e., more than one primary disorder) may be present. Nomograms, such as the one shown in Fig. 51-4, may also be used to differentiate between the various acid-base disorders.^{4,6} In this nomogram, each pathologic acid-base disorder, together with the appropriate range of in vivo physiologic compensation, is represented as a shaded band. Blood gas values—serum bicarbonate, pH, and carbon dioxide tension—falling within a band usually represent a single disturbance; however, a mixed disturbance may occasionally present in this way. Acid-base values falling outside any band almost certainly represent a mixed acid-base disturbance.⁶

When arterial blood gases differ significantly from those expected on the basis of the patient's clinical condition and previous laboratory determinations, additional venous blood samples should

FIGURE 51-4. Acid-base nomogram. (Reprinted with permission from Arbus.⁶)

be drawn to assess plasma electrolyte concentrations. The bicarbonate calculated from the patient's P_{aCO_2} and pH of the blood gas should be compared with the measured total CO_2 content (the amount of CO_2 gas extractable from plasma, consisting of HCO_3^- , H_2CO_3 , and PCO_2). Ordinarily, the blood gas bicarbonate value is approximately 1 to 2 mEq/L less than total CO_2 content.³ If these values do not correspond, the results should be interpreted with caution because the difference may reflect an error in the blood collection or storage of the sample, or in the calibration of the blood gas analyzer.

METABOLIC ACID-BASE DISORDERS

METABOLIC ACIDOSIS

PATHOPHYSIOLOGY

3 Metabolic acidosis is characterized by a decrease in pH as the result of a primary decrease in serum bicarbonate concentration. This can result from the buffering (consumption of HCO_3^-) of an exogenous acid, an organic acid accumulating because of a metabolic disturbance (e.g., lactic acid or ketoacids), or the progressive accumulation of endogenous acids secondary to impaired renal function (e.g., phosphates and sulfates).⁹ The serum HCO_3^- can also be decreased as the result of a loss of bicarbonate-rich body fluids (e.g., diarrhea, biliary drainage, or pancreatic fistula) or occur secondary to the rapid administration of non-alkali-containing intravenous fluids (dilutional acidosis).

The serum anion gap (SAG), as defined below, may be used to infer whether an organic or mineral acidosis is present.

$$SAG = [Na^+] - [Cl^-] - [HCO_3^-]$$

To maintain electroneutrality, the total concentration of cations in the serum must equal the total concentration of anions.

$$[Na^+] + [UCs] = ([Cl^-] + [HCO_3^-]) + [UAs]$$

The cation concentration is equal to the sodium concentration plus that of "unmeasured" cations (UCs), predominantly magnesium, calcium, and potassium. The anion concentration is equal to the concentrations of chloride, bicarbonate, and "unmeasured" anions (UAs), including proteins, sulfates, phosphates, and organic anions. Therefore, as the result of the combination of the two equations above the SAG can be expressed as:

$$SAG = [UAs] - [UCs]$$

The normal SAG is approximately 9 mEq/L, with a range of 3 to 11 mEq/L. This value is lower than the value of 12 mEq/L cited in the literature in the past because of changes in the instrumentation for measurement of serum electrolytes during the past decade.⁸ Increases in the anion gap to values in excess of 17 to 20 mEq/L are indicative of the accumulation of unmeasured anions in ECF.

These unmeasured anions are generated as the result of the consumption of HCO_3^- by endogenous organic acids such as lactic acid, acetoacetic acid, or β -hydroxybutyric acid or from the ingestion of toxins such as methanol or ethylene glycol. The degree of elevation in the SAG is dependent on the clearance of the anion, as well as the multiple factors that influence HCO_3^- concentrations. Thus the SAG is a relative rather than an absolute indication of the cause of metabolic acidosis. The SAG may also be elevated in the metabolic acidosis due to renal failure, as the result of the accumulation of various organic anions, phosphates, and sulfates.

TABLE 51–5. Common Causes of Metabolic Acidosis

| Increased Serum Anion Gap | Normal Serum Anion Gap/ Hyperchloremic States |
|-------------------------------------|---|
| Alcoholic ketoacidosis | Acid ingestion (hydrochloric acid or ammonium chloride) |
| Diabetic ketoacidosis | Carbonic anhydrase inhibitors |
| Lactic acidosis | Cholestyramine |
| Renal failure (acute or chronic) | Diarrhea |
| Methanol ingestion | Dilutional acidosis |
| Ethylene glycol ingestion | Gastrointestinal disorders |
| Salicylate overdose | Pancreatic fistula |
| Starvation | Potassium-sparing diuretic |
| | Renal tubular acidosis |
| | Ureterosigmoidostomy, ileostomy |

In hyperchloremic metabolic acidosis, bicarbonate losses from the ECF are replaced by chloride and the SAG remains normal. This decrease in bicarbonate results from losses from the gastrointestinal tract, dilution of bicarbonate in the ECF space by the addition of sodium chloride solutions, or the addition of chloride-containing acids to the ECF. Common causes of metabolic acidosis with an increased or a normal SAG are listed in Table 51–5.

HYPERCHLOREMIC METABOLIC ACIDOSIS

Hyperchloremic metabolic acidosis may result from increased gastrointestinal bicarbonate loss, renal bicarbonate wasting, impaired renal acid excretion, or exogenous acid gain. Gastrointestinal disorders such as diarrhea, biliary drainage, and pancreatic fistula may result in the loss of large volumes of bicarbonate-containing fluids, with diarrhea being the most common cause for hyperchloremic metabolic acidosis. Severe diarrhea can lead to a daily loss of 5 to 10 L of fluid containing 100 to 140 mEq/L of sodium, 20 to 40 mEq/L of potassium, 80 to 100 mEq/L of chloride, and 30 to 50 mEq/L of bicarbonate.⁴ Patients who have undergone ureteral diversion into the sigmoid colon or isolated ileal loop may also develop a hyperchloremic metabolic acidosis. In these patients, chloride is reabsorbed and the bicarbonate secreted by the gastrointestinal epithelial cells while urine retained in the colon or bowel loop results in a net loss of bicarbonate. Hyperchloremic metabolic acidosis caused by renal bicarbonate wasting is the defining disturbance in proximal renal tubular acidosis and is a complication of therapy with carbonic anhydrase inhibitors. During the treatment of diabetic ketoacidosis, renal losses of β -hydroxybutyrate and acetoacetate, which would otherwise be metabolized to yield bicarbonate, may contribute to the development of hyperchloremic metabolic acidosis. Impaired renal acid excretion as a result of distal tubular dysfunction characterizes the distal renal tubular acidoses. Impaired renal acid excretion is also characteristic of moderate to severe renal insufficiency. Initially, the metabolic acidosis of renal insufficiency is hyperchloremic, progressing to an anion-gap acidosis as the renal insufficiency worsens and sulfates, phosphates, and other anions accumulate. Hyperchloremic metabolic acidosis may also result from the exogenous administration of acid as hydrochloric acid or ammonium chloride or the unbuffered administration of acid salts of amino acids in parenteral nutrition fluids.

RENAL TUBULAR ACIDOSIS

4 Renal tubular disorders may involve the proximal tubule, with a resultant failure to reabsorb filtered bicarbonate, or affect acid

excretion in the distal tubule. The distal renal tubular acidoses (RTAs) are the most common and are all characterized by impaired net acid excretion. The distal RTAs are subdivided into those that are associated with hypokalemia (type I) and those associated with hyperkalemia (type IV). Patients with classic distal (type I) RTA have impaired H^+ ion secretion, and are unable to excrete the daily acid load necessary to maintain acid-base balance.⁴ These patients are unable to maximally acidify their urine (i.e., attain urine pH of <5.5), even in the face of an acid challenge. Type I RTA may be the result of a primary tubular defect or develop secondary to a wide variety of disorders including hypercalcemia, multiple myeloma, systemic lupus erythematosus, Sjögren's syndrome, sickle-cell disease, and renal transplant rejection, or following the administration of amphotericin B or ingestion of toluene. The primary form of this disorder usually occurs in children and can result in severe acidosis, slowed growth, nephrocalcinosis, and kidney stones.^{9,10} In adults, clinical complications include osteomalacia, nephrocalcinosis, and recurrent kidney stones. The hypokalemia associated with classic distal (type I) RTA results from secondary hypoaldosteronism associated with volume depletion. The renal potassium wasting decreases considerably when bicarbonate therapy is begun.

The hyperkalemic distal (type IV) RTAs are a heterogeneous group of disorders characterized by hypoaldosteronism or generalized distal tubule defects. The most common form of type IV RTA is hyporeninemic hypoaldosteronism. This syndrome is most commonly associated with mild renal insufficiency caused by diabetic nephropathy, but may also be seen in a variety of other disorders, including chronic interstitial nephritis, sickle-cell disease, human immunodeficiency virus (HIV) nephropathy, and obstructive uropathy. The clinical presentation of this syndrome is often exacerbated by pharmacologic therapy with agents that can interfere with the renin-angiotensin-aldosterone axis, such as β -adrenergic blockers, angiotensin-converting enzyme inhibitors, angiotensin receptor blockers, and nonsteroidal anti-inflammatory drugs. Heparin may induce the syndrome by inhibiting adrenal aldosterone biosynthesis. Patients with this form of RTA are able to maximally acidify their urine (urine pH <5.5).⁹ The primary defect in acid excretion is impaired ammoniogenesis caused by mild renal insufficiency. Hyperaldosteronism predisposes to the development of hyperkalemia, which results in further impairment of ammoniogenesis. Treatment to control the hyperkalemia is usually sufficient to reverse the metabolic acidosis, and mineralocorticoid replacement is frequently unnecessary.

Hyperkalemic distal (type IV) RTA resulting from generalized distal tubule defects is less common than hyporeninemic hypoaldosteronism, but is more common than classic distal (type I) RTA. Patients with this defect have impaired tubular potassium secretion in addition to impaired urinary acidification (urine pH >5.5 despite acidemia or acid loading). Urinary obstruction is the most frequent cause of this disorder, which may also be associated with sickle-cell nephropathy, systemic lupus erythematosus, HIV nephropathy, analgesic abuse nephropathy, amyloidosis, renal transplant rejection, and chronic cyclosporine nephrotoxicity.

Proximal (type II) RTA is characterized by defects in proximal tubular reabsorption of bicarbonate. Normally, more than 85% of filtered bicarbonate is reabsorbed in the proximal tubule. Defects in proximal tubular bicarbonate reabsorption result in increased delivery of bicarbonate to the distal nephron, which has a limited capacity for bicarbonate reabsorption. As a result, at a normal serum bicarbonate concentration, the filtered bicarbonate load is incompletely reabsorbed, and is lost in the urine. As the serum bicarbonate concentration falls, the filtered load of bicarbonate is proportionately decreased. A new equilibrium is established in which the kidney is

able to reabsorb the filtered bicarbonate load, albeit at a reduced serum bicarbonate concentration. Thus patients with proximal RTA present with a chronic, nonprogressive hyperchloremic metabolic acidosis. These patients are able to acidify their urine in response to an acid load, but develop bicarbonaturia at a reduced serum bicarbonate concentration following bicarbonate loading. The impaired bicarbonate reabsorption results in salt wasting and secondary hyperaldosteronism. Hypokalemia, which may be severe, develops as a result of the hyperaldosteronism and bicarbonaturia.^{4,9} Unlike patients with classic distal (type I) RTA, the hyperkalemia in proximal RTA is exacerbated by alkali replacement. Proximal RTA may develop as an isolated defect or it may be associated with generalized proximal tubular dysfunction (Fanconi's syndrome), with impaired proximal tubular glucose, phosphate, and amino acid reabsorption. Proximal RTA usually presents as an acquired disorder, secondary to a variety of diseases (amyloidosis, multiple myeloma, or nephrotic syndrome) or exposure to toxins (lead, cadmium, mercury, or outdated tetracyclines). Pharmacologic therapy with carbonic anhydrase inhibitors produces an iatrogenic form of proximal RTA.

ELEVATED ANION GAP METABOLIC ACIDOSIS

Metabolic acidosis with an increased SAG commonly results from increased endogenous organic acid production. In lactic acidosis, lactic acid accumulates as a by-product of anaerobic metabolism. Accumulation of the ketoacids β -hydroxybutyric acid and acetoacetic acid defines the ketoacidosis of uncontrolled diabetes mellitus, alcohol intoxication, and starvation (see Table 51–5). In advanced renal failure, accumulation of phosphate, sulfate, and organic anions is responsible for the increased SAG, which is usually less than 24 mEq/L.¹¹ The severe metabolic acidosis seen in myoglobinuric acute renal failure caused by rhabdomyolysis may be caused by the metabolism of large amounts of sulfur-containing amino acids released from myoglobin.

The presence of mild elevations in the SAG cannot be automatically attributed to the presence of a high SAG metabolic acidosis. Elevations in the SAG are commonly seen in hospitalized patients, especially those who are critically ill.¹² A variety of factors may contribute to this nonspecific elevation in the SAG, including the presence of alkalemia, which increases the anionic charge of albumin and other plasma proteins. The usefulness of the SAG as a marker of acid-base status is dependent on proper interpretation of a patient's clinical status.^{8,13} Despite these limitations, when the SAG exceeds 20 to 25 mEq/L a significant organic acidosis is likely to be present.

High anion gap metabolic acidosis may develop in many clinical settings, including uncontrolled diabetes mellitus (see Chap. 72), alcohol intoxication (see Chaps. 37 and 65), and starvation (see Chap. 62). Toxic ingestions of methanol, ethylene glycol, and salicylates are also associated with high anion gap metabolic acidosis (see Chap. 10). The mechanisms responsible for the development of acidosis in these settings are diverse.

Lactic Acidosis

Lactic acidosis is one of the most common causes of high SAG metabolic acidosis. Lactic acid is the end product of anaerobic metabolism of glucose (glycolysis). In normal individuals, lactic acid derived from pyruvate enters the circulation in small amounts and is promptly removed by the liver. In the liver, and to a lesser extent in the kidney, lactic acid is reoxidized to pyruvic acid, which is then metabolized to CO₂ and H₂O. The normal plasma lactate concentration in healthy subjects is approximately 1 mEq/L.^{7,14} The diagnosis of lactic acidosis should be considered in all patients with metabolic acidosis

TABLE 51–6. Causes of Lactic Acidosis

Primary decrease in tissue oxygenation

- Shock
- Severe anemia
- Congestive heart failure
- Asphyxia
- Carbon monoxide poisoning

Deranged oxidative metabolism

- Diabetes mellitus
- Liver failure
- Malignancy
- Seizures
- Medications (iron, isoniazid, metformin, or salicylates)
- Methanol, ethanol, or ethylene glycol
- Disorders associated with inborn errors of metabolism

associated with an increased SAG. Lactic acidosis is considered to be present when lactate concentrations exceed 4 to 5 mEq/L in an acidemic patient.

