FIGURE 17-4. A. Possible mechanism of proarrhythmia in the anatomic model of reentry. (1a) Nonviable reentrant loop owing to bidirectional block (*shaded area*). (1b) Instance where a drug slows conduction velocity without significantly prolonging the refractory period. The impulse is now able to reenter the area of unidirectional block (*shaded area*) because slowed conduction through the contralateral limb allows recovery of the block. A new reentrant tachycardia may result. (2a) Nonviable reentrant loop owing to a lack of a unidirectional block. (2b) Instance where a drug prolongs the refractory period without significantly slowing conduction velocity. The impulse moving antegrade meets refractory tissue (*shaded area*), allowing for unidirectional block. A new reentrant tachycardia may result. B. Mechanism of reentry and proarrhythmia. (a) Functionally determined (*leading circle*) reentrant circuit. This model should be contrasted with anatomic reentry. Here, the circuit is not fixed (it does not necessarily move around an anatomic obstacle), and there is no excitable gap. All tissue inside is held continuously refractory. (b) Instance where a drug prolongs the refractory period without significantly slowing conduction velocity. The tachycardia may terminate or slow in rate as shown owing to a greater circuit length. The dashed lines represent the original reentrant circuit prior to drug treatment. (c) Instance where a drug slows conduction velocity without significantly prolonging the refractory period (i.e., type Ic agents) and accelerates the tachycardia. The tachycardia rate may increase (proarrhythmia) as shown owing to a shorter circuit length. The dashed lines represent the original reentrant circuit prior to drug treatment. (From McCollam PL et al. *Proarrhythmia: A paradoxical response to antiarrhythmic agents. Pharmacotherapy 1989;9:146, with permission.*)

In a functional reentrant focus, the length of the circuit may vary depending on the conduction velocity and recovery characteristics of the impulse. The area in the middle of the loop is continually kept refractory by the inwardly moving impulse. The length of the circuit is not fixed but is the smallest circle possible such that the leading edge of the wavefront is continuously exciting tissue just as it recovers; i.e., the head of the impulse nearly catches its tail. It differs from

the anatomic model in that the leading edge of the impulse is not preceded by an excitable gap of tissue, and it does not have an obstacle in the middle nor a fixed anatomic circuit. Clinically, many reentrant foci probably have both anatomic and functional characteristics. In the figure-eight model, a zone of unidirectional block is present; allowing for two impulse loops that join and reenter the area of block in a retrograde fashion to form a pretzel-shaped reentrant circuit. This model combines functional characteristics with an excitable gap. All these theoretical models require a critical balance of refractoriness and conduction velocity within the circuit and, as such, have helped to explain the effects of drugs on terminating, modifying, and causing cardiac rhythm disturbances.

What causes reentry to become clinically manifest? Reentrant foci may occur at any level of the conduction system: within the branches of the specialized atrial conduction system, within the Purkinje network, and even within portions of the SA and AV nodes. The anatomy of the Purkinje system is felt to provide a suitable substrate for the formation of microreentrant loops and often is used as a model to facilitate understanding of reentry concepts (see Fig. 17–4). Of course, reentry usually does not occur in normal, healthy conduction tissue, and therefore, various forms of heart disease or conduction abnormalities usually must be present before reentry becomes manifest. In other words, the various forms of heart disease can result in changes in conduction in the pathways of a suitable reentrant substrate. An often-used example is reentry occurring as a consequence of ischemic or hypoxic damage: With inadequate cellular oxygen, cardiac tissue resorts to anaerobic glycolysis for adenosine triphosphate (ATP) production. As high-energy phosphate concentration diminishes, the activity of the transmembrane ion pumps declines, and the RMP rises. This rise in RMP causes inactivation in the voltage-dependent sodium channel, and the tissue begins to assume slow conduction characteristics. If changes in conduction parameters occur in a discordant manner owing to varying degrees of ischemia or hypoxia, then a reentry circuit may become manifest. Furthermore, an ischemic, dying cell liberates intracellular potassium, which also causes a rise in the RMP. In other cases, reentry may occur as a result of anatomic or functional variants in the normal conduction system. For instance, patients may possess two (instead of one) conduction pathways near or within the AV node or have an anomalous extranodal AV pathway that possesses different electrophysiologic characteristics from the normal AV nodal pathway. Reentry in these cases may occur within the AV node or encompass both atrial and ventricular tissue (see below). Reentrant tachycardias have the following characteristics: (1) The onset of the tachycardia is usually related to an initiating event (i.e., premature beat), (2) the initiating beat is usually different in morphology from subsequent beats of the tachycardia, (3) initiation of the tachycardia is usually possible with programmed cardiac stimulation, and (4) the initiation and termination of the tachycardia are usually abrupt without an acceleration or deceleration phase. There are many examples of reentrant tachycardias including atrial flutter and AV nodal or AV reentry and recurrent ventricular tachycardia.

ANTIARRHYTHMIC DRUGS

In a theoretical sense, drugs may have antiarrhythmic activity by directly altering conduction in several ways. First, a drug may depress the automatic properties of abnormal pacemaker cells. An agent may do this by decreasing the slope of phase 4 depolarization and/or by elevating threshold potential. If the rate of spontaneous impulse generation of the abnormally automatic foci becomes less than that of

the SA node, normal cardiac rhythm can be restored. Second, drugs may alter the conduction characteristics of the pathways of a reentrant loop.^{1,2} An agent may facilitate conduction (shorten refractoriness) in the area of unidirectional block, allowing antegrade conduction to proceed. On the other hand, an antiarrhythmic agent may further depress conduction (prolong refractoriness) in either the area of unidirectional block or in the pathway with slowed conduction and a relatively shorter refractory period. If refractoriness is prolonged in the area of unidirectional block, retrograde propagation of the impulse is not permitted, causing a “bidirectional” block. In the anatomic model, if refractoriness is prolonged in the pathway with slow conduction, antegrade conduction of the impulse is not permitted through this route. In either case, drugs that reduce the discordance and cause uniformity in conduction properties of the two pathways may suppress the reentrant substrate. In the functionally determined model, if refractoriness is prolonged without significantly slowing conduction velocity, the tachycardia may terminate or slow in rate owing to a greater circuit length (see Fig. 17–4). There are other possible ways to stop reentry. For example, a drug may eliminate the critically timed premature impulse that triggers reentry, or a drug may slow conduction velocity to such an extent that conduction is extinguished.

Antiarrhythmic drugs have specific electrophysiologic actions that alter cardiac conduction in patients with or without heart disease. These actions form the basis of grouping antiarrhythmic agents into specific categories based on their electrophysiologic actions in vitro. Vaughan Williams proposed the most frequently used classification system² (Table 17–1). This classification has been criticized because (1) it is incomplete and does not allow for the classification of agents such as digoxin or adenosine, (2) it is not pure, and many agents have properties of more than one class of drugs, (3) it does not incorporate drug characteristics such as mechanisms of tachycardia termination/prevention, clinical indications, or side effects, and (4) agents become “labeled” within a class, although they may be distinct in many regards.³ These criticisms formed the basis for an attempt to reclassify antiarrhythmic agents based on a variety of basic and clinical characteristics (called the *Sicilian gambit*³). Nonetheless, the Vaughan Williams classification remains the most frequently used system despite many proposed modifications and alternative systems. The type Ia drugs such as quinidine, procainamide, and disopyramide slow conduction velocity, prolong refractoriness, and decrease the automatic properties of sodium-dependent (normal and diseased) conduction tissue. Therefore, the type Ia agents can be effective in automatic tachycardias by decreasing the rate of spontaneous impulse generation of atrial or ventricular foci. In reentrant tachycardias, these drugs generally depress conduction and prolong refractoriness, theoretically transforming the area of unidirectional block into a bidirectional block. Clinically, type Ia drugs are broad-spectrum antiarrhythmics, being effective for both supraventricular and ventricular arrhythmias.

Historically, lidocaine and phenytoin were categorized separately from quinidine-like drugs. This was due to early work demonstrating that lidocaine had distinctly different electrophysiologic actions. In normal tissue models, lidocaine generally facilitates actions on cardiac conduction by shortening refractoriness and having little effect on conduction velocity. Thus it was postulated that these agents could improve antegrade conduction, eliminating the area of unidirectional block. Of course, arrhythmias usually do not arise from normal tissue, leading investigators to study the actions of lidocaine and phenytoin in ischemic and hypoxic tissue models. Interestingly, studies have shown these drugs to possess quinidine-like properties in diseased tissues. Therefore, it is probable that lidocaine acts in clinical

TABLE 17–1. Classification of Antiarrhythmic Drugs

| Type | Drug | Conduction Velocity ^a | Refractory Period | Automaticity | Ion Block |
|-----------------|--|----------------------------------|-------------------|--------------|--|
| Ia | Quinidine Procainamide Disopyramide | ↓ | ↑ | ↓ | Sodium (intermediate) Potassium |
| Ib | Lidocaine Mexiletine Tocainide | 0/↓ | ↓ | ↓ | Sodium (fast on/off) |
| Ic | Flecainide Propafenone ^c Moricizine ^d | ↓↓ | 0 | ↓ | Sodium (slow on/off) Potassium ^e |
| II ^b | β-Blockers | ↓ | ↑ | ↓ | Calcium (indirect) |
| III | Amiodarone ^f Bretylium ^c Dofetilide Sotalol ^c Ibutilide | 0 | ↑↑ | 0 | Potassium |

^aVariables for normal tissue models in ventricular tissue.
^bVariables for SA and AV nodal tissue only.
^cAlso has type II β-blocking actions.
^dClassification controversial.
^eNot clinically manifest.
^fAlso has sodium, calcium, and β-blocking actions; see Table 17–2.

tachycardias in a similar fashion to the type Ia drugs, i.e., accentuated effects in diseased ischemic tissues leading to bidirectional block in a reentrant circuit by prolonging refractoriness. Lidocaine and similar agents have accentuated effects in ischemic tissue owing to the local acidosis and potassium shifts that occur during cellular hypoxia. Changes in pH alter the time that local anesthetics occupy the sodium channel receptor and therefore affect the agent’s electrophysiologic actions. In addition, the intracellular acidosis that ensues owing to ischemia could cause lidocaine to become “trapped” within the cell, allowing increased access to the receptor. The type Ib agents such as lidocaine (and structural analogues such as tocainide and mexiletine) are considerably more effective in ventricular arrhythmias than in supraventricular arrhythmias.

The third group of type I drugs, type Ic drugs, includes propafenone, flecainide, and moricizine. These agents profoundly slow conduction velocity while leaving refractoriness relatively unaltered. Type Ic drugs theoretically eliminate reentry by slowing conduction to a point where the impulse is extinguished and cannot propagate further. Although the type Ic drugs are effective for both ventricular and supraventricular arrhythmias, their use for ventricular arrhythmias has been limited by the risk of proarrhythmia (see below).

Type I drugs exert their effects on a subcellular basis by inhibiting the transmembrane influx of sodium. In essence, type I agents can be referred to as *sodium channel blockers*. The receptor site for the antiarrhythmics is probably inside the sodium channel so that, in effect, the drug plugs the pore. The agent may gain access to the receptor either via the intracellular space through the membrane lipid bilayer or directly through the channel. There are several principles inherent in antiarrhythmic-sodium channel receptor theories, and these are listed below.⁴

1. Type I antiarrhythmics have predominant affinity for a particular state of the channel, e.g., during activation or inactivation. For example, lidocaine and flecainide block sodium current primarily when the cell is in the

inactivated state, whereas quinidine is predominantly an open (or activated) channel blocker.

2. Type I antiarrhythmics have specific binding and unbinding characteristics to the receptor. For example, lidocaine binds to and dissociates from the channel receptor quickly (termed *fast on/off*), but flecainide has very slow on/off properties. This explains why flecainide has such potent effects on slowing ventricular conduction, but lidocaine has little effect on normal tissue (at normal heart rates). In general, the type Ic drugs are slow on/off, the type Ib drugs are fast on/off, and type Ia drugs are intermediate in their binding kinetics.
3. Type I antiarrhythmics possess rate dependence; i.e., sodium channel blockade and slowed conduction are greatest at fast heart rates and least during bradycardia. For slow on/off drugs, sodium channel blockade is evident at normal rates (60 to 100 beats per minute), but for fast on/off agents, slowed conduction is apparent only at rapid rates of stimulation.
4. Type I antiarrhythmics (except phenytoin) are weak bases with a $pK_a > 7$ and block the sodium channel in their ionized form. Therefore, pH will alter these actions: Acidosis will accentuate and alkalosis diminishes sodium channel blockade.
5. Type I antiarrhythmics appear to share a single receptor site in the sodium channel. It should be noted, however, that a number of type I drugs have other electrophysiologic properties. For instance, quinidine has potent potassium channel blocking activity (manifest predominantly at low concentrations), as does *N*-acetylprocainamide (manifest predominantly at high concentrations), the primary metabolite of procainamide. Additionally, propafenone has β-blocking actions.

These principles are important in understanding additive drug combinations (e.g., quinidine and mexiletine), antagonistic combinations (e.g., flecainide and lidocaine), and potential antidotes to excess sodium channel blockade (e.g., sodium bicarbonate or propranolol). They also explain a number of clinical observations, such as why lidocaine-like drugs are relatively ineffective for supraventricular tachycardia. The type Ib drugs are fast on/off, inactivated sodium blockers; atrial cells, however, have a very brief inactivated phase relative to ventricular tissue.

The β -adrenergic antagonists are classified as type II antiarrhythmic drugs. For the most part, the clinically relevant acute antiarrhythmic mechanisms of the β -blockers result from their antiadrenergic actions. Because the SA and AV nodes are heavily influenced by adrenergic innervation, β -blockers would be most useful in tachycardias in which these nodal tissues are abnormally automatic or are a portion of a reentrant loop. These agents are also helpful in slowing ventricular response in atrial tachycardias (e.g., atrial fibrillation) by their effects on the AV node. Furthermore, some tachycardias are exercise-related or are precipitated by states of high sympathetic tone (perhaps through triggered activity), and β -blockers may be useful in these instances. β -Adrenergic stimulation results in increased conduction velocity, shortened refractoriness, and increased automaticity of the nodal tissues; β -adrenergic blockers will antagonize these effects. Propranolol is often noted to have “local anesthetic” or quinidine-like activity; however, suprapharmacologic concentrations usually are required to elicit this action. In the nodal tissues, β -blockers interfere with calcium entry into the cell by altering catecholamine-dependent channel integrity and gating kinetics. In sodium-dependent atrial and ventricular tissue, β -blockers shorten repolarization somewhat but otherwise have little direct effect. The antiarrhythmic properties of β -blockers observed with long-term, chronic therapy in patients with heart disease are less well understood. While it is clear that β -blockers decrease the likelihood of sudden death (presumably arrhythmic death) after myocardial infarction (MI), why this is so remains unclear but may relate to the complex interplay of changes in sympathetic tone, damaged myocardium, and ventricular conduction. In patients with heart failure, drugs such as β -blockers and angiotensin-converting enzyme (ACE) inhibitors may prevent arrhythmias such as atrial fibrillation that are linked to poor cardiac function by improving ventricular performance over time.^{5,6}

Type III antiarrhythmics include agents that specifically prolong refractoriness in atrial and ventricular tissue. This class includes very different drugs: bretylium, amiodarone, sotalol, ibutilide, and recently, dofetilide; they share the common effect of delaying repolarization by blocking potassium channels. The electrophysiologic actions of bretylium are related to its multifaceted pharmacology.

Bretylium is structurally similar to guanethidine and can, likewise, cause an initial increase in catecholamine release from the adrenergic neuron. This action potentially may affect arrhythmogenesis by an indirect mechanism—an increase in coronary blood flow and myocardial perfusion—that reverses ischemia-related arrhythmias (similar to epinephrine’s action in a patient with ventricular fibrillation). After causing catecholamine release, bretylium then causes an uncoupling of autonomic nerve stimulation from the release step, resulting in antiadrenergic effects. Theoretically, bretylium also may be antiarrhythmic by these sympatholytic actions. Nonetheless, bretylium prolongs repolarization owing to blockade of potassium conductance independent of the sympathetic nervous system, and many researchers feel that these direct actions account for its clinical effectiveness. Bretylium increases the ventricular fibrillation threshold and seems to have selective antifibrillatory but not antitachycardic effects. In other words, bretylium can be effective in ventricular fibrillation, but it is often ineffective in ventricular tachycardia.

In contrast, amiodarone and sotalol are effective in most tachycardias. Amiodarone displays electrophysiologic characteristics consistent with each class within the Vaughan Williams scheme; it is a sodium channel blocker with relatively fast on/off kinetics, has noncompetitive, nonselective β -blocking actions, blocks potassium channels, and also has a small degree of calcium antagonist activity (Table 17–2). At normal heart rates and with chronic use, its predominant effect is to prolong repolarization. On intravenous administration, its onset is relatively quick (unlike the oral form), and β -blockade predominates initially. Theoretically, amiodarone, like type I agents, may interrupt the reentrant substrate by transforming an area of unidirectional block into an area of bidirectional block. However, electrophysiologic studies using programmed cardiac stimulation imply that amiodarone may leave the reentrant loop intact. Rather, it is possible that amiodarone abolishes the premature impulse that usually triggers the reentry process. In addition, the potent β -blocking properties of amiodarone may contribute significantly to its acute and chronic efficacy. The impressive effectiveness of amiodarone, coupled with its low proarrhythmic potential, has challenged the notion that selective ion channel blockade by antiarrhythmic agents is preferable. Sotalol is a potent inhibitor of outward potassium movement during repolarization and also possesses β -blocking actions. Indeed, it was first synthesized as a nonselective β -antagonist but now has evolved into the prototypical type III agent on which most investigational agents are based. Ibutilide and, more recently, dofetilide have been approved for the conversion and prevention of atrial fibrillation, respectively; these agents are structurally similar to sotalol. Both possess type III activity by blocking the rapid component of the delayed potassium rectifier current (I_{Kr}).

TABLE 17–2. Time Course and Electrophysiologic Effects of Amiodarone

| Class | Mechanism | EP | ECG | IV | | PO | |
|----------|-------------------------------------|------------------|--------------|---------|----------|----------|---------|

| Type III | K ⁺ | ↑ VERP ↑ AERP | ↑ QT | 0 | + | ++ | ++++ |
| Type IV | Ca ²⁺ block ^a | ↑ AH | ↑ PR | + | + | + | + |
| | | | | Min–hrs | Hrs–days | Days–wks | Wks–mos |

^aRate-dependent.

HV = His-ventricle interval; AH = atria-His interval; VERP = ventricular effective refractory period; AERP = atrial effective refractory period; HR = heart rate; EP = electrophysiologic actions; ECG = electrocardiographic effects.

There are a number of different potassium channels that function during normal conduction, but the most relevant in terms of approved and investigational antiarrhythmic drugs is the delayed rectifier current (I_K) responsible for phase 2 and 3 repolarization. Subcurrents make up I_K ; an ultrarapid component I_{Kur} , a rapid component I_{Kr} , and a slow component I_{Ks} . *N*-acetylprocainamide (NAPA) and dofetilide selectively block I_{Kr} , whereas amiodarone and azimilide (investigational) block both I_{Kr} and I_{Ks} . The clinical relevance of selectively blocking components of the delayed rectifier current remains to be determined. Potassium current blockers (particularly those with selective I_{Kr} -blocking properties) display “reverse use-dependence”; i.e., their effects on repolarization are greatest at low heart rates. Sotalol and drugs like it also appear to be much more effective in preventing ventricular fibrillation (in dog models) than the traditional sodium blockers. They also decrease defibrillation threshold in contrast to type I agents, which tend to increase this parameter. This could be important in patients with automatic internal defibrillators because concurrent therapy with type I drugs may require more energy for successful cardioversion or, worse, render it ineffective in terminating the tachycardia. The Achilles’ heel of all type III agents is an extension of their underlying ionic mechanism, i.e., by blocking potassium and delaying repolarization they also may cause proarrhythmia in the form of torsade de pointes.

The calcium channel antagonists comprise the type IV antiarrhythmic category. At least two types of calcium channels are operative in SA and AV nodal tissues: an L-type channel and a T-type channel. Therefore, both L-channel blockers (verapamil and diltiazem) and selective T-channel blockers (mibefradil—previously approved but withdrawn from the market) will slow conduction, prolong refrac-

toriness, and decrease automaticity (e.g., owing to early or late afterdepolarizations) of the calcium-dependent tissue in the SA and AV nodes. Therefore, these agents are effective in automatic and reentrant tachycardias, which arise from or use the SA or AV nodes. In atrial tachycardias, these drugs can slow ventricular response (e.g., atrial fibrillation) by slowing AV nodal conduction. Furthermore, because calcium entry seems to be integral to exercise-related tachycardias and/or tachycardias owing to some forms of triggered automaticity, preliminary evidence shows effectiveness in these types of arrhythmias. In all likelihood, verapamil and diltiazem work at different receptor sites because of their dissimilar chemical structures and pharmacologic actions. Nifedipine (or any of the dihydropyridine calcium antagonists) does not have significant antiarrhythmic activity because a reflex increase in sympathetic tone owing to vasodilation counteracts this agent’s direct negative dromotropic action. Calcium antagonists can shorten repolarization slightly in normal sodium-dependent tissue but otherwise have little effect.

❖ All antiarrhythmic agents currently available have an impressive side-effect profile (Table 17–3). A considerable percentage of patients cannot tolerate long-term therapy with these drugs, and chances are good that an agent will have to be discontinued because of side effects. In one trial,⁷ over 50% of patients had to discontinue long-term procainamide (mostly due to a lupus-like syndrome) after MI. In another study,⁸ disopyramide caused anticholinergic side effects in about 70% of patients. Flecainide and disopyramide may precipitate congestive heart failure in a significant number of patients with underlying left ventricular (LV) dysfunction; they should not be used in patients with systolic heart failure.⁹ The type Ib agents such as tocainide and mexiletine cause neurologic and/or gastrointestinal

TABLE 17–3. Side Effects of Antiarrhythmic Drugs

| | |
|--------------|---|
| Amiodarone | CNS, corneal microdeposits/blurred vision, optic neuropathy/neuritis, GI, aggravation of underlying ventricular arrhythmias, torsade de pointes, bradycardia or AV block, bruising without thrombocytopenia, pulmonary fibrosis, hepatitis, hypothyroidism, hyperthyroidism, photosensitivity, blue-gray skin discoloration, myopathy, hypotension and phlebitis (IV use) |
| Bretium | Hypotension, GI |
| Disopyramide | Anticholinergic symptoms, GI, torsade de pointes, heart failure, aggravation of underlying conduction disturbances and/or ventricular arrhythmias, hypoglycemia, hepatic cholestasis |

toxicity in a high percentage of patients. Tocainide, specifically, has been reported to cause both pulmonary fibrosis and leukopenia, the significance of which came to light after Food and Drug Administration (FDA) approval. Clearly, the most frightening adverse effects related to antiarrhythmic drugs are the aggravation of underlying ventricular arrhythmias or the precipitation of new (and life-threatening) ventricular arrhythmias¹⁰ (see below).

3 Amiodarone has taken a prominent place in the treatment of both chronic and acute arrhythmias and is now the most commonly prescribed antiarrhythmic drug. Once considered a drug of last resort, it is now the first drug considered in many symptomatic tachycardias. Yet amiodarone is a peculiar and complex drug, displaying unusual pharmacologic effects, pharmacokinetics, dosing schemes, and multisystem side effects. Amiodarone has an extremely long elimination phase and large volume of distribution; therefore, onset of action with the oral form is delayed (days to weeks) despite a loading regimen, and effects persist long (months) after discontinuation. Amiodarone inhibits most cytochrome P450 enzymes (and P-glycoprotein), resulting in many common drug interactions (e.g., it will cause digoxin levels to approximately double, and one must reduce the maintenance dose of warfarin by one-third to one-half). Acute administration usually is tolerated well by patients, but severe toxicities may result with chronic use. Severe bradycardia (sometimes requiring pacing to allow the patient to remain on amiodarone), hyper-

and hypothyroidism, photosensitivity, and a blue-gray skin discoloration on exposed areas are common. Hepatitis (uncommon) and pulmonary fibrosis (5% to 10% of patients) have caused death.^{11,12} These side effects mandate close and continued monitoring (e.g., liver enzymes, thyroid function tests, eye examinations, chest x-rays, and pulmonary function tests) and have led to a proliferation of “amiodarone clinics” designed just for patients receiving this agent on a chronic basis.¹³

The pharmacokinetics of the antiarrhythmic agents are summarized in Table 17-4, and a nomogram for estimating effective dosages of the oral forms (except amiodarone) is shown in Fig. 17-5. Dosing recommendations for the intravenous forms are shown in Table 17-5.

SUPRAVENTRICULAR ARRHYTHMIAS

The common supraventricular tachycardias that often require drug treatment are (1) atrial fibrillation or atrial flutter, (2) paroxysmal supraventricular tachycardia, and (3) automatic atrial tachycardias. Other common supraventricular arrhythmias that usually do not require drug therapy include premature atrial complexes (PACs), wandering atrial pacemaker, sinus arrhythmia, and sinus tachycardia. As an example, PACs rarely cause symptoms and never cause hemodynamic compromise, and therefore, drug therapy usually is not

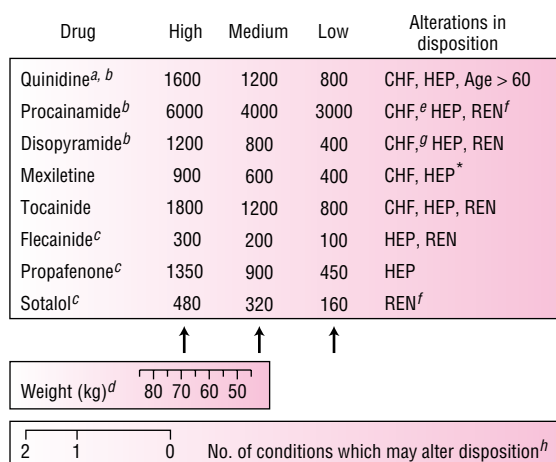

FIGURE 17-5. Nomogram for estimating effective doses of commonly used oral antiarrhythmic drugs for acute efficacy testing. The dosages are grouped into high, medium, and low categories based on commonly used regimens and commercially available dosage forms. The dosages for each drug are listed as milligrams per day and are expected to result in the average steady-state concentrations shown in Table 17-2. Abbreviations: CHF = congestive heart failure; HEP = hepatic disease; REN = renal insufficiency (creatinine clearance < 50 mL/min).

^aSulfate salt equivalents.

^bSustained-release forms may allow less fluctuation in concentrations.

^cBest to initiate low-dose regimens in all patients and escalate slowly.

^dIdeal body weight.

^eConflicting data regarding alteration in disposition.

^fSignificant accumulation of active metabolites or patent in renal disease limit use.

^gDisopyramide not recommended in congestive heart failure.

^hUse 1 for each suspected alteration but 2 where indicated (*).

Use of nomogram:

Step 1. Connect a straight line from the bar indicating the number of alterations in disposition, through the patient's weight to the base of the box.

Step 2. Approximate daily dosage is shown directly above the arrow. When the line connects between the arrows, use the crossbars between the arrows to choose high, medium, or low dosages or estimate an intermediate amount. Exercise caution when choosing dosages in the high range.

Example: A 70-kg patient with poor LV function (i.e., CHF) and frequent paroxysmal episodes of atrial fibrillation is to be treated with oral quinidine. A straight line drawn between 1 on the conditions bar and 70 kg on the weight bar will intersect near the center arrow on the box. Directly above the point of intersection are the medium dosage ranges; quinidine sulfate can be initiated at 1200 mg/day or 300 mg every 6 hours in this patient. (From Bauman JL, Schoen MD, Hoon TJ. *Practical optimization of antiarrhythmic drug therapy using pharmacokinetic principles*. *Clin Pharmacokinet* 1991;20:151-166, with permission.)

indicated. Likewise, sinus tachycardia is usually the result of underlying metabolic or hemodynamic disorders (such as infection, dehydration, hypotension, etc.), and therapy should be directed at the underlying cause, not at the tachycardia per se. Of course, there are exceptions to these suggestions. For example, sinus tachycardia may be deleterious in patients after cardiac surgery or MI. In another unusual tachycardia termed *nonparoxysmal sinus tachycardia*, chronically elevated heart rates may cause alterations in LV function. In these instances, antiarrhythmic drugs such as β -blockers indeed may be indicated. Stated in another way, although many arrhythmias generally do not require therapy, clinical judgment and patient-specific variables play an important role in this decision. Nevertheless, for the purpose of this discussion, only the tachycardias usually requiring antiarrhythmic drug therapy as listed above will be addressed.

TABLE 17-5. Intravenous Antiarrhythmic Dosing

| Drug | Clinical Situation | Dose |
|--------------|----------------------------|---|
| Amiodarone | Recurrent VT/VF | 150 mg/10 min IV push 1 mg/min for 6 h, then 0.5 mg/min infusion |
| Bretylum | Cardiac arrest Acute VF | 300 mg IV push 5 mg/min IV push (may repeat to total dose 30 mg/kg) 1-2 mg/min infusion if needed |
| Diltiazem | PSVT; rate control AF | 0.25 mg/kg IV push (may repeat with 0.35 mg/kg) 5-15 mg/h infusion |
| Ibutilide | Termination AF | 1 mg/10 min IV push (may repeat if needed) |
| Lidocaine | VT/VF | 100 mg IV push (may repeat up to total dose 300 mg) (limit total to 200 mg if CHF present) 2-4 mg/min infusion (1-2 mg/min if liver disease or CHF) |
| Procainamide | AF, VT | 15-18 mg/kg at 20-50 mg/min load 1-6 mg/min infusion |
| Verapamil | PSVT; rate control AF | 5 mg IV push (may repeat up to 20 mg) 5-15 mg/h infusion |

CLINICAL PRESENTATION: SUPRAVENTRICULAR TACHYCARDIA

ATRIAL FIBRILLATION/FLUTTER GENERAL

These rhythms are usually not directly life-threatening, nor do they generally cause hemodynamic collapse or syncope, but 1:1 atrial flutter (ventricular response ~300 beats per minute) is an exception. Also, patients with underlying forms of heart disease that are heavily reliant on atrial contraction to maintain adequate cardiac output (e.g., mitral stenosis and obstructive cardiomyopathy) will display more severe symptoms of atrial fibrillation/flutter.

SYMPTOMS

Most often patients complain of rapid beat rate/palpitations and/or worsening symptoms of heart failure (shortness of breath, fatigue). Medical emergencies are severe heart failure (i.e., pulmonary edema, hypotension) or atrial fibrillation occurring in the setting of acute MI.

DIAGNOSTIC TESTS/SIGNS (ECG)

Atrial fibrillation is an irregularly irregular supraventricular rhythm with no discernible, consistent atrial activity (*p* waves). Ventricular response is usually 120-180 beats per minute, and the pulse is irregular. Atrial flutter is (usually) a regular supraventricular rhythm with characteristic flutter waves (or sawtooth pattern) reflecting more organized atrial activity. Commonly, ventricular rate is in factors of 300 beats per minute (e.g., 150, 100, or 75 beats per minute).

PSVT DUE TO REENTRY**GENERAL**

These rhythms can be transient, resulting in few, if any, symptoms, or prolonged and life-threatening, causing hemodynamic collapse.

SYMPTOMS

Patients frequently complain of intermittent episodes of rapid heart rate/palpitations that start and stop abruptly, usually without provocation (but occasionally during exercise). Severe symptoms include syncope. Often (in particular, those with AV nodal reentry) patients complain of a chest pressure or a fullness in the neck sensation. This is due to simultaneous AV contraction with the right atrium contracting against a closed tricuspid valve. Life-threatening symptoms (syncope, hemodynamic collapse) are associated with extremely rapid rate (e.g., >200 beats per minute) and atrial fibrillation associated with an accessory AV pathway.

DIAGNOSTIC TESTS/SIGNS (ECG)

Most commonly, PSVT is a rapid, narrow-QRS-complex tachycardia, regular in rhythm, that starts and stops abruptly. Atrial activity, although present, is difficult to ascertain on surface ECG because P waves are “buried” within the QRS complex or T wave.

ATRIAL FIBRILLATION AND ATRIAL FLUTTER**MECHANISMS AND BACKGROUND**

Atrial fibrillation and atrial flutter are common supraventricular tachycardias. These tachycardias occur more often in men, especially elderly men. In the general population, the overall prevalence of atrial fibrillation is about 0.4% (independent of gender and age), and this increases with age (e.g., more than 6% in patients older than 80 years of age).¹⁴ About 10% to 30% of patients with heart failure have had episodes of atrial fibrillation.¹⁴ These arrhythmias may present as a chronic, established tachycardia, an acute tachycardia, or a self-terminating paroxysmal form. The following semantics and definitions are sometimes used^{14,15}: *acute atrial fibrillation* (onset within 48 hours), *paroxysmal atrial fibrillation* (terminates spontaneously in less than 7 days), *recurrent atrial fibrillation* (two or more episodes), *persistent atrial fibrillation* (duration longer than 7 days and does not terminate spontaneously), and *permanent atrial fibrillation* (does not terminate with attempts at pharmacologic or electrical cardioversion). Atrial fibrillation is characterized as an extremely rapid (400 to 600 atrial beats per minute) and disorganized atrial activation. With this disorganized atrial activity, there is a loss of the contribution of atrial contraction (atrial kick) to forward cardiac output. Supraventricular impulses penetrate the AV conduction system in variable degrees, resulting in an irregular activation of the ventricles and an *irregularly irregular* pulse. The AV junction will not conduct most of the supraventricular impulses, causing ventricular response to be considerably slower (120 to 180 beats per minute) than the atrial rate. Atrial flutter occurs less frequently than atrial fibrillation but is similar in its precipitating factors, consequences, and drug-therapy approach (exceptions noted below). This arrhythmia is characterized by rapid (270 to 330 atrial beats per minute) but regular atrial activation. The slower and regular electrical activity results in a regular ventricular response and a pulse that is in approximate factors of 300 beats per minute (i.e., 1:1 AV conduction = ventricular rate of 300 beats per minute;

2:1 AV conduction = ventricular rate of 150 beats per minute; 3:1 AV conduction = ventricular rate of 100 beats per minute). Atrial flutter may occur in two distinct forms (type I and type II). Type I flutter is the more common classic form with atrial rates of approximately 300 beats per minute and the typical “sawtooth pattern” of atrial activation, as shown by the surface ECG. Type II flutter tends to be faster, being somewhat of a hybrid between classic atrial flutter and atrial fibrillation. Although the ventricular response usually has a regular pattern, atrial flutter with varying degrees of AV block or that occurs with episodes of atrial fibrillation (“fib-flutter”) can cause an irregular ventricular rate and pulse.

It is generally accepted that the predominant mechanism of atrial fibrillation and atrial flutter is reentry. Atrial fibrillation appears to result from multiple atrial reentrant loops (or wavelets), and atrial flutter is due to a single, dominant reentrant substrate (counterclockwise circus movement around the tricuspid annulus). Atrial fibrillation or flutter usually occurs in association with forms of organic heart disease that causes atrial distension. Forms of heart disease that commonly lead to atrial stretch and precipitate atrial fibrillation or flutter include

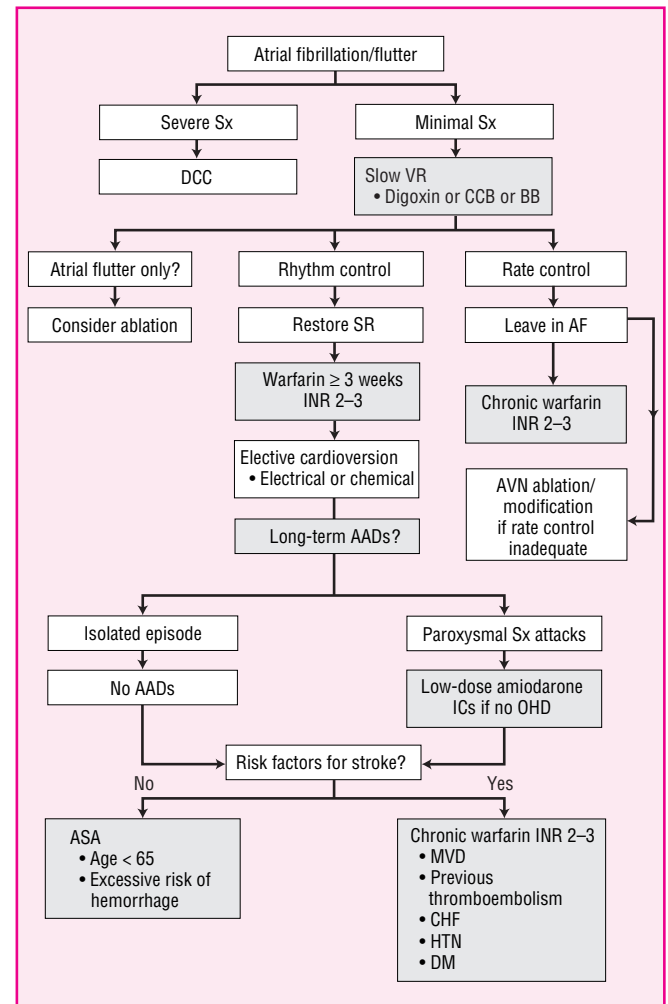

FIGURE 17-6. Algorithm for the treatment of atrial fibrillation and atrial flutter. Sx = symptoms; AVN = AV node; DCC = direct-current cardioversion; CCB = calcium channel antagonist (verapamil or diltiazem); BB = β -blocker; ASA = aspirin; OHD = organic heart disease; AADs = antiarrhythmic drugs; INR = international normalized ratio; MVD = mitral valve disease; CHF = congestive heart failure; HTN = hypertension; DM = diabetes mellitus.

ischemia or infarction, hypertensive heart disease, valvular disorders such as mitral stenosis, mitral insufficiency, congenital abnormalities such as septal defects, and primary myocardial disease such as dilated or hypertrophic cardiomyopathy. Disorders that cause right atrial stretch and are associated with atrial fibrillation or flutter include acute pulmonary embolus and chronic lung disease resulting in pulmonary hypertension and cor pulmonale. It is sometimes said that “atrial fibrillation begets atrial fibrillation.” That is, the arrhythmia tends to perpetuate itself; long episodes are more difficult to terminate, perhaps due to tachycardia-induced changes in atrial function (mechanical and/or electrical “remodeling”). Atrial fibrillation also may occur in association with states of high adrenergic tone such as thyrotoxicosis, alcohol withdrawal, sepsis, or excessive physical exertion. Established or paroxysmal atrial fibrillation occurring without identifiable heart disease or known precipitating factors is termed *lone atrial fibrillation*. Other states in which patients are predisposed to episodes of atrial fibrillation are the presence of an anomalous AV pathway (i.e., Kent bundle) and sinus node dysfunction (i.e., tachybrady or sick sinus syndrome). Finally, although unusual, some patients have atrial fibrillation that appears to be perpetuated by states of high cholinergic tone; episodes occur after meals or during sleep when vagal tone is high.

Patients with atrial fibrillation or flutter may experience the entire range of symptoms associated with other supraventricular tachycardias, although syncope as a presenting symptom is uncommon. Since atrial kick is lost with the onset of atrial fibrillation, severe low-output states may result in forms of heart disease that rely heavily on atrial contraction to maintain cardiac output (such as mitral stenosis or hypertrophic obstructive cardiomyopathy; see Chap. 18). An additional complication of atrial fibrillation is arterial embolization resulting from atrial stasis and poorly adherent mural thrombi. Of course, the most devastating complication in this regard is the occurrence of an embolic stroke. The overall incidence of stroke in patients with atrial

fibrillation not receiving antithrombotic therapy is about 3% to 6% per year.^{16,17} Patients with concurrent mitral stenosis or severe systolic heart failure and atrial fibrillation are at particularly high risk for cerebral embolism. Other risk factors for stroke identified from recent trials are increasing age, history of hypertension, previous transient ischemic event or stroke, and diabetes.¹⁷ Stroke can precede the onset of documented atrial fibrillation, probably due to undetected paroxysms prior to the onset of established atrial fibrillation. In contrast, young patients (age younger than 60 years) with atrial fibrillation in whom precipitating factors cannot be identified (i.e., lone atrial fibrillation) have a low risk of embolic stroke.¹⁷ The risk of stroke in patients with only atrial flutter traditionally has been felt to be low, prompting some to recommend only aspirin for prevention of thromboembolism. However, since isolated atrial flutter is relatively uncommon and the risk of stroke is not as well established (as it is for the more common atrial fibrillation), more recent recommendations suggest using the identical guidelines for both atrial fibrillation and atrial flutter.^{15,18}

MANAGEMENT

4 The traditional approach to the treatment of atrial fibrillation can be organized into several sequential goals: (1) Evaluate the need for acute treatment (usually administration of drugs that slow ventricular rate), (2) contemplate methods to restore sinus rhythm, taking into consideration the risks (e.g., thromboembolism), and (3) consider ways to prevent the long-term complications of atrial fibrillation such as arrhythmia recurrences and thromboembolism. A time-honored presumption, recently challenged, lies within this strategy; i.e., long-term maintenance of sinus rhythm is a desirable goal. Nevertheless, a discussion of the management and drug therapy of atrial fibrillation/flutter follows, organized according to these goals. An algorithm for the management of atrial fibrillation is shown in Fig. 17-6.

► TREATMENT: Atrial Fibrillation and Atrial Flutter

First, consider the patient with new-onset symptomatic atrial fibrillation or flutter. Although uncommon, patients may present with severe symptoms qualifying as a medical emergency. These include ischemic chest pain and acute pulmonary edema. In these situations, patients may require direct-current cardioversion (DCC) in an attempt to immediately restore sinus rhythm (without regard for the risk of thromboembolism). Atrial flutter often requires relatively low energy levels of countershock (i.e., 25 to 50 W/s), whereas atrial fibrillation often requires higher energy levels (i.e., >200 W/s). On the other hand, if tolerable symptoms are present, no such emergency measures are necessary. Type Ia and III antiarrhythmic agents may restore sinus rhythm but should not be administered initially. These agents paradoxically may increase ventricular response in the absence of drugs that slow AV nodal conduction. Traditionally, this observation has been attributed to the vagolytic action of these drugs despite the fact that only disopyramide displays significant anticholinergic side effects. Therefore, a more likely alternative explanation exists: All these agents slow atrial conduction, decreasing the number of impulses reaching the AV node, and as a result, the AV node paradoxically allows more impulses to gain entrance to the ventricular conduction system (increasing ventricular rate).

Because of this phenomenon and the lack of need for immediate restoration of sinus rhythm, drugs that slow conduction and increase

refractoriness in the AV node should be used as initial therapy. Loading dosages of digoxin historically have been recommended as first-line treatment to slow ventricular rate, particularly in patients with heart failure. However, the place of digoxin in therapy has been questioned in both the acute and chronic settings.^{19,20} Digoxin is sometimes ineffective and often slow in onset; although an initial decrease in ventricular response sometimes can be observed within 1 hour of intravenous administration, full control (resting heart rate of less than 80 beats per minute and less than 110 beats per minute during moderate exercise) usually is not achieved for 24 to 48 hours. Digoxin will not restore sinus rhythm, although spontaneous termination of atrial fibrillation may occur in some patients during the loading procedure. As mentioned previously, patients can present at two ends of the spectrum (i.e., either severely symptomatic or with no or mild symptoms), and often they present somewhere in between. Consequently, clinical judgment is necessary in choosing the proper treatment strategy. For example, intravenous calcium antagonists (e.g., diltiazem or verapamil) provide an alternative approach, allowing for a rapid decrease in ventricular rate and symptomatic relief without the need for DCC.^{21,22} Because control of ventricular response can be transient, verapamil or diltiazem can be given as an initial intravenous bolus, followed by a continuous infusion titrated to heart rate. Although digoxin in the past has been considered the drug of

first choice to slow ventricular rate, many practitioners now choose calcium antagonists in most patients with atrial fibrillation or flutter. Further, atrial fibrillation or flutter precipitated by states of high adrenergic tone, such as thyrotoxicosis, is often resistant to digoxin therapy (digoxin slows AV nodal conduction primarily through vagotonic mechanisms). In these cases, intravenous β -blockers (e.g., propranolol or esmolol) can be highly effective and should be considered first.

Although β -blockers and calcium channel blockers have taken a more prominent role in acutely controlling rate in patients with rapid atrial fibrillation or flutter, a cautionary note must be made. That is, most patients with these tachycardias also have concomitant symptoms of heart failure, and these two forms of drug therapy may worsen the situation initially. Usually, a prompt decline in rate and increase in stroke volume balances the decrease in contractility seen with β -blockers or calcium channel blockers such that heart failure symptoms remain unchanged. However, occasionally, severe reactions and hypotension may occur; one study implies that diltiazem may be safer than verapamil.²²

Patients may present with a slow ventricular response (in the absence of AV nodal-blocking drugs) and thus do not require therapy with digoxin, verapamil, or esmolol. This type of presentation should alert the clinician to the possibility of preexisting SA or AV nodal conduction disease such as sick sinus syndrome. DCC should not be attempted in these patients without a temporary pacemaker in place (see below).

RESTORATION OF SINUS RHYTHM?

After treatment with AV nodal-blocking agents and a subsequent decrease in ventricular response, the patient should be evaluated for the possibility of restoring sinus rhythm if atrial fibrillation persists. Within the context of this evaluation, several factors should be considered. First, many patients convert spontaneously to sinus rhythm without intervention, obviating therapy needed to achieve this goal. For instance, atrial fibrillation occurs frequently as a complication of cardiac surgery and often reverts spontaneously to sinus rhythm without therapy. Second, restoring sinus rhythm is not a necessary or realistic goal in some patients. Important in this regard is the recent publication of a number of trials,^{23,24} including the National Institutes of Health (NIH)-sponsored Atrial Fibrillation Follow-up Investigation of Rhythm Management (AFFIRM)²³ that compared strategies to maintain sinus rhythm with those just to control ventricular rate, allowing atrial fibrillation to remain. In AFFIRM, patients were randomized to receive rate-control therapy only or to drug therapy designed to achieve and maintain sinus rhythm. Rate-control treatment involved AV nodal-blocking drugs (e.g., digoxin, β -blockers, and/or calcium channel blockers) first and then nondrug treatment (AV nodal ablation with pacemaker implantation) if necessary to control rates. Treatment with type I or type III antiarrhythmic drugs (e.g., amiodarone, sotalol, and then propafenone were used most frequently) was used to maintain sinus rhythm. Cumulative mortality was not statistically different between the two strategies but tended ($p = .08$) to be higher in the group given antiarrhythmic drugs to maintain sinus rhythm. The results of other similar large multicenter trials are consistent with those of AFFIRM.²⁴ Clearly, these important findings **4** temper the old approach of aggressively attempting to maintain sinus rhythm. Many, if not most, patients now can be allowed to remain in atrial fibrillation, chronically treated with AV nodal-blocking

agents to control ventricular response (e.g., resting rate of approximately 80 beats per minute or less). Often, long-term therapy with digoxin alone for this purpose will not control exercise-related increases in ventricular response and tachycardia symptoms. In these patients, small doses of calcium antagonists or β -blockers can be added; the need for these ancillary agents can be evaluated readily by treadmill exercise testing or by simple ambulation. Alternatively, β -blockers alone can be used to control rate on a chronic basis. Since most patients with atrial fibrillation also have heart failure, β -blockers can control rate and improve systolic function. Occasionally, patients may be encountered who are highly refractory to AV nodal-blocking agents (including combination drug therapy), and ventricular response remains rapid. Aggressive attempts to lower rate are necessary; chronic tachycardias can result in a progressive decline in LV function causing so called tachycardia cardiomyopathy. Hence, in drug-refractory patients, ablation or modification of the AV node by a transvenous catheter delivering radiofrequency current is indicated.²⁵ This procedure often completely blocks conduction from the atrium to the ventricle, requiring the concurrent implantation of a permanent pacemaker with a ventricular lead. If it is decided in a given patient not to restore sinus rhythm but rather to allow atrial fibrillation to remain, one additional treatment consideration should be considered. That is, these individuals must remain on anticoagulant or antiplatelet therapy for at least as long as the atrial fibrillation remains; they are at continued risk for thromboembolic complications.

In which patients should restoration of sinus rhythm be considered? Post-AFFIRM, this decision is left to clinical judgment, but one could imagine that several groups of patients should undergo electrical or pharmacologic cardioversion. These include patients who are judged to have a relatively low chance of recurrence (e.g., first episodes of lone atrial fibrillation in young individuals or transient states of high sympathetic tone) or those with troublesome symptoms despite adequate rate control.

In patients in whom it is decided to restore sinus rhythm, one must consider that this very act (independent of the method chosen) places the patient at risk for thromboembolism. The reason for this is that the return of sinus rhythm restores an effective contraction, which may dislodge poorly adherent thrombi. Anticoagulation prior to cardioversion prevents clot growth and the formation of new thrombi and allows existing thrombi to become organized and well adherent to the atrial wall. This form of preventative therapy has been shown to prevent stroke associated with cardioversion, but several weeks of anticoagulation is necessary. Therefore, current recommendations are to institute warfarin treatment (international normalization ratio [INR] 2 to 3) for at least 3 weeks prior to cardioversion. The common clinical scenario is to discharge the patient from the hospital, monitor the patient on an ambulatory basis, and readmit for elective cardioversion after this time period.¹⁷ After restoration of sinus rhythm, full atrial contraction does not occur immediately. Rather, it returns gradually to a maximum contractile force over a 3- to 4-week period. Therefore, warfarin should be continued for at least 1 month after effective cardioversion and return of sinus rhythm (see below).

There are several exceptions to this recommended process of anticoagulation. In patients with atrial fibrillation of less than 48 hours' duration, anticoagulation prior to cardioversion probably is not necessary because there has not been sufficient time to form atrial thrombi. However, in most presentations of atrial fibrillation, the exact time of onset is unclear. In the past, patients with atrial flutter were felt to be at low risk for stroke, but current consensus recommendations

give strong consideration to treating atrial flutter in the same way as atrial fibrillation, i.e., generally at least 3 weeks of anticoagulation prior to elective cardioversion.^{14,17} Transesophageal echocardiography (TEE) is also being used as a tool to stratify which patients may require anticoagulation prior to DCC from those who may not. If an atrial thrombus or severe stasis (“smoke”) is not noted on TEE, then perhaps these patients can be cardioverted without the mandatory 3 weeks of warfarin pretreatment. Initial data are promising and seemingly cost-effective, obviating the need for more than 3 weeks of prior warfarin treatment and subsequent readmission to the hospital. The use of TEE in this manner has been compared with the conventional 3 weeks of anticoagulation before cardioversion in patients with atrial fibrillation.²⁶ In this large multicenter, randomized trial, the incidence of thromboembolic events was not different between the two strategies, but bleeding episodes were higher in the 3 weeks of warfarin group. Patients in the TEE strategy group had a higher success rate of achieving sinus rhythm probably because it is more difficult to terminate atrial fibrillation the longer a patient remains in it (i.e., “atrial fibrillation begets atrial fibrillation”). These impressive data will more than likely place the use of TEE in patients with atrial fibrillation in a much more prominent role.

After prior anticoagulation or TEE, the methods available to restore sinus rhythm can be considered (in those patients in whom maintenance of sinus rhythm is the goal). There are two methods of restoring sinus rhythm in patients with atrial fibrillation or flutter: pharmacologic cardioversion and DCC. Which of these is the method of choice generally is a matter of clinical preference, but it should be noted that international consensus guidelines recommend that DCC be considered first.¹⁴ Indeed, in one economic analysis, DCC as first-line therapy was less costly than the strategy of trying a drug first (such as ibutilide) and then proceeding to DCC in the event of drug failure.²⁷ Nonetheless, some clinicians elect to use antiarrhythmic drugs first and then resort to DCC in the event that these agents fail. Nearly all type Ia, Ic, and III agents have been demonstrated to possess some effectiveness in terminating atrial fibrillation, but because of the risk of proarrhythmia, they should be initiated in a monitored inpatient setting. A meta-analysis supported by the Agency for Healthcare Research and Quality (AHRQ) and published treatment guidelines from international cardiology groups both summarize the effectiveness and level of evidence of antiarrhythmic drugs to restore sinus rhythm. In sum, there is relatively strong evidence for efficacy the type III pure I_K blockers (e.g., ibutilide and dofetilide) and the type Ic (e.g., flecainide and propafenone).^{14,28} Oral loading doses of the type Ic antiarrhythmic (e.g., propafenone 600 mg as a single dose) have been demonstrated to be effective compared with placebo and provide a simple regimen.²⁹ Intravenous or oral amiodarone may both control ventricular rate (because of calcium and β -blocking actions) and restore sinus rhythm. Although often chosen, intravenous amiodarone is expensive, appears only modestly effective in restoring sinus rhythm, and has a delayed onset of action (days to weeks).³⁰ The disadvantages of pharmacologic cardioversion are the risk of significant side effects such as drug-induced torsade de pointes,³¹ the inconvenience of drug-drug interactions (e.g., digoxin-quinidine or digoxin-amiodarone), and the fact that drugs generally are less effective when compared with DCC. The advantages of DCC are that it is quick and more often successful. The disadvantages of DCC are the need for prior sedation/anesthesia and a risk (albeit small) of serious complications such as sinus arrest or ventricular arrhythmias. Contrary to past beliefs, DCC carries very little risk in patients receiving digoxin without evidence of digitalis toxicity.

LONG-TERM COMPLICATIONS

There are two forms of therapy that the clinician must consider in each patient: long-term antithrombotic therapy to prevent stroke and long-term antiarrhythmic drugs to prevent recurrences of atrial fibrillation. Consider the issue of antithrombotic therapy first. In the past, patients with atrial fibrillation were not anticoagulated routinely (unless there was a history of stroke or concurrent mitral valve disease) because it was felt that the risk of warfarin exceeded its potential (though unknown) benefit. More recently, a large number of randomized, placebo-controlled trials designed to evaluate this issue have been published. All possess relatively similar findings, and many were terminated prematurely because of a significant effect in the treatment group (warfarin). In all, these studies culminated in the American College of Chest Physicians Consensus Conference¹⁷ on antithrombotic therapy recommending the following: Warfarin (INR 2.0–3.0, target = 2.5) should be prescribed to all patients with atrial fibrillation who are at high risk for stroke (i.e., rheumatic valvular disease, previous history of thromboembolism, age greater than 75 years, LV dysfunction, or hypertension); those at low risk (age less than 65 years without discernible cardiovascular disease or lone atrial fibrillation) should receive aspirin 325 mg/day. In analyzing these recommendations, it becomes apparent that there is an intermediate-risk group, i.e., those with atrial fibrillation aged 65 to 75 years with minor risk factors for stroke (e.g., diabetes, coronary artery disease, or thyrotoxicosis). In these patients a careful risk-benefit assessment should be made between aspirin and warfarin, balancing the risk of stroke and hemorrhage on an individual basis. The current recommendation is that warfarin or aspirin should be continued until sinus rhythm has been maintained for at least 4 weeks, but this may be altered in the future. It has been shown that many patients have undetected recurrences of atrial fibrillation, placing the patient at risk for stroke. In other words, the clinician may think that sinus rhythm has been maintained, but in fact, brief, self-terminating episodes may have occurred.³² Adding fuel to this cautionary note were the results of AFFIRM²³: Thromboembolism rates were similar in patients with permanent atrial fibrillation (rate-control arm) and in *those in sinus rhythm*. Therefore, many practitioners now will continue warfarin treatment indefinitely even in patients who have appeared to remain successfully in sinus rhythm.

Clearly, in patients with permanent atrial fibrillation or documented, recurrent paroxysms, antithrombotic therapy should be continued indefinitely. Pharmacoeconomic analyses tend to support the use of aspirin only in patients with atrial fibrillation without risk factors for stroke.³³ Warfarin is more cost-effective in patients at risk for the complications of recurrent atrial fibrillation. New strategies to prevent stroke and thromboembolism more effectively are being evaluated continuously, including the use of new direct thrombin inhibitors which do not require intensive INR monitoring and dosage adjustment. One such agent, ximelagatran, though effective³⁴ was recently rejected by the FDA for use in the United States (it is available in Europe) mainly because of concerns about liver toxicity.

The second form of chronic therapy to be considered (at least in those patients in whom maintenance of sinus rhythm is a goal) is antiarrhythmic drugs to prevent recurrences of atrial fibrillation. With some exceptions (postoperative situations), atrial fibrillation often recurs after initial cardioversion because most patients have irreversible underlying heart or lung disease. Large atrial size, poor LV function, and the presence of long-standing atrial fibrillation are factors that make the restoration and maintenance of sinus rhythm difficult, if not

impossible. Nevertheless, historically, many clinicians have attempted aggressively to maintain sinus rhythm by prescribing oral antiarrhythmic drugs (usually quinidine) to prevent these recurrences despite the fact that only small studies with conflicting results have evaluated this approach. To evaluate the efficacy of quinidine in preventing atrial fibrillation, a well-known meta-analysis of the existing literature was completed.³⁵ This meta-analysis demonstrated that indeed more patients remain in sinus rhythm with quinidine therapy (compared with placebo), although about 50% have recurrences of atrial fibrillation within a year despite quinidine. However, this reported effectiveness was at the cost of an associated increase in mortality (presumably due to proarrhythmia) in the quinidine-treated patients. These disturbing results (published soon after the CAST³⁶) became widely quoted and highly visible, making clinicians question the wisdom of long-term prevention of recurrences of atrial fibrillation with antiarrhythmic drugs. Although the results were questioned because some of the reported causes of death in the treated patients could not be directly attributed to quinidine, subsequent studies³⁷ tended to support the findings of the meta-analysis.

These results, coupled with the recent findings of AFFIRM,²³ question the need to use antiarrhythmic drugs to prevent recurrences of atrial fibrillation. Perhaps this practice should now be totally abandoned, allowing patients to remain in atrial fibrillation once recurrences happen with strategies only to control rate and prevent thromboembolism. While it is true that these data certainly have led to a less aggressive approach, patients with paroxysmal atrial fibrillation and intolerable symptoms during recurrences do require antiarrhythmic drugs to prevent attacks.

Although nearly every type I or III antiarrhythmic drug has some published evidence of effectiveness in preventing recurrences of atrial fibrillation, amiodarone is clearly the most effective agent and now the most frequently chosen despite its impressive toxicity. Initially, uncontrolled studies³⁸ indicated that low doses (100 to 200 mg/day) of amiodarone are effective. Later, in a comparative trial,³⁹ amiodarone was shown to be superior to either sotalol or propafenone in maintaining sinus rhythm. Further, in a substudy of AFFIRM,²³ amiodarone was demonstrated to be the most effective antiarrhythmic agent of those used in the study.

Alternatives to amiodarone include the type Ic drugs (e.g., flecainide and propafenone) and the type III I_{Kr} blockers (e.g., sotalol and dofetilide). Because of the risk of proarrhythmia, the type Ic drugs should be reserved for those without heart disease (i.e., lone atrial fibrillation). Sotalol has been shown to be at least as effective as quinidine in preventing recurrences of atrial fibrillation.⁴⁰ However, treatment with either quinidine or sotalol is associated with a similar incidence of torsade de pointes. Since this form of proarrhythmia occurs primarily with higher doses of sotalol (quinidine usually causes torsade de pointes at low or therapeutic concentrations), it may be predicted more easily and therefore avoided. Nonetheless, it is possible that sotalol increases mortality in patients with atrial fibrillation similar to quinidine, and this requires further study.⁴¹

The newest type III agent, dofetilide, is effective in preventing recurrences of atrial fibrillation⁴² but has not been compared directly with amiodarone. In a large multicenter trial,⁴³ dofetilide (dose adjusted for renal function and QT interval) was more effective than placebo in maintaining sinus rhythm (about 40% to 60% at 1 year). Like sotalol and quinidine, dofetilide has significant potential to cause torsade de pointes (in a dose-related fashion), and because of this, we believe that dofetilide should not be considered first-line therapy for recurrent atrial fibrillation at this time.

In view of important studies implying increased mortality due to antiarrhythmic drugs such as quinidine and the results of AFFIRM, we suggest the following approach: Reserve chronic antiarrhythmic drugs only for patients with documented paroxysmal atrial fibrillation associated with intolerable symptoms. Those with an isolated episode should not receive chronic preventative therapy. In terms of drug choice, we feel that low-dose amiodarone should be given preference as the agent of first choice for most patients. After appropriate oral loading doses, patients should receive 200 mg/day on a chronic basis. If this dose has prevented recurrences, one may attempt to reduce it to 100 mg/day, but more data are required on this practice. Although the methods of oral amiodarone loading vary considerable, we recommend 800 mg/day for 1 week, followed by 400 mg/day for 1 month before initiation of the 200 mg/day maintenance dose for patients with recurrent atrial fibrillation. As second-line treatment in those who cannot tolerate amiodarone, sotalol or dofetilide can be considered. For patients with symptomatic recurrences of atrial fibrillation but no evidence of organic heart disease (e.g., recurrent lone atrial fibrillation), type Ic drugs such as flecainide and propafenone are highly effective and could be used safely as first-line drugs.

Nondrug forms of therapy designed to maintain sinus rhythm are either currently in use or actively being investigated. For patients who have “pure” (i.e., not associated with concurrent atrial fibrillation) type I atrial flutter, ablation of the reentrant substrate with radiofrequency current (see below) is highly effective (approximately 80%).⁴⁴ Recent guidelines place ablation as first-line treatment to prevent recurrences.^{14,45} For patients with atrial fibrillation, an innovative surgical procedure referred to as the *maze operation* has been used for over a decade.⁴⁶ Because of its highly complex nature, the maze was reserved for highly drug-refractory patients. Some have attempted to replicate the ideas of the maze procedure by using catheter ablation technologies. Success has been varied, and complications include recurrences of atrial fibrillation, new atrial flutter, and thromboembolism. Interestingly, a subset (often those with lone atrial fibrillation) of patients with paroxysmal atrial fibrillation appears to have their episodes initiated from premature beats that arise in the pulmonary veins. In these cases, ablation (see later) of the pulmonary venous foci or pulmonary vein isolation can result in prevention of recurrences in a high percentage of patients.^{47,48} Some believe these initial promising findings could lead to ablation being a first-line approach in the future.

PAROXYSMAL SUPRAVENTRICULAR TACHYCARDIA DUE TO REENTRY

5 Paroxysmal supraventricular tachycardia (PSVT) arising by reentrant mechanisms includes arrhythmias caused by AV nodal reentry, AV reentry incorporating an anomalous AV pathway, SA nodal reentry, and intraatrial reentry. AV nodal reentry and AV reentry are by far the most common of these tachycardias.

MECHANISMS

The underlying substrate of AV nodal reentry is the functional division of the AV node into two (or more) longitudinal conduction pathways, or dual AV nodal pathways.⁴⁹ Most practitioners now believe that there are not two distinct anatomic pathways inside the AV node itself. Rather, it is likely that a fanlike network of perinodal fibers inserts into the AV node and represents the second pathway. The two

FIGURE 17-7. Reentry mechanism of dual-AV-nodal pathway PSVT. *A.* Sinus rhythm. The impulse travels from the atrium through the fast pathway (F) and then to the His-Purkinje system. The impulse also travels through the slow pathway (S) but is stopped when refractory tissue is encountered. *B.* Dual-AV-nodal reentry. A critically timed premature impulse (*) is stopped in the fast pathway (because of prolonged refractoriness) but is able to travel antegrade down the slow pathway and retrograde through the fast pathway.

pathways possess key differences in conduction characteristics: One is a fast conducting pathway with a relatively long refractory period (fast pathway), and the other is a slower conducting pathway with a shorter refractory period (slow pathway). The presence of dual pathways does not necessarily imply that the patient will have clinical PSVT. In fact, it is estimated that between 10% and nearly 50% of patients have discernible dual pathways, but the incidence of PSVT is considerably lower.⁴⁹ Sustainance of the tachycardia depends on the critical electrophysiologic discrepancies and the ability of one pathway (usually the slow) to allow repetitive antegrade conduction and the ability of the other pathway (usually the fast) to allow repetitive retrograde conduction. During sinus rhythm, a patient with dual pathways conducts supraventricular impulses antegrade through both pathways. Electrical activity reaches the distal common pathway at the level of or above the bundle of His and continues to depolarize the ventricles in an antegrade direction. Conduction proceeds via the two pathways but reaches the distal common pathway first through the fast AV nodal route (Fig. 17-7). For this reason, a short PR interval is sometimes observed during sinus rhythm.

PSVT due to AV nodal reentry may occur by the following sequence of events: The occurrence of an appropriately timed premature impulse penetrates the AV node but is blocked in the fast pathway that is still refractory from the previous beat. However, the slow pathway, which has a shorter refractory period, permits antegrade conduction of the premature impulse. By the time the impulse has reached the distal common pathway, the fast pathway has recovered its excitability and now will permit retrograde conduction. The impulse reaches the common proximal pathway, preceded by an excitable gap of tis-

FIGURE 17-8. Reentry mechanism for AV-accessory-pathway PSVT in Wolff-Parkinson-White syndrome. *A.* Sinus rhythm. The impulse travels from the atrium to the ventricle by two pathways—the AV node and an accessory bypass pathway. *B.* AV reentry. A critically timed premature impulse (*) is stopped in the Kent bundle (because of prolonged refractoriness) but travels antegrade through the AV node and retrograde through the Kent bundle.

sue, and reenters the slow pathway. A reentrant circuit that does not require atrial or ventricular tissue is completed within (or nearly so) the AV node, and a tachycardia is thereby initiated (see Fig. 17-7). The common form of this tachycardia uses the slow pathway for antegrade conduction and the fast pathway for retrograde conduction; an uncommon form exists in which the reentrant impulse travels in the opposite direction.

AV reentrant tachycardia depends on the presence of an anomalous, or accessory, extranodal pathway that bypasses the normal AV conduction pathway. Several different types of accessory pathways have been described, depending on the specific anatomic areas they connect (e.g., atrioventricular bundles or nodoventricular tracts); some are also referred to as *eponyms*, such as the Kent bundle. A Kent bundle is an extranodal AV connection that is associated with the Wolff-Parkinson-White (WPW) syndrome. During sinus rhythm (Fig. 17-8), patients with WPW syndrome depolarize the ventricles simultaneously through both AV pathways (AV nodal pathway and the Kent bundle), creating a fusion pattern on the early portion of the QRS complex (delta wave). The degree of ventricular “preexcitation” depends on the contribution of antegrade ventricular activation through the accessory pathway. Patients may have an accessory pathway that is not evident on surface ECG or a “concealed” Kent bundle. These concealed accessory pathways often are incapable of antegrade conduction and can only accept electrical stimulation in a retrograde fashion. The ECG expression of preexcitation (delta wave) depends on the location of the accessory pathway, the distance from the wavefront of sinus activation, and the conduction characteristics of the various structures involved. It should be noted that (similar to patients with dual AV nodal pathways) not all patients with preexcitation with an accessory AV pathway are capable of having clinical PSVT.

Patients with an accessory AV pathway may have three forms of supraventricular tachycardia: orthodromic reentry, antidromic reentry, and/or atrial fibrillation or flutter. AV reentrant PSVT usually occurs by the following sequence of events: Analogous to AV nodal reentry, two pathways (the normal AV nodal pathway and the accessory AV pathway) exist that have different electrophysiologic characteristics. The AV nodal pathway usually has a relatively slower conduction velocity and shorter refractory period, and the accessory pathway has a faster conduction velocity and a longer refractory period. A critically timed premature impulse may block in the accessory pathway because it is still refractory from the previous sinus beat. However, the AV nodal pathway with its relatively shorter refractory period may accept antegrade conduction of the premature impulse. Meanwhile, the accessory pathway may recover its excitability and now allow retrograde conduction. A macroreentrant tachycardia is thereby initiated in which the antegrade pathway is the AV nodal pathway, the distal common pathway is the ventricle, the retrograde pathway is the accessory pathway, and the proximal common pathway is the atrium (Fig. 17-8). This sequence of events (down node, up Kent), termed

orthodromic PSVT, is the common variety of reentry in patients with an accessory AV pathway, resulting in a narrow QRS tachycardia. In the uncommon variety (down Kent, up node), conduction proceeds in the opposite direction, resulting in a wide QRS tachycardia termed *antidromic PSVT*. Patients with WPW syndrome can have a third type of tachycardia, namely, atrial fibrillation. The mechanism for its occurrence is unknown, but the occurrence of this arrhythmia can be very serious, and sudden death is well described. Since atrial fibrillation is an extremely rapid atrial tachycardia, conduction can proceed down the accessory AV pathway, resulting in a very fast ventricular response or even ventricular fibrillation. Unlike the AV nodal pathway, the refractory period of the accessory bundle shortens in response to rapid stimulation rates.

Sinus node reentry or intraatrial reentry occur less commonly, and neither is as well described as AV nodal or AV reentry. Aside from a characteristic abrupt onset and termination, coupled with subtle changes in P-wave morphology, these tachycardias can be difficult to diagnose. Electrophysiologic studies may be necessary to determine the ultimate mechanism of the PSVT.

► TREATMENT: Paroxysmal Supraventricular Tachycardia

Both pharmacologic and nonpharmacologic methods have been used to treat patients with PSVT. Drugs used in the treatment of PSVT can be divided into three broad categories: (1) those which directly or indirectly increase vagal tone to the AV node such as digoxin, (2) those which depress conduction through slow calcium-dependent tissue such as adenosine, β -blockers, and calcium channel blockers, and (3) those which depress conduction through fast sodium-dependent tissue such as quinidine, procainamide, disopyramide, and flecainide. Drugs within these categories alter the electrophysiologic characteristics of the reentrant substrate so that PSVT cannot be sustained.^{50,51} In PSVT due to AV nodal reentry, type I antiarrhythmic drugs such as procainamide act primarily on the retrograde fast pathway. Digoxin and propranolol may work on either the retrograde fast or the antegrade slow limb. Verapamil, diltiazem, and adenosine prolong conduction time and increase refractoriness primarily in the slow antegrade pathway of the reentrant loop. In PSVT due to AV reentry incorporating an extranodal pathway, type I drugs increase refractoriness in the fast accessory pathway or within the His-Purkinje system. Propranolol, digoxin, adenosine, and verapamil all act by their effects on the AV nodal (antegrade, slow) portion of the reentrant circuit. Regardless of the mechanism, treatment measures are directed at first terminating an acute episode of PSVT and then preventing symptomatic recurrences of PSVT.

As in any rapid reentrant tachycardia resulting in severe symptoms (e.g., syncope, near syncope, anginal chest pain, and severe heart failure), synchronized DCC is the treatment of choice. Even at low energy levels (e.g., 25 W/s), DCC for PSVT is almost always effective in quickly restoring sinus rhythm and correcting symptomatic hypotension. Patients with only mild to moderate symptoms usually do not require DCC, and nondrug measures that increase vagal tone to the AV node can be used first. Unilateral carotid sinus massage, Valsalva maneuver, ice water facial immersion, induced retching, and other more elaborate vagomimetic measures often are successful in terminating PSVT, although carotid massage and Valsalva maneuver are the simplest, least obtrusive, and most frequently used of these techniques.

6 In the event that these methods fail, drug therapy is the next option. A therapeutic approach to the acute therapy of the different forms of reentrant PSVT is presented in Fig. 17-9. This approach is based on analysis of the electrocardiographic characteristics of the rhythm because PSVT is not always discernible from other arrhythmias, and some forms of PSVT require different treatment. In patients with a narrow-QRS-complex, regular arrhythmia (AV nodal reentry or orthodromic AV reentry), intravenous verapamil (5 to 10 mg), intravenous diltiazem (15 to 25 mg), and adenosine (6 to 12 mg) all are equally efficacious; any may be chosen as the agent of first choice. About 80% to 90% of PSVT episodes will revert to sinus rhythm within 5 minutes of intravenous verapamil, diltiazem, or adenosine therapy.⁵² Verapamil has the advantage in terms of cost, being available in generic formulations, whereas adenosine (although it has a higher frequency of side effects) may be safer because of its ultrashort duration of action. Adenosine should not be used in patients with severe asthma; rapid reinitiation of PSVT also may occur.

5 The most recent guidelines for emergency care from the American Heart Association⁵³ and practice guidelines from the American College of Cardiology/American Heart Association/European Society of Cardiology⁴⁵ both promote adenosine as the drug of first choice in patients with PSVT. This recommendation is particularly important when treating a patient who presents with a wide-QRS-complex, regular tachycardia that may be ventricular tachycardia or PSVT (antidromic AV reentry or because of aberrancy). Because of its short duration of action (seconds), adenosine will not cause the severe and prolonged hemodynamic compromise seen in patients with ventricular tachycardia who were mistakenly treated with verapamil and suffer from its negative inotropic effects and vasodilator properties.⁵⁴ If in fact the arrhythmia is PSVT, adenosine likely will terminate it. An alternative treatment for this type of patient is intravenous procainamide, which works on the fast sodium-dependent extranodal pathway as well as for ventricular tachycardia. Likewise, intravenous procainamide or perhaps amiodarone (particularly in patients with LV dysfunction) should be used for the patient who presents with a wide-QRS-complex, irregular arrhythmia who is hemodynamically

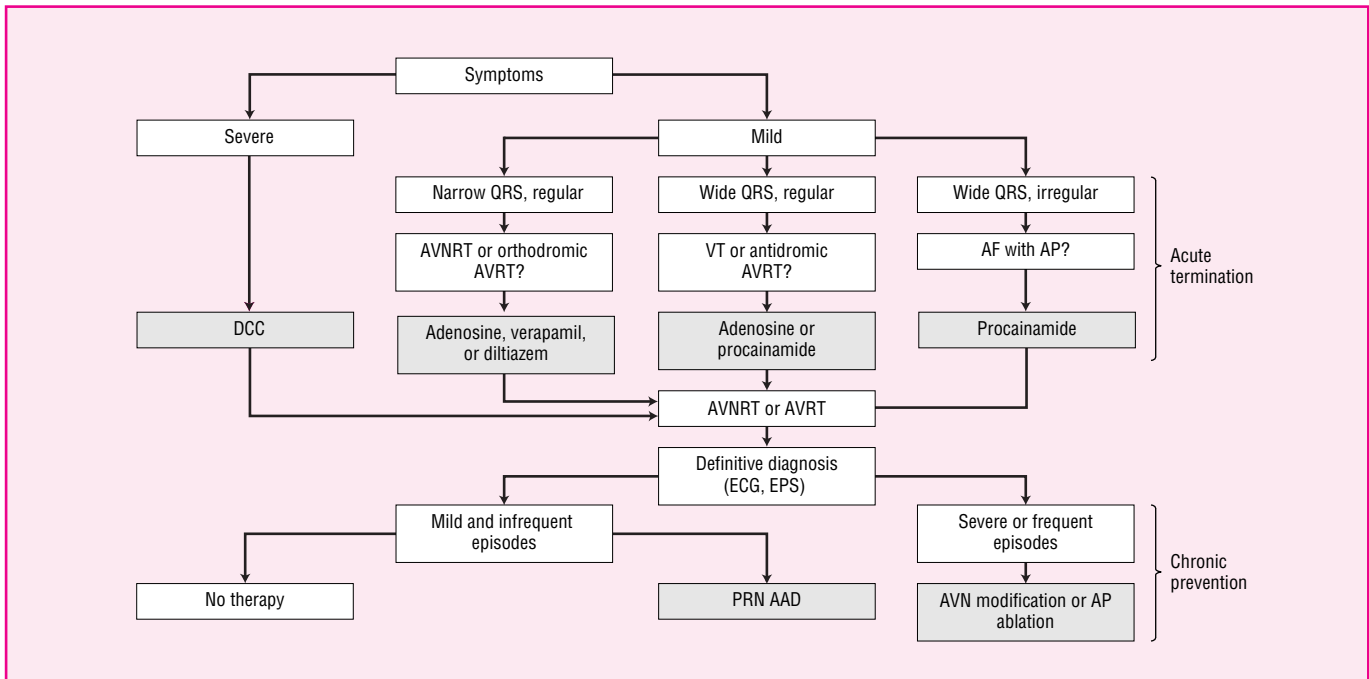

FIGURE 17-9. Algorithm for the treatment of acute (*above*) PSVT and chronic prevention of recurrences (*below*). DCC = direct current cardioversion, AVNRT = AV nodal reentrant tachycardia, AVRT = AV reentrant tachycardia, VT = ventricular tachycardia, AF = atrial fibrillation, AP = accessory pathway, ECG = electrocardiographic monitoring, EPS = electrophysiologic studies, PRN = as needed, AAD = antiarrhythmic drugs. Note: For empirical bridge therapy prior to radiofrequency ablation procedures, calcium antagonists (or other AV nodal blockers) should not be used if the patient has AV reentry with an accessory pathway.

stable.⁴⁵ This rhythm could represent atrial fibrillation with ventricular activation through an extranodal pathway. Administration of intravenous verapamil or adenosine to these patients could result in a paradoxical increase in ventricular response, causing severe symptoms that require cardioversion. These agents (particularly long-acting AV nodal-blockers such as verapamil, diltiazem, and digoxin) are to be considered contraindicated in this specific setting.

Once the acute episode of PSVT is terminated, a decision on long-term preventive therapy must follow. Most patients require long-term therapy; preventive treatment is indicated if (1) frequent episodes occur that necessitate therapeutic intervention (i.e., emergency room visits or interference with the patient's lifestyle) or (2) infrequent but severely symptomatic symptoms occur. For patients in whom a preventive treatment is deemed necessary, two methods of management have been used: preventative drug therapy and ablation.