Classically, lactic acidosis has been differentiated into disorders associated with tissue hypoxia (type A lactic acidosis) and disorders associated with deranged oxidative metabolism (type B lactic acidosis), although the distinction between them is blurred (Table 51–6). The etiologies of lactic acidosis can also be categorized on the basis of changes in lactate production and/or utilization.^{4,15} Metabolic disturbances can result in increased tissue pyruvate production or impaired utilization, with proportional increases in lactate concentrations. Increased lactate production is more commonly associated with alterations in tissue redox state, resulting in preferential conversion of pyruvate to lactate. During anaerobic metabolism, reduced nicotinamide adenine dinucleotide accumulates, driving the conversion of pyruvate to lactate and increasing the lactate:pyruvate ratio. States of enhanced metabolic activity (e.g., grand mal seizures, strenuous exercise, or hyperthermia), decreased tissue oxygen delivery (e.g., severe anemia, hypoxia, circulatory shock, or carbon monoxide poisoning) or impaired oxygen utilization (e.g., cyanide toxicity) all are associated with lactic acidosis. Impaired hepatic clearance of lactate, as seen in hypoperfusion states, liver failure, and alcohol intoxication, may also result in lactic acidosis.

Cardiovascular and septic shock, with resultant tissue hypoperfusion, are the most common causes of lactic acidosis. Poor tissue perfusion and hypoxia influence enzymatic pyruvate and lactate metabolism to stimulate anaerobic glycolysis and to decrease lactate utilization. This leads to hyperlactatemia and lactic acidosis. The mortality rate of this type of lactic acidosis may be as high as 80% and correlates with the degree of hyperlactatemia.

Lactic acidosis associated with liver disease, drugs (e.g., metformin), toxins, and congenital enzyme deficiency may be due to deranged oxidative metabolism or impaired lactate clearance.^{4,15} The exact role of diabetes mellitus in the induction of lactic acidosis is not clear. It may involve a decrease in pyruvate dehydrogenase activity, the enzyme responsible for pyruvate metabolism. Lactic acidosis in neoplastic disease is uncommon and reported mostly in patients with myeloproliferative disorders. Leukocytes and neoplastic cells in general have high rates of glycolysis. In the case of a large tumor or tightly packed bone marrow, oxygenation can be decreased, favoring the accumulation of lactate. Lactic acidosis has been reported in patients with massive liver tumors, and it has been postulated that the liver uptake of lactate is decreased in these patients. Lactic acidosis associated with seizures is usually transient and occurs because of excessive muscle activity.⁷

CLINICAL PRESENTATION

Chronic metabolic acidosis is usually not associated with severe acidemia and is relatively asymptomatic. The major manifestations are in the bones, where chronic acidemia causes bone demineralization with the development of rickets in children and osteomalacia and osteopenia in adults. In infants and children, chronic metabolic acidosis is associated with growth failure and short stature and may be associated with nonspecific symptoms including anorexia, nausea, weight loss, and muscle weakness.

CLINICAL PRESENTATION OF METABOLIC ACIDOSIS

GENERAL

The patient is usually relatively asymptomatic if the acidosis is acute and mild. In those with severe acidemia (pH <7.15 to 7.20) the cardiovascular, respiratory, and central nervous systems may be affected.

SYMPTOMS

The patient may complain of loss of appetite, nausea, and vomiting.

SIGNS

Cardiac: Flushing, a rapid heart rate, wide pulse pressure, and an increase in cardiac output may be seen initially. This may be followed by a reduction in cardiac output, blood pressure, and liver and kidney blood flow.

Cerebral: Obtundation or coma.

Metabolic: Insulin resistance; increased protein degradation; increased metabolic demands.

Gastrointestinal: Nausea, vomiting, loss of appetite.

Respiratory: Dyspnea, hyperventilation with deep, rapid respirations is seen in those with severe acidosis.

Chronic acidemia causes bone demineralization with the development of rickets in children and osteomalacia and osteopenia in adults.

LABORATORY TESTS

Hyperglycemia and hyperkalemia are common. In those with severe acidosis the pH is <7.2

Severe metabolic acidosis is usually associated with acute processes. The manifestations of severe acidemia (pH <7.15 to 7.20) involve the cardiovascular, respiratory, and central nervous systems. Hyperventilation is often the first sign of metabolic acidosis. At a pH of 7.2, pulmonary ventilation increases about fourfold and an eightfold increase has been noted at a pH of 7.¹⁷ Respiratory compensation may occur as Kussmaul's respirations—the deep, rapid respirations seen commonly in patients with diabetic ketoacidosis. In extremely severe acidosis (pH <6.8), central nervous system (CNS) function is disrupted to such a degree that the respiratory center is depressed.

CNS depression correlates more closely with spinal fluid pH than with blood pH. For this reason, neurologic symptoms tend to occur more frequently and to a greater degree in patients with respiratory acidosis, because the CO₂ accumulated in the respiratory form readily crosses the blood-brain barrier to cause acidosis in the CNS.¹ Because of the slow penetration of administered bicarbonate into the CNS, the CNS pH fails to normalize as rapidly as blood pH. Therefore patients continue to hyperventilate because of sustained CNS acidity, and severe respiratory alkalosis may occur. Sustained lowering of the PaCO₂ within 12 to 36 hours is to be anticipated during the correction of any metabolic acidosis.¹

Systemic acidosis can cause peripheral arteriolar dilatation, characterized by flushing, a rapid heart rate, and wide pulse pressure. Initially, cardiac output may be increased, but as acidosis becomes more severe, myocardial contractility becomes impaired and cardiac output falls. The effects of vagal stimulation are also enhanced at pH levels lower than 7.1, probably as a consequence of inhibition of acetylcholinesterase. This increases the danger of vagally mediated bradycardia and heart block during acidosis.

Gastrointestinal symptoms of metabolic acidosis include loss of appetite, nausea, and vomiting. Severe acidosis (pH <7.1) interferes with carbohydrate metabolism and insulin utilization, and results in hyperglycemia. Metabolic acidosis alters potassium homeostasis and contributes to the development of hyperkalemia. The magnitude of the effect on serum potassium depends on the type of acidosis: Acidosis caused by mineral acids (e.g., hydrochloric acid) are associated with a greater change in potassium levels than acidosis caused by organic acids (e.g., lactic acidosis), in which the increase in potassium attributable to the acidosis per se is minimal.

COMPENSATION

5 The patient's primary means to compensate for metabolic acidosis is to increase carbon dioxide excretion by increasing respiratory rate. This results in a decrease in PaCO₂. This ventilatory compensation results from stimulation of the respiratory center by changes in cerebral bicarbonate concentration and pH.¹ For every 1-mEq/L decrease in bicarbonate concentration below the average of 24, the PaCO₂ decreases by about 1 to 1.5 mm Hg from the normal value of 40 (see Table 51-4).

The anticipated PaCO₂ associated with a given bicarbonate concentration for patients with uncomplicated metabolic acidosis can be calculated as:¹⁸

$$\text{PaCO}_2 = (1.5 \times [\text{HCO}_3^-]) + 8 \pm 2$$

For example, 95% of patients with a plasma bicarbonate of 16 mEq/L should have an arterial PCO₂ of 30 to 34 mm Hg. An observed arterial PCO₂ within this range is consistent with physiologic respiratory compensation for a metabolic acidosis, and suggests that there is no respiratory disturbance. In contrast, if the PCO₂ is less than 30 mm Hg, a superimposed respiratory alkalosis may be present, whereas if the PCO₂ is greater than 34 mm Hg, a superimposed respiratory acidosis is present.

► TREATMENT: Metabolic Acidosis

■ CHRONIC METABOLIC ACIDOSIS

6 Asymptomatic patients with mild to moderate degrees of acidemia (plasma bicarbonate of 12 to 20 mEq/L; pH of 7.2 to

7.4) do not require emergent therapy. They can usually be managed with gradual correction of the acidemia, over a period of days to weeks, using oral sodium bicarbonate or other alkali preparations (Table 51-7). In all forms of chronic metabolic acidosis, primary therapy should be directed at treating the underlying disease state.

TABLE 51–7. Therapeutic Alternatives for Oral Alkali Replacement

| Generic Name | Trade Name(s) | Milliequivalents of Alkali | Dosage Form (s) | Comment |
|---|---|--|---|---|
| Shohl's solution Sodium citrate/citric acid | Bicitra (Willen) | 1 mEq Na/mL; equivalent to 1 mEq bicarbonate | Solution (500 mg Na citrate, 334 mg citric acid/5 mL) | Citrate preparations increase absorption of aluminum |
| Sodium bicarbonate | Various (e.g., Rugby) | 3.9 mEq bicarbonate/tablet (325 mg) 7.8 mEq bicarbonate/ tablet (650 mg) | 325 mg tablet 650 mg tablet | Bicarbonate preparations may cause bloating due to CO ₂ production |
| | Baking soda (various) | 60 mEq bicarbonate/tsp (5 g/tsp) | Powder | |
| Potassium citrate | Urocit-K (Mission) | 5 mEq citrate/tablet | 5 mEq tablet | See above |
| Potassium bicarbonate/ potassium citrate | K-Lyte (Bristol) | 25 mEq bicarbonate/tablet | 25 mEq tablet (effervescent) | |
| | K-Lyte DS (Bristol) | 50 mEq bicarbonate/tablet (double strength) | 50 mEq tablet (effervescent) | See above |
| Potassium citrate/citric acid | Polycitra-K (Willen) | 2 mEq K/mL; equivalent to 2 mEq bicarbonate 30 mEq bicarbonate/unit dose packet | Solution (1100 mg K citrate, 334 mg citric acid/5 mL) Crystals for reconstitution (3300 mg K citrate, 1002 mg citric acid/unit dose packet) | See above |
| Sodium citrate/potassium citrate/citric acid | Polycitra (Willen) Polycitra-LC (Willen) | 1 mEq K, 1 mEq Na/mL; equivalent to 2 mEq bicarbonate | Syrup (Polycitra) Solution (Polycitra-LC) (Both contain 550 mg K citrate, 500 mg Na citrate, 334 mg citric acid/5 mL) | See above |

Gastrointestinal pathology should be treated to reduce ongoing bicarbonate losses, and factors that exacerbate RTA should be treated. If acidemia persists, alkali therapy should be instituted, with the goal of normalization of blood pH. The loading dose (LD) of alkali to initially correct the acidemia can be calculated as follows:¹⁹

$$\text{LD(mEq)} = (V_D \text{HCO}_3^- \times \text{body weight [BW]}) \\ \times (\text{desired } [\text{HCO}_3^-] - \text{current } [\text{HCO}_3^-])$$

For a 60-kg patient with a serum bicarbonate of 15 mEq/L, the loading dose is calculated thusly:

$$\text{LD(mEq)} = (0.5 \text{ L/kg} \times 60 \text{ kg}) \times (24 \text{ mEq/L} - 15 \text{ mEq/L}) \\ = 30 \text{ L} \times 9 \text{ mEq/L} \\ = 270 \text{ mEq}$$

The calculated loading dose of alkali should be administered over several days to avoid volume overload from the accompanying sodium load. For this scenario, a regimen of 60 to 70 mEq three times a day for 3 to 5 days should result in an increase in HCO₃⁻ levels toward normal. In addition to the calculated loading dose, supplemental alkali must also be provided to replace ongoing losses, which can be approximated to be 2 mEq/kg per day or 40 mEq three times a day. In patients with associated volume depletion, bicarbonate replacement can be provided simultaneous with volume resuscitation by substituting bicarbonate for chloride in intravenous crystalloid solutions.

In patients with chronic metabolic acidosis because of gastrointestinal bicarbonate losses, maintenance therapy should provide sufficient alkali to replace ongoing bicarbonate losses. The magnitude of this replacement is variable and may be substantial (>10 mEq/kg per day). In addition, associated losses of other electrolytes, such as potassium and magnesium, may need to be replaced (see Chap. 50).

Proximal (type II) RTA is a bicarbonate-wasting disorder that requires the administration of large maintenance doses of alkali (10 to 15 mEq/kg per day). As alkali replacement raises the serum bicarbon-

ate concentration toward normal, the proximal tubule's capacity to reabsorb bicarbonate is overwhelmed and renal bicarbonate wasting increases. In children, aggressive therapy of proximal RTA is necessary to avoid growth retardation and osteopenia. Because this is generally a mild, nonprogressive acidosis in adults, the benefit of alkali therapy is frequently outweighed by the risks of increased potassium wasting. In patients with classic distal (type I) RTA, maintenance therapy usually requires only enough alkali to buffer the amount of acid generated from dietary intake and metabolism. This usually approximates 1 to 3 mEq/kg per day.

After initial potassium deficits are replaced, ongoing potassium supplementation may not be required, as renal potassium losses decrease following initiation of appropriate alkali therapy. The use of potassium alkali salts may, however, be desirable in patients with associated nephrolithiasis, because sodium salts may increase urinary calcium excretion.

The metabolic acidosis associated with hyperkalemic distal (type IV) RTA with hyporeninemic-hypoaldosteronemia that is often seen in patients with diabetes mellitus may be corrected by the treatment of hyperkalemia alone (see Chap. 50). The use of supplemental alkali (1 to 2 mEq/kg per day) to increase sodium intake and stimulate distal tubular potassium secretion may be beneficial. A minority of patients require the administration of pharmacologic amounts of fludrocortisone.⁴ Type IV RTA resulting from a generalized distal tubular disorder often responds to low doses of alkali (1.5 to 2.0 mEq/kg per day).²⁰ Corrections of the acidosis along with modest dietary potassium restriction (to 1 mEq/kg per day) will often result in the maintenance of serum potassium levels of 5 mEq/L or less.