There are a number of ways to develop an effective drug regimen for patients with recurrent PSVT. A trial-and-error approach on an ambulatory basis may be considered for patients with frequently recurrent, mildly symptomatic PSVT. Ambulatory ECG recordings (Holter) or telephonic transmissions of cardiac rhythm (event monitors) can be used to objectively document the efficacy or failure of drug therapy. Drugs known to be effective in preventing recurrences of PSVT are the AV nodal-blocking agents (e.g., digoxin, β -blockers, calcium channel blockers, or combinations of these agents) and the type Ic drugs (e.g., flecainide and propafenone). There are patterns of drug response in patients with PSVT; the tachycardia behaves as if it has a "weak link." That is, patients who respond to agents that act on

one limb of the reentrant loop are less likely to respond to drugs that block conduction on the other limb. For instance, in a patient with AV nodal reentry, one first may choose a calcium channel blocker or β -blocker (to affect the antegrade slow pathway). If symptomatic recurrences are documented subsequently, then it may be prudent to switch to a type Ic drug such as flecainide (to affect the retrograde fast pathway) in an attempt to find the weak link, or susceptible pathway. There are other considerations. Patients with evidence of preexcitation (delta waves during sinus rhythm) should not be treated only with AV nodal-blocking agents. If atrial fibrillation were to occur, these agents would facilitate rapid conduction over the accessory pathway. Also, the trial-and-error method for determining drug effectiveness has inherent shortcomings. If the PSVT episodes are infrequent, a considerable time period may be consumed before an effective regimen is realized, or if the patient has moderate to severe symptoms associated with PSVT, he or she may experience several troublesome episodes before the correct agent is identified. Therefore, serial testing of antiarrhythmic agents by invasive electrophysiologic techniques has been used to determine effective long-term therapy in patients with sporadic and/or symptomatic PSVT, and this method represents the third treatment strategy. Basically, the patient's clinical tachycardia is replicated in the laboratory by inserting appropriately timed premature extra stimuli via a transvenous right-sided heart catheter. The patient is first studied off of antiarrhythmic therapy; induction of the tachycardia by premature stimuli by programmed stimulation serves as a control study. Then, over a period of several days, specific drugs are administered in a serial fashion and tested for efficacy in preventing the induction of PSVT.^{50,51}

Regardless of the method for choosing long-term therapy, chronic antiarrhythmic drug treatment in these often young, otherwise healthy patients is problematic. Besides the necessity of taking daily medication possibly for life, antiarrhythmic drugs are not well tolerated, sometimes precipitate severe side effects, and commonly **5** are ineffective. For these reasons, nondrug therapies have been pioneered. One such procedure, namely, transcutaneous catheter ablation using radiofrequency current on the PSVT substrate has altered the traditional treatment of these patients dramatically (Fig. 17–10). Radiofrequency energy delivered through a transvenous or arterial catheter causes small, discrete lesions through thermal energy. During invasive electrophysiologic studies, portions of the reentrant circuit can be located (or “mapped”) by the use of a number of catheters. Once this is completed, radiofrequency energy is applied, creating thermal injury in the tissue necessary for reentry. In this way, the substrate for reentry is destroyed, “curing” the patient of recurrent episodes of PSVT and obviating the need for chronic drug therapy. Historically, ablation procedures were reserved for drug-refractory patients because they necessitated open-heart surgery. However, breakthroughs in technology have allowed, first, transvenous catheter approaches and then, later, the use of radiofrequency (rather than direct-current) energy. Complications, although unusual, include tamponade, pericarditis, valvular insufficiency, and AV block. Radiofrequency ablation is highly effective, preventing the recurrences of PSVT in 85% to 98% of patients.^{55,56} The procedure was used originally in patients with WPW syndrome.⁵⁵ In this syndrome, the extranodal pathway often is located at the left lateral free wall of the left ventricle (see Fig. 17–10). After the pathway is located, the catheter is put as close to the site as possible, and radiofrequency current is applied to make small burns in the tissue. Ablation of the extranodal connection occurs promptly, and evidence of preexcitation (delta waves) disappears. Thereafter, a similar approach was developed for patients with AV nodal reentry, placing the catheter in the coronary sinus, proximal to the AV node.⁵⁶ The preferred method in these individuals is to apply small amounts of radiofrequency current to the slow pathway of the reentrant circuit in order to modify its properties enough so that PSVT cannot recur.

It has been suggested that *all* patients with symptomatic PSVT undergo radiofrequency catheter ablation.⁵⁷ This is so because it is highly effective and curative, rarely resulting in complications, and obviates the need for chronic antiarrhythmic drug therapy. In other words, it should be considered in *any* patient who previously would have been considered for chronic antiarrhythmic drug treatment. Radiofrequency ablation is also a cost-effective approach (in the long term) because, if effective, the costs of drugs and repeated hospital visits are avoided. In one cost-effectiveness analysis, radiofrequency ablation improved quality of life and reduced lifetime medical expenditures by nearly \$30,000 compared with chronic drug treatment.⁵⁸

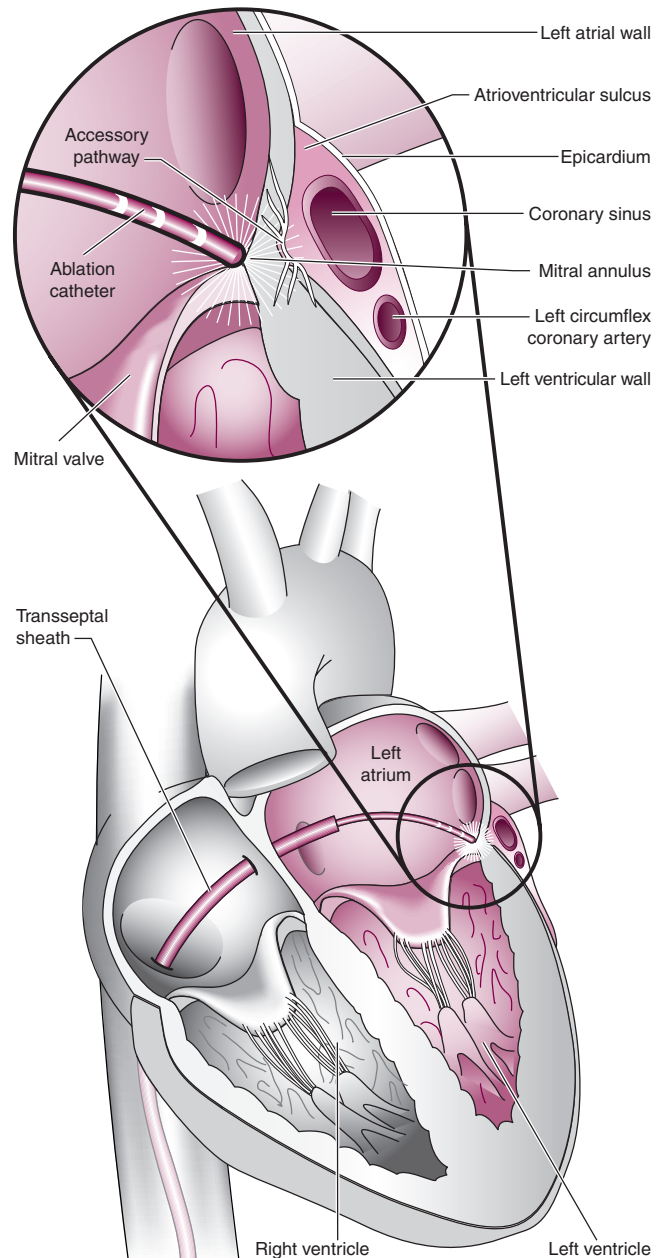

FIGURE 17–10. Drawing showing catheter placement for radiofrequency ablation of left free wall accessory pathway. Here, the retrograde arterial approach is taken, although a venous (atrial) transseptal puncture also has been used. (From Lerman BB, Basson CT. High-risk patients with ventricular preexcitation: A pendulum in motion. *N Engl J Med* 2003;349:1787–1789, with permission)

AUTOMATIC ATRIAL TACHYCARDIAS

Automatic atrial tachycardias such as multifocal atrial tachycardia appear to arise from supraventricular foci that have enhanced automatic properties.⁵⁹ It is presumed that multifocal atrial tachycardia is the result of multiple ectopic atrial pacemakers, which account for the variable and differing P-wave morphology. In unifocal atrial tachycardia (sometimes referred to as *ectopic atrial tachycardia*), a single P-wave morphology different from that of sinus rhythm is recorded. In either case, the underlying, precipitating disorder present in the major-

ity (60% to 80%) of these patients is severe pulmonary disease. Other disease states associated with these arrhythmias include acute infection (pneumonia and sepsis) and dilated congestive cardiomyopathy. It should be noted that young patients without associated precipitating factors rarely may present with rapid atrial tachycardias from unknown etiologies. In these cases, long-standing tachycardias cause the cardiomyopathic state. Effective treatment of the tachycardia may result in reversal of LV dysfunction. Traditionally, many factors (e.g., electrolyte disturbances, hypoxia, catecholamines, and tissue stretch) have caused an elevated slope of phase 4 depolarization and

theoretically resulted in abnormal heightened automaticity. Noteworthy is that many of these factors often are present clinically in patients with concurrent pulmonary disease and automatic atrial tachycardia. However, information implies that triggered activity (i.e., late after-

depolarizations) is a more likely mechanism in the genesis of these tachycardias. Atrial tachycardias with AV block or a slow ventricular response should alert the clinician to the possibility of digitalis toxicity.

► TREATMENT: Automatic Atrial Tachycardia

The first step in the treatment of automatic atrial tachycardia is to correct the underlying precipitating factors.⁵⁹ One should ensure proper oxygenation and ventilation and correct acid-base or electrolyte disturbances. These measures alone may result in the return of sinus rhythm, but in some cases, the tachycardia will persist. Patients with an asymptomatic atrial tachycardia and a relatively slow ventricular response usually require no drug therapy. In symptomatic patients, medical therapy can be tailored to either control ventricular response or restore sinus rhythm. Type I antiarrhythmic drugs such as procainamide and quinidine are effective only occasionally in restoring sinus rhythm, but these agents usually are not considered first-line therapy. DCC is ineffective in restoring sinus rhythm, and the use of programmed stimulation will not replicate the clinical tachycardia, so serial drug testing is of no value. The use of intravenous β -blockers

to slow ventricular response usually is contraindicated because of the frequent coexistence of bronchospastic pulmonary disease or uncompensated heart failure. Digoxin has been used but is controversial because of its ability to increase the automatic properties of atrial tissue, and the high sympathetic state of these patients frequently overrides the vagotonic effects of digoxin, rendering it ineffective. Calcium antagonists such as verapamil are most effective and now may be considered first-line drug therapy.⁶⁰ Interestingly, verapamil seems to decrease ventricular response by altering atrial automaticity, not by slowing AV nodal conduction.⁶⁰ Intravenous magnesium (independent of serum magnesium concentration) also can be effective, but high doses are required, and the effects are transient, rendering it impractical.⁵⁹ Both verapamil and parenteral magnesium probably act by suppressing calcium-mediated late after-depolarizations (LADs).

VENTRICULAR ARRHYTHMIAS

The common ventricular arrhythmias include (1) premature ventricular complexes (PVCs), (2) ventricular tachycardia, and (3) ventricular fibrillation. Again, these arrhythmias may result in a wide variety of symptoms. PVCs often cause no symptoms or only mild palpitations. Ventricular tachycardia may be a life-threatening situation associated with hemodynamic collapse or be totally asymptomatic. Ventricular fibrillation, by definition, is an acute medical emergency necessitating cardiopulmonary resuscitation (CPR).

PVCs AND PREVENTION OF SUDDEN CARDIAC DEATH

PVCs are very common ventricular rhythm disturbances that occur in patients with or without heart disease. Experimental models have shown that premature ventricular depolarizations may be elicited by abnormal automaticity, triggered activity, or reentrant mechanisms. It has become well known that PVCs can be observed commonly in apparently healthy individuals. However, PVCs occurring in overtly normal subjects without discernible heart disease seem to have little, if any, prognostic significance. PVCs occur more frequently and in more complex forms (see below) in patients with detectable heart disease than in healthy individuals. The prognostic meaning of PVCs has been well studied in patients with MI (acute or remote) with several consistent themes. Patients with some forms of PVCs (see below) are at higher risk for sudden death than if they did not have these minor rhythm disturbances. *Sudden cardiac death* can be defined as unexpected death occurring in a patient within 1 hour of experiencing symptoms. Studies of patients who experienced sudden cardiac death (and happened to be wearing an ECG monitor at the time) often demonstrate the cause to be ventricular fibrillation preceded by a short run of ventricular tachycardia and frequent PVCs.⁶¹ Therein lies the basis of the so-called PVC hypothesis; i.e., preventing more minor arrhythmias such as PVCs may prevent the occurrence of sudden death.

CLINICAL PRESENTATION: VENTRICULAR ARRHYTHMIAS

PVCs

PVCs are non-life-threatening and usually asymptomatic. Occasionally, patients will complain of palpitations or uncomfortable beats. Since the PVC, by definition, occurs early, and the ventricle contracts when it is incompletely filled, patients do not feel the PVC. Rather, the next beat (after the PVC and a compensatory pause) usually is responsible for the patient's symptoms.

VENTRICULAR TACHYCARDIA (VT)

The symptoms of VT (monomorphic VT or torsade de pointes), if prolonged (i.e., sustained), can vary from nearly completely asymptomatic to pulseless hemodynamic collapse. Fast rates and underlying poor ventricular function will result in more severe symptoms. Symptoms of nonsustained, self-terminating VT also correlate with duration of episodes (e.g., patients with 15-second episodes will be more symptomatic than those with three-beat episodes).

VENTRICULAR FIBRILLATION (VF)

By definition, VF results in hemodynamic collapse, syncope, and cardiac arrest. Cardiac output and blood pressure are not recordable.

SIGNIFICANCE

Historically, investigators promoted the concept that patients in the acute phase of MI may have types of PVCs that are predictive of ventricular fibrillation and sudden cardiac death. These types of PVCs were referred to as *warning arrhythmias* and include frequent ectopy (>5 per minute), multiform configuration (different morphology), couplets (two in a row), and R-on-T phenomenon (PVCs occurring during the repolarization phase of the preceding sinus beat in the

vulnerable period of ventricular recovery). However, using sophisticated monitoring techniques, it has become apparent that almost all patients have warning arrhythmias in the acute infarct setting. In patients who experience ventricular fibrillation, warning arrhythmias are no more common than in those without ventricular fibrillation. Therefore, warning arrhythmias observed during acute MI are neither a sensitive nor a specific predictive tool in determining which patients will have ventricular fibrillation. Hence, in patients with acute MI, there is little need to direct drug therapy specifically at PVC suppression. Studies have shown that effective prevention of ventricular fibrillation in the acute MI setting may be achieved without the abolition of PVCs. The inability of PVCs (warning arrhythmias) to predict the occurrence of ventricular fibrillation, coupled with the lack of correlation between a drug's effectiveness in preventing ventricular fibrillation and suppressing PVCs, forms the basis of suggesting antiarrhythmic drug prophylaxis (e.g., lidocaine and magnesium) for all patients with an uncomplicated acute MI (see below).

On the other hand, data strongly imply that PVCs documented in the convalescence period of MI do carry important long-term prognostic significance.⁶² PVCs occurring after an MI seem to be a risk factor for patient death that is independent of the degree of LV dys-

function or the extent of coronary atherosclerosis. Lown and Wolff⁶³ have developed a grading scale for classifying different types of PVCs. The grading scale is as follows: grade 0, no ectopy; grade I, less than 30 PVCs/h of uniform morphology; grade II, more than 30 PVCs/h of uniform morphology; grade III, multiform PVCs; grade Iva, couplets; grade Ivb, 3 or more consecutive PVCs (nonsustained ventricular tachycardia); and grade V, R-on-T phenomenon. A common assumption is that the higher grades of PVCs within this classification system imply a higher risk of subsequent arrhythmogenic death. It should be emphasized that this assumption has never been proven. Ruberman and coworkers⁶² devised a simple alternative classification based on the significance of simple or benign (infrequent and monomorphic) versus complex PVCs (all other types in the Lown classification). These investigators found that the presence of complex ventricular ectopy in the setting of ischemic heart disease was associated with a higher incidence of cardiac death (but not necessarily arrhythmogenic death). One can see that within the controversy of the significance of PVCs is a basic question: Are complex forms of PVCs simply an unimportant marker of underlying structural heart disease, or are PVCs an important electrical disorder that should be addressed independently?

► TREATMENT: Premature Ventricular Complexes

Because PVCs without associated heart disease, in apparently healthy individuals, carry little or no risk, drug therapy is unnecessary. However, owing to the prognostic significance of complex PVCs in patients with heart disease, the use of antiarrhythmic drug therapy to suppress them has been controversial. Traditionally, many clinicians supported aggressive drug therapy designed to suppress a high percentage of PVCs based on the Lown grading system. The underlying premise of this approach is to attempt to eliminate a risk factor for cardiac death in patients with coronary disease, namely, the presence of complex PVCs. However, others have favored a more conservative approach and have disregarded drug therapy in the absence of significant symptoms. The initial CAST results³⁶ clearly support the latter conservative approach.

■ THE CARDIAC ARRHYTHMIA SUPPRESSION TRIAL (CAST)

7 The CAST^{36,64} was initiated by the NIH in 1987 to determine if suppression of ventricular ectopy with encainide, flecainide, or moricizine could decrease the incidence of death from arrhythmia in patients who had suffered an MI. Entrance criteria included documented MI between 6 days and 2 years prior to enrollment and six or more PVCs per hour without runs of ventricular tachycardia greater than 15 beats in length. Also, patients were required to have an ejection fraction of 55% or less if recruited within 90 days of MI or 40% or less if recruited 90 days or more after MI. Patients with an ejection fraction of less than 30% were randomized only to encainide or moricizine. Patients were randomized to receive drug therapy or placebo after demonstrating PVC suppression with one of the agents. The drug and dose were determined during an open-label dose-titration phase that preceded randomization.

In April 1989, a routine preliminary review of the study by the Safety and Monitoring Board revealed alarming results, and the study was interrupted. The results showed that compared with placebo, treatment with encainide or flecainide was associated with a significantly

higher rate of total mortality and death due to arrhythmia, presumably due to drug-induced proarrhythmia (Fig. 17–11). Analysis of the moricizine arm indicated neither harm nor benefit from this therapy; therefore, only this portion of the study was allowed to continue as CAST II.⁶⁴ However, later (July 1991), CAST II also was stopped prematurely; there was a trend toward an increase in mortality in moricizine-treated patients. This was particularly true during the initiation of moricizine therapy (dose-titration phase) but was not observed during the chronic treatment phase. The overall results of the two CASTs prove conclusively that patients with PVCs after MI do not benefit from chronic antiarrhythmic drug therapy (beyond the

FIGURE 17–11. Life table curves from the CAST, specifically for patients receiving encainide or flecainide (lighter line) and matching placebo (darker line). Note the divergent slopes of each line implying sustained risk of death (presumed proarrhythmia). (From the CAST Investigators. Preliminary report: Effect of encainide and flecainide on mortality in a randomized trial of arrhythmia suppression after myocardial infarction. *N Engl J Med* 1989;321:406–412, with permission.)

general use of β -blocking agents) and that, in fact, such therapy is detrimental. The study also puts into perspective the risk associated with the use of antiarrhythmic therapy and the need to carefully select only patients with a defined therapeutic benefit.

Although now more than 15 years old, the CAST is considered one of the most important trials ever undertaken by the NIH, and it has had a tremendous influence on the overall approach to the treatment of tachycardias, in addition to a far-reaching impact on new drug development. The results have colored the long-term use of all antiarrhythmics, causing a broad skepticism in the risk-benefit ratio of this class of drugs. Pharmaceutical companies, as a result, have shifted their drug discovery and investigative efforts away from potent sodium channel blockers. As immediate fallout, encainide was withdrawn from the market, and another pharmaceutical manufacturer decided not to market the type Ic agent indecainide despite FDA approval. These findings also provided additional fuel for the pursuit of nondrug therapies for tachycardias, such as ablation and implantable devices.

Despite the discouraging results of the CAST, post-MI patients with complex ventricular ectopy remain at risk for death. Other drugs besides type Ic drugs have been studied, including sotalol. Sotalol is marketed as a racemic mixture of a D- and L-isomer; both are type III potassium blockers, but the L-isomer has β -blocking actions. Chronic therapy with D-sotalol was studied in patients with remote MI complicated by complex ectopy in the Survival With Oral D-Sotalol (SWORD) trial.⁶⁵ Unlike in the CAST, D-sotalol treatment was not designed to cause PVC suppression, yet (as in the CAST) the trial was halted prematurely because of excessive mortality in the treatment arm. Again, the presumed reason for this observation was D-sotalol-related proarrhythmia. Currently, only two antiarrhythmic

drugs have been shown *not* to increase mortality with long-term use: amiodarone and dofetilide. A number of trials^{66,67} have shown amiodarone to decrease the incidence of sudden (or arrhythmic) death but not total mortality in post-MI patients with complex ventricular ectopy. A meta-analysis of all trials (6553 combined patients) demonstrated a reduction in total mortality (by 13%) with long-term amiodarone therapy.⁶⁸ It is unclear if these findings can be attributed to one property (e.g., β -blocking) or a combination of amiodarone's complex pharmacologic effects on conduction. Noteworthy is that in two major studies patients treated with amiodarone *and* a β -blocker generally did better than when no β -blocker was used.^{66,67} Clearly, because of its impressive adverse-effect profile and its inability to improve survival, amiodarone cannot be recommended routinely in patients with heart disease such as remote MI and complex PVC's. Two randomized, controlled trials^{69,70} have shown chronic therapy with dofetilide to have no effect on overall mortality in patients who have suffered MI with LV dysfunction. Dofetilide (not approved for prevention of sudden death) caused torsade de pointes in about 5% of patients, necessitating a protocol amendment with dosage adjustments during both trials (particularly in those with renal disease because the primary route of elimination is through the kidney).

7 How should the clinician approach the patient with documented asymptomatic PVCs? Clearly, attempts to suppress asymptomatic PVCs should not be made with any antiarrhythmic drug. Indeed, those at risk for arrhythmic death (recent MI, LV dysfunction, complex PVCs) should not be given *any* type I or III antiarrhythmic agent routinely.⁷¹ Of the antiarrhythmic drugs in the Vaughn Williams classification, only β -blockers have been proven conclusively to prevent overall mortality in these patients, and therefore, chronic drug therapy should be restricted to these agents.

VENTRICULAR TACHYCARDIA

MECHANISMS AND TYPES OF VENTRICULAR TACHYCARDIA

Ventricular tachycardia is a wide-QRS-complex tachycardia that may occur acutely as a result of metabolic abnormalities, ischemia, or drug toxicity or recur chronically as a paroxysmal form. On ECG inspection, ventricular tachycardia may appear as either repetitive monomorphic or polymorphic ventricular complexes. The definition of ventricular tachycardia is three or more repetitive PVCs occurring at a rate greater than 100 beats per minute. An acute episode of ventricular tachycardia may be precipitated by severe electrolyte abnormalities (hypokalemia), hypoxemia, or digitalis toxicity or (most commonly) may occur during an acute MI or ischemia complicated by heart failure. In these cases, correction of the underlying precipitating factors usually will prevent further recurrences of ventricular tachycardia. For example, if ventricular tachycardia occurs during the first 24 hours of an acute MI and is treated effectively, it probably will not reappear on a chronic basis after the infarcted area has healed or ischemia has resolved. This form of acute ventricular tachycardia may be due to a transient reentrant mechanism within temporarily ischemic or dying ventricular tissue. In contrast, some patients have a chronic recurrent form of ventricular tachycardia that is almost always associated with some type of underlying organic heart disease. Common examples are paroxysmal ventricular tachycardia associated with idiopathic dilated cardiomyopathy or remote MI with a LV aneurysm. Indeed, LV dysfunction and aneurysm formation are risk factors for the development of ventricular tachycardia on a recurrent basis after

MI. In chronic, recurrent ventricular tachycardia, microreentry within the distal Purkinje network is presumed to be responsible for the underlying substrate in a large majority of patients (see Fig. 17-3). Theoretically, electrophysiologic discrepancies occur as a result of structural damage and heart disease within the ventricular conducting system. The reentrant circuit may possess both anatomically determined and functional properties coursing through normal tissue, damaged tissue, and around islands of necrosed tissue. In a minority of patients, macro reentrant circuits may be responsible for recurrent ventricular tachycardia, including reentry incorporating the bundle branches.

Patients with acute ventricular tachycardia associated with a precipitating factor often suffer severe symptoms requiring immediate treatment measures. *Chronic recurrent ventricular tachycardia* also may cause severe hemodynamic compromise, but sometimes only mild symptoms that are generally well tolerated result. *Sustained ventricular tachycardia* is that which requires therapeutic intervention to restore a stable rhythm or lasts a relatively long time (usually greater than 30 seconds). *Nonsustained ventricular tachycardia* (NSVT) is that which self-terminates after a brief duration (usually less than 30 seconds). If the patient has ventricular tachycardia more frequently than sinus rhythm (i.e., ventricular tachycardia is the dominant rhythm), this is referred to as *incessant ventricular tachycardia*. *Exercise-induced ventricular tachycardia* is that which occurs during times of high sympathetic tone such as physical exertion. *Monomorphic ventricular tachycardia* has a consistent QRS configuration, whereas *polymorphic ventricular tachycardia* has varying QRS complexes. A characteristic type of polymorphic ventricular tachycardia, in which the QRS complexes appear to undulate around a central axis

TABLE 17–6. Heritable Polymorphic Ventricular Tachycardia

| Syndrome | Channel Defect | Mutant Gene | Characteristics | Treatment |
|-------------------|---|---------------|--|----------------|
| LQTS ₁ | ↓I _{Ks} | <i>KVLQT1</i> | SD/TdP with exercise | BB/ICD |
| LQTS ₂ | ↓I _{Kr} | <i>HERG</i> | SD/TdP with arousal | BB/ICD |
| LQTS ₃ | ↑I _{Na+} during plateau/ repolarization | <i>SCN5A</i> | SD/TdP at rest/sleep | Mexilitine/ICD |
| Brugada | ↓I _{Na+} | <i>SCN5A</i> | SD/PMVT or VF at rest/ sleep in Asian males | ICD |

LQTS = long-QT syndrome; SD = sudden death; TdP = torsade de pointes; PMVT = polymorphic ventricular tachycardia; VF = ventricular fibrillation; BB = β -blocker; ICD = internal cardioverter-defibrillator.

Note: LQTS can be provoked by potassium channel blockers (e.g., quinidine, sotalol), and Brugada syndrome can be provoked by potent sodium channel blockers (e.g., cocaine, flecainide). LQTS₃ and Brugada may coexist.

and is associated with evidence of delayed ventricular repolarization (long QT interval or prominent U waves), is referred to as *torsade de pointes*.

Most but not all forms of recurrent ventricular tachycardia occur in patients with extensive heart disease. Ventricular tachycardia occurring in a patient without heart disease is sometimes referred to as *idiopathic ventricular tachycardia* and may take several forms.^{72–74} Fascicular tachycardia arises from a fascicle of the left bundle branch (usually posterior) and usually is not associated with severe underlying heart disease. Calcium channel blockers (but not adenosine) are effective in terminating an acute episode of fascicular ventricular tachycardia. Ventricular outflow tract tachycardia (usually originating from the right ventricular outflow tract and thus abbreviated RVOT) originates from near the pulmonic valve (or uncommonly the aortic) and also occurs in patients with normal LV without discernible cardiac disease.⁷⁴ Unlike other forms of ventricular tachycardia, RVOT

often terminates with adenosine and may be prevented with β -blockers and/or calcium channel blockers.

Some unusual forms of ventricular tachycardia are congenital or heritable (Table 17–6). Torsade de pointes can be associated with heritable defects in the flux of ions that govern ventricular repolarization. Although seven syndromes have been described, the more common examples are long-QT-interval syndromes (LQTS) 1 (depressed I_{Ks}), 2 (depressed I_{Kr}), and 3 (enhanced inward Na⁺ flux during repolarization).^{75,76} Polymorphic ventricular tachycardia (without a long QT interval) or ventricular fibrillation also may occur owing to a heritable defect in the sodium channel. This is the case in Brugada syndrome, described as a typical ECG pattern (ST-segment elevation in leads V₁–V₃) during sinus rhythm and associated with sudden death, commonly in males of Asian descent.⁷⁷ It has been estimated that Brugada syndrome accounts for about 40% of all cases of ventricular fibrillation in patients without heart disease.

► TREATMENT: Ventricular Tachycardia

Consider the patient with the more common form of sustained monomorphic ventricular tachycardia, i.e., a patient with structural heart disease, usually ischemic in nature. As with other rapid tachycardias, the initial management of an acute episode of ventricular tachycardia requires a quick assessment of the patient's status and symptoms. If severe symptoms are present, then DCC should be instituted to restore sinus rhythm immediately. An investigation should be made into possible precipitating factors, and these should be corrected, if possible. The diagnosis of acute MI should be entertained. If the episode of ventricular tachycardia is felt to be an isolated electrical event associated with a transient initiating factor (such as acute MI or digitalis toxicity), there is no need for long-term antiarrhythmic therapy once the precipitating factors are corrected (e.g., an infarct has healed and the patient is stable). Nevertheless, the patient should be monitored closely for possible recurrences of ventricular tachycardia.

Patients presenting with an acute episode of ventricular tachycardia associated with only mild symptoms can be treated initially with antiarrhythmic drugs (DCC should be readily available). The reader is referred to the most recent Guidelines for Cardiopulmonary Resuscitation and Emergency Cardiac Care put forth by the American Heart Association.⁵³ Intravenous amiodarone now usually is chosen first in this situation. Intravenous procainamide or lidocaine are suitable alternatives, although in one small study procainamide was shown to be superior to lidocaine in terminating ventricular tachycardia.⁷⁸ DCC should be instituted if the patient's status deteriorates, ventricular tachycardia degenerates to ventricular fibrillation, or drug therapy

fails. As an alternate to DCC, a transvenous pacing wire can be inserted and ventricular tachycardia terminated by overdrive pacing methods.

Once an acute episode of sustained ventricular tachycardia has been terminated successfully by electrical or pharmacologic means and an acute MI has been ruled out, the possibility of paroxysmal ventricular tachycardia reappearing on a recurrent basis should be considered. This possibility often can be confirmed by the use of invasive electrophysiologic studies using programmed ventricular stimulation. Management of a patient with chronic recurrent sustained ventricular tachycardia deserves considerable attention. Because such a patient is at extremely high risk for death, trial-and-error attempts to find effective therapy is unwarranted. Two methods using surrogate end points have been used: (1) inability to induce sustained ventricular tachycardia with programmed extrastimuli by invasive electrophysiologic studies and (2) suppression of ventricular ectopy by serial 24-hour continuous ECG (Holter) monitoring.

Electrophysiologic studies using programmed stimulation incorporate the concepts of reentry in order to replicate the patient's clinical tachycardia in a controlled laboratory setting. The patient is admitted to the hospital (often to an intensive care unit) and strips of the clinical tachycardia are analyzed carefully. All antiarrhythmic drugs are discontinued, and (after the systemic elimination of these drugs) the patient is brought to the electrophysiology laboratory in the nonsedated state. Here, transvenous multipolar catheters, which can both pace the heart and record electrical activity, are inserted into the right

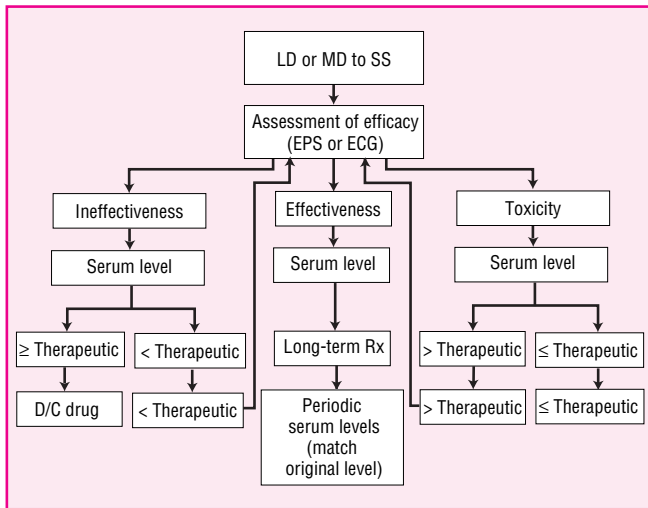

FIGURE 17-12. Algorithm for the clinical approach to therapeutic drug monitoring of antiarrhythmic drugs. EPS = electrophysiologic study; ECG = continuous electrocardiographic monitoring; D/C = discontinue drug.

side of the heart. Next, attempts to replicate the clinical tachycardia are made by the insertion of early beats and/or pacing methods via programmed stimulation. If replication of the clinical tachycardia is achieved, this initial study (without drug therapy) serves as a control that can be compared with subsequent studies on drug therapy. Once ventricular tachycardia is induced by programmed stimulation, it can be terminated by programmed stimulation, overdrive pacing, or DCC depending on the patient's status. Antiarrhythmic drugs then can be administered serially, and the electrophysiologic study is repeated (at presumed drug steady state). If a patient has sustained ventricular tachycardia induced during the control study, then the inability to reproduce ventricular tachycardia or the induction of only brief, self-terminating episodes of ventricular tachycardia (usually less than 15 beats) generally predicts that the drug will be effective in preventing recurrent episodes on a long-term basis. When ventricular tachycardia is rendered noninducible with drug therapy, a serum drug level determination should be done immediately. This serum level then serves as the patient's target level for chronic oral therapy (Fig. 17-12). Efforts should be directed at keeping the serum level at or above this target to prevent recurrence of the arrhythmia.⁷⁹

Although this method can be efficacious in determining effective antiarrhythmic drug therapy in patients with recurrent ventricular tachycardia, it has several drawbacks besides its invasive nature. Foremost in this regard is that the yield for finding an effective drug is low. Sustained monomorphic ventricular tachycardia can be rendered noninducible or nonsustained in only 20% to 25% of patients. Therefore, the clinician frequently must search for other therapeutic options or settle for other treatment end points such as slower and more tolerable inducible ventricular tachycardia. Amiodarone is clearly the most effective (about 50% effective after 2 years) agent in patients with recurrent ventricular tachycardia; however, electrophysiologic drug testing does not necessarily predict the clinical efficacy of amiodarone. Patients may have continued inducibility of ventricular tachycardia on amiodarone despite long-term success. Indeed, empirical amiodarone has been compared with therapy with other agents guided by electrophysiologic testing in patients at high risk for recurrent ventricular tachycardia.⁸⁰ In this trial, amiodarone therapy without invasive testing was superior in preventing cardiac

death and recurrences of severe ventricular arrhythmias at all time points.

Older trials that seemingly demonstrated that serial drug testing identifies effective chronic agents always lacked a control group (i.e., patients rendered noninducible after treatment with an antiarrhythmic drug who are not treated chronically with that agent). This obviously was done because of ethical concerns but raises the possibility that noninducibility simply identifies low-risk patients, independent of drug treatment.

The second method used to determine therapy for patients with chronic recurrent sustained ventricular tachycardia is the use of serial Holter monitors with drug testing. The surrogate end point in this case is the suppression of ventricular ectopy and total abolition of NSVT compared with control (drug-free) recordings. This method was not used routinely in the United States; initial small studies⁸¹ demonstrated a superiority of invasive electrophysiologic testing over serial Holter recordings. Nonetheless, enough controversy was generated to initiate a large study to compare the two methods of drug testing. The Electrophysiologic Study Versus Electrocardiographic Monitoring (ESVEM) trial^{82,83} enrolled patients with documented clinical ventricular tachycardia/ventricular fibrillation, inducible ventricular tachycardia, and frequent ventricular ectopy. These patients were randomized to electrophysiologic studies or serial Holter recordings to test up to seven antiarrhythmic drugs (i.e., imipramine, mexiletine, pirlenol, procainamide, quinidine, propafenone, and sotalol). Holter testing had a greater yield of identifying effective agents, and there was no statistical difference between this method and electrophysiologic testing in terms of ventricular tachycardia recurrence or sudden death. Although patients with poor LV systolic function could not receive it in the ESVEM trial, sotalol proved to be the most effective drug in the trial. The relatively impressive results in the ESVEM trial with racemic sotalol contrasted with the poor results of its D-isomer in the SWORD trial (albeit in a different population) speaks strongly for the importance of chronic treatment with β -blockers in patients with serious ventricular arrhythmias. Regardless of the methods of drug testing, recurrence rate of ventricular tachycardia in the ESVEM was high (20% to 50% per year depending on the drug chosen). These findings and the impressive side-effect profiles of antiarrhythmic agents have led investigators to study nondrug approaches to the treatment of recurrent ventricular tachycardia/ventricular fibrillation.⁸⁴

8 Some centers have had excellent results with the surgical excision of the ventricular tachycardia focus in appropriate candidates for this extensive procedure. With the aid of endocardial mapping techniques, procedures such as ventricular aneurysectomy, encircling ventriculotomy, and cryo- or laser ablation can abolish the arrhythmogenic substrate successfully. Less invasive techniques such as catheter-guided ablation with radiofrequency current also have been used. This approach is highly effective (~90%) in idiopathic ventricular tachycardia (RVOT or fascicular ventricular tachycardia) but less so in recurrent ventricular tachycardia associated with a cardiomyopathic processes or remote MI with LV aneurysm. In the latter patients, ablation usually is regarded as second-line therapy after other methods have failed. The introduction of and advances in the implantable automatic cardioverter-defibrillator (ICD), coupled with its demonstrated effectiveness, have obviated the need for serial drug testing (by invasive or noninvasive methods) and many risky surgical procedures⁸⁵ (Fig. 17-13). Early ICDs required a thoracotomy for placement and were programmed to tachycardia rate. Once the patient's rate rose to a certain level, a series of internal defibrillations was delivered. Although effective in terminating ventricular tachycardia/ventricular fibrillation, inappropriate shocks sometimes were

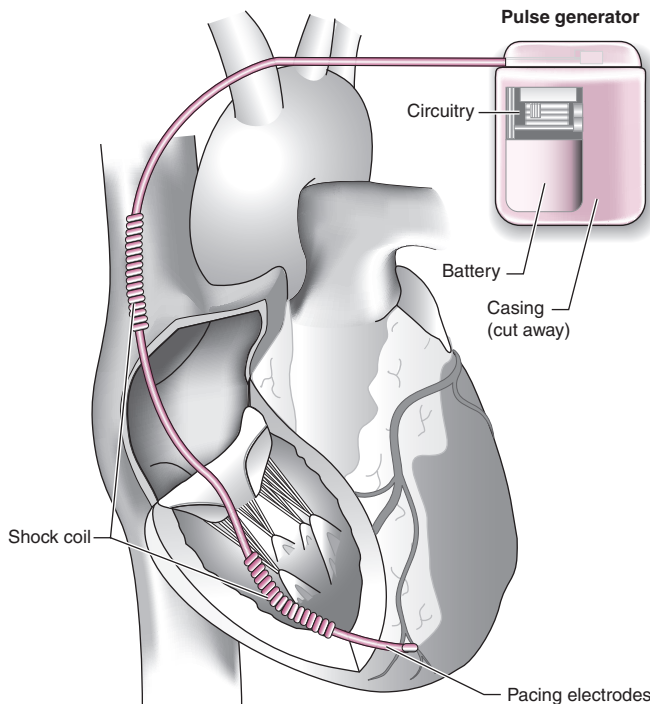

FIGURE 17-13. Drawing showing automatic implantable cardioverter-defibrillators with newer methods of device placement. It shows an endocardial lead system where the leads are placed transvenously without the need for a thoracotomy. The generator is now small enough to be placed in the pectoral region of the chest. (From DiMarco,⁸⁵ with permission.)

delivered for supraventricular tachycardias or NSVT. Further, a pulse generator was placed in the abdomen with a relatively short battery life in these early models. ICD technology has expanded rapidly⁸⁵ so that now the newer devices employ a “tiered-therapy approach”; i.e., new ICDs provide in a sequential fashion: programmed stimulation, overdrive pacing, and then low-energy (<5 J) synchronized shocks before unsynchronized internal defibrillation (10–30 J) is employed as a last step. In addition, backup bradycardia pacing and extended battery lives have made these devices much more attractive. All models store recordings during delivery of pacing shocks; this is extremely important in discerning appropriate from inappropriate shocks and in documenting recurrences of the patient’s tachycardia. Importantly, transvenous insertion techniques not requiring a thoracotomy are now being used routinely and the pulse generator is now small enough to implant in the pectoral region of the chest (see Fig. 17-13).

Most would agree that the ICD is a highly effective method in preventing sudden death due to recurrent ventricular tachycardia or ventricular fibrillation,⁸⁶ although several problems remain. First, the device and implantation are expensive. The actual device, implantation procedure, electrophysiologic studies, hospitalization, and physician fees are costly and, considering the expanding indications, place a great burden on the health care system. Second, many patients (as high as 50%) end up receiving antiarrhythmic drugs (usually amiodarone or sotalol⁸⁷) in addition to the ICD. Here, the end point of drug therapy is different from that without the ICD; i.e., the drugs do not necessarily need to prevent all sustained recurrences because the ICD is there as a backup. Antiarrhythmic drugs are prescribed in this instance to decrease the frequency of ventricular tachycardia/ventricular fibrillation episodes and NSVT, minimize patient discomfort, and save battery life. Each patient should be individualized, and antiarrhythmic

mic drugs should be administered in those with frequent ventricular tachycardia and shocks. If antiarrhythmic drugs are added to ICD therapy, one should note that many agents alter defibrillation thresholds, and therefore, the device should be reprogrammed to account for this.⁸⁸

Which is better, antiarrhythmic drugs or the ICD? The use of the ICD in patients with remote MI, LV dysfunction, and at least one episode of ventricular fibrillation or sustained ventricular tachycardia was compared with chronic antiarrhythmic drug (>90% empirical amiodarone) therapy in the Antiarrhythmic-drug versus Internal Defibrillator (AVID) trial.⁸⁹ The trial was stopped early because of a demonstrated superiority of the ICD; patients in the ICD group had a better overall survival (75% versus 64% at 3 years). In other words, in this important study, the ICD was superior to the most effective drug known, namely, amiodarone. Other large multicenter trials comparing the ICD with amiodarone in patients with a history of ventricular fibrillation and/or sustained ventricular tachycardia have shown similar results, with the ICD reducing overall mortality by 20% to 25%.^{90,91} Despite the high costs, these results provide strong support for the aggressive use of the ICD in patients at high risk for recurrent life-threatening ventricular arrhythmias. ICD implantation can be cost-effective, particularly in patients with poor LV function (depending on the indication, about \$30,000 per life-year saved).⁹² Although nearly all clinicians now consider the ICD as first-line treatment in patients with a history of recurrent sustained ventricular tachycardia/ventricular fibrillation (i.e., used as “secondary” prevention), there is at least one possible patient group that may do as well with drug therapy alone. In the AVID trial, patients with only mild LV dysfunction (EF > 35%) treated with amiodarone (especially with a β -blocker) did just as well as if they were treated with an ICD. It is possible that this specific subgroup of patients could be treated without an ICD.

The indications for implantation of an ICD have expanded considerably⁹² (Table 17-7). Initially, its efficacy was evaluated in patients who had already suffered a documented episode of ventricular tachycardia or ventricular fibrillation (secondary prevention), but now primary prevention trials have been published⁹³ or are being planned. These results will help clinicians in choosing the proper therapy for patients with life-threatening arrhythmias. For instance, the Sudden Cardiac Death in Heart Failure Trial (SCD-Heft) is a primary prevention trial that evaluated survival in patients with LV dysfunction

TABLE 17-7. Current Indications for ICD Implantation^a

1. Documented recurrent VT or VF
2. Patients successfully resuscitated from cardiac arrest (due to VT or VF) not due to an identifiable, reversible cause (e.g., AMI, severe electrolyte disturbances)
3. Syncope with sustained VT or VF induced at electrophysiologic study by programmed stimulation
4. NSVT, CAD (remote MI), LV dysfunction, and sustained VT or VF induced at electrophysiologic study by programmed stimulation
5. Heritable polymorphic VT (congenital long-QT syndromes or Brugada syndrome)
6. Severe LV dysfunction (EF < 30%) and remote MI

^aSummarized from national guidelines⁷¹ to include indications where there is clear evidence (class I) or conflicting evidence but the weight of it is in favor of implantation (class Ia) or evidence from large randomized trials may never be completed but there is clinical consensus (heritable polymorphic VT).

^bPrimary prevention; all others are secondary prevention.

VT = ventricular tachycardia; VF = ventricular fibrillation; AMI = acute myocardial infarction; MI = myocardial infarction; LV = left ventricular; NSVT = nonsustained ventricular tachycardia; CAD = coronary artery disease; EF = ejection fraction.

(ejection fraction $\leq 35\%$) at risk for sudden death treated with amiodarone or an ICD.⁹⁴ This important study, although completed, has not been published in full form at the time of this writing. Preliminary results show that ICD implantation resulted in a significantly lower

death rate compared with treatment with either placebo or amiodarone (there was no difference between placebo and amiodarone). Should all patients with severe heart failure receive an ICD? The economic implications of the answer to this question are enormous.

► TREATMENT: Nonsustained Ventricular Tachycardia (NSVT)

At this time, it is clear that patients with complex ventricular ectopy should not be treated with type I or III antiarrhythmic drugs and that those with recurrent sustained ventricular tachycardia definitely require some form of preventative treatment, generally an ICD with or without amiodarone, but the approach to NSVT remains an area of controversy. Obviously, patients with long symptomatic episodes require drug therapy, but most have asymptomatic NSVT. Asymptomatic NSVT can be documented frequently in patients with poor LV function of ischemic or nonischemic origin, and epidemiologic data indicate that patients with NSVT and coronary disease are at increased risk for sudden death.⁹⁵ However, owing in part to the results of the CAST and other similar trials with antiarrhythmic drugs, clinicians have sought clearer risk stratification before initiating drug therapy.

Traditionally, there are three strategies to approach the treatment of NSVT: (1) conservative (no antiarrhythmic drug treatment beyond β -blockers), (2) empirical amiodarone, and (3) aggressive, i.e., electrophysiologic studies with possible insertion of an ICD. A number of early studies^{96,97} have suggested that tests such as electrophysiologic studies could be used to determine long-term risk in patients with NSVT. For instance, Wilbur and colleagues⁹⁶ demonstrated that post-MI patients with NSVT and inducible sustained ven-

tricular tachycardia after programmed stimulation were at increased risk for subsequent ventricular tachycardia/ventricular fibrillation or sudden death compared with those in whom sustained ventricular tachycardia could not be induced. These data provide the basis for the Multicenter Unsustained Tachycardia Trial (MUST).⁹⁷ In the MUST, patients with asymptomatic clinical NSVT (more than 3 beats), inducible sustained ventricular tachycardia, and LV dysfunction were randomized to the conservative approach (no antiarrhythmic drug therapy beyond β -blockers) or electrophysiologically guided therapy (antiarrhythmic drugs and/or ICD). The results showed that the conservative approach had a significantly higher event rate (cardiac arrest or death). However, when the results of the electrophysiologically guided group were stratified further, only those treated with an ICD had a significantly lower event rate and greater survival. One problem with the MUST, however, is that because of the time frame that the trial was initiated (1989), nearly 50% of patients received type I antiarrhythmic drugs or drugs that are now known not to improve survival in patients with coronary disease and ventricular arrhythmias; only 10% received the most effective agent in this setting, amiodarone.

In summary, most patients with coronary disease, LV dysfunction and NSVT should undergo electrophysiologic studies. If

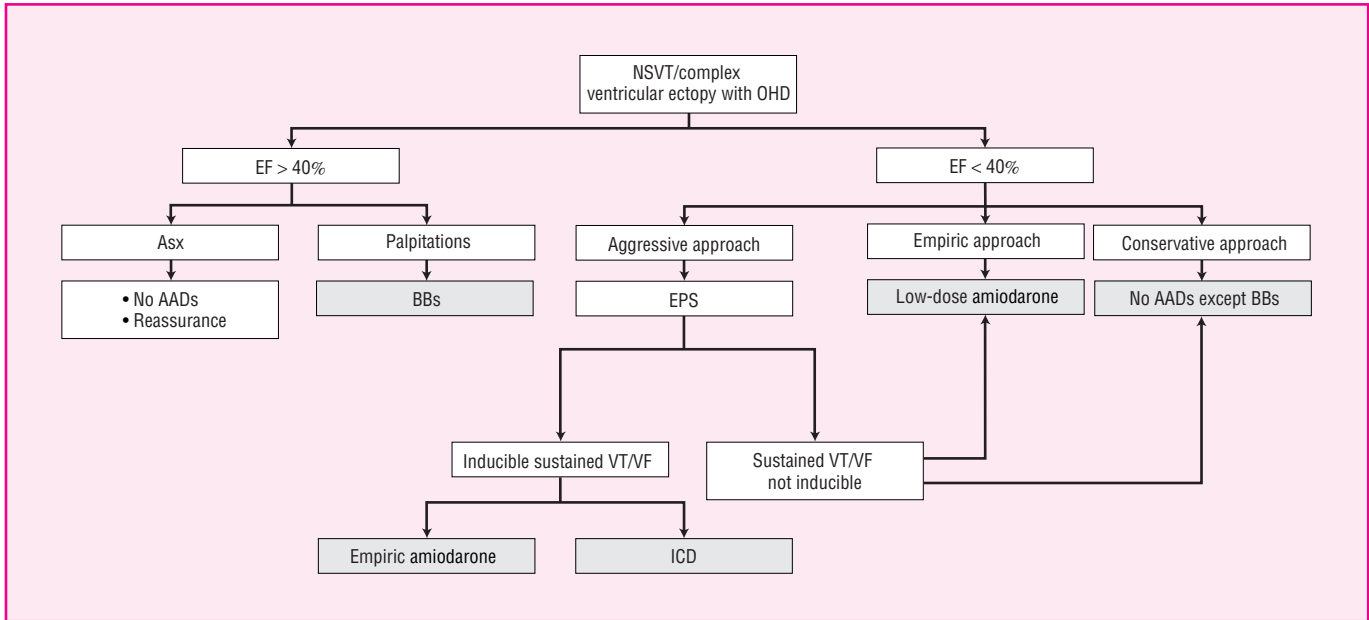

FIGURE 17-14. An algorithm for management of patients with ventricular ectopy or nonsustained ventricular tachycardia (NSVT) in patients with organic heart disease (OHD). In patients with significant LV dysfunction (EF < 40%), the type of OHD will influence the therapeutic pathway. Patients with ischemic heart disease will be treated more aggressively and those with idiopathic cardiomyopathy will be treated more conservatively (i.e., less commonly ICD and more commonly amiodarone). EF = ejection fraction; EPS = electrophysiologic studies; VT/VF = ventricular tachycardia/ventricular fibrillation; ICD = implantable cardioverter-defibrillator; F/U = follow-up; BB = β -blockers; AADs = antiarrhythmic drugs.

these patients do not have inducible sustained ventricular tachycardia/ventricular fibrillation, no antiarrhythmic drug therapy targeted specifically to the arrhythmia should be given on a chronic basis. On the other hand, if sustained ventricular tachycardia/ventricular fibrillation is inducible, chronic preventative therapy is warranted (Fig. 17–14). Because of the results of trials such as MUST and others,⁹⁸ many such patients will receive an ICD. For patients with NSVT but with idiopathic cardiomyopathy of nonischemic origin, the use of an ICD cannot be recommended routinely. In a recent

trial,⁹⁹ there was no difference in mortality or quality of life between treatment with empirical amiodarone and ICD implantation in these patients. Treatment with amiodarone was associated with lower cost, although 50% of patients randomized to amiodarone had to have it discontinued owing to side effects. There was no placebo in this trial, and mortality was surprisingly low, so it is conceivable that no therapy (drug or device) could have been as successful. Nonetheless, these results show the importance of the form of underlying heart disease in patients with ventricular tachycardia or NSVT.

VENTRICULAR PROARRHYTHMIA

All antiarrhythmic agents have the potential to aggravate existing arrhythmias or to cause new arrhythmias. It is believed that antiarrhythmic drugs may cause proarrhythmia in 5% to 20% of patients.¹⁰ Although drug-induced arrhythmias have been recognized for several years, it has only been recently that this adverse effect has gained widespread attention. Many definitions for proarrhythmia have been proposed; however, in simplest terms, it indicates the development of a significant new arrhythmia (such as ventricular tachycardia, ventricular fibrillation, or torsade de pointes) or worsening of an existing arrhythmia (episodes are longer, faster, or more frequent). As with all arrhythmias, the consequences of proarrhythmia are varied. Some patients who develop proarrhythmia may be totally asymptomatic, others may notice a worsening of symptoms, and some may die suddenly from this side effect. The development of proarrhythmia results from the same mechanisms that cause arrhythmias in general (e.g., quinidine-induced torsade de pointes due to early afterdepolarizations) or from an alteration in the underlying substrate owing to the antiarrhythmic agent (e.g., development of an accelerated tachycardia due to flecainide, which decreases conduction velocity without significantly altering the refractory period)¹⁰ (see Fig. 17–4). The diagnosis of proarrhythmia is sometimes difficult to make because of the variable nature of the underlying arrhythmias. However, in all cases, the agent should be discontinued if proarrhythmia is detected or suspected.

INCESSANT MONOMORPHIC VENTRICULAR TACHYCARDIA

◀ The prototypical form of proarrhythmia due to the type Ic drugs is a rapid, sustained, monomorphic ventricular tachycardia with a characteristic sinusoidal QRS pattern that is often resistant to resuscitation with cardioversion or overdrive pacing. It is sometimes referred to as *sinusoidal* or *incessant ventricular tachycardia* and is the result of excessive sodium channel blockade and slowed conduction. Sinusoidal ventricular tachycardia attributed to type Ic drugs was thought to occur within the first several days of drug initiation; however, the results of the CAST indicate that the risk may exist as long as the agent is continued. Patient factors that definitely predispose to this form of proarrhythmia are the presence of (1) underlying ventricular arrhythmias, (2) ischemic heart disease, and (3) poor LV function. Provocation of proarrhythmia caused by type Ic drugs is sometimes reported during exercise; this is more than likely due to augmented slowed conduction at rapid heart rates (i.e., rate-dependent sodium blockade). The incidence of proarrhythmia is greatest in patients with all three risk factors (approximately 10% to 20%) and extremely uncommon in those without risks, such as patients with good LV function and supraventricular tachycardias. In one study with patients with risk factors, the incidence of death caused by proarrhythmia from encainide and flecainide was approximately the same as the chance of

long-term effectiveness.¹⁰⁰ Other factors that have a less defined association with proarrhythmia are elevated antiarrhythmic serum concentrations and rapid dosage escalation. It has also been proposed that the presence of underlying ventricular conduction delays may pose a risk. As mentioned earlier, this arrhythmia is resistant to resuscitation; however, some practitioners have had success with intravenous lidocaine (competes for the sodium channel receptor) or the administration of sodium bicarbonate (reverses the excessive sodium channel blockade).

TORSADE DE POINTES

As defined previously, torsade de pointes (TdP) is a rapid form of polymorphic ventricular tachycardia (Fig. 17–15) that is associated with evidence of delayed ventricular repolarization (long QT interval or prominent U waves) on surface ECGs. It is important to note that most forms of polymorphic ventricular tachycardia occurring in the setting of a normal QT interval are similar to monomorphic ventricular tachycardia in terms of etiology and treatment strategies (thus a long QT interval is crucial to the diagnosis of TdP). TdP may occur in association with hereditary syndromes or may be acquired (e.g., caused by drugs or diseases). The underlying etiology in both cases is delayed ventricular repolarization due to blockade of potassium conductance. It is possible, however, that some individuals have a partially expressed form of these congenital syndromes but may never suffer TdP unless some other external factor (e.g., drugs or diseases) further delay ventricular repolarization. Acquired forms of TdP are associated with electrolyte disturbances (e.g., hypokalemia or hypomagnesemia), subarachnoid hemorrhage, myocarditis, liquid protein diets, arsenic poisoning, hypothyroidism, or most commonly, drug therapy (notably phenothiazines, antihistamines, antidepressants, and antiarrhythmics) (Table 17–8). The type Ia (especially quinidine) and type III I_{Kr} blockers are most notorious for precipitating TdP; type Ib and Ic drugs rarely, if ever, cause it. Quinidine-induced TdP occurs in 4% to 8% of patients treated with this agent. Associated features of quinidine-induced TdP have been identified and can be summarized as follows³¹: (1) low to “therapeutic” quinidine serum concentrations without other evidence of quinidine-related toxicity such as prolonged QRS duration, (2) concurrent organic heart disease, commonly ischemic, (3) evidence of mild delayed repolarization (prolonged QT interval) prior to quinidine therapy, (4) documentation usually within 1 week of initiating therapy, (5) high incidence of cross-sensitivity (recurrence of TdP) with other type Ia antiarrhythmic agents but not type Ib or Ic drugs or amiodarone, (6) frequent coexisting electrolyte disturbances such as hypokalemia or hypomagnesemia, (7) a characteristic long-short initiating sequence (so-called pause dependence) of the episode of TdP (see Fig. 17–15), and (8) female gender. However, none of these associations is an absolute prerequisite to the occurrence of quinidine syncope and TdP. For instance, although usually documented early in the course of therapy,

FIGURE 17-15. A. Torsade de pointes in a patient receiving procainamide. Note several characteristic features: (a) prolonged QT interval prior to torsade de pointes; (b) long-short initiating sequence—extra ventricular beat with a pause followed by a supraventricular beat followed by another premature ventricular beat on the preceding T wave, which initiates torsade de pointes; (c) polymorphic, undulating QRS morphology rate of 250 beats per minute. B. Torsade de pointes caused by quinidine. The reader should note a couplet and two triplets, which follow each extra systolic pause. The pause gets progressively longer until it is long enough to result in an episode of sustained torsade de pointes. Also, as the pause lengthens, discernible U waves (labeled ↑) (EADs?) begin to appear. The amplitude of the U wave is somewhat greater with the longest pause. (From Bauman JL: *Drug safety: Cardiac arrhythmias. Antihistamine update symposium. Hospital Medicine* 1995; 31:24, with permission.)

patients may suffer TdP during chronic quinidine treatment.¹⁰¹ Most of these associations also occur with TdP caused by drugs besides quinidine. One important exception is that other drug-related causes of TdP usually occur in association with high concentrations and doses, e.g., sotalolol, dofetilide, and *N*-acetylprocainamide. Quinidine's ability to block I_{Kr} is manifest clinically at low concentrations; at higher concentrations, its sodium-blocking properties predominate. Other agents that block I_{Kr} usually do so in a concentration-dependent fashion. Of the type Ia or III antiarrhythmic drugs, amiodarone is the least frequent cause of TdP; the incidence is estimated at 1% or less.

Drug-induced TdP has become an extremely visible hazard plaguing new drugs, sometimes resulting in public health disasters. For instance, cisapride, astemizole, and terfenadine are potent potassium channel blockers that were withdrawn from the market because of TdP. All these agents are metabolized rapidly to active moieties

by cytochrome P450 (CYP) 3A4. However, in the presence of drugs that block the CYP3A4 isozyme (e.g., ketoconazole, erythromycin, and diltiazem), accumulation of the parent compounds (which are potent I_{Kr} blockers) results in TdP, and death may result.¹⁰² Because of these experiences, all new drug entities under investigation should be screened for their ability to block I_{Kr} , delay repolarization and provoke TdP prior to approval.

Much has been learned about the underlying etiology of TdP. Basic defects (e.g., genetic, drugs, or diseases) that delay repolarization by influencing ion movement (usually by blocking potassium efflux) provoke early after-depolarizations (EADs) preferentially in cells deep in the heart muscle (termed M cells). EADs in these M cells, in turn, trigger reentry and TdP. Drugs that cause TdP usually delay ventricular repolarization in an inhomogeneous way (termed *dispersion of refractoriness*), and this facilitates the formation of multiple reentrant loops in the ventricle.¹⁰³

▶ TREATMENT: Torsade de Pointes

Acute treatment of TdP is different from treatment for the more common acute monomorphic ventricular tachycardia (or polymorphic VT with a normal QT interval). For an acute episode of TdP, most patients will require and respond to DCC. However, TdP tends to the paroxysmal in nature and often will recur rapidly after countershock. Therefore, after the initial restoration of a stable rhythm, therapy designed to prevent recurrences of TdP should be instituted. Drugs that further prolong repolarization such as intravenous procainamide are absolutely contraindicated. Lidocaine usually is inef-

fective. Intravenous magnesium sulfate, by suppressing early after-depolarizations, is now considered the drug of choice in preventing recurrences of TdP.¹⁰⁴ If ineffective, treatment strategies designed to increase heart rate, shorten ventricular repolarization, and prevent the pause dependency should be initiated—either temporary transvenous pacing (105–120 beats per minute) or pharmacologic pacing (isoproterenol or epinephrine infusion). All agents that prolong the QT interval should be discontinued, and exacerbating factors (such as hypokalemia or hypomagnesemia) should be corrected.

VENTRICULAR FIBRILLATION

BACKGROUND AND PREVENTION WITH ACUTE MI

Ventricular fibrillation is electrical anarchy of the ventricle resulting in no cardiac output and cardiovascular collapse. Death will ensue rapidly if effective treatment measures are not taken. Patients who die abruptly (within 1 hour of initial symptoms) and unexpectedly (i.e., sudden death) usually have ventricular fibrillation recorded at the time of death.⁶¹ Sudden cardiac death accounts for about 400,000 deaths per year or 1000 deaths per day in the United States. Sudden cardiac death occurs most commonly in patients with ischemic heart disease and primary myocardial disease associated with LV dysfunction, less commonly in those with WPW syndrome and mitral valve prolapse, and occasionally, in those without associated heart disease (e.g., Brugada syndrome). Patients who have sudden cardiac death (not associated with acute MI) but survive because of appropriate CPR often have inducible sustained ventricular tachycardia and/or ventricular fibrillation during electrophysiologic studies.¹⁰⁵ These individuals are at high risk for the recurrence of ventricular tachycardia and/or ventricular fibrillation.

In contrast, patients who have ventricular fibrillation associated with acute MI (i.e., during the first 24 hours after symptom appearance) usually have little risk of recurrence. Of all patients who die from an acute MI, approximately 50% die suddenly prior to hospitalization. Ventricular fibrillation associated with acute MI can be subdivided into two types: primary ventricular fibrillation and complicated or secondary ventricular fibrillation. Primary ventricular fibrillation occurs in an uncomplicated MI not associated with heart failure; secondary ventricular fibrillation occurs in an MI complicated by heart failure. The time course, incidence, mechanisms, treatment, and com-

plications of these two forms of ventricular fibrillation are different. For example, about 2% to 6% patients with acute MI suffer primary ventricular fibrillation within 24 hours of chest pain, but the risk of ventricular fibrillation declines rapidly over time and is nearly zero after the initial 24-hour period. Complicated ventricular fibrillation does not follow such a predictable time course and may occur in the late infarction period. The premise of prophylactic antiarrhythmic drugs administered to all patients with uncomplicated MI is based on (1) the inability to predict which patients are at risk for primary ventricular fibrillation and (2) the predictable time course of primary ventricular fibrillation (in contrast with complicated ventricular fibrillation). Of the prophylactic therapies used, lidocaine has been the debated and studied most widely. Lie and coworkers¹⁰⁶ performed the classic study showing the effectiveness of lidocaine in preventing primary ventricular fibrillation. Although lidocaine reduced the incidence of ventricular fibrillation significantly compared with placebo, there was not a decrease in total mortality between the groups. This fact and the effectiveness of rapidly instituted DCC in modern coronary care units with sophisticated monitoring techniques have caused most practitioners to reject the notion of prophylactic lidocaine administration for all patients with uncomplicated MI. In support of this, two meta-analyses^{107,108} concluded against the routine use of prophylactic lidocaine because of a trend toward increased mortality in lidocaine-treated patients¹⁰⁷ and the declining incidence of primary ventricular fibrillation documented in recent years (in the acute coronary intervention era with rapid treatment with β -blockade, thrombolytics, and acute coronary intervention).¹⁰⁸

The use of intravenous magnesium sulfate also has been entertained for the prevention of ventricular fibrillation during the acute infarct period. Small trials implying effectiveness subsequently were incorporated into a meta-analysis.¹⁰⁹ This meta-analysis found a

decrease in the incidence of ventricular tachycardia/ventricular fibrillation and a reduction in total mortality with magnesium therapy. A subsequent large multicenter trial¹¹⁰ found similar results, although most of the decrease in mortality was (surprisingly) attributed to heart failure deaths rather than deaths due to ventricular arrhythmias. These results would lead one to conclude that magnesium sulfate should be administered routinely to patients with suspected MI because of its

ease of administration and safety. However, data from another large trial (ISIS-4) apparently have verified no such effectiveness of magnesium therapy in this setting.¹¹¹ Hence prophylactic magnesium also cannot be recommended. Indeed, no therapies (i.e., lidocaine, magnesium, or other antiarrhythmic drugs) have shown a conclusive benefit in preventing ventricular fibrillation in the acute infarct period, and this form of therapy cannot be recommended at this time.

► TREATMENT: Ventricular Fibrillation

A patient with ventricular fibrillation (with or without associated myocardial ischemia) should be managed according to the American Heart Association’s recommendations for advanced cardiac life support (ACLS).⁵² Summarizing, DCC should be instituted immediately and repeated twice (if unsuccessful) prior to drug therapy. If DCC does not restore a stable rhythm, vasopressin or epinephrine should be administered prior to the next DCC. It has been debated whether the standard dose of epinephrine (1 mg) is sufficient (see Chap. 11). A large multicenter trial¹¹² found “high dose” epinephrine (0.2 mg/kg) to not affect success or survival (compared with 0.02 mg/kg) of patients with cardiac arrest (including ventricular fibrillation). A recent comparative trial¹¹³ found vasopressin (40 units twice) and epinephrine to be of equal efficacy in patients with ventricular fibrillation (in patients with asystole, however, vasopressin was superior). Nevertheless, if vasopressin or epinephrine (coupled with DCC) is unsuccessful, an antiarrhythmic drug should be selected and administered, and then DCC should be repeated as necessary. It appears clear from the most recent ACLS guidelines that intravenous amiodarone is now the antiarrhythmic drug of first choice in most situations of patients with ventricular fibrillation. Unlike its oral counterpart, intravenous amiodarone has a quick onset of action and may be effective in 40% to 60% of patients with ventricular tachycardia or ventricular fibrillation refractory to lidocaine. The promotion of intravenous amiodarone to the first antiarrhythmic drug used during ventricular fibrillation (and the corresponding demotion of lidocaine) is the result of (1) a lack of data demonstrating the effectiveness of other agents, (2) the Amiodarone in out-of-hospital Resuscitation of REfractory Sustained ventricular Tachycardia (ARREST) study,¹¹⁴ and (3) the Amiodarone versus Lidocaine In prehospital Ventricular Fibrillation Evaluation (ALIVE) study.¹¹⁵ In the ARREST,¹¹⁴ significantly more patients receiving 300 mg amiodarone intravenously survived to hospital admission than did a corresponding placebo group. Noteworthy was that the survival to hospital discharge was no different (although the study was not powered to determine this end point). In the ALIVE,¹¹⁵ amiodarone was more effective than lidocaine in increasing survival to hospital admission in patients with out-of-hospital ventricular fibrillation. Again, there were no differences in survival to hospital discharge between the groups. Nonetheless, these results stimulated a change (away from lidocaine and toward amiodarone) in the treatment of acute ventricular fibrillation. Indeed, amiodarone may be the only drug used during cardiac arrest caused by ventricu-

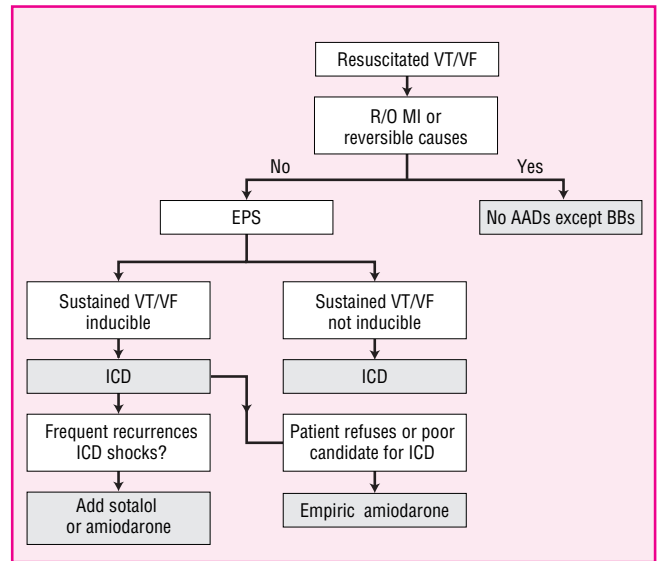

FIGURE 17–16. Example of an approach to the management of survivors of cardiac arrest (resuscitated VT/VF). Reversible causes of cardiac arrest (e.g., electrolyte abnormalities, acute phase of MI) should be treated with specific therapy. AADs = antiarrhythmic drugs; BBS = β -blockers; EPS = invasive electrophysiologic studies; ICD = implantable cardioverter - defibrillator; VT/VF = ventricular tachycardia/ventricular fibrillation; MI = myocardial infarction.

lar fibrillation because the new guidelines also suggest that only *one* antiarrhythmic agent be given to patients with ventricular fibrillation. This is in contrast to the tradition of adding drugs if the first fails (e.g., lidocaine, then bretylium, then procainamide, etc.).

Once the patient is resuscitated successfully, antiarrhythmics should be continued until the patient’s rhythm and overall status is stable. If the episode of ventricular fibrillation was associated with acute ischemia, long-term antiarrhythmic drugs probably are unnecessary, but the patient should be monitored closely for recurrence of ventricular tachycardia and/or ventricular fibrillation. If, on the other hand, ventricular fibrillation was not associated with acute MI (or a known precipitating factor), the patient should undergo invasive electrophysiologic studies and (depending on the results) probably ICD implantation (Fig. 17–16).

BRADYARRHYTHMIAS

SINUS NODE DYSFUNCTION

The preceding sections reviewed the pathophysiology and treatment of tachyarrhythmias, and this section serves to briefly consider the bradyarrhythmias. For the most part, the symptoms of bradyarrhyth-

mias result from a decline in cardiac output. Because cardiac output decreases as heart rate decreases (to a point), patients experience symptoms in association with hypotension, such as dizziness, syncope, fatigue, and confusion. If LV dysfunction exists, patients may have an exacerbation of congestive heart failure symptoms. Except in the case of recurrent syncope, these symptoms are often subtle and nonspecific.

SINUS BRADYCARDIA

Sinus bradyarrhythmias (heart rate <60 beats per minute) is a common finding, especially in young, athletically active individuals, and usually is neither symptomatic nor requires therapeutic intervention. On the other hand, some patients, particularly the elderly, have sinus node dysfunction. This may be the result of underlying organic heart disease and the normal aging process, which, over time, attenuate SA nodal function. *Sick sinus syndrome* refers to this process resulting in symptomatic sinus bradycardia and/or periods of sinus arrest.^{116,117} Sinus node dysfunction usually is reflective of diffuse conduction disease, and accompanying AV block is not uncommon. Furthermore, symptomatic bradyarrhythmias may be accompanied by alternating periods of paroxysmal tachycardias such as atrial fibrillation. In this instance, atrial fibrillation sometimes presents with a rather slow ventricular response (in the absence of AV nodal–blocking drugs) because of diffuse conduction disease. The occurrence of alternating bradyarrhythmias and tachyarrhythmias is referred to as the *tachy-brady syndrome*. The occurrence of paroxysmal atrial fibrillation in a patient with sinus node dysfunction may be due to underlying heart disease with atrial dysfunction or to atrial escape in response to reduced sinus node automaticity. In fact, because the rate of impulse generation by the sinus node generally is depressed or may fail altogether, other automatic pacemakers within the conduction system may “rescue” the sinus node. These rescue rhythms often present as paroxysmal atrial rhythms (e.g., atrial fibrillation) or as a junctional escape rhythm.

The treatment of sinus node dysfunction involves the elimination of symptomatic bradycardia and the possibility of managing alternating tachycardias such as atrial fibrillation. In general, the long-term therapy of choice is a permanent dual-chamber or ventricular pacemaker. Pacemaker therapy,⁹² however, should be reserved for patients with significant symptoms. In other words, the aim of pacing is not to correct ECG findings but to improve the patient’s symptoms and quality of life.

Drugs that are employed commonly to treat supraventricular tachycardias should be used with caution, if at all, in the absence of a functioning pacemaker.¹¹⁶ Type I agents such quinidine can suppress the escape or rescue rhythms that appear in severe sinus bradycardia or sinus arrest. In this way, they may transform an asymptomatic patient with bradycardia into a symptomatic one. It is also important to remember that the addition of type I antiarrhythmic agents can affect pacemaker threshold and result in loss of capture if the pacemaker is not interrogated and adjusted appropriately.⁸⁸ Other drugs that depress SA or AV nodal function such as β -blockers or calcium channel antagonists also may exacerbate bradycardia significantly. Even agents with indirect sympatholytic actions such as α -methyl dopa or clonidine may worsen sinus node dysfunction. Digitalis use in these patients is controversial, but in most cases, it can be used safely.

OTHER CAUSES

Another reason for paroxysmal bradycardia and sinus arrest that is not due directly to sinus node dysfunction is carotid sinus hypersensitivity.^{118,119} Again, this syndrome occurs commonly in the aged with underlying heart disease. Symptoms occur when the carotid sinus is stimulated, resulting in an accentuated baroreceptor reflex. Thus the patient may experience paroxysmal episodes of dizziness or syncope because of sinus arrest caused by either 1) increased vagal tone and sympathetic withdrawal (cardioinhibitory type), 2) drop in systemic blood pressure owing to sympathetic withdrawal (vasodepressor type), or 3) both (mixed cardioinhibitory and vasodepressor

types). The diagnosis can be confirmed by performing carotid sinus massage with ECG and blood pressure monitoring in controlled conditions. Symptomatic carotid sinus hypersensitivity also should be treated with permanent pacemaker therapy.¹¹⁸ However, some patients, particularly those with a significant vasodepressor component, still experience syncope or dizziness. In these cases, α -adrenergic stimulants such as midodrine, sometimes in combination (and caution) with β -blockers to achieve maximal α -sympathetic stimulation, can be tried in addition to the pacemaker.¹¹⁹

Vasovagal syndrome, by causing bradycardia, sinus arrest, and/or hypotension, is the cause of syncope in many patients who present with recurrent fainting of unknown origin.^{120,121} By history, many individuals can recount rare instances of fainting spells at times of duress or fear. These are most often due to vasovagal syncope. However, some of these patients have extremely frequent, unexpected syncopal episodes that interfere with their quality of life and cause physical danger (sometimes referred to as *neurocardiogenic syncope syndrome* or *malignant vasovagal syndrome*). Vasovagal syncope is presumed to be a neurally mediated paradoxical reaction involving stimulation of cardiac mechanoreceptors (i.e., Bezold-Jarisch reflex). Forceful contraction of the ventricle (e.g., as with adrenergic stimulation), coupled with low ventricular volumes (e.g., with upright posture or dehydration), provides a powerful stimulus for cardiac mechanoreceptors. Syncope results from the spontaneous development of transient hypotension (sympathetic withdrawal) and bradycardia (vago-tonia). However, the true mechanism of vasovagal syncope remains to be determined definitively. For instance, patients with denervated hearts (e.g., heart transplant recipients) still can experience this form of syncope. This observation has led some to question the ultimate role of the Bezold-Jarisch reflex in these patients.¹²² Regardless, patients believed to have frequent episodes of vasovagal syncope have been evaluated and diagnosed using the upright body-tilt test, a potent stimulus for the development of vasovagal symptoms. Although used commonly, the sensitivity and reproducibility of this test have been questioned.

Vasovagal syncope usually can be treated successfully with oral β -blockers. Although these agents may seem inappropriate to treat a syndrome resulting from vasodilation and bradycardia, the therapeutic approach is designed to block an inappropriate vasovagal reaction. β -Blockers act by inhibiting the sympathetic surge that causes forceful ventricular contraction and precedes the onset of hypotension and bradycardia. Drug testing with intravenous esmolol or metoprolol during repeat head-up tilt tests has been used to predict the long-term response of oral β -blockers.¹²³ Other drugs that have been used successfully (with or without β -blockers) include anticholinergic agents (e.g., scopolamine patches and dipyrpyramide), α -adrenergic agonists (e.g., midodrine), adenosine analogs (e.g., theophylline and dipyridamole), and selective serotonin receptor antagonists (e.g., sertraline and fluoxetine).¹²⁴ Permanent pacing has been used for patients with malignant vasovagal syncope, but its routine use is controversial. More information is required, particularly comparative trials with effective agents, in order to make definitive conclusions regarding the place of these alternatives to β -blockers in this disorder. Chronic pacing has been used with some success but should be reserved for drug-refractory patients.^{92,124}

ATRIOVENTRICULAR BLOCK

Conduction delay or block may occur in any area of the AV conduction system: the AV node, the His bundle, or the bundle branches. AV block usually is categorized into three different types based on surface ECG

TABLE 17–9. Forms of Atrioventricular Block

| Type | Criteria |
|---------------------|--|
| First-degree block | Prolonged PR interval (>0.2 s), 1:1 AV conduction |
| Second-degree block | |
| Mobitz I | Progressive PR prolongation until QRS is dropped, <1:1 AV conduction |
| Mobitz II | Random nonconducted beats (absence of QRS), <1:1 AV conduction |
| Third-degree block | AV dissociation, absence of AV conduction |

findings (see Table 17–9). First-degree AV block is 1:1 AV conduction with a prolonged PR interval. Second-degree AV block is divided into two forms: Mobitz I AV block (Wenkebach periodicity) is less than 1:1 AV conduction with progressively lengthening PR intervals until a ventricular complex is dropped; Mobitz II AV block is intermittently dropped ventricular beats in a random fashion without progressive PR-interval lengthening. Third-degree AV block is complete heart block where AV conduction is totally absent (AV dissociation). By using intracardiac His bundle ECGs, the actual site of conduction delay/block can be correlated to the preceding diagnoses. First-degree AV block usually represents prolonged conduction in the AV node. Mobitz I, second-degree AV block is also usually due to prolonged conduction in the AV node. Indeed, Wenkebach periodicity is a normal AV nodal response to rapid supraventricular stimulation or high vagal tone. In contrast, Mobitz II AV block is usually due to conduction disease below the AV node (i.e., His bundle). Third-degree AV block may be due to disease at any level of the AV conduction system: complete AV nodal block, His bundle block, or trifascicular block. The ventricle will beat independently of the atria (AV dissociation), and the rate of ventricular activation and QRS-complex configuration are determined by the site of AV block. The usual degree of automaticity of ventricular pacemakers declines progressively as impulses move down the conduction system. Therefore, the ventricular escape rate in cases of trifascicular block will be significantly less than in complete AV nodal block.

AV block may be found in patients without underlying heart disease, such as trained athletes or during sleep when vagal tone is high. Also, AV block may be transient where the underlying etiology is reversible, such as in myocarditis, myocardial ischemia, after cardiovascular surgery, or during drug therapy. β -Blockers, digitalis, or calcium antagonists may cause AV block primarily in the AV nodal area. Type I antiarrhythmic agents may exacerbate conduction delays below the level of the AV node (sodium-dependent tissue). In other cases, AV block may be irreversible, such as that owing to acute MI, rare degenerative diseases, primary myocardial disease, or congenital forms.

The cornerstone to the acute treatment of acute symptomatic bradycardia or AV block is temporary pacing, either through a transvenous wire or, in the event of an emergency, by transcutaneous leads.^{53,92} Intravenous atropine (0.5–1 mg) should be given as the leads for pacing are being placed. Drugs such as atropine will facilitate the effectiveness of transcutaneous pacing. In the past, isoproterenol infusion frequently was chosen for this purpose but now is not recommended because of its vasodilating properties and its ability to increase myocardial oxygen consumption (particularly during acute MI). Sympathomimetic infusions such as epinephrine and dopamine can be used in the event of atropine failure and are particularly effective in sinus bradycardia/arrest and AV nodal block. These agents usually will not help when the site of AV block is below the AV node (e.g., Mobitz II or trifascicular AV block).

Patients with chronic symptomatic AV block should be treated with the insertion of a permanent pacemaker. Patients without symptoms sometimes can be followed closely without the need for a pacemaker. The reader is referred to national consensus guidelines for pacemaker implantation, last updated in 2002.⁹² Because symptoms often correlate with the ventricular rate and the ventricular rate corresponds to the site of block, pacemaker therapy usually is necessary in distal AV blocks such as that occurring in the His bundle or the bundle branches. Patients with acute MI and evidence of new AV block or conduction disturbances often will require the insertion of a temporary transvenous pacemaker. AV block occurs more commonly as a complication of inferior wall infarcts because of high degree of vagal innervation at this site, and the coronary blood flow to the nodal areas usually supplies the inferior wall. However, the AV block may be only transient, obviating the need for permanent pacing. In patients with chronic AV conduction disturbances, intracardiac recordings (His bundle ECGs) sometimes are used to document the actual site of block and define the potential need for and specific type of pacemaker therapy.

EVALUATION OF THERAPEUTIC AND ECONOMIC OUTCOMES

Generally, patients who suffer from tachyarrhythmias can be monitored for one or several possible therapeutic outcomes. Obviously, the presence or recurrence of any arrhythmia can be documented by electrocardiographic means, e.g., surface ECG, Holter monitor, or event monitor. Further, patients may experience a decrease in blood pressure that may result in symptoms that range from light-headedness to abrupt syncope depending on the rate of the arrhythmia and the status of the underlying heart disease. For some patients, the potential alteration in hemodynamics may result in death if the arrhythmia is not detected and treated immediately. Besides these clinical outcomes, many patients with tachyarrhythmias experience alterations in quality of life caused by troublesome recurrent symptoms of the arrhythmia or to side effects of therapy. And finally, there are the economic considerations of medical or surgical intervention, continued medical care, and chronic drug or nondrug treatment.^{125,126} Most of the studies are limited to the use of nondrug therapies such as the ICD or radiofrequency ablation.^{45,92} Since that technology is evolving rapidly, what is not very cost-effective now indeed may be in the next several years. For example, original cost-effectiveness analysis of the ICD showed it to be highly sensitive to the life of the generator, yet newer-generation devices have made significant advances not only in the size but also with regard to battery life. More recent data on the effect of the ICD on mortality, coupled with the declining costs of an ICD, imply that the device is indeed cost-effective in certain subsets of patients, not unlike well-proven drug therapies used for other disorders.⁹² Other nondrug treatments such as radiofrequency for PSVT not only improve quality of life but also save money on medical expenditures compared with chronic drug therapy.⁴⁵

There are some therapeutic outcomes that are unique to certain arrhythmias. For instance, patients with atrial fibrillation or flutter need to be monitored for thromboembolism and for complications of anticoagulation therapy (bleeding, drug interactions) prescribed to prevent it. However, the most important monitoring parameters for most patients fall into the following categories: (1) mortality (total and arrhythmic), (2) arrhythmia recurrence (duration, frequency, symptoms), (3) hemodynamic consequences (rate, blood pressure, symptoms), and (4) treatment complications (need for alternative or additional drugs, devices, or surgery) (see Table 17–10). When evaluating

TABLE 17–10. Outcomes: Arrhythmias

| Economics |
| Outcomes specific to tachycardia (e.g., ventricular rate, systemic embolism in atrial fibrillation) |

the arrhythmia literature, care should be taken to consider real outcomes. For example, total mortality is more meaningful than only sudden death rates; it is possible that an intervention prevents arrhythmic death, but patients die from other causes, leaving all-cause mortality unaltered. Likewise, surrogate markers of drug efficacy (e.g., noninducible tachycardia, suppression of minor arrhythmias, etc.) should be judged with a degree of skepticism. One should ask oneself, did the treatment make patients live longer (reduce mortality)? Did it make them feel better (improve humanistic outcomes or quality of life)? And/or was it economically worth it (cost-effective)?

DIASTOLIC HEART FAILURE AND THE CARDIOMYOPATHIES

Jean M. Nappi and Michael R. Zile

Learning Objectives and other resources can be found at www.pharmacotherapyonline.com.

KEY CONCEPTS

- 1 Diastolic heart failure is a frequent cause of congestive heart failure (prevalence 35% to 50%) and has a significant effect on mortality (25% to 35% 5-year mortality rate) and morbidity (50% 1-year readmission rate).
- 2 Hypertension is a common cause of diastolic heart failure.
- 3 The diagnosis of diastolic heart failure can be made when a patient has (1) both symptoms and signs on physical examination of congestive heart failure and (2) preserved left ventricular (LV) function.
- 4 Treatment should be targeted at symptom reduction, causal clinical disease, and underlying basic mechanisms. Patients with diastolic heart failure may be treated differently than those with systolic dysfunction.
- 5 Symptom-targeted therapy includes decreasing pulmonary venous pressure, maintaining atrial contraction and atrioventricular (AV) synchrony, and reducing heart rate. Exercise tolerance is increased by reducing exercise-induced increases in blood pressure and heart rate.
- 6 Disease-targeted therapy includes preventing or treating myocardial ischemia and preventing or regressing LV hypertrophy.
- 7 Future directions may include modifying neurohumoral activation, inhibiting endothelin, and altering intracellular mechanisms and extracellular matrix structures.
- 8 Treatment strategies for patients with hypertrophic cardiomyopathy (HCM) are aimed at improving symptoms and preventing sudden cardiac death.
- 9 Patients with hypertrophic cardiomyopathy (HCM) who are at high risk for sudden cardiac death should receive an implantable cardioverter-defibrillator (ICD).
- 10 Patients with HCM who are symptomatic may benefit from β -blockade or verapamil.
- 11 Antibiotic prophylaxis for endocarditis is appropriate for HCM patients with evidence of outflow obstruction.

DIASTOLIC HEART FAILURE

Heart failure (HF) may be caused by a primary abnormality in systolic function, diastolic function, or both. Making the distinction is important because the prevalence, prognosis, and treatment of HF may be quite different depending on whether the predominant mechanism causing the symptoms is systolic or diastolic dysfunction. Some clinical studies have reported that as many as 30% to 50% of patients with congestive heart failure have preserved left ventricular (LV) function, making diastolic heart failure (DHF) very common.¹ In addition, abnormalities in diastolic function also can play an important role in the development of symptoms in patients with cardiomyopathy and systolic heart failure (SHF).

DHF can be defined as a condition in which myocardial relaxation and filling are impaired and incomplete. The ventricle is unable to accept an adequate volume of blood from the venous system, does not fill at low pressure, and/or is unable to maintain normal stroke volume. In its most severe form, DHF results in overt symptoms of congestive heart failure (CHF). In modest DHF, symptoms of dyspnea

and fatigue occur only during stress or activity, when heart rate and/or end-diastolic volume increase. In its mildest form, DHF can be manifested as a slow or delayed pattern of relaxation and filling with little or no elevation in diastolic pressure and few or no cardiac symptoms. The congestive symptoms that occur with DHF are a manifestation of increased pulmonary venous pressures. DHF is caused by impaired myocardial relaxation and/or increased diastolic stiffness. When CHF is caused by a predominant abnormality in diastolic function, the ventricular chamber is not enlarged, and the ejection fraction (EF) is normal.² Figure 18–1 demonstrates the pressure-volume relationship in a patient with normal versus abnormal diastolic function. Changes in the myocardium are associated with a shift upward and to the left of the pressure-volume curve so that for any increase in LV volume, diastolic pressure rises to a much greater level than normally would occur. Clinically, patients present with reduced exercise tolerance and dyspnea when they have elevated LV diastolic pressures. Patients with DHF have a predominant abnormality in diastolic function, whereas patients with SHF have a predominant abnormality in systolic function of the left ventricle.³

FIGURE 18-1. The diastolic pressure-volume relationship in a normal patient (*right*) and a patient with diastolic dysfunction (*left*).

EPIDEMIOLOGY

Recent studies suggest that as many as one-third to one-half of patients presenting with overt CHF have a preserved EF.^{4,5} The prevalence of DHF depends on a number of determinants: patient age, patient gender, study design, the particular population under consideration, and EF. It is important to recognize that these determinants are not independent but interdependent. The most important determinant appears to be patient age. DHF is relatively uncommon in young and middle-aged patients. The prevalence of DHF increases with age, approximating 15% in patients younger than 60 years of age, 35% in patients between 60 and 70 years of age, and 50% in patients over 70 years of age. Prospective community-based studies showed that in patients over 70 years of age, the prevalence of DHF approaches 50%.^{6,7}

ETIOLOGY

Several disorders can impair ventricular function and play a role in the development of DHF. DHF is seen often in patients with hypertension, coronary artery disease (CAD), valvular heart disease, and hypertrophic cardiomyopathies. Hypertension is the most common underlying cardiovascular disorder in patients with DHF.¹ There are several proposed mechanisms by which hypertension may impair diastolic function. Hypertension can alter diastolic function through its effects on (1) wall tension, (2) myocardial hypertrophy and fibrosis, and (3) small vessel structure and function, and (4) by predisposing to epicardial CAD. An association between impaired LV filling and subnormal high-energy phosphate metabolism has been shown in hypertensive patients, even in the absence of left ventricular hypertrophy (LVH).⁸

LVH plays a central role in the adaptation of the myocardium to pressure overload. Severe and long-standing pressure overload has been associated with phenotypic alterations at the myocyte level, which differs from the physiologic hypertrophy seen in athletes.⁹ Long-term chronic pressure overload stimulates cardiac growth and collagen production, which lead to an increase in myocardial mass and structural remodeling. The results of these changes are an increase in myocardial stiffness and a decrease in diastolic filling.

Diastolic dysfunction has been reported to be present in 90% of patients with CAD.⁹ Patients with CAD, such as (1) patients with

exercise-induced ischemia but normal function at rest, (2) patients with myocardial stunning, and (3) patients with previous myocardial infarction (MI), all may exhibit signs of diastolic dysfunction.

PATHOPHYSIOLOGY

The pathologic disease processes that cause DHF include myocardial ischemia with or without epicardial CAD, pressure overload hypertrophy, and genetic hypertrophy. Hypertrophy consequent to the physiologic adaptation to pregnancy, hypertrophy that occurs in athletes, and volume-overload hypertrophy do not cause abnormalities in diastolic function and do not result in the development of DHF.

Hypertrophic cardiomyopathy (HCM) is a prototype for DHF. The grossly thickened myocardium, structural changes, and interstitial fibrosis severely alter the passive elastic properties of the myocardium. Patients with HCM and LV outflow obstruction are sensitive to small changes in volume such that a small decrease in filling pressure can lead to a decrease in LV end-diastolic volume and a dramatic fall in stroke volume and cardiac output.

The basic mechanisms by which pressure-overload hypertrophy and genetic hypertrophy cause DHF include extramyocardial factors and factors intrinsic to the myocardium, which include changes in the cardiac muscle cell and in the extracellular matrix that surrounds the cardiomyocyte^{2,10,11} (Table 18-1). Intracellular processes such as changes in calcium homeostasis, contractile and noncontractile proteins, energetics, and the cytoskeleton contribute to abnormalities in myocardial relaxation and stiffness. Changes in the extracellular matrix, particularly changes in fibrillar collagen, alter relaxation and stiffness. In addition to the cardiomyocyte and the extracellular matrix, local myocardial neuroendocrine activation can impair relaxation and increase stiffness. Activation of neurohormones such as the renin-angiotensin-aldosterone system may act directly to alter diastolic properties or act indirectly by altering calcium homeostasis. Finally, extramyocardial changes in loading conditions and changes in heterogeneity occur in hypertrophied ventricles and contribute to changes in relaxation and stiffness so that even when the myocardium itself is normal, changes in these extramyocardial factors can cause abnormalities in diastolic function.¹²

Myocardial ischemia, particularly in the subendocardial region, is common when ventricular hypertrophy is present. Slow or delayed myocardial relaxation and perivascular fibrosis can affect coronary blood flow and coronary blood flow reserve adversely. This may contribute to the development of myocardial ischemia and sudden death.^{5,13} Therefore, myocardial ischemia may be part of clinical syndrome of DHF even if there is no epicardial CAD.

Endothelial dysfunction is associated with the progression of myocardial diastolic dysfunction in patients with CAD.¹⁴ Both in the acute manifestation of myocardial ischemia and within the chronic consequences of myocardial fibrosis, epicardial CAD is frequently the underlying pathologic cause of DHF.^{9,15,16} Myocardial ischemia caused either by an acute decrease in supply or an increase in demand (exercise and tachycardia) results in impaired relaxation and an acute increase in myocardial stiffness.¹⁶ Chronic coronary occlusions may result in myocardial fibrosis, remodeling, and DHF. It is clear that the same basic mechanisms causing diastolic dysfunction in the presence of pressure-overload hypertrophy also underlie changes produced by CAD.

DIAGNOSIS

The criteria used to make the diagnosis of DHF remain controversial. However, making the diagnosis accurately is extremely

TABLE 18–1. Potential Pathologic Mechanisms of Diastolic Heart Failure

| | |
|--|--|
| Mechanisms Directly Affecting Myocardial Tissue | |
| Cardiomyocyte | Increase in intracellular calcium, producing calcium overload <i>Myofilaments</i> Increased troponin-C calcium binding and increased myofilament calcium sensitivity <i>Cytoskeleton</i> Changes in cytoskeletal proteins <i>Energetics</i> Decrease in ATP availability, leading to a decreased rate or extent of actomyosin dissociation |
| Extracellular matrix | Increased content of fibrillar collagen Thickening of existing fibrillar collagen Decreased MMP and/or increased TIMP |
| Neurohormones | Increased renin-angiotensin-aldosterone Increased endothelin |
| Extramycardial Mechanisms | |
| Increased hemodynamic load: preload or afterload | |
| Increased heterogeneity | |
| Systemic neurohormones | Increased levels of angiotensin II |
| Pericardium | The pericardium may have a constraining effect as LV filling pressure and end-diastolic volume increase. |

MMP = matrix metalloproteinase; TIMP = tissue inhibitor of MMP; LV = left ventricular.

important. Guidelines from the European Society of Cardiology propose that three requirements must be present to make the diagnosis of DHF: (1) symptoms or signs of CHF, (2) normal systolic function, and (3) abnormal diastolic function (e.g., abnormal relaxation, filling, distensibility, or stiffness).¹⁷ The first two requirements appear to be well justified; the third requirement may not be.³

definite diagnosis of DHF: (1) definitive evidence of CHF, (2) objective evidence of normal LV systolic function within 72 hours of a CHF event, and (3) objective evidence of LV diastolic dysfunction. If the third criterion is lacking, then the patient would have *probable* DHF. If the objective evidence for normal systolic function is not apparent at the time of the CHF event and there is no conclusive information on LV dysfunction, then the patient would be classified as having *possible* DHF.

With few exceptions, DHF cannot be distinguished from SHF on the basis of the history, physical examination, chest x-ray, and electrocardiogram (ECG) alone. The frequency with which patients have symptoms of HF and signs of HF on physical examination or chest x-ray is not dependent on whether they have SHF or DHF.⁵ Patients with DHF are often elderly, hypertensive females.¹⁹ In one study, patients with DHF had a higher prevalence of hypertension with higher systolic, diastolic, and pulse pressures when compared with control patients and patients with SHF.²⁰

The data from a number of studies demonstrate that signs and symptoms of CHF do not predict EF. In contrast, they do predict the presence of increased LV diastolic pressure. The question then becomes whether the increase in LV diastolic pressure occurs in association with normal LV volume and EF, as would occur in DHF, or whether the increase in LV diastolic pressure occurs in association with an increased LV volume and decreased EF, as would occur with SHF. Therefore, determining whether CHF is caused by systolic or diastolic dysfunction requires some estimate of LV size and EF. These measurements can be made using echocardiography, radionuclide ventriculography, or contrast ventriculography. When a patient presents with dyspnea, pulmonary rales, and radiographic evidence of pulmonary venous hypertension, the detection of normal LV end-diastolic volume and normal EF supports the diagnosis of DHF. Conditions such as mitral stenosis, pulmonary disease, sleep apnea, anemia, cirrhosis, hypothyroidism, and drug-induced fluid retention must be ruled out because they can cause similar symptoms.²¹

CLINICAL PRESENTATION: DIASTOLIC HEART FAILURE

SYMPTOMS

- Exertional dyspnea
- Orthopnea
- Exercise intolerance

SIGNS

- Pulmonary congestion (rales)
- Exaggerated rise in blood pressure and heart rate in response to exercise

ECHOCARDIOGRAPHY OR CATHETERIZATION

- Normal (or increased) ejection fraction
- Normal (or decreased) cardiac output
- Increased LV pressure
- Pulmonary venous hypertension
- LV hypertrophy and/or concentric remodeling
- Abnormal LV relaxation and increased LV chamber stiffness

LABORATORY TESTS

- Increased BNP levels

Vasan and Levy proposed criteria for DHF according to the degree of diagnostic certainty.¹⁸ Three conditions would be met for a

B-type natriuretic peptide (BNP) is a cardiac neurohormone secreted from the myocardium in response to increases in ventricular volume and pressure. It is used frequently as an aid in the differential diagnosis of dyspnea. The Breathing Not Properly study evaluated 452 patients with echocardiography within 30 days of an emergency department visit. Of those 452 patients, 165 (36.5%) had an EF greater than 45% (mean EF 59%).²² In these patients with preserved EF who had been admitted to the hospital for dyspnea, BNP levels were significantly lower than those found in patients with SHF (413 versus 821 pg/mL). However, there was considerable overlap in the BNP levels in patients with DHF compared with those without HF, making BNP levels less useful. Furthermore, the sensitivity, specificity, and predictive accuracy of BNP levels in DHF are limited in part because BNP is altered by age, gender, and other factors.

PROGNOSIS

The prognosis in patients with DHF, although less ominous than in patients with SHF, is worse than that of age-matched control patients.

The 5-year mortality of patients with DHF approximates 25%, although mortality rates as high as 13% over a 6-month period have been reported.^{4,23,24} In comparison, the annual mortality of patients with SHF approximates 10% to 15%, whereas age-matched control mortality approaches 1%. In patients with DHF, the prognosis is also affected by the clinical pathologic etiology causing the disease. When patients with CAD are excluded, the annual mortality for DHF approximates 2% to 3%.⁶ In addition to the clinical pathologic etiology causing CHF, another important determinant of mortality is age. In patients older than 70 years of age, the mortality rates for DHF and SHF are similar.⁶ Of note, non-Caucasian patients with DHF may have a higher mortality rate than Caucasian patients.²³

The mode of death appears similar in patients with systolic versus diastolic HF. Sudden death and death from progressive pump failure occurred with equal frequency in systolic versus diastolic HF patients. Morbidity from DHF is quite high, requiring frequent outpatient visits, hospital admissions, and the expenditure of significant health care resources. The 1-year readmission rate approaches 50% in patients with DHF. This morbidity rate is nearly identical to that of patients with SHF.^{4,25}

► TREATMENT: Diastolic Heart Failure

The general principles used to guide the treatment of SHF are based on numerous large, randomized, double-blind, multicenter trials. Until recently, no such randomized trials had been performed in patients with DHF. Consequently, the guidelines for the management of DHF are based primarily on clinical investigations in relatively small groups of patients, clinical experience, and concepts based on the knowledge and understanding of the pathophysiology of the disease process. The treatment regimen outlined below (Table 18–2) applies to patients with DHF who have clear manifestations of congestion either at rest or with exertion. Whether treatment of asymptomatic diastolic dysfunction confers any benefit has not been examined.

■ DESIRED OUTCOME

4 Treatment should be targeted at reducing symptoms, principally those of increased pulmonary venous pressure. Treatment should include decreasing diastolic pressure by decreasing LV volume, maintaining atrial contraction, and reducing heart rate. If symptoms are controlled, the need for hospitalization is reduced. Second, treatment should be targeted at the pathologic diseases that cause DHF. For example, CAD, hypertensive heart disease, and aortic stenosis provide relatively specific therapeutic targets, such as lowering blood

TABLE 18–2. General Approach to Treatment of Diastolic Heart Failure

| | | |
|---|---|---|
| Symptom-Targeted Treatment | | |
| Decrease pulmonary venous pressure | Reduce left ventricular volume Maintain atrial contraction | Diuretics, salt restriction Cardioversion of atrial fibrillation |
| | Reduce heart rate | β -Blockers, diltiazem, verapamil |
| Improve exercise tolerance | As above | |
| Use positive inotropic agents with caution | | |
| Disease-Targeted Treatment | | |
| Prevent/treat myocardial ischemia | | β -Blockers, diltiazem, verapamil, nitrates |
| Prevent/regress ventricular hypertrophy | | Antihypertensive therapy |
| Mechanism-Targeted Treatment | | |
| Modify myocardial and extramyocardial mechanisms | | Possibly ACE inhibitors or ARBs, diuretics, spironolactone |
| Modify intracellular and extracellular mechanisms | | Possibly ACE inhibitors or ARBs, spironolactone |

ACE = angiotensin-converting enzyme; ARBs = angiotensin-receptor blockers.

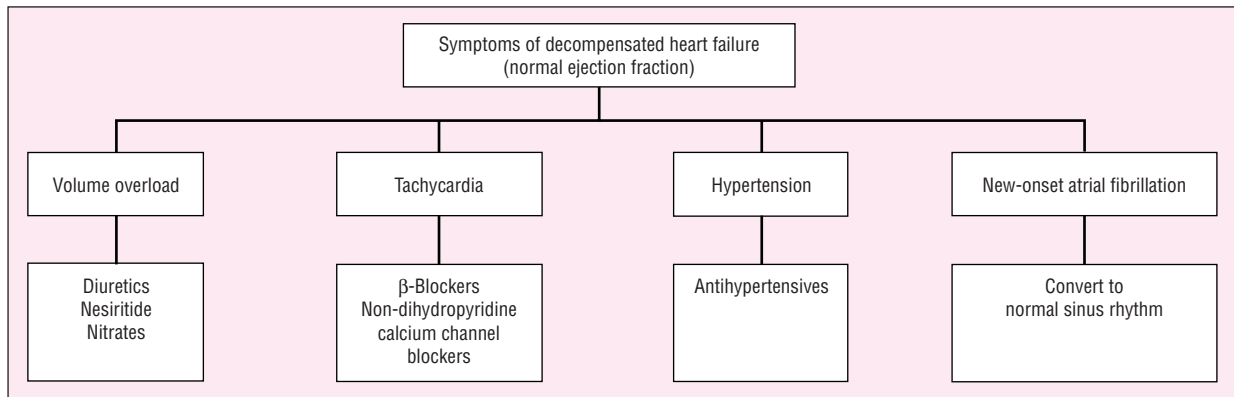

FIGURE 18–2. Treatment of acute decompensated diastolic heart failure.

pressure, inducing LVH regression, performing aortic valve replacement, and treating ischemia by increasing myocardial blood flow and reducing myocardial oxygen demand. Third, treatment should be targeted at the underlying mechanisms that are altered by the disease processes just mentioned.²⁶

■ NONPHARMACOLOGIC THERAPY

■ DIET AND LIFESTYLE

The initial effort in the treatment of DHF is aimed at decreasing symptoms. The first step in this effort is to decrease pulmonary congestion by decreasing LV volume using sodium and fluid restriction. A low-sodium diet (<2 g/day) and moderate fluid restriction will help to prevent volume overload. Both sodium and fluid restriction must be done with care. Excessive restriction can lead to hypotension, low-output state, and/or renal insufficiency. Daily weights may help to assess volume status. Dietary and lifestyle factors that decrease the risk of development of epicardial CAD and high blood pressure should be encouraged.

■ EXERCISE

Moderate aerobic exercise to improve cardiovascular conditioning is beneficial to maintain a slower heart rate, improve cardiac reserve, and maintain skeletal muscle function. Isometric exercise should be avoided.²⁷

■ INTERVENTIONAL/SURGICAL PROCEDURES

An important step in symptom-targeted therapy that acts to decrease pulmonary venous pressures is to maintain atrial contraction and atrioventricular (AV) synchrony. Maintaining atrial contraction and AV synchrony is important both in preserving normal cardiac output and in keeping LV diastolic pressure low. Chemical or electrical cardioversion of persistent atrial tachyarrhythmias will decrease diastolic pressure, increase cardiac output, and resolve pulmonary edema. An AV sequential pacemaker should be used to treat bradyarrhythmias in patients requiring pacing.

Therapy also should be aimed at preventing or treating the underlying pathologic cause of DHF. Aortic valve replacement should be performed in symptomatic patients with pressure-overload

hypertrophy caused by aortic stenosis. Revascularization should be performed in selected patients with DHF caused by CAD-induced myocardial ischemia. In addition, myocardial oxygen consumption and myocardial blood flow should be increased using medical treatment, including nitrates, β -blockers, and calcium channel blockers.

■ INDICATIONS FOR HOSPITALIZATION

Patients with DHF may present with an acute onset of pulmonary edema. There are a number of potential causes for the acute decompensation of these patients, including: volume overload, uncontrolled hypertension, acute myocardial ischemia, progressive valvular disease (aortic stenosis), and new-onset or uncontrolled tachyarrhythmias. Treatment strategies for these patients eventually may include the need for surgery, as in the case of valvular disease.

The initial management focuses on relieving pulmonary congestion and maintaining oxygenation (Fig. 18–2). Intravenous diuretic agents and nesiritide for patients are effective for volume overload. Caution must be exercised to avoid overdiuresis or an excessive lowering of LV end-diastolic volume, which can lead to a decrease in stroke volume. Morphine and nitroglycerin also are effective in reducing LV end-diastolic pressure.²⁸

A study involving patients who required emergency treatment for pulmonary edema assessed the association of clinical findings with prognosis or outcome.²⁹ In this study of 186 patients, 40% had no recognized precipitating factor identified for their hospitalization. Patients who responded to diuretic therapy with a good urine output had a better outcome than patients who did not respond as well. This study did not examine whether prognosis was related to the presence of systolic or diastolic heart failure. Based on this information, diuretics are appropriate first-line therapeutic agents for acute decompensation and pulmonary edema.

■ PHARMACOLOGIC TREATMENT

■ DRUG TREATMENTS OF FIRST CHOICE

With a few notable exceptions, many of the drugs used to treat systolic heart failure are in fact the same as those used to treat DHF (Fig. 18–3). However, the rationale for their use, the pathophysiologic process that is being altered by the drug, and the dosing regimen may be entirely different depending on whether the patient has systolic or diastolic

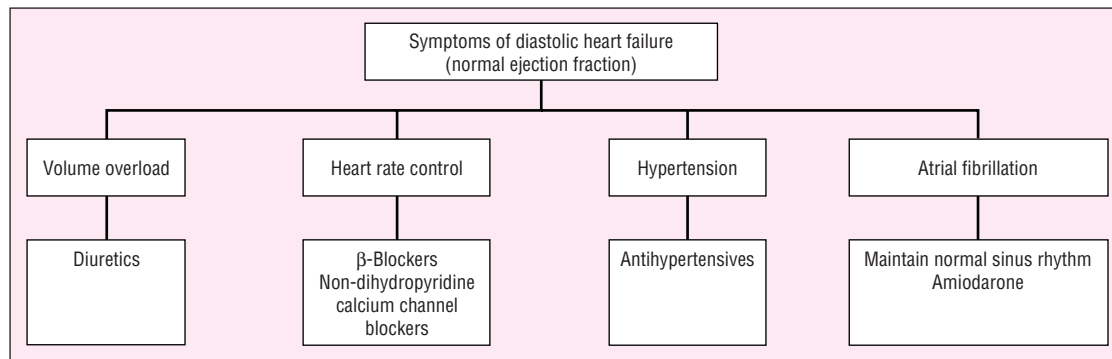

FIGURE 18-3. Treatment of chronic diastolic heart failure.

HF. For example, β -blockers are recommended for the treatment of both SHF and DHF. In DHF however, β -blockers are used to decrease heart rate, increase diastolic duration, and modify the hemodynamic response to exercise. In SHF, β -blockers are used in the long run to increase inotropic state and modify LV remodeling. Diuretics also are used in the treatment of both SHF and DHF. However, the doses of diuretics used to treat DHF are in general much smaller than the dose used in SHF. Antagonists of the renin-angiotensin-aldosterone system are useful in lowering blood pressure and reducing LVH. Some drugs, however, are used only to treat either SHF or DHF but not both. Calcium channel blockers such as diltiazem, nifedipine, and verapamil have little utility in the treatment of SHF. In contrast, each of these has been proposed as being useful in the treatment of DHF.

■ PUBLISHED GUIDELINES

In 2001, the American College of Cardiology and the American Heart Association released a revision to the 1995 guidelines for the evaluation and management of heart failure.³⁰ In general, the guidelines recommend treating comorbid conditions by controlling heart rate and blood pressure, alleviating causes of myocardial ischemia, and reducing volume.

■ GENERAL INFORMATION

Although dozens of trials evaluating pharmacologic therapy have been conducted in patients with SHF, there are few trials focusing on patients with isolated DHF. In fact, most published HF trials have specifically excluded patients with a preserved EF. There are a few published studies and several trials underway that are examining various agents in the treatment of DHF. With these studies and others that are currently under development, an effective treatment for DHF will be defined more completely.

There were almost 1000 patients with EF greater than 45% in the Digitalis Investigation Group (DIG) trial who were randomized to either digoxin or placebo.²⁵ After 37 months of follow-up, the mortality rate was identical in each group (23.4%). There was no statistically significant difference in the combined end point of death or hospitalization owing to worsening HF in the DHF patients who were receiving digoxin (risk ratio 0.82; 95% confidence interval 0.63–1.07). In contrast, in patients with SHF, digoxin reduced hospitalization owing to worsening heart failure by 28% ($p < .001$).

The CHARM-Preserved trial was one of three studies evaluating the use of candesartan in heart failure. The CHARM-Preserved

trial investigated the effects of candesartan, an angiotensin-receptor blocker (ARB), versus placebo in over 3000 patients with New York Heart Association (NYHA) functional class II–IV symptoms of HF and an EF of greater than 40%.³¹ The two groups were well matched for medical treatment at the times of randomization. Candesartan had no effect on mortality in the patients with DHF. On the composite end point of cardiovascular death or hospitalization for worsening HF, there was a 14% relative risk reduction ($p = .051$) using an adjusted hazards ratio. Hospital readmissions for CHF were reduced by 16% ($p = .047$) using an adjusted hazards ratio. The data were analyzed by intention to treat, and it should be noted that by the end of the study, 22% of the candesartan-treated patients had discontinued the medication. As expected, there were more adverse events (e.g., hypotension, hyperkalemia, and increase in serum creatinine concentration) in the candesartan group. Interestingly, there was a significant reduction in the number developing diabetes in the patients receiving candesartan. It appears that for a cardiovascular patient with DHF, the addition of candesartan to a typical medical regimen including angiotensin-converting enzyme (ACE) inhibitors, β -blockers, diuretics, digoxin, and calcium channel blockers provides a modest reduction in the need for hospitalization owing to worsening HF.

■ ALTERNATIVE DRUG TREATMENT

As a result of the controversy regarding the diagnosis of DHF, the development and design of large clinical trials have been hindered. At this point in time, most antihypertensive agents would be acceptable forms of therapy for hypertensive heart disease, with the exception of α -blockers (e.g., doxazosin). In the Antihypertensive and Lipid-Lowering Treatment to Prevent Heart Attack Trial (ALLHAT), the doxazosin treatment arm was dropped because patients randomized to doxazosin had an increased risk of developing HF and stroke when compared with the chlorthalidone arm.³²

■ SPECIAL POPULATIONS

DHF is associated with hypertension and aging, making it a common diagnosis in elderly Caucasian women. Since these women are often frail, with low muscle mass, their creatinine clearance and renal function may be compromised. Special care must be taken in selecting and titrating doses of drugs, as well as in monitoring serum creatinine and electrolytes, when using diuretics, ACE inhibitors, and ARBs.

Diabetes is often a comorbid condition in patients with HF. Since the thiazolidinediones (pioglitazone and rosiglitazone) are associated

with fluid retention, caution is warranted when initiating these drugs in patients with a history of DHF. Thiazolidinediones should be discontinued in patients with symptoms related to volume overload.

■ DRUG CLASS INFORMATION

■ DIURETICS

5 Diuretics can provide symptom-targeted therapy by acting to decrease systemic and LV volume. By decreasing LV diastolic volumes, LV pressures slide down the curvilinear diastolic pressure-volume relationship toward a lower, less steep portion of the curve. As pressure throughout diastole falls, mean diastolic pressure, pulmonary capillary wedge pressure, and pulmonary venous pressure fall. These agents effectively reduce the central blood volume, lower diastolic pressures, and thus alleviate the symptoms of the congestive state. Diuretics can provide disease-targeted therapy by decreasing blood pressure and favorably affecting the myocardial oxygen supply-versus-demand ratio. Lower LV diastolic pressures may increase subendocardial blood flow, preventing or alleviating the imbalance between myocardial oxygen supply and demand (see Fig. 18–1). Diuretics alone and especially in combination with other anti-hypertensive drugs are an effective approach to therapy.

Treatment with diuretics should be initiated at low doses in order to avoid hypotension and fatigue. Hypotension can be a significant problem in the treatment of DHF because these patients have a very steep LV diastolic pressure-volume curve such that a small change in volume causes a large change in filling pressure and cardiac output. After the acute treatment of DHF has been completed, long-term treatment should include small to moderate doses of diuretics (furosemide 20 to 40 mg/day orally or hydrochlorothiazide 25 mg/day orally). If prompt and sustained diuresis is not achieved, the dosage of a single diuretic should be increased, or a loop and thiazide or thiazide-like diuretic should be used in combination. Aldosterone antagonists such as spironolactone and eplerenone may be especially effective in long-term use because of their potassium-sparing effects and because their antagonism of renin-angiotensin-aldosterone system activation may alter intra- and extramyocardial mechanisms causing abnormalities in diastolic function.³³ Thiazide diuretics generally are ineffective in patients with a creatinine clearance of less than 30 mL/min.

Excessive diuresis may result in hypotension, low-output syndrome, and worsening renal insufficiency. In some cases, loop diuretics may be withdrawn safely from elderly patients without any worsening of HF symptoms and with improvement in symptoms of orthostatic hypotension.³⁴ Electrolyte imbalances, including hypokalemia and hypomagnesemia, are common with diuretics. Carbohydrate intolerance and hyperuricemia are dose-related adverse drug reactions seen with thiazide diuretics. Spironolactone can cause hyperkalemia and gynecomastia. Eplerenone may be used as an alternative to spironolactone in patients who complain of gynecomastia. In general, diuretic agents are very cost-effective agents in the management of DHF.

■ NITRATES

6 Similar to diuretics, nitrates can provide symptom-targeted therapy by acting to decrease LV volume by increasing venous capacitance. In addition, nitrates can provide disease-targeted therapy by providing anti-ischemic effects in patients with DHF owing to CAD.

Like diuretics, therapy should be initiated at low doses in order to avoid hypotension. Isosorbide dinitrate 10 mg three or four times daily, isosorbide mononitrate (Imdur) 30 mg/day, nitroglycerin paste 1/2 to 1 inch every 4 to 6 hours, and nitroglycerin patch 0.1 to 0.2 mg/h applied each day are common initial doses. Doses can be increased during long-term therapy and titrated against symptoms. Nitrate tolerance has not been studied in this patient population but probably occurs. Similar to diuretics, nitrates can cause hypotension and a low-output syndrome. Headaches are common but may be less frequent with continued use.

Sublingual nitroglycerin tablets or nitroglycerin spray may be used for patients who develop shortness of breath with mild exercise, and they may be used much in the same way as in patients with ischemic symptoms. Nitroglycerin will decrease LV end-diastolic volume resulting in relief of breathlessness.

■ β -ADRENERGIC BLOCKERS

β -Blockers can provide symptom-targeted therapy by decreasing heart rate and can provide disease-targeted therapy by treating high blood pressure and CAD. By decreasing heart rate and increasing the duration of diastole, β -blockers can help to lower and maintain low pulmonary venous pressures. Tachycardia is poorly tolerated in patients with DHF for several reasons. First, rapid heart rates cause an increase in myocardial oxygen demand and a decrease in coronary perfusion time. This rapid rate can promote ischemic diastolic dysfunction even in the absence of epicardial CAD, especially in patients with LVH. Second, there may be incomplete relaxation between cardiac cycles, resulting in an increase in diastolic pressure relative to volume. Thus LV distensibility is reduced. Third, a rapid rate reduces diastolic filling time and ventricular filling. Fourth, hearts with diastolic dysfunction exhibit a flat or even negative relaxation rate versus frequency relationship. Thus, as heart rate increases in these hearts, relaxation does not become augmented and may become slower and incomplete, causing diastolic pressures, especially early in diastole, to increase.²⁶ For these and other reasons, most clinicians use β -blockers (and calcium channel blockers) to prevent excessive tachycardia and produce a relative bradycardia in patients with diastolic dysfunction. However, excessive bradycardia can result in a fall of cardiac output despite an increase in LV filling. Such considerations underscore the need for individualizing therapeutic interventions that affect heart rate. While the optimal heart rate must be individualized, an initial goal might be a resting heart rate of approximately 60 beats per minute with a blunted exercise-induced increase in heart rate not to exceed 110 beats per minute.²⁶

There is no evidence to suggest that there is a specific therapeutic advantage to one β -blocker over another. Selective and nonselective β -blockers appear equally effective in DHF. β -Blockers with intrinsic sympathomimetic activity (ISA) may be less effective because they slow the heart rate less. In general, it is not necessary to start the drug at an extremely low dose and titrate the β -blocker in a slow, progressive fashion in DHF, as it is in SHF. Since the population is older, it is prudent to start with a moderate dose of β -blockers, such as metoprolol 25 mg twice daily or atenolol 25 mg/day and titrate to a higher dose with a treatment target of a heart rate of approximately 60 beats per minute.

Prinzmetal's vasospastic angina, bronchospastic chronic obstructive pulmonary disease (COPD), asthma, occlusive peripheral vascular disease, type I diabetes mellitus that is prone to hypoglycemia, heart block, and excessive bradycardia are contraindications to β -blockers. The main side effects of β -blockers are

depression, fatigue, bradycardia, bronchospasm, and impotence. Many of the β -blockers are eliminated via hepatic metabolism and may be affected by other drugs that either inhibit (e.g., cimetidine and verapamil) or enhance (e.g., barbiturates) hepatic enzymes. Since the doses are titrated to patient response, these interactions are managed easily. Several β -blockers (e.g., propranolol, metoprolol, atenolol, nadolol, and timolol) are available as generic formulations, making them very cost-effective.

■ CALCIUM CHANNEL BLOCKERS (CCBs)

CCBs can provide symptom-targeted treatment by decreasing heart rate and increasing exercise tolerance. They can provide disease-targeted treatment by treating high blood pressure and CAD. However, the beneficial effect of these agents on exercise tolerance is not always paralleled by improved LV diastolic function or increased relaxation rate.²⁶ Nonetheless, a number of small clinical trials have shown that the use of these agents results in both short- and long-term improvement in exercise capacity in patients with DHF.³⁵

Of the CCBs, the nondihydropyridines (verapamil and diltiazem) are the most effective because they lower heart rate in addition to lowering blood pressure.³⁶ Nifedipine, because of its strong vasodilator properties, tends to cause hypotension and reflex tachycardia. In addition, nifedipine causes peripheral edema. These characteristics make it less useful in DHF. Amlodipine is also effective because it reduces blood pressure. Initial doses are verapamil 120 to 240 mg/day, diltiazem 90 to 120 mg/day, and amlodipine 2.5 mg/day.

Heart block is a contraindication for the nondihydropyridines. The most common side effects are bradycardia and heart block (for the nondihydropyridines). Peripheral edema and headache are also common. Nondihydropyridines exacerbate bradycardic effects of β -blockers, and verapamil raises digoxin serum concentrations by 70%. Diltiazem raises cyclosporine serum concentrations. Intravenous calcium salts inhibit the pharmacologic effect of CCBs. Generic formulations or similar products, but not necessarily generic equivalents to the original brand names, are available for verapamil, nifedipine, and diltiazem.

■ NEUROHUMORAL ANTAGONISTS

Both basic and clinical studies suggest that DHF is associated with activation of systemic and local cardiac neuroendocrine systems such as the renin-angiotensin-aldosterone system. One mechanism causing fluid retention and the increases in central and systemic volume in patients with DHF is activation of these neuroendocrine systems. Therefore, treatment for DHF should include agents such as ACE inhibitors, ARBs, and aldosterone antagonists that attenuate the fluid retention caused by neuroendocrine activation. In addition to promoting fluid retention, neuroendocrine activation can have direct effects on cellular and extracellular mechanisms that contribute to the development of DHF. Modulation of neuroendocrine activation may provide mechanism-targeted treatment by decreasing fibroblast activity and interstitial fibrosis, improving intracellular calcium handling, and decreasing myocardial stiffness. Finally, renin-angiotensin-aldosterone system antagonists provide disease-targeted treatment by treating hypertension.^{26,37}

The mechanisms that evoke activation of the neuroendocrine system remain incompletely understood in patients with DHF. A number of factors have been suggested. Myocardial ischemia, uncontrolled hypertension, and excessive dietary sodium or sodium-retaining

medications may contribute to neuroendocrine activation. Limited distensibility of the atria may attenuate the secretion of atrial natriuretic factor and thereby reduce its diuretic effect. In others, low systemic vascular resistance and/or low arterial pressure may contribute to an increase in renin-angiotensin-aldosterone system activation and salt and water retention. Elevated venous pressure may cause renal sodium retention directly. The reduction in blood volume that follows the use of diuretics triggers an increase in sympathetic tone and further activation of the renin-angiotensin-aldosterone system. Such neurohormonal activation can lead to vasoconstriction and a worsening of the congestive state. Some vasodilators, particularly nitrates and pure arteriolar vasodilators, evoke a similar response. By contrast, ACE inhibitors (and β -blockers) blunt neurohormonal activation and decrease the salt and water retention that complicates the treatment of CHF.

■ ANGIOTENSIN-CONVERTING ENZYME (ACE) INHIBITORS

ACE inhibitors can provide symptom-targeted treatment by decreasing LV volume and directly improving relaxation. They can provide disease-targeted treatment by treating high blood pressure, preventing LVH, promoting regression, and preventing fibrosis. Treatment of high blood pressure with ACE inhibitors has been shown to normalize load, prevent and/or regress LV hypertrophy, correct the abnormality in intracellular processes, and modify the extracellular matrix response.³⁸ ACE inhibitors may reduce the incidence of HF by 23% among patients with CAD and preserved EF.³⁹

A small, prospective, double-blind, randomized trial compared lisinopril with hydrochlorothiazide in 35 patients with primary hypertension, LVH, and LV diastolic dysfunction.⁴⁰ After 6 months of therapy, lisinopril caused regression of myocardial fibrosis and improved LV diastolic function, although LVH was unchanged.

At this time, there is no evidence to suggest advantage of one ACE inhibitor over another. Their effects appear to be a class effect. Initial doses should be small to moderate in order to avoid hypotension, especially if the patient examination does not indicate volume overload. Examples of initial starting doses are captopril 6.25 mg three times daily, enalapril 2.5 mg/day, or lisinopril 2.5 mg/day.

Severe renal failure, history of angioedema, and pregnancy are contraindications to ACE inhibitors. Hyperkalemia, persistent cough, hypotension, taste disturbances, and worsening renal function are common side effects but are managed by decreasing the dose or discontinuing the drug.

■ ANGIOTENSIN-RECEPTOR BLOCKERS (ARBs)

ARBs can provide symptom-targeted treatment by decreasing LV pressure, decreasing LV volume, and increasing exercise tolerance. They can provide disease-targeted treatment by lowering blood pressure. As mentioned previously, the CHARM-Preserved trial showed a reduction in hospitalizations for worsening HF in patients receiving candesartan in addition to usual treatment.³¹

Losartan was evaluated in a randomized, double-blind, placebo-controlled trial in 20 patients with diastolic dysfunction.⁴¹ In this trial, losartan or placebo was added to the current medical regimen for a 2-week period. Patients enrolled in the study had a marked hypertensive response to exercise, an EF of greater than 50%, and no evidence of ischemia on stress echocardiogram. The blood pressure at rest was well controlled (143/79 mm Hg), but the mean peak systolic blood

pressure after 11 minutes of exercise was 226 mm Hg. The resting systolic and diastolic blood pressures were not changed with placebo or losartan. However, the peak systolic blood pressure with losartan was reduced to 193 mm Hg compared with placebo (217 mm Hg) and baseline (226 mm Hg). Losartan increased exercise time, NYHA class, and quality of life as assessed by the modified Minnesota Living with Heart Failure Survey.

The specific mechanism of the losartan-induced improvement is not known. However, angiotensin II slows the rate of LV relaxation and increases LV diastolic pressures. In a 2-week period of time, there was no evidence of improved diastolic function. Losartan did slow the increase in systolic blood pressure during exercise and decreased the peak systolic blood pressure by a mean of 33 mm Hg. Although the patients had no evidence of myocardial ischemia, losartan may have improved endothelial function and coronary perfusion.

No ARB has yet been shown to have any major advantage over another. Initial doses of candesartan start at 4 mg/day, irbesartan 150 mg/day, losartan 25 mg/day, telmisartan 40 mg/day, and valsartan 80 mg/day. As with the ACE inhibitors, ARBs are contraindicated in pregnancy. The side effects of ARBs are similar to those of ACE inhibitors, but they are not associated with persistent cough.

■ ALDOSTERONE ANTAGONISTS

Aldosterone antagonists can provide symptom-targeted treatment by decreasing LV volume. They can provide disease-targeted treatment by decreasing the fibrosis that accompanies LVH. An analysis of the RALES study found that spironolactone significantly decreased the levels of serum markers for cardiac collagen turnover. The benefit from spironolactone was seen in patients with the higher level collagen synthesis markers. This was the first study to show that serum levels of markers of cardiac collagen synthesis were associated with a poor clinical outcome and could be decreased with spironolactone. This property distinguishes spironolactone from other diuretics that have no effect on myocardial necrosis or collagen turnover.

Like other diuretics, spironolactone should be initiated at a low dose and increased to treat symptoms. Spironolactone may be initiated at doses of 12.5 to 25 mg/day. Spironolactone should be avoided in severe renal failure. Hyperkalemia and gynecomastia are the most common side effects. Eplerenone is a viable alternative to

spironolactone in patients complaining of sex hormone–related side effects.³³

■ POSITIVE INOTROPIC AGENTS

Positive inotropic agents, like β -agonists and phosphodiesterase inhibitors, generally are not used in the treatment of patients with isolated DHF because the LV ejection fraction is preserved and there appears to be little potential for a beneficial effect. Positive inotropic agents have the potential to worsen DHF by adversely affecting energetics, inducing ischemia, raising heart rate, and inducing arrhythmias.²⁶ In contrast to long-term use, positive inotropic drugs may be beneficial in the short-term treatment of pulmonary edema associated with DHF. These agents can enhance sarcoplasmic reticular function, promote more rapid and complete relaxation, increase splanchnic blood flow, increase venous capacitance, and facilitate diuresis.²⁶ However, these agents should be used with caution, if they are used at all, because the risk-benefit ratio is not clearly established.

■ DIGITALIS DERIVATIVES

Digoxin, by inhibiting the Na^+, K^+ -potassium-ATPase pump, augments intracellular calcium and thereby augments contractile state. In this manner, digoxin produces an increase in systolic energy demands while adding to a relative calcium overload in diastole. These effects may not be apparent clinically under many circumstances, but during hemodynamic stress or ischemia, digoxin may promote or contribute to diastolic dysfunction.²⁶ Therefore, until recently, and with the exception of patients with chronic atrial fibrillation (to slow ventricular rate), digoxin was not used in the treatment of DHF. However, results of the DIG trial suggested that even patients with a normal EF may have fewer symptoms and fewer hospitalizations if they are treated with digoxin.²⁵ This salutary effect was not likely a result of digoxin's effect on inotropy but rather of its blunting of neuroendocrine activation. Others have found that patients treated chronically with digoxin have higher levels of serum markers associated with excessive extracellular matrix turnover.⁴² Whether this is due to digoxin or to the condition for which digoxin is being used remains unclear.

PHARMACOECONOMIC CONSIDERATIONS

Frequent admission to the hospital is common in patients with DHF. Unfortunately, there are no pharmacoeconomic data associated with the only large clinical outcome trial (CHARM-Preserved) published to date. Since DHF is primarily a disease of the elderly, comorbid conditions will create challenges in any trial designed. At the present time, cost to the patient should be considered because adherence to an antihypertensive regimen is paramount to a beneficial outcome.

CLINICAL CONTROVERSIES

- Digoxin may not be beneficial in patients with isolated DHF who are in normal sinus rhythm.
- Drugs that antagonize the renin-angiotensin-aldosterone system may be the preferred antihypertensive drugs for patients with DHF.

EVALUATION OF THERAPEUTIC OUTCOMES

The end points used in assessing effective therapies for DHF include mortality, hospitalization for worsening HF, functional status or quality-of-life indicators, and cost. Other end points may target underlying mechanisms of disease, such as calcium homeostasis or regression of fibrosis. A number of clinical trials are underway that will address this important clinical problem.

CARDIOMYOPATHIES

Diastolic dysfunction plays a role in the presentation of some types of cardiomyopathy. The cardiomyopathies represent a variety of diseases affecting the myocardium in either a diffuse or multifocal manner that frequently results in HF. The terminology and classification used for the cardiomyopathies are confusing owing to overlap among the diseases and/or classification schemes. Cardiomyopathies sometimes are defined according to etiology or as primary or secondary

TABLE 18–3. Characteristics of the Cardiomyopathies

| | Dilated | Hypertrophic | Restrictive |
|-------------------------|--|---|--------------------------------------|
| Myocardial mass | ↑→↑↑ | ↑↑↑ | nl→↑ |
| Ventricular cavity size | ↑↑→↑↑↑↑ | ↓↓→nl | nl→↓ |
| Contractile function | ↓↓↓ | ↑↑→↓ | nl→↓ |
| LV filling pressure | ↑↑ | nl→↑ | ↑ |
| Chest x-ray | Moderate to marked cardiac enlargement | Mild to moderate cardiac enlargement | Mild cardiac enlargement |
| Electrocardiogram | ST-segment and T-wave abnormalities | ST-segment and T-wave abnormalities | Low voltage, conduction defects |
| Echocardiogram | LV dilatation and dysfunction | Left ventricular hypertrophy Asymmetric septal hypertrophy Systolic anterior motion of the mitral valve | Increased LV wall thickness possible |
| Radionuclide studies | LV dilatation and dysfunction | Vigorous systolic function | Normal systolic function |

↑ = increased; ↓ = decreased; nl = normal; LV = left ventricular.

forms. *Primary* cardiomyopathies are disorders in which either the structure or function of the myocardium is affected in the *absence* of other known causes of heart disease or systemic diseases known to affect the heart. *Secondary* forms of cardiomyopathy are conditions in which the myocardial abnormality is due to a recognized factor. Infectious agents, inflammation, metabolic disorders, infiltrative diseases, and toxins are a few of the causative factors of secondary cardiomyopathy.⁴³

Frequently, a specific etiology is not evident. Therefore, another commonly used categorization of the cardiomyopathies is based on the structural and/or functional abnormalities present. The three groups of cardiomyopathies usually are described as dilated (congestive), hypertrophic, and restrictive. An understanding of the pathophysiologic basis for each type of cardiomyopathy leads to a rational selection of drug therapy or other treatment modality. The characteristics for each of the types of cardiomyopathy are presented in Table 18–3. The distinction among the cardiomyopathies is not absolute, and there is some overlap in the functional abnormalities.

In dilated cardiomyopathy, the cardinal feature is dilatation of the ventricles. Systolic function is abnormal, leading to a decreased cardiac output. In patients with hypertrophic cardiomyopathy (HCM), the ventricular cavity is not dilated, and the ventricular muscle mass is increased. Ventricular cavity size is normal or decreased, and systolic function often is preserved. Patients with HCM may have an obstructive or nonobstructive form. Patients with restrictive cardiomyopathy have inadequate ventricular compliance causing diastolic dysfunction owing to endocardial and/or myocardial disease. The clinical presentation is similar to that of constrictive pericarditis.

Other terms are encountered frequently in discussions of patients with cardiomyopathy. *Familial cardiomyopathy* is used to denote a condition found in more than one family member. Genetic predisposition may occur in all three functional types. *Ischemic cardiomyopathy* is another frequently used term. Patients with occlusive atherosclerotic CAD and LV dysfunction are said to have ischemic cardiomyopathy. Ischemic cardiomyopathy is not a true cardiomyopathy because there is an identifiable cause of the ventricular muscle dysfunction.

HYPERTROPHIC CARDIOMYOPATHY

Hypertrophic cardiomyopathy is a primary myocardial disorder characterized by a hypertrophied and nondilated left ventricle existing in the absence of known causes of LVH.⁴⁴ HCM is inherited as an autosomal dominant trait caused by mutations in any of 10 genes.^{44,45} The distribution of the hypertrophy is usually asymmetric, meaning

that segments of the left ventricle are thickened to varying degrees. There also may be enlargement of the atria, thickening of the mitral valve leaflets, and fibrotic areas within the ventricular wall. In the past, the terms of *idiopathic hypertrophic subaortic stenosis* (IHSS) and *hypertrophic obstructive cardiomyopathy* (HOCM) were used to describe patients with HCM with an outflow obstruction. These terms are used less frequently now because they overemphasize the obstructive component of the disease, which is present in a minority of patients.⁴⁵

EPIDEMIOLOGY

Recent epidemiologic investigations estimate the prevalence of phenotypically expressed HCM in the general adult population to be approximately 0.2% (1 in 500).⁴⁵ Therefore, HCM is the most common genetic cardiovascular disease. However, many individuals have a mutant gene but go undetected.

ETIOLOGY

The genetic predisposition to HCM is thought to be an autosomal dominant trait with variable penetrance. Owing to the wide variability of presentation, not all cases in a family may be detected. HCM usually is caused by mutations in the genes for β -myosin heavy chain, myosin-binding protein C, and cardiac troponin T.^{45,46}

PATHOPHYSIOLOGY

HCM appears to have several different pathophysiologic mechanisms leading to similar clinical manifestations, although the prognoses for patients will vary. The pathophysiology of HCM is a complex relationship among several factors, including: (1) asymmetric LVH, (2) diastolic dysfunction, (3) dynamic obstruction of the outflow tract, and (4) myocardial ischemia. Each of these components contributes to the overall presentation of the patient to a varying degree.

Left Ventricular Hypertrophy

The hypertrophy seen in HCM usually is diffuse and involves the septum and LV anterolateral free wall to a greater degree than the posterior segment. Asymmetric septal hypertrophy is a sensitive marker for HCM but is not specific for this disorder. In patients with outflow obstruction, the basal septum usually is markedly thickened at the level of the mitral valve. In patients with nonobstructive HCM, the outflow tract is larger, and the septal hypertrophy that occurs has a more distal or apical distribution.

Cellular disorganization is a common histologic finding in HCM. Morphologic abnormalities are found at the gross, microscopic, and ultrastructural levels. The disarray of myocytes may contribute to diastolic and systolic dysfunction, as well as serving as a nidus for ventricular arrhythmias.⁴⁵ The degree of LVH is associated with a worse clinical course. The presence of hypertrophy correlates directly with MI, HF, stroke, and ventricular arrhythmias.⁴⁷ Spirito and colleagues found that the magnitude of LVH was directly related to the risk of sudden cardiac death.⁴⁸

Diastolic Dysfunction

Diastolic dysfunction is the most common abnormality found in patients with HCM. Approximately 80% of patients will exhibit symptoms associated with diastolic dysfunction. Studies of the left ventricle led to the realization that diastolic dysfunction is the result of abnormalities in relaxation, distensibility (compliance), and filling. The abnormalities of diastolic function can be both regional and global and lead to an incoordination of contraction and relaxation. β -Adrenergic stimulation can aggravate these abnormalities, whereas β -blockade may diminish them.^{43,49}

Abnormalities in filling are also associated with changes in chamber stiffness that occur in HCM. This stiffness may be the result of myocardial fibrosis, cellular disorganization, or increased myocardial mass. The decreased distensibility leads to an abnormally steep slope of the diastolic pressure-volume curve such that an increase in LV volume results in a disproportionate increase in diastolic pressure.

Myocardial relaxation is an energy-dependent process that is sensitive to episodes of ischemia. Diastolic resequestration of calcium ions by the sarcoplasmic reticulum is an energy-dependent process. In the event of ischemia, the sequestration of calcium is inhibited, allowing the calcium to continue its interaction with the myofibrillar contractile proteins. CCBs have been used with some success in patients with diastolic dysfunction.⁴³

Systolic Function and Outflow Tract Obstruction

Abnormalities of systolic function also occur in patients with HCM. The hypertrophied left ventricle may cause a powerful but sometimes uncoordinated contraction presumably owing to the abnormal architecture of the myocardium. The increase seen in the LV wall thickness results in decreased wall stress during systole. Therefore, the left ventricle contracts against a decreased afterload so that the left ventricle is described as being *hyperdynamic*. EF often is increased.

Considerable controversy has surrounded the issue of the importance of outflow tract obstruction in conjunction with HCM. The presence of a gradient (the systolic pressure difference between the body and the outflow tract of the left ventricle) is indicative of a dynamic obstruction of the LV outflow tract. Outflow tract gradients occur in about 25% of patients with HCM.⁵⁰ The obstruction that occurs usually shows spontaneous variability and may be reduced by interventions that decrease myocardial contractility. The gradient can be augmented by factors that increase contractility⁴³ (Table 18–4). LV outflow tract obstruction at rest has been found to be a predictor of progression to severe HF symptoms, stroke, and death.⁵⁰

Myocardial Ischemia

Chest pain in the absence of CAD is a common symptom of patients with HCM. However, it is appropriate to consider typical CAD in any patient with HCM if they have the usual risk factors for atherosclerosis.^{43,45,51} There are several mechanisms proposed for the myocardial ischemia seen in this patient population. There may be inadequate capillary density in relation to the increased LV muscle mass. The small intramural coronary arteries may be abnormally narrowed

TABLE 18–4. Factors Known to Affect Outflow Gradients in HCM

or excessively compressed during systole. Impaired relaxation during diastole may inhibit blood flow to the subendocardium. Once myocardial ischemia develops, further increases in LV filling pressure may occur, which, in turn, leads to more ischemia. Repeated episodes of ischemia may be responsible for progressive myocyte loss and fibrosis. The subendocardium is at greatest risk for ischemic damage owing to the lower capillary density and higher oxygen demand secondary to wall tension.⁴³

DIAGNOSIS

It may be difficult to make the diagnosis of HCM because the disorder may be confused with CAD, aortic stenosis, or mitral regurgitation. Patients with HCM can be young and physically active. The physical signs of the cardiac examination depend on the presence of a systolic pressure gradient within the left ventricle. If a gradient is present, a late-onset systolic murmur is heard often. The murmur is intensified by standing and the Valsalva maneuver and lessened with squatting or handgrip. Very rarely, some patients develop an end-stage LV dilatation and a declining LV ejection fraction, which is often confused with idiopathic dilated cardiomyopathy.

Echocardiography is used to confirm the diagnosis. The diagnosis of HCM is made with two-dimensional echocardiography, with the usual criteria being LV wall thickness greater than or equal to 15 mm.⁵¹ Magnetic resonance imaging (MRI) of the entire left ventricle may add valuable information, especially if the echocardiogram is of suboptimal quality.

The development of or increase in a murmur suggests progression of disease, but disappearance of a murmur does not imply improvement. In fact, disappearance of a murmur may herald further impairment of systolic function. Some patients will progress to CHF owing to atrial fibrillation, mitral regurgitation, or MI. If SHF develops, the patient has a poor prognosis.

CLINICAL PRESENTATION: HYPERTROPHIC CARDIOMYOPATHY

GENERAL

The clinical presentation varies widely, ranging from no symptoms to severe symptoms of angina, HF, and/or sudden cardiac death. The severity of symptoms corresponds to the degree of LVH, but this relationship is not absolute.

SYMPTOMS

- Dyspnea
- Chest pain
- Fatigue

- Palpitations
- Presyncope
- Syncope

SIGNS

- Systolic murmur

ELECTROCARDIOGRAM

- LV hypertrophy
- ST-segment and T-wave abnormalities

ECHOCARDIOGRAM

- Increased myocardial mass

PROGNOSIS

The clinical course for a patient with HCM should be viewed in terms of the specific subtypes of the disease spectrum. Patients fall into one of several relatively discrete pathways: (1) high risk for sudden death, (2) symptoms of DHF, including syncope, (3) progression toward advanced end-stage HF, and (4) atrial fibrillation and its sequelae.⁵¹ Of major concern is the incidence of sudden cardiac death among patients with HCM. Approximately 10% to 20% of HCM patients are at increased risk for sudden death. The mechanism responsible for sudden cardiac death is thought to be related to an electrically unstable myocardium leading to complex ventricular arrhythmias. Less often, sudden death may be the result of hemodynamic changes. The onset of atrial fibrillation in the face of severe LV diastolic dysfunction may result in a significant decrease in stroke volume. This decrease in cardiac output could lead acute LV failure, MI, or sudden death. Sudden death can be a complication, especially in young athletes with

TABLE 18–5. Risk Factors Associated with Sudden Cardiac Death in HCM

| |
|---|
| Prior cardiac arrest |
| Spontaneous sustained ventricular tachycardia |
| Positive family history of premature death related to HCM |
| Multiple syncopal or near-syncopal episodes, especially if associated with exertion |
| Multiple and repetitive or prolonged episodes of nonsustained ventricular tachycardia |
| Marked left ventricular hypertrophy |
| Hypotensive blood pressure response to exercise |

HCM. It is recommended that young patients with HCM refrain from competitive athletics.⁵¹

Quantification of the risk of sudden death remains elusive for patients with HCM. The clinical markers associated with an increased risk for sudden death (Table 18–5) have a high negative predictive value. The absence of all these markers can be used to develop a profile for a patient at low risk of sudden death. The magnitude of hypertrophy appears to be a strong predictor, with the cumulative risk nearly zero for patients with a wall thickness of 19 mm or less.⁴⁸ Young patients with severe hypertrophy (wall thickness > 30 mm) are at a high risk for sudden death even if they are asymptomatic. A high LV outflow tract pressure gradient (>30 mm Hg) is a strong predictor for older patients.⁵² Presentation of HCM in the latter decades of life is common. Patients who present with HCM at an advanced age (>65 years) usually have a prognosis that is no different from that of age- and gender-matched controls. Elderly patients with HCM tend to have mild degrees of LVH, and their symptoms are not severe.⁵³ Since systolic hypertension and diastolic HF are common in the elderly, the diagnosis of HCM may be challenging. However, marked LVH out of proportion to blood pressure, unusual patterns of LVH, or an outflow obstruction at rest strongly suggests HCM.⁵¹

► TREATMENT: Hypertrophic Cardiomyopathy**■ DESIRED OUTCOMES**

Because there are no known means available to prevent HCM, the focus must be on methods to minimize the consequences of the disorder.

■ GENERAL APPROACH TO TREATMENT

The treatment of HCM is designed to reduce symptoms, improve exercise tolerance, retard disease progression, and improve prognosis. Agents that decrease contractility, improve diastolic dysfunction, reduce ischemia, and suppress arrhythmias have been used with some success (Fig. 18–4). In 2003, the American College of Cardiology in conjunction with the European Society of Cardiology published a consensus document on HCM.⁵¹

■ NONPHARMACOLOGIC THERAPY

Surgical treatment generally is reserved for patients who are refractory to medical management, have an outflow gradient of 50 mm Hg or more, a very thick ventricular septum, and high LV pressures. Surgical

intervention is designed to relieve the outflow obstruction and the elevated LV pressures. The surgeon accomplishes this by performing a myectomy, or removal of excess tissue. The procedure results in a reduction in LV filling pressures and a long-term improvement in symptoms. However, early mortality rates of up to 5% have been reported.^{49,51} Other complications may include septal perforation and late occurrence of CHF.

The results of uncontrolled studies suggested that dual-chamber pacing decreased LV outflow gradients and improved symptoms. Subsequent controlled trials were not able to replicate the initial findings but demonstrated more modest improvement. Consequently, the American College of Cardiology, the American Heart Association, and the North American Society of Pacing and Electrophysiology (ACC/AHA/NASPE) have issued guidelines suggesting pacing for severely symptomatic patients who have failed medical management (class IIB recommendation, or one in which the efficacy is less well established by evidence).⁵⁴

Ablation of the myocardium using alcohol is another alternative to surgery. Septal ablation with alcohol results in the same type of outcomes as seen with myectomy. Long-term follow-up is limited because this procedure has been used for less than a decade. Since it is a percutaneous procedure (similar to cardiac catheterizations), it is being done more frequently than myectomy.⁵¹ There is some concern that the risk for arrhythmia-related cardiac events may increase following alcohol ablation. Long-term follow-up is needed to assess this risk. Complete heart block is a common complication of septal

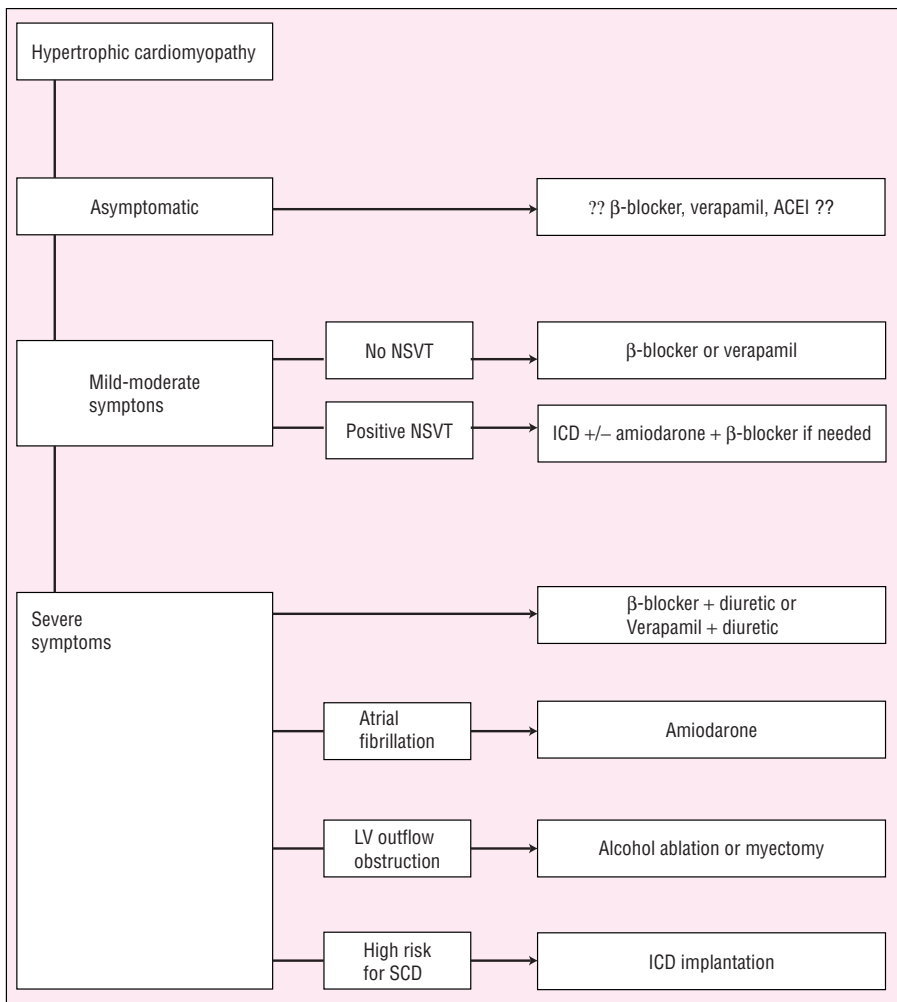

FIGURE 18–4. Treatment algorithm for hypertrophic cardiomyopathy. ACEI = angiotensin-converting enzyme inhibitor; NSVT = nonsustained ventricular tachycardia; ICD = implantable cardioverter-defibrillator; LV = left ventricular; SCD = sudden cardiac death.

ablation (14% in one case series) and requires a permanent pacemaker if it occurs.⁵⁵

■ IMPLANTABLE CARIOVERTER-DEFIBRILLATOR (ICD)

8 Sudden death is the most worrisome outcome of HCM, and the ICD is the most effective treatment for the prevention of sudden death.⁵⁶ It is difficult to know when to implant an ICD, especially in a young patient diagnosed with HCM. Patients who are candidates for an ICD for primary prevention will be young and relatively asymptomatic. The ACC/AHA/NASPE 2002 guidelines have designated the ICD for primary prevention of sudden death (class IIb recommendation) and for secondary prevention following cardiac arrest (class I recommendation, where there is evidence or general agreement that the procedure is beneficial).⁵⁴ Conducting a clinical trial to provide evidence for a higher-level recommendation for primary prevention is unlikely to occur.⁵⁶

■ PHARMACOLOGIC THERAPY

■ β-BLOCKING AGENTS

9 β-Blocking agents have been used in obstructive and nonobstructive forms of HCM since the 1960s. Approximately one-

third to one-half of patients with angina, dyspnea, light-headedness, or syncope will have a favorable response to these agents.⁴³ Doses of up to 480 mg/day of propranolol or its equivalent are used. Resting heart rate should be 60 beats per minute, and the maximum exercise heart rate should be less than 120 beats per minute. The mechanism by which β-blockade is beneficial is by inhibiting sympathetic stimulation of the heart. Myocardial oxygen demand is reduced by decreasing heart rate, LV contractility, and myocardial wall stress during systole. Outflow tract obstruction may be minimized with β-blockade, especially under conditions of stress or exercise, when sympathetic stimulation is high.

■ CALCIUM CHANNEL BLOCKING AGENTS

Patients who have an inadequate response to β-blockade may respond to verapamil.⁴⁶ Doses of verapamil up to 480 mg/day have beneficial effects on symptoms.⁵¹ There are several reasons why CCBs may be of benefit to patients with HCM. Increased calcium concentrations have been shown to play a role in prolonging the ventricular action potential, as well as the duration of isometric contraction and relaxation. Patients with HCM have a hyperdynamic ventricle in systole and delayed relaxation and decreased compliance during diastole. CCBs decrease the myocardial oxygen demand, resulting in an improved balance between oxygen supply and demand; therefore, diastolic function may be improved.

Most patients with HCM who have been treated with a CCB have received verapamil, although others also have been used. Intravenous verapamil has been noted to reduce the outflow tract gradient in patients with obstructive HCM. The mechanism may be a decrease in systolic function, as well as an increase in LV volumes owing to an enhanced LV diastolic filling.

The adverse effects associated with the use of verapamil include constipation, sinus node blockade, prolongation of the PR interval, AV dissociation, hypotension, and pulmonary congestion.⁴³ The risks may outweigh the benefits in patients with (1) a markedly elevated pulmonary capillary wedge pressure or pulmonary artery occlusion pressure, (2) a history of paroxysmal nocturnal dyspnea or orthopnea, (3) sick sinus syndrome or significant AV nodal disease in the absence of a permanent pacemaker, (4) low systolic blood pressure, and (5) a substantial outflow gradient. Verapamil should be avoided in patients with heart failure owing to systolic dysfunction.⁵¹ There is no evidence that either β -blockade or verapamil protects the patient from sudden cardiac death.

Studies using other CCBs are limited. Improvement in diastolic dysfunction may occur, but the dihydropyridines may cause a reflex increase in heart rate or hypotension or worsen the outflow tract gradient.

■ ANTIARRHYTHMIC AGENTS

Disopyramide has been used in treating both the supraventricular and ventricular arrhythmias occurring in patients with HCM. In addition, the negative inotropic effect and the ability to increase peripheral vascular resistance attributed to disopyramide have been used to reduce

outflow tract obstruction. The anticholinergic side effects (blurred vision, dry mouth, and urinary retention) make disopyramide a problematic agent for long-term therapy in some patients. The QT interval on the ECG should be monitored in patients on disopyramide.⁵¹

A significant number of patients with HCM develop atrial fibrillation. Amiodarone is one of the most effective agents available to maintain normal sinus rhythm in these patients. For patients in chronic atrial fibrillation requiring rate control, a β -blocker or verapamil may be used.⁴⁵ Anticoagulation should be considered because these patients are at a risk for systemic embolization and stroke. If amiodarone is added to a patient already receiving warfarin, the prothrombin time or international normalized ratio (INR) will be increased and should be monitored closely.

■ OTHER DRUGS

◀ There is a small risk for bacterial endocarditis in HCM patients with LV outflow obstruction under resting conditions and in those with intrinsic mitral valve disease.⁵¹ Patients undergoing dental or selected surgical procedures that cause blood-borne bacteremia should receive appropriate antibiotic therapy. The administration of nitroglycerin and digoxin generally is discouraged in the presence of a LV outflow obstruction.⁵¹

CLINICAL CONTROVERSY

Some clinicians believe that ACE inhibitors have no role in the management of HCM with LV outflow obstruction. Others believe that they may be beneficial by limiting hypertrophy.

EVALUATION OF THERAPEUTIC OUTCOMES

The goal of treatment of patients with HCM is primarily to reduce their symptoms of dyspnea and exercise intolerance. Either β -blockers or CCBs may be used. If a β -blocker is chosen, it is best to use an agent that does not have intrinsic sympathomimetic activity. The dose should be maximized. If the patient does not tolerate a β -blocker or has a contraindication to the use of a β -blocker, then verapamil may be tried. Patients should be monitored for resolution of symptoms and an increase in exercise tolerance. Resolution of symptoms may take months to occur. In addition, both β -blockers and CCBs may cause hypotension and conduction abnormalities. β -Blockers may worsen pulmonary function. If dyspnea continues with maximal doses of a β -blocker or CCB, a diuretic agent or a nitrate may be added with caution. Patients who are at high risk for sudden cardiac death should be considered candidates for an ICD.

For patients with a significant obstruction to LV outflow who do not respond to medical management, a surgical approach may be necessary. Septal myectomy and alcohol ablation have been employed. These approaches generally are reserved for patients who have an outflow gradient of more than 50 mm Hg and/or severe symptoms and who have failed an adequate trial of medical therapy.

RESTRICTIVE CARDIOMYOPATHY

Restrictive cardiomyopathy is primarily an abnormality of diastolic function that results in impaired filling and increases in ventricular end-diastolic pressures with normal or decreased diastolic volume. It is associated with normal systolic function early in the course of the disease but a decrease in systolic function later in the disease

process. Either one or both of the ventricles may be affected; therefore, restrictive cardiomyopathy may present as either left- or right-sided heart failure.⁵⁷

CLINICAL PRESENTATION: RESTRICTIVE CARDIOMYOPATHY

SYMPTOMS

- Dyspnea
- Orthopnea
- Fatigue
- Edema
- Ascites
- Chest pain

SIGNS

- Significant jugular venous distention
- Mitral and/or tricuspid regurgitant murmurs
- Thromboembolic complications
- Kussmaul's sign may be present

ELECTROCARDIOGRAM

- Atrial arrhythmias
- Tachy-brady syndrome
- Conduction abnormalities

EPIDEMIOLOGY AND ETIOLOGY

Restrictive cardiomyopathy is the type of cardiomyopathy encountered least frequently in Western countries. Since the occurrence

of restrictive cardiomyopathy is rare, the natural course of the disease is not well characterized, and reports on prognosis have been highly variable. Restrictive cardiomyopathies may be classified as either myocardial or endomyocardial. The myocardial types may be noninfiltrative, infiltrative, or storage diseases. The endomyocardial types are due to endomyocardial fibrosis, hypereosinophilic syndrome, carcinoid heart disease, metastatic cancers, radiation, and anthracycline toxicity or secondary to drugs known to cause fibrosis.⁵⁷

Restrictive myocardial disease may result from several local or systemic disorders. Amyloidosis, hemochromatosis, scleroderma, carcinoid, sarcoidosis, diabetes, pseudoxanthoma elasticum, and endomyocardial fibrosis have been known to cause restrictive cardiomyopathy. The most common cause of restrictive cardiomyopathy in the industrialized world is amyloidosis, whereas endomyocardial fibrosis is a common cause in tropical areas of the world. There may be a genetic predisposition to idiopathic restrictive cardiomyopathy.⁵⁷

The cause of the disease, the severity of HF symptoms, and the presence of cardiac thrombi and arrhythmias are factors that affect long-term survival. Children diagnosed with restrictive

cardiomyopathy have a worse prognosis than adults and should be considered for early cardiac transplantation.⁵⁸

PATHOPHYSIOLOGY

The major hemodynamic abnormality in restrictive cardiomyopathy is a limitation in ventricular filling leading to increased filling pressures. The cavity size and wall thickness of the ventricles are usually normal. Atrial dimensions often are increased. Thrombi are found frequently in the cardiac chambers. Patients have signs and symptoms consistent with CHF. The abnormality is similar to what is seen in pericardial disease causing constriction or tamponade.