ACUTE SEVERE METABOLIC ACIDOSIS

The management of patients with life-threatening acute metabolic acidosis (plasma bicarbonate of 8 mEq/L and pH

<7.20) is dependent on the underlying cause and the patient's cardiovascular status. Patients with hyperchloremic acidosis (e.g., diarrhea-induced) are unable to regenerate bicarbonate, and the generation of new bicarbonate by the kidneys may require several days before one can observe a meaningful change in their status.¹⁴ Thus intravenous alkali therapy is often required for these patients.

CLINICAL CONTROVERSY

The role of alkali therapy in patients with severe lactic acidosis is controversial. Treatment should be directed at the underlying causes since serial bicarbonate administration is often not effective and in some settings may be deleterious.

Although conventional wisdom recommends the use of alkali replacement in patients with severe acidemia caused by the deleterious effects of acidemia on circulatory function,^{7,14,15} studies have not demonstrated improved outcome with alkali replacement.^{21–24}

There are several therapeutic alternatives available for the acute correction of severe metabolic acidosis. Sodium acetate, sodium citrate, and sodium lactate are unreliable sources of alkali because their alkalizing effect is dependent on their oxidative conversion to bicarbonate. This process is often impaired in critically ill patients, especially those with liver disease or circulatory failure. Although sodium bicarbonate is the most widely used intravenous alkalitic agent,¹⁴ several studies suggest that it is frequently ineffective and may actually be deleterious, especially in patients with lactic acidosis.^{21–24} Two of the three remaining alternatives (carbicarb and dichloroacetate) are investigational and not available in most clinical settings. Tromethamine, or THAM, is a carbon dioxide-consuming, commercially available solution that buffers respiratory as well as metabolic acids.

■ SODIUM BICARBONATE

In theory, sodium bicarbonate administration provides fluid and electrolyte replacement and increases arterial pH, thereby improving cardiac function, perfusion and oxygenation of peripheral tissues, and intracellular pH, and should therefore decrease lactate production and increase clearance. However, sodium bicarbonate administration can actually have an adverse effect on intracellular pH. When bicarbonate is given by IV infusion, the carbon dioxide generated diffuses more readily than bicarbonate across cell membranes and into cerebrospinal fluid. Therefore the intracellular pH can actually be decreased by administration of bicarbonate.⁴

CLINICAL CONTROVERSY

Although it has been recommended that sodium bicarbonate be administered to raise the arterial pH to about 7.15 to 7.20, there are no controlled clinical trials demonstrating that sodium bicarbonate administration is significantly better than general supportive care in reducing morbidity and mortality in these patients.^{4,14,21–24}

Excessive sodium bicarbonate administration may result in (1) a shift of the oxyhemoglobin saturation curve to the left, and thereby impaired oxygen release from hemoglobin to tissues; (2) sodium and water overload, with subsequent pulmonary congestion and hypernatremia; (3) paradoxical acidosis as a result of the production of CO₂ that freely diffuses into myocardial and cerebral cells;²⁵ and (4) decreased ionized calcium with resultant decreased

myocardial contractility. If there is an endogenous source of bicarbonate, such as can occur in the case of ketoacidosis or lactic acidosis, a bicarbonate “overshoot” may develop because the ketoacids (acetoacetic acid and β -hydroxybutyric acid) or lactic acid are converted in the liver to bicarbonate once the underlying cause of acidosis is corrected.^{12,14,26} Alkalosis may also result if too much is given too fast.

If intravenous sodium bicarbonate is used, one must be mindful that the goals are to increase, not normalize, pH (to approximately 7.20) and plasma bicarbonate (to 8 to 10 mEq/L). There is no calculative method that will assure attainment of these goals with a given dose of sodium bicarbonate because of the multiplicity of competing processes that can affect acid-base status (vomiting, potential increases in endogenous acid production, and renal failure) and the marked variability in the volume of distribution of bicarbonate (50% of body weight in patients with mild acidosis to approximately 100% in those with severe acidosis).¹⁹ Adroge and Madias¹⁴ recommended that the dose of sodium bicarbonate be calculated using a distribution volume of 50% of body weight for all patients to avoid overtreatment. The total dose calculated as described previously in the RTA section should be administered as an infusion over one-half to several hours. Follow-up monitoring of arterial blood gases beginning no sooner than 30 minutes after the end of the infusion should be used to guide further therapeutic decisions.

Bicarbonate therapy is generally not necessary in the routine patient with cardiac arrest, even if the initial arrest was unmonitored. The standards and guidelines from the National Conference on Cardiopulmonary and Emergency Cardiac Care state that sodium bicarbonate is most useful in cardiac life support when combined with ventilation in an attempt to maintain near-normal arterial pH during an arrest.²⁷ During a cardiac arrest, sodium bicarbonate (initial dose 1 mEq/kg) may be administered by rapid, direct intravenous injection. It should be used only after more proven interventions such as defibrillation, cardiac compression, support of ventilation including intubation, and drug therapies such as epinephrine and antiarrhythmic agents have been employed. Subsequent doses of sodium bicarbonate should be based on measurements of arterial blood pH and PaCO₂.

■ TROMETHAMINE

THAM, available as a 0.3 N solution, is a highly alkaline, sodium-free organic amine that acts as a proton acceptor to prevent or correct acidosis.²⁸ Tromethamine combines with hydrogen ions from carbonic acid to form bicarbonate and a cationic buffer. THAM also acts as an osmotic diuretic to increase urine flow, urine pH, and the excretion of fixed acids, CO₂, and electrolytes. At pH 7.4, 30% of THAM is not ionized and therefore may penetrate into cells and neutralize acidic anions of the intracellular fluid. Intracellular pH increases have been noted within 1 hour after the infusion of THAM. There is, however, no clinical or physiologic evidence that this action is beneficial, or that THAM is more efficacious than sodium bicarbonate.^{14,29}

When THAM is used, it must be administered slowly, with careful monitoring to avoid alkalosis. The usual empiric dosage range for tromethamine is 1 to 5 mmol/kg administered intravenously over 1 hour, but doses up to 1.25 mmol/kg may be given over 5 to 15 minutes in acute situations. The dose of THAM can be individualized using the following equation:²⁸

$$\text{Dose of THAM (in mLs)} = 1.1 \times \text{BW (in kilograms)} \\ \times \text{base deficit}$$

where base deficit = normal [HCO₃⁻] minus current [HCO₃⁻].

The need for additional THAM is determined by serial measurements of the serum bicarbonate concentration and calculation of the base deficit. Large doses may cause respiratory depression as a result of an increase in blood pH and a decrease in PaCO₂ concentration.²⁹ Tromethamine solution is highly alkaline and may cause severe inflammation, vascular spasm, or tissue damage (necrosis, sloughing, pain, chemical phlebitis, or thrombosis) if infiltration occurs. Hyperkalemia, hypoglycemia, hypocalcemia, and impaired coagulation have also been reported.^{29,30} This agent should only be used with extreme caution in patients with severe liver or kidney failure.

■ CARBICARB

Carbicarb is an equimolar mixture of sodium carbonate (Na₂CO₃) and sodium bicarbonate (NaHCO₃).^{31,32} It is no longer commercially available in Canada, and its use in the United States is still investigational. The carbonate ion is a stronger base than bicarbonate, and thus preferentially buffers hydrogen ions. The result of this reaction is the formation of bicarbonate rather than CO₂. Thus carbicarb limits, but does not eliminate, the generation of CO₂. Unlike bicarbonate, which can produce a paradoxical intracellular acidosis and thereby impair cardiac function, carbicarb appears to correct intracellular acidosis if present.^{33,34} In a prospective, double-blind, randomized, multicenter trial, Leung and colleagues³¹ compared carbicarb to sodium bicarbonate in surgical patients with mild intraoperative metabolic acidosis. Carbicarb proved as effective as sodium bicarbonate in correcting mild metabolic acidosis. Furthermore, cardiac output increased with carbicarb as compared to sodium bicarbonate. Carbicarb also appears to be beneficial in the management of lactic acidosis.

Although the optimal dosage of carbicarb has not been determined, it can be approximated as:³¹

$$\begin{aligned} &\text{Dose (in milliequivalents of Na)} \\ &= 0.2 \text{ L/kg} \times \text{BW (in kilograms)} \times (\text{base deficit}) \end{aligned}$$

The risk of hypervolemia and hypertonicity after carbicarb administration is similar to that of bicarbonate. The small number of trials reporting the clinical utility of this agent and its continued investigational status in most of the world limits its use and availability for the foreseeable future.

■ DICHLOROACETATE

Dichloroacetate (DCA), another investigational agent, significantly lowers serum lactate levels and increases blood pH in patients with lactic acidosis.^{35,36} DCA facilitates aerobic lactate metabolism by stimulating the activity of lactate dehydrogenase, reverses hyperlactatemia, and decreases morbidity in acquired and congenital forms of lactic acidosis. In a randomized, multicenter, placebo-controlled trial, Stacpoole and associates³⁵ studied the effects of DCA (50 to 100 mg/kg) in 252 patients with lactic acidosis. Serum lactate was significantly lowered and blood pH increased, but there was no improvement in patient outcome as compared to conventional management. A subsequent study in patients undergoing liver transplantation demonstrated that DCA attenuated lactate acid accumulation and reduced the need for bicarbonate therapy in this high-risk patient population.³⁷ The drug also improves cardiac output and left ventricular mechanical efficiency under conditions of myocardial ischemia or failure, probably by facilitating myocardial glucose utilization and inhibiting gluconeogenesis. DCA administration has also been reported to reverse the abnormal glucose metabolism, branched chain amino acid utilization, and muscle catabolism in septic patients.³⁸ DCA can cause a reversible peripheral neuropathy that may be ameliorated or prevented with thiamine supplementation. Mild drowsiness has been reported in approximately half of the adult recipients, but no other drug-related adverse effects have been reported.³⁶ The future role of DCA in the management of metabolic acidosis, particularly lactic acidosis, remains to be clarified.

METABOLIC ALKALOSIS

PATHOPHYSIOLOGY

Metabolic alkalosis is a simple acid-base disorder that presents as alkalemia (increased arterial pH) with an increase in plasma bicarbonate. It is an extremely common entity in hospitalized patients with acid-base disturbances. Under normal circumstances, the kidney is readily able to excrete an alkali load. Thus evaluation of patients with metabolic alkalosis must consider two separate issues: (1) the initial process that generates the metabolic alkalosis; and (2) alterations in renal function that maintain the alkalemic state.^{39,40}

Generation

9 The generation of metabolic alkalosis can also result from excessive losses of H⁺ via the kidneys or from the gain of exogenous bicarbonate-rich fluids. Gastric secretory volume is usually less than 50 mL/h in the basal state, but may increase up to five-fold with stimulation. The gastric juice is rich in chloride and H⁺. In the gastric parietal cells, hydrogen ion and bicarbonate are generated from CO₂ and water.⁴⁰ The hydrogen ion is secreted into gastric fluid and the bicarbonate is retained in the ECF. Normally, an amount of bicarbonate equal to the bicarbonate generated in the stomach is eliminated in the alkaline pancreatic and small-bowel secretions, maintaining hydrogen ion balance. With vomiting and nasogastric suctioning, hydrogen ion is lost externally and metabolic alkalosis

results. Diarrhea, as seen with secretory villous adenomas and other secretory diarrheas, often results in excessive gastrointestinal losses of chloride-rich, bicarbonate-poor fluid and thus leads to the generation of metabolic alkalosis.

10 Diuretic agents acting on the thick ascending limb of the loop of Henle (e.g., furosemide, bumetanide, and torsemide) and distal convoluted tubule (thiazides), have most commonly been associated with the generation of metabolic alkalosis.⁴¹ These agents promote the excretion of sodium and potassium almost exclusively in association with chloride, without a proportionate increase in bicarbonate excretion. Collecting duct hydrogen ion secretion is stimulated directly by the increased luminal flow rate and sodium delivery, and indirectly by intravascular volume contraction, which results in secondary hyperaldosteronism. Renal ammoniogenesis may also be stimulated by concomitant hypokalemia, further augmenting net acid excretion.

Increased renal acid excretion may also be the result of excess mineralocorticoid activity. Elevated mineralocorticoid levels directly stimulate collecting duct hydrogen ion secretion and indirectly increase ammoniogenesis by causing hypokalemia.¹⁷ Increased mineralocorticoid activity may result from Cushing's syndrome, primary hyperaldosteronism, or hyperaldosteronism secondary to increased renin activity (e.g., malignant hypertension). In Bartter's and Gitelman's syndromes, defects in sodium transport in the loop of Henle (Bartter's) or distal convoluted tubule (Gitelman's) lead to hypokalemia, secondary hyperaldosteronism, and metabolic alkalosis.⁴⁰ In Liddle's syndrome, enhanced sodium reabsorption by the cortical

collecting duct epithelial sodium channel results in a syndrome of pseudohyperaldosteronism.³⁹ Administration of high doses of penicillins (e.g., ticarcillin) may produce metabolic alkalosis because they act as nonreabsorbable anions. High concentrations of poorly reabsorbable anions in the distal renal tubule increase luminal flow rate and luminal electronegativity, which enhances the secretion of potassium and hydrogen ion and results in hypokalemia and metabolic alkalosis.

Metabolic alkalosis may also be generated by the gain of exogenous alkali. This may be seen as a result of bicarbonate administration or from the infusion of organic anions that are metabolized to bicarbonate, such as acetate, lactate, and citrate. The milk-alkali syndrome was historically a common cause of metabolic alkalosis in patients with peptic ulcer disease secondary to the ingestion of large quantities of milk products and antacids. This syndrome has become increasingly uncommon with the advent of alternative effective therapies for dyspeptic syndromes.

Maintenance

No matter which condition initiated the metabolic alkalosis, abnormalities in renal function underlie its maintenance. Normally, the kidneys are capable of excreting all of the excess bicarbonate presented to them, even during periods of increased bicarbonate loads.⁴ As the serum bicarbonate concentration increases, the filtered bicarbonate load exceeds the maximal rate for bicarbonate reabsorption, and the excess bicarbonate is excreted in the urine. Under normal circumstances, the excess bicarbonate is rapidly excreted and metabolic alkalosis does not occur, or is corrected in a matter of hours.⁴⁰

Several mechanisms may impair renal bicarbonate excretion, and contribute to the maintenance phase of metabolic alkalosis.³⁹ In general, these mechanisms can be divided into volume-mediated processes (sodium chloride–responsive) and volume-independent processes (sodium chloride–resistant) that are predominantly associated with excess mineralocorticoid activity and hypokalemia (Table 51–8). Intravascular volume depletion maintains metabolic alkalosis through a number of mechanisms. Decreases in the glomerular filtration rate reduce the filtered load of bicarbonate at any given serum concentration, thereby decreasing the kidney's ability to excrete a bicarbonate load. While this may play a role in patients with chronic kidney disease, it is also an important factor in patients in whom intravascular volume contraction accompanies metabolic alkalosis. Decreased effective arterial blood volume also enhances proximal and distal tubular sodium reabsorption. Sodium reabsorption must be coupled with reabsorption of an anion, such as chloride or bicarbonate, or exchange with a cation, such as potassium or hydrogen, in order to maintain charge neutrality. In the proximal tubule, increased sodium reabsorption stimulates bicarbonate reabsorption. In the distal nephron, enhanced sodium reabsorption, particularly in the setting of hypokalemia, stimulates hydrogen ion secretion.