DIAGNOSIS

The diagnosis of restrictive cardiomyopathy should be considered in any patient who presents with signs and symptoms of CHF but has only mild cardiomegaly. Differentiation from constrictive pericarditis is important because pericardectomy is an effective form of treatment for constrictive pericarditis.

► TREATMENT: Restrictive Cardiomyopathy

The treatment of restrictive cardiomyopathy is complex because of the heterogeneity of the pathophysiologic abnormalities. Diuretics are used for the symptoms of venous congestion in the presence of restrictive cardiomyopathy, but caution is advised because these patients require high filling pressures to maintain an adequate stroke volume and cardiac output. Hypotension and hypoperfusion may occur as a result of the excessive use of diuretics. Because systolic function is often normal, digoxin is of little benefit and may be proarrhythmic.

Amiodarone may be used to maintain normal sinus rhythm in patients who have episodes of atrial fibrillation. Anticoagulation is needed to decrease the risk of systemic embolization, particularly in patients with atrial fibrillation, valvular regurgitation, and low cardiac output. In the case of hemochromatosis, chelation therapy and/or repeated phlebotomy may be of benefit. Treatment with corticosteroids and cytotoxic drugs has been used with some success in the early phase of endomyocardial fibrosis and eosinophilic cardiomyopathy.⁵⁷

EVALUATION OF THERAPEUTIC OUTCOMES

The first step in assessing and treating a patient with restrictive cardiomyopathy is to rule out constrictive pericarditis because the two conditions have a similar presentation. Constrictive pericarditis is treated easily with surgery, whereas patients with restrictive cardiomyopathy have a varied approach to therapy depending on the etiology of their disorder. The treatment is aimed at relieving the symptoms associated with high filling pressures. This is achieved generally through the use of diuretics. Diuretic therapy should be initiated with low doses. Normalization of filling pressures is not possible or desirable. Patients' symptoms should be monitored for improvement. Excessive diuresis will result in an inadequate cardiac output. Chelation therapy has been advocated for patients with hemochromatosis. Prednisone has been suggested for patients with sarcoidosis. There is no curative treatment for restrictive cardiomyopathy.

VENOUS THROMBOEMBOLISM

Stuart T. Haines, Mario Zeolla, and Daniel M. Witt

Learning Objectives and other resources can be found at www.pharmacotherapyonline.com.

KEY CONCEPTS

- 1 The risk of venous thromboembolism (VTE) is related to several easily identifiable factors, including age, major surgery (particularly orthopedic procedures of the lower extremities), previous VTE, trauma, malignancy, and hypercoagulable states. These risks are additive.
- 2 The diagnosis of VTE must be confirmed by an objective test.
- 3 Antithrombotic therapies require meticulous and systematic monitoring as well as ongoing patient education. Well-organized anticoagulation management services improve the quality of patient care and reduce overall cost.
- 4 Bleeding is the most common adverse effect associated with anticoagulant drugs. A patient's risk of major hemorrhage is related to the intensity and stability of therapy, concurrent drug use, history of gastrointestinal bleeding, risk of fall/trauma, recent surgery, and age.
- 5 Warfarin is prone to numerous clinically important drug-drug and drug-food interactions.
- 6 At the time of hospital admission, all patients should receive prophylaxis against VTE that corresponds to their level of risk. Prophylaxis should be continued throughout the period of risk.
- 7 In the absence of contraindications, the treatment of VTE initially should include a rapid-acting anticoagulant (e.g., unfractionated heparin [UFH], a low-molecular-weight heparin [LMWH], or fondaparinux) overlapped with warfarin for at least 5 days and until the patient's international normalized ratio (INR) is greater than 2.0. Anticoagulation therapy should be continued for a minimum of 3 months. The duration of anticoagulation therapy should be based on the patient's risk of VTE recurrence and major bleeding.
- 8 Most patients with an uncomplicated deep vein thrombosis (DVT) can be managed safely on an outpatient basis.
- 9 Heparin-induced thrombocytopenia (HIT) frequently goes unrecognized and is associated with a high risk of thrombosis and mortality. HIT is diagnosed based on clinical and laboratory data. It requires aggressive treatment with a direct thrombin inhibitor.

Venous thromboembolism (VTE) is a potentially fatal disorder and a significant national health problem in our aging society.^{1,2} Although it can strike young, otherwise healthy adults, it occurs most frequently in patients who sustain multiple traumas, undergo major surgery, are immobile for a lengthy period of time, or have a hypercoagulable disorder. Resulting from clot formation within the venous circulation (Fig. 19–1), VTE is manifested as deep vein thrombosis (DVT) and pulmonary embolism (PE). Death from pulmonary embolism can occur within minutes of the onset of symptoms, before effective treatment can be given.

Unfortunately, the disease is often clinically silent and the first manifestation may be sudden death. In some case series, 80% of patients who died suddenly had some evidence of pulmonary embolism at the time of autopsy.³ Beyond the symptoms produced by the acute event, the long-term sequelae of VTE, such as the postthrombotic syndrome and recurrent thromboembolic events, also cause substantial pain and suffering.¹

The treatment of VTE is fraught with substantial risks.⁴ Antithrombotic drugs require precise dosing and meticulous monitoring.^{5–8} Systematic approaches to drug-therapy management substantially reduce the risks, but bleeding remains an all too common

and serious complication of administering antithrombotic drugs.^{8,9} Therefore, the prevention of VTE in at-risk patients is paramount to improving outcomes.³ When there is a suspicion of VTE, the rapid and accurate diagnosis of the disorder is critical to making appropriate treatment decisions.¹⁰ The optimal use of antithrombotic drugs requires not only an in-depth knowledge of their pharmacology and pharmacokinetic properties but also a comprehensive approach to patient management.^{6,11}

EPIDEMIOLOGY

The true incidence of VTE in the general population is unknown because a substantial portion of patients, perhaps greater than 50%, have clinically silent disease. An estimated 2 million people in the United States develop VTE each year; 600,000 are hospitalized, and 60,000 die.¹² The estimated annual direct medical costs of managing the disease are well over \$1 billion and growing. The best available data indicate the age-adjusted annual incidence of symptomatic VTE in Caucasians to be 117 per 100,000.¹³ The incidence of VTE nearly doubles in each decade of life over the age of 50 and is slightly higher

FIGURE 19-1. Venous circulation.

in men. The age-adjusted incidence of PE has declined slightly in recent years, presumably because of heightened awareness of VTE, effective prevention strategies, early diagnosis, and prompt treatment. However, as the population ages, the total number of cases of DVT and PE continues to climb.

Relatively little is known about the risk of VTE in ethnic populations. African-Americans appear to be at somewhat higher risk of VTE than are Americans of predominantly European ancestry, whereas Hispanic-Americans may be somewhat protected.¹⁴ Asian-Americans and Pacific Islanders appear to have a strikingly lower incidence of VTE.

The incidence of VTE in specific high-risk patient populations has been studied extensively.³ Patients who sustain multiple trauma or undergo an orthopedic procedure involving a lower extremity are at particularly high risk, with the incidence of VTE often exceeding 50% in the absence of effective prophylaxis. Among those undergoing major surgeries other than procedures involving the lower extremities, the incidence of VTE is 20% to 40% when one or more other risk factors are present, such as age over 60 years. The long-term incidence of VTE among patients who have a prior history of VTE or who have metastatic cancer is extremely high.^{15,16} Likewise, the incidence of VTE after myocardial infarction, stroke, and spinal cord injury is high.³ Several disorders of hypercoagulability also have been linked to a high lifetime incidence of VTE.^{17,18}

ETIOLOGY

▶ A number of factors increase the risk of developing VTE (Table 19-1). These risk factors are additive and can be identified easily in clinical practice. A prior history of venous thrombosis is perhaps the strongest risk factors for recurrent VTE, presumably because of the destruction of venous valves and obstruction of blood flow caused by the initial event.¹⁹ Rapid blood flow has an inhibitory effect on thrombus formation, but a slow rate of flow reduces the clearance and dilution of activated clotting factors in the zone of injury and slows the influx of regulatory substances. Stasis tips the delicate balance of procoagulation and anticoagulation in favor of thrombogenesis. The rate of blood flow in the venous circulation, particularly in the deep veins of the lower extremities, is relatively slow. Valves in the deep veins of the legs, as well as contraction of the calf and thigh muscles, facilitate the flow of blood back to the heart and lungs. Damage to the venous valves and prolonged periods of immobility result in venous stasis. Vessel obstruction, either from external compression or a thrombus, also promotes clot propagation. Reduced venous blood flow explains, at least in part, why numerous medical conditions and surgical procedures are associated with an increased risk of VTE (see Table 19-1). Greater than normal blood viscosity, as seen in myeloproliferative disorders such as polycythemia vera, for example, also may contribute to slowed blood flow and thrombus formation.

TABLE 19–1. Risk Factors for Venous Thromboembolism

| Risk Factor | Example |
|------------------------|--|
| Age | Risk doubles with each decade after age 50 |
| History of VTE | Strongest known risk factor for DVT and PE |
| Venous stasis | Major medical illness (e.g., CHF, MI) Major surgery (e.g., general anesthesia >30 minutes) Paralysis (e.g., stroke, spinal cord injury) Polycythemia vera Obesity Varicose veins |
| Vascular injury | Major orthopedic surgery (e.g., knee and hip replacement) Trauma (esp. fractures of the pelvis, hip, or leg) Indwelling venous catheters |
| Hypercoagulable states | Malignancy, diagnosed or occult Activated protein C resistance/factor V Leiden Prothrombin (<i>20210A</i>) gene mutation Protein C deficiency Protein S deficiency Antithrombin (AT) deficiency Factor VIII excess (>90th percentile) Factor XI excess (>90th percentile) Antiphospholipid antibodies Dysfibrinogenemia Hyperhomocysteinemia Plasminogen activator inhibitor (PAI-1) excess Inflammatory bowel disease Nephrotic syndrome Pregnancy/postpartum |
| Drug therapy | Estrogen-containing oral contraceptive pills Estrogen-replacement therapy Selective estrogen-receptor modulators (SERMs) Heparin-induced thrombocytopenia (HIT) |

From refs. 3, 17, and 18.

A growing list of hereditary deficiencies, gene mutations, and acquired diseases has been linked to hypercoagulability^{17,18} (see Table 19–1). Activated protein C resistance is the most common genetic disorder of hypercoagulability, with a prevalence rate approaching 5% among community-dwelling Caucasians and a rate as high as 40% among those who suffer an idiopathic DVT or who have a strong family history of VTE. Although these patients have normal plasma concentrations of protein C, they often have a mutation on factor V that renders it resistant to degradation by activated protein C. This mutation is known as *factor V Leiden*, named after the city of Leiden, Holland, where the defect was initially reported. The prothrombin 20210A mutation also appears to be a relatively common defect, occurring in as many as 3% of healthy individuals of southern European ancestry and 16% of those with an idiopathic DVT. Although less common, inherited deficiencies of the natural anticoagulants protein C, protein S, and antithrombin place patients at a high lifetime risk for VTE. Conversely, excessively high concentrations of factors VIII, IX, and XI also increase the risk of VTE. Given the prevalence of these inherited abnormalities in the general population, some patients have multiple genetic defects that have additive effects in terms of increasing the lifetime thrombotic risk.

Acquired disorders of hypercoagulability may result from malignancy, the presence of antiphospholipid antibodies, and estrogen use. The strong link between cancer and thrombosis has been recognized

since the late 1800s.²⁰ Tumor cells secrete a number of procoagulant substances that activate the coagulation cascade. Further, patients with cancer often have suppressed levels of protein C, protein S, and antithrombin. It has been postulated that cancer cells use thrombotic mechanisms to recruit a blood supply (angiogenesis), metastasize, and create a barrier against host defense mechanisms. Antiphospholipid antibodies, most commonly found in patients with autoimmune disorders such as systemic lupus erythematosus (SLE) and inflammatory bowel disease, can cause venous and arterial thrombosis.¹⁷ These antibodies are also associated with repeated pregnancy loss due to placental thrombosis. The precise mechanism by which the antiphospholipid antibodies provoke thrombosis is unclear, but they appear to activate the coagulation cascade and platelets, as well as to inhibit the anticoagulant activity of proteins C and S. Estrogen-containing contraceptives, estrogen-replacement therapy, and the selective estrogen-receptor modulators (SERMs) all have been linked to venous thrombosis.²¹ Women with an underlying disorder of hypercoagulability are at particularly high risk of developing venous thrombosis while taking estrogens. While the mechanisms are not clearly understood, estrogens increase serum clotting factor concentrations and induce activated protein C resistance. Increased serum estrogen concentrations may explain, in part, the increased risk of VTE observed during pregnancy and the immediate postpartum period.²²

PATHOPHYSIOLOGY

The arrest of bleeding following vascular injury, or hemostasis, is essential to life.^{23,24} Within the vascular system, blood remains in a fluid state, transporting oxygen, nutrients, plasma proteins, and waste. With vascular injury, a dynamic series of reactions involving a complex interplay of thrombogenic and antithrombotic stimuli results in the local formation of a hemostatic plug that seals the vessel wall and prevents further blood loss (Table 19–2 and Figs. 19–2, 19–3, and 19–4). A disruption of this delicate system of checks and balances may lead to inappropriate clot formation within the blood vessel that

subsequently obstructs blood flow or embolizes to a distant vascular bed. In the late 1800s, Dr. Rudolf Virchow, a German pathologist, recognized the role played by blood vessels, circulating elements in the blood, and the speed of blood flow in the regulation of clot formation²³ (see Table 19-2). Alterations in any one of these elements, known today as *Virchow's triad*, may lead to pathologic clot formation.

Under normal circumstances, the endothelial cells that form the intima of vessels maintain blood flow by producing a number of substances that inhibit platelet adherence, prevent the activation of the coagulation cascade, and facilitate fibrinolysis.^{23,24} Vascular injury can expose the subendothelium (see Fig. 19-3). Platelets readily adhere to the subendothelium, using glycoprotein Ib receptors found on their surfaces and facilitated by von Willebrand factor. This causes platelets to become activated, releasing a number of procoagulant substances into the local circulation that stimulate platelets to expose glycoprotein IIb-IIIa receptors. These receptors allow the platelets to adhere to one another, resulting in platelet aggregation. In addition, the damaged vascular tissue releases tissue factor, also known as *tissue thromboplastin*, which activates the extrinsic pathway of the coagulation cascade (see Fig. 19-4).

The coagulation cascade is a stepwise series of enzymatic reactions that results in the formation of a fibrin mesh.^{23,24} Clotting factors

FIGURE 19-3. Vascular injury and thrombolysis. circulate in the blood in inactive forms. Specific stimuli convert an inactive precursor into an active form that, in turn, converts the next precursor in the sequence. It was once believed that all clotting factors were proteolytic enzymes, known as *zymogens*. It is now known that factors V and VIII have no enzymatic activity themselves but rather serve as cofactors that greatly accelerate the enzymatic activity of their respective partners. The final steps in the cascade are the conversion of prothrombin to thrombin and fibrinogen to fibrin. Thrombin plays a key role in the coagulation cascade; it is responsible not only for the production of fibrin but also for the conversion of factors V and VIII, creating a positive-feedback loop that greatly accelerates the production of more thrombin. Additionally, thrombin enhances platelet aggregation through its interactions with the glycoprotein IIb-IIIa receptor.

Traditionally, the coagulation cascade has been divided into three distinct parts: the intrinsic, extrinsic, and common pathways^{23,24} (see Fig. 19-4). This artificial division is somewhat misleading because there are numerous interactions among the three pathways. The extrinsic pathway, sometimes referred to as the *tissue factor pathway*, appears to be the principal mechanism that triggers the coagulation

cascade. Tissue factor, released from the subendothelium, forms a complex with factor VIIa. The factor VIIa–tissue factor complex activates factor X in the common pathway and factor IX in the intrinsic pathway. The intrinsic pathway may begin in several ways. Negatively charged surfaces in contact with the blood will activate factor XII, and activated platelets can convert factor XI. Both the intrinsic and extrinsic pathways meet at a common point with the activation of factor X. With its partner, factor Va, factor Xa converts prothrombin (II) to thrombin (IIa), which then cleaves fibrinogen to form fibrin monomers. Finally, as the fibrin monomers reach a critical concentration, they begin to precipitate and polymerize to form fibrin strands. Factor XIIIa covalently bonds these strands to one another.

Normally, a number of tempering mechanisms control coagulation^{23,24} (see Table 19-2 and Fig. 19-2). Without effective self-regulation, the coagulation cascade would proceed unabated until all the clotting factors and platelets were consumed. Thus the intact endothelium adjacent to the damaged tissue actively secretes several antithrombotic substances. As its name implies, thrombomodulin modulates thrombin activity by converting protein C to its active form. When joined with its cofactor, protein S, protein C enzymatically

inactivates factors Va and VIIIa. Activated protein C also stimulates the release of tissue plasminogen activator (t-PA). Antithrombin is a circulating protein that inhibits thrombin and factor Xa. Heparan sulfate, a heparin-like compound secreted by endothelial cells, exponentially accelerates antithrombin activity. By a similar mechanism, heparin cofactor II also inhibits thrombin. Tissue factor pathway inhibitor (TFPI) plays an important role by regulating the initiation of the coagulation cascade. When these self-regulatory mechanisms are intact, the formation of the fibrin clot is limited to the zone of tissue injury. However, disruptions in the system, so-called hypercoagulable states, often result in thrombosis.^{23,24}

The fibrinolytic protein plasmin degrades the fibrin mesh into soluble end products collectively known as *fibrin split products* or *fibrin degradation products*.^{23,24} The fibrinolytic system is also under the control of a series of stimulatory and inhibitory substances. Tissue plasminogen activator (t-PA) and urokinase plasminogen activator (u-PA) convert plasminogen to plasmin. Plasminogen activator inhibitor-1 (PAI-1) inhibits the plasminogen activators, and α_2 -antiplasmin inhibits plasmin activity. Aberrations in the fibrinolytic system also have been linked to hypercoagulability.

CLINICAL PRESENTATION AND DIAGNOSIS

Although a thrombus can form in any part of the venous circulation, the majority begin in the lower extremities. Once formed, a venous thrombus may either (1) remain asymptomatic, (2) lyse spontaneously, (3) obstruct the venous circulation, (4) propagate into

TABLE 19–3. Clinical Presentation of Deep Vein Thrombosis (DVT)

General

Venous thromboembolism most commonly develops in patients with identifiable risk factors (see Table 19–1) during or following a hospitalization. Many patients, perhaps the majority, have asymptomatic disease. Patients may die suddenly of pulmonary embolism.

Symptoms

The patient may complain of leg swelling, pain, or warmth.

Symptoms are nonspecific, and objective testing must be performed to establish the diagnosis.

Signs

- The patient's superficial veins may be dilated, and a "palpable cord" may be felt in the affected leg.
- The patient may experience pain in back of the knee when the examiner dorsiflexes the foot of the affected leg.

Laboratory Tests

- Serum concentrations of D-dimer, a by-product of thrombin generation, usually are elevated.
- The patient may have an elevated erythrocyte sedimentation rate (ESR) and white blood cell (WBC) count.

Diagnostic Tests

- Duplex ultrasonography is the most commonly used test to diagnosis DVT. It is a noninvasive test that can measure the rate and direction of blood flow and visualize clot formation in proximal veins of the legs. It cannot reliably detect small blood clots in distal veins. Coupled with a careful clinical assessment, it can rule in or out the diagnosis in the majority of cases.
- Venography (also known as phlebography) is the "gold standard" for the diagnosis of DVT. However, it is an invasive test that involves injection of radiopaque contrast dye into a foot vein. It is expensive and can cause anaphylaxis and nephrotoxicity.

more proximal veins, (5) embolize, or (6) act in any combination of these ways.¹⁰ Most patients with VTE never develop symptoms from the acute event.²⁵ However, even those who experience no symptoms may suffer long-term consequences, such as the postthrombotic syndrome and recurrent VTE. Even when symptoms of DVT or PE are present (Tables 19–3 and 19–4), they are nonspecific.^{1,26} It is extremely difficult to distinguish VTE from other disorders, and additional objective tests are required to confirm or exclude the diagnosis. Patients with DVT frequently present with unilateral leg pain and swelling. The postthrombotic syndrome, a long-term complication of DVT caused by damage to the venous valves, can produce symptoms very similar to those of an acute thrombotic event, including chronic lower extremity swelling, pain, tenderness, skin discoloration, and ulceration. Symptomatic PE often produces dyspnea, tachypnea, and tachycardia. Hemoptysis, while distressing, occurs in less than one-third of patients. Cardiovascular collapse, characterized by cyanosis, shock, and oliguria, is an ominous sign.

Given that VTE can be debilitating or fatal, it is important to treat it quickly and aggressively.^{2,10} On the other hand, because major bleeding induced by antithrombotic drugs can be equally harmful, it is important to avoid treatment when the diagnosis is not a reasonable

TABLE 19–4. Clinical Presentation of Pulmonary Embolism

General

Pulmonary embolism most commonly develops in patients with risk factors for VTE (see Table 19–1) during or following a hospitalization. While many patients develop a symptomatic DVT prior to developing a PE, many do not. Patients may die suddenly before effective treatment can be initiated.

Symptoms

The patient may complain of cough, chest pain, chest tightness, shortness of breath, or palpitation. The patient may spit or cough up blood (hemoptysis). When PE is massive, the patient may complain of dizziness or light-headedness. Symptoms may be confused with a myocardial infarction or pneumonia, and objective testing must be performed to establish the diagnosis.

Signs

The patient may have tachypnea (increased respiratory rate) and tachycardia (increased heart rate). The patient may appear diaphoretic (sweaty). The patient's neck veins may be distended. In massive PE, the patient may appear cyanotic and may become hypotensive. In such cases, oxygen saturation by pulse oximetry or arterial blood gas likely will indicate that the patient is hypoxic. In the worse case, the patient may go into circulatory shock and die within minutes.

Laboratory Tests

- Serum concentrations of D-dimer, a by-product of thrombin generation, usually are elevated.
- The patient may have an elevated erythrocyte sedimentation rate (ESR) and white blood cell (WBC) count.

Diagnostic Tests

- Ventilation-perfusion (\dot{V}/\dot{Q}) and computed tomographic (CT) scans are the most commonly used tests to diagnosis PE. A \dot{V}/\dot{Q} scan measures the distribution of blood and airflow in the lungs. When there is a large mismatch between blood and airflow in one area of the lung, there is a high probability that the patient has a PE. Spiral CT scans can detect emboli in the pulmonary arteries.
- Pulmonary angiography is the "gold standard" for the diagnosis of PE. However, it is an invasive test that involves injection of radiopaque contrast dye into the pulmonary artery. The test is expensive and associated with a significant risk of mortality.

certainty. Assessment of the patient's status should focus on a search for risk factors in the patient's medical history²⁷ (see Table 19–1). Venous thrombosis is uncommon in the absence of risk factors, and the effects of these risks are additive. Conversely, even when the symptoms are mild or vague, VTE should be strongly suspected in those with multiple risk factors.

2 Because radiographic contrast studies are the most accurate and reliable methods for the diagnosis of VTE, they are considered the “gold standards” in clinical trials.¹⁰ Contrast venography allows visualization of the entire venous system in the lower extremity and abdomen. Pulmonary angiography allows visualization of the pulmonary arteries. The diagnosis of VTE can be made if there is a persistent intraluminal filling defect observed on multiple x-ray films. Contrast studies are expensive, invasive procedures that are technically difficult to perform and evaluate. Severely ill patients are often unable to tolerate the procedure, and many develop hypotension and cardiac arrhythmias. Furthermore, the contrast medium is irritating to vessel walls and toxic to the kidneys. For these reasons, noninvasive tests, such as ultrasonography, computed tomographic (CT) scans, and the ventilation-perfusion (V/Q) scan, are used frequently in clinical practice for the initial evaluation of patients with suspected VTE.^{1,10}

Despite its pitfalls, clinical assessment improves the diagnostic accuracy of a noninvasive test.^{1,10} Simple assessment checklists can be used to stratify patients into high, moderate, and low probability of a DVT or PE (Table 19–5). Patients with a high pretest probability of VTE have a greater than 60% chance of having VTE compared with only 5% in the low pretest probability group. Clinical assessment can rule in or rule out the diagnosis of VTE with reasonable certainty when its results are concordant with those of a noninvasive test.^{1,10,26} In patients with a moderate pretest probability of VTE and an abnormal lower extremity ultrasonogram, the diagnosis of VTE can be reasonably concluded. If the results of the

clinical assessment and the ultrasonogram are discordant, venography or angiography should be performed to make the definitive diagnosis.

► TREATMENT: Venous Thromboembolism

■ PHARMACOLOGIC AGENTS USED IN THE MANAGEMENT OF VTE

■ UNFRACTIONATED HEPARIN (UFH)

Since the 1930s, clinicians have used unfractionated heparin (UFH) for the prevention and treatment of thrombosis.⁷ McLean discovered UFH in 1916 when he found that an extract of dog liver was an inhibitor of coagulation.²⁸ While it has been known since 1939 that UFH requires a “heparin cofactor” to produce an anticoagulant effect, it was not until 1968 that antithrombin (previously known as antithrombin III) was identified and isolated. Soon thereafter it was recognized that UFH greatly accelerated the activity of antithrombin. Commercially available UFH preparations are derived from bovine lung or porcine intestinal mucosa. Although some differences exist between those two preparations, no differences in antithrombotic activity have been demonstrated. Today, UFH and the low-molecular-weight heparins (LMWHs) are the mainstays for the acute treatment of arterial and venous thrombosis.⁷

■ Pharmacology

UFH is a heterogeneous mixture of sulfated glycosaminoglycans of variable lengths and pharmacologic properties²⁸ (Table 19–6). Each

heparin molecule is composed of repetitive units of D-glycosamine and uronic acid. The molecular weights of these molecules range from 5000 to 30,000 Da, with a mean of 15,000 Da.⁷ The anticoagulant profile and clearance of each UFH molecule varies based on its length. The smaller chains are cleared less rapidly than their longer counterparts.

The anticoagulant effect of UFH is mediated through a specific pentasaccharide sequence on the heparin molecule that binds to antithrombin, provoking a conformational change⁷ (Fig. 19–5). Only one-third of the UFH molecules possess the unique pentasaccharide sequence with affinity for antithrombin.⁷ The UFH-antithrombin complex is 100 to 1000 times more potent as an anticoagulant compared with antithrombin alone. Antithrombin inhibits the activity of several clotting factors, including factors IXa, Xa, and XIIa and thrombin⁷ (see Fig. 19–4). Through its action on thrombin, the UFH-antithrombin complex also inhibits the thrombin-induced activation of factors V and VIII.⁷ UFH prevents the growth and propagation of a formed thrombus and allows the patient's own thrombolytic system to degrade the clot.

Factors IIa and Xa are the most sensitive to inhibition by the UFH-antithrombin complex. In order to inactivate thrombin, the heparin molecule must form a ternary complex bridging between antithrombin and thrombin⁷ (see Fig. 19–5). Only molecules that contain more than 18 saccharides are able to bind to both antithrombin and thrombin simultaneously. Smaller heparin molecules cannot facilitate

TABLE 19–6. Comparison of the Chemical and Pharmacokinetic Properties of Antithrombotic Drugs Used for VTE

| Agent (Trade Name) | FDA-Approved (2004) | Method of Preparation | Mean Molecular Weight (Da) | Plasma Half-Life | Anti-Xa–Anti-IIa activity | Bioavailability |

the interaction between antithrombin and thrombin.⁷ In contrast, the inactivation of factor Xa does not require UFH to form a bridge with antithrombin. It only requires that UFH bind to antithrombin using the specific pentasaccharide sequence. Heparin molecules with as few as five saccharide units are able to catalyze the inhibition of factor Xa.⁷ Heparin uncouples from antithrombin after it has produced its effect and quickly recouples with another antithrombin molecule. Because of its relatively large size, the UFH-antithrombin complex is incapable of inactivating thrombin or factor Xa within a formed clot or bound to surfaces. At high doses, UFH also binds to heparin cofactor II, further inhibiting the activity of thrombin.⁷ UFH increases the release of TFPI from vascular endothelium, augmenting its inhibitory effect on factor Xa.⁷ UFH, especially high-molecular-weight heparin fractions, also binds to platelets and inhibits platelet aggregation.

■ Pharmacokinetics

UFH is not absorbed reliably when taken orally because of its large molecular size and anionic structure. The bioavailability and biologic activity of UFH are limited by its propensity to bind to plasma proteins, platelet factor-4 (PF-4), macrophages, fibrinogen, lipoproteins, and endothelial cells.^{7,28} This may explain the substantial inter- and inpatient variability observed in the anticoagulation response to UFH. Patients who are acutely ill or have active thrombosis have rapid changes in the circulating levels of these heparin-binding proteins.

These patients often appear to have “heparin resistance,” requiring relatively high doses of UFH to achieve a therapeutic response.⁷

The subcutaneous bioavailability of UFH is dose-dependent and ranges from 30% at low doses to as much as 70% at high doses. Higher doses presumably saturate protein-binding sites, thereby permitting a larger proportion to reach the systemic circulation. The onset of anticoagulant effect is usually evident 1 to 2 hours after subcutaneous injection.⁷ Because of its unpredictable absorption and delayed onset when administered subcutaneously, heparin should be administered intravenously when the patient requires rapid anticoagulation. A continuous intravenous infusion is preferable. Intermittent intravenous boluses produce relatively high peaks in anticoagulation activity and have been associated with a greater risk of major bleeding.⁷ Intramuscular administration is discouraged because the absorption is erratic, and it may result in large hematomas.

The volume of distribution of UFH is similar to blood volume ($V_D = 60 \text{ mL/kg}$).⁷ The dose required to achieve a therapeutic anticoagulation response is correlated to weight. Obese patients do not have a proportional increase in blood volume relative to body weight. However, it is unclear if the patient’s actual or adjusted body weight should be used when calculating initial heparin doses for obese patients.

UFH has a dose-dependent half-life of approximately 30 to 90 minutes but may be prolonged to as much as 150 minutes when given in high doses to some patients.⁷ There are two primary mechanisms for the elimination of UFH.^{7,28} The relative contribution of each mechanism to the total clearance of heparin is related to the

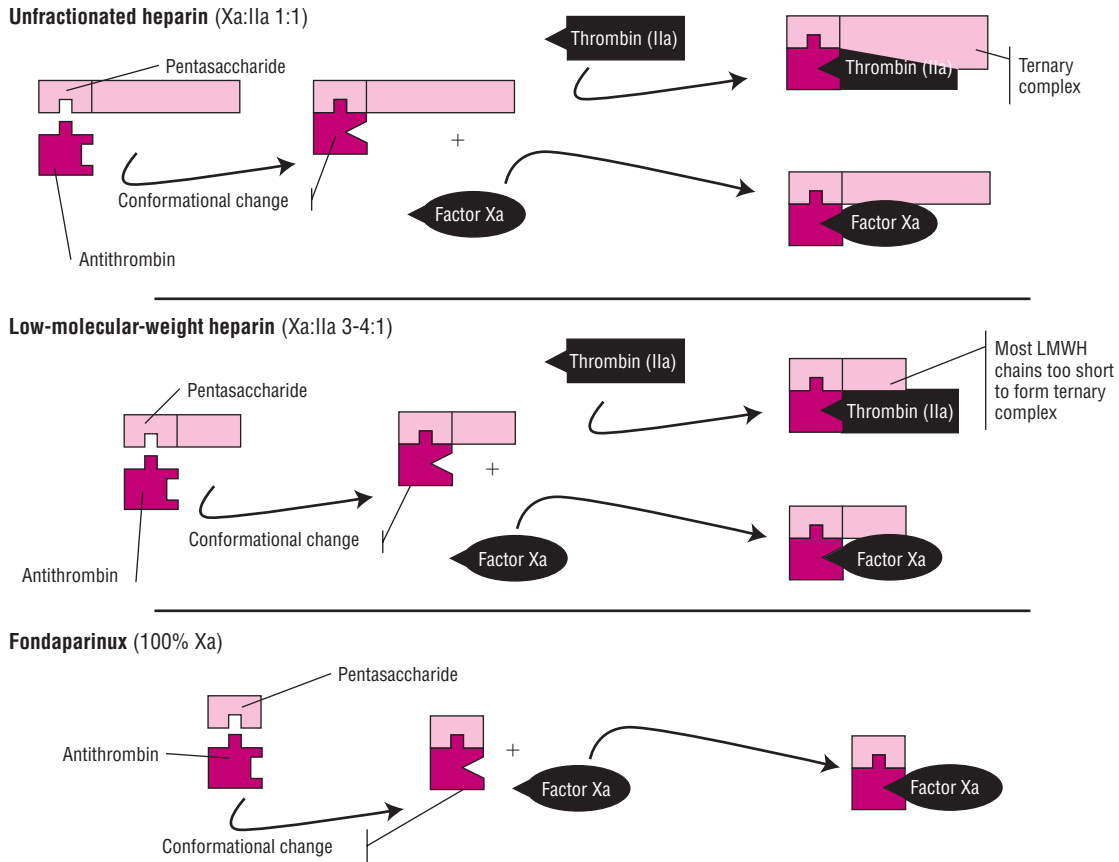

FIGURE 19-5. Pharmacologic activity of unfractionated heparin, low-molecular-weight heparins, and fondaparinux. AT = antithrombin.

dose and size of the UFH molecules. One mechanism is a rapid but saturable zero-order process. Heparinases and desulfatases enzymatically inactivate heparin molecules bound to endothelial cells and macrophages, reducing them to smaller and less sulfated molecules. Heparin is also eliminated renally. This first-order process is slower and nonsaturable. Low doses of UFH are cleared principally by the saturable, rapid zero-order mechanism, whereas the renal route predominates at very high doses. With typical regimens, a combination of the two mechanisms is used to eliminate UFH. Renal and hepatic dysfunction reduces the rate of clearance of UFH. Patients with active thrombosis may eliminate UFH more rapidly, possibly because of increased binding to acute-phase reactants.

Dose and Administration

The dose and route of administration for UFH heparin are based on the indication, the therapeutic goals, and the patient’s individual response to therapy.⁷ The dose of UFH is expressed in units of activity. The number of units per milligram is variable and depends on the manufacturing process.²⁸ For the prevention of VTE, UFH is given by subcutaneous injection in the abdominal fat layer. The typical dose for prophylaxis is 5000 units every 8 to 12 hours. When immediate and full anticoagulation is required, a weight-based intravenous bolus dose followed by a continuous infusion is preferred^{7,29} (Table 19-7). While some clinicians continue to use the time-honored “standard” dosing regimen consisting of a 5000-unit bolus followed by an infusion rate of 1000 to 1200 units per

TABLE 19-7. Weight-Based^a Dosing for UFH Administered by Continuous Intravenous Infusion

| Indication | Initial Loading Dose | Initial Infusion Rate |
|---|---|---|
| DVT/PE | 80–100 units/kg Maximum = 10,000 units | 17–20 units/kg/h Maximum = 2300 units/h |
| aPTT (s) | | Maintenance Infusion Rate Dose Adjustment |
| <37 (or > 12 s below institution-specific therapeutic range) | | 80 units/kg bolus; then increase infusion by 4 units/kg/h |
| 37–47 (or 1–12 s below institution-specific therapeutic range) | | 40 units/kg bolus; then increase infusion by 2 units/kg/h |
| 48–71 (within institution-specific therapeutic range) | | No change |
| 72–93 (or 1–22 s above institution-specific therapeutic range) | | Decrease infusion by 2 units/kg/h |
| >93 (or >22 s above institution-specific therapeutic range) | | Hold infusion for 1 h; then decrease by 3 units/kg/h |

^aUse actual body weight for all calculations. Adjusted body weight may be used for obese patients (>130% of IBW).
From refs. 7 and 29.

hour, a weight-based approach to UFH dosing is clearly superior. In clinical trials, weight-based dosing protocols substantially increased the proportion of patients who achieved a therapeutic response in the first 24 hours of therapy and decreased the number of recurrent thromboembolic events.²⁹ Specialized inpatient anticoagulation management services that actively monitor patients receiving UFH and warfarin therapy not only improve the quality of care but also have been shown to reduce the overall cost of care.⁹

Therapeutic Monitoring

Administration of UFH requires close monitoring because of the unpredictable anticoagulant response among patients.^{7,30} Several tests are available to monitor UFH therapy, including whole blood clotting time, activated partial thromboplastin time (aPTT), activated clotting time (ACT), anti-factor Xa activity, and plasma heparin concentrations. The aPTT is the most widely used test to determine the degree of anticoagulation. The therapeutic range of aPTT is traditionally considered to be 1.5 to 2.5 times the mean normal control value.^{7,30} Different commercial aPTT reagents vary in their responsiveness to heparin.^{31,32} The use of a fixed aPTT therapeutic range of 1.5 to 2.5 times the control represents a subtherapeutic response in many instances. Furthermore, there is no standard definition for the term *control value*, which may be interpreted to be either the average aPTT in healthy volunteers or the patient's baseline prior to treatment.

Recognizing the substantial variability in the aPTT, the College of American Pathologists recommends monitoring UFH therapy by establishing an institution-specific aPTT therapeutic range that correlates with a plasma heparin concentration of 0.2 to 0.4 units/mL by a protamine titration assay or 0.3 to 0.7 units/mL by an amidolytic anti-factor Xa assay.³⁰ Ideally, this should be done by comparing aPTT measurements with heparin levels or antifactor Xa activity in plasma samples obtained from patients treated with heparin. Alternatively, but considered a less reliable method, the aPTT reagent can be calibrated by adding heparin at several clinically relevant concentrations in vitro to several plasma samples.

The use of aPTT has several limitations.^{7,31} First, the aPTT does not reliably correlate with heparin concentrations because factors such as reagent sensitivity, temperature, collection methods, and hemodilution produce variability. Second, the turnaround time in most institutions is relatively slow because of the time required to collect and process the sample in a central laboratory. Third, while the aPTT can measure the intensity of anticoagulation when the heparin concentration is 0.1–1 units/mL, it is prolonged beyond measurable limits when the concentration exceeds 1 unit/mL. Fourth, the lower-molecular-weight heparin fragments accumulate but have little effect on the aPTT in vivo.^{7,31} Lastly, the data supporting the currently recommended heparin concentration therapeutic range are not robust. Despite these problems, most experts advocate using the aPTT to monitor UFH provided that institution-specific therapeutic ranges are defined.^{31,32}

When used in full therapeutic doses, UFH must be monitored to determine the appropriate dose to administer.^{7,30} The choice of assay is based on clinician preference and institutional availability. The aPTT remains the most commonly used test to monitor UFH therapy in North America. In some European countries, anti-factor Xa heparin activity is used commonly. The aPTT should be measured prior to the initiation of therapy to determine the patient's baseline. When administered by intravenous infusion, the response to therapy

should be measured 6 hours after the initiation of therapy or a dose change. This is the time required for heparin to reach steady state. The dose of heparin should be adjusted promptly based on the patient's response and the institution-specific therapeutic range (see Table 19–7). The aPTT is not suitable to monitor heparin therapy in patients requiring doses of heparin that will produce serum concentrations of greater than 1 unit/mL. The ACT is the most suitable assay when high doses of heparin are used, especially during coronary angioplasty or coronary bypass surgery.³⁰

Many patients with acute VTE and myocardial infarction have a diminished response to heparin, presumably because of variations in the plasma concentrations of heparin-binding proteins.^{7,28,33} Some patients have been reported to have acute elevations in factor VIII, preventing the prolongation of the aPTT by UFH. In some cases, antithrombin deficiency may be the culprit. The recommended management of patients with “heparin resistance” is to adjust the UFH dose based on anti-factor Xa concentrations. Approximately 50% of patients with this “heparin resistance” have dissociation between aPTT and heparin concentration as a result of an elevated factor VIII concentration. If anti-factor Xa concentrations cannot be measured readily, the dose of UFH should be increased until a therapeutic aPTT is achieved.

Adverse Effects

Bleeding is the primary adverse effect associated with all anticoagulant drugs⁴ (Table 19–8). UFH should not be administered to patients with contraindications to anticoagulation therapy (Table 19–9). The risk of bleeding is related to treatment intensity. Low-dose subcutaneous UFH is associated with a minimal risk of major bleeding. The rates of major bleeding for patients with VTE receiving full therapeutic doses of UFH via intravenous infusion for 5 to 10 days range from 2% to 4%, and the rate of fatal bleeding ranges from approximately 0% to 2%.⁴ The presence of concomitant bleeding risks such as thrombocytopenia, the use of other antithrombotic therapy, and a preexisting source of bleeding increase the risk of UFH-induced hemorrhage. The risk of bleeding also increases with age. Recent surgery, hemostatic defects, heavy alcohol consumption, renal failure, peptic ulcers, and neoplasms also increase the risk of major bleeding while receiving UFH.

The most common sites for bleeding are the gastrointestinal and urinary tracts, as well as soft tissues. Bruising at the site of injection is common. Local irritation, mild pain, erythema, histamine-like

reactions, and hematoma can occur. The calcium UFH preparation has been reported to cause hematoma less frequently than the sodium preparation.

Thrombocytopenia, defined as a platelet count less than 150,000/mm³, is common with UFH therapy.³⁴ Up to 30% of patients have some appreciable decline in their platelet count. Thrombocytopenia occurs more frequently with UFH preparations derived from bovine lung tissue than those from porcine gut. Two distinct clinical presentations for thrombocytopenia can occur during heparin therapy. Heparin-associated thrombocytopenia (HAT) is a benign, transient, and mild phenomenon generally occurring within the first few days of treatment in the heparin-naïve patient. Platelet counts rarely drop below 100,000/mm³ in patients with HAT and recover with continued therapy. On the other hand, heparin-induced thrombocytopenia (HIT) is a serious drug-induced problem requiring immediate intervention (see “Heparin-Induced Thrombocytopenia” section). Platelet counts must be monitored every 1 to 2 days, and the patient should be evaluated rigorously for HIT if the platelet count drops by more than 50% or to below 100,000/mm³.

Hypersensitivity reactions involving chills, fever, urticaria, and rarely, bronchospasm, nausea, vomiting, and shock have been reported in patients with HIT. Cutaneous necrosis is a rare but serious complication of UFH therapy that can occur in the setting of HIT.

Long-term UFH has been reported to cause alopecia, priapism, and suppressed aldosterone synthesis with subsequent hyperkalemia. The use of UFH for longer than 1 month has been associated with significant bone loss and may lead to osteoporosis.⁷

Few drug interactions have been reported with UFH. Concurrent use with other antithrombotic drugs, thrombolytics, and antiplatelet agents will increase the risk of bleeding, however.

Management of Bleeding and Excessive Anticoagulation

Hemorrhage can occur at any site in patients receiving UFH, and close monitoring for signs and symptoms of bleeding is crucial.^{4,7} In addition to an appropriate coagulation study to measure the response to UFH, it is necessary to monitor hemoglobin, hematocrit, and blood pressure regularly. Bleeding can produce a wide variety of symptoms, depending on the site of hemorrhage. Symptoms may include severe headache, joint pain, chest pain, abdominal pain, swelling, tarry stools, frank hematuria, or the passage of bright red blood through the rectum. Life-threatening bleeding owing either to a significant volume loss or to the location (e.g., bleeding into a critical space) must be recognized swiftly and treated immediately. Critical areas include intracranial, pericardial, and intraocular sites, as well as the adrenal gland.

When major bleeding occurs, UFH should be discontinued immediately, and the underlying source of bleeding should be identified and treated.²⁸ Intravenous protamine sulfate, 1 mg/100 units of UFH up to a maximum of 50 mg can be administered to reverse the anticoagulant effects of UFH. Protamine sulfate has intrinsic anticoagulation activity, but when administered with UFH, it forms a stable salt that results in the loss of anticoagulation activity of both drugs. Protamine sulfate neutralizes UFH in 5 minutes, and its activity persists for 2 hours. It should be given by slow intravenous infusion over 10 minutes. In cases of large heparin overdoses or in patients with renal failure, a “rebound” effect may occur, with a return of some anticoagulant activity several hours after the administration of protamine sulfate. Therefore, the patient’s coagulation status should be monitored closely. Multiple doses of protamine sulfate may be necessary if hemorrhage continues.

Use in Special Populations

UFH is the anticoagulant of choice during pregnancy.^{7,22} Although UFH appears to be safer for pregnant women than warfarin, it is not without risks. UFH use has been associated with stillbirths and prematurity. UFH should be used cautiously during the last trimester of pregnancy and the peripartum period owing to the risk of maternal hemorrhage. UFH is not excreted in breast milk and thus is considered safe to use by women who are breast-feeding.

For the treatment of acute thrombosis in children, the dosage of UFH is 50 units/kg bolus followed by a continuous infusion at 20,000 units/m² per day.³⁵ Alternatively, an initial loading dose of 75 units/kg over 10 minutes followed by a maintenance dose of 28 units/kg per hour for infants up to 12 months of age and 20 units/kg per hour for children 1 year of age or older may be used.

LOW-MOLECULAR-WEIGHT HEPARINS

Produced by either chemical or enzymatic depolymerization (see Table 19–6), LMWHs are fragments of UFH.^{7,28} They are heterogeneous mixtures of sulfated glycosaminoglycans with approximately one-third the molecular weight of UFH. Although all the LMWHs share similarities in their mechanisms of action with UFH, their molecular weight distributions vary, resulting in differences in their activity against factor Xa and thrombin, affinity for plasma proteins, propensity to release TFPI, and duration of activity.⁷ The mean molecular weight of the LMWHs is product-specific. These agents have

| Unstable angina or non-Q-wave MI | 1 mg/kg SC q 12 h ^a | 100 units/kg SC q 12 h (maximum dose 10,000 units) ^a | |

^aDose approved by the Food and Drug Administration for indication.

SC = subcutaneous; DVT = deep vein thrombosis; PE = pulmonary embolism; MI = myocardial infarction.

From ref. 3.

several advantages over UFH, including (1) predictable anticoagulation dose response, (2) improved subcutaneous bioavailability, (3) dose-independent clearance, (4) longer biologic half-life, (5) lower incidence of thrombocytopenia, and (6) a reduced need for routine laboratory monitoring.

Currently, there are three LMWH products available in the United States. The usefulness of LMWHs has been evaluated extensively for a wide array of indications, including the treatment of acute coronary syndromes, DVT, and PE, as well as the prevention of VTE in several high-risk populations. The Food and Drug Administration (FDA)-approved indications and doses for the LMWHs are product-specific (Table 19–10). The LMWHs largely have replaced UFH for the prevention and treatment of VTE in some hospitals. However, institutional resources and individual patient needs should determine their precise role in the management of VTE.

■ Pharmacology

The LMWHs prevent the growth and propagation of formed thrombi. Like UFH, the LMWHs enhance and accelerate the activity of antithrombin which binds to a specific pentasaccharide sequence.³⁶ Approximately 20% of the LMWH molecules contain the specific

sequence necessary to interact with antithrombin compared with nearly 30% for UFH. The principal difference in the pharmacologic activity of the LMWHs and UFH is their relative inhibition of factor Xa and thrombin (IIa). Owing to their smaller chain length, the LMWHs have limited activity against thrombin (see Fig. 19–5). Fewer than 50% of the LMWH molecules have the requisite chain length to bind antithrombin and thrombin simultaneously. For this reason, the LMWHs have proportionally greater anti-factor Xa activity. The ratio of anti-factor Xa–IIa activity varies between 4:1 and 2:1. By comparison, UFH has an anti-factor Xa–IIa activity ratio of 1:1. Like UFH, the LMWHs cause the endothelium to release TFPI, which is believed to enhance the inhibition of factor Xa and to inactivate factor VIIa.

■ Pharmacokinetics

Compared with UFH, the LMWHs have a more predictable anticoagulation response. The improved pharmacokinetic profile of LMWHs is the result of reduced binding to proteins and cells.⁷ The bioavailability of LMWHs varies between 85% and 99% when it is administered subcutaneously, whereas the absorption of UFH is relatively poor and erratic. The subcutaneous bioavailability of the LMWH products differs only slightly. The peak anticoagulation effect is seen in 3 to 5 hours.

The renal route is the predominant mode of elimination for the LMWHs.^{7,28} Consequently, their biologic half-life may be prolonged in patients with renal impairment. Longer heparin chains bind to macrophages and are degraded rapidly. Therefore, anti-factor Xa activity, which is mediated by smaller heparin molecules, persists longer than antithrombin activity. The plasma half-life of the LMWH preparations is two to four times longer than that of UFH. The clearance of LMWHs is independent of dose.

■ Dosing and Administration

The LMWHs are given in fixed or weight-based doses based on the product and indication^{7,28} (see Table 19–10). The dose for enoxaparin is expressed in milligrams, whereas dalteparin and tinzaparin doses are expressed in units of anti-factor Xa activity. Although they can be given by continuous intravenous infusion, the LMWHs generally are given by subcutaneous injection in the abdominal area while the patient is in a supine position. The clinician or patient pinches a layer of skin between the thumb and forefinger and then introduces the entire length of the needle into a skin fold at a 90-degree angle. Injection sites should be alternated between right and left sides. Following subcutaneous administration, the drug is absorbed slowly, resulting in sustained antithrombotic activity over several hours.

The dosing interval for the LMWHs is every 12 or 24 hours depending on the indication and product. Larger doses are given once daily and produce significantly higher peak plasma concentrations. Given that the elimination half-life of the LMWHs is prolonged in patients with severe renal impairment, high doses may lead to a significant accumulation in these patients. Enoxaparin should be dosed once daily in patients with creatinine clearances of less than 30 mL/min.³⁷ Given that few published data are available regarding the use of LMWHs in the setting of renal insufficiency, some experts recommend measuring anti-factor Xa activity if therapy is continued for more than a few days.

For the prevention of VTE, the LMWHs have been studied in a variety of high-risk circumstances, including orthopedic surgery, abdominal surgery, acute spinal cord injury, neurosurgery, multiple trauma, and critical illness.³ The effectiveness of the LMWHs has been evaluated extensively for the treatment of VTE in hospitalized patients and used in the outpatient management of DVT.¹² They are also a reasonable alternative to warfarin therapy in cancer patients with recurrent VTE and circumstances where a prothrombin time/international normalized ratio (PT/INR) cannot be obtained routinely.

■ Therapeutic Monitoring

The LMWHs achieve a predictable anticoagulant response when given subcutaneously. Therefore, routine laboratory monitoring is unnecessary to guide the dosing of these agents. The PT, the ACT, and the aPTT are minimally affected by LMWHs.⁷ Prior to initiation of LMWH, a baseline PT/INR, aPTT, complete blood count (CBC) with platelet count, and serum creatinine concentration determination should be obtained. Most experts recommend monitoring the CBC every 5 to 10 days during the first 2 weeks of LMWH therapy and every 2 to 4 weeks thereafter.

While several methods to monitor LMWHs have been explored, measurement of anti-factor Xa activity has been the most widely used method in clinical practice. Routine anti-factor Xa activity measurement is not necessary in a patient whose condition is stable and

uncomplicated.⁷ Although very limited data support the use of laboratory monitoring to guide LMWH therapy, measuring anti-factor Xa activity may be helpful in patients who have significant renal impairment (e.g., creatinine clearance of less than 30 mL/min), weigh less than 50 kg, have morbid obesity (e.g., BMI \geq 40 kg/m² or weigh \geq 120 kg), or require prolonged therapy (e.g., >14 days). Periodic anti-factor Xa activity monitoring also may be useful in women treated with a LMWH during pregnancy because of changing pharmacokinetic variables (e.g., volume of distribution and renal function).²² Patients who are at very high risk of bleeding or thrombotic recurrence also may benefit from anti-factor Xa monitoring to avoid periods of over- or underanticoagulation. Newborns have unpredictable pharmacokinetic profiles and therefore may require monitoring to ensure adequate therapy.

When anti-factor Xa activity is used to monitor LMWH therapy, the sample should be drawn approximately 4 hours after the subcutaneous injection, during the peak period of anti-factor Xa activity.⁷ A calibrated LMWH heparin should be used to establish the standard curve for the assay. The therapeutic range for anti-factor Xa activity is not well defined and to date has not been correlated clearly with efficacy or the risk of bleeding.³⁸ For the treatment of VTE, an acceptable target range is 0.5 to 1.0 unit/mL. Specific algorithms for dosing adjustments based on anti-factor Xa activity are not available at the present time.

■ Adverse Effects

As with UFH, bleeding is the most common adverse effect of the LMWHs.^{4,7} Although not demonstrated consistently in clinical trials, the frequency of major bleeding is purported to be less with the LMWHs than with UFH.^{7,39} This difference may be due in part to their reduced effects on platelet function, endothelial cells, and microvascular permeability. The incidence of major bleeding reported in clinical trials is less than 3% and varies among the LMWH preparations, their indication for use, patient population, and dose administered. Minor bleeding, particularly at the site of injection, occurs frequently with LMWH use. Several cases of epidural and spinal hematoma resulting in long-term or permanent paralysis have been reported with the use of enoxaparin during spinal and epidural anesthesia or spinal puncture.³⁷ The risk of these events is higher with the use of in-dwelling epidural catheters and concomitant use of drugs that affect hemostasis. Epidural catheters should be removed only after a minimum of 12 hours has elapsed after the last dose of the LMWH, and any subsequent dose should be given at least 2 hours later.

If major bleeding occurs in a patient receiving an LMWH, it is recommended that protamine sulfate be administered intravenously.⁷ However, because of its limited binding to the shorter LMWH chains, protamine sulfate cannot neutralize their anticoagulant effects completely. When given in equimolar concentrations, protamine sulfate neutralizes an estimated 60% to 75% of the antithrombotic activity. The recommended dose of protamine sulfate is 1 mg/1 mg of enoxaparin or 1 mg/100 anti-factor Xa units of dalteparin or tinzaparin administered in the previous 8 hours. If the LMWH dose was given in the previous 8 to 12 hours, a 0.5-mg dose of protamine should be given for every 100 anti-factor Xa units. The use of protamine sulfate is not recommended if the LMWH was administered more than 12 hours earlier.

While thrombocytopenia can occur with the use of a LMWH, the incidence of HIT is substantially lower than that observed with the use of UFH.^{7,34} The explanation may lie in the reduced propensity of the LMWHs to bind to platelets and platelet factor-4 (PF-4). The

LMWHs exhibit nearly 100% cross-reactivity with heparin antibodies *in vitro*.³⁴ Therefore, the LMWHs should be avoided in patients with an established diagnosis or history of HIT. Platelet counts must be monitored periodically in all patients receiving a LMWH, and thrombocytopenia of any degree should be evaluated promptly.

The risk of osteoporosis appears to be substantially lower with the LMWHs compared with UFH. The LMWHs have not caused appreciable changes in bone mineral density after several months of use.²² They have been used in a limited number of patients with established heparin-induced osteoporosis. Although these reports are promising, it cannot be concluded that the LMWHs have no effect on bone formation until well-designed clinical trials are available.

■ Use in Special Populations

There is growing experience with the use of LMWHs during pregnancy.²² The LMWHs do not cross the placenta. According to the results of a few large case series, the LMWH appear to be relatively safe to use during pregnancy and are an attractive alternative to UFH when long-term anticoagulation therapy is required. Furthermore, the LMWHs do not appear to affect bone formation. Dalteparin, enoxaparin, and tinzaparin are classified as FDA pregnancy category B. The safety and effectiveness of the LMWHs to treat VTE in children and infants has not been studied extensively.³⁵ Limited data exist on enoxaparin. The recommended treatment dose for enoxaparin in patients younger than 1 year of age is 1.5 mg/kg every 12 hours and 1 mg/kg every 12 hours in children 1 year of age or older. Until more data are available, it is prudent to monitor anti-factor Xa activity periodically in these special populations during long-term use.

■ DANAPAROID

Danaparoid is a glycosaminoglycan that is structurally distinct from but mechanistically related to heparin.⁷ It is a mixture of three sulfated glycosaminoglycans: heparan (84%), dermatan (12%), and chondroitin (4%). Like heparin, danaparoid's anticoagulant activity is mediated, in part, through its interaction with antithrombin. Compared with the LMWHs, danaparoid is fivefold more selective for factor Xa. It is approved by the FDA for the prevention of VTE in patients undergoing elective hip replacement surgery. Historically, danaparoid was used primarily for the treatment of thrombosis in patients who developed HIT. In 2002, the manufacturer discontinued the distribution of danaparoid, citing shortages in the United States.³⁸

■ FONDAPARINUX

■ Pharmacology

Fondaparinux, also known as pentasaccharide, is a synthetic molecule consisting of the five critical saccharide units that bind specifically but reversibly to antithrombin^{40,41} (see Fig. 19–5). Fondaparinux is the first in a class of anticoagulants that selectively inhibits factor Xa activity.⁴² Similar to UFH and the LMWHs, fondaparinux prevents thrombus generation and clot formation by indirectly inhibiting factor Xa activity through its interaction with antithrombin. When fondaparinux binds to antithrombin, it causes a conformational change in antithrombin's active site and catalyzes anti-factor Xa activity by about 300-fold. Fondaparinux is not destroyed during this process and is released to bind many other antithrombin molecules. Unlike

UFH and the LMWHs, fondaparinux has no direct effect on thrombin activity at therapeutic plasma concentrations. Selective inhibition of factor Xa may provide more efficient control over fibrin generation while preserving thrombin's regulatory functions in the control of hemostasis. Fondaparinux has no known effect on platelet function.

■ Pharmacokinetics

Fondaparinux is absorbed rapidly and completely following subcutaneous administration (absolute bioavailability 100%).^{40,42} Peak plasma concentrations are achieved in approximately 2 hours after a single dose and 3 hours with repeated once-daily dosing. It is distributed primarily in blood. At therapeutic concentrations, fondaparinux is highly and specifically bound to antithrombin. It does not bind to red blood cells or other plasma proteins, including albumin, glycoprotein, platelets, or PF-4. Fondaparinux is eliminated primarily unchanged in the urine. It is contraindicated in patients with severe renal function impairment (creatinine clearance < 30 mL/min) due to an increased risk for bleeding. The terminal elimination half-life is 17 to 21 hours and is independent of the patient's age or sex.⁴⁰ The anticoagulant effect of fondaparinux persists for 2 to 4 days following discontinuation of the drug in patients with normal renal function. Fondaparinux has no known pharmacokinetic drug interactions. However, concurrent use with other antithrombotic agents increases the risk of hemorrhage.

■ Dose and Administration

Fondaparinux is approved by the FDA for the prevention of VTE following orthopedic surgery (e.g., hip fracture, hip replacement, and knee replacement) and for the treatment of DVT and PE.⁴⁰ In the setting of VTE prevention, the dose of fondaparinux is 2.5 mg injected subcutaneously once daily starting 6 to 8 hours following surgery. It is important to avoid initiating fondaparinux too soon because there is a significant relationship between the timing of the first dose and the frequency of major bleeding complications. Patients who weigh less than 50 kg should not be given fondaparinux for VTE prophylaxis. The usual duration of therapy is 5 to 9 days, but fondaparinux may be given as extended prophylaxis following hospital discharge for up to 21 days.⁴³ Fondaparinux has been evaluated for the treatment of DVT and PE in two phase III clinical trials.^{44,45} For the treatment of DVT or PE, the dose of fondaparinux is 7.5 mg given subcutaneously once daily. Patients who weigh more than 100 kg should be given 10 mg once daily, and those who weigh less than 50 kg should receive only 5 mg daily.

Similar to the LMWHs, fondaparinux is administered into the fatty tissue of the abdominal wall. Patients should be instructed to pinch a fold of skin at the injection site and hold it throughout the injection. The needle should be inserted at a 90-degree angle. Injection sites should be alternated from side to side.⁴⁰

■ Therapeutic Monitoring

A CBC should be measured at baseline and monitored periodically to detect the possibility of occult bleeding.⁴⁰ Baseline kidney function should be determined and monitored closely in patients at risk of developing renal failure. Fondaparinux should be discontinued if the creatinine clearance drops below 30 mL/min. Signs and symptoms of bleeding should be monitored daily, particularly in patients with a

baseline creatinine clearance of between 30 and 50 mL/min. If neuraxial anesthesia has been used, patients should be monitored closely for signs and symptoms of neurologic impairment.

Fondaparinux does not alter coagulation tests such as the aPTT and PT. The role of anti-factor Xa monitoring during fondaparinux is not well defined. Patients receiving fondaparinux therapy do not require routine coagulation testing.

■ Adverse Effects

The primary adverse effect associated with fondaparinux therapy is bleeding.^{40,46} The rate of major bleeding in the VTE prophylaxis trials was approximately 2% to 3%. The risk of major bleeding appears to be related to weight; therefore, in patients who weigh less than 50 kg, fondaparinux is contraindicated for VTE prophylaxis, and the treatment dose is only 5 mg every 24 hours. Similar to UFH and the LMWHs, fondaparinux should be used with extreme caution in patients with neuraxial anesthesia or following a spinal puncture owing to the risk for spinal or epidural hematoma formation. Unlike UFH and the LMWHs, fondaparinux does not cause heparin-induced thrombocytopenia and does not produce cross-sensitivity *in vitro*.⁴⁷ A specific antidote to reverse the antithrombotic activity of fondaparinux is not currently available, but several potential products have been evaluated.⁴²

■ Use in Special Populations

Fondaparinux has been used safely in elderly patients, but the risk of major bleeding increases with age (1.8% in patients younger than 65 years of age, 2.2% in patients 65 to 74 years of age, and 2.7% in patients 75 years of age or older).⁴⁰ This is an important consideration because many patients who undergo orthopedic surgery are elderly. Elderly patients are also more likely to have decreased renal function, and careful assessment of renal status should be conducted prior to initiating therapy. Fondaparinux is contraindicated in patients with a creatinine clearance of less than 30 mL/min.

Fondaparinux is a pregnancy category B drug.⁴⁰ There is very limited information regarding fondaparinux use during pregnancy. The drug is excreted in the milk of lactating rats, but excretion in human milk is unknown. Until more data become available, UFH and the LMWHs should remain the agents of choice in pregnant patients. Fondaparinux use in pediatric populations has not been studied.

■ IDRAPARINUX

Idraparinux is an analog of fondaparinux that has a very long duration of effect (see Table 19–6) and has been developed to be administered once weekly by subcutaneous injection.⁴⁸ Idraparinux is currently undergoing phase III clinical trials evaluating its utility for both the acute and long-term management of VTE.⁴⁹

■ DIRECT THROMBIN INHIBITORS

A relatively new class of very potent anticoagulant agents, the direct thrombin inhibitors (DTIs), includes lepirudin, desirudin, bivalirudin, argatroban, and ximelagatran (see Table 19–6). These agents have been studied for a number of indications, including the prophylaxis and treatment of VTE, acute coronary syndromes, and HIT.⁴⁹ Given

their immediate onset of action, good oral bioavailability, wide therapeutic window, fixed dosing, and promising results from early clinical trials, oral DTIs could revolutionize the treatment of VTE in the next 5 years.^{11,49}

■ Pharmacology and Pharmacokinetics

The direct thrombin inhibitors, as their name implies, interact directly with the thrombin molecule⁴⁹ (Fig. 19–6). The agents in this class differ in terms of their molecular weight, chemical structure, and binding to the thrombin molecule. Unlike the UFH, the LMWHs, and fondaparinux, DTIs do not require antithrombin to have antithrombotic activity. They are capable of inhibiting both circulating and clot-bound thrombin, a potential advantage over UFH and the LMWHs. Further, DTIs have not been shown to induce immune-mediated thrombocytopenia and have been used widely for the treatment of HIT.

Hirudin, the prototype of this class, was isolated from the salivary secretions of the medicinal leech (*Hirudo medicinalis*).⁴¹ Mass production of several synthetic hirudin analogs with the potential for wide clinical application only became possible with the advent of recombinant DNA technology. Lepirudin, a recombinant analog of hirudin, is a 65-amino-acid polypeptide that irreversibly binds with high specificity to thrombin. The hirudins (i.e., lepirudin, desirudin, and bivalirudin) form a noncovalent bond in a 1:1 ratio with the catalytic and fibrinogen binding sites on the thrombin molecule (see Fig. 19–6). These agents must be administered parenterally, either by continuous intravenous infusion or by subcutaneous injection.^{41,50} The primary route of elimination for lepirudin is through renal excretion, and systemic clearance is directly proportional to the glomerular filtration rate. Dose adjustment is required in the setting of impaired renal function, a potential disadvantage of this agent. Many patients develop antibodies to lepirudin. Up to 40% of patients treated with lepirudin for 10 days or more will develop antibodies. However, antibody formation has not been associated with adverse clinical outcomes.⁵¹

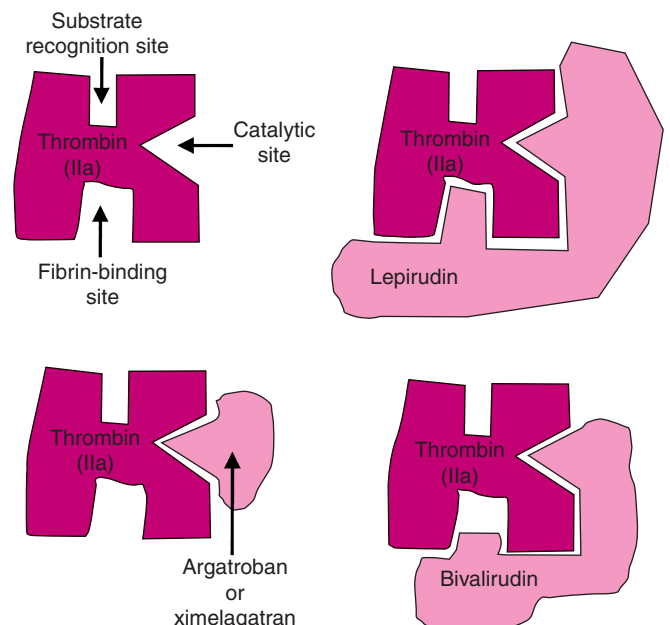

FIGURE 19–6. Pharmacologic activity of lepirudin, bivalirudin, argatroban, and ximelagatran.

Bivalirudin, formerly known as hirulog, is a semisynthetic 20-amino-acid polypeptide analog of recombinant hirudin approved by the FDA for use in patients with unstable angina undergoing percutaneous transluminal angioplasty (PCTA).⁵² Unlike lepirudin, bivalirudin is a reversible inhibitor of thrombin and provides transient antithrombotic activity with an estimated 20- to 30-minute half-life.^{49,53} This difference may reduce the risk of bleeding and antibody production. Approximately 20% of an intravenous dose of bivalirudin is eliminated in the urine. The manufacturer recommends reducing the dose by 20% to 60% in patients with renal impairment and monitoring the ACT closely.⁵²

Desirudin is a recombinant hirudin analog administered by subcutaneous injection approved by the FDA in 2003 for the prevention of venous thrombosis in patients undergoing elective hip surgery. For acute myocardial infarction and unstable angina, desirudin has been given via continuous intravenous infusion.⁵⁰ Similar to lepirudin, desirudin is eliminated renally, and patients with moderate to severe renal impairment require dosage reductions. Antihirudin antibodies have been documented with desirudin, but the incidence appears to be lower than with lepirudin.

Argatroban differs from the hirudins in that it is a small synthetic molecule derived from arginine that reversibly binds only to the active catalytic site of thrombin. Its small size relative to other DTIs enables it to inhibit both clot-bound and soluble thrombin, offering a potential therapeutic advantage over other agents in its class. Argatroban is eliminated primarily by hydroxylation and aromatization in the liver to inactive metabolites. A small percentage is excreted unchanged in the bile. Dosage adjustment is required in patients with hepatic impairment.

Ximelagatran is a prodrug converted by hydrolysis and reduction in the liver to melagatran, the active moiety.⁵³ Unlike other DTIs, ximelagatran has good oral bioavailability that does not appear to be affected by food. Peak ximelagatran plasma concentrations are seen within 120 minutes following an oral dose, providing relatively rapid antithrombotic activity.⁵⁴ The elimination half-life is approximately 3 to 5 hours, therefore requiring twice-daily administration. Ximelagatran is eliminated primarily in the urine.

■ Therapeutic Monitoring

Although the DTIs produce changes in the PT, the aPTT is used to monitor a patient's response to lepirudin and argatroban.^{51,55} After obtaining baseline coagulation studies, doses of lepirudin and argatroban should be titrated to achieve the institution-specific therapeutic range or an aPTT of 1.5 to 3.0 times the mean normal control. Daily aPTT monitoring is also recommended for patients on desirudin, particularly those with impaired renal function.⁵⁰ Bivalirudin doses should be adjusted based on the ACT.⁵² The ecarin clotting time is a potentially more suitable test to measure the antithrombotic activity of the DTIs, but it is not readily available in the United States. Ximelagatran appears to produce a predictable antithrombotic response in fixed doses and has a relatively large therapeutic window.^{49,54} Consequently, routine anticoagulation monitoring is not required for this agent. A CBC should be obtained at baseline and periodically thereafter to detect potential bleeding.

■ Adverse Effects

Contraindications for use of the DTIs and risk factors for bleeding are similar to those of other antithrombotic drugs (see Table 19-9).

Hemorrhage is the most serious and common adverse effect related to the DTIs.³⁴ In studies evaluating the use of lepirudin for the treatment of patients with HIT, the incidence of major bleeding was relatively high (13% to 17%).⁵¹ However, no fatal or intracranial bleeding events occurred. A slightly lower rate of major hemorrhage was reported in HIT trials using argatroban (approximately 5%), and similarly, there were no reports of fatal or intracranial bleeding. Bleeding complications with desirudin were similar to those with enoxaparin in a trial of patients undergoing elective hip surgery. Serious bleeding occurred in less than 1% of all patients in the trial.⁵⁰ Minor bleeding and small reductions in red blood cell counts occurred relatively frequently but typically did not require drug discontinuation. There are no known agents that reverse the activity of the DTIs. Nonhemorrhagic effects such as fever, nausea, vomiting, and allergic reactions occur infrequently.

Ximelagatran was associated with a relative high incidence (6% to 9%) of elevated liver function tests (LFTs) in phase III clinical trials. In most cases, this effect was reversible with continued use. However, a very small percentage (<1%) of patients may have had severe, irreversible liver injury. In 2004, the FDA denied approval of ximelagatran until more safety data are available and an effective risk management strategy is developed.

■ Drug-Drug and Drug-Food Interactions

The concurrent use of DTIs and thrombolytic agents substantially increases the bleeding risk, particularly intracranial hemorrhage, and should be undertaken with great caution. Warfarin and antiplatelet agents can be initiated concurrently with these agents. Because the DTIs prolong the PT and INR, close monitoring for bleeding complications is required. Few pharmacokinetic drug interactions with this class of agents are known. Drugs that alter renal function could prolong lepirudin and desirudin activity. Drugs that inhibit liver enzymes have the potential to interact with argatroban. However, erythromycin did not alter argatroban pharmacokinetics appreciably in healthy volunteers in one small study.⁵⁶

■ Use in Special Populations

Lepirudin and argatroban are classified by the FDA as pregnancy category B drugs, but they should be used cautiously in women of childbearing age because experience is very limited.^{51,55} Desirudin is classified as pregnancy category C with no controlled trials in pregnant women.⁵⁰ Lepirudin has been evaluated in a small number of children. Further study is required to develop dosing guidelines in patients with renal and hepatic insufficiency.

■ WARFARIN

The most widely prescribed anticoagulant in North America is warfarin sodium (Coumadin). It was discovered serendipitously in the early 1940s at the University of Wisconsin after hemorrhagic deaths occurred in cattle eating spoiled sweet clover.⁶ Warfarin is approved by the FDA for the prevention and treatment of VTE as well as for the prevention of thromboembolic complications associated with atrial fibrillation, heart valve replacement, and myocardial infarction. Because of its narrow therapeutic index, predisposition to drug and food interactions, and propensity to cause hemorrhage, warfarin requires

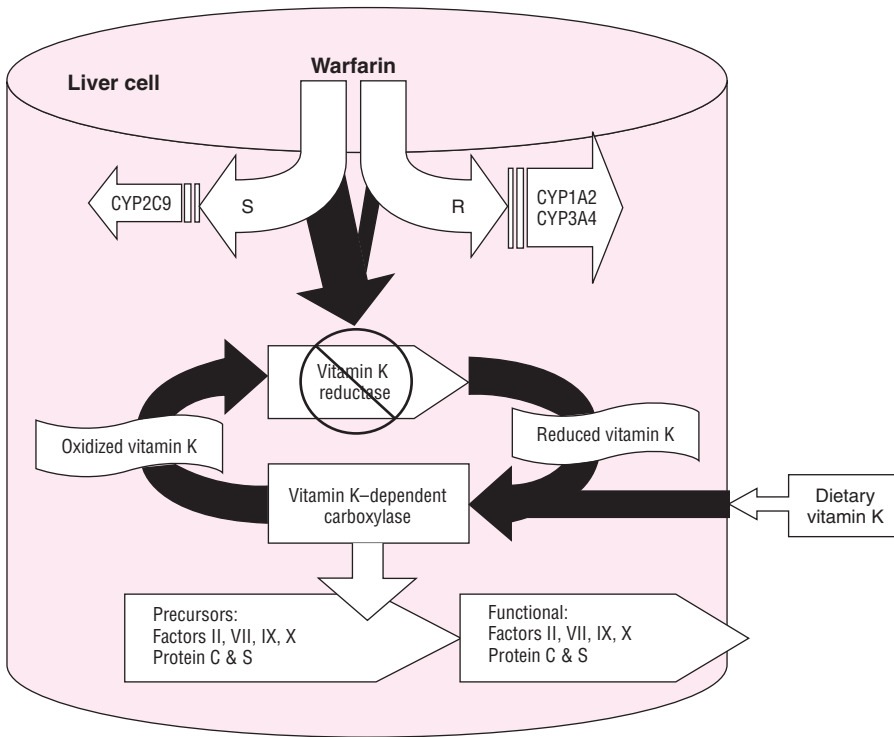

FIGURE 19–7. Pharmacologic activity and metabolism of warfarin.

continuous patient monitoring and education in order to achieve optimal outcomes.

■ Pharmacology

Warfarin exerts its anticoagulation effect by inhibiting the enzymes responsible for the cyclic interconversion of vitamin K in the liver²³ (Fig. 19–7). Reduced vitamin K is a cofactor required for the carboxylation of the vitamin K–dependent coagulation proteins, namely, factors II (prothrombin), VII, IX, and X, as well as the endogenous anticoagulant proteins C and S. Carboxylation of the N-terminal region of these proteins in the liver is required for biologic activity. By inhibiting the supply of vitamin K to serve as a cofactor in the production of these proteins, warfarin indirectly slows their rate of synthesis. Warfarin has no direct affect on previously circulating clotting factors or previously formed thrombus. The time required for warfarin to achieve its pharmacologic effect depends on the elimination half-lives of the coagulation proteins⁵ (see Table 19–11). Given that prothrombin has a 2- to 3-day half-life, warfarin’s full antithrombotic effect is

TABLE 19–11. Biologic Half-Life of Vitamin K–Dependent Coagulation Proteins

| Protein | Half-life (Hours) |
|-------------------------|-------------------|
| Prothrombin (factor II) | 60–100 |
| Factor VII | 4–6 |
| Factor IX | 20–30 |
| Factor X | 24–40 |
| Protein C | 8–10 |
| Protein S | 40–60 |

From ref. 23.

not achieved for 8 to 15 days after initiation of therapy. By suppressing the production of clotting factors, warfarin prevents the initial formation and propagation of thrombus.

■ Pharmacokinetics

Commercially available warfarin is a racemic mixture of *R*- and *S*-isomers.^{5,6} The *S*-isomer is two to five times more potent than the *R*-isomer. Rapidly and extensively absorbed from the gastrointestinal track, warfarin reaches peak plasma concentration in approximately 90 minutes, with a bioavailability of greater than 90% following oral administration. In plasma, both the *R*- and *S*-isomers are bound extensively (97% to 99%) to albumin. Warfarin undergoes stereoselective metabolism via CYP1A2, -2C9, -2C19, -2C18, and -3A4 isoenzymes in the liver (see Fig. 19–7). The pharmacokinetic parameters of warfarin, particularly hepatic metabolism, vary substantially between individuals. Genetic variations in the 2C9 isoenzyme are relatively common (up to 35% in some studies), and patients with the CYP2C9*2 and CYP2C9*3 polymorphisms require significantly lower doses of warfarin.^{5,7} Given the relatively greater potency of *S*-warfarin, drugs that induce or inhibit the CYP2C isoenzymes are more likely to cause a clinically significant effect.⁵ These and other pharmacokinetic variations in warfarin metabolism likely explain the large interpatient dose-response seen with warfarin in clinical practice.

■ Dosing and Administration

The dose of warfarin is patient-specific, based on the desired intensity of anticoagulation and the patient’s individual response.^{5,6} There is tremendous interpatient variability with regard to the pharmacodynamic response and pharmacokinetic disposition of warfarin.

Furthermore, there is substantial variability in these parameters over time. Therefore, the dose of warfarin must be based on continual clinical and laboratory monitoring. At the initiation of therapy, it is difficult to predict the specific dose that an individual will require.

Although the average weekly dose of warfarin is between 30 and 40 mg, some patient-related variables are associated with a lower than usual dose: advanced age (>65 years), elevated baseline INR, poor nutritional status, liver disease, hyperthyroidism, and concurrent use of medications known to enhance the effect of warfarin (Table 19–12). Prior to initiating therapy, the clinician should screen for the presence of contraindications to anticoagulation therapy and risk factors for

TABLE 19–12. Clinically Important Warfarin Drug Interactions

| Increased Anticoagulation Effect (↑ INR) | Decreased Anticoagulation Effect (↓ INR) | Increased Bleeding Risk |
|--|--|-------------------------|

NSAIDs = nonsteroidal anti-inflammatory drugs. Compiled from ref. 5.

CLINICAL CONTROVERSY

Some clinicians recommend that warfarin therapy be started using no more than 5 mg daily based on evidence that the majority of patients will achieve a therapeutic INR by day 5, but some patients become excessively anticoagulated when higher doses are used. However, some clinicians recommend initiating warfarin therapy with 10 mg daily because a therapeutic INR is achieved 1 day sooner, thereby facilitating earlier hospital discharge and more rapid discontinuation of LMWH therapy. In addition, they argue, there is no evidence that bleeding complications occur more frequently when a higher initial dose is used.

major bleeding (see Tables 19–8 and 19–9). It is essential to collect a complete medication history, including the use of herbal and nutritional products (Table 19–13).

There is some controversy regarding the optimal dosing regimen when initiating warfarin therapy.^{6,58,59} To achieve a therapeutic INR in the least amount of time, some clinicians have used relatively high

doses of warfarin (10 or 15 mg) and then adjusted the dose based on the patient's response. Recent studies in patients with atrial fibrillation comparing a 5-mg initial dose with a 10-mg dose called into the question this practice.⁶⁰ Although a 10-mg dose produced a more rapid response in the INR, many patients became excessively anticoagulated. However, a more recent study in patients with acute venous thrombosis refutes these findings.⁵⁸

While data on the optimal induction regimen are conflicting, there is a pharmacodynamic rationale for avoiding doses larger than 10 mg.⁵ Large doses result in a more rapid depression in factor VII concentrations.⁶⁰ This early response to therapy may give the clinician a false impression that a therapeutic INR has been achieved after only 2 or 3 days. It is important to remember that patients are not truly anticoagulated at this point because a significant reduction in prothrombin concentrations requires at least 5 days to occur. Large doses also may increase the theoretical risk for early thrombotic complications, such as warfarin-induced skin necrosis. After the initiation of warfarin therapy, protein C becomes depleted rapidly, but prothrombin concentrations will remain near normal for several days. If protein C concentrations are severely suppressed relative to prothrombin, there is a potential for inducing a hypercoagulable state.

For most patients, initiating therapy with 5 mg daily and adjusting the dose based on response will produce therapeutic INRs in

4 to 5 days (Fig. 19-8). Lower or higher starting doses may be acceptable based on patient-related factors and how quickly follow-up laboratory monitoring can be performed. Several dosing nomograms have been developed and have been evaluated prospectively.^{6,58-61} For patients with acute venous thrombosis, UFH, LMWH, or fondaparinux should be overlapped with warfarin therapy for at least 4 to 5 days regardless of whether the target INR has been achieved earlier.¹²

Warfarin therapy can be initiated safely on an outpatient basis, provided that there is no urgent need for anticoagulation (i.e., prevention of venous thrombosis). Given that laboratory monitoring is performed less frequently in the outpatient setting, warfarin therapy should be undertaken a bit more cautiously. In most circumstances, the initial dose should not exceed the anticipated maintenance dose. The response to therapy should be measured every 3 to 5 days until stabilized. The full antithrombotic effect may require up to 15 days to be achieved.⁵

When adjusting the dose of warfarin, the clinician should allow sufficient time for changes in the INR to occur.⁶ In general, dose changes should not be made more frequently than every 3 days. Doses should be adjusted by calculating the weekly dose and reducing or increasing the weekly dose by 5% to 25%. The effect of a small dose change may not become evident for 5 to 7 days; therefore,

patients should not have follow-up PT tests obtained prior to that time.

Therapeutic Monitoring

Warfarin requires frequent laboratory monitoring to ensure optimal therapeutic outcomes and minimize bleeding complications. The PT, also known as the *protime* and *one-step quick test*, has been used for decades to monitor the anticoagulation effects of warfarin.^{5,62} The PT measures the biologic activity of factors II, VII, and X and correlates well with warfarin’s anticoagulation effect. The test is performed by measuring the time required for clot formation after adding calcium and a thromboplastin to citrated plasma. Several thromboplastins are available commercially and are extracted from mammalian tissue rich in tissue factor (e.g., rabbit brain) or produced from recombinant human tissue factor. Although an effective tool for monitoring warfarin therapy, the PT is problematic to interpret because there is wide variability in the sensitivity of the thromboplastin reagents. Given the same blood sample, different thromboplastins will produce substantially different results that may prompt clinicians to make potentially inappropriate dosing decisions. The World Health Organization (WHO) addressed the need for standardization in the late 1970s by developing a reference thromboplastin and recommending use of the INR to monitor warfarin therapy. The INR corrects for differences in thromboplastin reagents through the following formula:

$$INR = \left(\frac{PT^{Patient}}{PT^{Control}} \right)^{ISI}$$

The International Sensitivity Index (ISI) is a measure of the thromboplastin’s responsiveness compared with the WHO reference standard. Each thromboplastin reagent manufactured has an ISI value that should be used to calculate the INR. Although the INR system has a number of potential problems, it is currently the best means available

to interpret the PT and the preferred method for monitoring oral anticoagulation therapy.

The recommended target INR and goal range is based on the therapeutic indication.⁵ For most indications, the target INR is 2.5, with an acceptable range of 2.0 to 3.0. The target INR is higher for patients with mechanical prosthetic heart valves (target INR 3.0, range 2.5–3.5). A lower target INR (range 1.5–2.0) may be acceptable for the long-term prevention of recurrent VTE after the first 6 months of treatment in patients with an idiopathic DVT.⁶³ A baseline PT and CBC should be obtained prior to initiating warfarin therapy. In patients with an acute thromboembolic event, a PT should be measured minimally every 3 days during the first week of therapy. In this situation, UFH, LMWH, or fondaparinux therapy should be continued for at least 5 days and until the INR is greater than 2.0. The concurrent use of antithrombotic drugs with warfarin may prolong the PT slightly. Once the patient’s dose-response is established, an INR should be determined every 7 to 14 days until it stabilizes and optimally every 4 weeks thereafter.

At each encounter, patients should be questioned meticulously regarding their medication use and symptoms related to bleeding and thromboembolic complications. Any changes in medications, including changes in dose, as well as nonprescription drug and dietary supplement use, should be explored carefully (see Tables 19–12 and 19–13). Dietary intake of vitamin K–rich foods also should be evaluated (Table 19–14).

Anticoagulation therapy management services can improve the care of patients who take warfarin therapy by providing structured, comprehensive patient education and evaluation.^{6,8} When staffed by experienced and knowledgeable practitioners, anticoagulation management services improve the safety and effectiveness of warfarin therapy compared with “usual” medical care. Anticoagulation patient management services lower the overall cost of care by reducing the frequency of major bleeding and recurrent thromboembolic events.

TABLE 19–14. Vitamin K Content of Select Foods^a

| Very High (>200 mcg) | High (100–200 mcg) | Medium (50–100 mcg) | Low (<50 mcg) |

Portable PT monitoring devices have enhanced patient management. Not only do these devices permit clinicians to do “real time” therapeutic drug monitoring, but they also enable patients to engage in self-testing at home.⁶⁴ Self-monitoring, in its simplest form, requires the patient to report the test results to a health care professional. In such arrangements, the clinician continues to make warfarin-dosing decisions. Highly motivated and sophisticated patients can be trained to manage themselves, independently altering the dose of warfarin therapy based on their INR results. Patients who engage in INR self-monitoring and warfarin self-management report high levels of satisfaction with care and maintain the INR within the therapeutic range more frequently than those managed by “usual care.” Home INR testing and self-management are clearly not for everyone, however. It requires careful patient selection and considerable education. Unfortunately, PT monitoring systems remain relatively expensive and rarely are covered by medical insurance.

■ Adverse Effects

Warfarin’s primary adverse effect is bleeding. Hemorrhagic complications, ranging from mild to life-threatening, can occur at any site in the body. Although warfarin is not believed to cause bleeding per se, it can “unmask” an existing lesion or enable a massive hemorrhage from an ordinarily minor bleeding source. The gastrointestinal tract is the most frequent site of bleeding. Bruising on the arms and legs is commonplace, but a painful hematoma may necessitate the temporary discontinuation of therapy. Intracranial hemorrhage is the most serious and feared complication related to warfarin therapy, often resulting in permanent disability or death.

The annual incidence of major bleeding ranges from 1% in highly selected patients who are managed carefully to greater than 10% in patients managed in less structured environments, according to some studies.^{4,6,8} There are no universally accepted criteria for defining a bleeding event as major or minor. Most studies have defined major bleeding as any bleeding event that required hospitalization, transfusion of 2 units of blood or plasma, or leads to a greater than 2 gm/dL drop in hematocrit. Bleeding that does not meet the criteria for a major hemorrhage generally is considered to be minor. Minor bleeding is very common. Few studies have prospectively evaluated the incidence of minor bleeding, but it is likely to be greater than 15% annually even in the most expertly managed patients.

Several risk factors for bleeding while taking anticoagulation therapy have been identified⁴ (see Table 19–8). Intensity of anticoagulation therapy appears to be the most powerful risk factor. Patients whose target INR is greater than 3.0 have twice the incidence of major bleeding compared with those with a goal range of 2.0 to 3.0. The risk of intracranial hemorrhage increases significantly when the INR remains greater than 4.0 for prolonged periods of time. Patients given low-intensity warfarin therapy (goal INR 1.3–1.9) have a level of anticoagulation that is insufficient protection against thrombosis for most indications. Wide variability in the anticoagulation response, as seen in patients with very unstable INR values, also appears to be associated with an increased risk of bleeding. The risk of hemorrhage is greatest during the first few weeks of therapy; however, bleeding can occur at any time, and the cumulative incidence increases steadily over time.

Nonhemorrhagic adverse effects associated with warfarin are uncommon but can be serious when they do occur.⁶⁵ The purple toe syndrome, manifested as a purplish discoloration of the toes, is an extremely rare event reported in a small percentage of patients receiving warfarin. The etiology of this unusual phenomenon is unknown, but

it is thought to be the result of cholesterol microembolization into the arterial circulation of the toes.

Warfarin-induced skin necrosis is an uncommon but very serious dermatologic reaction that is manifested by a painful maculopapular rash and ecchymosis or purpura that subsequently progresses to necrotic gangrene. It appears most frequently in areas of the body rich in subcutaneous fat, such as the breasts, thighs, buttocks, and abdomen. The incidence of warfarin-induced skin necrosis is less than 0.1%. It occurs most commonly in middle-aged women who are being treated for acute venous thrombosis. Although symptoms generally appear during the first week of therapy, it has been reported in a small number of patients who had taken warfarin for months and even years. The pathogenesis of warfarin-induced skin necrosis is not clearly understood. Many believe that it is the result of imbalances between procoagulant and anticoagulant proteins occur early in the course of warfarin therapy, resulting in capillary thrombosis and secondary hemorrhages. The observation that patients with deficiency of protein C or protein S appear to be at greater risk for warfarin-induced skin necrosis supports this theory. Warfarin-induced skin necrosis also has been reported in patients with other disorders of hypercoagulability, such as antithrombin deficiency and antiphospholipid antibodies. Patients who receive large “loading” doses of warfarin also may be at greater risk. It is recommended that heparin therapy be overlapped for a minimum of 7 days when initiating therapy in any patient suspected of having a hypercoagulable state or who has a strong family history of venous thrombosis. If the diagnosis of skin necrosis is suspected, warfarin therapy should be discontinued immediately, vitamin K administered, and full-dose UFH or LMWH therapy initiated. Warfarin therapy should be restarted with extreme caution in patients with a history of skin necrosis, if at all.

Gastrointestinal side effects of warfarin therapy are uncommon and usually self-limited. Because warfarin interferes with vitamin K metabolism, there has been some theoretical concern that it may adversely affect bone formation and cause osteoporosis with long-term use.⁶⁶ To date, the association between warfarin and osteoporosis is inconclusive, and the risk of fracture appears to be negligible.

■ Management of Bleeding and Excessive Anticoagulation

Specific recommendations for the management of patients with an elevated INR are published by the American College of Chest Physicians (ACCP) Consensus Conference on Antithrombotic Therapy⁶ (Fig. 19–9). Patients with a mildly elevated INR (3.5 to 5.0) should be examined for signs and symptoms of bleeding, as well as for factors that increase bleeding risk. In this circumstance, either reducing the dose of warfarin or withholding one or two doses will manage most patients safely. When a swift reduction in an elevated INR is required, oral or intravenous vitamin K₁ (phytonadione) can be given.^{6,67,68} In the absence of major bleeding, the oral route of administration is preferred. While the intravenous route produces a more rapid reversal, it is associated with rare but serious anaphylactoid reactions. If the INR is between 5 and 9, doses of warfarin should be withheld or may be combined with a low dose of oral vitamin K (1 to 5 mg). Low doses of oral vitamin K will reduce the INR consistently within 24 hours without making the patient refractory to warfarin therapy. Overcorrection of the INR in a patient who is not bleeding is unnecessary but common. Simply withholding warfarin will result in correction of INRs between 5 and 9 within 36 to 48 hours for most patients. The decision to administer vitamin K should be individualized based on the patient’s bleeding risk and the underlying indication for anticoagulation therapy. Vitamin K should be used with caution in patients

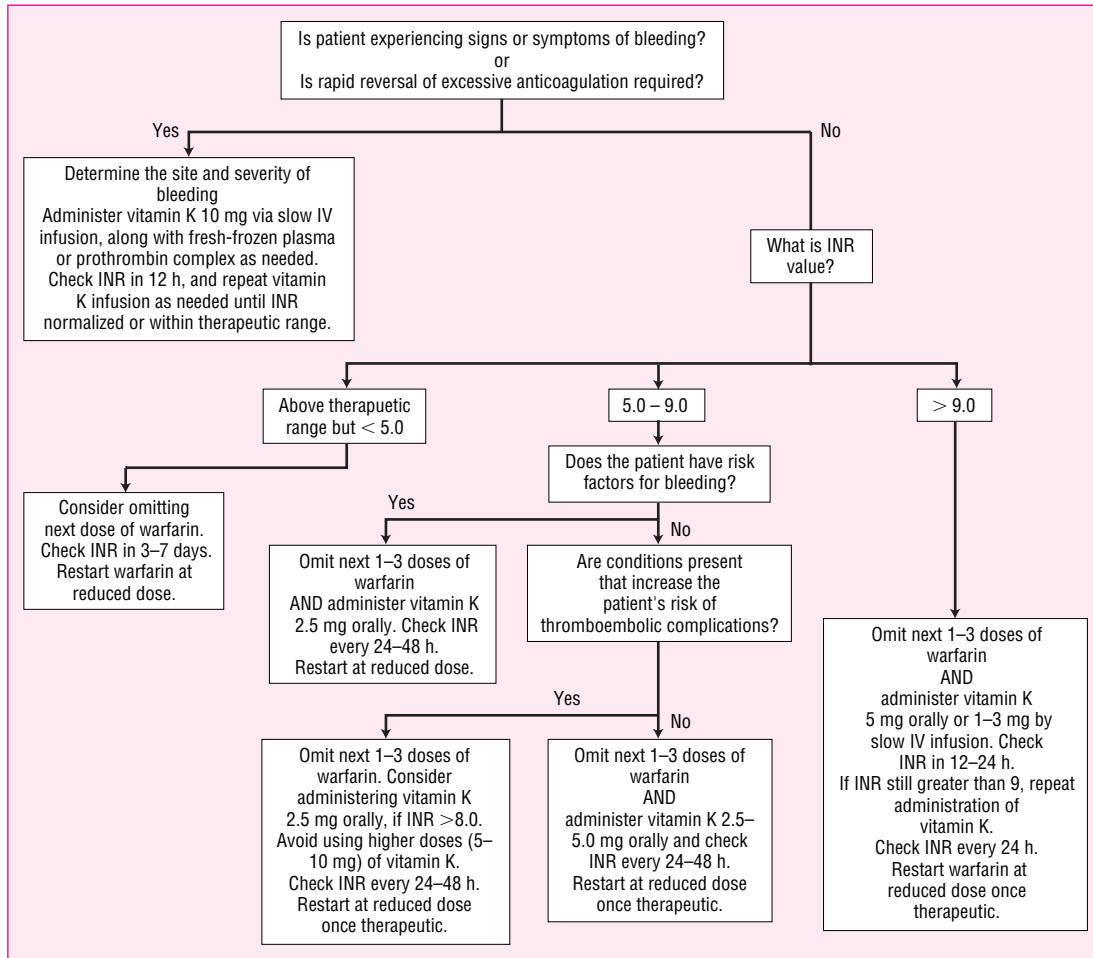

FIGURE 19-9. Management of an elevated international normalized ratio (INR) in patients taking warfarin. Dose reductions should be made by determining the weekly warfarin dose and reducing the weekly dose by 10% to 25% based on degree of INR elevation. Conditions that increase the risk of thromboembolic complications include history of hypercoagulability disorders (e.g., protein C or S deficiency, presence of antiphospholipid antibodies, antithrombin deficiency, activated Protein C resistance), arterial or venous thrombosis within the previous month, thromboembolism associated with malignancy, and mechanical mitral valve in conjunction with atrial fibrillation, previous stroke, poor ventricular function, or coexisting mechanical aortic valve.

at high risk of recurrent thromboembolism because of the possibility of INR overcorrection. Conversely, simply withholding warfarin therapy may not lower a high INR quickly enough in patients at high risk for developing bleeding complications. If the INR is greater than 9, a 5 mg oral dose of vitamin K is recommended. High doses of vitamin K (e.g., 10 mg) have been associated with prolonged resistance to warfarin and the occurrence of thromboembolic complications. In the event of a serious or life-threatening bleed, intravenous vitamin K should be administered, as well as fresh frozen plasma or clotting factor concentrates.

■ Drug-Drug and Drug-Food Interactions

5 The pharmacokinetic and pharmacodynamic properties of warfarin, coupled with its narrow therapeutic index, predispose this agent to numerous clinically important food and drug interactions^{5,69} (see Tables 19-12, 19-13, and 19-14). Vitamin K can reverse warfarin’s pharmacologic activity, and many foods contain sufficient

vitamin K to reduce the anticoagulation effect of warfarin if a patient consumes them in large portions or repetitively in a short period of time.⁶⁹ Patients should be given a list of vitamin K–rich foods and instructed to maintain a relatively consistent intake. It is important to stress consistency and moderation rather than absolute abstinence. Abrupt changes in vitamin K intake should be considered when unexplained changes in the INR occur. Alternative sources of vitamin K, such as multivitamins and nutritional supplements (e.g., Sustical or Ensure), should also be considered. Patients who require parenteral nutrition should not receive a weekly bolus dose of vitamin K if they are taking warfarin therapy.

Pharmacokinetic drug interactions with warfarin are due primarily to alterations in hepatic metabolism or binding to plasma proteins. Drugs that inhibit or induce the CYP2C9, -1A2, and -3A4 isoenzymes have the greatest potential to significantly alter the response to warfarin therapy. Protein-binding displacement interactions can also occur. However, in the absence of hepatic disease or a diminished capacity to metabolize warfarin, changes in protein binding result in only transient changes in the INR. Drugs that

alter hemostasis, platelet function, or the clearance of clotting factors (e.g., thyroid hormone replacement) can alter the response to warfarin therapy or increase the risk of bleeding by pharmacodynamic mechanisms.

The explosive increase in the use of herbal and alternative therapies in North America has raised concern regarding their potential to interact with warfarin therapy.⁷⁰ Although there are a growing number of case reports and some *in vivo* data, the clinical importance of specific warfarin-herbal interactions remains unclear. All patients on warfarin therapy should be questioned regarding the use of herbal drugs and dietary supplements. Clinicians should advise patients on warfarin therapy to seek information about potential interactions with warfarin whenever they start to take a new drug product, whether it is prescribed or purchased over the counter. If there is a known drug interaction or doubt about its potential to alter the response to warfarin, more frequent PT testing following the initiation of the new agent is prudent.

■ Use in Special Populations

In the absence of a clear and compelling indication, warfarin should not be used during pregnancy because of the potential for fetal hemorrhage and teratogenic complications.²² Warfarin crosses the placenta and has been associated with several embryopathies, particularly central nervous system abnormalities, which have occurred throughout gestation. The FDA has designated warfarin a pregnancy category X agent. Because UFH and the LMWHs are large molecules that do not cross the placental barrier, they are considered the drugs of choice for anticoagulation during pregnancy. Warfarin is excreted in the breast milk in very low concentrations and generally is considered safe to use by women who are breast-feeding.

Patients scheduled to undergo major surgery or other invasive procedures often require temporary discontinuation of warfarin therapy.⁶ The decision to withhold warfarin therapy should be based on the type of surgical procedure being performed and the patient's risk of bleeding and thromboembolism. Warfarin therapy generally should not be discontinued in patients undergoing minimally invasive procedures such as dental work.⁷¹ If the bleeding risk from the procedure is considerable, warfarin should be stopped 4 to 5 days prior to the procedure to allow the INR to return to near-normal values. Alternatively, warfarin can be stopped and a low dose (2.5 mg) of oral vitamin K may be given 2 days prior to the procedure.⁶ Patients at moderate or high risk of thromboembolism (i.e., DVT or PE in the previous month) should be given so-called "bridge therapy" with UFH or a LMWH before and/or after the procedure.

Warfarin use among elderly patients is increasingly common. While the drug has been studied extensively in this population, some debate still remains regarding the relative risks of warfarin therapy in the elderly.⁴ Data supporting the notion that age increases hemorrhagic risk are somewhat conflicting. Age greater than 75 years has been associated with an increased risk of intracranial hemorrhage, but the overall incidence of major bleeding is similar to that in younger users. Elderly patients may be more prone to excessive anticoagulation due to nutritional deficiencies, comorbidities, and multiple drug interactions. Furthermore, they are often at greater risk for falls. Although they often derive the greatest benefit from anticoagulation therapy, elderly patients should be monitored with greater vigilance, and warfarin dose changes should be made more cautiously.

■ GENERAL APPROACH TO THE PREVENTION OF VTE

Given that VTE is often clinically silent and potentially fatal, strategies to prevent DVT in at-risk populations will have the greatest impact on patient outcomes.³ To rely on the early diagnosis and treatment of VTE is unacceptable because many patients will die before treatment can be initiated. Furthermore, even clinically silent disease is associated with long-term morbidity from the postphlebotic syndrome and predisposes the patient to future thromboembolic events. Despite an immense body of literature that overwhelmingly supports the widespread use of pharmacologic and nonpharmacologic strategies to prevent VTE, prophylaxis is underutilized in most hospitals.^{3,72} Even when prophylaxis is given, many patients receive prophylaxis that is less than optimal. Educational programs and clinical decision-support systems have been shown to improve the appropriate use of VTE prevention methods.³

6 The goal of an effective VTE prophylaxis program is to identify all patients at risk, determine each patient's level of risk, select and implement regimens that provide sufficient protection for the level of risk, and avoid or limit complications from the selected regimens. Since hospitalized patients are frequently at high risk for VTE, screening all patients prior to or at the time of admission to determine their level of risk is the first step in an effective prophylaxis program. The risk-classification criteria and recommended prophylaxis strategies promulgated by the ACCP Conference on Antithrombotic Therapy are used widely in North America³ (Table 19–15). Several pharmacologic and nonpharmacologic methods are effective for preventing VTE, and these can be used alone or in combination. Nonpharmacologic methods improve venous blood flow by mechanical means, whereas drug therapy counteracts the propensity for thrombus formation by dampening the coagulation cascade.

■ NONPHARMACOLOGIC STRATEGIES

Resumption of ambulation as soon as possible following surgery has been shown to reduce the incidence of VTE in low-risk patients.³ Walking increases venous blood flow and promotes the flow of natural antithrombotic factors into the lower extremities. During prolonged surgeries, electrical calf muscle stimulation devices that mimic the pumping action produced during ambulation can be beneficial. Although these devices can reduce the risk of DVT by more than 50%, their use is painful, and they can be used only when the patient is under general anesthesia. Continuous passive motion devices and plantar compression systems are also available, but their effectiveness is not certain.

Graduated compression stockings reduce the incidence of VTE by approximately 60% following general surgery, neurosurgery, and stroke.^{3,73} Compression stockings work by increasing the velocity of venous blood flow. They apply a graded amount of pressure, with the greatest amount of pressure applied at the ankle. Inexpensive and safe, they are an excellent choice when pharmacologic interventions are either contraindicated or difficult to monitor adequately. When combined with pharmacologic interventions, graduated compression stockings have an additive effect. Some patients are unable to wear compression stockings because of the size or shape of their legs, however.

Similar to graduated compression stockings, intermittent pneumatic compression (IPC) devices increase the velocity of blood flow

TABLE 19–15. Risk Classification and Consensus Guidelines for VTE Prevention

| Level of Risk | Calf Vein Thrombosis, % | Symptomatic PE, % | Fatal PE, % | Prevention Strategies |
|---|-------------------------|-------------------|-------------|---|
| Low | | | | |
| Minor surgery, age < 40 years, and no clinical risk factors | 2 | 0.2 | 0.002 | Ambulation |

IPC = intermittent pneumatic compression.

From ref. 3.

in the lower extremities.^{3,74} The technique involves the sequential inflation of a series of cuffs wrapped around the patient's legs. Using graded pressure, the cuffs inflate in 1- to 2-minute cycles continually throughout the day from the ankles to the thighs. IPC has been shown to reduce the risk of VTE by more than 60% following general surgery, neurosurgery, and orthopedic surgery.³ There is some theoretical concern that external compression may dislodge a previously formed clot.⁷⁵ Although IPC is well tolerated and safe to use in patients who have contraindications to pharmacologic therapies, it does have a few drawbacks. It is more expensive than the use of graduated compression stockings, it is a relatively cumbersome technique, and some patients may have difficulty sleeping while using it.³ Like graduated compression hose, IPC can increase the effectiveness of pharmacologic prophylaxis.

Inferior vena cava (IVC) filters, also known as Greenfield filters, provide short-term protection against pulmonary embolism in very high-risk patients by preventing the embolization of a thrombus formed in the lower extremities into the pulmonary circulation.^{3,76,77} Percutaneous insertion of a filter into the IVC is a minimally invasive procedure performed via fluoroscopy. Despite the widespread use of IVC filters, there are very limited data regarding their effectiveness and long-term safety. The evidence suggests that IVC filters, particularly in the absence of effective antithrombotic therapy, increase the long-term risk of recurrent DVT. In the only randomized clinical trial examining the short- and long-term effectiveness of the filters in

patients with a documented proximal DVT, treatment with IVC filters in combination with anticoagulation therapy reduced the risk of PE by more than 75% during the first 12 days following insertion.⁷⁷ However, this benefit was not sustained during 2 years of follow-up, and the long-term risk of recurrent DVT was nearly twofold higher in those who received a filter. Although IVC filters can reduce the short-term risk of PE in patients at highest risk, they should be reserved for patients in whom other prophylactic strategies cannot be used. Further, to reduce the long-term risk of VTE in association with IVC filters, pharmacologic prophylaxis is necessary, and warfarin therapy should begin as soon as the patient is able to tolerate it.

■ PHARMACOLOGIC STRATEGIES

Several pharmacologic interventions have been evaluated extensively in numerous randomized clinical trials.³ Appropriately selected drug therapies can reduce the incidence of VTE dramatically following hip replacement, knee replacement, general surgery, myocardial infarction, and ischemic stroke (see Table 19–15). The choice of agent and dose to use for VTE prevention must be based on the patient's level of risk for thrombosis and bleeding complications, as well as cost and the availability of an adequate drug therapy monitoring system.

CLINICAL CONTROVERSY

A recent and widely publicized study found that “low dose” warfarin (INR goal range 1.5 to 2.0) was substantially more effective than placebo for the long-term treatment of patients with an idiopathic DVT following an initial 6 months of “full intensity” therapy (INR goal range 2.0 to 3.0). However, another study found that long-term “full intensity” warfarin was more effective than the “low dose” regimen. Whereas the full-intensity warfarin appears to be slightly more effective in terms of recurrent VTE, the lower-intensity regimen is easier to manage and requires less frequent monitoring (every 8 weeks rather than every 3 to 4 weeks). It remains unclear whether the tradeoff in terms of reduced quality of life justifies long-term “full intensity” treatment.

Although a meta-analysis by the Antiplatelet Trialists’ Collaboration challenges this view, most randomized, controlled trials fail to show a significant benefit from aspirin therapy in the prevention of VTE.^{3,78} The ACCP Consensus Conference continues to recommend against the use of aspirin as the primary method of VTE prophylaxis. Antiplatelet drugs clearly reduce the risk of coronary artery and cerebrovascular events in patients with arterial disease, but aspirin produces a very modest reduction in VTE following orthopedic surgeries of the lower extremities. The relative contribution of platelets in the pathogenesis of venous thrombosis compared with that of arterial thrombosis can explain the reason for this difference. Venous thrombosis results primarily from venous stasis, whereas arterial thrombosis is most often the result of vascular wall injury.

The most extensively studied agents for the prevention of VTE are UFH, the LMWHs, and fondaparinux.^{3,46} The LMWHs and fondaparinux provide superior protection against VTE compared with low-dose UFH.^{3,46} Their more predictable absorption when given by subcutaneous injection may be the explanation. Even so, UFH remains a highly effective, cost-conscious choice for many patient populations, provided that it is given in the appropriate dose (see Table 19–15). Low-dose UFH (5000 units every 12 hours or every 8 hours) given subcutaneously has been shown to reduce the risk of VTE by 55% to 70% in patients undergoing a wide range of general surgical procedures and following a myocardial infarction or stroke. For the prevention of VTE following hip and knee replacement surgery, the effectiveness of low-dose UFH is considerably lower.³ Adjusted-dose UFH therapy provided subcutaneously, which requires dose adjustments to maintain the aPTT at the high end of the normal range, appears to be substantially more effective than low-dose UFH in the highest-risk patient populations. However, adjusted-dose UFH has been studied in only a few relatively small clinical trials and requires frequent laboratory monitoring. The LMWHs and fondaparinux appear to provide a high degree of protection against VTE in most high-risk populations. The appropriate prophylactic dose for each LMWH product is indication-specific (see Table 19–10). There is no evidence that one LMWH is superior to another for the prevention of VTE. Fondaparinux was significantly more effective than enoxaparin in several clinical trials that enrolled patients undergoing high-risk orthopedic procedures but has not been shown to reduce the incidence of symptomatic pulmonary embolism or mortality.⁴⁶ To provide optimal protection, some experts believe that the LMWHs should be initiated prior to surgery.^{3,79}

Warfarin is a commonly used option for the prevention of VTE following orthopedic surgeries of the lower extremities.³ The evidence is equivocal regarding the relative effectiveness of warfarin

compared with the LMWHs for the prevention of clinically important VTE events in the highest-risk populations. When used to prevent VTE, the dose of warfarin must be adjusted to maintain an INR between 2.0 and 3.0. Oral administration and low drug cost give warfarin some advantages over the LMWHs and fondaparinux. However, warfarin does not achieve its full antithrombotic effect for several days, requires frequent monitoring and periodic dosage adjustments, and carries a substantial risk of major bleeding. For these reasons, warfarin is reserved for the highest-risk patients. Furthermore, warfarin should be recommended only when a well-developed monitoring system is available.⁶

The optimal duration for VTE prophylaxis following surgery is not well established.^{3,80} Prophylaxis should be given throughout the period of risk. For general surgical procedures and medical conditions, once the patient is able to ambulate regularly and other risk factors are no longer present, prophylaxis can be discontinued. Because of the relatively high incidence of VTE in the first month following hospital discharge among patients who have undergone a lower extremity orthopedic procedure, extended prophylaxis following hospital discharge with either an LMWH, fondaparinux, or warfarin appears to be beneficial. Most clinical trials support the use of antithrombotic therapy for 21 to 35 days following total hip replacement, hip fracture repair, and knee replacement surgeries.^{43,81,82}

PHARMACOECONOMIC CONSIDERATIONS

Only a handful of studies have formally evaluated the cost-effectiveness of VTE prevention strategies. The acquisition costs of graduated compression stockings, heparin, and warfarin are considerably less than those of the LMWHs, DTIs, and fondaparinux. However, the acquisition cost for drug therapy is relatively small when compared with the overall cost of care. Economic analyses must take into account the efficacy of the strategy, treatment complications, and monitoring costs.

Determination of the cost-effectiveness of VTE prophylaxis is based on the premise that a reduction in future VTE events will reduce future costs.⁸³ Furthermore, the incremental cost per patient will decrease proportionally with an increase in the frequency of VTE in the population. Stated another way, the cost of providing prophylaxis to 1000 patients will decline as the incidence of VTE in the given population increases. More expensive and effective strategies, therefore, become more cost-effective in higher-risk populations. In populations at low risk for VTE, early ambulation appears to be the most cost-effective strategy. In populations at moderate risk, the use of graduated compression stockings, the least expensive intervention, results in a lower overall cost of care, whereas low-dose UFH is estimated to increase the cost by \$50 (1990 U.S. dollars) per patient when compared with no prophylaxis.⁸⁴ This compares favorably with the incremental costs associated with other routinely employed preventative measures. While the LMWHs provide slightly greater reductions in the risk of VTE in patients at moderate risk of VTE, the additional cost is estimated to be \$107 (1999 U.S. dollars) per patient when compared with low-dose UFH.⁸⁵ Whether universal use of LMWHs in moderate-risk patients is a cost-effective strategy remains controversial.

In high-risk patients, the cost-effectiveness of prevention is far greater because the incidence of VTE is higher. Following hip replacement surgery, regardless of the strategy selected, prophylaxis saves money when compared with no prophylaxis.⁸³ The LMWHs and fondaparinux slightly increase the total mean cost of care after total hip and knee replacement when compared with low-dose

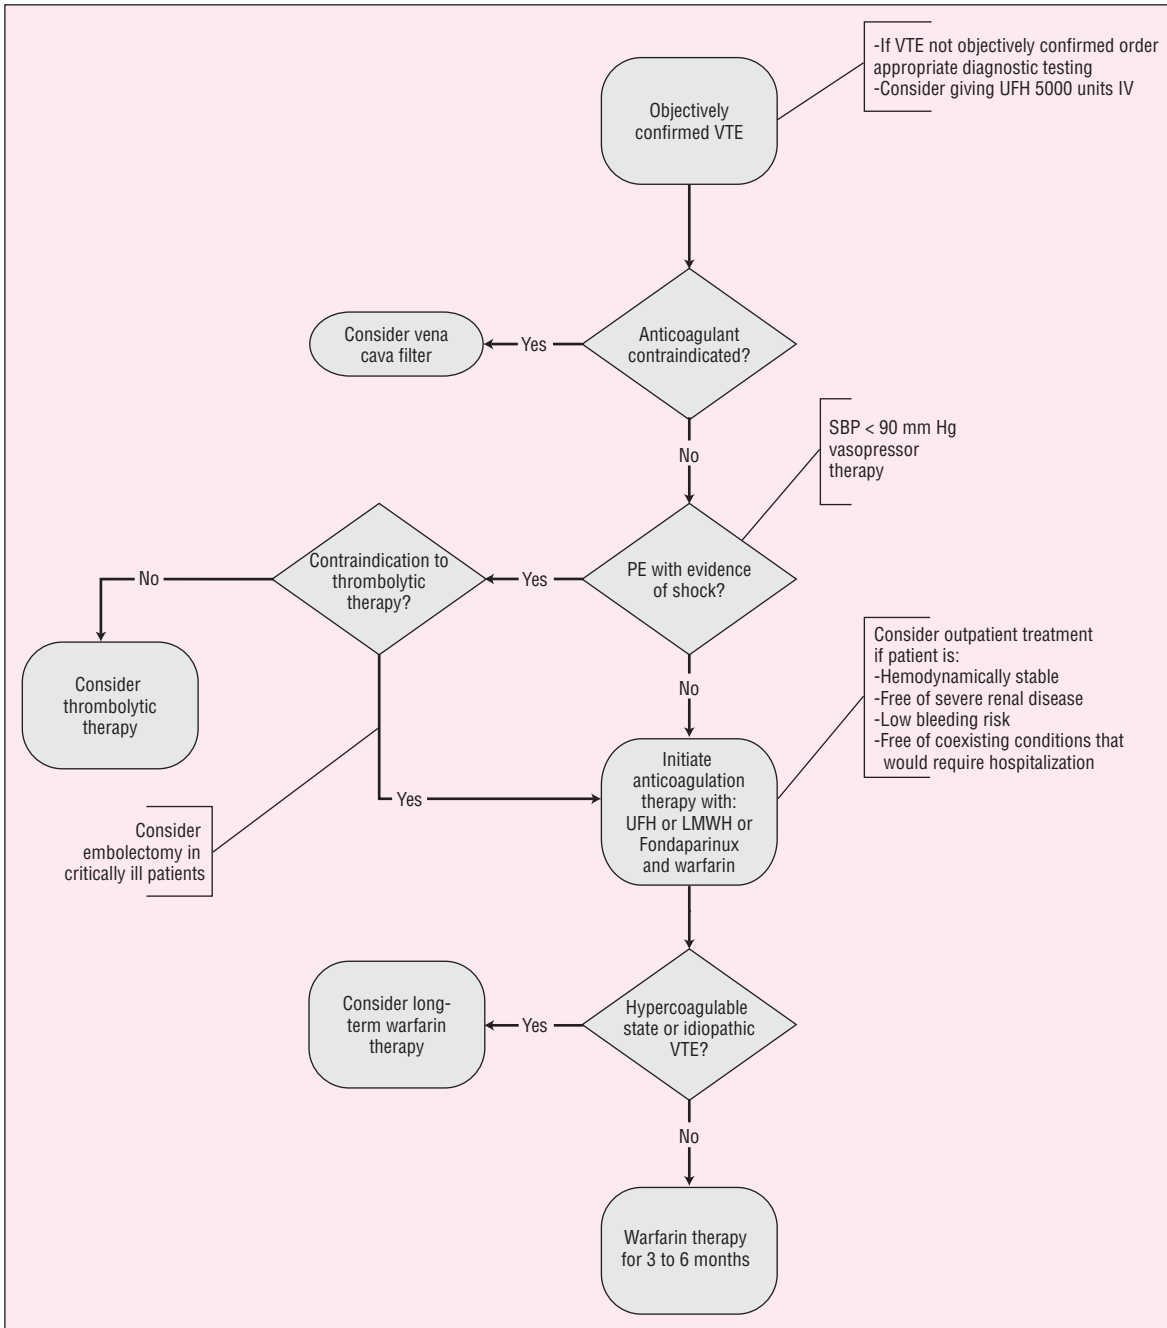

FIGURE 19-10. Treatment of venous thromboembolism.

UFH and warfarin.^{86,87} However, because of their superior effectiveness, the LMWHs have a significantly lower cost per DVT and PE avoided.⁸³ Based on typical drug acquisition costs, the LMWHs and fondaparinux appear to be a cost-effective choice in the highest-risk patient populations.⁸⁸

■ GENERAL APPROACH TO THE TREATMENT OF VTE

Anticoagulation therapy remains the mainstay of treatment for VTE. DVT and PE are manifestations of the same disease

process and are treated similarly.¹² Full “therapeutic” doses of anti-thrombotic drugs not only prevent thrombus extension and embolization but also reduce the risk of long-term sequelae such as the postthrombotic syndrome, pulmonary hypertension, and recurrent thromboembolism.^{12,89} The standard approach is to initiate therapy with UFH by continuous intravenous infusion or a LMWH by subcutaneous injection and to make the transition to warfarin for maintenance therapy (Fig. 19-10 and Table 19-16). Newer approaches using ximelagatran alone or fondaparinux plus warfarin have been investigated recently in phase III clinical trials^{11,44,45,90} (Table 19-17). In rare circumstances, elimination of the obstructing thrombus is warranted, and the use of venous thrombectomy or thrombolysis can be considered.¹² IVC interruption with a filter is also an option in those

TABLE 19–16. Consensus Guidelines for VTE Treatment

| | Recommendation | Grade ^a |
|-----------------------------|---|--------------------|
| Acute anticoagulation | Acute treatment of DVT or PE should be with LMWH, fondaparinux, intravenous UFH, or adjusted-dose subcutaneous UFH. | 1A |
| | The dose of UFH should be sufficient to prolong the aPTT to a range that correlates to an anti-Xa activity of 0.3 to 0.6 units mL. | 1C+ |
| | LMWH or fondaparinux are preferred over UFH. | 1A |
| Duration of acute treatment | A LMWH is preferred in patients with cancer. | 1A |
| | Treatment with UFH, LMWH, or fondaparinux should be overlapped with warfarin for at least 5 days and can be stopped when the INR is >2.0. Most patients should have warfarin started at the same time as UFH, LMWH, or fondaparinux. | 1C |
| | Patients with cancer should be treated with a LMWH for at least 6 months. | 1A |
| | A longer period of heparin therapy (approximately 10 days) is recommended for massive PE or severe iliofemoral thrombosis. | 1C |
| | | |
| Long-term anticoagulation | Oral anticoagulation therapy (target INR 2.5; range 2.0–3.0) should be continued for at least 3 months. If oral anticoagulation therapy is contraindicated (e.g., pregnancy), a treatment dose of LMWH or adjusted-dose UFH should be used. | 1A |
| | Patients with an idiopathic VTE, an inherited disorder of hypercoagulability, or antiphospholipid antibodies should be treated for at least 6 to 12 months and considered for indefinite therapy. | 1A |
| | Patients with two or more episodes of documented DVT should be treated indefinitely. | 1A |

^aRefers to grade of recommendation (1A = strong recommendation applying to most patients without reservation; 1C = intermediate-strength recommendation that may change when stronger evidence becomes available; 1C+ = strong recommendation that applies to most patients in most circumstances. From ref. 12.

with contraindications to anticoagulation therapy or in whom anticoagulant therapy has failed.

Once the diagnosis of VTE has been confirmed objectively (see “Clinical Presentation and Diagnosis” section), anticoagulant therapy with either UFH, LMWH, or fondaparinux should be instituted as soon as possible. Although LMWHs and fondaparinux are highly effective and can be administered in the outpatient setting, most patients in the United States continue to receive intravenous UFH for the initial treatment of VTE.¹¹ The decision to initiate therapy with an LMWH or fondaparinux on an outpatient basis should

be based on institutional resources and patient-specific variables (Table 19–18).

■ UNFRACTIONATED HEPARIN (UFH)

The parenteral administration of UFH followed by warfarin has been the conventional treatment of patients with VTE for more than 40 years.^{11,89,91} Although UFH can be given by either subcutaneous or intravenous injection, continuous intravenous infusion is preferable

TABLE 19–17. Emerging Treatment Options for VTE: Major Findings from Recent Phase III Clinical Trials

| Trial | Treatments | Duration of Trial | Recurrent VTE | Major Bleeding |
|--------------------------------|---|-------------------|--------------------------------------|--------------------------------------|
| Matisse-DVT ⁴⁴ | Fondaparinux 7.5 mg SC q24h versus enoxaparin 1 mg/kg SC q12h All patients received warfarin (INR = 2.0–3.0) for 3 months | 3 months | 3.9% versus 4.1% (<i>p</i> = NS) | 1.1% versus 1.2% (<i>p</i> = NS) |
| Matisse-PE ⁴⁵ | Fondaparinux 7.5 mg SC q24h versus adjusted-dose UFH IV infusion All patients received warfarin (INR = 2.0–3.0) for 3 months | 3 months | 2.4% versus 3.6% (<i>p</i> = NS) | 1.3% versus 1.1% (<i>p</i> = NS) |
| Thrive treatment ⁹⁰ | Ximelagatran 36 mg PO q12h for 6 months versus enoxaparin 1 mg/kg SC q12h followed by warfarin (INR = 2.0–3.0) for 6 months | 6 months | 2.0% versus 2.1% (<i>p</i> = NS) | 1.3% versus 2.2% (<i>p</i> = NS) |

TABLE 19–18. Outpatient Treatment Protocol for Venous Thrombosis (Kaiser Permanente of Colorado)

| | |
|---|--|
| Target Population | Inclusion/exclusion criteria for outpatient VTE treatment |
| Inclusion | Patients with objectively diagnosed VTE |
| Relative exclusion | Patients with clinical evidence of pulmonary embolus or suspected embolism who are hemodynamically stable |
| Exclusion | Arterial thromboembolism or patients who are currently receiving dialysis, actively bleeding, have had recent (within 2 weeks) major surgery/trauma, or have other severe uncompensated co-morbid conditions |
| Recommended Procedure | May vary depending on the patient's clinical condition |
| A. Confirm diagnosis of VTE by objective testing | |
| 1. Venous ultrasound | |
| 2. \dot{V}/\dot{Q} scan | |
| 3. CT scan | |
| B. Day 1 | |
| 1. Baseline laboratory evaluation | |
| a. Prothrombin time (PT) and calculated international normalized ratio (INR) | |
| b. Activated partial thromboplastin time (aPTT) | |
| c. Serum creatinine (Cr_s) | |
| d. Complete blood count (CBC) with platelets | |
| 2. Medication | |
| a. LMWH or fondaparinux injections | |
| i. Enoxaparin 1 mg/kg SC q12h or | |
| ii. Enoxaparin 1.5 mg/kg SC q24h (not recommended for patients with cancer and obese patients) | |
| iii. Dalteparin 100 units/kg SC q12h or | |
| iv. Dalteparin 200 units/kg SC q24h or | |
| v. Tinzaparin 175 units/kg SC q24h or | |
| vi. Fondaparinux 7.5 mg SC q24h (5 mg if < 50 kg and 10 mg if > 100 kg) | |
| b. Warfarin sodium 5–10 mg orally every evening | |
| c. Pain medication if necessary (avoid NSAIDs) | |
| 3. Patient education | |
| a. Clinical pharmacy/nursing | |
| i. Educate patient regarding the importance of proper monitoring of anticoagulation therapy and indications for additional medical evaluation. Document activities in the medical record. | |
| ii. Teach patient how to self-administer LMWH or fondaparinux (if patient or family member unwilling or unable to self-administer LMWH injection, visiting nurse services should be arranged). Initial LMWH or fondaparinux injection should be administered in the medical office or hospital. | |
| iii. Instruct patient regarding local therapy: elevation of affected extremity, localized heat, antiembolic exercises (flexion/extension of ankle for lower extremity VTE, or hand squeezing/relaxation for upper extremity VTE). | |
| b. Pharmacy operations | |
| i. Provide back up for clinical pharmacy/nursing. Reinforce patient education regarding indication, use, monitoring, side effects, and drug interactions with antithrombotic therapy | |
| ii. Repackage LMWH or fondaparinux syringes (if indicated) in patient-specific doses and dispense 5 to 7 days of therapy. | |
| iii. Screen patient's pharmacy profile for potential drug-drug interactions with anticoagulation therapy. | |
| c. Clinical pharmacy anticoagulation service (CPAS) enrollment | |
| i. The physician should forward outpatient VTE treatment orders to the anticoagulation service. | |
| C. Day 2 | |
| 1. Laboratory evaluation: Not required on day 2 of therapy. | |
| 2. Medications: Continue LMWH or fondaparinux and warfarin as directed. | |
| 3. Anticoagulation service | |
| a. Contact patient and evaluate for symptoms of PE, clot extension, and/or bleeding. | |
| b. Arrange for visiting nursing services if family or family member is having difficulty with outpatient therapy. | |
| c. Continue reduced activity as long as pain persists (when possible, elevate extremity); increase activity as tolerated. | |
| d. Document activities in medical record. | |
| D. Day 3 | |
| 1. Laboratory evaluation: Check INR. | |
| 2. Medications: Continue LMWH or fondaparinux and warfarin as directed. | |
| 3. Anticoagulation service | |
| a. Contact patient and evaluate for symptoms of PE, clot extension, and/or bleeding. | |
| b. Interpret results of INR and adjust dose of warfarin to achieve a target INR of 2.5. | |
| c. Patient activity: Continue reduced activity as long as pain persists (when possible, elevate extremity); increase activity as tolerated. | |
| d. Document activities in medical record. | |
| E. Day 4 | |
| 1. Laboratory evaluation: Check INR. | |
| 2. Medications: Continue LMWH or fondaparinux and warfarin as directed. | |
| 3. Anticoagulation service | |
| a. Contact patient and evaluate for symptoms of PE, clot extension, and/or bleeding. | |
| b. Interpret results of INR and adjust dose of warfarin to achieve a target INR of 2.5. | |
| c. Patient activity: No restrictions; if pain increases, contact anticoagulation service or provider. | |
| d. Document activities in medical record. | |

TABLE 19–18. (Continued)

- F. Day 5
1. Laboratory evaluation: Check INR and CBC with platelets.
 2. Medications: Continue LMWH or fondaparinux if indicated and warfarin as directed.
 3. Anticoagulation service
 - a. Contact patient and evaluate for symptoms of PE, clot extension, and/or bleeding.
 - b. Interpret results of INR and adjust dose of warfarin to achieve a target INR of 2.5.
 - c. Patient activity: No restrictions; if pain increases, contact CPAS or provider.
 - d. Document activities in medical record.
- G. Day 6
1. Laboratory evaluation: Check INR.
 2. Medications: Continue LMWH or fondaparinux if indicated and warfarin as directed.
 3. Anticoagulation service
 - a. Contact patient and evaluate for symptoms of PE, clot extension, and/or bleeding.
 - b. Interpret results of INR and adjust dose of warfarin to achieve a target INR of 2.5.
 - c. If LMWH or fondaparinux has not been discontinued, continue until INR > 2.0.
 - d. Patient activity: No restrictions; if pain increases, contact CPAS or provider.
 - e. Document activities in medical record.

because of improved dosing precision and a lower risk of major bleeding¹² (see Table 19–7). The aPTT or a suitable coagulation study should be used to monitor the effect of UFH. The infusion rate should be adjusted to maintain an appropriate therapy range corresponding to a heparin concentration of 0.2 to 0.4 units/mL or an anti-factor Xa level of 0.3 to 0.7 units/mL. Weight-based dosing of UFH achieves a therapeutic aPTT in the vast majority of patients in the first 24 hours^{11,29} (see Table 19–7). Failure to give a sufficient dose of heparin increases the risk of VTE recurrence. Intravenous UFH requires hospitalization with frequent monitoring and dose adjustment.¹² Well-organized inpatient anticoagulation management services have been shown to improve patient care by increasing the proportion of aPTT values in the therapeutic range, reducing the length of hospital stay, and lowering total hospital costs when compared with usual care.⁹ However, despite the widespread use of weight-based dosing protocols, as many as 25% of patients still fail to achieve an adequate response to UFH therapy.¹¹ There is also evidence that UFH does not prevent thrombus progression in some patients with DVT. These limitations of UFH in the acute treatment of VTE have led to the use of alternative agents.

■ LOW-MOLECULAR-WEIGHT HEPARIN

Because of their improved pharmacokinetic and pharmacodynamic profile, as well as ease of use, the LMWHs have replaced UFH for the treatment of VTE in many institutions. The LMWHs given subcutaneously in fixed, weight-based doses (see Table 19–10) are at least as effective as UFH given intravenously for the treatment of VTE.¹² A number of meta-analyses comparing LMWHs with UFH in the treatment of VTE have been conducted.^{12,39} These analyses demonstrate no differences in clinically important end points, including recurrent VTE, PE, major or minor bleeding, and thrombocytopenia. Surprisingly, patients who received LMWH have a significantly lower mortality rate. The reduction in mortality was seen primarily in patients with cancer. The explanation for this survival advantage is unknown, but studies are underway to further examine this observation.⁹² There appears to be no difference in the risk of recurrent VTE among patients who are treated on an inpatient or outpatient basis with an LMWH for DVT.³⁹ However, outpatient treatment was associated with a slightly greater risk of major bleed, indicating the need for close monitoring

when LMWH is given in this setting. There appears to be no difference in the efficacy or safety of once-daily versus twice-daily dosing regimens.^{39,93} However, a subgroup analysis in one study suggested that patients with cancer and obese patients have higher recurrence rates with once-daily enoxaparin.⁹³

CLINICAL CONTROVERSY

Some clinicians advocate strict criteria for the outpatient management of VTE in order to minimize the potential for treatment failure and bleeding complications. These criteria often exclude patients with cancer and the morbidly obese. Proponents of a less restrictive approach argue that strict exclusion criteria unnecessarily withhold outpatient treatment with LMWHs or fondaparinux from those patients who may benefit the most; namely, those with cancer. Each health care system must develop outpatient DVT criteria that fit its resources, philosophy, and patient population best.

8 Given the predictable response and the reduced need for laboratory monitoring with the LMWHs, stable patients with DVT who have normal vital signs, low bleeding risk, and no other comorbid conditions requiring hospitalization can be discharged early or treated entirely on an outpatient basis^{12,94} (see Table 19–18). The efficacy and safety of LMWHs in the home-based treatment of proximal DVT was established initially in large clinical studies.⁹¹ The results of randomized, controlled clinical trials, as well as the experience of several successful outpatient DVT treatment programs in a variety of health care settings, have led to an increased acceptance of outpatient management.^{11,91,94} Indeed, surveys of patients who received outpatient DVT treatment indicate a high degree of satisfaction and comfort, with 96% preferring at-home treatment.

Patients presenting with PE and no evidence of hemodynamic instability are at low risk of subsequent morbidity and mortality. Recent evidence suggests that patients with submassive PE who are hemodynamically stable can be managed safely as outpatients with LMWHs or fondaparinux. However, hemodynamically unstable patients with PE should be admitted and treated with intravenous UFH.⁹² Patients with PE who present with shock have the highest risk of mortality and require aggressive interventions such as volume expansion,

TABLE 19–19. Patient Education for Outpatient VTE Therapy**General Information Regarding VTE and the Goals of Treatment**

Anticoagulant medications injections and tablets have been prescribed to prevent the blood clot from growing larger so that the body can begin to dissolve the clot.

Your body may be able to completely dissolve the clot, but in some cases the clot never goes completely away; even with adequate anticoagulation therapy, some people will have chronic pain and swelling in the affected extremity; people who have had one clot are at increased risk of having future clots.

Warfarin tablets take several days to begin to work; LMWH or fondaparinux injections work right away, so at first, LMWH or fondaparinux injections and warfarin tablets are used together.

When the warfarin has become effective, you will be able to stop the LMWH or fondaparinux injections; you will continue to take warfarin tablets for 3 to 6 months or more to prevent blood clots from returning.

It is important for you to administer your LMWH or fondaparinux and warfarin exactly as directed.

Subcutaneous Injection Technique

You must learn to give yourself a subcutaneous injection of LMWH or fondaparinux. Alternatively, you may have a family member or visiting nurse give it to you.

If your LMWH or fondaparinux syringes were filled by the manufacturer, they can be stored at room temperature; if your syringes were filled by the pharmacy, they should be stored in the refrigerator; if you were instructed to fill your own syringes, you should prepare the syringe immediately prior to injecting its contents.

If you see a bubble in the syringe, do not try to get it out; you may accidentally squirt out part of your dose.

Choose an injection site on your abdomen; clean the area with alcohol; then position an uncapped syringe at a 90-degree angle; pinch the skin, stick the needle in as far as it will go, and gently but firmly push the plunger down; this will inject the medicine into the skin; when all the medication has been injected, remove the needle and dispose of it in an appropriate container.

You likely will experience a burning sensation when the medication is injected; this will go away after a few minutes.

Rotate injection sites from side to side; do not inject into the same site more than once; avoid the area around your navel; do not inject into any bruises.

Blood Test Monitoring

Regular blood tests will be required to make sure that your medication is working properly.

The prothrombin time tells how quickly your blood forms a clot; it is used to tell how well warfarin is working.

The INR is a way to standardize the prothrombin time between laboratories; your goal INR range is between 2.0 and 3.0; if your INR is less than 2.0, you are at higher risk for clotting, if your INR is greater than 3.0, you are at higher risk for bleeding; your dose of warfarin will be adjusted based on the results of this test.

You will need to have a complete blood count test before you begin therapy and after you have been on LMWH or fondaparinux for about 5 days; this will help detect internal bleeding and the occurrence of a rare side effect of heparin therapy that can decrease a component of your blood called platelets.

Warfarin Information

Each strength of warfarin has a unique color; each time your refill your prescription, make sure that your new tablets are the same color as the ones you have been taking; if they are not the same color, ask your pharmacist why.

Warfarin should be taken at approximately the same time each day.

The most common and serious side effect of warfarin is bleeding; you should be careful to avoid situations or activities that increase your risk of injury; apply direct pressure to control bleeding from superficial cuts.

Warfarin has many drug interactions; always check with your provider before taking any new medications (including over-the-counter medication and dietary supplements).

Foods rich in vitamin K (green leafy vegetables, etc.) may interfere with warfarin; you do not need to avoid foods rich in vitamin K, but you should try to maintain consistent dietary habits.

Alcohol can increase your risk for bleeding and interfere with warfarin therapy; drink alcohol in moderation (one to two drinks per day); avoid binge drinking.

Contact Your Provider If You Experience:

Persistent bleeding from a cut or scrape

Blood in your urine

Blood in your stool

Persistent nose bleeding

Increased swelling or pain in your affected extremity

Go to the Emergency Department If You Experience:

Shortness of breath

Chest pain

Coughing up blood

Black, tarry-appearing stool

Severe headache of sudden onset

Slurred speech

LMWH = low-molecular-weight heparin.

vasopressor therapy, intubation, and mechanical ventilation, in addition to antithrombotic therapy.⁹⁵

Not all patients are appropriate candidates for outpatient VTE treatment. At a minimum, patients must be reliable or have adequate caregiver support.¹² Patients and their caregivers must be willing and

active participants in the outpatient management of VTE (Table 19–18 and Table 19–19). Patients who are unable or decline at-home treatment should be admitted to the hospital. These patients may opt subsequently for early discharge on LMWH or fondaparinux. Daily patient contact either in person or via telephone is essential to

identify potential complications and to address questions and concerns promptly. During daily contacts, patients must be asked about symptoms that may indicate bleeding, thrombus extension, and PE.⁹⁴ Once acute treatment with a LMWH or fondaparinux has been transitioned to long-term warfarin therapy (approximately 5 to 10 days), patient contact can occur less frequently.

■ FONDAPARINUX

Fondaparinux has been shown in two recent clinical trials to be a safe and effective alternative to enoxaparin and intravenous UFH for the treatment of VTE (see Table 19–17). In the MATISSE DVT trial, a fixed-dose regimen of fondaparinux (7.5 mg/day) given by subcutaneous injection was compared with the standard weight-adjusted dosing of enoxaparin (1 mg/kg every 12 hours) for the acute treatment of DVT followed by 3 months of warfarin therapy. In the MATISSE PE trial, fondaparinux (7.5 mg subcutaneously every 24 hours) was compared with UFH administered by intravenous infusion. In both trials, the dose of fondaparinux was increased to 10 mg subcutaneously every 24 hours for patients who weighed more than 100 kg and reduced to 5 mg every 24 hours for those who weighed less than 50 kg. Fondaparinux received FDA approval for the acute treatment of DVT and PE in 2004.

CLINICAL CONTROVERSY

In a series of large, well-designed phase III clinical trials, fondaparinux was superior to enoxaparin for the prevention of VTE in patients undergoing lower extremity orthopedic surgery. However, the rate of symptomatic PE and death was not different between the two treatments in any of these studies. Furthermore, fondaparinux has not been compared with warfarin for the prevention of VTE in high-risk patients. Based on these findings, some experts contend that fondaparinux offers no clinical advantages over enoxaparin or warfarin. In addition, although there was no difference in the risk of major hemorrhage seen in the clinical trials compared with enoxaparin, some clinicians worry about the potential for bleeding with fondaparinux because it has a long half-life and cannot be reversed with protamine sulfate. Despite these concerns, some experts believe that fondaparinux should be used preferentially because asymptomatic DVTs and PEs may increase the future risk of recurrent thrombotic events and the post-thrombotic syndrome.

■ WARFARIN

Warfarin monotherapy is an unacceptable choice for the acute treatment of VTE because it does not produce a rapid anticoagulation effect and is associated with a high incidence of recurrent thromboembolism.⁹¹ However, warfarin is very effective in the long-term management of VTE and should be started concurrently with UFH, LMWH, or fondaparinux therapy.¹² The acute treatment regimen should overlap with warfarin therapy for at least 5 days and until a therapeutic INR has been achieved. The initial dose of warfarin should be 5 to 10 mg (see Fig. 19–8), and it should be adjusted periodically to achieve and maintain an INR between 2.0 and 3.0.

The appropriate duration of warfarin maintenance therapy requires careful consideration of the circumstances surrounding the initial thromboembolic event, the presence of ongoing thromboembolic risk factors, and the risk of bleeding.¹² A major consideration in

determining the risk of recurrent VTE once anticoagulation therapy is stopped is whether the initial thrombotic event was associated with a transient or reversible risk factor (e.g., trauma, prolonged immobility, surgery, pregnancy, estrogen use, or major medical illness). For patients in this situation, the risk of recurrence is relatively small, approximately 3% per year, and only short-term anticoagulation treatment is warranted.¹² Six to 12 weeks of warfarin therapy is sufficient for patients with symptomatic isolated calf vein DVT.¹² For patients with a proximal vein DVT, warfarin should be continued for at least 3 months. If the patient has a large iliofemoral DVT or PE, most experts recommend at least 6 months of therapy.⁹⁶ If the patient has ongoing risk factors for recurrent VTE, such as malignancy, antiphospholipid antibodies, or an inherited disorder of hypercoagulability, the risk of recurrence during the first year after stopping treatment exceeds 10%.⁹⁷ In this situation, long-term anticoagulation therapy should be considered. Several recent clinical trials provide clear evidence that long-term treatment with warfarin reduces the risk of recurrent VTE by 70% to 90% in patients with inherited deficiencies of coagulation factors (e.g., protein C or S and antithrombin) or an idiopathic VTE.^{63,97,98} Similar results have been observed with the long-term use of ximelagatran.⁹⁹ The optimal duration for long-term anticoagulation therapy for patients with ongoing risk factors for VTE or an idiopathic VTE remains unknown.^{63,98} The benefit of continuing warfarin therapy longer than 2.5 years has not been studied. Further, the data supporting long-term warfarin therapy in patients with factor V Leiden, prothrombin 20210A gene mutation, increased factor VIII activity, and hyperhomocysteinemia is less compelling. For patients with stable INRs who are able to obtain follow-up blood tests at recommended intervals and who are at low risk for developing bleeding complications, long-term anticoagulation therapy can be continued indefinitely but should be reassessed annually. A decision with the patient to continue anticoagulation therapy should consider the patient's long-term prognosis, financial resources, lifestyle, and quality of life. For patients who are unable to keep follow-up appointments every 3 to 4 weeks, low-intensity warfarin therapy (goal INR 1.5 to 2.0) can be considered following the first 6 months of therapy.⁶³

■ THROMBOLYSIS AND THROMBECTOMY

Most cases of VTE require only anticoagulation therapy. In some cases, however, removal of the occluding thrombus by either pharmacologic or surgical means may be warranted.¹² There is a relative paucity of data supporting either thrombolysis or thrombectomy in the management of VTE, and more study clearly is needed to clarify their precise role.¹⁰⁰ Thrombolytic agents are proteolytic enzymes that enhance the conversion of plasminogen to plasmin, which subsequently degrades the fibrin matrix.

Thrombolytic therapy for DVT was once believed to improve long-term outcomes by preventing the postthrombotic syndrome.¹² While thrombolytic therapy has been shown to improve venous patency, clinical trials have failed to demonstrate any sustained benefit from the routine use of thrombolytic therapy. There is no evidence that thrombolytic therapy is superior to anticoagulation therapy alone in preventing the postthrombotic syndrome. Patients who present with massive DVT and limb gangrene despite anticoagulation therapy are candidates for thrombolysis (Table 19–20). Some authorities recommend thrombolytic treatment for patients with massive iliofemoral venous thromboembolism who are at low risk for bleeding. Catheter-directed instillation of a thrombolytic agent directly into the clot has been used in recent years.¹⁰¹ The risk of bleeding associated with catheter-directed drug administration appears to be less than systemic

TABLE 19–20. Thrombolysis for the Treatment of VTE

Thrombolytic therapy should be reserved for patients who present with shock, hypotension, right ventricular strain, or massive DVT with limb gangrene.

Diagnosis must be confirmed objectively before initiating thrombolytic therapy.

Thrombolytic therapy is most effective when administered as soon as possible after PE diagnosis, but benefit may extend up to 14 days after symptom onset.

Approved PE Thrombolytic Regimens

Streptokinase 250,000 units intravenously over 30 minutes followed by 100,000 units/h for 24 h^a

Urokinase 4400 units/kg intravenously over 10 min followed by 4400 units/kg/h for 12 to 24 h^a

Alteplase 100 mg intravenously over 2 h

Factors that increase the risk of bleeding must be evaluated before thrombolytic therapy is initiated (i.e., recent surgery, trauma or internal bleeding, uncontrolled hypertension, recent stroke or intracranial hemorrhage).

Baseline laboratory tests should include CBC and blood typing in case transfusion is needed.

UFH should not be used during thrombolytic therapy. The aPTT or any other anticoagulation parameter should not be monitored during the thrombolytic infusion.

aPTT should be measured following the completion of thrombolytic therapy.

If aPTT is less than 2.5 times control value, UFH infusion should be started and adjusted to maintain aPTT in therapeutic range.

If aPTT is greater than 2.5 times control value, remeasure every 2 to 4 hours and start UFH infusion when aPTT is less than 2.5.

Avoid phlebotomy, arterial puncture, and other invasive procedures during thrombolytic therapy to minimize the risk of bleeding.

^aTwo-hour infusions of streptokinase and urokinase are as effective and safe as alteplase.
From ref. 102.

administration. Prospective clinical trials are necessary to clarify the clinical utility of catheter-directed thrombolysis in the treatment of DVT.

In the management of acute PE, alteplase, streptokinase, and urokinase all have been shown to restore pulmonary artery patency more rapidly than UFH alone.¹⁰² However, this early benefit does not improve long-term patient outcomes. One week following acute treatment, clot lysis and vessel patency are similar with or without thrombolytic therapy. Thrombolytic therapy has never been shown to improve morbidity or mortality but has been associated with a substantial risk of hemorrhage. Admittedly, clinical trials to date have been underpowered to detect a benefit from thrombolytic therapy. The association of thrombolytic therapy with hemorrhage is particularly problematic because PE frequently occurs following a surgical procedure and the risk of bleeding is high.¹⁰¹ Given the relative lack of data to support their routine use, thrombolytic agents should be reserved for patients with PE who are most likely to benefit (see Table 19–20). Patients who have hemodynamic compromise, as evidenced by significant hypotension (systolic blood pressure 90 mm Hg or less) or severe right ventricular strain due to a large clot burden, may benefit from thrombolytic therapy.^{12,102} Between 5% and 10% of patients diagnosed with PE present with shock. Mortality among these patients is as high as 50%, thus justifying the risks associated with thrombolytic therapy. Although thrombolytic therapy for patients with massive PE manifested by shock and cardiovascular collapse is considered the standard of care, only one trial has demonstrated a mortality benefit.⁹⁵ A significant number of hemodynamically stable patients with PE have evidence of right ventricular dysfunction and appear to be at higher risk for recurrent PE and death when treated with heparin alone.¹⁰² Some experts believe that thrombolytic therapy is beneficial in patients with evidence of right ventricular dysfunction because it restores pulmonary blood flow and reduces pulmonary artery pressure. However, convincing data are lacking.^{95,102}

Although it is an uncommon choice, venous thrombectomy is a reasonable approach to remove a massive obstructive thrombus in a patient with significant iliofemoral venous thrombosis, particularly if the patient is either not a candidate for, or has not responded to, thrombolysis.¹² In cases of chronic PE—where persistent emboli produce progressive pulmonary hypertension, hypoxemia, and right-sided heart failure—surgical embolectomy offers greater benefit than

anticoagulants and may be the treatment of choice. The surgical technique has been refined over the past 20 years. The procedure uses a balloon catheter to extract the thrombus while the patient is under general anesthesia. Fluoroscopy and venography guide the procedure. Balloon angioplasty, with or without stent placement, can be used if a focal iliac vein stenosis is discovered. Full-dose anticoagulation therapy is essential during the entire operative and postoperative periods. These patients still need chronic anticoagulation therapy for the usual recommended duration.

■ VENA CAVA INTERRUPTION

Anticoagulation therapy is the accepted standard for treating DVT and PE. However, an IVC filter may be indicated in special situations when anticoagulants are ineffective or unsafe, including (1) in patients with an absolute contraindication to anticoagulation therapy due to active bleeding or anticipated bleeding from a predisposing lesion, (2) in patients with a massive PE who survive but in whom recurrent embolism may be fatal, or (3) in patients who have recurrent VTE despite adequate anticoagulation therapy.¹⁰³ Interruption of the IVC can be accomplished with an occlusive filter, often called a Greenfield filter, inserted percutaneously through the femoral or jugular vein. There is little evidence to support the widespread use of IVC filters. IVC filters have not been shown to reduce the risk of rehospitalization for PE. Indeed, the permanent IVC interruption appears to increase the long-term risk for recurrent DVT presumably owing to the accumulation of thrombus on the filter resulting in venous stasis.¹⁰³ Whether patients with permanent IVC filters should receive anticoagulant therapy remains unresolved, but many clinicians opt to continue warfarin therapy indefinitely whenever possible. Given these concerns, retrievable filters that can be removed after the period of greatest risk for PE have been developed.

■ ANCILLARY THERAPY

In addition to anticoagulant therapy for patients with proximal DVT, wearing graduated compression stockings can reduce the risk of developing the postthrombotic syndrome by as much as 50%.⁸⁹ To be

^aAnti-Xa monitoring is preferred because the relationship between aPTT and heparin levels differs in pregnant compared with nonpregnant patients.

^bAs pregnancy progresses, the volume of distribution of LMWH changes; glomerular filtration rate increases, and most women gain weight. From ref. 121.

effective, graduated compression stockings must fit properly. Antiembolic leg exercise also may be useful. To perform the exercise, patients should elevate the legs above the hips (7 to 10 degrees) with feet supported. The patient then flexes one foot at a time back and forth for 3 to 5 minutes or until the calf muscle group is fatigued. This exercise should be repeated four to six times daily.¹⁰⁴ Patients also should be instructed not to remain in a sitting position for more than 20 minutes without ambulating briefly or stretching the leg for a few minutes.

Strict bed rest traditionally was recommended following acute DVT based on the assumption that leg movement would dislodge the clot, resulting in PE. However, the evidence contradicts this assumption. Ambulation in conjunction with graduated compression stockings results in faster reduction in pain and swelling with no apparent increase in the rate of clot embolization.¹² Patients should be encouraged to ambulate as much as their symptoms permit. If pain and swelling increase with ambulation, the patient should be instructed to lie down and elevate the affected leg until symptoms subside.

■ TREATMENT OF VTE IN SPECIAL POPULATIONS

■ Pregnancy

The use of anticoagulation therapy for the treatment of DVT or PE in pregnant women is common.²² UFH and LMWHs are the preferred

anticoagulants for use during pregnancy (Table 19–21). They do not cross the placenta, and evidence suggests that they are safe for the fetus.^{22,105} Warfarin should be avoided because it crosses the placenta and can produce fetal bleeding, central nervous system abnormalities, and embryopathy. The DTIs also cross the placenta. To date, fondaparinux has not been formally evaluated in pregnant patients.

Long-term UFH therapy has been linked to significant bone loss and osteoporosis, requires multiple daily injections, and must be monitored frequently (every 1 to 2 weeks) throughout pregnancy. Because of these limitations, many experts recommend the use of LMWHs over UFH throughout pregnancy.²²

■ Pediatric Patients

VTE in children has become increasingly common secondary to prematurity, cancer, trauma, surgery, congenital heart disease, and SLE.³⁵ Children often develop DVTs associated with an indwelling central venous catheter. In contrast to adults, children rarely develop idiopathic VTE.

Anticoagulation with UFH and warfarin remains the most frequently used approach for the treatment of VTE in pediatric patients.³⁵ The recommended target aPTT and INR ranges, as well as the duration of therapy, are extrapolated from clinical trials in adults. The

recommended initial bolus dose of UFH is 75 to 100 units/kg given intravenously over 10 minutes, followed by a maintenance infusion of 28 units/kg per hour for infants 2 to 12 months of age and 20 units/kg per hour for children 1 year of age or older. Subsequent adjustments should be made every 4 to 6 hours to maintain the aPTT within the institution-specific therapeutic range. The usual warfarin starting dose is 0.2 mg/kg, with a maximum of 10 mg.^{35,106} Infants require higher doses of warfarin per kilogram to maintain a therapeutic INR compared with teenagers and adults (mean doses 0.33 mg/kg, 0.09 mg/kg, and 0.04 to 0.08 mg/kg, respectively). The INR target range is 2.0 to 3.0. Frequent INR monitoring and warfarin dose adjustments typically are required. When compared with adults, only 10% to 20% of pediatric patients can be monitored safely once monthly. Obtaining coagulation monitoring tests in pediatric patients is problematic because many have poor or nonexistent venous access. To address this problem, many clinicians recommend using finger-stick blood samples with a portable PT monitor. Since LMWHs have low drug-interaction potential, are less likely to cause HIT or osteoporosis, and require less frequent laboratory testing, they are an attractive alternative in pediatric patients.³⁵ Enoxaparin, dalteparin, tinzaparin, and reviparin have been evaluated in pediatric patients. Most experts recommend that anti-factor Xa activity be monitored and the dose adjusted to maintain anti-factor Xa levels between 0.5 and 1.0 unit/mL. Compared with adults, children younger than 2 to 3 years of age or weighing less than 5 kg have higher per-kilogram dose requirements to achieve a “therapeutic” response. The doses of LMWH for older children generally are similar to the weight-adjusted doses used in adults.³⁵ Warfarin can be initiated concurrently with UFH or LMWH therapy. Therapy should be overlapped for a minimum of 5 days and until the INR is therapeutic. Warfarin should be continued for at least 3 months. Thrombolysis and thrombectomy have been employed successfully in pediatric patients, but published data are very limited.

■ Patients with Cancer

VTE is a frequent complication of malignancy.⁹² Further, compared with patients without cancer, the rate of recurrent VTE in patients with cancer is threefold higher, and the risk of bleeding is two- to sixfold higher.¹⁰⁷ Several meta-analyses and one randomized clinical trial comparing LMWH with UFH for the treatment of VTE have shown a survival advantage for patients with cancer who received LMWHs. While the reduction in mortality may be attributable to a decline in fatal PE, several other mechanisms have been postulated, including

altering tumor angiogenesis and metastasis.²⁰ In vitro data suggest that small to mid-sized heparin molecules have antiangiogenic properties. Warfarin therapy in cancer patients is often complicated by drug interactions (e.g., chemotherapy and antibiotics) and the need to frequently interrupt therapy for invasive procedures (e.g., thoracentesis, percutaneous biopsy, and abdominal paracentesis).¹⁰⁷ Maintaining stable INR control is more difficult in this patient population due to nausea, anorexia, and vomiting.

Two recent randomized trials provide evidence that long-term LMWH therapy for VTE in cancer patients significantly decreases the rate of recurrent VTE without increasing bleeding risks compared with traditional therapy with oral anticoagulants.^{108,109} In one relatively small study in cancer patients with VTE, fixed-dose subcutaneous enoxaparin for 3 months appeared to be more effective than conventional warfarin therapy, with only 10.5% of enoxaparin-treated patients compared with 21% warfarin-treated patients reaching the composite outcome of major bleeding and recurrent VTE ($p = .09$).¹⁰⁸ In the Comparison of LMWH versus Oral Anticoagulation Therapy for the Prevention of Recurrent Venous Thrombosis (CLOT) trial, continuous treatment with dalteparin for 6 months was compared with conventional therapy with dalteparin followed by warfarin in cancer patients following an acute VTE.¹⁰⁹ The probability of recurrent VTE was reduced by nearly 50% in the long-term dalteparin treatment group, from 17.4% to 8.8% ($p = .0017$). There was no difference in the rate of major bleeding. While this provides compelling data that cancer patients should be given LMWH instead of warfarin for the long-term treatment of VTE, the economic implications of this strategy have not yet been evaluated. In the absence of insurance coverage to offset the relatively high cost of long-term LMWH therapy, most patients are unable to afford it.

■ PHARMACOECONOMIC CONSIDERATIONS

Hospitalization is the main cost driver in the management of VTE.⁹⁴ Although the drug acquisition cost for the LMWHs is substantially higher than UFH, avoiding hospitalization dramatically decreases the overall costs of VTE treatment. A number of cost-effectiveness analyses using decision modeling suggest that the treatment of DVT with LMWHs is more cost effective than the treatment with UFH in both inpatient and outpatient settings.¹¹⁰ Based on this decision model, the LMWHs will reduce overall health care cost if as few as 8% of patients are treated entirely on an outpatients basis or 13% of patients are discharged from the hospital early.

HEPARIN-INDUCED THROMBOCYTOPENIA

9 Heparin-induced thrombocytopenia (HIT) is an uncommon but extremely serious adverse effect associated with heparin use.^{34,111} The immune-mediated platelet activation and thrombin generation seen during HIT can lead to severe and unusual thrombotic complications. Morbidity and mortality associated with HIT are disturbingly high—up to 50% of patients who develop the disorder will suffer a thrombotic complication or die within 30 days in the absence of treatment. The diagnosis of HIT is based on clinical and laboratory findings that confirm heparin antibody formation and platelet activation. To prevent the thrombotic complications associated with HIT, prompt discontinuation of heparin and initiation of an alternative anticoagulant therapy is imperative.

ETIOLOGY AND PATHOPHYSIOLOGY OF HIT

Two types of thrombocytopenia associated with heparin use have been described.^{7,34,111} As many as 25% of patients receiving heparin therapy develop a benign, mild reduction in platelet counts referred to as *non-immune-mediated heparin-associated thrombocytopenia* (HAT) or previously called *HIT type 1*. HAT produces a transient fall in platelet count that occurs early, typically between days 2 and 4, during the course of therapy. The degree of thrombocytopenia is usually mild, with platelet counts rarely going below 100,000/mm³. It is not necessary to discontinue heparin therapy in these patients because platelet counts generally rebound to baseline values despite continued use. The exact mechanism of HAT is unknown, but it may be the result of platelet aggregation, a dilutional effect, or diminished platelet

FIGURE 19-11. Pathogenesis of heparin-induced thrombocytopenia.

production often seen in acutely ill patients. No clinical sequelae are associated with this benign phenomenon.

The second type of thrombocytopenia associated with heparin use is known as *immune-mediated HIT* (formally known as *HIT type 2*).^{7,34,111} HIT is a severe pathologic adverse effect of heparin with a significant potential to cause thrombotic complications. The time course and magnitude of thrombocytopenia associated with HIT differ from those of HAT. Platelets counts typically begin to fall after 5 or more days of continuous heparin use, most often between days 7 and 14 of therapy. The development of thrombocytopenia can be delayed up to 20 days in patients naive to heparin therapy. Conversely, so-called rapid-onset HIT can occur in 24 to 48 hours in patients with recent exposure to heparin (i.e., in the previous 3 to 6 months).¹¹² Platelet counts commonly fall below $100,000/\text{mm}^3$ but rarely nadir lower than $20,000/\text{mm}^3$. In some cases, overt thrombocytopenia may not occur, but a drop in platelet count greater than 50% from baseline is considered indicative of HIT.