Mineralocorticoid excess also plays a significant role in the maintenance of metabolic alkalosis. In patients with volume-responsive metabolic alkalosis, intravascular volume depletion stimulates aldosterone secretion. As discussed earlier, excess mineralocorticoid activity may also underlie the generation of metabolic alkalosis. In either situation, the increased mineralocorticoid effect stimulates collecting duct H⁺ secretion. Metabolic alkalosis may also be maintained by persistent hypokalemia. Hypokalemia has a multitude of effects on renal acid-base homeostasis, enhancing proximal tubular bicarbonate reabsorption, stimulating ammoniogenesis and increasing distal tubular H⁺ secretion.⁴⁰

 Mild/moderate potassium deficiency

Sodium chloride–resistant (urinary chloride concentration >20 mEq/L)

Excess mineralocorticoid activity
 Hyperaldosteronism
 Cushing's syndrome
 Bartter's syndrome
 Gitelman's syndrome
 Excessive black licorice intake
 Profound potassium depletion
 Magnesium deficiency
 Liddle's syndrome

Unclassified

Alkali administration
 Milk-alkali syndrome
 Massive blood or plasma protein fraction transfusion
 Nonparathyroid hypercalcemia
 Carbohydrate refeeding after starvation
 Large doses of penicillin

CLINICAL PRESENTATION

There are no unique signs or symptoms associated with mild to moderate metabolic alkalosis, but patients may complain of symptoms related to the underlying cause of the disorder (e.g., muscle weakness with hypokalemia or postural dizziness with volume depletion). They may have a history of vomiting, gastric drainage, or diuretic use, all of which contribute to the development of metabolic alkalosis. Severe alkalemia (blood pH >7.60) has been associated with cardiac arrhythmias, particularly in patients with heart disease, and hyperventilation with hypoxemia.⁴² Neuromuscular irritability may be present, with signs of tetany or hyperactive reflexes, possibly caused by the decreased ionized calcium concentration that occurs secondary to the increase in pH. This decrease in ionized calcium may be caused by a conformational change in the albumin molecules to which the calcium is bound, resulting in increased binding, or by decreased competition from hydrogen ions for binding sites on the albumin molecule. Mental confusion, muscle cramping, and paresthesias may also occur.

COMPENSATION

The respiratory response to metabolic alkalosis is hypoventilation, which results in an increased PaCO₂. Respiratory compensation is initiated within hours when the central and peripheral chemoreceptors sense an increase in pH. The PaCO₂ increases 6 to 7 mm Hg for each 10-mEq/L increase in bicarbonate, up to a PaCO₂ of about 50 to 60 mm Hg (see Table 51–4) before hypoxia sensors react to prevent further hypoventilation. If the PaCO₂ is normal or less than normal, one should consider the presence of a superimposed respiratory alkalosis, which may be secondary to fever, gram-negative sepsis, or pain.

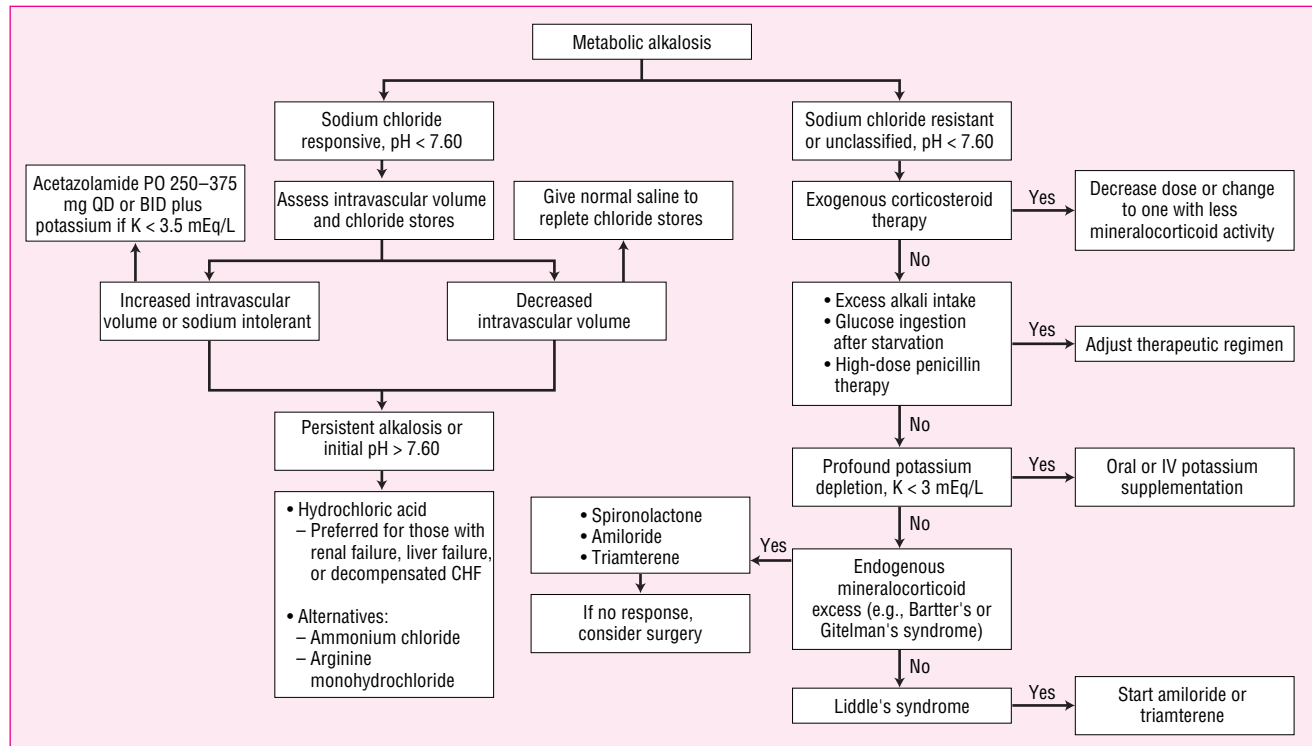

FIGURE 51–5. Treatment algorithm for patients with primary metabolic alkalosis.

► TREATMENT: Metabolic Alkalosis

Treatment of metabolic alkalosis should be aimed at correcting the factor(s) responsible for the maintenance of the alkalosis.^{39,40,42} For example, vomiting should be treated with antiemetics, gastric losses of H⁺ during nasogastric suction may be modulated by giving histamine blockers such as ranitidine or proton pump inhibitors such as omeprazole, and reducing or discontinuing diuretic therapy.^{43,44} Metabolic alkalosis will persist until the renal mechanism responsible for maintaining the disorder is corrected, despite the fact that the original cause of the elevated plasma bicarbonate may have resolved. For example, hypovolemia should be treated with sodium chloride (i.e., diuretic

abuse or nasogastric suction) to allow excretion of bicarbonate by the kidney. However, patients with severely compromised cardiovascular function may not be able to tolerate this therapeutic approach. In situations such as this and/or the presence of life-threatening alkalosis, some have advocated reduction in pH by control of ventilation.⁴ Although controlled hypoventilation, sometimes using inspired CO₂ with supplemental oxygen to prevent hypoxia may be life-saving,⁴ this approach is not universally accepted.^{40,42} Therapy for metabolic alkalosis can be conceptualized on the basis of the sodium chloride responsiveness of the disorders as shown in Fig. 51–5.

SODIUM CHLORIDE-RESPONSIVE DISORDERS

Sodium chloride-responsive disorders usually result from volume depletion and chloride loss, which may accompany severe vomiting, prolonged nasogastric suction, and diuretic therapy. Initially therapy is directed at expanding intravascular volume and replenishing chloride stores. Sodium and potassium chloride-containing solutions should be administered to patients who can tolerate the volume load.^{40,42} Patients with metabolic alkalosis who are volume overloaded or intolerant to volume administration because of congestive heart failure may benefit from the carbonic anhydrase inhibitor acetazolamide. This agent inhibits the action of carbonic anhydrase, thereby inhibiting renal bicarbonate reabsorption. Unfortunately, it also increases the renal losses of potassium and phosphate. Administration of acetazolamide (250 to 375 mg once or twice daily) may promote a sufficient bicarbonate diuresis and return the pH toward normal. However, because the clinical effectiveness of the drug declines as the HCO₃⁻

concentration falls, only rarely will this approach fully correct the alkalosis.³⁹

Acidifying agents including hydrochloric acid, ammonium chloride, and arginine monohydrochloride may be used to treat severe (pH > 7.6) symptomatic metabolic alkalosis. In general, this management is reserved for patients who are unresponsive to conventional fluid and electrolyte management or who are unable to tolerate the requisite volume load because of decompensated congestive heart failure or advanced renal failure.^{39,42} Alternatively, hemodialysis using a low-bicarbonate dialysate may be used for the rapid correction of metabolic acidosis.

HYDROCHLORIC ACID

Hydrochloric acid is usually infused intravenously via a large central vein as a 0.1 to 0.25 N HCl solution in either 5% dextrose or normal saline, although sterile water has also been used. Extemporaneously prepared solutions can be made by adding 100 to 250 mEq of HCl

through a 0.22-mm filter into a glass container of saline or dextrose. Hydrochloric acid may also be added to parenteral nutrient solutions and administered via a central line without serious degradation of proteins.⁴⁵ The rate of infusion should be 100 to 125 mL/h (10 to 25 mEq/h), with frequent monitoring of arterial blood gases. To prevent overcorrection, the infusion should be stopped when the arterial pH falls to 7.50.⁴⁰

The dose of hydrochloric acid may be based on an estimate of the total body chloride deficit:²⁸

$$\text{Dose HCl (in mEq)} = [0.2 \text{ L/kg} \times \text{BW (in kilograms)}] \\ \times [103 - \text{observed serum chloride}]$$

where the estimated chloride space is 0.2 times the body weight and the average serum chloride is 103 mEq/L. Alternatively, the dose may be calculated based on the estimated base deficit:⁴²

$$\text{Dose HCl (in mEq)} = [0.5 \text{ L/kg} \times \text{BW (in kilograms)}] \\ \times (\text{desired } [\text{HCO}_3^-] - \text{observed } [\text{HCO}_3^-])$$

CLINICAL CONTROVERSY

At present, there are no comparative data that address the relative accuracy of these two formulas for determining the dose of hydrochloric acid.

The dose of hydrochloric acid is usually infused intravenously over 12 to 24 hours.⁴⁹ A severe transient respiratory acidosis may occur if the hydrochloric acid is infused too quickly because of the slower reduction of the elevated bicarbonate concentration in the cerebrospinal fluid than in the extracellular fluid. Improvement is usually seen within 24 hours of initiating therapy. Arterial blood gases and serum electrolytes should be drawn every 4 to 8 hours to evaluate and adjust therapy.

AMMONIUM CHLORIDE

Ammonium chloride has a limited role in the treatment of metabolic alkalosis. The liver converts ammonium chloride to urea and free hydrochloric acid:²⁸

The dose of ammonium chloride can be calculated on the basis of the chloride deficit using the same method as for HCl, using the conversion of 20 g ammonium chloride providing 374 mEq of H⁺. However, only half of the calculated dose of ammonium chloride should be administered so as to avoid ammonia toxicity. Ammonium chloride is available as a 26.75% solution containing 100 mEq in 20 mL, which should be further diluted prior to administration. A dilute solution may be prepared by adding 100 mEq of ammonium chloride to 500 mL of normal saline and infusing the solution at a rate of no more than 1 mEq/min. Improvement in metabolic status is usually seen within 24 hours. CNS toxicity, marked by confusion, irritability, seizures, and coma, has been associated with more rapid rates of administration. Ammonium chloride must be administered cautiously to patients with renal or hepatic impairment. In patients with hepatic dysfunction, impaired conversion of ammonia to urea may result in increased ammonia levels and worsened encephalopathy. In patients with renal failure, the increased urea synthesis may exacerbate uremic symptoms.²⁸

ARGININE MONOHYDROCHLORIDE

Arginine monohydrochloride at a dose of 10 g/h given intravenously has been used to treat metabolic alkalosis, although it was never FDA-

approved for this purpose.²⁸ Like ammonium chloride, arginine must undergo metabolism by the liver to produce hydrogen ions, with a conversion of 100 g to 475 mEq of H⁺. Unlike ammonium chloride, arginine combines with ammonia in the body to synthesize urea; thus it may be used in patients with relative hepatic insufficiency. Patients with renal insufficiency should not receive arginine monohydrochloride because it may significantly elevate BUN and is associated with severe hyperkalemia.^{28,30} The increase in potassium is caused by arginine-induced shifts of potassium from the intracellular to the extracellular space.

SODIUM CHLORIDE-RESISTANT DISORDERS

Management of these disorders usually consists of treatment of the underlying cause of the mineralocorticoid excess. Patients who are taking corticosteroids may require a dosage reduction or may need to be switched to a corticosteroid with less mineralocorticoid activity. Patients with an endogenous source of excess mineralocorticoid activity may require surgery or the administration of spironolactone, amiloride, or triamterene.^{39,42,46}

Spironolactone is a competitive antagonist of the mineralocorticoid receptor. Amiloride and triamterene are potassium-sparing diuretics that inhibit the epithelial sodium channel in the distal convoluted tubule and collecting duct. All three agents inhibit aldosterone-stimulated sodium reabsorption in the collecting duct. In addition, spironolactone directly inhibits aldosterone-stimulation of the hydrogen ion secretory pump. Thus most patients with mineralocorticoid excess, including Bartter's and Gitelman's syndromes, respond to therapy with these agents.^{39,40,46} Liddle's syndrome, which is a form of pseudohyperaldosteronism caused by overactivity of the epithelial sodium channel, is not responsive to spironolactone, but may be treated with either amiloride or triamterene. Although experience is limited, some patients with Bartter's and Gitelman's syndromes may respond to nonsteroidal anti-inflammatory agents or angiotensin-converting enzyme inhibitors.^{47,48} Finally, aggressive potassium repletion may correct the alkalosis in those who have not responded to the approaches outlined above.

RESPIRATORY ACID-BASE DISORDERS

As with the metabolic acid-base disturbances, there are two cardinal respiratory acid-base disturbances: respiratory acidosis and respiratory alkalosis. These disorders are generated by a primary alteration in carbon dioxide excretion, which changes the concentration of carbon dioxide, and therefore the carbonic acid concentration in body fluids. A primary reduction in PaCO₂ causes a rise in pH (respiratory alkalosis), and a primary increase in PaCO₂ causes a decrease in pH (respiratory acidosis). Unlike the metabolic disturbances, for which respiratory compensation is rapid, metabolic compensation for the respiratory disturbances is slow. Hence these disturbances can be further divided into acute disorders, with a duration of minutes to hours that is too short for metabolic compensation to have occurred, and chronic disorders, that have been present long enough for metabolic compensation to be complete.

RESPIRATORY ALKALOSIS

Respiratory alkalosis is characterized by a primary decrease in PaCO₂ that leads to an elevation in pH. The PaCO₂ falls when the excretion of CO₂ by the lungs exceeds the metabolic production of CO₂. It is the

Mechanical or voluntary hyperventilation

most frequently encountered acid-base disorder, occurring physiologically in normal pregnancy and in persons living at high altitudes.⁴⁹ Respiratory alkalosis also occurs frequently among hospitalized patients (Table 51–9).

PATHOPHYSIOLOGY

A decrease in PaCO_2 occurs when ventilatory excretion exceeds metabolic production. Because endogenous production of CO_2 is relatively constant, negative CO_2 balance is primarily caused by an increase in ventilatory excretion of CO_2 (hyperventilation). The metabolic production of CO_2 , however, may be increased during periods of stress or with excess carbohydrate administration (e.g., parenteral nutrition). Hyperventilation may develop from an increase in neurochemical stimulation via either central or peripheral mechanisms, or be the result of voluntary or mechanical (iatrogenic) hyperventilation.

A decrease in PaCO_2 may occur in patients with cardiogenic, hypovolemic, or septic shock because oxygen delivery to the carotid and aortic chemoreceptors is reduced. This relative deficit in PaO_2 stimulates an increase in ventilation. The hyperventilation in sepsis is also mediated via a central mechanism. Hyperventilation-induced respiratory alkalosis with an elevation in cardiac index and hypotension without peripheral vasoconstriction may therefore be an early sign of sepsis.

CLINICAL PRESENTATION

Although most patients are asymptomatic, respiratory alkalosis may cause adverse neuromuscular, cardiovascular, and gastrointestinal effects.⁴⁹ During periods of decreased PaCO_2 , there is a decrease in cerebral blood flow, which may be responsible for symptoms of light-headedness, confusion, decreased intellectual functioning, syncope, and seizures. Nausea and vomiting may occur, probably as a result of cerebral hypoxia. In severe respiratory alkalosis, cardiac arrhythmias may occur, due to sensitization of the myocardium to the

arrhythmogenic effects of circulating catecholamines.² Acute respiratory alkalosis has no effect on blood pressure or cardiac output in awake individuals. Anesthetized patients, however, may experience a decrease in both cardiac output and blood pressure, possibly owing to the lack of a tachycardic response.⁵⁰

CLINICAL PRESENTATION OF RESPIRATORY ALKALOSIS**GENERAL**

The patient is usually asymptomatic if the condition is chronic and mild.

SYMPTOMS

The patient may complain of light-headedness, confusion, muscle cramps and tetany, and decreased intellectual functioning.

Nausea and vomiting may occur, probably as a result of cerebral hypoxia.

SIGNS

In severe respiratory alkalosis $\text{pH} > 7.60$
Syncope and seizures
Cardiac arrhythmias
Hyperventilation

LABORATORY TESTS

Serum chloride concentration is usually slightly increased. Serum ionized calcium, potassium, and phosphorus concentration may be decreased.

The concentration of serum electrolytes may also be altered secondary to the development of respiratory alkalosis. The serum chloride concentration is usually slightly increased, and serum potassium concentration may be slightly decreased. Clinically significant hypokalemia can be a consequence of extreme respiratory alkalosis, although the effect is usually very small or negligible.^{2,50} Serum phosphorus concentration may decrease by as much as 1.5 to 2.0 mg/dL because of the shift of inorganic phosphate into cells. Reductions in the blood ionized calcium concentration may be partially responsible for symptoms such as muscle cramps and tetany. Approximately 50% of calcium is bound to albumin, and an increase in pH results in an increase in binding.⁴⁹

COMPENSATION

The initial response of the body to acute respiratory alkalosis is chemical buffering. Hydrogen ions are released from the body's buffers—intracellular proteins, phosphates, and hemoglobin—and titrates down the serum bicarbonate concentration. This process occurs within minutes. Acutely, the bicarbonate concentration can be decreased by a maximum of 3 mEq/L for each 10-mm Hg decrease in PaCO_2 ¹⁷ (see Table 51–4). When only the physicochemical buffering has occurred, the disturbance is referred to as acute respiratory alkalosis.

Metabolic compensation occurs when respiratory alkalosis persists for more than 6 to 12 hours. In response to the alkalemia, proximal tubular bicarbonate reabsorption is inhibited and the serum bicarbonate concentration falls. Renal compensation is usually complete within 1 to 2 days. The renal bicarbonaturia, as well as decreased NH_4^+ and titratable acid excretion, are direct effects of the reduced PaCO_2 and pH on renal reabsorption of chloride and bicarbonate.² The

acuity of the respiratory alkalosis can be assessed on the basis of the degree of renal compensation (see Table 51–4). In fully compensated respiratory alkalosis, the bicarbonate concentration falls by 4 mEq/L below 24 for each 10–mm Hg drop in PaCO₂. For example, a sustained

decrease in PaCO₂ of 20 mm Hg will lower serum bicarbonate from 24 to 14 mEq/L with a resultant pH of 7.46. Bicarbonate concentrations differing from those anticipated using the preceding guidelines suggest a mixed acid-base disorder (refer to Fig. 51–4).

► TREATMENT: Respiratory Alkalosis

Because most patients with respiratory alkalosis, especially chronic cases, have few or no symptoms and pH alterations are usually mild (pH not exceeding 7.50), treatment is often not required.⁴² The first consideration in the treatment of acute respiratory alkalosis with pH >7.50 is the identification and correction of the underlying cause. Relief of pain, correction of hypovolemia with intravenous fluids, treatment of fever or infection, treatment of salicylate overdose, and other direct measures may prove effective. A rebreathing device, such as a paper bag, may be useful in controlling hyperventilation in patients with the anxiety/hyperventilation syndrome.⁴⁹ Oxygen therapy should be initiated in patients with severe hypoxemia. Patients with life-threatening alkalosis (pH >7.60) and complications such as arrhythmia or seizures may require mechanical ventilation with sedation and/or paralysis to control hyperventilation. Simple respiratory alkalosis rarely requires such aggressive therapy, but it may be necessary for patients with mixed respiratory and metabolic alkalosis.

Respiratory alkalosis in patients receiving mechanical ventilation is usually iatrogenic. It may often be corrected by decreasing the minute ventilation (i.e., the number of mechanical breaths per minute times the volume delivered), although other measures can also be employed. The use of a capnograph and spirometer in the breathing circuit enables a more precise adjustment of the ventilator settings. Another method of treating respiratory alkalosis is to increase the amount of dead space in the ventilator circuit by placing a known length of tubing between the artificial airway and the “Y” piece of the ventilator. This results in “rebreathing” of expired gas, and therefore an increase in the inspired carbon dioxide concentration, which should increase the carbon dioxide tension of the patient, correcting the respiratory alkalosis. In patients breathing more rapidly than the ventilator settings, sedation with or without paralysis may be beneficial.

RESPIRATORY ACIDOSIS

PATHOPHYSIOLOGY

Respiratory acidosis, a primary retention of carbon dioxide that lowers the pH, results from a failure of the lungs to excrete carbon dioxide normally. This may be the result of neuromuscular diseases that inhibit central control of ventilation or neuromuscular function, intrinsic airway or parenchymal pulmonary disease, or interruption in pulmonary perfusion (Table 51–10). Acute respiratory acidosis with hypoxemia, hypercarbia, and acidosis is life-threatening. Those disorders that produce an increase in PaCO₂ and hypoxemia to a degree compatible with life (e.g., chronic obstructive pulmonary disease), with or without oxygen therapy, may result in chronic respiratory acidosis (Table 51–11). These patients can function normally without noticeable neurologic defects with PaCO₂ concentrations in the range of 90 to 100 mm Hg (normal, 40 mm Hg), provided adequate oxygenation is maintained.⁵⁰

CLINICAL PRESENTATION

Respiratory acidosis may produce neuromuscular symptoms, including altered mental status, abnormal behavior, seizures, stupor, and coma. Hypercapnia may mimic stroke or CNS tumors by producing headache, papilledema, focal paresis, and abnormal reflexes. Carbon dioxide acts as a vasodilator in the brain, thus causing an increase in cerebral blood flow.² This increase in cerebral blood flow is thought to be partially responsible for the CNS symptoms. The CNS response to hypercapnia is extremely variable between patients and is also influenced by the acuity of presentation. Chronic hypercapnia blunts the usual respiratory stimulus resulting from increased PaCO₂. In patients with severe chronic respiratory acidosis, hypoxemia rather than hypercapnia provides the primary ventilatory stimulus.⁵⁰

The degree to which cardiac contractility and heart rate are altered depends on the severity of the acidosis and the rapidity with which it develops. Modest acute hypercapnia (PaCO₂ of 50 to 55 mm Hg) stimulates a stress-like response, with elevated catecholamines and corticosteroid hormone levels, and can result in increased cardiac output and pulmonary artery pressure.⁵¹ As the severity increases, cardiac output declines and vascular resistance decreases. Refractory hypotension may be present in some patients.²

Inadequate frequency or tidal volume settings
Large dead space

Total parenteral nutrition (increased CO₂ production)

CLINICAL PRESENTATION OF RESPIRATORY ACIDOSIS

GENERAL

The patient is usually symptomatic.

SYMPTOMS

The patient may complain of confusion or difficulty thinking and headache.

SIGNS

In severe respiratory acidosis:

Cardiac: Increased cardiac output if moderate, that decreases if severe. Refractory hypotension may be present in some patients.

CNS: Abnormal behavior, seizures, stupor, and coma. Pappilledema, focal paresis, and abnormal reflexes may also be present.

LABORATORY TESTS

Serum potassium concentration may be modestly increased. Hypercapnia may be moderate (P_{aCO_2} of 50 to 55 mm Hg) to severe (P_{aCO_2} of >80 mm Hg). Hypoxia (P_{aO_2} is <70 mm Hg) is often present.

In respiratory acidosis, the serum potassium concentration increases modestly secondary to cellular shifts. The increases are less than those seen with inorganic metabolic acidosis and are difficult to predict for individual patients (see Chap. 50).

COMPENSATION

The body responds to acute respiratory acidosis with chemical buffering. The increase in P_{aCO_2} results in increased carbonic acid levels.

► TREATMENT: Respiratory Acidosis

The treatment of respiratory acidosis is dependent on the chronicity of the patient's condition. Respiratory decompensation in patients with chronic elevations in P_{aCO_2} are frequently seen in those with acute infections and those recently started on narcotic analgesics or oxygen therapy.⁴² Aggressive treatment of these conditions can offer considerable benefit and should be initiated. Furthermore, tranquilizers and sedatives should be avoided and supplemental oxygen, if used, should be minimized.

■ ACUTE RESPIRATORY ACIDOSIS

13 When carbon dioxide excretion is severely impaired (P_{aCO_2} >80 mm Hg) and/or life-threatening hypoxia is present (P_{aO_2} <40 mm Hg), the immediate therapeutic goal is to provide adequate oxygenation. Under these circumstances, hypoxia, not acidemia, is the principal threat to life. A patent airway needs to be established, which may necessitate intubation. Excessive secretions must be cleared from the airway and oxygen administered to restore adequate oxygenation. Mechanical ventilation is likely to be required.

The underlying cause of the acidosis should be treated aggressively (e.g., bronchodilators for treatment of severe bronchospasm;

Interstitial pulmonary disease

Overzealous parenteral feeding

The carbonic acid dissociates, releasing hydrogen ions, which are buffered by nonbicarbonate buffers (i.e., proteins, phosphate, and hemoglobin) and bicarbonate. Thus on the basis of physicochemical factors, increases in P_{aCO_2} raise the serum bicarbonate concentration. In general, in acute respiratory acidosis, the bicarbonate concentration increases by 1 mEq/L above 24 for each 10-mm Hg increase in P_{aCO_2} above 40 (see Table 51–4).

Metabolic compensation occurs when respiratory acidosis is prolonged beyond 12 to 24 hours. In response to hypercapnia and acidemia, proximal tubular bicarbonate reabsorption, ammoniogenesis, and distal tubular hydrogen secretion are enhanced, resulting in an increase in serum bicarbonate concentration and raising the pH toward normal. Renal compensation for chronic hypercapnia generally results in the plasma bicarbonate concentration increasing by 4 mEq/L above 24 for each 10-mm Hg increase in P_{aCO_2} above 40 (see Table 51–4). The new steady state in acid-base values is generally achieved within 5 days of the onset of hypercapnia in dogs; the time interval necessary for compensation in humans has not been established.

narcotic or benzodiazepine antagonists to reverse the effects of these respiratory depressant drugs). Bicarbonate administration is rarely necessary in the treatment of respiratory acidosis. Furthermore, rapid correction of acidosis with bicarbonate may eliminate the patient's respiratory drive or precipitate a metabolic alkalosis. Cautious use of alkali (bicarbonate or THAM) can restore the responsiveness of bronchial muscles to β -adrenergic agonists and thus may be beneficial for those patients with severe bronchospasm.⁵¹ Arterial blood gases should be monitored closely to ensure that the respiratory acidosis is resolving without creating a metabolic alkalosis as the result of compensatory elevation in HCO_3^- and decrease in P_{aCO_2} . Arterial blood gases should be obtained every 2 to 4 hours during the acute phase and less frequently (every 12 to 24 hours) as the acidosis improves.