The frequency of immune-mediated HIT is related most powerfully to the duration and type of heparin used and, to a lesser extent, to the dose and route of administration.¹¹¹ The incidence of HIT associated with intravenous full-dose UFH given for prolonged periods is significantly higher than that of low-dose subcutaneous UFH or LMWHs. The estimated overall incidence of HIT after 5 days of UFH use is 1% to 3%, but the cumulative incidence may be as high as 6% after 14 days of continuous intravenous use. LMWHs are associated with a significantly lower risk of HIT (<1%).^{7,113}

The pathogenesis of HIT involves an immunoglobulin-mediated response to the heparin molecule leading to platelet activation and thrombin generation¹¹¹ (Fig. 19-11). With platelet activation, there is release of PF-4 from platelet granules. Heparin binds to PF-4 (1), forming a negatively charged polysaccharide molecule that is highly

antigenic and stimulates the production of IgG antibodies (2). Although heparin-induced antibody formation occurs in 10% to 20% of patients treated with heparin, most of these patients never develop HIT. In patients who develop HIT, the heparin-PF-4-IgG complexes bind to the Fc receptor on platelets (3), leading to further platelet activation and the release of PF-4 and procoagulant microparticles from platelet granules. In addition, PF-4 and heparin-like molecules bind to the surface of endothelial cells, resulting in antibody-induced endothelial cell damage and the release of tissue factor (4,5). The net result of this cascade of events is an increased risk of thrombotic events secondary to platelet activation, endothelial damage, and thrombin generation despite moderate to severe thrombocytopenia. Antibodies to the heparin-PF-4 complex are transient, but the exact duration of continued immunogenicity is unknown.

CLINICAL PRESENTATION AND DIAGNOSIS OF HIT

Thrombotic complications are the most common clinical sequelae of HIT³⁴ (Table 19-22). The incidence of thrombosis is as high as 50% in patients with laboratory-confirmed immune-mediated thrombocytopenia. Thrombosis may occur in patients with seemingly mild thrombocytopenia, but platelet counts invariably have dropped more than 50% from baseline. This syndrome is poorly recognized, and many, perhaps most, patients diagnosed with HIT initially presented with thrombosis. Even among those who are diagnosed prior to the development of thrombosis, the prognosis is poor. In one case series of patients who were diagnosed with HIT without thrombosis, the cumulative incidence of thrombosis over the next 30 days was greater than 50% despite the discontinuation of heparin therapy.¹¹⁴

Venous thrombosis is the most common thrombotic complication associated with HIT, and most patients develop proximal DVT.¹¹⁴

TABLE 19–22. Presentation of Heparin-Induced Thrombocytopenia (HIT)**General**

Venous thromboembolism is the most common presentation of HIT, although arterial events (e.g., myocardial infarction and stroke) can occur. HIT should be suspected if a patient develops a DVT or PE while or soon after receiving unfractionated heparin.

Symptoms and Signs

Thromboembolic events secondary to HIT produce the same signs and symptoms as those of other etiologies (see “Presentation of Deep Venous Thrombosis and Pulmonary Embolism”).

Laboratory Tests

The patient’s platelet count typically will be below 100,000/mm³ or drop more than 50% from baseline. The platelet count usually drops after 5 days of UFH therapy but may drop sooner if the patient has been given heparin in the past 6 months.

Other Diagnostic Tests

An enzyme-linked immunosorbent assay (ELISA) for the presence of antibodies to the heparin–PF-4 complex should be performed to confirm the diagnosis. Functional assays including the heparin-induced platelet-activation assay (HIPAA), the serotonin-release assay (SRA), and the platelet-aggregation assay (PAA) also may be performed to confirm the diagnosis.

A large percentage of patients develop asymptomatic VTE. PE occurs in 25% of patients with thrombotic complications and contributes significantly to mortality. Arterial thrombosis occurs less commonly. Limb artery occlusion, stroke, and myocardial infarction are the most commonly reported arterial events. Heparin-induced skin lesions occur in 10% to 20% of patients with HIT. Lesions range from painful, localized erythematous plaques to widespread dermal necrosis. Amputation in such cases frequently is required. Mortality from HIT may be as high as 36% in patients with acute thrombosis. The relatively high frequency of thrombotic complications and poor outcomes

associated with HIT emphasize the need for prompt recognition and diagnosis.

The diagnosis of immune-mediated HIT is made based on clinical findings supplemented by laboratory tests confirming the presence of antibodies to heparin or platelet activation induced by heparin.^{34,111} While thrombocytopenia is the most common initial event suggesting the diagnosis of HIT, clinicians should evaluate all the potential causes. New thrombosis shortly after the development of thrombocytopenia is a distinguishing feature in nearly half of all patients with HIT.¹¹⁴ The time course and magnitude of thrombocytopenia are the features distinguishing immune-mediated HIT from HAT. Acute thrombosis and skin lesions also may occur prior to the development of overt thrombocytopenia. HIT should be suspected immediately when these events occur in any patient on UFH or LMWH therapy.

Laboratory testing must be performed to confirm the diagnosis of HIT.¹¹⁵ Laboratory testing is very helpful in patients with only mild to moderate thrombocytopenia in whom HIT is suspected. Two types of assays are available to detect the presence of heparin antibodies. Platelet activation assays, also known as *functional assays*, confirm in vitro platelet activation in the presence of therapeutic heparin levels. Functional assays include the heparin-induced platelet-activation assay (HIPAA), the serotonin-release assay (SRA), and the platelet-aggregation assay (PAA). The HIPAA and SRA tests have higher sensitivity and specificity than the PAA assay but are technically more difficult to perform. Antigen assays that detect the presence of specific antibodies against the heparin–PF-4 complex using enzyme-linked immunosorbent assays (ELISA) are also available. These tests have reasonably high sensitivity and specificity. The optimal test for laboratory confirmation of immune-mediated HIT is unclear. The most readily available test with the greatest sensitivity and specificity should be used. The combined use of functional and ELISA assays may reduce false-negative results. When results of one test are negative or indeterminate in patients suspected of HIT, another test should be considered.

► TREATMENT: Heparin-Induced Thrombocytopenia

■ GENERAL APPROACHES TO THE TREATMENT OF HIT

The ACCP has established recommendations for the treatment of HIT.⁷ Once the diagnosis of HIT is established or strongly suspected, *all* sources of heparin, including heparin flushes, should be discontinued, and an alternative anticoagulant agent should be initiated^{7,34,111} (Fig. 19–12). Even in the absence of thrombosis, patients with HIT are at extremely high risk for developing serious thrombotic complications over the next 30 days without treatment. The time required for laboratory results to be reported can be prolonged. It is crucial that patients be anticoagulated by some other means to prevent new thrombosis. Anticoagulant agents that rapidly inhibit thrombin activity and are devoid of significant cross-reactivity with heparin–PF-4 antibodies are the drugs of choice for the management of HIT.³⁴ In cases of severe or life-threatening thrombosis, surgical extraction of thrombi may be required. Limited data exist regarding the use of thrombolytic therapy in severe HIT with thrombosis. The use of warfarin for long-term anticoagulation in HIT with thrombosis patients is recommended. However, care must be taken when initiating warfarin in these patients because the risk of inducing further thrombosis secondary to inhibition of proteins C and S is possible.

■ PHARMACOLOGIC TREATMENT OPTIONS

DTIs are the drugs of choice for the treatment of HIT with or without thrombosis (Table 19–23). For the treatment of HIT, lepirudin and argatroban are administered by intravenous infusion.^{7,34} Lepirudin and argatroban should be titrated based on aPTT testing with a target of 1.5 to 3.0 times the normal control or the institution-specific therapeutic range. The comparative efficacy of these agents has not been evaluated formally, and they are considered equally suitable for the initial treatment of HIT. Some clinicians prefer argatroban because it has a shorter half-life, modest bleeding risk, and lower cost compared with lepirudin. Fondaparinux is an attractive option for the management of HIT, but it has not yet been studied systematically for this indication. If the oral DTIs receive FDA approval, they may prove to be the ideal agents for the acute and long-term management of patients with HIT. Patient-related factors, such as the presence of renal or hepatic dysfunction, as well as institutional preference, availability, and cost, should be used to determine the most appropriate agent. The LMWHs are not recommended for use in HIT because they have nearly 100% cross-reactivity with heparin-antibodies by in vitro testing.³⁴

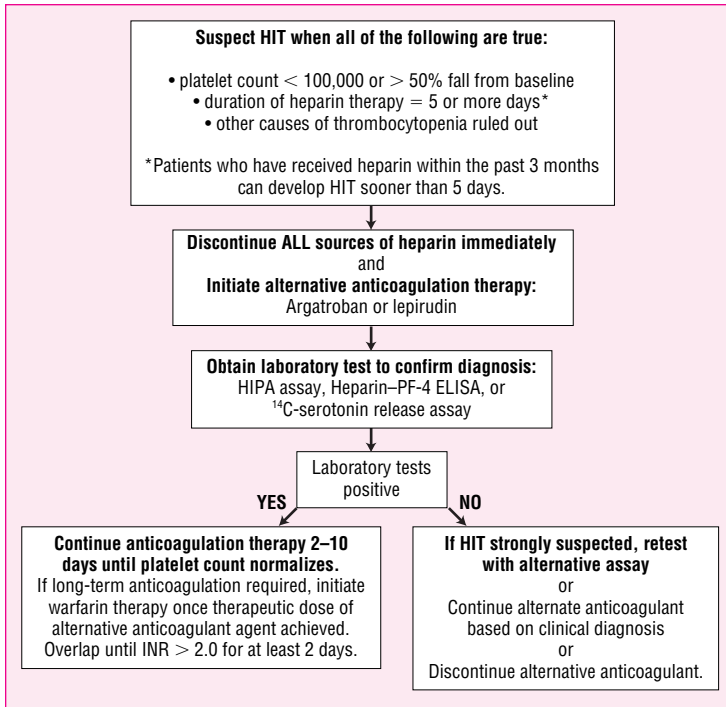

FIGURE 19-12. Treatment of heparin-induced thrombocytopenia (HIT). HIPA assay = heparin-induced platelet activation assay; ELISA = enzyme-linked immunosorbent assay; INR = international normalized ratio.

The use of warfarin during the initial treatment of HIT is potentially dangerous.^{34,116} The rapid reduction in protein C concentrations induced early in the course of warfarin therapy further increases the risk of thrombosis in patients with HIT. This concern is supported by the observation that several patients with HIT have developed venous limb gangrene when treated with warfarin alone. Patients with venous limb gangrene had relatively high INRs after the initiation of warfarin therapy and presumably had rapid depletion of protein C. However, one case series found a low incidence of venous limb gangrene among HIT patients treated with low to moderate dose of warfarin.¹¹⁷ Despite conflicting data, warfarin is not recommended

for the initial treatment of patients diagnosed with HIT.^{7,34} However, patients requiring long-term anticoagulation for the management of HIT can use warfarin safely. The appropriate timing for initiating warfarin in these patients remains unclear. A conservative approach is to withhold warfarin until the patient is stabilized and platelet counts have rebounded above 100,000/mm³. This may prevent the development of further thrombotic adverse events due to protein C depletion. Therapy should be overlapped with a DTI until the thrombocytopenia has resolved and the full anticoagulant effect of warfarin has been achieved. Initial doses of warfarin greater than 5 mg should be strictly avoided in these patients.

TABLE 19-23. Recommended Dose and Monitoring Parameters for Direct Thrombin Inhibitors to Treat Heparin-Induced Thrombocytopenia

| Agent | Dose | Monitoring Parameters | Clinical Considerations |
|------------|---|--|---|
| Lepirudin | 0.4 mg/kg slow IV bolus, followed by 0.15 mg/kg/h IV infusion | Obtain baseline PT, aPTT, CBC, and serum Cr; check aPTT 4 hours after initiation and adjust dose to achieve aPTT of 1.5–3.0 times control; once stable, monitor aPTT q12h. | Initial dose must be reduced in patients with renal impairment. Antihirudin antibodies can occur in up to 40% of patients and can lead to reduced clearance. Concomitant warfarin requires dose adjustment. |
| Argatroban | 2 mcg/kg/min continuous IV infusion | Obtain baseline PT and aPTT; monitor aPTT 2 hours after initiation, and adjust dose to achieve therapeutic aPTT | Reduce initial dose to 0.5 mcg/kg/min for those with hepatic impairment. Will cause significant elevation in PT/INR; concurrent warfarin therapy requires special management. |

CLINICAL CONTROVERSY

Many clinicians and patients have eagerly waited for FDA approval of ximelagatran—the first oral DTI. Many argue that it should replace warfarin therapy because it has few known drug-drug or drug-food interactions, does not require coagulation monitoring, and is effective for both the acute and long-term treatment of VTE in fixed doses. Opponents argue that ximelagatran does not have a favorable safety record and will require periodic liver function monitoring. Further, they argue, adherence and persistence with ximelagatran therapy may be unacceptably low because it must be taken twice daily, and unlike with warfarin therapy, patients will not receive ongoing monitoring and education. As noted previously, the FDA did not approve ximelagatran, however, the sponsor may resubmit for approval.

The management of pregnant patients with a history of HIT who require anticoagulation therapy presents a challenge. Both UFH and LMWH are the anticoagulants of choice for pregnant patients requiring anticoagulation therapy.²² Women who develop HIT during pregnancy or have a recent history of HIT cannot use UFH safely. LMWHs, while known to be cross-reactive with HIT antibodies, may be considered an option, but continuous monitoring of platelet count, clinical parameters, and laboratory evidence of HIT is

required. Limited evidence exists for the use of DTIs in pregnancy. Lepirudin is known to cross the placenta, but case reports suggest that it may be safe for the management of HIT with thrombosis in pregnancy.¹¹⁸

EVALUATION OF THERAPEUTIC OUTCOMES

The appropriate duration of therapy for HIT is unknown.^{7,34} Platelet counts should be monitored frequently, and patients should be watched closely for the development of new thrombosis after starting an alternate anticoagulant. Patients with HIT without thrombosis should be continued on an alternative agent until the platelet counts have normalized. Patients with thrombosis, either at the time of presentation or following the diagnosis of HIT, require warfarin therapy for at least 6 months. The initial anticoagulant used should be continued until the INR is persistently greater than 2.0. In addition, it is important to clearly document the occurrence of immune-mediated HIT in the patient's medical record and educate the patient regarding this adverse effect. Future use of UFH, particularly in the next 3 to 6 months, should be strictly avoided. Patients with a history of HIT should be tested for HIT antibodies prior to any future use of UFH. There are few data regarding the use of UFH in patients with a remote history of HIT.¹¹⁸

STROKE

Susan C. Fagan and David C. Hess

Learning Objectives and other resources can be found at www.pharmacotherapyonline.com.

KEY CONCEPTS

- 1 Stroke is one of the leading killers of individuals worldwide.
- 2 Stroke can be either ischemic (88%) or hemorrhagic (12%).
- 3 Carotid endarterectomy should be performed in ischemic stroke patients with 70% to 99% stenosis of the ipsilateral carotid artery, provided that it is done in an experienced center.
- 4 Early reperfusion (<3 hours from onset) with tissue plasminogen activator (tPA) has been shown to reduce the ultimate disability due to ischemic stroke.
- 5 Antiplatelet therapy is the cornerstone of secondary prevention of ischemic stroke.
- 6 Warfarin is the drug of choice for secondary prevention of cardioembolic stroke.
- 7 Blood pressure lowering is effective in both the primary and secondary prevention of both ischemic and hemorrhagic stroke regardless of blood pressure.
- 8 Blood pressure lowering in the acute stroke period (first 7 days) may result in decreased cerebral blood flow and worsened symptoms.
- 9 Statin therapy is recommended for all ischemic stroke patients, regardless of baseline cholesterol, to reduce stroke recurrence.

1 Stroke is a leading killer worldwide and the third leading cause of death in the United States, behind cardiovascular disease and all cancers. Despite improvements in the stroke mortality rates in the second half of the twentieth century, stroke occurs in more than 700,000 individuals per year and results in 150,000 deaths.¹ Recent advances in our knowledge of the pathophysiology of stroke have led to evidence-based recommendations on the management of the stroke patient.

EPIDEMIOLOGY

There are currently 4.6 million stroke survivors in the United States, and stroke is the leading cause of adult disability.¹ Approximately 20% of patients in nursing homes have had a stroke,² and stroke is also a leading diagnosis in inpatient rehabilitation. Owing in part to the need for these expensive posthospitalization care environments, stroke is also one of the most expensive diseases in the United States, with annual costs greater than \$50 billion.¹ Current projections are that death due to stroke will increase exponentially in the next 30 years owing to aging of the population and our inability to control risk factors.³

Stroke risk is increased above that of the general population in the elderly male individuals and in African-Americans.¹ In addition, geographic disparity in stroke incidence exists, such that several areas of the southeastern United States have stroke mortality rates more than twice that of the national average.⁴ This phenomenon, originally describing areas of the coastal Carolinas and Georgia, has been named the “Stroke Belt.”

ETIOLOGY AND CLASSIFICATION

2 Stroke can be either ischemic or hemorrhagic (88% and 12%, respectively, of all strokes in the 2003 American Heart Association report).¹ A classification of stroke by mechanism is given in Figure 20–1. Hemorrhagic strokes include subarachnoid hemorrhage, intracerebral hemorrhage, and subdural hematomas. Subarachnoid hemorrhage occurs when blood enters the subarachnoid space (where cerebrospinal fluid is housed) owing to either trauma, rupture of an intracranial aneurysm, or rupture of an arteriovenous malformation (AVM). By contrast, intracerebral hemorrhage occurs when a blood vessel ruptures within the brain parenchyma itself, resulting in the formation of a hematoma. These types of hemorrhages very often are associated with uncontrolled high blood pressure and sometimes antithrombotic or thrombolytic therapy. Subdural hematomas refer to collections of blood below the dura (covering of the brain), and they are caused most often by trauma. Hemorrhagic stroke, although less common, is significantly more lethal than ischemic stroke, with 30-day case-fatality rates that are two to six times higher.⁵

Ischemic strokes are due either to local thrombus formation or to embolic phenomenon, resulting in occlusion of a cerebral artery. Atherosclerosis, particularly of the cerebral vasculature, is a causative factor in most cases of ischemic stroke, although 30% are cryptogenic. Emboli can arise either from intra- or extracranial arteries (including the aortic arch) or, as is the case in 20% of all ischemic strokes, the heart. Cardiogenic embolism is presumed to have occurred if the patient has concomitant atrial fibrillation, valvular heart disease, or any other condition of the heart that may lead to clot formation.⁶ Distinguishing between cardiogenic embolism and other causes of

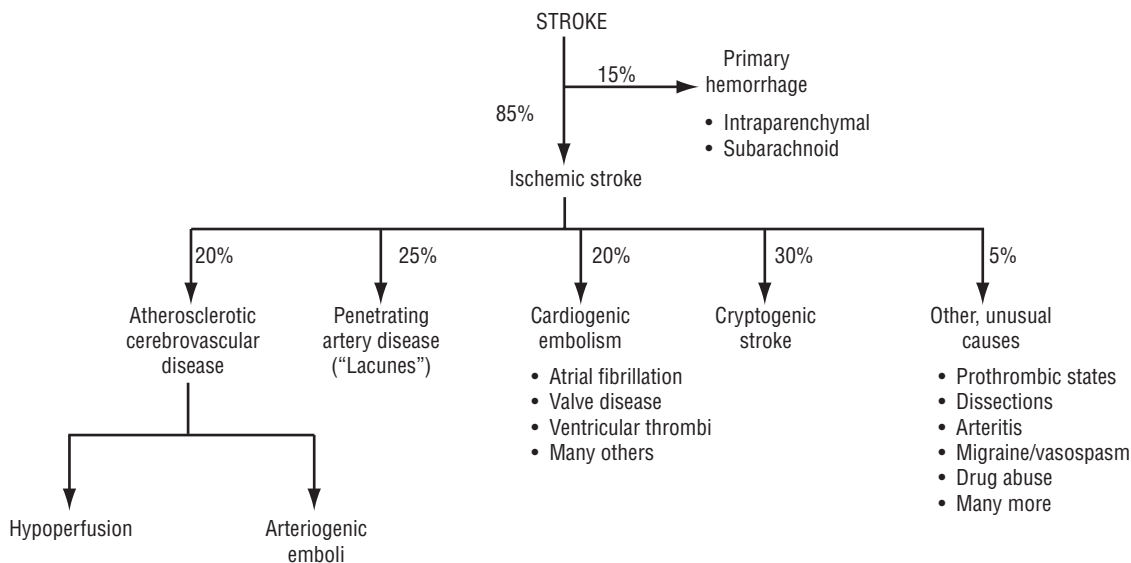

FIGURE 20-1. A classification of stroke by mechanism with estimates of the frequency of various categories of abnormalities. Approximately 30% of ischemic strokes are cryptogenic.

ischemic stroke is important in determining long-term pharmacotherapy in a given patient.

RISK FACTORS

Risk factors for stroke can be subdivided into nonmodifiable and modifiable. The main risk factors of stroke are listed in Table 20-1. An individual's risk of having a stroke increases substantially as he or she ages, with a doubling of risk for each decade after age 55. Men are at a higher risk of stroke than women when matched for age, but women who suffer from a stroke are more likely to die from

it.¹ Ethnicity is another nonmodifiable risk factor for stroke, with African-Americans, Asian-Pacific Islanders, and Hispanics experiencing higher death rates than their Caucasian counterparts.^{1,4}

The most important modifiable risk factor for stroke is hypertension.¹ The treatment of hypertension, beginning in the mid-twentieth century, is thought to be primarily responsible for the drastic reduction in stroke death rates between 1950 and 1980 in the United States.⁴ A second very important risk factor for stroke is cardiac disease. Patients with coronary artery disease, congestive heart failure, left ventricular hypertrophy, and especially atrial fibrillation are at increased risk of stroke.⁷⁻⁹ In fact, the presence of atrial fibrillation is one of the most potent risk factors for ischemic stroke, with stroke

TABLE 20-1. Risk Factors in Ischemic Stroke

Single Risk Factors

Nonmodifiable risk factors or risk markers

- Age
- Gender
- Race
- Ethnicity
- Heredity

Potentially modifiable

- Hypertension—single most important risk factor for ischemic stroke
- Cardiac disease
 - Atrial fibrillation—most important and treatable cardiac cause of stroke
 - Mitral stenosis
 - Mitral annular calcification
 - Left atrial enlargement
 - Structural abnormalities such as atrial-septal aneurysm
 - Myocardial disease
 - 1% to 6% of myocardial infarction patients develop a stroke
- Transient ischemic attacks—major independent risk factor
- Diabetes—independent risk factor
- Hypercholesterolemia—positive risk factor for extracranial atherosclerosis but link still under study for ischemic stroke
- Cigarette smoking

Alcohol

Illicit drug use—cocaine, heroin, amphetamines, LSD, PCP and others linked with stroke

Lifestyle factors—associated with stroke risk

- Obesity
- Physical inactivity
- Diet

Acute triggers—emotional stress

Oral contraceptives—positive only with estrogen content >50 μg

Migraine—risk not clear

Hemostatic and inflammatory factors—fibrinogen linked to increased risk; elevated hematocrit and sickle cell disease are positive risk factors

Homocysteine—still under study, but hyperhomocysteinemia may be related to increased stroke risk

Asymptomatic carotid stenosis

Subclinical disease—aortic arch atheromas

Multiple Risk Factors—Stroke Is Increased by the Presence of Multiple Risk Factors

- Framingham profile
 - Elevated systolic blood pressure
 - Elevated serum cholesterol
 - Glucose intolerance
 - Cigarette smoking
 - Left ventricular hypertrophy

rates from 5% to 20% per year depending on the patient's comorbid conditions.^{10,11} Other known risk factors for atherosclerosis are also known to place patients at risk of stroke. Diabetes mellitus, hypercholesterolemia, and cigarette smoking are known atherogenic states that lead to cerebrovascular disease and ischemic stroke.^{7–9,12}

PATHOPHYSIOLOGY

ISCHEMIC STROKE

In carotid atherosclerosis, progressive accumulation of lipids and inflammatory cells in the intima of the affected arteries, combined with hypertrophy of arterial smooth muscle cells, results in plaque formation. Eventually, sheer stress may result in plaque rupture, collagen exposure, platelet aggregation, and clot formation. The clot may remain in the vessel, causing local occlusion, or travel distally as an embolism, eventually lodging downstream in a cerebral vessel. In the case of cardiogenic embolism, stasis of blood in the atria or ventricles of the heart leads to the formation of local clots that can become dislodged and travel directly through the aorta to the cerebral circulation. The final result of both thrombus formation and embolism is an arterial occlusion, decreasing cerebral blood flow and causing ischemia distal to the occlusion.¹³

Normal cerebral blood flow averages 50 mL/100 g per minute, and this is maintained over a wide range of blood pressures (mean arterial pressures of 50 to 150 mm Hg) by a process called *cerebral autoregulation*. Cerebral blood vessels dilate and constrict in response to changes in blood pressure, but this process can be impaired by atherosclerosis and acute injury, such as stroke. When local cerebral blood flow decreases below 20 mL/100 g per minute, ischemia ensues, and when further reductions below 12 mL/100 g per minute persist, irreversible damage to the brain occurs, and this is called *infarction*. Tissue that is ischemic but maintains membrane integrity is referred to as the ischemic *penumbra* because it usually surrounds the infarct core. This penumbra is potentially salvageable through therapeutic intervention.

Reduction in the provision of nutrients to the ischemic cell eventually leads to depletion of the high-energy phosphates (e.g., ATP) necessary for the maintenance of membrane integrity. Subsequently, extracellular potassium accumulates at the same time that sodium and water are sequestered intracellularly, leading to cell swelling and eventual lysis. Electrolyte imbalance also leads to depolarization of the cell and influx of calcium into the cell. The increase in intracellular calcium results in the activation of lipases, proteases, and endonucleases and the release of free fatty acids from membrane phospholipids. The depolarization of the neuron leads to the release of excitatory amino acids, such as glutamate and aspartate, that perpetuate the neuronal damage when released in excess. The accumulation of free fatty acids, including arachidonic acid, results in the formation of prostaglandins, leukotrienes, and free radicals. In ischemia, the magnitude of free-radical production overwhelms normal scavenging systems, leaving these reactive molecules to attack cell membranes and contribute to the mounting intracellular acidosis. All these events occur within 2 to 3 hours of the onset of ischemia and contribute to the ultimate cell death.¹³

Later targets for intervention in the pathophysiologic process involved after cerebral ischemia include the influx of activated inflammatory cells, starting from 2 hours after the onset of ischemia and lasting for several days. Also, the initiation of apoptosis, or programmed cell death, is thought to occur many hours after the acute insult and may interfere with recovery and repair of brain tissue.¹⁴

HEMORRHAGIC STROKE

The pathophysiology of hemorrhagic stroke is not as well studied as that of ischemic stroke. However, it is known that the presence of blood in the brain parenchyma causes damage to the surrounding tissue through the mechanical effect it produces (mass effect) and the neurotoxicity of the blood components and their degradation products.⁵ Compression of the tissue surrounding the hematoma also may lead to secondary ischemia in some cases. Approximately 30% of intracerebral hemorrhages continue to enlarge over the first 24 hours, and clot volume is the most important predictor of outcome, regardless of location.¹⁵ Much of the early mortality of hemorrhagic stroke (up to 50% at 30 days) is due to the abrupt increase in intracranial pressure that can lead to herniation and death.¹

CLINICAL PRESENTATION (INCLUDING DIAGNOSTIC CONSIDERATIONS)

Stroke is a term used to describe an abrupt-onset focal neurologic deficit that lasts at least 24 hours and is of presumed vascular origin. A *transient ischemic attack* (TIA) is the same but lasts less than 24 hours and usually less than 30 minutes. The abrupt onset and the duration of the symptoms are determined through the history. The use of sensitive imaging techniques (magnetic resonance imaging) has revealed that symptoms lasting more than 1 hour and less than 24 hours, although technically TIAs, are associated with infarction, making TIA and minor stroke clinically indistinguishable. The location of the central nervous system injury and its reference to a specific arterial distribution in the brain are determined through the neurologic examination and confirmed by imaging studies such as computed tomographic (CT) scanning and magnetic resonance imaging (MRI). The main arterial supply to the brain is illustrated in Figure 20–2. Further diagnostic tests are performed to identify the cause of the patient's stroke and to design appropriate therapeutic strategies to prevent further events.¹⁶

CLINICAL PRESENTATION OF STROKE

GENERAL

- The patient may not be able to reliably report the history owing to cognitive or language deficits. A reliable history may have to come from a family member or another witness.

SYMPTOMS

- The patient may complain of weakness on one side of the body, inability to speak, loss of vision, vertigo, or falling. Ischemic stroke is not usually painful, but patients may complain of headache, and with hemorrhagic stroke, it can be very severe.

SIGNS

- Patients usually have multiple signs of neurologic dysfunction, and the specific deficits are determined by the area of the brain involved.
- Hemi- or monoparesis occurs commonly, as does a hemisensory deficit.
- Patients with vertigo and double vision are likely to have posterior circulation involvement.

FIGURE 20-2. Main arterial blood supply to the brain.

- Aphasia is seen commonly in patients with anterior circulation strokes.
- Patients also may suffer from dysarthria, visual field defects, and altered levels of consciousness.

LABORATORY TESTS

- Tests for hypercoagulable states (protein C deficiency, antiphospholipid antibody) should be done only when the cause of the stroke cannot be determined based on the presence of well-known risk factors for stroke. Protein C, protein S, and antithrombin III are best measured in the “steady state,” not in the acute stage. Antiphospholipid antibodies as measured by anticardiolipin antibodies, β_2 -glycoprotein I, and lupus anticoagulant screen are of higher yield than protein C, protein S, and antithrombin III but should be reserved for patients who are young (<50 years), have had multiple venous/arterial thrombotic events, or have livedo reticularis (a skin rash).

OTHER DIAGNOSTIC TESTS

- CT scan of the head will reveal an area of hyperintensity (white) in the area of hemorrhage and will be normal or hypointense (dark) in the area of infarction. The CT scan

may take 24 hours (and rarely longer) to reveal the area of infarction.

- MRI of the head will reveal areas of ischemia with higher resolution and earlier than the CT scan. Diffusion-weighted imaging (DWI) will reveal an evolving infarct within minutes.
- Carotid Doppler (CD) studies will determine whether the patient has a high degree of stenosis in the carotid arteries supplying blood to the brain (extracranial disease).
- The electrocardiogram (ECG) will determine whether the patient has atrial fibrillation, a potent etiologic factor for stroke.
- A transthoracic echocardiogram (TTE) will determine whether valve abnormalities or wall motion abnormalities are sources of emboli to the brain. A “bubble test” can be done to look for an intraatrial shunt indicating an atrial septal defect or a patent foramen ovale.
- A transesophageal echocardiogram (TEE) is a more sensitive test for thrombus in the left atrium. It is effective at examining the aortic arch for atheroma, a potential source of emboli.
- Transcranial Doppler (TCD) will determine whether the patient is likely to have intracranial arterial sclerosis (e.g., middle cerebral artery stenosis).

► TREATMENT: Stroke

■ DESIRED OUTCOME

The goals of treatment of acute stroke are (1) to reduce the ongoing neurologic injury and decrease mortality and long-term disability, (2) prevent complications secondary to immobility and neurologic dysfunction, and (3) prevent stroke recurrence. Primary prevention of stroke is reviewed elsewhere.⁹

■ GENERAL APPROACH TO TREATMENT

The initial approach to the patient with a presumed acute stroke is to ensure that the patient is supported from a respiratory and cardiac standpoint and to quickly determine whether the lesion is ischemic or hemorrhagic based on a CT scan. Ischemic stroke patients presenting within hours of the onset of their symptoms should be evaluated for

TABLE 20–2. Blood Pressure Treatment Guidelines in Acute Ischemic Stroke Patients¹⁷

| Treatment | Received tPA | Did Not Receive tPA |
|---|-----------------|---------------------|
| None | <180/105 | <220/120 |
| Labetolol IV ^a or Nicordipine IV ^b | 180–230/105–120 | >220/121–140 |
| Nitroprusside ^c | Diastolic >140 | Diastolic >140 |

^aLabetolol IV = 10–20 mg, doubled every 10–20 minutes, to a maximum of 300 mg. Also can use an infusion of 2–8 mg/min.

^bNicordipine IV = infusion starting at 5 mg/hr up to 15 mg/hr.

^cNitroprusside IV = infusion starting at 0.5 mcg/kg/min, with continuous arterial BP monitoring.

reperfusion therapy. Patients with elevated blood pressure should remain untreated unless their blood pressure exceeds 220/120 mm Hg or they have evidence of aortic dissection, acute myocardial infarction (AMI), pulmonary edema, or hypertensive encephalopathy. If blood pressure is treated, short-acting parenteral agents, such as labetalol, nicordipine, and nitroprusside, are favored. Current recommendations regarding management of arterial hypertension in stroke patients is given in Table 20–2.¹⁷

In patients with hemorrhagic stroke, an assessment of whether the patient is a candidate for surgical intervention via an endovascular or craniotomy approach should be made. Once the patient is out of the hyperacute phase, attention is placed on preventing worsening, minimizing complications, and instituting appropriate secondary prevention strategies. The acute phase of the stroke includes the first week after the event.¹⁷

■ NONPHARMACOLOGIC THERAPY

■ ISCHEMIC STROKE

Surgical interventions in the acute ischemic stroke patient are limited. In certain cases of ischemic cerebral edema owing to a large infarction, craniectomy to release some of the rising pressure has been tried. In cases of significant swelling associated with a cerebellar infarction, surgical decompression can be lifesaving. Beyond surgical intervention, however, the use of an organized, multidisciplinary approach to stroke care that includes early rehabilitation has been shown to be very effective in reducing the ultimate disability owing to ischemic stroke. In fact, the use of “stroke units” has been associated with outcomes similar to those achieved with early thrombolysis when compared with usual care.¹⁷

3 In secondary prevention, carotid endarterectomy of an ulcerated and/or stenotic carotid artery is a very effective way to reduce stroke incidence and recurrence in appropriate patients and in centers where the operative morbidity and mortality are low. In fact, in ischemic stroke patients with 70% to 99% stenosis of an ipsilateral internal carotid artery, recurrent stroke risk can be reduced by up to 48% compared with medical therapy alone when combined with aspirin 325 mg daily.¹⁸ In patients in whom the risk of endarterectomy is thought to be excessive, carotid stenting may be effective in reducing recurrent stroke risk but is less invasive.¹⁹ Carotid stenting is still considered investigational, however, and issues remain regarding the optimal methods and patients for this procedure.

■ HEMORRHAGIC STROKE

In patients with subarachnoid hemorrhage owing to a ruptured intracranial aneurysm or an AVM, surgical intervention to either clip or ablate the offending vascular abnormality substantially reduces mortality owing to rebleeding.²⁰ In the case of primary intracerebral hemorrhage, however, the benefits of surgery are less well documented. Although many patients undergo surgical treatment of intracerebral hematomas, the procedures have not been studied adequately in clinical trials.^{5,15} Insertion of an extraventricular drain (EVD) and subsequent monitoring of intracranial pressure are done commonly and are the least invasive of the procedures done in these patients. Surgical decompression of a hematoma is more controversial, except when it is a last option in a life-threatening situation. Guidelines have been developed for the use of surgical intervention in the treatment of intracerebral hemorrhage, but they are limited in their impact by the lack of clinical trial data to support them.¹⁵

■ PHARMACOLOGIC THERAPY

■ ISCHEMIC STROKE

■ Drug Treatments of First Choice: Published Guidelines

The Stroke Council of the American Stroke Association has created and published guidelines that address the management of acute ischemic stroke.¹⁷ In general, the only two pharmacologic agents recommended with a grade A recommendation are intravenous tissue plasminogen activator (tPA) within 3 hours of onset and aspirin within 48 hours of onset.

4 Early reperfusion (<3 hours from onset) with intravenous tPA has been shown to reduce the ultimate disability due to ischemic stroke.²¹ Caution must be exercised when using this therapy, and adherence to a strict protocol is essential to achieving positive outcomes.¹⁷ The essentials of the treatment protocol can be summarized as (1) stroke team activation, (2) onset of symptoms within 3 hours, (3) CT scan to rule out hemorrhage, (4) meet inclusion and exclusion criteria (Table 20–3), (5) administer tPA 0.9 mg/kg over 1 hour, with 10% given as initial bolus over 1 minute, (6) avoid antithrombotic (anticoagulant or antiplatelet) therapy for 24 hours, and (7) monitor the patient closely for response and hemorrhage.¹⁷

Early aspirin therapy also has been shown to reduce long-term death and disability^{22,23} but should never be given within 24 hours of the administration of tPA because it can increase the risk of bleeding in such patients.¹⁷

The premier guidelines for the use of antithrombotic therapy in the secondary prevention of ischemic stroke are the American College of Chest Physicians (ACCP) guidelines, which are updated every 3 years.⁶ It is clear that antiplatelet therapy is the cornerstone of secondary prevention of ischemic stroke and should be used in noncardioembolic strokes. All three currently used agents, aspirin, clopidogrel, and extended-release dipyridamole plus aspirin (ERDP + ASA), are considered first-line antiplatelet agents by the ACCP. In patients with atrial fibrillation and a presumed cardiac source of embolism, warfarin is the antithrombotic agent of first choice. Current recommendations regarding the acute treatment and secondary prevention of stroke are given in Table 20–4.

TABLE 20–3. Inclusion and Exclusion Criteria for Alteplase Use in Acute Ischemic Stroke

| | |
|--|---|
| Inclusion Criteria (all YES boxes must be checked before treatment) | |
| YES | |
| <input type="checkbox"/> | Age 18 years or older |
| <input type="checkbox"/> | Clinical diagnosis of ischemic stroke causing a measurable neurologic deficit |
| <input type="checkbox"/> | Time of symptom onset well established to be less than 180 minutes before treatment would begin |
| Exclusion Criteria (all NO boxes must be checked before treatment) | |
| NO | |
| <input type="checkbox"/> | Evidence of intracranial hemorrhage on noncontrast head CT |
| <input type="checkbox"/> | Only minor or rapidly improving stroke symptoms |
| <input type="checkbox"/> | High clinical suspicion of subarachnoid hemorrhage even with normal CT |
| <input type="checkbox"/> | Active internal bleeding (e.g., GI/GU bleeding within 21 days) |
| <input type="checkbox"/> | Known bleeding diathesis, including but not limited to platelet count <100,000/mm ³ |
| <input type="checkbox"/> | Patient has received heparin within 48 hours and had an elevated APTT |
| <input type="checkbox"/> | Recent use of anticoagulant (e.g., warfarin) and elevated PT (>15 sec)/INR |
| <input type="checkbox"/> | Intracranial surgery, serious head trauma, or previous stroke within 3 months |
| <input type="checkbox"/> | Major surgery or serious trauma within 14 days |
| <input type="checkbox"/> | Recent arterial puncture at noncompressible site |
| <input type="checkbox"/> | Lumbar puncture within 7 days |
| <input type="checkbox"/> | History of intracranial hemorrhage, arteriovenous malformation, or aneurysm |
| <input type="checkbox"/> | Witnessed seizure at stroke onset |
| <input type="checkbox"/> | Recent acute myocardial infarction |
| <input type="checkbox"/> | SBP >185 mm Hg or DBP >110 mm Hg at time of treatment |

GENERAL INFORMATION REGARDING SAFETY AND EFFICACY (INCLUDING PIVOTAL CLINICAL TRIALS)

tPA

The effectiveness of intravenous (IV) tPA in the treatment of ischemic stroke was demonstrated in the National Institutes of Neurologic Disorders and Stroke (NINDS) rt-PA Stroke Trial, published in 1995.²¹

In 624 patients treated in equal numbers with either tPA 0.9 mg/kg IV or placebo within 3 hours of the onset of their neurologic symptoms, 39% of the treated patients achieved an “excellent outcome” at 3 months compared with 26% of the placebo patients. An “excellent outcome” was defined as minimal or no disability by several different neurologic scales. This beneficial effect was reported despite a 10-fold increase in the risk of symptomatic intracerebral hemorrhage in the tPA-treated patients (0.6% versus 6.4%). Overall mortality was not different between the two groups (17% with tPA and 21% with placebo). Patients with very severe symptoms at baseline (NIH Stroke Scale [NIHSS] > 20) and early ischemic changes on CT scan were shown to be at highest risk for the development of symptomatic intracranial hemorrhage. Even in patients at highest risk for bleeding, however, those receiving tPA had better outcomes at 90 days than those who received placebo.²¹ The publication of the NINDS trial results significantly changed the way in which acute stroke is managed in the community, promoting the development of acute stroke teams and emphasis on the early diagnosis and treatment of acute stroke. Currently, only 2% to 3% of ischemic stroke patients in the United States receive tPA, primarily owing to failure of patients to present in time to facilities equipped to administer the therapy safely.^{24,25} Hemorrhage rates associated with tPA use in the community have been reported to be similar to those reported in the NINDS trial (5%),²⁴ but significantly higher rates (up to 15%) have been reported when a strict protocol is not followed.²⁵

Aspirin

5 The use of early aspirin to reduce long-term death and disability owing to ischemic stroke is supported by two large, randomized clinical trials. In the International Stroke Trial (IST),²³ aspirin 300 mg/day significantly reduced stroke recurrence within the first 2 weeks without effect on early mortality, resulting in a significant decrease in death and dependency at 6 months. In the Chinese Acute Stroke Trial (CAST),²² aspirin 160 mg/day reduced the risk of recurrence and death in the first 28 days, but long-term death and disability were not different than with placebo. In both trials, a small but significant increase in hemorrhagic transformation of the infarction was demonstrated. Overall, the beneficial effects of early aspirin have been embraced and adopted into clinical guidelines.

TABLE 20–4. Recommendations for Pharmacotherapy of Ischemic Stroke

| | Primary Agents | Alternatives |
|--|---|--|
| Acute Treatment | tPA 0.9 mg/kg IV ^{6,17} (maximum 90 kg) over 1 hour in selected patients within 3 hours of onset. ASA 160–325 mg daily ^{6,17} started within 48 hours of onset | tPA (various doses) intraarterially up to 6 hours after onset in selected patients |
| Secondary Prevention | | |
| Noncardioembolic | Aspirin 50–325 mg daily ⁶ Clopidogrel 75 mg daily ⁶ Aspirin 25 mg + extended-release dipyridamole 200 mg twice daily ⁶ | Ticlopidine 250 mg twice daily ⁶ |
| Cardioembolic (esp. atrial fibrillation) | Warfarin (INR = 2.5) ⁶ | |
| All | ACE inhibitor + diuretic or ARB ⁴⁵ blood pressure lowering ^{33,34} Statin ³⁹ | |

■ Antiplatelet Agents

All patients who have had an acute ischemic stroke or TIA should receive long-term antithrombotic therapy for secondary prevention.⁶ In patients with noncardioembolic stroke, this will be some form of antiplatelet therapy. In a recent meta-analysis, the overall benefit of antiplatelet therapy in patients with atherothrombotic disorders was estimated to be 22%.²⁶ Aspirin is the best-studied of the available agents and, until recently, was considered the sole first-line agent. However, published literature has supported the use of clopidogrel and the aspirin plus extended-release dipyridamole combination product (ERDP + ASA) as additional first-line agents in secondary stroke prevention.

The efficacy of clopidogrel as an antiplatelet agent in atherothrombotic disorders was demonstrated in the CAPRIE trial.²⁷ In this study of more than 19,000 patients with a history of either myocardial infarction (MI), stroke, or peripheral arterial disease (PAD), clopidogrel 75 mg/day was compared with aspirin 325 mg/day for its ability to decrease MI, stroke, or cardiovascular death. In the final analysis, clopidogrel was slightly (8% relative risk reduction [RRR]) more effective than aspirin ($p = .043$) and had a similar incidence of adverse effects. It is not associated with the blood dyscrasias (neutropenia) common with its congener, ticlopidine, and is used widely in patients with atherosclerosis.

In the European Stroke Prevention Study 2 (ESPS-2), aspirin 25 mg and extended-release dipyridamole (ERDP) 200 mg twice daily were compared alone and in combination with placebo for their ability to reduce recurrent stroke over a 2-year period.²⁸ In a total of more than 6600 patients, all three treatment groups were shown to be superior to placebo— aspirin alone, 18% RRR; ERDP alone, 16% RRR; and the combination, 37% RRR. Importantly, this study was the first to show a significant benefit of combination antiplatelet therapy in stroke prevention, with the combination demonstrating a significant advantage over the aspirin-alone group (23% RRR; $p = .006$) and the ERDP-alone group (24% RRR; $p = .002$). Headache resulting in discontinuation occurred in about 15% of the ERDP groups (four times more common than in the placebo group), and the aspirin-treated patients, even at the low dose of 50 mg/day, experienced significantly more bleeding than the other groups. The combination of aspirin 25 mg and ERDP 200 mg twice daily is a highly effective treatment to prevent recurrence in patients with stroke or TIA. No data exist on the ability of this combination to reduce MI and/or cardiovascular death in patients with other indications for antiplatelet therapy.

■ Warfarin

◀6 Warfarin is the most effective treatment for the prevention of stroke in patients with atrial fibrillation.^{10,11,29,30} In patients with atrial fibrillation and a recent history of stroke or TIA, the risk of recurrence places these patients in one of the highest risk categories known. In the European Atrial Fibrillation Trial (EAFT), 669 patients with nonvalvular atrial fibrillation (NVAF) and a prior stroke or TIA were randomized to either warfarin (INR = 2.5–4), aspirin 300 mg/day, or placebo. Patients in the placebo group experienced stroke, MI, or vascular death at a rate of 17% per year compared with 8% per year in the warfarin group and 15% per year in the aspirin group. This represents a 53% reduction in risk with anticoagulation.¹⁰ Subsequent studies in the primary prevention of stroke in patients with NVAF have demonstrated that targeting an international normalization ratio (INR) of 2.5 prevents stroke with the lowest bleeding risk (SPAF III); therefore,

a target INR of 2.5 is recommended in the secondary prevention of stroke.^{11,29,30}

Use of warfarin in the secondary prevention of noncardioembolic stroke was addressed in the Warfarin Aspirin Recurrent Stroke Study.³¹ In 2206 patients with recent stroke, warfarin (INR = 1.4–2.8) was not superior to aspirin 325 mg/day in the prevention of recurrent events. This led many clinicians to abandon the practice of using warfarin as an alternative agent in patients who suffered recurrent events while on antiplatelet therapy in favor of combination or alternate antiplatelet therapy.

■ Blood Pressure Lowering

◀7 Elevated blood pressure is very common in ischemic stroke patients, and treatment of hypertension in these patients is associated with a decreased risk of stroke recurrence.³² In the PROGRESS study, a multinational stroke population (40% Asian) was randomized to receive either blood pressure lowering with the angiotensin-converting enzyme (ACE) inhibitor perindopril (with or without the thiazide diuretic indapamide) or placebo.³³ Treated patients achieved an overall 9/4 mm Hg blood pressure reduction, and this was associated with a 28% reduction in stroke recurrence. In the patients who received the combination treatment (clinician's discretion), the blood pressure lowering achieved was 12/5 mm Hg, and this was associated with an even larger reduction in stroke recurrence (43%). Similar results were achieved in patients with and without hypertension. Based on the results of this study and other evidence of the tolerability and vascular protective properties of the ACE inhibitors, the Joint National Committee (JNC7) recommends an ACE inhibitor and a diuretic for the reduction of blood pressure in patients with stroke or TIA.³⁴

◀8 Blood pressure lowering in the acute stroke period (first 7 days) may result in decreased cerebral blood flow and worsened symptoms; therefore, recommendations are limited to patients out of the acute stroke period.

■ Statins

◀9 The statins have been shown to reduce the risk of stroke by approximately 30% in patients with coronary artery disease and elevated plasma lipids.^{35–37} The National Cholesterol Education Program (NCEP) considers ischemic stroke or TIA to be a coronary “equivalent” and has recommended the use of statins to achieve a low-density lipoprotein (LDL) concentration of less than 100 mg/dL.³⁸ More recently, the Heart Protection Study was published, and it provided evidence that simvastatin 40 mg/day reduced stroke risk in high-risk individuals (including patients with prior stroke) by 25% ($p < .0001$), even in patients with LDL concentrations of less than 116 mg/dL.³⁹ The investigators also showed that this practice is extremely safe, with an excess incidence of myopathy of 0.01%. The study even recommended abandoning the routine monitoring of liver function tests in these individuals because elevations are rarely significant or sustained. Other evidence in primary prevention of patients with hypertension suggests that similar stroke risk reduction can be achieved with other statins in patients with normal total cholesterol values.⁴⁰ Statin therapy is an effective way to reduce stroke risk and should be considered in all ischemic stroke patients.

■ Heparin for Prophylaxis of Deep Vein Thrombosis (DVT)

The use of low-molecular-weight heparins or low-dose subcutaneous unfractionated heparin (5000 units twice daily) can be recommended

for the prevention of DVT in hospitalized patients with decreased mobility owing to their stroke and should be used in all but the most minor strokes.⁶

ALTERNATIVE DRUG TREATMENTS

ASPIRIN PLUS CLOPIDOGREL

In the MATCH study, clopidogrel in combination with aspirin 75 mg daily was no better than clopidogrel alone in secondary stroke prevention.⁴³ However, the combination has been studied in patients with acute coronary syndromes and patients undergoing percutaneous coronary interventions and shown to be significantly more effective than aspirin alone in reducing MI, stroke, and cardiovascular death.^{41,42} Also, when clopidogrel was used with aspirin, the risk of life-threatening bleeding increased from 1.3% to 2.6%.⁴³ This combination can only be recommended in patients with ischemic stroke and a recent history of MI or other coronary events and only with ultra-low-dose aspirin to minimize bleeding risk.⁴⁴

ANGIOTENSIN II RECEPTOR ANTAGONISTS (ARBs)

Angiotensin II receptor antagonists (ARBs) also have been shown to reduce the risk of stroke. In the LIFE study, losartan and metoprolol were compared for their ability to reduce blood pressure and prevent cardiovascular events in a group of severely hypertensive patients.⁴⁵ Despite similar reductions in blood pressure of approximately 30/16 mm Hg, the losartan group experienced a 24% reduction in the risk of stroke. The ARBs should be considered in patients unable to tolerate ACE inhibitors (LIFE) after acute ischemic stroke.

HEPARINS

The use of full-dose unfractionated heparin in the acute stroke period has never been proved to positively affect stroke outcome, and it significantly increases the risk of intracerebral hemorrhage.⁶ Trials of low-molecular-weight heparins or heparinoids have been largely negative and do not support their routine use in stroke patients.^{46–48} Other potential but unproven uses for treatment doses of either unfractionated or low-molecular-weight heparins include bridge therapy in patients being initiated on warfarin, carotid dissection, or continuous worsening of ischemia despite adequate antiplatelet therapy.⁶

TICLOPIDINE

Ticlopidine is a thienopyridine antiplatelet agent, similar in structure and mechanism of action to clopidogrel. It has been shown to reduce the risk of stroke by 30% compared with placebo and by 21% compared with aspirin 325 mg/day in patients at risk.⁶ The use of ticlopidine has been severely restricted by its side-effect profile, however. It causes bone marrow suppression, rash, diarrhea, and elevation of the serum cholesterol concentration. Neutropenia occurs in up to 2% of patients and generally is reversible. More problematic, however, is the increased risk of aplastic anemia and thrombotic thrombocytopenic purpura.⁴⁹ Ticlopidine 250 mg twice daily is still available as an alternative in patients who fail or are intolerant of other therapies but is rarely needed.

DRUG CLASS INFORMATION

Aspirin

Aspirin exerts its antiplatelet effect by irreversibly inhibiting cyclooxygenase, which, in platelets, prevents conversion of arachidonic acid to thromboxane A₂ (TXA₂), which is a powerful vasoconstrictor and stimulator of platelet aggregation. Platelets remain impaired for their life span (5 to 7 days) after exposure to aspirin. Aspirin also inhibits prostacyclin (PGI₂) activity in the smooth muscle of vascular walls. PGI₂ inhibits platelet aggregation, and the vascular endothelium can synthesize prostacyclin such that the platelet antiaggregating effect is maintained. The suppression of PGI₂ production by aspirin has been found to be dose- and duration-related; the higher the dose, the longer the cyclooxygenase production is suppressed. Therefore, the lower the aspirin dose, the less effect on prostacyclin.⁶ The optimal dose of aspirin is still under study, but it should be the dose that inhibits TXA₂ with the least amount of prostacyclin inhibition. It has been shown that an aspirin dose of 325 mg/day will inhibit TXA₂ but will not significantly inhibit PGI₂ production. There is probably a point at which lower doses of aspirin do not completely block TXA₂, and recent studies indicate that the lowest effective dose may be in the range of 50 mg/day.⁵⁰ Upper gastrointestinal (GI) discomfort and bleeding are the most common adverse effects of aspirin and have been shown to be dose-related. The highest rates of GI bleeding (5%) have been reported in patients receiving 1200 mg/day as compared with rates of 2% in patients taking the more commonly prescribed, 300 mg/day. Upper GI symptoms are much more common than frank bleeding, however, with 40% of patients affected at 1200 mg/day and 25% at 300 mg/day.⁵¹ In the ESPS-2 study, even 50 mg/day of aspirin was associated with a twofold increase in bleeding over the placebo group.²⁸

Low doses (<100 mg) of aspirin quickly inhibit cyclooxygenase in all the platelets in the circulation. Therefore, the onset of the antiplatelet effect of aspirin is less than 60 minutes.⁵² It has been reported, however, that some patients either have or develop “aspirin resistance” and may require higher doses to achieve the desired antiplatelet effect.⁵³ Despite this, routine testing for aspirin resistance is not recommended. It was observed recently that administration of ibuprofen prior to the administration of a daily aspirin dose prohibits the aspirin from binding irreversibly to the cyclooxygenase and may decrease its antiplatelet effect.⁵⁴ Current recommendations are to administer aspirin at least 2 hours before ibuprofen or to wait at least 4 hours after an ibuprofen dose.

Extended-Release Dipyridamole plus Aspirin

Early studies of the role of dipyridamole in stroke prevention failed to show a benefit over that realized by aspirin alone. Dipyridamole, in high doses, is thought to inhibit platelet aggregation by inhibiting phosphodiesterase, leading to accumulation of cyclic adenosine monophosphate (cAMP) and cyclic guanosine monophosphate (cGMP) intracellularly, which prevent platelet activation. In addition, dipyridamole also enhances the antithrombotic potential of the vascular wall.⁵⁵ The ESPS-2 demonstrated the efficacy of high-dose extended-release dipyridamole alone and in combination with aspirin in secondary stroke prevention.²⁸ This was the first study to demonstrate the benefits of combination antiplatelet therapy in stroke prevention (the combination was significantly more effective than either agent alone). The extended-release formulation of dipyridamole is important in that it allows twice-daily administration and higher doses

to be tolerated in patients. The use of immediate-release generic dipyridamole in combination with regular aspirin, in order to reduce costs, is unproven and should be discouraged.

In the ESPS-2, 25% of the patients who received combination dipyridamole and aspirin discontinued the therapy early, and the rate of discontinuation owing to headache was more than three times as common (10%) as in the aspirin-alone group (3%). Other reasons for discontinuation were GI problems. Slow initiation of ERDP + ASA at one capsule at bedtime daily for 2 or 3 days can be tried in order to lessen headache symptoms. The headache due to ERDP + ASA is mostly self-limiting and decreases after several days.⁵⁶

■ Clopidogrel

Clopidogrel has a unique platelet antiaggregatory effect in that it is an inhibitor of the adenosine diphosphate (ADP) pathway of platelet aggregation and inhibits known stimuli to platelet aggregation.^{6,27} This effect causes an alteration of the platelet membrane and interference with the membrane-fibrinogenic interaction leading to a blocking of the platelet glycoprotein IIb/IIIa receptor. A time lag of 3 to 7 days before the antiplatelet effect is maximal should be expected. The tolerability of clopidogrel 75 mg/day is at least as good as medium-dose (325 mg/day) aspirin, and GI bleeding is less.²⁷ Clopidogrel is associated with an increased risk of diarrhea and rash, but discontinuation rates owing to adverse effects are similar to those with aspirin 325 mg/day (5.3% to 6%, respectively).²⁷ There is no excess neutropenia in patients taking clopidogrel, and rates of thrombotic thrombocytopenic purpura probably are no greater than background rates.⁵⁷

Clopidogrel is a thienopyridine prodrug and needs to be biotransformed by the liver to an active metabolite. Evidence suggests that the enzyme responsible for the conversion is human cytochrome P450 3A4 (CYP3A4) and that the platelet effects of clopidogrel may be diminished in patients receiving agents that inhibit this enzyme.⁵⁸ Although high doses of the lipophilic statins atorvastatin and simvastatin may diminish the effectiveness of clopidogrel to inhibit platelet aggregation *in vitro*, there does not appear to be any adverse effect on atherothrombotic event rates.⁵⁹ Concomitant administration of clopidogrel with lipophilic statins is often recommended.

■ Ticlopidine

Ticlopidine, another thienopyridine, inhibits activation of the ADP receptor on the platelet, as does clopidogrel. However, in contrast to clopidogrel, ticlopidine possesses a significant side-effect profile and is costly. Side effects include suppression of bone marrow, rash and diarrhea, and elevation of serum cholesterol levels. Neutropenia may occur in up to 2% of patients but is reversible on discontinuation of therapy.⁶ Postmarketing surveillance of the compound revealed an excess in the number of cases of serious blood dyscrasias such as thrombotic thrombocytopenic purpura (TTP).⁴⁸ Monitoring is required because of these side effects, and it is recommended that patients have complete blood counts (CBCs) with differentials every 2 weeks for 3 months. More than 50% of patients report at least one side effect, with GI complaints being the most common. Drug interactions may occur with digoxin, theophylline, and antacids, and these effects should be monitored. Ticlopidine was relegated to third-line status in stroke prevention owing to its adverse-event profile.⁶ Ticlopidine (500 mg/day) in two divided doses of 250 mg is used rarely but

can be recommended as an alternative antiplatelet therapy in extreme cases of intolerance to the other options available.

■ INVESTIGATIONAL STRATEGIES

■ REPERFUSION

Various investigations aimed at shortening the time required to open the occluded cerebral artery and preserve its patency are underway in acute ischemic stroke patients.⁶⁴ Strategies being tried include longer-acting fibrinolytic agents, intraarterial fibrinolysis with tPA and other agents, endovascular clot removal using mechanical and laser-guided approaches, and use of the glycoprotein IIb/IIIa receptor antagonists, both alone and in combination with fibrinolysis. In addition, investigators are trying to identify, using sensitive MRI techniques, which patients may benefit from reperfusion at time points outside the approved 3-hour time window. Undoubtedly, efforts to reperfuse the ischemic brain will continue to be explored, so more patients will be eligible for this therapy.

■ NEUROPROTECTION AND NEURORESTORATION

Although many different neuroprotective agents have been studied in clinical trials of acute ischemic stroke, none has been successful.⁶⁵ The only strategy that has been shown to provide neuroprotection in patients has been hypothermia.⁶⁶ Currently, clinical trials are underway to optimize the mechanism of cooling the ischemic brain (intravascular coils versus surface cooling) and rewarming the patient after hypothermia. Despite discouraging results in previous attempts, however, there is still great interest in developing pharmacologic agents that provide neuroprotection. Some of the most promising agents include free-radical scavengers, anti-inflammatory agents, and agents with multiple proposed mechanisms of protection (e.g., albumin infusions).⁶⁷ In addition, hope still exists that clinicians will be able to enhance the reparative process of the brain (neurorestoration) through targeted neurorehabilitation and the use of neural and cell transplantation.⁶⁸

HEMORRHAGIC STROKE

There are currently no proven pharmacologic strategies for treating intracerebral hemorrhage (ICH).¹⁵ Medical guidelines for the management of blood pressure, raised intracranial pressure, and other medical complications of ICH are those required for the management of any acutely ill patient in a neurointensive care unit.

Subarachnoid hemorrhage (SAH) owing to aneurysm rupture is associated with a high incidence of delayed cerebral ischemia (DCI) in the 2 weeks following the bleeding episode. Vasospasm of the cerebral vasculature is thought to be responsible for DCI and occurs between 4 and 21 days after the bleed, peaking at days 5 through 9.²⁰ The calcium channel blocker nimodipine is recommended to reduce the incidence and severity of neurologic deficits owing to DCI. Nimodipine at a dose of 60 mg every 4 hours should be initiated on diagnosis and continued for 21 days in all SAH patients. Administration of nimodipine therapy is complicated by a fairly high incidence of hypotension. This can be managed by reducing the dosing interval to 30 mg every 2 hours (same daily dose), reducing the total daily dose (30 mg every 4 hours), and maintaining intravascular volume and pressor therapy.²⁰

PHARMACOECONOMIC CONSIDERATIONS

Cost-analysis data on the NINDS trial with tPA estimates that total health care costs (including acute and long-term costs) could be reduced by almost \$5 million for every 1000 patients treated with tPA. Although tPA is expensive, when the total health care costs are factored in, savings can accrue to the health care system as a direct result of appropriate tPA therapy.⁶⁰

In antithrombotic prophylaxis for atrial fibrillation, warfarin therapy was evaluated using quality-adjusted life-years saved (QALYs).⁶¹ It was found that in patients with atrial fibrillation and one additional risk factor, warfarin therapy cost \$8000 per QALY saved. In high-risk patients, those with atrial fibrillation and two or more risk factors, warfarin use was estimated to save \$6200 in costs from stroke and TIA. Costs of monitoring and hemorrhages from warfarin were estimated to be \$5500, thus showing a positive savings from warfarin use. Those without risk factors were much more costly to treat at an estimated \$370,000 per QALY saved when compared with aspirin treatment. Warfarin is cost-effective in high-risk patients, particularly if the hemorrhagic side effects are lower relative to the stroke risk. For comparison purposes, hypertension screening is estimated to cost \$10,000 to \$50,000 per QALY saved. A Swedish study reported the cost-effectiveness of primary stroke prevention in atrial fibrillation patients with oral anticoagulants or aspirin based on four published clinical trials.⁶² The authors found that the total cost per stroke prevented was a \$16 savings if the intracerebral bleeding was 0.3% and \$43 if the bleeding rate was 2%. At a bleeding complication rate of 1.3%, warfarin would prevent 1000 strokes per year and save about \$29 million. The cost-effectiveness of the various first-line antiplatelet agents have been compared as well.⁶³ Without a doubt, aspirin, owing to its extremely low acquisition cost (pennies daily), is cost saving. In other words, it reduces costs at the same time as saving

QALYs. The use of clopidogrel or ERDP + ASA is associated with higher efficacy but significantly greater costs as well (up to \$3 daily). Despite this, both options have been deemed “cost-effective” when administered to a 65-year-old patient with a history of stroke or TIA for the prevention of recurrence. In a recent analysis, ERDP + ASA was associated with \$5000 to \$15,000 per QALY (adjusted for the acquisition cost) and clopidogrel was \$26,580 per QALY. Any cost per QALY less than \$50,000 is thought to be “cost-effective.”⁶³ These estimates are extremely dependent on the assumptions made in the model. Cost-effectiveness in an individual patient is much more difficult to discern.

Primary prevention strategies that address the risk factors for ischemic stroke can be powerful in reducing the costs of stroke. Many of the stroke risk factors can be modified and some eliminated at very low costs (lifestyle changes), therefore developing risk-factor-reduction strategies may be the most cost-effective measure of all. More research is needed in identifying the cost-effectiveness of other forms of acute stroke treatment.

CLINICAL CONTROVERSIES

The use of full-dose unfractionated heparin in the management of acute ischemic stroke remains controversial despite years of debate and a lack of evidence supporting its use. Proponents of the therapy cite strong anecdotal evidence of positive responses in selected patients who have never been studied in clinical trials.

The use of intracranial angioplasty and stenting is strongly supported in the few institutions where the technology exists. Whether these procedures should be attempted in patients outside clinical trials remains controversial.

The use of surgical evacuation of intracranial hemorrhage with and without instillation of fibrinolytic agents is

TABLE 20–5. Monitoring the Stroke Patient

| | Treatment | Parameter(s) | Frequency | Comments |
|--------------------|------------------------------|--|--|---|
| Ischemic stroke | tPA | BP, neurologic function, bleeding | Every 15 min × 1 h; every 0.5 h × 6 h; every 1 h × 17 h; every shift after | |
| | Aspirin | Bleeding | Daily | |
| | Clopidogrel | Bleeding | Daily | |
| | ERDP/ASA | Headache, bleeding | Daily | |
| | Ticlopidine | CBC, bleeding, diarrhea | CBC every 2 weeks × 3 months; other, daily | |
| | Warfarin | Bleeding, INR, Hb/Hct | INR daily × 3 days; weekly until stable; monthly | |
| Hemorrhagic stroke | | BP, neurologic function, ICP | Every 2 h in ICU | Many patients require intervention with short-acting agents to reduce BP to <180 mm Hg systolic |
| | Nimodipine (for SAH) | BP, neurologic function, fluid status | Every 2 h in ICU | |
| All | | Temperature, CBC | Temp. every 8 h; CBC daily | For infectious complications such as UTI or pneumonia |
| | | Pain (calf or chest) Electrolytes and ECG | Every 8 h Up to daily | For DVT, MI, acute headache For fluid and electrolyte imbalances, cardiac rhythm abnormalities |
| | Heparins for DVT prophylaxis | Bleeding, platelets | Bleeding daily, platelets if suspected thrombocytopenia | |

controversial. Although fervently pursued in select centers and countries, indications and outcomes are not known. Results of ongoing clinical trials may assist in settling this controversy.

EVALUATION OF THERAPEUTIC OUTCOMES

MONITORING OF THE PHARMACEUTICAL CARE PLAN

Patients with acute stroke should be monitored intensely for the development of neurologic worsening (recurrence or extension), complications (thromboembolism or infection), or adverse effects from pharmacologic or nonpharmacologic interventions. The most common reasons for deterioration in a stroke patient are (1) extension of the original lesion— ischemic or hemorrhagic—in the brain, (2) development of cerebral edema and raised intracranial pressure, (3) hypertensive emergency, (4) infection (urinary and respiratory most common), (5) venous thromboembolism (deep venous thrombosis and pulmonary embolism), (6) electrolyte abnormalities and cardiac rhythm disturbances (can be associated with brain injury), and (7) recurrent stroke.

The approach to monitoring the stroke patient is summarized in Table 20–5. Customization of the plan should be made for each patient based on his or her comorbidities and ongoing disease processes.

ABBREVIATIONS

ACE: angiotensin-converting enzyme
 ADP: adenosine diphosphate
 ARB: angiotensin II receptor blocker
 ATP: adenosine triphosphate
 AVM: arteriovenous malformation
 cAMP: cyclic adenosine monophosphate
 CAST: Chinese Acute Stroke Trial
 CBC: complete blood count
 CD: carotid Doppler
 cGMP: cyclic guanosine monophosphate
 CT scan: computed tomographic scan
 CYP3A4: cytochrome P450 3A4
 DCI: delayed cerebral ischemia
 EAFT: European Atrial Fibrillation Trial
 ECG: electrocardiogram
 ERDP + ASA: extended-release dipyridamole plus aspirin
 GI: gastrointestinal
 ICH: intracerebral hemorrhage
 INR: international normalized ratio
 IST: International Stroke Trial
 JNC: Joint National Committee
 LDL: low-density lipoprotein
 MI: myocardial infarction
 MRI: magnetic resonance imaging
 NCEP: National Cholesterol Education Program
 NIHSS: National Institutes of Health Stroke Scale
 NINDS: National Institute of Neurologic Disorders and Stroke
 NVAF: nonvalvular atrial fibrillation
 PAD: peripheral arterial disease
 PGI₂: prostacyclin
 QALY: quality-adjusted life-year

RRR: relative risk reduction
 SAH: subarachnoid hemorrhage
 TCD: transcranial Doppler
 TIA: transient ischemic attack
 TTP: thrombotic thrombocytopenic purpura
 TXA₂: thromboxane A₂
 tPA: tissue plasminogen activator

KEY CONCEPTS

- 1 Hypercholesterolemia, elevated low-density lipoprotein (LDL), and low high-density lipoprotein (HDL) are unequivocally linked to increased risk for coronary heart disease and cerebrovascular morbidity and mortality; LDL is the primary target.
- 2 Multiple genetic abnormalities and environmental factors are involved in clinical lipid abnormalities, and routinely used clinical laboratory measurements do not define the underlying abnormalities.
- 3 Initial therapy for any lipoprotein disorder is therapeutic lifestyle changes with restricted intake of total and saturated fat and cholesterol and a modest increase in polyunsaturated fat intake, along with a program of regular exercise and weight reduction if needed.
- 4 If pharmacologic therapy is insufficient after therapeutic lifestyle changes, lipid-lowering agents should be chosen based on the specific lipoprotein disorder presentation and the severity of the lipid abnormality.
- 5 Considering compliance, adverse effects, and effectiveness, statins are the drugs of choice for patients with hypercholesterolemia because they are the most potent form of monotherapy and are cost-effective in patients with known coronary artery disease (CAD) or multiple risk factors and in high-risk primary prevention patients.
- 6 Patients not responding to statin monotherapy may be treated with combination therapy for hypercholesterolemia but should be monitored closely because of an increased risk for adverse effects and drug interactions.
- 7 Hypertriglyceridemia usually responds well to niacin, gemfibrozil, or high-dose/potency statins (e.g., atorvastatin or simvastatin); niacin should be used cautiously in diabetics because of worsening glycemic control.
- 8 Low HDL cholesterol is addressed with lifestyle modifications such as smoking cessation and increased exercise; niacin and gemfibrozil can increase HDL cholesterol significantly as well.
- 9 Reductions in elevated total cholesterol and LDL cholesterol reduce coronary heart disease mortality and total mortality; increasing HDL reduces coronary heart disease events as well. Aggressive treatment of hypercholesterolemia results in fewer patients progressing to myocardial infarction, angina, and stroke and reduces the need for interventions such as coronary artery bypass grafting and percutaneous transluminal coronary angioplasty.

Cholesterol, triglycerides, and phospholipids are the major lipids in the body, and they are transported as complexes of lipid and proteins known as *lipoproteins*. Plasma lipoproteins are spherical particles with surfaces that consist largely of phospholipid, free cholesterol, and protein and cores that consist mostly of triglyceride and cholesterol ester. The three major classes of lipoproteins found in serum are low-density lipoproteins (LDLs), high-density lipoproteins (HDLs), and very low-density lipoproteins (VLDLs). Intermediate-density lipoprotein resides between VLDL and LDL and is included in the LDL measurement in routine clinical measurement. Abnormalities of plasma lipoproteins can result in a predisposition to coronary, cerebrovascular, and peripheral vascular arterial disease. Accumulating evidence over the last decades had linked elevated total and LDL and reduced HDL to the development of coronary heart disease (CHD). Premature coronary atherosclerosis, leading to the manifestations of ischemic heart disease (see Chap. 15), is the most common and significant consequence of hyperlipidemia. The National Cholesterol Education Program (NCEP) Adult Treatment Panel III (ATP III) published its third report summarizing these data and giving recommendations for the management of hypercholesterolemia in adults.¹

This report modifies earlier recommendations and provides a new way of risk-stratifying patients based on multiple risk factors and the presence of diabetes and the metabolic syndrome.^{1,2} The American Heart Association (AHA) also provides guidelines for primary and secondary prevention of CHD.^{3–5}

Total cholesterol and LDL cholesterol increase throughout life in men and women, representing an atherogenic pattern characteristic of Western society diets (Fig. 21–1).⁶ Based on the National Health and Nutrition Examination Survey (NHANES 1999–2000) and the ATP III guidelines, slightly more than 50% or nearly 105 million American adults over 20 years of age have total cholesterol levels of 200 mg/dL or higher.^{1,6,7} Only about one-third are aware that they have hypercholesterolemia, and 12% were on therapy for hypercholesterolemia.⁶ Changes in the NCEP guidelines have increased the number of persons eligible for therapeutic lifestyle changes (TLCs) or lipid-lowering therapy by millions. NCEP estimates that only 26% of patients have an optimal LDL cholesterol (<100 mg/dL) and that large numbers of patients are either untreated or undertreated.^{1,8} Unfortunately, the patients at highest risk are less likely to be treated to desirable levels of LDL.⁹ Although these numbers seem staggering in their enormity,

FIGURE 21-1. Serum cholesterol in men and women 20 years of age and older based on the 3rd National Health and Nutrition Survey.⁶

substantial progress has been made, and the number of Americans with a desirable blood cholesterol level (<200 mg/dL) has risen to 49% from 45% in the earlier survey (1976–1980), whereas the average total cholesterol level in this country has fallen from 220 mg/dL in 1960 to 196 to 203 mg/dL in 1988–1994.⁶ Unfortunately, there has been little change in total cholesterol between 1994 and 2000.⁶ Patients who are at risk but who have not yet experienced their first cardiovascular or cerebrovascular event (e.g., myocardial infarction [MI]) are termed *primary prevention*, whereas those with manifest vascular disease are termed *secondary intervention*.

▶ Data from the Framingham Study and from other studies demonstrate that the risk for developing cardiovascular disease is related to the degree of total cholesterol and LDL elevation in a graded, continuous fashion.^{10,11} Hypercholesterolemia is additive to the other nonlipid risk factors for CHD, including cigarette smoking, hypertension, diabetes, low HDL levels, and electrocardiographic (ECG) abnormalities. The presence of established CHD or prior MI increases the risk of MI five to seven times that seen in men or women without CHD, and LDL is a significant predictor of subsequent morbidity and mortality.¹⁰ About 50% of all MIs and at least 70% of CHD deaths occur in patients with known CHD, and these patients therefore should be a target for screening, identification, and treatment. Unfortunately, the identification of patients at high risk because of hypercholesterolemia or other lipid disorders is too frequently overlooked because blood lipid levels are not always evaluated in this population even after an event such as MI.¹⁰

A comparison of the United States with other countries shows similar relationships between total cholesterol and LDL and an inverse relationship with HDL and coronary artery disease (CAD) mortality.¹² On a positive note, the U.S. mortality rate is midway among the countries studied, and this country has had the greatest decline in CAD mortality (35% to 40%) in men and women over the last 10 years compared with other countries. A decline in the prevalence of hypercholesterolemia in certain segments of the U.S. population parallels these trends in mortality.¹ LDL and the ratio of LDL to HDL also have been used to assess risk, but their use adds little information to total cholesterol alone unless HDL is abnormally high or low. HDL transports cholesterol from lipid-laden foam cells to the liver. HDL has been shown to be protective for the occurrence of CHD, and an inverse relationship exists between CHD and HDL levels.¹³

LDL is enriched with cholesterol esters and is smaller, denser, and more atherogenic than less-dense VLDL. Routine measurement of triglycerides cannot distinguish between the types of VLDL

present in plasma. Elevation of triglyceride-rich lipoproteins is associated with low HDL, and this ratio predicts increased risk. The 8-year follow-up of the Copenhagen male study found a clear gradient of risk of ischemic heart disease (IHD) with increasing triglyceride levels within each level of HDL cholesterol. When compared with the lowest tertile of triglyceride concentrations, the highest tertile had 2.2 relative risk for IHD, and the relationship extended across all concentrations of HDL.¹⁴ The Helsinki Heart Study shows that hypertriglyceridemia and low HDL levels are associated with obesity (body mass index [BMI] > 26 kg/m²), smoking, sedentary lifestyle, blood pressure of 140/90 mm Hg or greater, and a blood glucose concentration above 4.4 mmol/L and that the benefit of gemfibrozil (risk reduction 68%, $p < .03$) was confined largely to overweight subjects.¹⁵ Hypertriglyceridemia in certain instances—e.g., diabetes mellitus, nephrotic syndrome, and chronic renal disease and perhaps in women—is associated with increased cardiovascular risk. This is thought to be a consequence of the presence of atherogenic lipoproteins and of hypertriglyceridemia being a marker for them, since triglycerides usually are not independently predictive for CHD.¹⁶

LIPOPROTEIN METABOLISM AND TRANSPORT

Cholesterol and triglycerides, as the major plasma lipids, are essential substrates for cell membrane formation and hormone synthesis and provide a source of free fatty acids.¹⁷ *Hyperlipidemia* is defined as an elevation of one or more of cholesterol, cholesterol esters, phospholipids, or triglycerides. Lipids, being water immiscible, are not present in free form in the plasma but rather circulate as lipoproteins. *Hyperlipoproteinemia* describes an increased concentration of the lipoprotein macromolecules that transport lipids in the plasma. The density of plasma lipoproteins is determined by their relative content of protein and lipid. Density, composition, size, and electrophoretic mobility divide lipoproteins into four classes (Table 21-1).

LDL has been further divided into LDL₁, or intermediate-density lipoprotein (density 1.006–1.019 g/mL), and LDL₂ (1.019–1.063 g/mL). LDL₂ is the major LDL component in plasma, and it carries 60% to 70% of the total serum cholesterol. HDL has been subfractionated into HDL₂ (density 1.063–1.125 g/mL) and HDL₃ (1.125–1.21 g/mL). Fluctuations in HDL usually are caused by alterations in the levels of HDL₂. HDL normally carries about 20% to 30% of the total cholesterol. VLDL also has been subdivided into three classes, and it carries about 10% to 15% of serum cholesterol and most of the triglyceride in the fasting state. VLDL is the precursor for LDL, and VLDL remnants also may be atherogenic. Table 21-2 shows the characteristics of the protein constituent of lipoproteins known as *apolipoproteins*.