■ ACUTE RESPIRATORY ACIDOSIS IN A COMPENSATED CHRONIC RESPIRATORY ACIDOTIC PATIENT

Patients with a history of chronic respiratory acidosis (e.g., those with chronic obstructive pulmonary disease) may experience an acute worsening of their respiratory acidosis. This may result in severe life-threatening hypoxemia. As with acute respiratory acidosis, the goals

of therapy are maintenance of a patent airway and adequate oxygenation. Individuals with chronic respiratory acidosis are routinely able to tolerate a low PaO_2 and an elevated PaCO_2 because of compensation (increased number of red blood cells, hemoglobin content, and 2,3-diphosphoglycerate). The drive to breathe in these patients is dependent on hypoxemia rather than hypercarbia. Administration of oxygen to a patient with chronic respiratory acidosis can eliminate this drive to breathe and result in the syndrome of carbon dioxide narcosis. In this case, if the PaO_2 is 50 mm Hg, no oxygen treatment is necessary. If the PaO_2 is <50 mm Hg, oxygen therapy should be initiated carefully using a controlled flow of oxygen.²

Arterial blood gases should be checked periodically to ensure adequate oxygenation. If the PaCO_2 increases during oxygen therapy, it may be a sign of impending carbon dioxide narcosis and oxygen therapy may need to be discontinued. The underlying cause of the acute exacerbation should be aggressively managed. Pulmonary infections should be treated with the appropriate antibiotics and bronchodilators administered as necessary. Excess secretions should be cleared from the airway to allow proper gas exchange. This may involve increasing oral fluid intake to decrease the viscosity of secretions, deep breathing, and postural drainage, suction, or bronchoscopy.

MIXED ACID-BASE DISORDERS

DIAGNOSIS

The diagnosis of a mixed disorder depends on an understanding of the appropriate quantitative response of the compensatory mechanisms for each of the simple acid-base disturbances. To diagnose mixed disorders, one must know how each of the four simple disorders alters pH, PaCO_2 , and $[\text{HCO}_3^-]$ (see Table 51-4). If a given set of blood gases does not fall within the range of expected responses for a simple acid-base disturbance (see Fig. 51-4), a mixed disorder should be suspected. In addition to laboratory information, a thorough history and physical examination of the patient will often lead to the diagnosis, even before the laboratory data are available. Examples of common mixed disturbances follow.

MIXED RESPIRATORY ACIDOSIS AND METABOLIC ACIDOSIS

In mixed respiratory and metabolic acidosis, there is a failure of compensation. The respiratory disorder prevents the compensatory decrease in PaCO_2 expected in the defense against metabolic acidosis. The metabolic disorder prevents the buffering and renal mechanisms from raising the bicarbonate concentration as expected in the defense against respiratory acidosis. In the absence of compensatory mechanisms, the pH decreases markedly.

Mixed respiratory and metabolic acidosis may develop in patients with cardiorespiratory arrest, in those with chronic lung disease who are in shock, and in metabolic acidosis patients who develop respiratory failure. This mixed disorder should be treated by responding to both the respiratory and metabolic acidosis. Improved oxygen delivery must be initiated to improve hypercarbia and hypoxia. Mechanical ventilation may be needed to reduce PaCO_2 . During the initial stage of therapy, appropriate amounts of alkali should be given to reverse the metabolic acidosis (see section on treatment of metabolic acidosis earlier in this chapter).

MIXED RESPIRATORY ALKALOSIS AND METABOLIC ALKALOSIS

The combination of respiratory and metabolic alkalosis is the most common mixed acid-base disorder. This mixed disorder occurs frequently in critically ill surgical patients with respiratory alkalosis caused by mechanical ventilation, hypoxia, sepsis, hypotension, neurologic damage, pain, or drugs, and with metabolic alkalosis caused by vomiting or nasogastric suctioning and massive blood transfusions. It may also occur in patients with hepatic cirrhosis who hyperventilate, receive diuretics, or vomit, as well as in patients with chronic respiratory acidosis and an elevated plasma bicarbonate concentration

who are placed on mechanical ventilation and undergo a rapid fall in PaCO_2 .

The decrease in bicarbonate concentration that usually compensates for respiratory alkalosis is prevented by the complicating metabolic alkalosis. Likewise, the increase in PaCO_2 expected to compensate for metabolic alkalosis is prevented by primary respiratory alkalosis. The failure of compensation that occurs with mixed respiratory and metabolic alkalosis may result in a severe alkalemia.

Correction of the metabolic component by administration of sodium chloride and potassium chloride solutions should be undertaken, and readjustment of the ventilator or treatment of an underlying disorder causing hyperventilation may correct or ameliorate the respiratory component of this mixed disorder.

MIXED METABOLIC ACIDOSIS AND RESPIRATORY ALKALOSIS

This mixed disorder is often seen in patients with advanced liver disease, salicylate intoxication, and pulmonary-renal syndromes. The respiratory alkalosis decreases the PaCO_2 beyond the appropriate range of the respiratory compensation for metabolic acidosis. The plasma bicarbonate concentration also falls below the level expected in compensation for a simple respiratory alkalosis. In a sense, the defense of pH for either disorder alone is enhanced; thus the pH may be normal or close to normal, with a low PaCO_2 and a low $[\text{HCO}_3^-]$. Treatment of this disorder should be directed at the underlying cause. Because of the enhanced compensation, the pH is usually closer to normal than in either of the two simple disorders.

MIXED METABOLIC ALKALOSIS AND RESPIRATORY ACIDOSIS

This mixed disorder often occurs in patients with chronic obstructive pulmonary disease and chronic respiratory acidosis who are treated with salt restriction, diuretics, and possibly glucocorticoids. When diuretics are initiated, the plasma bicarbonate may increase because of increased renal bicarbonate generation and reabsorption, providing mechanisms for both generating and maintaining metabolic alkalosis. The elevated pH diminishes respiratory drive and may therefore worsen the respiratory acidosis.

Although the pH may not deviate significantly from normal, treatment may need to be initiated to maintain PaO_2 and PaCO_2 at acceptable levels. Because it is often difficult to correctly identify this mixed disorder, it is helpful to observe the patient's response to discontinuation of diuretics and administration of sodium and potassium chloride.² If the patient has a simple metabolic alkalosis, the PaCO_2 will normalize, but it will only minimally affect the PaCO_2 if it is a mixed disorder. Treatment should be aimed at decreasing the plasma bicarbonate with sodium and potassium chloride therapy,

thereby allowing the renal excretion of retained bicarbonate from the diuretic-induced metabolic alkalosis. This therapy should be used cautiously to avoid exacerbating any underlying congestive heart failure.

EVALUATION OF THERAPEUTIC OUTCOMES

Because acid-base disorders are such a common and widespread problem, pharmacists may play a key role in identifying, preventing, and properly treating acid-base abnormalities. Acid-base disorders do not occur only in the intensive care unit setting. Patients in ambulatory and extended care settings have many chronic conditions and drug therapies that commonly affect acid-base balance. Thus pharmacists in all practice settings should use their knowledge to identify patients at high risk for developing drug-related problems and to undertake appropriate prevention and treatment measures to improve the quality of life of the patients they care for.

ABBREVIATIONS

BW: body weight
 CNS: central nervous system
 DCA: dichloroacetate
 ECF: extracellular fluid
 H_2CO_3 : carbonic acid
 H^+ : hydrogen ion
 HCO_3^- : bicarbonate
 HIV: human immunodeficiency virus
 NH_4^+ : ammonium
 PaCO_2 : partial pressure of carbon dioxide from arterial blood
 PaO_2 : partial pressure of oxygen from arterial blood
 pH: the negative logarithm (base 10) of the hydrogen ion concentration
 pK: the negative logarithm of the dissociation constant
 PvCO_2 : partial pressure of carbon dioxide from venous blood
 PvO_2 : partial pressure of oxygen from venous blood
 RTA: renal tubular acidosis
 SAG: serum anion gap
 THAM: tromethamine [tris(hydroxymethyl)aminomethane]
 UC: unmeasured cations
 UA: unmeasured anions

EVALUATION OF NEUROLOGIC ILLNESS

Susan C. Fagan and Fenwick T. Nichols

Learning Objectives and other resources can be found at www.pharmacotherapyonline.com.

KEY CONCEPTS

- 1 The clinical neurologic history and examination are the cornerstones of the neurologic diagnosis and management.
- 2 Through the history, one can determine the main symptoms, the mode of onset (gradual or sudden), progression over time (maximal at onset or steadily gaining intensity), and associated illnesses/risk factors.
- 3 The neurologic examination is directed at localization of the

disease process so that evaluation and management may be planned appropriately.

- 4 The neurologic examination of a specific patient may be adapted to the patient's specific deficit. For example, a patient with double vision may warrant an extensive cranial nerve examination but a less extensive assessment of finger strength.

In order to contribute most effectively to the care of patients with neurologic illness, one must understand the tools used in the diagnosis and management of these patients. In addition, clinicians must be able to gather their own data through a targeted neurologic examination and history taking in order to ensure optimal pharmacotherapy in neurologic patients. Despite technologic advances that have led to the development of sensitive diagnostic tests in neuroscience, the clinical neurologic history and examination are still the cornerstones of the neurologic diagnosis and management.¹

SIGNS AND SYMPTOMS

- 1 As in all of medicine, obtaining an accurate and complete history is of utmost importance in the evaluation of neurologic diseases. In many instances, the diagnosis can be made on the basis of the history, and the neurologic examination can be tailored to optimally evaluate the patient and confirm the diagnosis. The clinician depends on the patient or family for the details of the illness. Care must be taken to avoid "leading" the patient. Obtaining an accurate history may be difficult because a number of neurologic diseases may affect patients' speech and memory. Through the history, one can determine the main symptoms, the mode of onset (gradual or sudden), progression over time (maximal at onset or steadily gaining intensity), and associated illnesses/risk factors (recent head injury from a motor vehicle accident).

The physical examination is important in revealing evidence of systemic disease that may have affected the nervous system secondarily (e.g., a seizure in a patient with elevated temperature and stiff neck may suggest meningitis). The neurologic examination is only one component of a complete general physical examination.

THE NEUROLOGIC EXAMINATION

- 3 An assessment of patient effort is necessary to interpret the results of the neurologic examination. It can identify any abnormalities, particularly asymmetry of function, and help to localize the lesion within the nervous system (central versus peripheral and specific location within the central nervous system or the peripheral nervous system). The neurologic examination consists of six main components: higher cortical function (mental status), cranial nerves, motor function, reflexes, sensory function, and gait. Table 52–1 describes the common approaches to assessing each of the six domains and includes examples of the diseases in which abnormal findings are common. A targeted neurologic examination can be performed when a specific deficit is suspected. Table 52–2 describes the cranial nerve examination in more detail. The reader is encouraged to consult other references to better understand the intricacies of the neurologic examination.² The clinician must synthesize the results of the history and physical examination to arrive at an anatomic localization of the lesion and create a differential diagnosis.

PROCEDURES USED IN THE DIAGNOSIS

In addition to the neurologic examination, certain imaging techniques and procedures may be essential in the diagnosis of neurologic disorders. Some of the more commonly used procedures are described next.²

Lumbar puncture (LP) is used to obtain cerebrospinal fluid (CSF). It is used most often as an evaluation of CNS infections such as meningitis and encephalitis, but it is also useful in subarachnoid hemorrhage, multiple sclerosis, and dementia. Opening pressure, cell count and differential, glucose concentration, total protein

TABLE 52–1. The Neurologic Examination

| Domain | Tests Performed | Diseases |
|------------------|---|---|
| Mental status | While obtaining the history: general mental and emotional status, speech, memory, alertness, abstract reasoning, ability to follow commands (motor integration), ability to communicate | Dementias, stroke, metabolic encephalopathies |
| Cranial nerves | Visual acuity, visual fields, eye movements, jaw strength, corneal reflex, facial symmetry, auditory acuity, gag reflex, shoulder and neck strength | Myasthenia gravis, Parkinson’s disease, stroke, amyotrophic lateral sclerosis (ALS) |
| Motor function | Motor strength with and without resistance, coordination (rapid alternating movements, finger-to-nose), tremors, atrophy, fasciculations | Stroke, myasthenia gravis, Parkinson’s disease, ALS |
| Reflexes | Biceps, triceps, tendon reflexes, plantar response (Babinski sign is an upgoing toe and is abnormal), superficial cutaneous reflexes (abdominal) | Stroke, spinal cord lesions, endocrine diseases (e.g., diabetes, hypothyroidism), peripheral neuropathy |
| Sensory function | Asymmetry to pin-prick, vibration, temperature | Stroke, peripheral neuropathy, migraine aura, diabetes, spinal cord lesions |
| Gait | Walking, standing (Romberg test = eyes closed will accentuate disequilibrium) | Stroke, Parkinson’s disease, spinal cord lesions |

concentration, and culture and sensitivity are obtained routinely. A space-occupying lesion in the brain with mass effect is a relative contraindication to LP because herniation could result. Prior to performing an LP, the patient should be checked for papilledema, which may indicate increased intracranial pressure (ICP). The opening CSF

pressure usually is less than 180 mm H₂O. Normal CSF is clear and colorless and should not contain any red blood cells (RBCs) or polymorphonuclear cells. The presence of up to five mononuclear cells is considered normal. Total protein in the CSF usually is 45 mg/dL or less. Protein may increase with infection, breakdown of the blood-brain barrier (e.g., tumors, stroke, and trauma), and diabetes.

TABLE 52–2. Cranial Nerve Function and Examples of Testing

- I. Olfactory nerve. Smell: Identify odors (coffee, cinnamon, lemon; test each nostril separately).
- II. Optic nerve. Visual acuity: Eye card; Visual fields: Peripheral vision and blind spot; Funduscopic exam; Pupil size and reaction; Color vision (rarely done).
- III. Oculomotor. (Cranial nerves III, IV, and VI have similar functions and are tested as a unit.) Eye movements: Patient is asked to watch a light as it moved up, down, and on both sides, while eye movements are observed.
- IV. Trochlear. See III.
- V. Trigeminal nerve. Motor: Tests power of jaw opening and sideways deviation against the resistance of a hand placed against the jaw. Sensory: Test corneal reflex by touching cornea (also nasal mucosa) with a wisp of cotton.
- VI. Abducens. See III.
- VII. Facial nerve. Observe asymmetry of face at rest or on speaking, baring teeth, raising eyebrows, or wrinkling forehead. Reflex eye closure to a threatening movement. Glabellar tap: Repetitive tapping over bridge of nose—initial blinking should cease after the first few taps.
- VIII. Auditory nerve. Vestibular division: Observe for nystagmus, positional testing. Auditory division: Test acuity with light sound; watch, whisper, rubbing of fingers close to ear.
- IX. Glossopharyngeal nerve. Test for gag reflex by touching back of throat with tongue depressor; test swallowing and coughing and note any drooling or pooling of saliva. Test symmetry of palate movement on vocalizing “ah.”
- X. Vagus nerve. Test gag reflex as in IX.
- XI. Spinal accessory nerve. Trapezius and sternomastoid muscles: Test power of shrugging shoulders and turning the head to one side against resistance.
- XII. Hypoglossal nerve. Motor function of tongue. Look for wasting and abnormal movements.

Electroencephalography (EEG) records the electrical activity of the brain. The record is interpreted by observing the basic rhythms and waveforms, the symmetry of the recording, and abnormal electrical discharges. It also may be used to assess the response to photic stimulation or hyperventilation. It is used primarily in the diagnosis of seizures and may be helpful in the evaluation of patients with altered mental status. EEG also may be used to measure evoked potentials (EPs). The EPs are the EEG response to repetitive stimuli (visual, auditory, or tactile) and provide information about the presence of abnormalities and disturbances (but not the cause) in the specific pathways tested.

Electromyography (EMG) and nerve conduction velocities (NCVs) are used to assess the function of the peripheral nerves, neuromuscular junction, and muscles. NCVs are measured by stimulating the nerve and recording the speed of conduction of the impulse. NCVs can be used to detect the presence of localized peripheral nerve injuries (carpal tunnel, etc.) or diffuse symmetric neuropathies (which may be inherited or acquired). EMG assesses muscle dysfunction due to primary muscle disease or secondary to nerve injury. This test is used to diagnose peripheral neuropathies (inherited and acquired), Guillain-Barré syndrome, myasthenia gravis, amyotrophic lateral sclerosis, radiculopathies, and muscle diseases.

The cerebral circulatory system can be imaged or evaluated in a number of different ways depending on the type and location of the abnormality suspected. Imaging techniques can be used to identify local arterial stenosis, aneurysms, or arteriovenous malformations. Atherosclerosis of the extracranial arteries, a frequent cause of stroke, can be evaluated using ultrasound (referred to as *duplex sonography*, *carotid Doppler*, or *color-flow Doppler*), magnetic resonance angiography (MRA), spiral computed tomographic angiography (CTA), or intraarterial angiography. The intracranial arterial circulation can be evaluated using transcranial Doppler (TCD), MRA, CTA, or intraarterial angiography. Each technique has its own advantages and disadvantages. Intraarterial angiography provides the best imaging of the

smaller arteries of the cerebral circulation but is more invasive than the other measures.

Computed tomography (CT) uses x-rays to produce images of “slices” of the brain that are 1 to 10 mm in thickness. CT revolutionized the practice of neurology by allowing direct imaging of the brain anatomy. CT is currently available in most communities and is used to evaluate patients with intracranial disease. CT scans are used to identify tumors, hemorrhages, infarctions, hydrocephalus, and atrophy. Intravenous contrast agents (a contrast-enhanced scan) can be administered to enhance the image of blood vessels and areas of blood-brain barrier damage that may be caused by abscesses, other inflammatory conditions, tumors, or stroke.

Magnetic resonance imaging (MRI) uses the magnetic properties of the hydrogen atom nucleus and proton to produce computer-processed scans that provide improved anatomic detail when compared with CT scans. MRI offers the advantages of better differentiating between white and gray matter and delineating lesions close to bone (brain stem and cerebellum) and has no radiation risk; however, it is not as readily available as CT and is more expensive. MRI has a proven advantage over CT in evaluating lesions in the posterior fossa and in detecting lesions in the white matter such as plaques in multiple sclerosis. MRI is also useful in the diagnosis of tumors and very early ischemic stroke (diffusion-weighted imaging, or DWI). Imaging of the spinal canal and its contents can be accomplished either by MRI myelography or CT myelography.

Other imaging techniques such as positron-emission tomography (PET) and single-photon-emission computed tomography (SPECT) are considered tests of brain function. These tests are being studied extensively in epilepsy as well as in cerebrovascular disorders, cerebral tumors, movement disorders, and dementia. PET scans use a positron-emitting isotope to display chemical activity and the rates of biologic processes within the brain. This method can assess regional metabolic changes in the brain. The expense, technical complexity (a cyclotron is needed), and limited availability of this technique limit its clinical utility.

SPECT scans measure radiotracer uptake by tissues and provide cross-sectional images of the brain. This technique has been used extensively to assess cerebral blood flow. Although the resolution of SPECT is not as good as PET, the availability has led to wide clinical use in disorders such as stroke, dementia, and epilepsy.

CONCLUSION

Assessment of the patient with neurologic disease is challenging. The patient by virtue of the neurologic deficit, may or may not be able to provide reliable information regarding medication history or extent of illness. The clinician must develop alternate strategies to obtain a complete data set and develop a pharmacotherapy plan. Ability to interpret and synthesize the results of the neurologic examination and other diagnostic tests will help a great deal in this quest.

ABBREVIATIONS

CSF: cerebrospinal fluid

MULTIPLE SCLEROSIS

Jacquelyn L. Bainbridge and John R. Corboy

Learning Objectives and other resources can be found at www.pharmacotherapyonline.com.

KEY CONCEPTS

- 1 The etiology of multiple sclerosis (MS) is unknown, and currently there is no cure.
- 2 MS appears to be an immunologic disorder that is characterized by central nervous system demyelination and axonal damage.
- 3 Diagnosis of MS is made primarily on the basis of clinical examination and magnetic resonance imaging (MRI) findings.
- 4 Acute exacerbations or relapses usually are treated with high-dose glucocorticoids, such as methylprednisolone.
- 5 In most patients suffering from an acute exacerbation, a clinical response to steroid treatment can be expected within 3 to 5 days.
- 6 Treatment with interferon- β or glatiramer acetate (Avonex, Betaseron, Copaxone, and Rebif, or ABC-R, therapy) can reduce annual relapse rate, slow progression of disability, slow cognitive decline, and slow changes seen on the brain MRIs.
- 7 Treatment with immunomodulating interferon- β or glatiramer acetate (ABC-R therapy) should begin promptly after the diagnosis of relapsing MS is made and after a single attack if the MRI is suggestive of high risk of further attacks. Therapy after interferon- β or glatiramer acetate (ABC-R therapy) “treatment failure” and in patients with secondary progressive MS and primary progressive MS is not clear.
- 8 The only treatments approved for secondary progressive MS are mitoxantrone and interferon- β -1b.
- 9 Patients suffering from MS frequently will have symptoms such as spasticity, bladder dysfunction, fatigue, pain, and depression that may require treatment. Patients must be counseled that therapies such as interferon- β and glatiramer acetate will not relieve these symptoms.
- 10 Depression is common in MS and may pose the risk of suicide.

Multiple sclerosis (MS) is an inflammatory disease of the central nervous system (CNS) that affects between 250,000 and 350,000 persons in the United States.¹ It is one of the major causes of neurologic disability in young and middle-aged adults. The term *multiple sclerosis* refers to two characteristics of the disease: the numerous affected areas of the brain and spinal cord producing multiple neurologic symptoms that accrue over time and the characteristic plaques or sclerosed areas that are the hallmark of the disease.

1 Although MS was first described almost 130 years ago, the cause remains a mystery, and a cure is still unavailable. Nevertheless, many advances have been made in treating and managing the complications of the disease and improving the quality of life of individuals affected by MS.

EPIDEMIOLOGY

MS usually is diagnosed in patients between the ages of 20 and 45 years (although cases in children have been reported), with the peak incidence occurring in the fourth decade of life.² Reported onset can occur as early as age 10 and as late as the eighth decade, and one of the authors (Corboy) has seen a child with first symptoms at age 4.³ Women are afflicted more than men by a ratio of approximately 2:1.³ Men usually develop the first signs of MS at a later

age than women and are also more likely to develop the progressive form of the disease.³ The most important factors in the determination of individuals at risk for developing the disease are geography, age, environmental influences, and genetics.²⁻⁵

In general, the greater the distance from the equator, the higher is the prevalence of the disease.^{2,6,7} Within the United States, the prevalence of MS is higher in states above the thirty-seventh parallel. MS occurs more frequently in whites of Scandinavian ancestry than in other ethnic groups.^{8,9}

It is thought that a crucial environmental agent that may predispose one to developing MS is contacted by susceptible individuals between the ages of 10 and 15 years who usually have lived in a high-risk area for at least 2 years.⁹ Interestingly, an individual who migrates from a low- to a high-risk area prior to age of 15 years acquires the same chance of developing MS as those who live in a high-risk area all their lives.¹⁰ If the move is made in the opposite direction, from a high- to a low-risk area, the individual retains the high risk if the move is made after the age of 15 years but acquires the lower risk if the move is made prior to this age.^{9,10}

The familial recurrence rate of MS is approximately 5%, with siblings being the most commonly reported relationship.⁸ Concordance data show a higher prevalence of MS between monozygotic than between dizygotic twins, and a recent study has confirmed the overall concordance among monozygotic twins at about 25%, with a

risk among females of 34% and males just 5%, similar to that seen in dizygotic twins.¹¹ Genetic studies also have determined an association between MS and the major histocompatibility complex (MHC) and, in particular, with the human leukocyte antigen (HLA) region on the sixth chromosome that is associated with the genetic control of immune mechanisms.^{8,12,13} This association between HLA haplotype and MS susceptibility may vary between ethnic groups. In whites, the strongest association appears to be with the MHC class II allele DR2 haplotype. The relative risk of developing MS is approximately four times as great in DR2+ versus DR2- individuals.¹² This association is not specific enough to be used for diagnostic purposes given a 30% to 50% false-negative rate and that the DR2+ haplotype is found in at least 20% of the healthy white population. Although the significance of the association between MS and the HLA region remains unclear, the fact that certain HLA antigens are neither necessary nor sufficient to lead to the development of MS suggests that inheritance is most likely polygenic in nature and that there may only be a genetic susceptibility to developing this disease following an as-yet-unknown etiologic challenge. In addition, a number of genes have been identified that may alter the speed of progression of the illness, such as apolipoprotein E ε4 homozygosity.^{14,15}

ETIOLOGY

AUTOIMMUNE THEORY

In the autoimmune theory (Fig. 53-1), MS results from an autoimmune attack against self-myelin or self-oligodendrocyte antigens. The actual mediator of myelin destruction has not been established, but this activity has been attributed to the action of macrophages, killer T cells, lymphokines, antibodies, or a combination of these elements.¹⁶ T-helper cells (CD4+) appear to be key initiators of myelin destruction in MS. These autoreactive CD4+ cells are activated in the periphery, perhaps following a viral infection, and express adhesion molecules on their surfaces that allow them to attach and roll along the endothelial cells that constitute the blood-brain barrier (BBB). These

activated T cells also produce matrix metalloproteinases that help to create openings in the BBB, allowing entry of the activated T cells past the BBB and into the CNS. Once inside the CNS, the T cells produce cytokines, which further create openings in the BBB, allowing entry of B cells, complement, macrophages, and antibodies. The T cells also interact within the CNS with the resident microglia, astrocytes, and macrophages, further enhancing production of proinflammatory cytokines and other potential mediators of CNS damage, including reactive oxygen intermediates and nitric oxide. The exact trigger for the activation of the T cells in the periphery remains unclear, but the T cells recognize myelin basic protein (MBP), proteolipid protein, myelin oligodendrocyte glycoprotein, and myelin-associated glycoprotein in the blood of patients with MS. A reduction in T-suppressor cells, or suppressor activity, has been reported during active MS and in patients with progressive disease; however, a relative increase in the T-helper/suppressor ratio is not found consistently and does not always correlate with disease activity.¹⁷⁻¹⁹

ROLE OF CYTOKINES

Cytokines are molecules whose physiologic functions are numerous and include modulating inflammatory and anti-inflammatory responses in the immune system. Cytokines such as tumor necrosis factor alpha (TNF-α), interleukin-2 (IL-2), and interferon-γ (INF-γ) have been alleged as contributors to the pathogenesis of MS. TNF-α may contribute to demyelination by upregulation of MHC class I expression, direct injury of oligodendrocytes, and/or promotion of BBB breakdown.²⁰ INF-γ is produced predominantly by CD4+ cells and is involved in antiviral responses. Because of this, INF-γ was at one time evaluated as a potential MS disease-modifying agent. Clinical trials, however, clearly demonstrated that treatment with this compound resulted in disease exacerbation.²¹ INF-γ upregulates MHC class II expression on macrophages, microglia, and astrocytes, leading to an inflammatory response. INF-γ also upregulates adhesion molecules, which are crucial in the early stages of inflammation by facilitating the migration of T cells across the endothelial cells of the BBB.²²

FIGURE 53-1. Autoimmune theory of the pathogenesis of MS. The immune response is initiated in the peripheral immune compartment when antigen is processed and presented to an inducer cell by a macrophage or antigen-presenting cell. The inducer cell becomes activated and releases a number of soluble factors, including interleukins and interferons, that act on both B and T cells to augment the immune response. T-suppressor cells act to dampen the immune response. Activated T cells traffic into the central nervous system, where they again release factors, presumably after having antigen presented to them. In this regard, astrocytes are capable of presenting antigens to T cells. Other cellular elements also enter the CNS (macrophages, B cells), where the potential for a local immune response occurs. B cells are known to produce immunoglobulin locally within the CNS, and macrophages function within the CNS to phagocytose myelin, in addition to their antigen-presenting properties. (Reprinted with permission from *Ann Neurol* 1988;23: 214.)