Chylomicrons, large triglyceride-rich particles containing apolipoprotein B-48, B-100, and E, are formed from dietary fat solubilized by bile salts in intestinal mucosal cells (Fig. 21-2). Chylomicrons normally are not present in the plasma after a fast of 12 to 14 hours and are catabolized by lipoprotein lipase (LPL), which is activated by apolipoprotein C-II, in the vascular endothelium and hepatic lipase to form chylomicron remnants. The remnants that contain apolipoprotein E (see Fig. 21-2) are taken up by the “remnant receptor,” which may be an LDL-receptor-related protein, in the liver. Free cholesterol is liberated intracellularly after attachment to the remnant receptor. Chylomicrons also function to deliver dietary triglyceride to skeletal muscle and adipose tissue. During the catabolism of nascent chylomicrons to remnants, triglyceride is converted to free fatty acids and apolipoproteins A-I, A-II, A-IV (free in plasma), C-I, C-II, and

TABLE 21–1. Composition of Lipoprotein Isolated from Normal Subjects

| Lipoprotein Class | Density Range (g/mL) | Diameter (nm) | Composition (Weight %) | | | | |
|-------------------|----------------------|---------------|------------------------|--------------|------|-------|--------------|
| | | | Cholesterol | | | | Phospholipid |
| | | | Protein | Triglyceride | Free | Ester | |
| Chylomicrons | <0.94 | 75–1200 | 1–2 | 80–95 | 1–3 | 2–4 | 3–9 |
| VLDL | 0.94–1.006 | 30–80 | 6–10 | 55–80 | 4–8 | 16–22 | 10–20 |
| LDL | 1.006–1.063 | 18–25 | 18–22 | 5–15 | 6–8 | 45–50 | 18–24 |
| HDL | 1.063–1.21 | 5–12 | 45–55 | 5–10 | 3–5 | 15–20 | 20–30 |

VLDL = very low-density lipoprotein; LDL = low-density lipoprotein; HDL = high-density lipoprotein.

C-III, and phospholipids are transferred to HDL. Apolipoproteins E and C-II are transferred to chylomicrons from HDL and eventually back through these metabolic events. Hepatic VLDL synthesis is regulated in part by diet and hormones and is inhibited by uptake of chylomicron remnants in the liver. VLDL is secreted from the liver and serially converted via LPL to intermediate-density lipoprotein (IDL) and finally to LDL. VLDL receptors are found in adipose tissue and muscle and bear close homology to the structure of LDL receptors.

LDL, the major cholesterol transport lipoprotein, having virtually only apolipoprotein B-100, is mostly derived from VLDL catabolism and cellular synthesis. When fasting and when normal subjects are on low-fat intake, most cholesterol is synthesized and used in the extrahepatic organs, whereas most of the cholesterol carried by LDL is taken up by the liver for catabolism.¹⁷ In patients with homozygous familial hypercholesterolemia, enhanced synthesis of LDL may occur because LDL clearance is reduced as a consequence

of the lack of LDL receptors. LDL is catabolized through interaction of cell surface receptors found on liver, adrenal, and peripheral cells (including fibroblasts and smooth muscle cells). These cells recognize apolipoprotein B-100 on LDL, and after binding to a receptor on the cell membrane, LDL is internalized and degraded. In the normal fasting state, approximately 70% of LDL is cleared through receptor-dependent mechanism, although this is highly dependent on the availability and type of saturated and mono- or polyunsaturated fat from dietary sources. Ingestion of cholesterol and saturated fatty acids such as C12:0, C14:0, and C16:0 is associated with reduction in LDL receptor activity, increased LDL production rate, and elevation in LDL plasma concentration. Receptor-independent mechanisms are also involved to a lesser extent in the catabolism of LDL, and these receptors are present in many tissues but are most active in animals in the adrenals and ovary.¹⁷ Increased intracellular cholesterol resulting from LDL catabolism inhibits the activity of 3-hydroxy-3-methylglutaryl coenzyme A reductase (HMG-CoA reductase),

TABLE 21–2. Characteristics and Functions of Apolipoproteins

| Apolipoprotein | Lipoprotein Density Class | Approximate Plasma Concentration (mg/dL) | Approximate Molecular Weight (kDa) | Reported Functions | Major Site of Synthesis |
|----------------|---------------------------|--|------------------------------------|--|-------------------------|
| A-I | Chylomicrons, HDL | 120 | 28 | Cofactor with LCAT, structural protein on HDL, ligand for HDL receptor | Liver, intestine |
| A-II | Chylomicrons, HDL | 35 | 17 | Structural protein for HDL, ligand for HDL receptor | Liver |
| A-IV | Chylomicrons, 1.21B | 15 | 46 | Possibly facilitates transfer of other apos between HDL and chylomicrons | Intestine |
| ApoLp(a) | LDL, HDL | 10 | 500± | Bound to B-100, high homology with plasminogen, may prevent LDL uptake by B, E receptor | Liver |
| B-100 | VLDL, LDL, IDL | 100 | 540 | Necessary for assembly and secretion of VLDL from the liver, structural protein of VLDL, IDL, LDL, ligand for LDL receptor | Liver |
| B-48 | Chylomicrons | Trace | 264 | Necessary for assembly and secretion of chylomicrons from the small intestine | Intestine |
| C-I | Chylomicrons, VLDL, HDL | 7 | 6.6 | Cofactor with LCAT, may inhibit hepatic uptake of chylomicron and VLDL remnants | Liver |
| C-II | Chylomicrons, VLDL, HDL | 4 | 8.9 | Activator of LPL | Liver |
| C-III | Chylomicrons, VLDL, HDL | 13 | 8.8 | Inhibitor with LPL, may inhibit hepatic uptake of chylomicron and VLDL remnants | Liver |
| D | HDL | 6 | 32 | ? | ? |
| E2–E4 | Chylomicrons, VLDL, HDL | 5 | 34 | Ligand for several lipoproteins to LDL receptor, LRP, and possibly to a separate hepatic apo E receptor | Liver |

LCAT = lecithin-cholesterol acyltransferase; HL = hepatic lipase; IDL = intermediate-density lipoprotein; LRP = LDL receptor-related protein. Other abbreviations are in Table 21–1.

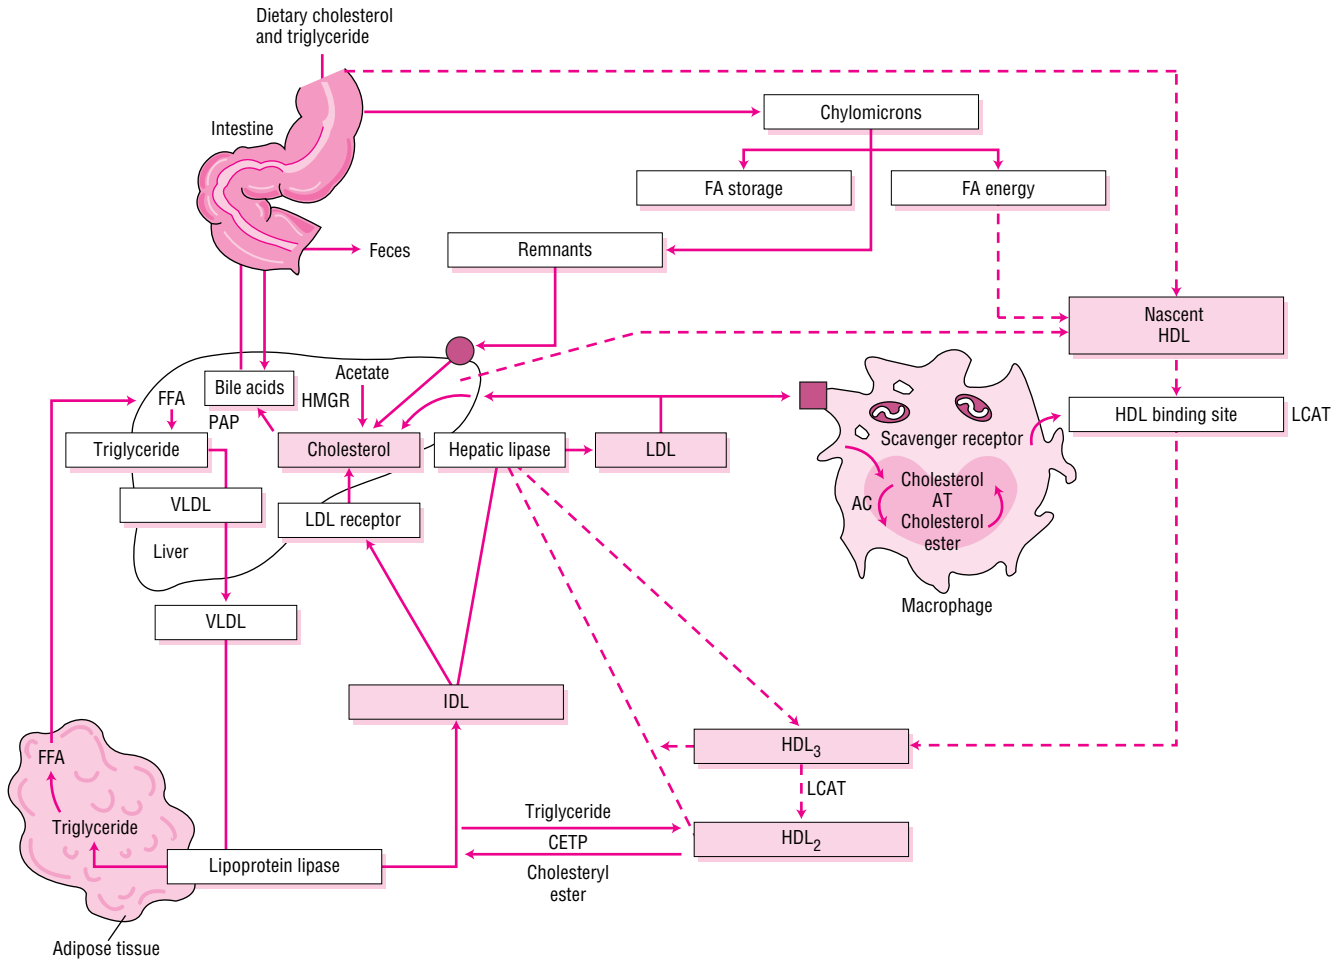

FIGURE 21-2. Overview of lipoprotein metabolism. (ACAT = acyl CoA:cholesterol acyltransferase; CETP = cholesteryl ester transfer protein; FA = fatty acid; FFA = free fatty acid; HMGR = HMG CoA reductase; LCAT = lecithin:cholesterol acyltransferase; PAP = phosphatidic acid phosphatase). (From Ref. 17 with permission.)

the rate-limiting enzyme for intracellular cholesterol biosynthesis (Fig. 21-3). Additional consequences of increased intracellular cholesterol include reduced synthesis of LDL receptors, which limits subsequent cholesterol uptake from the plasma, and accelerated activity of acyl coenzyme-A:cholesterol acyltransferase (ACAT) to facilitate cholesterol storage within cells. LDL cholesterol also may be excreted into bile and become part of the enterohepatic pool or may be lost in the stool. Lp(a) is a cholesterol-rich lipoprotein similar to LDL in composition and density and with close homology to fibrinogen; it is reported to be an important independent risk factor for the development of premature cardiovascular disease.

Nascent HDL is derived from liver and gut synthesis primarily in the form of apolipoprotein A-I phospholipid disks. Esterification of free cholesterol in nascent HDL and from peripheral tissues to cholesteryl esters by lecithin: cholesterol acyltransferase (LCAT) results in the production of HDL₃. Further addition of tissue cholesterol to HDL₃ results in the formation of HDL₂. HDL₂ also can be formed from remodeling of chylomicrons and VLDL catabolism. HDL₂ may be converted back to HDL₃ by the action of hepatic lipase and by the transfer of cholesteryl esters to the liver, LDL, and VLDL. Apolipoprotein A-I production is increased by estrogens, leading to higher HDL levels in women and in individuals receiving estrogen. Transfer of excess cholesterol from peripheral tissues by HDL is called

reverse cholesterol transport. Putative HDL receptors in peripheral cells facilitate the uptake of cholesterol by HDL, which transfers cholesterol to either VLDL and LDL or to the liver for secretion into bile or conversion into bile acids. These processes serve to rid peripheral tissue (e.g., coronary arteries) of excessive amounts of cholesterol and account for some of the protective effects noted with increasing HDL in women and other factors that elevate HDL levels. Variants of the cholesteryl ester transfer protein (CETP) have been demonstrated in humans, and the *B1/B1* genotype is associated with lower HDL and progression of coronary atherosclerosis. Inhibition of CETP leads to elevations in HDL, and this may prove to be an important therapeutic approach for the future if the HDL produced is fully functional in the process of reverse cholesterol transport.^{18,19}

The response-to-injury hypothesis states that risk factors such as oxidized LDL, mechanical injury to the endothelium (e.g., percutaneous transluminal angioplasty), excessive homocysteine, immunologic attack, or infection-induced (e.g., *Chlamydia*, herpes simplex virus 1) changes in endothelial and intimal function lead to endothelial dysfunction and a series of cellular interactions that culminate in atherosclerosis.²⁰ C-reactive protein (CRP) is an acute-phase reactant and a marker for inflammation; it may be useful in identifying patients at risk for developing CAD.²¹ The eventual outcomes of this atherogenic cascade are clinical events such as angina, MI, arrhythmias,

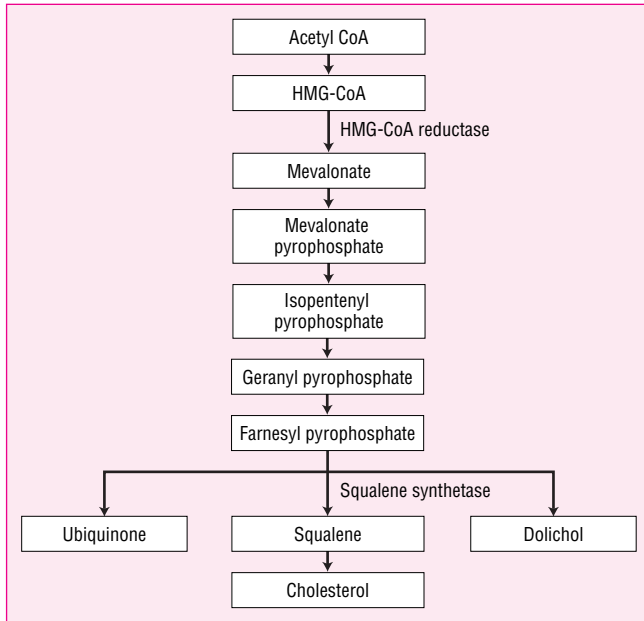

FIGURE 21-3. Biosynthetic pathway for cholesterol. The rate-limiting enzyme in this pathway is 3-hydroxy-3-methylglutaryl coenzyme A reductase (HMG-CoA reductase).

stroke, peripheral arterial disease, abdominal aortic aneurysm, and sudden death. Atherosclerotic lesions are thought to arise from transport and retention of plasma LDL cholesterol through the endothelial cell layer into the extracellular matrix of the subendothelial space. Once in the artery wall, LDL is chemically modified through oxidation and nonenzymatic glycation. Mildly oxidized LDL then recruits monocytes into the artery wall, which become transformed into macrophages. Macrophages have tremendous potential for accelerating LDL oxidation and apolipoprotein B accumulation and altering the receptor-mediated uptake of LDL into the artery wall from the usual LDL receptor to a “scavenger receptor” not regulated by cell content of cholesterol. Oxidized LDL increases plasminogen inhibitor levels (promotion of coagulation), induces the expression of endothelin (vasoconstrictive substance), inhibits the expression of nitric oxide (a vasodilator and platelet inhibitor), and is toxic to macrophages if highly oxidized. As oxidation of biologically active lipids proceeds, other lipids such as lysophosphatidylcholine, hydroperoxides, aldehydic breakdown products of fatty acids, and oxysterol are formed, which continue the reaction within the tissue. These events lead to a massive accumulation of cholesterol. The cholesterol-laden cells are called *foam cells*; foam cells are the earliest recognized cells of the arterial fatty streak.

Oxidized LDL provokes an inflammatory response, which is mediated by a number of chemoattractants and cytokines. Examples of each that appear to be involved at different stages of lesion development include monocyte chemoattractant protein 1 (MCP-1), monocyte colony-stimulating factor (M-CSF), *gro*, vascular cell adhesion molecule (VCAM-1), E-selectin (ELAM-1), intercellular adhesion molecule (ICAM-1), platelet-derived growth factor (PDGF), vascular endothelial growth factor (VEGF), transforming growth factors (TGF- α and TGF- β); interleukin-1 and interleukin-6 (IL-1, IL-6), and the ratio of interleukin-10 and interleukin-12 (IL-10, IL-12). It appears that some of these factors (e.g., MCP-1 and M-CSF) participate early in the process of monocyte-macrophage attachment and transmigration across the endothelium, whereas others (PDGF and

VCAM-1) promote later lesion growth.²² The extent of oxidation and the inflammatory response are under genetic control of a major gene termed *Ath-1* based on murine model studies. The process of aging may lead to lipoproteins that are more susceptible to oxidation and have longer resident time in the vascular compartment.²³ Two proteins associated with HDL—apolipoprotein J (apoJ) and paraoxonase (PON)—appear to play an important role in minimizing the oxidation of LDL cholesterol.²⁴ Increased recognition of the role of these growth-regulatory molecules provides the possibility of future directions for antagonists to regulatory molecules such as PDGF, TGF- β , and the interleukins. Repeated injury and repair within an atherosclerotic plaque eventually leads to a fibrous cap protecting the underlying core of lipids, collagen, calcium, and inflammatory cells such as T-lymphocytes. Maintenance of the fibrous plaque is critical to preventing plaque rupture and subsequent coronary thrombosis. An imbalance between plaque synthesis and degradation may lead to a weakened or vulnerable plaque prone to rupture. The fibrous cap may become weakened through decreased synthesis of the extracellular matrix or increased degradation of the matrix. The cytokine interferon- γ , produced by T-lymphocytes, inhibits the ability of smooth-muscle cells to synthesize collagen, a structurally important component of the fibrous cap. A family of enzymes known as *matrix metalloproteinases* can degrade all major constituents of the vascular extracellular matrix: collagen, elastin, and proteoglycans.²²

Lipoprotein disorders are classified into six categories, which are commonly used for phenotypic description of hyperlipidemia (Table 21-3). Specific genetic defects with disrupted protein, cell, and organ function give rise to several disorders within each family of lipoproteins (Table 21-4). In other words, an elevated cholesterol level does not necessarily equate with familial hypercholesterolemia, or type IIa, because cholesterol also may be elevated in other lipoprotein disorders, and the lipoprotein pattern does not describe the underlying genetic defect. The preceding discussion has focused on primary or genetic hyperlipoproteinemia; it should be remembered that secondary forms exist and that several drugs also may elevate lipid levels (Table 21-5). These secondary forms of hyperlipidemia should be managed initially by correcting the underlying abnormality, including modification of drug therapy when appropriate.

❖ Familial hypercholesterolemia is characterized by (1) a selective elevation in the plasma level of LDL, (2) deposition of LDL-derived cholesterol in tendons (xanthomas) and arteries (atheromas), and (3) inheritance as an autosomal dominant trait, with homozygotes affected more severely than heterozygotes. Homozygotes (prevalence 1 in 1 million) have severe hypercholesterolemia (650–1000 mg/dL), with the early appearance of cutaneous xanthomas and fatal CHD generally before age 20. The primary defect in familial hypercholesterolemia is the inability to bind LDL to the LDL receptor (LDL-R)

TABLE 21-3. Fredrickson-Levy-Lees Classification of Hyperlipoproteinemia

| Type | Lipoprotein Elevation |
|------|-------------------------|
| I | Chylomicrons |
| IIa | LDL |
| IIb | LDL + VLDL |
| III | IDL (LDL ₁) |
| IV | VLDL |
| V | VLDL + chylomicrons |

LDL = low-density lipoprotein; VLDL = very low-density lipoprotein; IDL = intermediate-density lipoprotein.

TABLE 21-4. Lipoprotein Disorders

| Lipid Phenotype | Plasma Lipid Levels, mmol/L (mg/dL) | Lipoproteins | | Clinical Signs |
|--|--|--------------------------|-----------|--|
| | | Elevated | Phenotype | |
| Isolated Hypercholesterolemia | | | | |
| Familial hypercholesterolemia | Heterozygotes TC = 7–13 (275–500) | LDL | IIa | Usually develop xanthomas in adulthood and vascular disease at 30–50 years |
| | Homozygotes TC > 13 (>500) | LDL | IIa | Usually develop xanthomas in adulthood and vascular disease in childhood |
| Familial defective apo B100 | Heterozygotes TC = 7–13 (275–500) | LDL | IIa | Usually asymptomatic until vascular disease develops; no xanthomas |
| Polygenic hypercholesterolemia | TC = 6.5–9 (250–350) | LDL | IIa | |
| Isolated Hypertriglyceridemia | | | | |
| Familial hypertriglyceridemia | TG = 2.8–8.5 (250–750) | VLDL | IV | Asymptomatic; may be associated with increased risk of vascular disease |
| Familial LPL deficiency | TG > 8.5 (750) | Chylomicrons, VLDL | I, V | May be asymptomatic; may be associated with pancreatitis, abdominal pain, hepatosplenomegaly |
| Familial apo CII deficiency | TG > 8.5 (>750) | Chylomicrons, VLDL | I, V | As above |
| Hypertriglyceridemia and Hypercholesterolemia | | | | |
| Combined hyperlipidemia | TG = 2.8–8.5 (250–750); TC = 6.5–13 (250–500) | VLDL, LDL | IIb | Usually asymptomatic until vascular disease develops; familial form also may present as isolated high TG or an isolated high LDL cholesterol |
| Dysbetalipoproteinemia | TG = 2.8–8.5 (250–750); TC = 6.5–13 (250–500) | VLDL, IDL; LDL normal | III | Usually asymptomatic until vascular disease develops; may have palmar or tuberous xanthomas |

TC = total cholesterol; TG = triglycerides; LPL = lipoprotein lipase.

or, rarely, a defect of internalizing the LDL-R complex into the cell after normal binding. Homozygotes have essentially no functional LDL receptors. This leads to a lack of LDL degradation by cells and unregulated biosynthesis of cholesterol, with total cholesterol and LDL cholesterol levels being inversely proportional to the deficit in LDL receptors. Heterozygotes have only about one-half the normal number of LDL receptors, total cholesterol levels in the range of 300–600 mg/dL, and cardiovascular events beginning in the third and fourth decades of life.

Familial LPL deficiency is a rare, autosomal recessive trait characterized by a massive accumulation of chylomicrons and a corresponding increase in plasma triglycerides, or a type I lipoprotein pattern. VLDL concentration is normal. The presenting manifestations include repeated attacks of pancreatitis and abdominal pain, eruptive cutaneous xanthomatosis, and hepatosplenomegaly beginning in childhood. Symptom severity is proportional to dietary fat intake and, consequently, to the elevation of chylomicrons. LPL normally is released from vascular endothelium or by heparin and hydrolyzes chylomicrons and VLDL (see Fig. 21-3). Diagnosis is based on low or absent enzyme activity with normal human plasma or apolipoprotein C-II, a cofactor of the enzyme. Accelerated atherosclerosis is not associated with this disease. Abdominal pain, pancreatitis, eruptive xanthomas, and peripheral polyneuropathy characterize type V (VLDL and chylomicrons). Symptoms may occur in childhood, but usually the disorder is expressed at a later age. The risk of atherosclerosis is increased with this disorder. These patients commonly are obese, hyperuricemic, and diabetic, and alcohol intake, exogenous estrogens, and renal insufficiency tend to be exacerbating factors.

Patients with familial type III hyperlipoproteinemia (also called *dysbetalipoproteinemia*, *broad-band*, or β -VLDL) develop these

clinical features after 20 years of age: xanthoma striata palmaris (yellow discoloration of the palmar and digital creases), tuberous or tuberous xanthomas (bulbous cutaneous xanthomas), and severe atherosclerosis involving the coronary arteries, internal carotids, and abdominal aorta. A defective structure of apolipoprotein E does not allow normal hepatic surface receptor binding of remnant particles derived from chylomicrons and VLDL (known as IDL); aggravating factors such as obesity, diabetes, or pregnancy may promote overproduction of apo-B-containing lipoproteins. Although homozygosity for the defective allele (E_2/E_2) is common (1 in 100), only 1 in 10,000 express the full-blown picture, and interaction with other genetic or environmental factors, or both, is needed to produce clinical disease.

Familial combined hyperlipidemia is characterized by elevations in total cholesterol and triglycerides, decreased HDL, increased apolipoprotein B, and small, dense LDL.²⁵ It is associated with premature CHD and may be difficult to diagnose because the lipid levels do not consistently display the same pattern.

Type IV hyperlipoproteinemia is common and occurs in adulthood primarily in patients who are obese, diabetic, and hyperuricemic and do not have xanthomas. It may be secondary to alcohol ingestion and can be aggravated by stress, progestins, oral contraceptives, thiazides, or β -blockers. Two genetic patterns occur in type IV hyperlipoproteinemia: familial hypertriglyceridemia, which does not carry a great risk for premature CAD, and familial combined hyperlipidemia, which is associated with increased risk of cardiovascular disease.

Rare forms of lipoprotein disorders may include hypobetalipoproteinemia, abetalipoproteinemia, Tangier disease, LCAT deficiency (fish-eye disease), cerebrotendinous xanthomatosis (CTX),

TABLE 21–5. Secondary Causes of Lipoprotein Abnormalities

| | |
|----------------------|---|
| Hypercholesterolemia | Hypothyroidism Obstructive liver disease Nephrotic syndrome Anorexia nervosa Acute intermittent porphyria Drugs: Progestins, thiazide diuretics, glucocorticoids, β -blockers, isotretinoin, protease inhibitors, cyclosporine, mirtazapine, sirolimus |
| Hypertriglyceridemia | Obesity Diabetes mellitus Lipodystrophy Glycogen storage disease Ileal bypass surgery Sepsis Pregnancy Acute hepatitis Systemic lupus erythematosus Monoclonal gammopathy: multiple myeloma, lymphoma Drugs: Alcohol, estrogens, isotretinoin, beta blockers, glucocorticoids, bile-acid resins, thiazides; asparaginase, interferons, azole antifungals, mirtazapine, anabolic steroids, sirolimus, bexarotene |
| Hypocholesterolemia | Malnutrition Malabsorption Myeloproliferative diseases Chronic infectious diseases: AIDS, tuberculosis Monoclonal gammopathy Chronic liver disease |
| Low HDL | Malnutrition Obesity Drugs: non-ISA β -blockers, anabolic steroids, probucol, isotretinoin, progestins |

and sitosterolemia. Most of these rare lipoprotein disorders do not result in premature atherosclerosis, with the exceptions of familial LCAT deficiency, cerebrotendinous xanthomatosis, and sitosterolemia with xanthomatosis. Their treatment consists of dietary restriction of plant sterols (sitosterolemia with xanthomatosis) and chenodeoxycholic acid (CTX) or, potentially, blood transfusion (LCAT deficiency).

CLINICAL PRESENTATION

GENERAL

- Most patients are asymptomatic for many years prior to clinically evident disease.
- Patients with the metabolic syndrome may have three or more of the following: abdominal obesity, atherogenic dyslipidemia, raised blood pressure, insulin resistance with or without glucose intolerance, prothrombotic state, or proinflammatory state.

SYMPTOMS

- None to chest pain, palpitations, sweating, anxiety, shortness of breath, loss of consciousness or difficulty with speech or movement, abdominal pain, and sudden death.

SIGNS

- None to abdominal pain, pancreatitis, eruptive xanthomas, peripheral polyneuropathy, high blood pressure, body mass index greater than 30 kg/m², or waist size greater than 40 inches in men (35 inches in women).

LABORATORY TESTS

- Elevations in total cholesterol, LDL, triglycerides, apolipoprotein B, and C-reactive protein.
- Low HDL.

OTHER DIAGNOSTIC TESTS

- Lipoprotein(a), homocysteine, serum amyloid A, and small, dense LDL (pattern B).
- Various screening tests for manifestations of vascular disease (ankle-brachial index, exercise testing, magnetic resonance imaging) and diabetes (fasting glucose, oral glucose tolerance test).

PATIENT EVALUATION

A fasting lipoprotein profile (FLP) including total cholesterol, LDL cholesterol, HDL cholesterol, and triglycerides should be measured in all adults 20 years of age or older at least once every 5 years.¹ If the profile is obtained in the nonfasted state, only total cholesterol and HDL cholesterol will be usable because LDL cholesterol usually is a calculated value; if total cholesterol is 200 mg/dL or more, or if HDL cholesterol is less than 40 mg/dL, a follow-up fasting lipoprotein profile should be obtained. After a lipid abnormality is confirmed (Table 21–6), major components of the evaluation are the history (including age, gender, and if female, menstrual and estrogen-replacement status), physical examination, and laboratory investigations. A complete history and physical examination should assess (1) presence or absence of cardiovascular risk factors (Table 21–7) or definite cardiovascular disease in the individual, (2) family history of

TABLE 21–6. Classification of Total, LDL, and HDL Cholesterol and Triglycerides

| | | |
|-------------------|---------------|-----------------------|
| Total cholesterol | <200 mg/dL | Desirable |
| | 200–239 mg/dL | Borderline high |
| | ≥240 mg/dL | High |
| LDL cholesterol | <100 mg/dL | Optimal |
| | 100–129 mg/dL | Near or above optimal |
| | 130–159 mg/dL | Borderline high |
| | 160–189 mg/dL | High |
| | ≥190 mg/dL | Very high |
| HDL cholesterol | <40 mg/dL | Low |
| | ≥60 mg/dL | High |
| Triglycerides | <150 mg/dL | Normal |
| | 150–199 mg/dL | Borderline high |
| | 200–499 mg/dL | High |
| | ≥500 mg/dL | Very high |

HDL = high-density lipoproteins; LDL = low-density lipoproteins.

TABLE 21–7. Major Risk Factors (Exclusive of LDL Cholesterol) that Modify LDL Goals^a

| |
|---|
| Age |
| Men: ≥45 years |
| Women: ≥55 years or premature menopause without estrogen-replacement therapy |
| Family history of premature CHD (definite myocardial infarction or sudden death before 55 years of age in father or other male first-degree relative or before 65 years of age in mother or other female first-degree relative) |
| Cigarette smoking |
| Hypertension (≥140/90 mm Hg or on antihypertensive medication) |
| Low HDL cholesterol (<40 mg/dL) ^b |

^aDiabetes is regarded as a coronary heart disease (CHD) risk equivalent; LDL = low-density lipoprotein; HDL = high-density lipoprotein.

^bHDL cholesterol (60 mg/dL) counts as a “negative” risk factor; its presence removes one risk factor from the total count.

premature cardiovascular disease or lipid disorders, (3) presence or absence of secondary causes of lipid abnormalities, including concurrent medications (see Table 21–5), and (4) presence or absence of xanthomas or abdominal pain or history of pancreatitis, renal or liver disease, peripheral vascular disease, abdominal aortic aneurysm, or cerebral vascular disease (e.g., carotid bruits, stroke, or transient ischemic attack). An important change in the ATP III guidelines is that diabetes mellitus is regarded as a CHD risk equivalent.¹ The presence of diabetes in patients without known CHD is associated with the same level of risk as patients without diabetes but having confirmed CHD.²⁶ ATP III identifies three categories of risk that modify the goals and modalities of LDL-lowering therapy (Table 21–8). The highest category is known CHD or CHD risk equivalents, which is defined as the risk for major coronary events equal to or greater than established CHD; that is, more than 20% per 10 years (2% per year). The next category consists of patients with multiple (2+) risk factors in which 10-year risk for CHD is 20% or less. The lowest risk category is persons with 0 to 1 risk factor, which is usually associated with a 10-year risk of CHD of less than 10%. Risk is estimated from Framingham risk scores.² Risk is estimated based on the patient’s age, LDL cholesterol or total cholesterol level, blood pressure, the presence of diabetes, and smoking status (see Table 21–7). This approach for a single patient is referred to as *case finding* or *patient-based*, whereas large-scale screening and recommendations for the general populace, health care providers, and the food industry are called a *population-based approach*.

Measurement of plasma cholesterol (which is about 3% lower than serum determinations), triglyceride, and HDL cholesterol levels after a 12-hour or longer fast is important because triglycerides may be elevated in nonfasted individuals; total cholesterol is only modestly affected by fasting. Analytic and biologic variability can have a major impact on the measurement and interpretation of cholesterol (or any other laboratory test). Analytic variability can be minimized through the use of adequate quality control procedures, including internal training, routine calibration and monitoring, and external proficiency testing. Even with these measures, the coefficient of variability in the best procedures acceptably can be up to 5%, and when combined with average biologic variability, total variability may be as high as about 22%. Analytic variability with desktop equipment generally is greater in the fingerstick capillary blood methods, usually yielding measurements less than those from a clinical laboratory, and this technology should be considered for use only as a screening method. Reliance on desktop methods can result in misclassification of 7% to 14% of patients if capillary blood is used. Two determinations 1 to 8 weeks apart with the patient on a stable diet and weight and in the absence of acute illness are recommended to minimize variability and to obtain a reliable baseline.¹ If the total cholesterol level is greater than 200 mg/dL, a second determination is recommended, and if the values are more than 30 mg/dL apart, the average of three values should be used. Familiarity with the method and quality control procedures employed by local laboratories are essential for interpretation of reported values. If the physical examination and history are insufficient to diagnose a familial disorder, then agarose-gel lipoprotein electrophoresis is useful to determine which class of lipoproteins is affected. If the triglyceride levels are below 400 mg/dL and neither type III hyperlipidemia nor chylomicrons are detected by electrophoresis, then one can calculate VLDL and LDL concentrations: VLDL = triglyceride/5; LDL = total cholesterol – (VLDL + HDL).

Because total cholesterol is comprised of cholesterol derived from LDL, VLDL, and HDL, determination of HDL is useful when total plasma cholesterol is elevated. HDL may be elevated by moderate alcohol ingestion (less than two drinks per day), physical exercise, smoking cessation, weight loss, oral contraceptives, phenytoin, and terbutaline. Smoking, obesity, a sedentary lifestyle, and drugs such as β-blockers lower HDL. Only exercise and smoking cessation could be recommended as interventions for low HDL concentrations. Niacin and gemfibrozil also increase HDL concentrations.

The range of lipid concentrations represents a population mean plus or minus 2 standard deviations and does not define the risk of disease. Reference values for plasma total, LDL, and HDL cholesterol

TABLE 21–8. LDL Cholesterol Goals and Cutpoints for Therapeutic Lifestyle Changes (TLCs) and Drug Therapy in Different Risk Categories

| Risk Category | LDL Goal (mg/dL) | LDL Level at Which to Initiate TLCs (mg/dL) | LDL Level at Which to Consider Drug Therapy (mg/dL) |
|---|------------------|---|--|
| CHD or CHD risk equivalents (10-year risk >20%) | <100 | ≥100 | ≥130 (100–129: drug optional) ^a |
| 2+ Risk factors (10-year risk ≤20%) | <130 | ≥130 | 10-year risk 10–20%; ≥130 10-year risk <10%: ≥160 |
| 0–1 Risk factor ^b | <160 | ≥160 | ≥190 (160–189: LDL-lowering drug optional) |

^aSome authorities recommend use of LDL-lowering drugs in this category if an LDL cholesterol level of less than 100 mg/dL cannot be achieved by TLCs. Others prefer use of drugs that primarily modify triglycerides and HDL, e.g., nicotinic acid or fibrates. Clinical judgment also may call for deferring drug therapy in this subcategory.

^bAlmost all people with 0–1 risk factor have a 10-year risk of less than 10%; thus 10-year risk assessment in people with 0–1 risk factor is not necessary.

LDL = low-density lipoprotein; CHD = coronary heart disease.

TABLE 21–9. Classification of Total and Low-Density Lipoprotein Cholesterol Levels in Children and Adolescents from Families with Hypercholesterolemia or Premature Cardiovascular Disease^a

| Category | Total Cholesterol (mg/dL) | LDL Cholesterol (mg/dL) | Dietary Intervention |
|------------|---------------------------|-------------------------|--|
| Acceptable | <170 | <110 | Recommended population eating pattern |
| Borderline | 170–199 | 110–129 | Step 1 diet prescribed and other risk factor interventions |
| High | ≥200 | ≥130 | Step 1 diet prescribed and then step 2 diet if necessary |

^aFor use in children with a definite family history of premature (<50 years in females; <60 years in males) coronary heart disease, including diagnostic coronary arteriography, angioplasty, coronary artery bypass grafting, myocardial infarction, angina pectoris, peripheral vascular disease, or cerebrovascular disease before age 55 years. Screening also should be done in the offspring of a parent or sibling with blood cholesterol of 240 mg/dL or greater or, in the absence of family history, the presence of other risk factors (e.g., corticosteroid use, juvenile diabetes mellitus, hypothyroidism or other renal, endocrine, or hepatic disease known to affect cholesterol level).

From Expert Panel. National Cholesterol Education Program. Report of the Expert Panel on Blood Cholesterol Levels in Children and Adolescents. *Pediatrics* 1998;101:141–147.

concentrations for men and women, as well as various ethnic groups, are available from the NHANES III.⁶ Cholesterol and triglycerides increase throughout life until about the fifth decade for men and the sixth decade for women. Past these ages, total cholesterol and LDL plateau and fall slightly. HDL tends to fall slightly with time and more rapidly after menopause in women. Institution of a population-based approach to cholesterol reduction should shift the entire curve to the left, and the potential reduction in cardiovascular mortality would be proportional to mean reductions at any cholesterol concentration.

Based on a careful review of the experimental pathologic, genetic, and epidemiologic evidence relating to the relationship between blood cholesterol levels and CHD, the ATP III of the NCEP recommends that a fasting lipoprotein profile and risk factor assessment be used in the initial classification of adults.¹ If total cholesterol concentration is less than 200 mg/dL, then the patient has a *desirable blood cholesterol level* (see Table 21–6). Cholesterol levels between 200 and 239 mg/dL are classified as *borderline-high blood cholesterol levels*, and assessment of risk factors (see Table 21–7) is needed to more clearly define disease risk. Blood cholesterol levels of 240 mg/dL and above are classified as *high blood cholesterol levels*. If the total cholesterol concentration is below 200 mg/dL and the HDL is above 40 mg/dL, no further follow-up is recommended for patients without known CHD and who have fewer than two risk factors. In patients with evidence of CHD or other clinical atherosclerotic disease, the LDL goal is less than 100 mg/dL, and most patients will require diet and/or drug intervention. Decisions regarding classification and management are based on the LDL cholesterol levels as outlined in Table 21–8. An increasing number of persons have the metabolic syndrome that is characterized by abdominal obesity, atherogenic dyslipidemia (elevated triglycerides, small LDL particles, low HDL cholesterol), raised blood pressure, insulin resistance (with or without glucose intolerance), and prothrombotic and proinflammatory states. ATP III recognizes the metabolic syndrome as a secondary target of

risk-reduction therapy after LDL cholesterol has been addressed, and if the metabolic syndrome is present, the patient is considered to have a CHD risk equivalent.

The Expert Panel on Children and Adolescents of the NCEP recommends screening in higher-risk children (positive family history or parental high blood cholesterol ≥ 240 mg/dL).²⁷ The rationale, in part, for this approach is based on the recognition that atherosclerosis begins in the childhood and adolescent years, as documented in the Pathobiologic Determinants of Atherosclerosis in Youth (PDAY) and the Bogalusa studies.²⁸ Similarly, if children with high blood lipids or lipoprotein levels are identified and the levels in the parents are unknown, the parents should be screened as well because they are likely to be at high risk. Racial and gender differences do exist in the determination of lipoprotein fractions, and these factors should be considered in screening. Use of the serum cholesterol level alone may be of insufficient specificity or sensitivity depending on the cut points used in screening, and other discretionary factors, such as hypertension, smoking, obesity, high-fat diet, and use of cholesterol-raising medication, may be needed to correctly identify children at risk. Table 21–9 presents these recommendations. Presently, children older than age 10 years are candidates for drug therapy if a trial of diet (6 months to 1 year) proves to be inadequate and the LDL cholesterol level remains above 190 mg/dL or above 160 mg/dL if two or more risk factors or CHD is present in the child or adolescent or if there is a history of premature CHD. The Dietary Intervention Study in Children (DISC) in pubertal children found that a fat-restricted diet modestly lowered LDL cholesterol level and maintained psychological well-being.²⁹ Bile acid sequestrants are the recommended drugs for this population.³⁰ The long-term consequences of drug therapy in this population are unknown. In special instances, familial hypercholesterolemia (particularly the homozygous form) or the existence of CHD or two or more risk factors in the child would prompt the earlier institution of drug therapy after a trial of dietary intervention.³¹

► TREATMENT: Hyperlipidemia

■ DESIRED OUTCOMES

3 The goals of therapy expressed as LDL cholesterol levels and the level of initiation of therapeutic lifestyle change (TLC) and drug therapy are provided in Tables 21–8 and Tables 21–9 for adults and

children, respectively. While these goals are surrogate end points, the primary reason to institute TLC and drug therapy is to reduce the risk first or recurrent events such as MI, angina, heart failure, ischemic stroke, or other forms of peripheral arterial disease such as carotid stenosis or abdominal aortic aneurysm.

GENERAL APPROACH

Establishing targeted changes and outcomes with consistent reinforcement of goals and measures at follow-up visits to attain goals are important to reduce barriers for optimizing TLC and pharmacologic therapy. TLC should be implemented in all patients prior to considering drug therapy. The components of TLC include reduced intakes of saturated fats and cholesterol, dietary options to reduce LDL such as plant stanols and sterols and increased soluble fiber intake, weight reduction, and increased physical activity. In general, physical activity of moderate intensity 30 minutes per day for most days of the week should be encouraged. Patients with known CAD or at high risk should be evaluated before undertaking vigorous exercise. Weight and body mass index (BMI) should be measured at each visit, and lifestyle patterns to induce a weight loss of 10% should be discussed in persons who are overweight. All patients also should be counseled to stop smoking and to meet the Joint National Committee 7 (JNC7) guidelines for control of hypertension.

NONPHARMACOLOGIC THERAPY

Individualized diet counseling that provides acceptable substitutions for unhealthy foods and ongoing reinforcement by a registered dietitian are necessary for maximal effect. The objectives of dietary therapy are to decrease the intake of total fat, saturated fatty acids (i.e., saturated fat), and cholesterol progressively and to achieve a desirable body weight. Typical American diets now include 13% to 20% of total calories from saturated fat and a cholesterol intake of 350–450 mg/day, both in excess of a “heart healthy” diet for normal Americans, let alone patients with a lipid disorder. Excessive dietary intake of cholesterol and saturated fatty acids leads to decreased hepatic clearance of LDL and deposition of LDL and oxidized LDL in peripheral tissues. The targeted saturated fatty acids have carbon chain lengths of 12 (lauric acid), 14 (myristic acid), and 16 (palmitic acid). The rationale for using a nutritionally balanced low-fat, low-cholesterol diet for the treatment of hypercholesterolemia is based on these principles: (1) It represents a reasonable extension of the diet recommended for the general public, (2) it progressively decreases the major cholesterol-raising constituent of the diet, (3) it precludes large intakes of polyunsaturated fats, and (4) it facilitates weight reduction by removing foods of high caloric density.

Dietary expertise in providing a wide range of options and suggestions in the preparation of food can make the difference between a good or an inadequate response to diet. Information concerning eating out in a healthy fashion and advice for shopping are also important factors for success in diet therapy. An example is being aware of products with misleading labels such as coffee creamers that state they contain “no cholesterol” when they may contain hydrogenated (saturated) fats or oils (e.g., palmitic acid, palm kernel oil, or coconut oil), which makes them undesirable because of their saturated fat content. Variations in polyunsaturated and saturated fat and cholesterol intake influence the LDL concentration, but the amount of cholesterol has been found to have a greater effect than the proportion of polyunsaturated or saturated fat. There also were racial differences in elevations of LDL, with high saturated fat diets being greater in whites than in other racial groups. The isomeric form of fatty acids is also important. Fatty acids with the *cis* configuration are the preferred substrate for the ACAT reaction and significantly increase hepatic LDL receptor clearance while reducing LDL cholesterol production rate.

TABLE 21–10. Macronutrient Recommendations for the TLC Diet

| Component ^a | Recommended Intake |
|----------------------------|---|
| Total fat | 25–35% of total calories |
| Saturated fat | <7% of total calories |
| Polyunsaturated fat | Up to 10% of total calories |
| Monounsaturated fat | Up to 20% of total calories |
| Carbohydrates ^b | 50–60% of total calories |
| Cholesterol | <200 mg/day |
| Dietary fiber | 20–30 g/day |
| Plant sterols | 2 g/day |
| Protein | Approximately 15% of total calories |
| Total calories | To achieve and maintain desirable body weight |

^aCalories from alcohol not included.

^bCarbohydrates should derive from foods rich in complex carbohydrates, such as whole grains, fruits, and vegetables.

The *trans* isomeric form cannot be used by ACAT and is biologically inactive with no effect on LDL concentration.¹⁷

Ideally, therapeutic TLC, including reduced intake of saturated fats and cholesterol, increased stanol/sterol and fiber intake, weight reduction, and increased physical activity, should be used to attain lower LDL cholesterol levels and to achieve reductions in CHD risk (Table 21–10). TLC may obviate the need for drug therapy, augment LDL-lowering drug therapy, and allow for lower doses. Weight control plus increased physical activity reduces risk beyond LDL cholesterol lowering, is the primary management approach for the metabolic syndrome, and raises HDL and reduces non-HDL cholesterol. Many persons should be given a 3-month trial (two visits spaced 6 weeks apart) of dietary therapy and TLC before advancing to drug therapy unless patients are at very high risk (e.g., severe hypercholesterolemia, known CHD, CHD risk equivalents, multiple risk factors, and strong family history). Although changes in blood lipid levels may occur before 3 months, adoption of a different eating pattern may require a longer period of time. It is important to involve all family members, especially if the patient is not the primary person preparing food. The NCEP and AHA both have excellent Internet-based resources to aid patients in altering their diet in a culturally sensitive manner (e.g., <http://www.americanheart.org/presenter.jhtml?identifier=1200009> and <http://www.nhlbi.nih.gov/health/index.htm>). If all the recommended dietary changes from NCEP were instituted, the estimated reduction, on average, in LDL would range from 20% to 30%.¹ Adherence to diet and interindividual variability in macronutrient intake obviously would influence the eventual LDL level achieved. Based on the NHANES data, less than one-half of the patients who should be instructed on heart-healthy diet receive any dietary instructions.

Other dietary interventions or diet supplements may be useful in certain patients with lipid disorders. Increased intake of soluble fiber in the form of oat bran, pectins, certain gums, and psyllium products can result in useful adjunctive reductions in total and LDL cholesterol, but these dietary alterations or supplements should not be substituted for more active forms of treatment. Total daily fiber intake should be about 20 to 30 g/day, with about 25%, or 6 g/day, being soluble fiber.¹ Studies with psyllium seed in doses of 10 to 15 g/day show reductions in total and LDL cholesterol ranging from about 5% to 20%.³² They have little or no effect on HDL cholesterol or triglyceride concentrations. These products also may be useful in managing constipation associated with the bile acid sequestrants. Psyllium binds cholesterol in the gut but also reduces hepatic production and clearance. Fish

oil supplementation provides an increased amount of the omega-3 polyunsaturated fatty acids such as eicosapentaenoic acid and docosahexaenoic acid. In epidemiologic studies, ingestion of large amounts of cold water fish is associated with a reduction in CHD risk, but it is unclear whether the same advantage is conferred with commercially prepared fish oil products. Each 20 g/day ingestion of fish lowers CHD risk by 7%, and eating fish once weekly or more should reduce CHD mortality.³³ Fish oil supplementation has a fairly large effect in reducing triglycerides and VLDL cholesterol, but it either has no effect on total and LDL cholesterol or may cause elevations in these fractions. Other actions of fish oil may account for its protective effects. These effects include quantitative and qualitative alterations in the synthesis of prostanoid substances, changes in immune function and cellular proliferation, and potential antioxidative actions.³⁴ Responses noted with fish oil are further discussed under drug therapy.

Fat substitutes such as Olestra (Olean, sucrose polyester; Procter and Gamble), a mixture of hexa-, hepta-, and octaesters formed from the reaction of sucrose with long-chain fatty acids, are approved by the Food and Drug Administration (FDA) as a nondigestible, non-absorbable, noncaloric fat substitute for snack foods. Olestra is heat-stable, an advantage over several other fat substitutes, enabling it to be used in the preparation of fried and baked foods. It is similar in composition to triglycerides, but Olestra is not hydrolyzed in the gastrointestinal tract by pancreatic lipase and, consequently, is not taken up by the intestinal mucosa. The principal adverse effects associated with Olestra use are bloating, flatulence, diarrhea, and “anal leakage.” Because of the ability of Olestra to solubilize lipophilic substances, there has been concern over potential drug interactions in which lipophilic drugs (e.g., digitoxin, cyclosporin, or colchicine) or vitamins (vitamins A, D, E, and K) are solubilized in Olestra and excreted in the feces.

Recent studies have demonstrated the LDL-lowering effect of plant sterols, which are isolated from soybean and tall pine tree oils. Ingestion of 2 to 3 g/day will reduce LDL by 6% to 15%.¹ Plant sterols can be esterified to unsaturated fatty acids (creating sterol esters) to increase lipid solubility. Hydrogenating sterols produces plant stanols and, with esterification, stanol esters. The efficacy of plant sterols and plant stanols is considered to be comparable. Because lipids are needed to solubilize stanol/sterol esters, they are usually available in commercial margarines. The presence of plant stanols/sterols is listed on the food label. When margarine products are used, persons must be advised to adjust caloric intake to account for the calories contained in the products. Benecol (McNeil), as an example, is a butter-like spread that contains a plant stanol ester, an ingredient that can lower cholesterol and which is derived from plant stanols found naturally in small amounts in foods such as wheat, rye, and corn.

Drug therapy is indicated following an adequate trial of TLC changes as outlined in Tables 21–8 and Tables 21–9.

■ PHARMACOLOGIC THERAPY

There are now numerous randomized, double-blinded clinical trials demonstrating that reduction of LDL reduces CHD event rates in primary prevention, secondary intervention, and angiographic trials.^{13,15,35–37} Generally speaking, for every 1% reduction in LDL, there is a 1% reduction in CHD event rates.¹ However, if treatment extends beyond the typical duration of a clinical trial (2–5 years), the accumulated benefit could be greater. Elevations of HDL of 1% result in approximately 2% reduction in CHD events.¹⁵ Of interest, angiographic trials, which typically cause small changes in luminal

diameter (e.g., about a 0.04-mm difference in change between placebo and active treatment), result in fewer clinical events such as MI or the need for revascularization.³⁷ This unexpected finding suggests that plaque size and luminal encroachment by plaque may be less important than the effects that cholesterol lowering may have on the activity in the plaque and endothelial dysfunction. These studies provide a strong rationale for attempting to lower plasma cholesterol and LDL levels in patients with hypercholesterolemia.

4 Although many efficacious lipid-lowering drugs exist, none is effective in all lipoprotein disorders, and all such agents are associated with some adverse effects.³⁸ Lipid-lowering drugs can be divided broadly into agents that decrease the synthesis of VLDL and LDL, agents that enhance VLDL clearance, agents that enhance LDL catabolism, agents that decrease cholesterol absorption, agents that elevate HDL, or some combination of these characteristics (Table 21–11). Table 21–12 lists recommended drugs of choice for each lipoprotein phenotype and alternate agents. Table 21–13 lists available products and their doses.

Treatment of type I hyperlipoproteinemia is directed toward reduction of chylomicrons derived from dietary fat with the subsequent reduction in plasma triglycerides. Total daily fat intake should be no more than 10 to 25 g, or approximately 15% of total calories. Secondary causes of hypertriglyceridemia (see Table 21–5) should be excluded, or if present, the underlying disorder should be treated appropriately. Type V hyperlipoproteinemia also requires a stringent restriction of the fat component of dietary intake; in addition, drug therapy is indicated, as outlined in Table 21–12, if the response to diet alone is inadequate. Medium-chain triglycerides, which are absorbed without chylomicron formation, may be used as a dietary supplement for caloric intake if needed for types I and V. Hepatic fibrosis has been reported with medium-chain triglycerides. Omega-3 fatty acids may be useful in lipoprotein lipase deficiency in some patients. In patients with apolipoprotein C-II deficiency, infusion of plasma may normalize plasma triglyceride levels.

Primary hypercholesterolemia (i.e., familial hypercholesterolemia, familial combined hyperlipidemia, and type IIa hyperlipoproteinemia) is treated with the bile acid resins (BARs) or sequestrants (colestipol, cholestyramine, and colestevlam), HMG-CoA reductase inhibitors (statins), niacin, or ezetimibe. Of these choices, statins are first choice because they are the most potent LDL-lowering agents. Statins interrupt the conversion of HMG-CoA to mevalonate, the rate-limiting step in de novo cholesterol biosynthesis, by inhibiting HMG-CoA reductase (see Fig. 21–3). Currently available products include lovastatin, pravastatin, simvastatin, fluvastatin, and atorvastatin. Rosuvastatin is the most potent statin currently on the market. Table 21–14 lists the pharmacokinetic properties of the statins.³⁹ The plasma half-lives for all the statins are reported to be short, except for atorvastatin and rosuvastatin, and this may account for their potency.⁴⁰ In CURVES, the largest head-to-head comparison of statins, atorvastatin was found to be the most potent drug for lowering total cholesterol and LDL cholesterol prior to the introduction of rosuvastatin, with reductions in LDL cholesterol of 38%, 46%, 51%, and 54% for the 10-, 20-, 40-, and 80-mg doses, respectively.⁴¹ Metabolic studies with statins in normal volunteers and in patients with hypercholesterolemia suggest reduced synthesis of LDL cholesterol, as well as enhanced catabolism of LDL mediated through LDL receptors, as the principal mechanisms for lipid-lowering effects. Total and LDL cholesterol are reduced in a dose-related fashion by 30% or more on average when added to dietary therapy, with the effects being more pronounced in nonfamilial than in familial hypercholesterolemia.

6 Combination therapy with bile acid sequestrants and lovastatin is rational because LDL receptor numbers are increased, leading

TABLE 21–11. Effects of Drug Therapy on Lipids and Lipoproteins

| Drug | Mechanism of Action | Effects on Lipids | Effects on Lipoproteins | Comment |
|--|--|---|------------------------------------|--|
| Cholestyramine, colestipol, and colesevelam Niacin | ↑LDL catabolism ↓Cholesterol absorption ↓LDL and VLDL Synthesis | ↓Cholesterol ↓Triglyceride and cholesterol | ↓LDL ↑VLDL ↓VLDL, ↓LDL, ↑HDL | Problem with compliance; binds many coadministered acidic drugs Problems with patient acceptance; good in combination with bile acid resins; extended-release niacin causes less flushing and is less hepatotoxic than sustained-release niacin |
| Probucol | ↑LDL clearance | ↓Cholesterol | ↓LDL and HDL | Lowers HDL; modest efficacy but inhibits LDL oxidation and facilitates reverse cholesterol transport |
| Gemfibrozil, fenofibrate, clofibrate | ↑VLDL clearance ↓VLDL synthesis | ↓Triglyceride and cholesterol | ↓VLDL, ↓LDL, ↑HDL | Clofibrate causes cholesterol gallstones; modest LDL lowering; raises HDL; gemfibrozil inhibits glucuronidation of simvastatin, lovastatin, and atorvastatin |
| Lovastatin, pravastatin, simvastatin, fluvastatin, atorvastatin, rosuvastatin Ezetimibe | ↑LDL catabolism; inhibit LDL synthesis Inhibits cholesterol absorption across the intestinal border | ↓Cholesterol ↓Cholesterol | ↓LDL ↓LDL | Highly effective in heterozygous familial hypercholesterolemia and in combination with other agents Few adverse effects; effects additive to other drugs |

to greater degradation of LDL cholesterol, intracellular synthesis of cholesterol is inhibited, and enterohepatic recycling of bile acids is interrupted. Combination therapy with a statin plus ezetimibe is also rational because ezetimibe inhibits cholesterol absorption across the gut border and adds 12% to 20% further reduction when combined with a statin or other drugs.^{42,43} In the Expanded Clinical Evaluation of Lovastatin (EXCEL) in more than 8000 patients, lovastatin reduced LDL cholesterol by 24% to 40% when given in doses ranging from

TABLE 21–12. Lipoprotein Phenotype and Recommended Drug Treatment

| Lipoprotein Type | Drug of Choice | Combination Therapy |
|------------------|---|--|

| V | Fibrates Niacin | Niacin Fish oils |

^aBARs are not used as first-line therapy if triglycerides are elevated at baseline because hypertriglyceridemia may worsen with BARs alone.
BAR = bile acid resins; fibrates include gemfibrozil or fenofibrate.

20 mg once daily to 40 mg twice daily.⁴⁴ Constipation in placebo-treated patients occurred in 4.7% of patients, whereas lovastatin was associated with constipation in 4.2% to 7.7% of patients (20 mg twice a day). Elevation of serum transaminase levels (primarily alanine aminotransferase) to greater than three times the upper limit of normal and associated muscle symptoms (myopathy) were most common at higher doses (40 mg given twice a day)—1.5% compared with placebo at 0.1%. Creatine kinase (CK) concentrations greater than 10 times the upper limit of normal and muscle symptoms occurred in 0% of the placebo group versus 0.2% of the lovastatin group, and any elevation of CK was highest at 40 mg given twice a day, 3.5% versus 1.6% for placebo. Meta-analyses of placebo-controlled studies with statins demonstrate a low risk of abnormal alanine aminotransferase (ALT) or CK levels and a low risk of myopathy with or without rhabdomyolysis.⁴⁵ Lens opacities have been reported with lovastatin; however, in the age groups studied, these abnormalities are common and tend to wax and wane with time irrespective of drug therapy, and no statistical association is known to exist. As a category of monotherapy, the HMG-CoA reductase inhibitors are the most potent total and LDL cholesterol-lowering agents and among the best tolerated.^{35,36,46–49} Recently, a potential mechanism for poor response to statin therapy was described.⁵⁰ Poor responders had a low basal rate of cholesterol synthesis that may be secondary to a genetically determined increase in cholesterol absorption, possibly mediated by apolipoprotein E4 or by polymorphisms in the HMG-CoA reductase gene.^{39,40} Interestingly, statins may reduce the risk of cancer based on observational studies.⁵¹

The primary action of BARs is to bind bile acids in the intestinal lumen, with a concurrent interruption of enterohepatic circulation of bile acids and a markedly increased excretion of acidic steroids in the feces. This decreases the bile acid pool size and stimulates hepatic synthesis of bile acids from cholesterol. Depletion of the hepatic pool of cholesterol results in an increase in cholesterol biosynthesis and an increase in the number of LDL receptors on the hepatocyte membrane.

TABLE 21–13. Comparison of Drugs Used in the Treatment of Hyperlipidemia

| Drug | Manufacturer | Dosage Forms | Usual Daily Dose | Maximum Daily Dose |
|---|-----------------------|--|------------------------------------|-------------------------------------|
| Cholestyramine (Questran) | BMS | Bulk powder/4-g packets | 8 g tid | 32 g |
| Cholestyramine (Questran Light) | BMS | Bulk powder/4-g packets | | |
| Cholestyramine (Cholybar) | Parke-Davis | 4 g resin per bar | | |
| Colestipol hydrochloride (Colestid) | Upjohn | Bulk powder/5-g packets | 10 g bid | 30 g |
| Colesevelam (Welchol) | Sankyo | 625-mg tablets | 1875 mg bid | 4375 mg |
| Niacin | Various | 50-, 100-, 250-, and 500-mg tablets; 125-, 250-, and 500-mg capsules | 2 g tid | 9 g |
| Extended-release niacin (Niaspan) | Kos | 500-, 750-, and 1000-mg tablets | 500 mg | 2000 mg |
| Extended-release niacin + lovastatin (Advicor) ^a | Kos | Niacin/lovastatin 500-mg/20-mg tablets Niacin/lovastatin 750-mg/20-mg tablets Niacin/lovastatin 1000-mg/20-mg tablets | Niacin/lovastatin 500 mg/20 mg | Niacin/lovastatin 1000 mg/20 mg |
| Clofibrate (Atromid-S) | Wyeth-Ayerst | 500-mg capsules | 1 g bid | 2 g |
| Fenofibrate (Tricor) | Abbott, various | 43-, 67-, 87-, 134-, and 200-mg capsules (micronized); 48-, 54-, 145- and 160-mg tablets | 54 mg or 67 mg | 201 mg |
| Gemfibrozil (Lopid) | Parke-Davis | 600-mg capsules | 600 mg bid | 1.2 g |
| Lovastatin (Mevacor) | MSD | 20- and 40-mg tablets | 20–40 mg | 80 mg |
| Pravastatin (Pravachol) | Bristol-Myers Squibb | 10- and 20-mg tablets | 10–20 mg | 40 mg |
| Simvastatin (Zocor) | MSD | 5-, 10-, 20-, 40-, and 80-mg tablets | 10–20 mg | 80 mg |
| Atorvastatin (Lipitor) | Pfizer | 10-mg tablets | 10 mg | 80 mg |
| Rosuvastatin (Crestor) | Astra-Zeneca | 5- and 10-mg tablets | 5 mg | 40 mg |
| Ezetimibe (Zetia) | MSD | 10-mg tablet | 10 mg | 10 mg |
| Atorvastatin/amlodipine (Caduet) | Pfizer | Atorvastatin/amlodipine 10 mg/5 mg Atorvastatin/amlodipine 20 mg/5 mg Atorvastatin/amlodipine 40 mg/5 mg Atorvastatin/amlodipine 80 mg/5 mg Atorvastatin/amlodipine 10 mg/10 mg Atorvastatin/amlodipine 20 mg/10 mg Atorvastatin/amlodipine 40 mg/10 mg Atorvastatin/amlodipine 80 mg/10 mg | Atorvastatin/amlodipine 10 mg/5 mg | Atorvastatin/amlodipine 80 mg/10 mg |
| Pravastatin/aspirin (Pravigard PAC) | BMS | Pravastatin/aspirin 20 mg/81 mg Pravastatin/aspirin 20 mg/325 mg Pravastatin/aspirin 40 mg/81 mg Pravastatin/aspirin 40 mg/325 mg Pravastatin/aspirin 80 mg/81 mg Pravastatin/aspirin 80 mg/325 mg | | |
| Simvastatin/ezetimibe (Vytorin) | Merck/Schering-Plough | Simvastatin/ezetimibe 10 mg/10 mg Simvastatin/ezetimibe 20 mg/10 mg Simvastatin/ezetimibe 40 mg/10 mg | Simvastatin/ezetimibe 20 mg/10 mg | Simvastatin/ezetimibe 40 mg/10 mg |

^aThe manufacturer does not recommend use of the fixed combination as initial therapy of primary hypercholesterolemia or mixed dyslipidemia. It is specifically indicated in patients receiving lovastatin alone plus diet who require an additional reduction in triglyceride levels or increase in HDL cholesterol levels; it is also indicated in those treated with niacin alone who require additional decreases in LDL cholesterol.

bid = twice daily; probucol is no longer on the market in the United States; gemfibrozil, fenofibrate, and lovastatin are available as generic products; BMS = Bristol-Myers Squibb; MSD = Merck Sharp & Dohme.

TABLE 21–14. Pharmacokinetics of the Statins

| Parameter | Lovastatin | Simvastatin | Pravastatin | Fluvastatin | Atorvastatin | Rosuvastatin |
|-----------------------------|------------|-------------|-------------|-------------|--------------|--------------|
| Isoenzyme | 3A4 | 3A4 | None | 2C9 | 3A4 | 2C9/2C19 |
| Lipophilic | Yes | Yes | No | Yes | Yes | No |
| Protein binding (%) | >95 | 95–98 | ~50 | >90 | 96 | 88 |
| Active metabolites | Yes | Yes | No | No | Yes | Yes |
| Elimination half-life (hr.) | 3 | 2 | 1.8 | 1.2 | 7–14 | 13–20 |

Isoenzyme refers to the specific isoenzyme in the cytochrome P450 system that is responsible for the metabolism of each drug. Pharmacokinetic parameters in this table are based on studies and reviews presented in the literature.

The increased number of receptors stimulates an enhanced rate of catabolism from plasma and lowers LDL levels. Cholesteryl ester transfer protein (CETP), which is correlated with total and LDL cholesterol concentrations, is also reduced by BARs, perhaps by interfering with hepatic microsomal cholesterol content.⁵³ Patients with homozygous familial hypercholesterolemia genetically lack the ability to increase synthesis of LDL receptors, and bile acid resins generally are ineffective. The increase in hepatic cholesterol biosynthesis may be paralleled by increased hepatic VLDL production, and consequently, bile acid resins may aggravate hypertriglyceridemia in patients with combined hyperlipidemia. Gastrointestinal complaints of constipation, bloating, epigastric fullness, nausea, and flatulence are reported most commonly.¹ With intensive education, patients can learn to tolerate resins on a long-term basis, as evidenced by adherence in clinical trials to active drug regimens, but in routine clinical practice, 40% or more of patients will discontinue therapy within 1 year.^{54,55} These adverse effects can be managed by increasing the fluid intake, modifying the diet to increase bulk, and using stool softeners. The other major limiting complaint is the gritty texture and bulk; these problems may be minimized by mixing the powder with orange drink or juice. Tablet forms of bile acid sequestrants should help in improving compliance with this form of therapy, whereas the bar form does not improve compliance.³⁰ Other potential adverse effects include impaired absorption of fat-soluble vitamins A, D, E, and K, hypernatremia and hyperchloremia, gastrointestinal obstruction, and reduced bioavailability of acidic drugs such as coumarin anticoagulants, digitoxin, nicotinic acid, thyroxine, acetaminophen, hydrocortisone, hydrochlorothiazide, loperamide, and possibly iron. Hyperchloremic metabolic acidosis, hypernatremia, and gastrointestinal obstruction have been reported almost exclusively in children, and malabsorption of fat-soluble vitamins is probably most common with high doses (e.g., 30 g/day of cholestyramine) of the BARs. Drug interactions may be avoided by alternating administration times with an interval of 6 hours or greater between the BAR and other drugs. Colestipol and cholestyramine have comparable side effects, but colestipol may have better palatability because it is odorless and tasteless. Colesevelam is the newest BAR, and total and LDL cholesterol reduction is dose-related. The adverse effects are similar qualitatively to the older BARs but may occur less often. Because of adverse effects occurring commonly with BARs at higher doses, BARs are used increasingly in combination with other drugs because low doses are tolerated well, and they work in a complementary fashion with other agents.

Niacin (nicotinic acid) also may be used in primary hypercholesterolemia in combination with bile acid sequestrants or as monotherapy for this disorder and others (see Table 21–12). Niacin reduces the hepatic synthesis of VLDL, which, in turn, leads to a reduction in the synthesis of LDL. Factors responsible for decreased production of VLDL include inhibition of lipolysis with a decrease in free fatty acids in plasma, decreased hepatic esterification of triglycerides, and a possible direct effect on the hepatic production of apolipoprotein B. The complementary action of niacin and bile acid sequestrants to increase catabolism and decrease synthesis of LDL may account for the additive effects of this combination in hyperlipidemia. Niacin also increases HDL by reducing its catabolism. Niacin selectively decreases hepatic removal of HDL apoA-I but not removal of cholesterol esters, thereby increasing the capacity of retained apoA-I to augment reverse cholesterol transport in isolated hepatic cells. The principal use of niacin is for mixed hyperlipidemia or as a second-line agent in combination therapy for hypercholesterolemia. It is also considered to be the first-line agent or an alternative for the treatment of hypertriglyceridemia and diabetic dyslipidemia.^{56,57} There are numerous smaller trials suggesting that lower doses of niacin may be combined

with statins or gemfibrozil to minimize adverse effects and maximize response. These combinations require careful monitoring because interactions do occur.

Niacin has many adverse drug reactions that occur commonly; fortunately, most of the symptoms and biochemical abnormalities seen do not require discontinuation of therapy. Cutaneous flushing and itching appear to be prostaglandin-mediated and can be reduced by aspirin 325 mg given shortly before niacin ingestion.¹ Flushing seems to be related to rising plasma concentrations of niacin; taking the dose with meals and slowly titrating the dose upward may minimize these effects. Gastrointestinal intolerance and flushing are common problems. Acanthosis nigricans, a darkening of the skin in skinfold areas and an external marker of insulin resistance, may be seen with high doses of niacin. Sustained-release products may minimize these complaints in some patients, but controlled trials with regular-release products do not demonstrate much of a difference between sustained- and regular-release products. The only legend form of niacin, Niaspan (Kos), is an extended-release form with pharmacokinetics intermediate between instant and sustained-release products that are sold as food supplements rather than legend products. In controlled trials, Niaspan is reported to have fewer dermatologic reactions and has a low risk for hepatotoxicity.^{58,59} Potentially important laboratory abnormalities occurring with niacin therapy include elevated liver function tests, hyperuricemia, and hyperglycemia. Recent experience with niacin in diabetes suggests that some diabetic patients do not have worsened glycemic control with dose titration and sustained-release products.⁶⁰ With less than 3 g/day, the degree of liver function test elevation generally is not marked and often is transient, and a temporary reduction in dosage frequently corrects the problem. Niacin-associated hepatitis is more common with sustained-release preparations, and their use should be restricted to patients intolerant of regular-release products.⁶⁰ Sustained-release products often are more expensive, and given the lack of data for reduced adverse effects and the increased incidence of hepatitis, regular-release products always should be used first. Preexisting gout and diabetes may be exacerbated by niacin; these patients should be monitored more closely, and their medication should be titrated appropriately. Patients with well-controlled type 2 diabetes mellitus do not have significant changes in glycemic control with niacin at doses of 2 g/day or less.^{62,63} Niacin is contraindicated in patients with active liver disease. Dry eyes and other ophthalmologic complaints are also noted occasionally. Concomitant alcohol and hot drinks may magnify flushing and pruritus with niacin, and they should be avoided at the time of ingestion. Nicotinamide should not be used in the treatment of hyperlipidemia because it does not lower cholesterol or triglyceride levels effectively.

Combined hyperlipoproteinemia (type IIb) may be treated with statins, niacin, or gemfibrozil to lower LDL cholesterol without elevating VLDLs and triglycerides. Niacin is the most effective agent and may be combined with a bile acid sequestrant. BARs alone in this disorder may elevate VLDLs and triglycerides, and their use as single agents for treating combined hyperlipoproteinemia should be avoided. Fibric acid (e.g., gemfibrozil, fenofibrate, or clofibrate) monotherapy is effective in reducing VLDL, but a reciprocal rise in LDL may occur, and total cholesterol values may remain relatively unchanged. Gemfibrozil reduces the synthesis of VLDL and, to a lesser extent, apolipoprotein B, with a concurrent increase in the rate of removal of triglyceride-rich lipoproteins from plasma. Plasma HDL concentrations may rise 10% to 15% or more with fibrates. Ezetimibe also could be used in combination therapy in type IIb. Gastrointestinal complaints with fibric acid derivatives occur in 3% to 5% of patients, rash in 2% of patients, dizziness in 2.4% of patients, and transient

elevations in transaminase and alkaline phosphatase levels in 4.5% and 1.3% of patients, respectively. Similar to clofibrate, gemfibrozil may enhance the formation of gallstones associated with an increase in the lithogenic index; however, the rate is low (0.6%) and similar to that seen with placebo in the Helsinki Heart Study.¹⁵ Other studies have found the relative risk for gallstones to be 1.7.⁶⁴ Fibric acid derivatives may potentiate the effects of oral anticoagulants, and the prothrombin time and international normalized ratio should be monitored very closely with this combination.

Type III hyperlipoproteinemia may be treated with fibric acid derivatives or niacin. Although clofibrate has been suggested as the drug of choice for this disorder, given the lack of data supporting its efficacy in altering cardiovascular mortality in the major studies on hypercholesterolemia and its numerous, well-documented, and serious adverse effects, it is reasonable to consider niacin, gemfibrozil, or fenofibrate prior to the use of clofibrate. Clofibrate increases the activity of lipoprotein lipase and reduces to a lesser extent the synthesis or secretion of VLDL from the liver into the plasma. Clofibrate is less effective than gemfibrozil or niacin in reducing VLDL production. The most disturbing aspects of clofibrate's adverse effects are its potential to induce gallstones (4.7%, clofibrate; 0.54%, placebo), promote ventricular ectopy, and potentially cause gastrointestinal malignancy, resulting in a greater overall mortality than placebo alone.¹ A myositis syndrome of myalgia, weakness, stiffness, malaise, and elevations in creatinine phosphokinase and aspartate aminotransaminase is seen with the fibric acid derivatives, and it seems to be more common in patients with renal insufficiency. Enhanced hypoglycemic effects are reported to occur when fibric acid derivatives are given to patients on sulfonylurea compounds, but the mechanisms for these interactions are not well understood. Rifampin, a hepatic enzyme inducer of oxidative pathways, may induce the metabolism of clofibrate, but the long-term consequences are unknown.

Three fibric acid derivatives (clofibrate, gemfibrozil, and fenofibrate) are approved in the United States; however, several others are under development or are being used in Europe, including bezafibrate and ciprofibrate. All reduce LDL cholesterol by 20% to 25% in heterozygous familial hypercholesterolemia. The response of LDL cholesterol, HDL cholesterol, and triglycerides to this category of drug is very dependent on the specific lipoprotein type (e.g., type IIa versus IIb) and the baseline triglyceride concentration.⁶⁸

As a potential alternative therapy for this phenotype, numerous epidemiologic and normal volunteer studies have found that diets high in omega-3 polyunsaturated fatty acids (from fish oil), mostly commonly eicosapentaenoic acid, reduce cholesterol, triglycerides, LDL cholesterol, and VLDL cholesterol and may elevate HDL cholesterol.^{17,33} The effects of fish oil on lipoprotein metabolism are mediated through a reduction in VLDL production and suppression of VLDL apolipoprotein B. In patients with hypertriglyceridemia, either type IIb or type V phenotype, a diet high in omega-3 fatty acids given for 4 weeks reduced cholesterol 27% and 45% and triglyceride 64% and 79%, respectively.³³ A diet high in eicosapentaenoic acid given to hyperlipidemic hemodialysis patients resulted in significant decreases in cholesterol and triglycerides for as long as 13 weeks. Fish oil supplementation may be most useful in patients with hypertriglyceridemia; however, its role in treatment is not well defined. Potential complications of fish oil supplementation, such as thrombocytopenia and bleeding disorders, have been noted, especially with high doses (eicosapentaenoic acid 15–30 g/day), and well-controlled trials are needed to determine if fish oils are safe and effective before their use may be broadly recommended. Based on a recent meta-analysis, fish consumption lowers the risk of CHD, but nutraceuticals have not been tested adequately.³³

Combination drug therapy may be considered after adequate trials of monotherapy and for patients documented to be compliant with the prescribed regimen. Two or three lipoprotein profiles at 6-week intervals should confirm lack of response prior to initiation of combination therapy. Cholestyramine may be added in patients with fasting hypertriglyceridemia, but it should not be used as the initial drug because triglycerides are likely to increase. Contraindications to and drug interactions with combined therapy should be screened carefully, as well as consideration of the extra cost of drug product and monitoring that may be required. In general, a statin and a BAR or niacin with a BAR provides the greatest reduction in total and LDL cholesterol. Regimens intended to increase HDL levels should include either gemfibrozil or niacin, and it should be remembered that statins combined with either of these drugs may result in a greater incidence of hepatotoxicity or myositis. This is particularly important for statins that are eliminated via cytochrome P450 3A4 or through glucuronidation.^{39,65} Familial combined hyperlipidemia may respond better to a fibric acid and a statin than to a fibric acid and a BAR.^{66,67}

Severe forms of hypercholesterolemia—such as familial hypercholesterolemia, familial defective apolipoprotein B-100, severe polygenic hypercholesterolemia, familial combined hyperlipidemia, and familial dysbetalipoproteinemia (type III)—may require more intensive therapy. In particular, familial hypercholesterolemia patients often require combination therapy (two or three drugs) and are managed with surgical therapy (partial ileal bypass), plasmapheresis (LDL-apheresis), and liver transplantation (to replace LDL receptors).

■ HYPERTRIGLYCERIDEMIA

It is important to remember that lipoprotein pattern types I, III, IV, and V are associated with hypertriglyceridemia and that these primary lipoprotein disorders and underlying diseases should be excluded prior to implementing therapy (see Table 21–5). A positive family history of CHD is important in identifying patients at risk for premature atherosclerosis.^{16,68} If a patient with CHD has elevated triglycerides, the associated abnormality is probably a contributing factor to CHD and should be treated.⁵⁶

High serum triglycerides (see Tables 21–6 and Tables 21–12) should be treated by achieving desirable body weight, consumption of a low saturated fat and cholesterol diet, regular exercise, smoking cessation, and restriction of alcohol (in selected patients). ATP III identifies the sum of LDL + VLDL (termed *non-HDL* [total cholesterol–HDL]) as a secondary target of therapy in persons with high triglycerides (≥ 200 mg/dL). This approach is used when triglycerides exceed 200 mg/dL and accounts for atherogenic particles carried in VLDL and remnant particles. The goal for non-HDL in persons with high serum triglycerides can be set at 30 mg/dL higher than that for LDL on the premise that a VLDL level of 30 mg/dL or less is normal. In patients with borderline high triglycerides but with accompanying risk factors of established CHD disease, family history of premature CHD, concomitant LDL elevation or low HDL, and genetic forms of hypertriglyceridemia associated with CHD (familial dysbetalipoproteinemia, familial combined hyperlipidemia), drug therapy with niacin should be considered. Niacin may be used cautiously in diabetics based on the results of the ADMIT trial, which found that triglycerides were reduced by 23%, HDL cholesterol was increased by 29%, there was only a slight increase in glucose (mean 8.7 mg/dL), and there was no change in hemoglobin A_{1c}.⁶³ Alternative therapies include gemfibrozil, statins, and fish oil.^{70,71} Fibrates may increase LDL, and their use in borderline high triglyceridemia requires careful

monitoring to detect this deleterious change in lipid profile. Statins also may be used because they provide modest reductions in triglycerides and modest elevations in HDL. Higher doses of atorvastatin and fluvastatin may reduce HDL as well as LDL and triglycerides.⁷² The goal of therapy in this situation is to lower triglycerides and VLDL particles that may be atherogenic, increase HDL, and reduce LDL.