In contrast, the role of modulating, or downregulating, cytokines also has been described. In patients with stable or mild disease, increased numbers of cells are found that express mRNA for transforming growth factor beta (TGF- β) and IL-10 compared with patients with severe disease.^{23,24}

QUESTIONABLE MICROBIAL ETIOLOGY

Although no clear association with any microbial agent has been identified, there are several ways in which a virus or bacteria could play a role in the pathogenesis of MS. These might include either a direct attack on myelin and/or the oligodendrocyte or stimulation of an autoimmune response leading to demyelination.^{16,25} Evidence to support a viral etiology includes increased immunoglobulin G (IgG) synthesis in the CNS, increased antibody titers to certain viruses, and epidemiologic studies indicating a childhood exposure factor and suggesting that “viral” infections may precipitate exacerbations. Immunoglobulin patterns in the cerebrospinal fluid (CSF) are similar in subacute sclerosing panencephalitis (SSPE) and MS. SSPE is a chronic measles infection of the CNS known to be associated with the production of oligoclonal bands in the CSF.²⁶ In addition, viruses have been shown to cause diseases with prolonged incubation periods, myelin destruction, and a relapsing/remitting course in both humans and experimental animal models.^{2,27}

The most compelling evidence against a microbial etiology is the fact that no single infectious agent has been identified as the cause of MS. Many possible agents have been implicated, including mycoplasma, spirochetes, rabies virus, herpes simplex, canine distemper virus, coronavirus, human T-cell leukemia virus type I (HTLV-I), MS-associated retrovirus, measles, and most recently, human herpes virus type 6 (HHV-6)²⁸ and *Chlamydia pneumoniae*.²⁹ However, to date, no causal relationship has been established.^{27,30}

PATHOPHYSIOLOGY

2 The basic physiologic derangement in MS is the stripping of the myelin sheath surrounding neurons in the CNS. Demyelination, coupled with an inflammatory response, leads to the formation of the characteristic MS lesions, or plaques, that are found primarily in the brain, spinal cord, and optic nerves. Initially, neuronal axons, although stripped bare of their myelin sheath, usually are well preserved.²⁵ Recent studies, however, have shown that damage to axons can be significant, even early in the course of the illness.³¹ Axonal damage may be seen as a hypointense lesion, or T₁ hole, on magnetic resonance imaging (MRI), and these correlate with disability.³²

Demyelination and axonal transection cause disruption in the transmission of nerve impulses, which leads to neurologic symptoms reflecting the area of the brain or spinal cord that is affected. Demyelinated nerve fibers have prolonged refractory periods that impair conduction of electrical impulse volleys. Maximal electrical impulse frequency may be reduced substantially before impulse conduction is interrupted entirely. A single plaque may extend across several nerve pathways, producing symptoms involving several nervous system functions. Smaller plaques may cause isolated disturbances; however, typically several plaques develop at the same time, causing multiple but unrelated problems such as disturbed vision and decreased sensation.

The pathology of MS lesions is different in early stages of the disease, during chronic MS, and during acute exacerbations.³³ Active and inactive lesions can be found side by side in the brain. Both

types of lesions display some degree of perivascular inflammation, but inflammation is much more pronounced and usually associated with BBB damage in active lesions.³³

Decreased numbers of oligodendrocytes (myelin-producing cells) are observed within the MS plaques, causing speculation as to whether myelin or the oligodendrocyte is the target of an immunologic attack.^{18,25,34} Oligodendrocyte destruction appears to occur in a nonspecific manner in early or acute MS, whereas selective destruction of myelin and oligodendrocytes occurs in chronic stages of MS.³³ More recent studies have identified four immunopathologic subtypes of demyelinating lesions, with variable amounts of T cells or immunoglobulins present in the plaques. All type IV patients studied so far have primary progressive multiple sclerosis (PPMS), but otherwise, there is no obvious association of immunopathology and clinical type.³⁵

CLINICAL PRESENTATION

The clinical presentation of MS is extremely variable among patients and typically varies over time in a given patient (Table 53–1). The signs and symptoms of MS usually are divided into three categories. Primary symptoms are a direct consequence of conduction disturbances produced by demyelination and axonal damage and reflect the area of the brain or spinal cord that is damaged. Secondary symptoms are complications resulting from primary symptoms. For example, urinary retention, a primary symptom, may lead to frequent urinary tract infections, considered a secondary symptom. Tertiary symptoms relate to the effect of the disease on the patient’s everyday life.³⁶

The most widely used clinical rating scale in MS is the Expanded Disability Status Scale (EDSS), in which a numerical value ranging from 0 (no disability) to 10 (death from MS) is assigned based on the evaluation of several neurologic functions.³⁷ The limitations of this scale are the relative insensitivity to clinical changes not involving impairment of gait and ambulation, such as changes in cognition, fatigue, and affect. Other tools, such as the Multiple Sclerosis Functional Composite (MSFC), are being evaluated for possible increased sensitivity and utility in describing changes in MS-related disability over time.³⁸ Increasingly, MRI is being used as an index of both disease activity and progression.^{39,40} Specifically, the appearance of new lesions or changes in lesion number, size, and volume (burden of disease) are being used as outcome measures. It is important to note, however, that the correlation between MRI lesion load and clinical disability is modest at best.⁴¹

The unpredictable nature of MS makes it impossible to anticipate when an exacerbation will occur. However, certain factors have been reported to aggravate symptoms or even lead to an acute attack (new episode of demyelination). These implicated factors include infections, hyperventilation, heat (including fever), sleep deprivation, stress, malnutrition, anemia, concurrent organ dysfunction, exertion, and childbirth.^{2,3,42} Interestingly, many patients experience a significant reduction in acute relapses during the third trimester of pregnancy, followed by a relative increase postpartum.⁴² There are no significant epidemiologic data that support an association between physical trauma and the development or worsening of MS, but this may reflect inadequacy of the studies reported to date.^{43,44}

The clinical course of MS is classified into four categories⁴⁵ (Fig. 53–2). About 85% of patients have attacks—new symptoms lasting at least 24 hours and separated from other new symptoms by at least 30 days—followed by remissions (complete or incomplete) at the outset of the illness. Attacks frequently are referred to as *relapses* or *exacerbations*, and the first attack is called a *clinically isolated*

TABLE 53–1. Presentation of Multiple Sclerosis

General

Most patients with multiple sclerosis will present with nonspecific complaints. Many will have problems with their vision or paresthesias.

Primary Symptoms/Signs

- Visual complaints
- Gait problems
- Paresthesias
- Pain
- Spasticity
- Weakness
- Ataxia
- Speech difficulty
- Psychological changes
- Cognitive changes
- Fatigue
- Bowel/bladder dysfunction
- Sexual dysfunction
- Tremor

Secondary Symptoms

- Recurrent urinary tract infections
- Urinary calculi
- Decubiti
- Muscle contractures
- Respiratory infections
- Poor nutrition

Tertiary Symptoms

- Financial problems
- Personal/social problems
- Vocational problems
- Emotional problems

Laboratory Tests

Multiple sclerosis is a diagnosis of exclusion. Magnetic resonance imaging, cerebrospinal fluid studies, and sometimes evoked potentials are useful in confirming the diagnosis. Magnetic resonance imaging may be positive for periventricular white matter lesions. Enhancing T₁ gadolinium lesions may show signs of active disease. Cerebrospinal fluid synthesis of immunoglobulin G is increased, presence of two or more oligoclonal bands, and increased protein.

syndrome (CIS). This course is called *relapsing-remitting MS* (RRMS). In RRMS patients, attack frequency tends to decrease over time and becomes independent of the development of progressive disabilities.^{45,46} Neurologic recovery following an acute exacerbation is usually quite good early in the disease course, but following repeated relapses, recovery tends to be less complete. Given these features, interpretation and evaluation of potential therapeutic interventions must be done quite cautiously, and control groups are essential in the design of clinical studies.

Up to 10% to 20% of RRMS patients have a benign course, characterized by few relapses, often sensory, with minimal disability accruing over time. Most RRMS patients, however, do not have a benign course and eventually enter a progressive phase in which

attacks and remissions generally are difficult to identify. This is referred to as *secondary-progressive MS* (SPMS). Disability tends to accumulate more significantly during this phase of the illness. New brain MRI lesions, especially those seen only after the injection of contrast material, are less common, and brain atrophy increases.⁴⁷

About 15% of patients never have acute attacks and remissions but have progressive disease from the outset. These patients with PPMS have symptoms, especially spastic paraparesis, that may worsen rapidly or relatively slowly over time, and they accrue progressively more disability. In general, PPMS patients tend to have a worse prognosis than those who present initially with RRMS. Finally, a small percentage of patients may have a mixture of both progression and relapses, referred to as *progressive-relapsing MS* (PRMS).⁴⁵

MS usually does not directly diminish life expectancy. The development of secondary complications such as pneumonia or septicemia (secondary to aspiration of mouth contents with swallowing difficulties, decubitus ulcers, or urinary tract infections) or rapid progression of primary lesions affecting respiratory function may lead to a shorter than expected life span. Most of this decrease in life span is seen in patients with rapidly progressive disease. Suicide rates as high as seven times that expected in the general population have been reported.⁴⁸ Clinical and demographic factors that have been used to predict prognosis of MS are listed in Table 53–2.^{49,50} Several MRI

FIGURE 53–2. Clinical course and treatment of multiple sclerosis. The horizontal axis represents time, and the vertical axis represents level of disability. The vertical dotted line represents the onset of the progressive disease phase. The progressive phase may evolve after a number of relapses or, in a subcategory of patients, may be the clinical course of the disease from the onset. (Reprinted with permission from *Ann Neurol* 1988;23:212.)

TABLE 53–2. Prognostic Indicators In Multiple Sclerosis

| Indicator | Favorable Prognosis | Unfavorable Prognosis |
|-----------------------------------|------------------------------------|------------------------------|
| Age at onset | <40 years | >40 years |
| Gender | Female | Male |
| Initial symptoms | Optic neuritis or sensory symptoms | Motor or cerebellar symptoms |
| Attack frequency in early disease | Low | High |
| Course of disease | Relapsing/remitting | Progressive |

features also have been shown to correlate with progression of disease (see below).^{51–53} World Health Organization (WHO) statistics suggest that mortality from MS has decreased up to 25% during the past 30 years, most likely reflecting improvements in overall care.⁵⁰

DIAGNOSIS

MS symptoms frequently can be attributed to other neurologic diseases, just as many syndromes can mimic MS. Some patients may have typical symptoms consistent with classic CIS, whereas many others may have symptoms that are more vague. In the past, the unpredictable nature of MS and the lack of laboratory tests and imaging techniques specific for the disease led to difficulties in making this diagnosis, especially in the early stages of the disease. The diagnosis remains primarily a clinical one that requires the demonstration of “lesions separated in space and time,” referring to the occurrence of at least two episodes of neurologic disturbance reflecting distinct sites of damage in the CNS that cannot be explained by another mechanism.⁵⁴ Older diagnostic criteria used a complicated system of clinical outcomes and types of laboratory support that might define MS.⁵⁵ An international panel of MS experts was convened in 2000 to reevaluate diagnostic criteria and to incorporate MRI knowledge. The result of this panel’s work is the McDonald criteria,⁵⁶ which allow brain MRI lesions to substitute for clinical lesions in defining “separated in space and time.” In the new scheme, diagnostic categories are MS, possible MS (for those individuals at high risk of developing MS), and not MS. In comparison with older criteria, the McDonald criteria allow for earlier diagnosis.^{57,58} Indeed, a new consensus panel of the American Association of Neurology endorses the utility of MRI for this purpose,⁵⁹ and the Food and Drug Administration (FDA) has now approved one of the immunotherapies to be used after a single attack of demyelination in the context of an appropriately abnormal brain MRI. Thus the definition of MS itself has been altered by the introduction of MRI technology.

LABORATORY STUDIES

3 To date, there are no tests specific for MS. Tests that are used frequently include MRI of the brain and spine, CSF evaluation, and evoked potentials. Evidence provided by these studies, used in conjunction with the clinical history, aids in establishing the diagnosis of MS.

IMAGING STUDIES

MRI is able to produce images of the brain and spine that reflect damage in the CNS that is characteristic of MS plaques in multiple forms, as well as more generalized abnormalities such as brain atrophy. Images may be referred to as T₁ or T₂ (including proton-density and fluid attenuated inversion recovery [FLAIR] images) and may be visualized before and/or after the injection of contrast material. MRI, especially after the injection of contrast material, is much more sensitive than computed tomographic (CT) scans in the detection of MS lesions⁶⁰ and currently is considered the preferred imaging technique. It is extremely helpful for diagnosis but also, in part, useful for prognosis. Patients with a single, typical attack of demyelination (possible MS or CIS, e.g., optic neuritis) and three or more T₂-weighted lesions on the brain MRI have an almost 90% likelihood of developing a second attack (clinically definite MS) over 15 years.⁵¹ In contrast, similar individuals with normal brain MRIs have only a 19% likelihood of

developing MS over 15 years.⁵¹ Total volume of T₂-weighted lesions (called T₂ *burden of disease*) at the onset of CIS also appears to correlate with the development of disability.⁶¹ Lesions that enhance after injection of the contrast material gadolinium indicate new lesions and disruption of the BBB and are associated with early conversion to MS in CIS/possible MS patients⁶¹ but do not correlate well over time with progression of disability. Brain atrophy, even early in the course of the illness, probably correlates better with progression of disability.⁶²

CSF EVALUATION

In MS patients, CNS synthesis of IgG is increased, whereas serum IgG levels are normal. Electrophoretic studies of the CSF show that the IgG separates into a small number of discrete bands, which, when similar bands are not seen in the serum samples taken at the same time, are called *oligoclonal bands* (OCBs).⁶³ Oligoclonal banding of IgG is present in 90% to 95% of patients with clinically definite, established MS but also may be seen in lower percentages of diseases that mimic MS or are quite different clinically.⁶³ After CIS (e.g., after initial symptoms), CSF may be positive in only 30% to 50% of patients. Increasingly, with advances in MRI, CSF analysis is reserved only for patients with atypical clinical scenarios or individuals with possible MS⁵⁶ in whom a CSF positive for OCBs may help to define a more definite diagnosis of MS. Myelin basic protein is detected in the CSF of 90% of patients shortly after an acute attack but is nonspecific and usually not obtained. Additional nonspecific CSF abnormalities may include increased CSF protein concentrations in approximately 25% of patients and a mild CSF leukocytosis.⁶⁴ The presence of greater than 50×10^6 mononuclear cells in the CSF usually indicates a diagnosis other than MS.⁶⁴