Very high triglycerides are associated with pancreatitis and other consequences of the chylomicron syndrome. At this level of elevation of triglycerides, a genetic form of hypertriglyceridemia often coexists with other causes of elevated triglycerides such as diabetes. Dietary fat restriction (10% to 20% of calories as fat), weight loss, alcohol restriction, and treatment of the coexisting disorder are the basic elements of management. Drugs useful in hypertriglyceridemia include gemfibrozil, niacin, and higher-potency statins (e.g., atorvastatin, rosuvastatin, and simvastatin). Gemfibrozil is the preferred drug in diabetics because of the effect of niacin on glycemic control unless the newer extended-release forms are used. Fenofibrate may be preferred in combination with statin therapy because it does not impair glucuronidation and minimizes potential drug interactions. Success in treatment is defined as a reduction in triglycerides below 500 mg/dL.¹

■ LOW HDL CHOLESTEROL

Low HDL is a strong independent risk predictor of CHD. The ATP III redefined low HDL cholesterol as less than 40 mg/dL but specified no goal for HDL cholesterol raising.¹ Low HDL may be a consequence of insulin resistance, physical inactivity, type 2 diabetes, cigarette smoking, very high carbohydrate intake, and certain drugs (see Table 21–5). **8** In low HDL, the primary target remains LDL according to the ATP III, but emphasis shifts to weight reduction, increased physical activity, and smoking cessation and, if drug therapy is required, to fibric acid derivatives and niacin. Niacin has the potential for the greatest increase in HDL, and the effect is more pronounced with regular or immediate-release forms than with sustained-release forms.⁶¹

■ DIABETIC DYSLIPIDEMIA

Diabetic dyslipidemia is characterized by hypertriglyceridemia, low HDL, and LDL that is minimally elevated. Small, dense LDL (pattern B) in diabetes is more atherogenic than larger, more buoyant forms of LDL (pattern A); routine lipoprotein profiles do not differentiate between pattern A and pattern B.⁷² Diabetes in the ATP III is a CHD risk equivalent, and the primary target is LDL, with a goal of treatment being to lower LDL cholesterol to less than 100 mg/dL.¹ When the LDL concentration is greater than 130 mg/dL, most patients will require simultaneous therapeutic lifestyle changes and drug therapy. When the LDL cholesterol concentration is between 100 and 129 mg/dL, intensifying glycemic control, adding drugs for the atherogenic dyslipidemia (fibric acid derivatives and niacin), and intensifying LDL cholesterol-lowering therapy are options. Because the primary target is LDL cholesterol in diabetic dyslipidemia, statins are considered by many to be the initial drugs of choice.^{1,28} The relative risk reduction for CHD in diabetics versus nondiabetics was greater in the West of Scotland (37% versus 20%),³⁵ AFCAPS/TexCAPS (43% versus 36%),⁴⁷ CARE (25% versus 23%),⁴⁸ and 4S (55% versus 32%) trials.³⁶ All statins are fairly comparable in triglyceride lowering, and because statins differ in potency for LDL reduction, a ratio of LDL reduction to triglyceride reduction can be applied. Statin therapy may

protect against the development of diabetes, but the observations from the West of Scotland study with pravastatin need to be confirmed in a prospective trial.⁷³ The most recent trial of LDL lowering in type 2 diabetes mellitus is the Collaborative Atorvastatin Diabetes Study (CARDS).⁷⁴ This was a randomized, double-blind, placebo comparison of atorvastatin 10 mg/day versus placebo in 2838 diabetes patients to reduce first CHD events. Baseline LDL concentration was 118 mg/dL, and with atorvastatin, LDL concentration fell by 46 mg/dL. The primary end point, a composite of acute CHD death, nonfatal MI, hospitalized unstable angina, resuscitated cardiac arrest, coronary revascularization, or stroke, was reduced by 37%. This study suggests that all diabetics should have an LDL concentration that is much lower than 100 mg/dL, and these results are consistent with the Heart Protection Study analysis of diabetic patients.⁷⁵

Fenofibrate, according to the DIAS trial, reduced the angiographic progression of CAD in type 2 diabetes.⁷⁶ Fewer CHD events were seen with fenofibrate compared with placebo, but the difference was not significant. Fibric acids principally lower VLDL and triglycerides while increasing HDL with only modest lowering of total and LDL cholesterol; on occasion, fibric acid derivatives may increase LDL levels. Fibric acid derivatives tend to improve glucose tolerance, in contrast to niacin; the greatest effect has been seen with bezafibrate. The Helsinki Heart Study found gemfibrozil to be most effective in diabetic dyslipidemia.¹⁵ Although the effect of statins on triglycerides and HDL abnormalities commonly seen in diabetes is less than with fibric acids, the subgroup analyses cited earlier suggest that they reduce CHD risk significantly. Cholestyramine in diabetic patients may result in lower LDL levels, but VLDL and triglyceride levels, which are commonly elevated in diabetes, may be further increased in this population. Resins may aggravate constipation, which is common in diabetics. As demonstrated in the ADMIT and ADVENT trials, immediate- and extended-release niacins are very effective in raising HDL concentrations and lowering triglyceride and LDL concentrations.^{62,63}

■ SPECIAL CONSIDERATIONS

■ ELDERLY

Hypercholesterolemia is an independent risk factor for CHD in the elderly (>65 years old), as it is in the younger patient. The attributable risk, which is the difference in absolute rates of CHD between segments of the population with higher or lower serum cholesterol levels, increases with age. Older patients potentially benefit to a greater extent from cholesterol lowering than younger populations. Data from studies of elderly men in a variety of settings are consistent with a relative risk of at least 1.5 in the highest compared with the lowest quartile of cholesterol levels.⁷⁵ Treatment of hypercholesterolemia in the elderly may bring about a comparable reduction in absolute risk to that obtained in younger persons.¹ Subgroup analyses of the West of Scotland (primary) and 4S (secondary) intervention studies show that elderly patients have lower CHD risk reduction (relative risk reduction of 27% and 29%, respectively) as compared with younger patients (relative risk reduction of 40% and 39%, respectively).^{35,36} The Framingham Study suggests that elderly women are at higher risk because of high blood cholesterol levels, but no other large studies included women; and their risks or benefits from cholesterol reduction are not well defined. Primary prevention in younger patients requires about 2 years before reduction in CHD risk is apparent, and this lag time should be taken into consideration in patient selection for therapy. Nonlipid CHD risk factors do not decline in relative risk with

aging, and aggressive management of the modifiable nonlipid risk factors is important in older patients. High-risk elderly patients are less likely to be prescribed statins, and their potent benefits are not realized.⁷⁸ Because most women with CHD are elderly and also at risk for osteoporosis, they are logical candidates for diet therapy with consideration of calcium intake consistent with osteoporosis prevention, exercise, and perhaps estrogen-replacement therapy. Recent evidence suggests that statins may reduce the risk of osteoporosis; however, there are conflicting data from various studies.⁷⁹

Drug therapy in principle differs little from that in younger patients, and older patients respond to lipid-lowering drugs as well as younger patients.^{80,81} Based on the Heart Protection Study with more elderly patients than any other trial, simvastatin 40 mg/day produced the same CHD event rate reduction in patients over 70 years of age as in younger patients.⁸¹ The gain in life expectancy may be small depending on age at the start of treatment and magnitude of cholesterol reduction.⁸² Changes in body composition, renal function, and other physiologic changes of aging may make older patients more susceptible to adverse effects of lipid-lowering drug therapy. In particular, older patients are more likely to have constipation (bile acid resins), skin and eye changes (niacin), gout (niacin), gallstones (fibric acid derivatives), and bone/joint disorders (fibric acid derivatives, statins). Therapy should be started with lower doses and titrated up slowly to minimize adverse effects.

■ WOMEN

Cholesterol is an important determinant of CHD in women, but the relationship is not as strong as that seen in men. HDL may be a more important predictor of disease in women.^{83,84} LDL and HDL genetic regulation in women and men does not appear to be different. Based on the Nurses' Health Study, obesity is an important determinant of CHD in women, with the relative risk being 3.3 in the highest Quetelet index (weight in kilograms divided by the square of the height in meters) as compared with the lowest category (i.e., <21 versus ≥ 29); low HDL levels usually accompany obesity.⁸⁵ No major differences exist in the influence of exercise, alcohol ingestion, and smoking on lipid levels between men and women. Women in the highest tertile of cholesterol appear to be more responsive to dietary therapy than those in the lower tertiles and more responsive than formulas based on men predict.

Based on the HERS⁸⁶ and WHI^{87,88} trials, recently published national guidelines recommended similar types of lifestyle and risk factor goals and interventions as recommended by NCEP for the entire population.⁸³ Hormone therapy may continue to have a role for postmenopausal symptoms; however, a notable exception is hormone-replacement therapy and heart protection. Combined estrogen plus progestin hormone therapy should not be initiated to prevent cardiovascular disease (CVD) in postmenopausal women. Combined estrogen plus progestin hormone therapy should not be continued to prevent CVD in postmenopausal women. Other forms of menopausal hormone therapy (e.g., unopposed estrogen) should not be initiated or continued to prevent CVD in postmenopausal women pending the results of ongoing trials.⁸³

Cholesterol and triglyceride levels rise progressively throughout pregnancy, with an average increment in cholesterol of 30 to 40 mg/dL occurring around the thirty-sixth to thirty-ninth weeks. Triglyceride levels may go up by as much as 150 mg/dL. Drug therapy is not instituted, nor is it usually continued, during pregnancy. If the patient is very high risk, a BAR may be considered because there is no systemic drug exposure.¹ Statins are category X and are contraindicated. Ezetimibe might be an alternative because it is a category C drug (animal

studies have shown that the drug exerts teratogenic or embryocidal effects, and there are no adequate, well-controlled studies in pregnant women, or no studies are available in either animals or pregnant women) but no data are available in humans. Dietary therapy is the mainstay of treatment, with emphasis on maintaining a nutritionally balanced diet as per the needs of pregnancy.

■ CHILDREN

Drug therapy in children is not recommended until the age of 10 years or older, and the guidelines for institution of therapy and the goals of therapy are different from those in adults²⁷ (see Table 21–9). Younger children generally are managed with TLCs until after the age of 2 years.^{89,90} Bile acid sequestrants are used in children because they minimize the risks of systemic toxicity.³⁰ Some literature does exist suggesting that resins and perhaps statins are safe and effective in children.^{31,89,90} Severe forms of hypercholesterolemia (e.g., familial hypercholesterolemia) may require more aggressive treatment.

■ CONCURRENT DISEASE STATES

Nephrotic syndrome, end-stage renal disease and nephrotic syndrome, and hypertension compound the risk of dyslipidemia and may present difficult-to-treat lipid abnormalities. Abnormalities of lipoprotein metabolism in the nephrotic syndrome include elevated total and LDL cholesterol, Lp(a), VLDL, and triglycerides. The apolipoprotein C-III to C-II ratio is elevated, consistent with greater lipoprotein lipase inhibitor activity, and the extent of hypoalbuminemia is correlated with dyslipidemia. The basic abnormality appears to be one of overproduction of LDL-apoB from VLDL rather than reduced clearance of LDL cholesterol and related proteins. Protein restriction and a “vegan” diet correct lipid abnormalities to some extent. Statins have been shown to be effective in reducing elevated total and LDL cholesterol in the nephrotic syndrome, although the levels usually do not return to normal.⁹¹ The pharmacokinetics of gemfibrozil are apparently not altered by renal insufficiency, and it is effective in lowering total cholesterol by about 15% for this disorder.⁹² Fenofibrate reduces remnant lipoproteins. Fibric acid derivatives and statins reduce small, dense LDL cholesterol by different mechanisms, suggesting a potential role for combination therapy to optimize lowering of small, dense LDL cholesterol and remnant lipoproteins.⁹³

Renal insufficiency without proteinuria leads to hypertriglyceridemia, slightly elevated total and LDL cholesterol (particularly with chronic ambulatory peritoneal dialysis), and low HDL levels (especially during hemodialysis). These abnormalities are thought to be caused by a deficiency in apolipoprotein C-II, perhaps as a result of sustained use of heparin during hemodialysis and depletion of lipoprotein lipase, carbohydrate-induced obesity and hypertriglyceridemia, loss of carnitine during hemodialysis, use of acetate buffer (acetate is a precursor to fatty acid synthesis) during hemodialysis, and decreased LCAT activity during hemodialysis. Dialysis does not correct the lipid abnormalities. Renal transplantation may correct lipid abnormalities in some patients, but in others, the use of transplantation-related medications such as corticosteroids, cyclosporine, and certain antihypertensive agents (see Chaps. 13 and 87) may aggravate the lipid abnormalities. Cyclosporine interferes with the metabolism of statins metabolized by cytochrome P450 3A4 (Table 21–14), and patients need to be observed closely for myositis and worsening renal function. Of interest, correction of lipid abnormalities may improve renal hemodynamics. Pravastatin and fluvastatin may be safer than

other statins, but this needs to be validated in larger, long-term trials. Diet will modify lipoprotein levels and polyunsaturated fatty acids may have a role in impeding the progression of renal disease as well as the cardiovascular complications. Bile acid sequestrants do not correct the lipid abnormalities seen in renal insufficiency. Lovastatin or its active metabolite may accumulate in renal insufficiency, and lower doses of reductase inhibitors should be used to avoid adverse effects. Gemfibrozil may be used with caution because its pharmacokinetics are unchanged, and it lowers triglycerides and increases HDL.⁶⁵ Statins (simvastatin, lovastatin, and atorvastatin) and fibric acid derivatives may increase the risk of severe myopathy, and attention to symptoms of myositis is needed. Niacin also may be useful in nondiabetic patients with renal insufficiency.

Hypertensive patients have a greater than expected prevalence of high blood cholesterol levels, and conversely, patients with hypercholesterolemia have a higher than expected prevalence of hypertension caused by the metabolic syndrome. Recommendations for the management of hypertension in patients with hypercholesterolemia include avoiding the use of drugs that elevate cholesterol such as diuretics and β -blockers and using agents that are either lipid-neutral or that may reduce cholesterol slightly¹ (see Chap. 13). Bile acid sequestrants may bind to thiazide diuretics and some β -blockers and may interfere with their absorption; reaction may be avoided by giving the antihypertensive 1 hour before or 4 hours after the resin. Niacin may magnify the hypotensive effects of vasodilators.

■ OTHER THERAPIES

Partial ileal bypass has been used in severe heterozygous and homozygous familial hypercholesterolemia; however, it is ineffective in the latter case. Ileal bypass removes the site of bile acid reabsorption, depleting the bile acid pool and increasing the catabolism of cholesterol. A randomized trial of diet versus surgery, called Program On the Surgical Control of the Hyperlipidemias (POSCH), reported

that total and LDL cholesterol were decreased (23.3% and 37.7%, respectively) and HDL increased (4.3%) in patients who had undergone ileal bypass for hypercholesterolemia.⁹⁷ Overall death was delayed by nearly 3 years ($p = .032$) and CHD mortality was delayed by nearly 4 years ($p = .046$) by surgery as compared with the control group. Revascularization procedures were delayed by an average of 7 years ($p < .001$). Postoperative diarrhea was more common in the surgical group, as was the rate of kidney stones (4% versus 0.4%), gallstones (10% versus 2%), and bowel obstruction (13.5% versus 3.6%).

Portacaval shunts have been used to decrease the formation of LDL cholesterol, and reductions of 10% to 20% have been reported. Plasma exchange combined with niacin was found to reduce plasma cholesterol levels by about 50% in homozygous familial hypercholesterolemia over 5 years, and coronary atherosclerosis did not progress, as documented by angiography. LDL-apheresis, selective removal of LDL cholesterol via a filtering system, and statin therapy are effective in lowering LDL cholesterol and appear to affect the progression of vascular disease. LDL-apheresis may be combined with statin therapy for greater effect. Combined liver and heart transplantation in homozygous familial hypercholesterolemia reduces total and LDL cholesterol concentrations from about 1100 and 900 mg/dL to about 300 and 185 mg/dL prior to and after surgery, respectively. Liver transplantation replaced the missing LDL receptors, enhanced catabolism, and reduced lipoprotein synthesis in this patient.

■ SUMMARY OF MAJOR STUDIES

9 Primary and secondary prevention diet and drug trials have been performed to determine whether lowering of cholesterol will prevent CHD; Tables 21–15 and Tables 21–16 summarize these trials. A number of earlier angiographic studies demonstrated that cholesterol reduction leads to regression of atherosclerosis and plaque stabilization. Most of the primary and secondary studies were double-blinded, randomized, and placebo-controlled, lasting for 5 years or

VA-HIT = Veterans Administration-High-Density Lipoprotein Cholesterol (HDL-C) Intervention Trial; AVERT = The Atorvastatin Versus Revascularization Treatments; CARE = Cholesterol and Recurrent Events (Melendez et al., 1996); CDP = Coronary Drug Project (Berge et al., 1975); HERS = Heart and Estrogen Replacement Study (Hulley et al., 1998); LIPID = Long-Term Intervention with Pravastatin in Ischaemic Disease Study (MacMahon et al., 1995); 4S-Scandinavian Simvastatin Survival Study (Pederson et al., 1994); WHO = World Health Organization (Committee of Principal Investigators, 1978); BIP = Bezafibrate Infarction Prevention; TIMI-22 = Thrombolysis in Myocardial Infarction Study 22; also known as the PROVE-IT trial (Cannon et al., 2004); HPS = Heart Protection Study; results expressed as all-cause mortality (HPS Collaborative Group, 2002); MIRACL = Myocardial Ischemia Reduction with Aggressive Cholesterol Lowering (Schwartz et al., 2001); PROSPER = PROspective Study of Pravastatin in the Elderly at Risk; RRR = relative risk reduction; ARR = absolute risk reduction; NNT = number needed to treat.

longer, and most had sufficient patient numbers to be meaningful. Exceptions to these qualifications were seen in the early studies, such as the Newcastle and Edinburgh trials, which were small and generally did not show much benefit; and the Coronary Drug Project (CDP) using dextrothyroxine, which was terminated early owing to adverse effects on CHD mortality. The Helsinki Heart Study, using gemfibrozil, resulted in a reduction in nonfatal MI, which was the primary contributor to reduced CHD incidence¹⁵ (see Table 21–15).

Total and LDL cholesterol concentrations were reduced an average of 13.4% and 20.3%, respectively, by cholestyramine in the LRC-CPPT, and the reduction of lipid levels was related to the amount of drug ingested (e.g., 1 to 2 packets, 5.4% reduction in total cholesterol, versus 5 or more packets, 19.0% reduction).⁹⁸ The prescribed dose of cholestyramine was 24 g, or 6 packets, per day. The cholestyramine group experienced a 19% reduction in risk ($p < .05$) of the primary end point—definite CHD death and/or definite nonfatal MI—reflecting a 24% reduction in definite CHD death and a 19% reduction in nonfatal MI. Other end points were reduced by 25%, 20%, and 21% for new positive exercise tests, angina, and coronary bypass surgery, respectively. Death from all causes was not significantly reduced by cholestyramine secondary to more accidents and violence in this group. The mean falls in total and LDL cholesterol concentrations in the cholestyramine group were 8% and 12% relative to levels in placebo-treated men, providing evidence that for every 1% reduction in cholesterol, a 2% decline in CHD mortality can be realized.

In AFCAPS/TexCAPS, a primary prevention trial conducted in 6605 men and women aged 57 to 63 years with average total cholesterol and LDL concentrations (<221 mg/dL and <150 mg/dL, respectively) who were treated with lovastatin 20–40 mg/day for 5.2 years, a 37% reduction ($p < .001$) was shown in the risk for first acute major coronary event (fatal or nonfatal MI, unstable angina, or sudden cardiac death).⁴⁷ The need for revascularization procedures also was reduced by 33% ($p < .001$). The implications of this trial are enormous; potentially millions of “normal” people could benefit

from lipid lowering with statins based on these results. The number of patients who need to be treated (NNT; see Table 21–15) for primary prevention ranges from 43 in the West of Scotland trial to 71 in the Helsinki Heart Study. This range is within the typical boundary used for treatment decisions and described previously; cost-effectiveness is achieved routinely in patients with moderate to high risk. The Anti-hypertensive and Lipid-Lowering Treatment to Prevent Heart Attack Trial (ALLHAT-LLT) tested pravastatin 40 mg/day versus placebo in hypertensive patients with at least one CHD risk factor. Pravastatin did not reduce either all-cause mortality or CHD significantly when compared with usual care in older participants with well-controlled hypertension and moderately elevated LDL cholesterol. The results may be due to the modest differential in total cholesterol (9.6%) and LDL cholesterol (16.7%) between pravastatin and usual care compared with prior statin trials supporting cardiovascular disease prevention.⁹⁹ The long-awaited Women’s Health Initiative trial proved to be disappointing, with no beneficial effects on CHD event reduction in the hormone-replacement arm (conjugated equine estrogens [CEE] + medroxyprogesterone), or the CEE alone arm compared with placebo.^{87,88} Women did experience greater risk for thromboembolism and a slight increase in breast cancer and a reduced risk of hip fracture. Consequently, hormone-replacement therapy can no longer be recommended for cardiovascular protection.⁸³

Niacin in the CDP significantly reduced definite, nonfatal MI as compared with placebo (10.1% versus 13.9%), whereas clofibrate did not reduce death from any cause or nonfatal or fatal MI at the 5-year follow-up period.¹⁰⁰ Clofibrate did increase the rate of definite or suspected fatal or nonfatal pulmonary embolism or thrombophlebitis compared with placebo (5.8% versus 3.6%) after adjusting for baseline characteristics for total follow-up.¹⁰⁰ Other findings with clofibrate that occurred more frequently than with placebo included intermittent claudication, arrhythmias, palpable spleen, cholelithiasis (including cholecystectomy), and more frequent use of anticoagulants. Skin reactions, gastrointestinal complaints, and the use of gout

medication were more common with niacin than with placebo. The 5-year total mortalities were 20.0% for clofibrate and 20.9% for placebo. The 5-year total mortality for niacin was 21.2%. Long-term follow-up of the CDP has shown a reduction in total mortality with niacin that occurred 9 years after the drug had been stopped.¹⁰⁰ The mechanism for this effect is unclear.

One of the most important studies published in the last few years is the 4S trial, a secondary intervention trial in a large number of patients.³⁵ Simvastatin, 20–40 mg/day, reduced LDL cholesterol by 35% and reduced the risk of death from any cause by 30%. Coronary deaths also were reduced with simvastatin (relative risk 0.58; confidence interval, 0.46–0.73). Therapy also was shown to be effective in women (18% to 19% of patients enrolled) and in the elderly (≥ 60 years). Indeed, the relative risk of death or major coronary event was reduced to a greater extent in the elderly than in younger patients. Death from noncardiovascular causes was similar for simvastatin and placebo (2.1% and 2.2%, respectively). The survival curves for simvastatin and placebo began to separate at 1 year and became more divergent with additional follow-up. The 4S study clearly demonstrates the benefit in cholesterol lowering and placates long-held fears of death from non-CHD causes. The Long-term Intervention with Pravastatin in Ischemic Disease (LIPID) study ($N = 7498$ men and 1516 women) has investigated the effect of pravastatin on CHD mortality in patients with prior MI or unstable angina and a mean cholesterol level of 219 mg/dL over 6 years.¹⁰¹ Pravastatin reduced the risk of CHD mortality by 24% (8.3% versus 6.4%; $p = .0004$) and total mortality by 23% (14.1% versus 11.0%; $p = .00002$); stroke also was reduced by 20% (4.3% versus 3.5%; $p = .22$), as was the need for coronary artery bypass grafting (11.3% versus 8.9%; $p = .0001$) or percutaneous transluminal coronary angioplasty (5.3% versus 4.4%; $p = .04$).

The Veterans Administration High-Density Lipoprotein Intervention Trial (VA-HIT) was a double-blind trial that compared gemfibrozil (1200 mg/day) with placebo in 2531 men with CHD, an HDL cholesterol level of 40 mg/dL or less, and an LDL cholesterol level of 140 mg/dL or less.¹³ The primary study outcome was nonfatal MI or death from coronary causes. The median follow-up was 5.1 years. At 1 year, the mean HDL cholesterol level was 6% higher, the mean triglyceride level was 31% lower, and the mean total cholesterol level was 4% lower in the gemfibrozil group than in the placebo group. LDL cholesterol levels did not differ significantly between the groups. A primary event occurred in 21.7% of the patients assigned to placebo and in 17.3% of the patients assigned to gemfibrozil. The overall reduction in the risk of an event was 4.4 percentage points, and the reduction in relative risk was 22% ($p = 0.006$). This trial presents the strongest evidence to date that raising HDL cholesterol level and lowering triglyceride level reduce the risk for CHD.

The Heart and Estrogen/Progestin Replacement Study (HERS) was undertaken to determine whether estrogen plus progestin therapy alters the risk for CHD events in postmenopausal women with established CAD.⁸⁶ A total of 2763 women (mean age 66.7 years)

with CAD who were younger than 80 years and postmenopausal with an intact uterus were randomized to receive either 0.625 mg CEEs plus 2.5 mg medroxyprogesterone acetate in 1 tablet daily ($n = 1380$) or a placebo of identical appearance ($n = 1383$). Follow-up averaged 4.1 years. The primary outcome was the occurrence of nonfatal MI or CHD death. There were no significant differences between groups in the primary outcome or in any of the secondary cardiovascular outcomes. More women in the hormone group than in the placebo group experienced venous thromboembolic events and gallbladder disease. Based on the finding of no overall cardiovascular benefit and a pattern of early increase in risk of CHD events, the authors did not recommend starting this treatment for the purpose of secondary prevention of CHD. In this study of secondary intervention of relatively elderly postmenopausal women, there was no evidence of benefit from hormone-replacement therapy (HRT), and only an increase in thromboembolism was seen. If women are on HRT at the time of event, then they should be given a choice to continue. HRT in the Women's Health Initiative did not prevent CHD events with or without hysterectomy, and HRT can no longer be recommended for primary or secondary intervention^{87,88} (see Table 21–15).

The Atorvastatin Versus Revascularization Treatments (AVERT) study compared atorvastatin 80 mg/day with percutaneous transluminal coronary angioplasty.¹⁰² The follow-up period was 18 months. Of the patients who received aggressive lipid-lowering treatment with atorvastatin, 13% had ischemic events compared to 21% of the patients who underwent angioplasty. The incidence of ischemic events thus was 36% lower in the atorvastatin group over an 18-month period ($p = 0.048$, which was not statistically significant after adjustment for interim analyses). This reduction in events was because of a smaller number of angioplasty procedures, coronary artery bypass operations, and hospitalizations for worsening angina (the most common end point). As compared with the patients who were treated with angioplasty and usual care, the patients who received atorvastatin had a significantly longer time to the first ischemic event ($p = 0.03$). In low-risk patients with stable CAD, aggressive lipid-lowering therapy is at least as effective as angioplasty and usual care in reducing the incidence of ischemic events.

In the PROSPER study, in men and women in the age range of 70 to 82 years it was found that pravastatin 40 mg/day reduced CHD events by 24%, with no effect on cognitive function.¹⁰³ The most recent trial, TIMI-22 (also known as PROVE-IT, Pravastatin or Atorvastatin Evaluation and Infection Therapy) enrolled 4162 patients who had been hospitalized for an acute coronary syndrome within the preceding 10 days and compared 40 mg pravastatin daily (standard therapy) with 80 mg atorvastatin daily (intensive therapy).¹⁰⁴ An intensive lipid-lowering statin regimen with atorvastatin 80 mg/day provided greater protection against death or major cardiovascular events than does a standard regimen. This study clearly points to “lower is better” for LDL concentration and likely will lead to a revision in guideline goals to lower LDL levels.

PHARMACOECONOMIC CONSIDERATIONS

The clinical benefits of lipid-lowering therapy for primary and secondary intervention are now well established based on the results of the AFCAPS/TexCAPS, 4S, and other studies showing a reduction in CHD morbidity and mortality. The balance of benefits and costs has been examined in a few studies.^{82,95} The cost per year of life saved has been estimated to range from less than \$10,000 to over \$1 million dollars depending on the presence or absence of CHD, age of the patient, baseline total or LDL cholesterol level and reduction in cholesterol,

and number of risk factors present. In general, intervention in patients with known CHD, those who have CHD risk equivalents, or those with a 10-year risk of 10% to 20% are cost-effective with statin therapy, whereas other types of therapy may be cost-effective if certain assumptions concerning compliance, efficacy, and so forth are met. The range for secondary intervention based on the 4S study is \$3800 for a 70-year-old man with a high cholesterol level to \$27,400 per year of life gained for a middle-aged woman with an average cholesterol level.⁸² In contrast, primary prevention in men based on the West of Scotland trial averages about \$35,000 per year of life gained.⁹⁵ These

studies demonstrate that primary and secondary interventions are well within the accepted boundary of less than \$50,000 for a medical intervention to be considered cost-effective. Based on the specific lipoprotein phenotype, fibric acid derivatives, niacin, or combination therapy of statins plus BAR may be cost-effective. Cost-effectiveness is maximized by treating high-risk patients and those with established CHD.

Specialty lipid clinics have become increasingly popular, and many use pharmacists to provide direct patient care in this setting. An interesting recent analysis shows that a specialty clinic may be more expensive ($\$659 \pm \43 versus $\$477 \pm \42 per patient; $p < .001$) than usual care. However, the overall cost-effectiveness is improved when expressed as program costs per unit (mmol/L) reduction in the LDL cholesterol, a measure of cost-effectiveness that was significantly lower for specialized care ($\$758 \pm \58 versus $\$1058 \pm \70 ; $p = .002$) because more patients achieve their targeted goal.⁹⁵ Project ImPACT demonstrated that pharmacists working collaboratively with patients and physicians can improve persistence and compliance and that nearly two-thirds of patients achieved their NCEP lipid goal.⁹⁶

CLINICAL CONTROVERSIES

The optimal LDL level has been hotly debated for more than 10 years. Based on a few recent trials, the optimal LDL level may need to be redefined below the current goal (<100 mg/dL). An update from ATP III suggests that an LDL of <70 mg/dL is a therapeutic option in very high-risk patients (known CHD + \geq risk factors).¹⁰⁵

Statins differ in their pharmacokinetic properties and in pleiotropic effects (i.e., non-lipid-lowering). The contribution of lipid lowering alone (a class effect) versus other effects (anti-inflammatory, antithrombotic, etc.) continues to create controversy.

The role of nontraditional risk factors (hsCRP, homocysteine, etc.) is continuing to be clarified and may lead to recommendations for the use of these tests in patient evaluation.

EVALUATION OF THERAPEUTIC OUTCOMES

Short-term evaluation of therapy for hyperlipidemia is based on response to diet and drug treatment, as measured in the clinical laboratory by total cholesterol, LDL cholesterol, HDL cholesterol, and triglyceride levels for patients being treated for primary intervention, as well as on response to secondary intervention. The interval for follow-up depends on the severity of illness, and patients with known CAD or multiple risk factors should be monitored more closely. Less commonly used laboratory measurements include C-reactive protein, homocysteine, apolipoprotein B, and Lp(a) levels. Because many patients being treated for primary hyperlipidemia have no symptoms and may not have any clinical manifestations of a genetic lipid disorder such as xanthomas or eruptions, monitoring and outcome are solely laboratory-based. In patients treated for secondary intervention, symptoms of atherosclerotic cardiovascular disease, such as angina or intermittent claudication, may improve over months to years. If patients have xanthomas or other external manifestations of hyperlipidemia, these lesions should regress with therapy. Lipid measurements should be obtained in the fasted state to minimize interference from chylomicrons, and once the patient is stable, monitoring is needed at intervals of 6 months to 1 year. The goals for LDL and HDL cholesterol levels are provided in Tables 21–8 and Tables 21–9.

Patients with multiple risk factors and established CHD also should be monitored and evaluated for progress in managing their

other risk factors such as hypertension, smoking cessation, exercise and weight control, and glycemic control if diabetic. The goals are to maintain a blood pressure of below 130/85 mm Hg or less (presence of diabetes or renal insufficiency), stop smoking, maintain an ideal body weight, exercise for at least 20 minutes three or more times per week, and keep the plasma glucose concentration below 100 mg/dL (threshold for glucose intolerance). Invasive evaluation, such as cardiac catheterization, is useful in patients with established CHD and typically is used for planning revascularization rather than monitoring of lipid-lowering therapy.

Evaluation of dietary therapy is part of the outcome evaluation for treating hyperlipidemia, and the assistance of a dietitian is recommended. Use of diet diaries and recall survey instruments enable information about diet to be collected in a systematic fashion and may improve patient adherence to dietary recommendations. Patients on resin therapy should have an FLP panel checked every 4–8 weeks until a stable dose; triglycerides should be checked at a stable dose to ensure they have not increased. Niacin requires baseline liver function tests and tests for uric acid and glucose; repeat tests are appropriate at doses of 1000 to 1500 mg/day. Symptoms of myopathy or diabetes-like symptoms should be investigated and may require CK or glucose determinations; more frequent monitoring in diabetics may be necessary. An FLP 4 to 8 weeks after the initial dose or dose changes with statins is appropriate. Liver function tests should be obtained at baseline and periodically thereafter based on package insert information; recognized experts believe that monitoring for hepatotoxicity and myopathy should be symptom-triggered.⁴⁵ Ezetimibe requires little specific monitoring.

PERIPHERAL ARTERIAL DISEASE

Barbara J. Hoeben and Robert L. Talbert

Learning Objectives and other resources can be found at www.pharmacotherapyonline.com.

KEY CONCEPTS

- 1 The prevalence of peripheral arterial disease is dependent upon age and the presence of traditional risk factors for cardiovascular disease and many patients are undiagnosed; undiagnosed patients have substantial risk for coronary and cerebrovascular events.
- 2 The clinical presentation of peripheral arterial disease is variable and includes a range of symptoms. The two most common characteristics of peripheral arterial disease are intermittent claudication and pain at rest in the lower extremities.
- 3 The ankle-brachial index (ABI) is a simple, noninvasive, quantitative test that has been proven to be a highly sensitive and specific tool in the diagnosis of peripheral arterial disease.
- 4 As with any atherosclerotic condition, several risk factors play an important role in the morbidity and mortality of peripheral vascular disease. Many of these risk factors are modifiable with the help of various nonpharmacologic and pharmacologic interventions.
- 5 Nonpharmacologic interventions such as smoking cessation and walking exercise programs have the ability to positively impact several of the pathophysiologic abnormalities present in patients with peripheral arterial disease.
- 6 Data proving that antiplatelet therapies can prevent or delay the progression of peripheral arterial disease are currently unavailable. However, aspirin therapy has repeatedly been proven to significantly reduce serious vascular events in these “high-risk” patients and, in the absence of contraindications, is highly recommended.
- 7 After appropriate exercise therapy and therapeutic lifestyle changes have been implemented, patients who continue to experience severe intermittent claudication may benefit from additional pharmacologic therapy with cilostazol.

Peripheral arterial disease (PAD), the most common form of peripheral vascular disease, is a manifestation of progressive narrowing of arteries due to atherosclerosis.¹ PAD is associated with elevated risk of cardiovascular disease (CVD) morbidity and mortality, even in the absence of prior history of acute myocardial infarction (AMI), stroke, or other manifestations of CVD.^{1,2} Patients with PAD have approximately the same relative risk of death from CVD as do patients with a history of coronary or cerebrovascular disease, and PAD should be considered a surrogate marker of subclinical coronary artery disease (CAD) and other vascular territories.^{1,3,4} The treatment of PAD focuses on decreasing the functional impairment caused by symptoms of intermittent claudication through nonpharmacologic and pharmacologic therapy and by minimizing the impact of other cardiovascular risk factors.⁵

EPIDEMIOLOGY

1 The National Health and Nutrition Examination Survey (NHANES) found that the prevalence of PAD among adults age 40 years and older in the United States was 4.3% using the definition of an ankle-brachial index (ABI) of less than 0.9 in either leg.² The prevalence of PAD is highly dependent on age, being infrequent in younger individuals and common in older individuals (Fig. 22-1). In age- and gender-adjusted logistic regression analyses, black race/ethnicity (odds ratio [OR] 2.83) current smoking (OR 4.46), diabetes (OR 2.71), hypertension (OR 1.75), hypercholesterolemia (OR 1.68)

and impaired renal function (estimated glomerular filtration rate less than 60 ml/min/1.73 m²) (OR 2.00) were associated with more prevalent PAD.^{2,6} Individuals with PAD are also more likely to have a self-reported history of any CAD or cardiovascular disease but interestingly, no association with elevated body mass index. The relative risk of death from CVD in patients with PAD is reported to range from 2 to 5.1 in patients with or without CVD and 2.9 to 5.7 in patients with known CVD.⁷ Cardiovascular disease accounts for 75% of all deaths in patients with PAD.⁸ It is important to recognize that the risk of death is approximately the same in men and women and is elevated even in asymptomatic patients. Patients with critical leg ischemia who have the lowest ABI values have an annual mortality of 25%.⁹

More than 5 million (estimated range 4 to 7 million) adults age 40 years or more have PAD and 95% of individuals with PAD have at least one cardiovascular risk factor; the majority of patients have multiple risk factors for CVD.² Based on the PAD Awareness, Risk, and Treatment: New Resources for Survival (PARTNERS) program, the prevalence of PAD in primary care practices is high, yet physician awareness of the PAD diagnosis is relatively low.¹⁰ In this cross-sectional study, PAD was detected in 29% of 6979 patients and 83% of the patients were aware of their diagnosis but only 49% of their patients' physicians were aware. The reason for this observation is that patient self-report of symptoms and the use of questionnaires to detect PAD are not sufficiently sensitive and specific to reproducibly diagnose PAD and the cardinal symptom of PAD, intermittent claudication, is present in the minority of patients (1 to 27%).⁷ A simple ABI measurement will identify a large number of patients with previously

FIGURE 22-1. Prevalence of PAD by age and gender.

unrecognized PAD. Atherosclerosis risk factors were very prevalent in PAD patients, but these patients received less intensive treatment for lipid disorders and hypertension and were prescribed antiplatelet therapy less frequently than were patients with CVD. These results demonstrate that underdiagnosis of PAD in primary care practice may be a barrier to effective secondary prevention of the high ischemic cardiovascular risk associated with PAD.¹⁰ Because of the systemic nature of atherosclerosis and the high risk of ischemic events, patients with PAD should be considered for secondary prevention strategies including aggressive risk-factor modification and antiplatelet drug therapy.^{7,11,13}

ETIOLOGY AND PATHOPHYSIOLOGY

PAD is most commonly a manifestation of systemic atherosclerosis in which the arterial lumen of the lower extremities becomes progressively occluded by atherosclerotic plaque.⁸ The major risk factors for the development of atherosclerosis are older age (greater than 40 years), cigarette smoking, diabetes mellitus, hypercholesterolemia, hypertension and hyperhomocysteinemia.^{7,8} The arteries most commonly involved, in order of occurrence, are the femoropopliteal-tibial, aortoiliac, carotid and vertebral, splenic and renal, and brachiocephalic.¹⁴ Familial hypercholesterolemia (FH) leading to hypercholesterolemia and elevated low-density lipoprotein (LDL) levels is associated with accelerated development of atherosclerosis earlier and with more severe symptoms (e.g., intermittent claudication) and abnormal blood flow studies compared to controls.¹⁵ Intima-media thickness can be used as a surrogate phenotype for cardiovascular risk in FH and carotid and/or femoral artery atherosclerosis results in increased intima-media thickness and it is correlated to cardiovascular risk in FH patients compared with normolipidemic individuals.

CLINICAL PRESENTATION AND DIAGNOSIS

2 The clinical presentation of PAD is variable and includes a range of symptoms from no symptoms at all (typically early

in the disease) to pain and discomfort. The two most common characteristics of PAD are intermittent claudication (IC) and pain at rest in the lower extremities.¹⁶⁻¹⁸ IC is generally regarded as the primary indicator of PAD and has been described as fatigue, discomfort, cramping, pain, or numbness in the affected extremities (typically the buttock, thigh or calf) during exercise and is resolved within a few minutes by resting.^{16,17,19-21} Resting pain typically occurs later in the disease when the blood supply is not adequate to perfuse the extremity (critical limb ischemia). This most often can be felt at night, while the patient is lying in bed, in the feet (typically the toes or heel).¹⁶⁻¹⁸

As with any good medical encounter, a detailed patient history of symptoms and atherosclerosis risk factors (e.g., smoking, hypertension, hyperlipidemia, and diabetes) can be helpful in the diagnosis of PAD. Unfortunately, as illustrated by the PARTNERS program, providers who rely on a history alone will miss approximately 85% to 90% of patients with PAD.¹⁹ Therefore, examination of the patient is vital to proper diagnosis. Requesting that the patient remove socks and shoes may reveal nonspecific signs of decreased blood flow to the extremities (i.e. cool skin temperature, shiny skin, thickened toenails, lack of hair on the calf, feet and/or toes) or, in severe cases, visible sores or ulcers that are slow to heal and may even be black in appearance.^{16-18,22,23}

An important criterion for the accurate diagnosis of PAD is the exclusion of other conditions that possess similar signs and symptoms. A differential diagnosis should rule out other neurologic conditions (e.g., peripheral neuropathy), inflammatory conditions (e.g., arthritis) and vascular conditions (e.g., deep venous thrombosis) which may mimic PAD.^{17,21,24}

3 The ABI is a simple, noninvasive, quantitative test that has been proven to be a highly sensitive and specific ($\geq 90\%$) tool in the diagnosis of PAD.^{19,25-27} To measure the ABI, the patient lies in the supine position as the systolic blood pressure is measured at the brachial arteries on both arms and the dorsalis pedis and posterior tibial arteries of the legs with a standard sphygmomanometer and a continuous-wave Doppler device. The pressures obtained at the dorsalis pedis and posterior tibial arteries are averaged and divided by the mean measurement taken at the left and right brachial arteries.^{7,22,28,29} An ABI of 1 is considered normal while a measurement under 0.9 is consistent with PAD. Further, the range of 0.7 to 0.9 correlates with mild PAD, 0.4 to 0.7 indicates moderate disease, and under 0.4 denotes severe PAD.^{8,20,28} In addition to providing diagnostic information, the ABI measurement has been shown to be a strong predictor of future cardiovascular events associated with PAD.³⁰ The ABI can also be useful after a test of exercise tolerance (e.g., 5 minutes on a treadmill or 30 to 50 repetitions of heel raises). Patients with PAD will have a significant drop in the ABI after exercise while pain with a normal or unchanged ABI can rule out PAD and suggest to the provider that an alternate diagnosis exists.^{8,20,22}

Alternatively, arteriography is an expensive, invasive test that may be used to diagnose PAD. However, as ABI is a sufficient means of diagnosis, arteriography is not necessary or encouraged.^{16,21,26}

► TREATMENT: Peripheral Arterial Disease

■ GOALS OF TREATMENT

Due to the fact the PAD is the result of atherosclerotic plaque formation in the arteries that results in decreased blood flow to the legs,

several of the treatment goals for these patients involve the reduction of confounding variables that attribute to the disease process, progress, and eventual outcome. Specific goals should include increasing maximal walking distance, duration and pain-free walking, improving control of comorbid conditions contributing to the morbidity

of the condition (i.e. hypertension, hyperlipidemia, and diabetes), improvement in overall quality of life and reduction in cardiovascular complications and death.

■ GENERAL APPROACH TO TREATMENT

4 As with any atherosclerotic condition, several risk factors play an important role in the morbidity and mortality of PAD. Thankfully, many of these risk factors are modifiable with the help of various nonpharmacologic and pharmacologic interventions.

■ NONPHARMACOLOGIC THERAPY

■ Smoking Cessation

5 It has been thoroughly documented that cigarette smoking not only increases the risk of developing PAD and other cardiovascular disorders, but that the duration and quantity smoked can negatively impact disease progression (i.e. increase the risk of amputation) and increase mortality.^{7,24,30–35} As a result, providers must advise patients to quit and should offer nonpharmacologic and pharmacologic means to aid the patient in that goal. Individual or group behavior modification therapy with or without the addition of certain antidepressants (i.e., bupropion) or nicotine replacement therapies (i.e., gum or patches) has been proven effective in numerous studies. Reassessment of smoking status and progress encouragement at each encounter can help to reemphasize to the patient the vital importance of this lifestyle change.

■ Exercise

5 Walking exercise programs for patients with PAD have been proven to result in an increase in walking duration and distance, an increase in pain-free walking, and a delayed onset of claudication by 179%.^{23,24,32,33,36–41} Walking, or any aerobic exercise program conducted under the supervision of a healthcare provider, has the ability to positively impact several of the pathophysiologic abnormalities present in patients with PAD. Benefits of exercise programs include improving diabetes and lipid management, reducing weight, improving blood viscosity and flow, and reducing blood pressure.⁵ The type of aerobic activity recommended, as well as the duration and frequency of the activity, should be individually designed on a patient-to-patient basis.

■ Surgical Interventions

Various surgical procedures are available for patients with severe, debilitating claudication who have attempted, and failed, other means of nonpharmacologic and pharmacologic therapy. The TransAtlantic Inter-Society Consensus (TASC) document on peripheral arterial disease is very clear on the recommendations for invasive therapy.²³ First, there must be a lack of adequate response to exercise therapy and risk factor modification. Second, the patient must have severe disability from intermittent claudication resulting in impairment of daily activities. Third, there must be a thorough evaluation of the risks versus benefits of an invasive intervention including probability of success, the anticipated future course of the disease if an intervention is not

performed, as well as an evaluation of concomitant disease states.²³ The decision to attempt percutaneous revascularization is often made with the guidance of diagnostic angiography. Angiography can help to identify the location and size of lesions and provide valuable information as to the likelihood of success with surgical revascularization.²³

Percutaneous transluminal angioplasty (PTA) is an example of an invasive treatment for PAD. A randomized controlled clinical trial performed by Whyman and colleagues determined that in a 2 years' postintervention, the PTA outcomes on maximum walking distance and ABI were not significantly different than in patients that had only received daily low-dose ASA ($p > 0.05$).⁴² Nevertheless, patients who had received PTA had significantly fewer occluded arteries ($p = 0.003$), but the true clinical significance of this finding was not able to be realized in the time allotted for the study.

Stent placement in PAD patients has also been an area of study and controversy. A meta-analysis examining the use of stent placement versus PTA for the treatment of aortoiliac occlusive disease determined that, although stent placement and PTA yielded similar complication and mortality rates, posttreatment ABI were more improved with stents (0.87 with PTA and 0.76 with stents, $p < 0.03$) and the risk of long-term failure was 39% less with stent placement.⁴³ However, other studies have not demonstrated improvement in patency rates in peripheral arteries versus PTA alone.¹⁶ The TASC document provides specific recommendations for PTA, with or without stenting, depending on how diffuse the disease process is, the number and size of the lesions, and the location of the lesions.²³

For patients with severe IC resulting in critical leg ischemia, physicians may need to discuss alternate surgical interventions including aortofemoral bypass, femoralpopliteal bypass, or even amputation.^{16,17,32}

■ PHARMACOLOGIC THERAPY

■ Hypertension

Hypertension (HTN) is a major risk factor for PAD and can lead to AMI, stroke, heart failure (HF), and death.⁴¹ Current guidelines recommend the treatment goal for blood pressure in patients with PAD to mirror those in patients with documented cardiovascular disease (CVD), 130/85 mm Hg.^{31,41} Although, the Heart Outcomes Prevention Evaluation study (HOPE trial), demonstrated that angiotensin-converting-enzyme (ACE) inhibitors reduced not only blood pressure, but other cardiovascular events (e.g., AMI, stroke, and death) in high-risk patients, including those with PAD, no specific class of antihypertensives are recommended over another for the treatment of hypertension in patients with PAD. Therefore, selection of drug therapy for hypertension should be made on the basis of comorbid disease states, drug costs and availability, drug allergies, or other possible limiting factors. For example, patients with documented CAD may receive a dual benefit by the selection of a beta-blocker while calcium-channel-blockers may be desired in a patient with concomitant Raynaud's phenomenon.^{31,41,44} Dosing, monitoring guidelines and contraindications for specific agents may be found in Chapter 13, *Hypertension*.

■ Hyperlipidemia

Although it has been shown that a reduction in lipid levels can reduce the progression of PAD and the severity of claudication, the

current recommendations for the management of hyperlipidemia in PAD are based on only a few small studies and sub-hoc analyses from larger trials.^{7,31,45,46} However, PAD is considered by the Expert Panel on Detection, Evaluation, and Treatment of High Blood Cholesterol in Adults (Adult Treatment Panel III, or ATP III) to be in the category of highest risk, or a coronary heart disease (CHD) risk equivalent. Therefore, it was recommended by the Expert Panel that levels of LDL be maintained at <100 mg/dL and non-high-density lipoprotein (HDL) levels (total cholesterol—HDL cholesterol) at <130 mg/dL.⁴⁵ Clinical trials have been conducted since the time of this recommendation, specifically the Heart Protection Study (HPS)⁴⁷ and the Pravastatin or Atorvastatin Evaluation and Infection—Thrombolysis in Myocardial Infarction (PROVE IT)⁴⁸ trial, that have led many clinical experts to now recommend an LDL goal of <70 mg/dL for additional retardation of atherosclerotic plaque formation in persons considered to be at very high risk, including patients with PAD.¹⁶ Regardless of the goal, LDL chosen, initiation of patient therapeutic lifestyle changes (TLC) (i.e., reduction in saturated fat, weight reduction, and increased physical activity) are vital to achieving these recommendations.^{13,45} Unfortunately, in many cases, TLC alone will not achieve the desired goals.

Several options are available for the initiation of drug therapy for LDL-lowering in patients with PAD. Statins, bile acid sequestrants, and nicotinic acid are all effective treatment options. However, in most cases, statins are the preferred starting agent in this patient population.^{19,32,45,47} As proven in the Heart Protection Study, simvastatin demonstrated potent action in reducing not only LDL, but also provided a significant reduction in cardiovascular events overall as well (e.g., AMI, stroke, and death).⁴⁷ Additionally, if an increase in HDL levels is also necessary, niacin should be considered alone or in combination with a statin without the fear of worsening glucose metabolism, as previously believed.^{7,17,24,44,49} Dosing, monitoring guidelines and contraindications for specific agents may be found in Chapter 21, *Hyperlipidemia*.

■ Diabetes Mellitus

A recent meta-analysis of over 95,000 diabetic patients provided additional support for the accepted premise that glycemic control serves as a risk factor for cardiovascular disease.⁵⁰ The analysis demonstrated an increasing risk of death from cardiovascular events as blood glucose concentrations increased, with the same relationship observed even at levels below the threshold of clinically defined diabetes mellitus. This relationship is just one illustration of the criticality of good glycemic control. Due to the high prevalence of PAD among diabetic patients, the American Diabetes Association recommends ABI screening of all diabetics above 50 years of age for PAD.⁵¹ Due to the presence of peripheral neuropathy, patients with diabetes may be less likely to experience or report symptoms of PAD and the first sign may be as drastic as the appearance of a gangrenous foot ulcer. Therefore, although there is currently a lack of randomized-controlled studies illustrating that the degree of glycemic control is predictive of the extent of PAD present, it is recommended that all patients with concomitant diabetes and PAD maintain good glycemic control, as evidenced by a hemoglobin A-1c level of <7%.^{7,23,24,31,33,51,52} Oral antidiabetic agents, insulin regimens, as well as other pharmacologic and nonpharmacologic strategies to reduce the risk of complications associated with diabetes mellitus are discussed at length in Chapter 72, *Diabetes Mellitus*.

■ ANTIPLATELET DRUG THERAPY (See Table 22–1)

■ Aspirin (ASA)

6 By far, the most compelling evidence for the use of any pharmacologic agent in PAD can be found with ASA. The Antithrombotic Trialists' Collaboration (ATC) conducted a meta-analysis of 195 randomized trials, composed of over 135,000 patients at high risk for occlusive arterial disease, and concluded that low-dose ASA (75 to 160 mg) and medium-dose ASA (160 to 325 mg/day) lead to a significant reduction in serious vascular events (12%) in “high-risk” patients, such as those with PAD.⁵³ It was also noted in this analysis that the risk of major extracranial bleed was similar between the low-dose and medium-dose regimens.

More recently, Tran and Anand conducted a systematic review of the literature in an effort to summarize the best evidence for oral antiplatelet therapy in patients with cerebrovascular disease, CAD, and PAD.⁵⁴ This review included 111 trials (42 of which included patients with PAD, n = 9214) and concluded that patients with PAD should use ASA (160 to 325 mg/day) or clopidogrel (75 mg/day) when ASA is not tolerated or contraindicated.^{54,55} This is in concordance with the recommendations of the Seventh American College of Chest Physicians (ACCP) Conference on Antithrombotic and Thrombolytic Therapy which recommends lifelong ASA (75 to 325 mg/day) over clopidogrel, ticlopidine, and no antithrombotic therapy in patients with PAD.⁵⁶ Unfortunately, no data are currently available from large, clinical, randomized trials that ASA, or any other antiplatelet therapies, can actually prevent or delay the progression of PAD.⁵⁶

■ ASA + Dipyridamole Extended-Release (ER) (Aggrenox)

The ATC also examined the use of dipyridamole ER in combination with ASA in “high risk” patients, such as those with PAD. Their meta-analysis of 25 trials (over 10,000 patients) concluded that the addition of dipyridamole to aspirin led to an additional reduction in serious vascular events over ASA alone (6%), however, this reduction was unable to reach statistical significance ($p = 0.32$).^{53,54} It should also be taken into consideration that most of the reduction in nonfatal stroke in this analysis came from one trial, and these data are not replicated in the other studies.^{53,55,57} The addition of dipyridamole to ASA may cause an increased risk of bleeding and gastrointestinal side effects when compared to placebo and should not be used with CAD.⁵⁷

■ Clopidogrel (Plavix)

The ATC meta-analysis also reviewed the effectiveness of clopidogrel 75 mg/day in “high risk” patients, including those with PAD. The Collaboration concluded that although clopidogrel was able to reduce serious vascular events by 10%, this was significantly less than the reduction seen with ASA (12%, $p = 0.03$), as described previously.⁵³ Included in this meta-analysis was the report from the Clopidogrel versus ASA in Patients at Risk of Ischemic Events (CAPRIE) trial which had concluded that clopidogrel (75 mg daily) was more effective than ASA (325 mg daily) in preventing vascular events in “high risk” patients. In comparison to the ASA therapy, the clopidogrel regimen resulted in an overall reduction in ischemic stroke, MI or vascular death from 5.83% to 5.32% ($p = 0.043$). This difference was even more pronounced in the subgroup analysis of PAD patients (clopidogrel therapy led to a significant reduction of 4.86% versus 3.71% in the ASA group, $p = 0.0028$).^{4,25,30} It must be noted that clopidogrel

TABLE 22–1. Pharmacotherapy Options for Patients with PAD^{4,18,24,25,53,55,56,67–72}

| Agent | Daily Dose (oral) | Mechanism of Action (MOA) | Side Effects | Contraindications | Level of Evidence [†] |
|----------------------------|--------------------------|---|---|--|--|
| Aspirin | 81–325 mg | Irreversibly inhibits prostaglandin cyclooxygenase in platelets, prevents formation of thromboxane A ₂ | Gastrointestinal upset and/or bleeding | Active bleeding; hemophilia; thrombocytopenia | With coronary or cerebrovascular (Grade 1A), without (Grade 1C+) |
| Dipyridamole ER (Aggrenox) | 400 mg (+ aspirin 50 mg) | May act by inhibiting platelet aggregation (complete MOA unknown) | Angina; dyspnea; hypotension; headache; dizziness | Active bleeding; CAD (“coronary steal syndrome”) | Recommendation for use not specified in report |
| Cilostazol (Pletal)* | 100 mg BID | Phosphodiesterase inhibitor, suppresses platelet aggregation; direct artery vasodilator | Fever; infection; tachycardia | All CHF patients (decreased survival) | With IC (Grade 2A) |
| Clopidogrel (Plavix) | 75 mg | Inhibits binding of ADP analogues to its platelet receptor causing irreversible inhibition of platelets | Chest pain; purpura generalized pain; rash | Active pathological bleeding (i.e., peptic ulcer, intracranial hemorrhage) | Recommend clopidogrel over no antiplatelet therapy (Grade 1C+) |
| Pentoxifylline (Trental) | 1.2 g | Alters RBC flexibility; decreases platelet adhesion; reduces blood viscosity; decreases fibrinogen concentration | Dyspnea; nausea; vomiting; headache; dizziness | Recent retinal or cerebral hemorrhage; active bleeding | Not recommended in patients with IC (Grade 1B) |
| Ticlopidine (Ticlid) | 500 mg | Inhibits binding of ADP analogues to its platelet receptor causing irreversible inhibition of platelets | Leukopenia; rash; thrombocytopenia; neutropenia; agranulocytosis; aplastic anemia | Active bleeding; hemophilia; thrombocytopenia | Clopidogrel recommended over ticlopidine (Grade 1C+) |

Abbreviations: ER, extended-release; mg, milligrams; g, grams; BID, twice-daily; ADP, adenosine 5'-diphosphate; RBC, red blood cell; CAD, coronary artery disease; CHF, congestive heart failure; IC, intermittent claudication.

*Cilostazol should be used in combination with antiplatelet therapy.

[†]Grades of recommendation for antithrombotic and thrombolytic therapy is part of the Seventh ACCP Conference on Antithrombotic and Thrombolytic Therapy.⁷³

is significantly more expensive than ASA therapy, not only in drug costs, but clopidogrel remains a by-prescription-only medication and, thus, requires a physician visit to obtain a prescription for the medication. It is for all these reasons that the current recommendations list clopidogrel as a first-line agent, but only in cases where ASA therapy is either not tolerated or contraindicated.^{53,55}

■ Ticlopidine (Ticlid)

Although ticlopidine has the same mechanism of action as clopidogrel and possesses a similar molecular structure, the results of clinical trials among the two agents are strikingly different.¹⁸ The Swedish Ticlopidine Multicenter Study (STIMS) had determined that ticlopidine therapy (500 mg/day) was able to reduce total mortality in comparison to placebo in patients with intermittent claudication ($p = 0.015$).^{18,58,59} Regardless, the once promising results seen with ticlopidine therapy have now been overshadowed by the severe hematologic side effects unique to this agent. Other agents, namely clopidogrel, are now used in its stead.^{7,24,33}

■ INTERMITTENT CLAUDICATION (See Table 22–1)

■ Cilostazol (Pletal)

7 In a head-to-head, randomized, placebo-controlled study in 698 patients with moderate-to-severe claudication, Dawson and

colleagues assigned patients to cilostazol (100 mg twice a day), pentoxifylline (400 mg 3 times a day), or placebo in an effort to improve maximal walking distance.⁶⁰ After 24 weeks, the cilostazol group demonstrated a 54% mean increase in distance versus pentoxifylline which demonstrated only a 30% mean increase ($p < 0.001$).⁶⁰ Similarly, a meta-analysis of 8 randomized, double-blind, placebo-controlled, parallel-design trials supported this conclusion with a reported increase in maximal walking distance and pain-free walking distance over placebo with cilostazol at doses of 50 mg and 100 mg twice-daily ($p < 0.05$ for all).⁶¹ Regrettably, improvement in walking distance has appeared to come with a price (in addition to the high drug cost); cilostazol has a “black box” warning from the Food and Drug Administration (FDA) warning providers not to use this medication in patients with PAD and coexisting heart failure.³¹ If patients with PAD are not candidates for surgical interventions to improve severe intermittent claudication, and after appropriate exercise therapy and therapeutic lifestyle changes have been implemented, the Seventh ACCP Conference on Antithrombotic and Thrombolytic Therapy then suggests the use of this agent.⁵⁶

■ Pentoxifylline (Trental)

Unlike cilostazol, pentoxifylline has produced less promising results in clinical trials. An illustration of this is the randomized, placebo-controlled trial by Dawson and colleagues mentioned above.⁶⁰ Not only did cilostazol outperform pentoxifylline in improvement in

walking distance, the improvement seen with pentoxifylline was no different from placebo ($p = 0.82$).⁶⁰ This nonsignificant improvement in walking distance has been observed in other studies as well.^{7,62} Meanwhile, other meta-analyses of pentoxifylline in comparison to placebo for the improvement of maximal walking distance, have shown some minimal improvement over placebo, but the average effects were relatively small.^{7,63–66} For these reasons, the Seventh ACCP Conference on Antithrombotic and Thrombolytic Therapy does not recommend the use of this agent.⁵⁶

EVALUATION OF THERAPEUTIC OUTCOMES

It is vital that the patient be counseled on the evaluation measures that will be used to monitor the outcomes of therapeutic interventions for

PAD. Various laboratory measurements will assess patient progress in glycemic control (i.e., hemoglobin A1C) and lipid management (i.e., total cholesterol, LDL, HDL, and non-HDL cholesterol), while blood pressure checks in the clinic and patient home blood pressure monitoring can assess the effectiveness of antihypertensive therapy. Repeat exercise treadmill walking testing should be repeated at regular intervals (i.e., quarterly to biannually) to assess improvement or decline in walking duration and distance, as well as the time to pain onset while performing this activity. Repeat ABI measurements should be assessed at each patient visit to determine if there has been stabilization or progression of the disease process. Most importantly to many patients, simple concern and questioning about improvements to their daily quality of life will highlight your concern for their well-being and aid in an overall picture of the patient's general state of health.

USE OF VASOPRESSORS AND INOTROPES IN THE PHARMACOTHERAPY OF SHOCK

Maria I. Rudis and Joseph F. Dasta

Learning Objectives and other resources can be found at www.pharmacotherapyonline.com.

KEY CONCEPTS

- 1 Continuous hemodynamic monitoring either with an arterial catheter or with a pulmonary artery (or central venous) catheter with central venous oxygen saturation measurement should be used early and throughout the course of septic shock to assess intravascular fluid status and ventricular filling pressures, determine cardiac output, and monitor arterial and venous oxygenation. They also should be used for monitoring the response to drug therapy and guide dosage titration.
- 2 Early goal-directed therapy with aggressive fluid resuscitation in the emergency department within the first 6 hours of presentation improves survival in sepsis and septic shock.
- 3 Derangements in adrenergic receptor sensitivity or activity frequently result in resistance to vasopressor and inotropic therapy in critically ill patients. These changes may be a function of endogenous catecholamine concentrations, dose/duration of exposure to and type of exogenously administered vasopressors, stage of septic shock, preexisting illness, and other factors.
- 4 In refractory septic shock, the rational use of vasopressor or inotropic agents should be guided by receptor activity, pharmacologic characteristics, and regional and systemic hemodynamic effects of the drug and should be tailored to the patient's physiologic needs. Pharmacologically sound combinations of agents should be initiated early to optimize response.
- 5 Goals of therapy with vasopressors and inotropes should be predetermined and should optimize regional perfusion to tissues (e.g., cardiac, renal, mesenteric, and periphery). This can be accomplished by continuous or intermittent measurements. Central venous oxygen saturation (SvCO₂) should be maintained in excess of 70%. Arbitrarily targeting vasopressor and inotrope therapy to supranormal global oxygen transport variables cannot be recommended because there is no clear benefit, and morbidity may be increased.
- 6 Much higher dosages of all vasopressors and inotropes than recommended traditionally are required to improve the hemodynamic and oxygen transport variables in septic shock.
- 7 Dose titration and monitoring of vasopressor and inotropic therapy should be guided by the "best clinical response" while observing for and minimizing evidence of myocardial ischemia (e.g., tachydysrhythmias, electrocardiographic changes), renal (decreased glomerular filtration rate and/or urine output), splanchnic/gastric (low pHi, bowel ischemia), or peripheral (cold extremities) hypoperfusion, and worsening of PaO₂, pulmonary artery opening pressure (PAOP), and other hemodynamic variables.
- 8 Dopamine typically is used as an initial vasopressor agent for hemodynamic support but is limited by its ability to increase cardiac output (by only 35%). Its use is frequently complicated by tachycardia and tachydysrhythmias and occasionally by an increase in PAOP. In contrast to norepinephrine, it decreases splanchnic oxygen use. Low-dose dopamine should not be used to prevent renal failure.
- 9 Phenylephrine may be a particularly useful alternative in those who cannot tolerate tachycardia or tachydysrhythmia with dopamine or norepinephrine or in patients with known underlying myocardial dysfunction.
- 10 Epinephrine appears to be effective as a single agent and as an add-on agent. It is particularly useful in the young, in patients with otherwise healthy myocardia, and potentially when used early in the course of treatment. However, because it causes a significant increase in lactate and worsening of splanchnic oxygen utilization, it is not the agent of first choice in septic shock. It also should be used cautiously in patients with a history of coronary artery disease (CAD) or underlying cardiac disturbances.
- 11 Therapy with vasopressors and inotropes is continued until the myocardial depression and vascular hyporesponsiveness of septic shock improve, usually measured in hours to days. Discontinuation of vasopressor or inotropic therapy should be executed slowly; therapy should be "weaned" to avoid a precipitous worsening in regional and systemic hemodynamics.

TABLE 23–1. Hemodynamic and Oxygen-Transport Monitoring Parameters

| Parameter | Normal Value |
|--|---|
| Blood pressure (systolic/diastolic) | 100–130/70–85 mm Hg |
| Mean arterial pressure (MAP) | 80–100 mm Hg |
| Pulmonary artery pressure (PAP) | 25/10 mm Hg |
| Mean pulmonary artery pressure (MPAP) | 12–15 mm Hg |
| Central venous pressure (CVP) | 8–12 mm Hg |
| Pulmonary artery occlusion pressure (PAOP) | 12–15 mm Hg* |
| Heart rate (HR) | 60–80 beats/min |
| Cardiac output (CO) | 4–7 L/min |
| Cardiac index (CI) | 2.8–3.6 L/min/m ² |
| Stroke volume index (SVI) | 30–50 mL/m ² |
| Systemic vascular resistance index (SVRI) | 1300–2100 dyne · s/m ² · cm ⁵ |
| Pulmonary vascular resistance index (PVRI) | 45–225 dyne · s/m ² · cm ⁵ |
| Arterial oxygen saturation (SaO ₂) | 97% (range 95–100) |
| Mixed venous oxygen saturation (SvO ₂) | 70–75% |
| Arterial oxygen content (CaO ₂) | 20.1 vol% (range 19–21) |
| Venous oxygen content (CvO ₂) | 15.5 vol% (range 11.5–16.5) |
| Oxygen content difference (C[a-v]O ₂) | 5 vol% (range 4–6) |
| Oxygen consumption index (VO ₂) | 131 mL/min/m ² (range 100–180) |
| Oxygen delivery index (DO ₂) | 578 mL/min/m ² (range 370–730) |
| Oxygen extraction ratio (O ₂ ER) | 25% (range 22–30) |
| Mucosal pH (pHi) | 7.40 (range 7.35–7.45) |
| Index (I) | Parameter indexed to body surface area |

*These normal values may not necessarily be the same as optimal values needed to optimize the management of a critically ill patient.

Shock is an acute, generalized state of inadequate perfusion of critical organs that can produce serious pathophysiologic consequences, including death. Thirty years ago, mortality from septic or cardiogenic shock exceeded 70%.¹ Currently, approximately 10% of patients are admitted to hospitals with severe sepsis or experience cardiogenic shock following a myocardial infarction, with mortality rates of at least 30% to 50% despite enhanced treatment modalities and sophisticated monitoring techniques.^{1,2} This chapter will review the theory and current status of hemodynamic monitoring and will present an update on the optimal use of inotropes and vasopressor drugs in shock states.^{3,4}

Hemodynamic and perfusion monitoring can be categorized into two broad areas: global and regional monitoring. Global parameters, such as systemic blood pressure and pulse oximetry, assess perfusion and oxygen utilization of the entire body. Regional monitoring techniques, such as tonometry, focus on flow and subsequent changes in metabolism of individual organs and tissues. Normal values for commonly monitored parameters are listed in Table 23–1.

GLOBAL PERFUSION MONITORING

ARTERIAL BLOOD PRESSURE MEASUREMENT

Arterial blood pressure is the product of cardiac output and systemic vascular resistance. Conditions that may lower blood pressure in the critically ill include cardiac failure or hypovolemia (by lowering of cardiac output) and vasodilation (by sepsis, drugs, or neurotrauma).

Arterial blood pressure can be determined by noninvasive and invasive methods. All noninvasive blood pressure monitoring techniques depend on the use of an occluding cuff. Systolic and diastolic blood pressures are further determined by auscultation, palpation (systolic pressure only), oscillometry, or Doppler technique (systolic pressures most reliable). Auscultation is the most commonly used method outside the intensive care unit (ICU). Its use, however, is limited in patients with hypovolemia, hypothermia, or cardiogenic shock when pulses or Korotkoff sounds may be difficult to hear. Similar constraints exist for the palpation and oscillometric methods. However, oscillometry is preferred in edematous patients. Oscillometry measures blood pressure by sensing arterial blood pressure changes, or oscillations, against an inflated cuff. Rapid changes in oscillation amplitude correspond to systolic and diastolic pressure. It is the only noninvasive method to measure mean arterial pressure even in low-flow states and lends itself to automatic cycling and serial measurements (every 1 to 3 minutes) that do not require operator intervention, a key component in ICU monitoring. The use of narrow cuffs or cuffs applied too loosely can result in falsely high readings, whereas wide cuffs may produce falsely low readings.⁵ Fingertip devices offer another avenue for continuous indirect blood pressure measurement, but their accuracy in ICU patients may be significantly diminished by concurrent administration of vasoactive drugs.

The use of invasive arterial catheters makes it possible to measure arterial blood pressures continuously, as well as to obtain blood samples for blood gas monitoring. The radial artery is the most commonly used vessel, but the dorsalis pedis, femoral, brachial, and axillary arteries and the umbilical artery in the newborn also can be accessed. This method of blood pressure monitoring is a standard technique against which all other methods are compared. Major complications of peripheral artery catheterization include infection and distal ischemia. Acute distal ischemia and catheter-related bacteremia occur in less than 1% of catheter insertions. This translates into 2.9% of bloodstream infections per 1000 catheter-days.⁶ Ischemia is most common in patients with multiple or prolonged arterial cannulations, hypertension, or vasopressor therapy.⁵ Invasive techniques are labor-intensive, require aseptic techniques, and offer potential sources of equipment errors, such as length and quality of tubing, air bubbles, stopcocks, thrombus formation, tube kinking, and placement of transducer. Hypertension, advanced age, and atherosclerosis also may affect the accuracy of invasive blood pressure readings.⁷

CENTRAL VENOUS CATHETER

The central venous catheter is used to measure the central venous pressure (CVP), to obtain venous blood gas samples, and to administer drugs or fluids directly to the central circulation. A triple-lumen catheter frequently is used, whereby drugs with known incompatibility can be administered. Blood volume, venous wall compliance, right-sided cardiac function, intraabdominal and intrathoracic pressure, and vasopressor therapy affect CVP. The CVP is not a reliable estimate of blood volume but can be used to qualitatively assess blood volume changes in patients during the early phases of fluid resuscitation. Sustained elevated pressures may indicate fluid overloading. There are few data supporting the use of CVP monitoring in the ICU. However, initial reports in septic patients suggest that CVP monitoring of fluid therapy during shock was associated with an over 50% reduction in mortality.

PULMONARY ARTERY CATHETER

▶ Pulmonary artery catheterization, introduced in 1970, is a routinely performed bedside procedure in many ICUs. With this

catheter, also known as the *Swan-Ganz catheter*, the practitioner can obtain multiple cardiovascular parameters, including central venous, pulmonary artery, and pulmonary artery occlusive pressures and cardiac output. Mixed-venous blood samples from the pulmonary artery also may be obtained. In an effort to reduce blood loss from samples, many clinicians are using special pulmonary artery catheters, called a *fiberoptic catheter*, that measure mixed-venous oxygen saturation (SvO_2). Hence trends in the venous oxygen saturation can be observed, and necessary action can be taken, if needed. Most important, inflation of the balloon at the catheter tip occludes the pulmonary artery, isolates the distal catheter tip from the right side of the heart, and allows the user to measure the pulmonary capillary “occlusive” pressure (PAOP), an approximate measure of the left ventricular (LV) end-diastolic volume and a major determinant of LV preload. Ideally, the pulmonary artery catheter should be positioned fluoroscopically; however, satisfactory placement also may be obtained by observing pulmonary artery pressure readings during catheter advancement. Proper positioning in the lower lung (zone 3) is essential to measure PAOP and to prevent distal pulmonary artery collapse. Poor wedging may be caused by catheter migration, patient movement, mechanical ventilation, or eccentric balloon inflation. Pulmonary artery catheters equipped with a distal thermistor also allow measurement of cardiac output by thermodilution. Rapid injection of saline solutions via the right atrial port allows complete mixing of blood with injectate, and the resulting change in blood temperature is measured in the pulmonary artery. From the temperature change, the patient’s cardiac output can be calculated. Newer pulmonary artery catheters contain a temperature coil that intermittently warms the blood in the right ventricle for near-continuous cardiac output measurement. Significant tricuspid regurgitation, an intracardiac shunt, and significant positive end-expiratory pressure (PEEP) decrease the validity of cardiac output measurements. The most common complications of pulmonary artery catheterization include mural thrombus formation (14% to 91%), transient ventricular tachyarrhythmias (11% to 63%), pulmonary infarction (1% to 7%), pulmonary artery rupture (0.06% to 2.0%), and sepsis (0.3% to 0.5%).⁸ Most pulmonary artery catheters are heparin-bonded, and the relative risk of infection is 2.6 per 1000 patient days, similar to central venous catheters, 2.3 per 1000 patient days.⁶ Despite its ubiquitous use, much controversy surrounds the utility and safety of the pulmonary artery catheter, including issues surrounding correct placement and impact of the device on patient outcome.⁹ As a result, recommendations have been made to standardize and monitor physician and nurse education on proper use of the catheter (see www.pacep.org), to conduct clinical trials assessing the safety and efficacy of the catheter, and to evaluate new device technology on patient outcome.⁸ The most recent guidelines suggest a careful evaluation of the indications and the risk of placing a pulmonary artery catheter for the resuscitation of critically ill patients.¹⁰

▶ The optimal PAOP needs to be individualized for each patient. Administering a fluid bolus followed by simultaneous PAOP and cardiac output (CO) measurements with the goal of increasing the PAOP until the CO does not change can be accomplished and is based on Starling’s law of the heart. However, clinical experience suggests that most patients have an optimal response to PAOP values in the range of 12 to 15 mm Hg.

OXYGEN TENSION AND SATURATION MONITORING

Arterial oxygen pressure (PaO_2) and saturation (SaO_2) may be measured invasively by obtaining an arterial blood sample. Arterial blood gases measured by conventional arterial sampling are considered

standard, but their accuracy and usefulness are affected by poor sampling techniques, transportation and analysis delays, analyzer accuracy, sample cellular metabolism, and inability to trend results. Indwelling fiberoptic and electrochemical systems allow continuous monitoring and trend analyses of blood pH, PaO_2 , and $PaCO_2$ while decreasing patient blood loss owing to frequent sampling. Unfortunately, studies evaluating the in vitro accuracy of these devices may not apply to the ICU environment. The indwelling sensors may exhibit lower PaO_2 , higher $PaCO_2$, and lower pH than central arterial blood when peripheral flow is diminished. Furthermore, sensor contact with blood vessel wall and vigorous arterial line flushing also will diminish sensor accuracy.

▶ Mixed venous oxygen saturation (SvO_2) depends on cardiac output, oxygen demand, hemoglobin, and arterial oxygen saturation. It may be measured in patients with a pulmonary artery catheter. Initially, critically ill septic patients may present with a low SvO_2 value (<70%) indicating a high extraction of oxygen by tissues and a lack of adequate oxygen delivery to tissues. In patients with sepsis and other conditions who present with a low SvO_2 value, prompt, rapid intervention should be undertaken to increase oxygen delivery to tissues with a goal of an SvO_2 of greater than 70% to 75%.¹¹ As sepsis progresses, however, SvO_2 values may exceed 70% to 75%. This occurs because of a maldistribution of blood flow and a lack of extraction of oxygen in the arteriolar beds.

▶ Central venous oxygen saturation ($ScvO_2$) is a less invasive measure of venous oxygen saturation because the catheter is placed at the junction of the inferior and superior venae cavae and only requires a central line rather than a pulmonary artery catheter. It is as accurate as SvO_2 . Concentrations of $ScvO_2$ of less than 70% reliably indicate inadequate oxygenation in shock states and detect subclinical (“cryptic”) shock much earlier than hypotension.¹² Targeting fluid and hemodynamic resuscitation to achieve $ScvO_2$ concentrations of greater than 70% to 75% may be a more sensitive indicator of the extent of global tissue hypoxia, as well as a more sensitive measure of the adequacy of hemodynamic resuscitation than vital signs, including systolic, diastolic, and mean arterial blood pressures.¹³ Targeting resuscitation to achieve $ScvO_2$ concentrations of greater than 70% to 75% is associated with improved survival in patients with sepsis and septic shock.¹²

OXYGEN DELIVERY AND CONSUMPTION

The concept of tissue oxygen debt as a determinant of organ damage in critical illness was proposed over 10 years ago. In normal individuals, oxygen consumption (VO_2 or VO_2I , indexed to body surface area) depends on oxygen delivery (DO_2 or DO_2I , indexed to body surface area) up to a certain critical level (VO_2 flow dependency). At this point, tissue oxygen requirements apparently have been satisfied, and further increases in DO_2 will not alter VO_2 (VO_2 flow independency) (Fig. 23–1). Although animal models of sepsis have substantiated this relationship, studies in critically ill humans show a continuous,

FIGURE 23–1. Relationship between oxygen consumption (VO_2) and oxygen delivery (DO_2).

pathologic dependence relationship of VO_2 on DO_2 . Furthermore, ICU survivors exhibited higher DO_2 and VO_2 values than nonsurvivors. This became the basis for targeting supranormal DO_2 and VO_2 values in the treatment of ICU patients.¹⁴ However, a recent meta-analysis of randomized clinical trials involving 1016 adult ICU patients failed to show that achievement of this goal improved patient mortality.¹⁵ This may have been due in part to the heterogeneous nature of the ICU patients studied, lack of study blinding, crossover patients (control patients who achieve supranormal DO_2 and VO_2 values by themselves), or lack of adequate control of cointerventions.

The debate continues in more homogeneous patient populations. In high-risk surgical patients, supranormal DO_2 values decreased mortality. Two recent randomized studies further evaluated the effect of increasing DO_2 I values to above 600 mL/m² per minute in a homogeneous population of elderly surgical patients with systemic inflammatory response syndrome (SIRS), sepsis, severe sepsis, or septic shock with conflicting results. Yu and colleagues¹⁶ demonstrated that the intervention group had a significant increase in survival at 24 hours (21% versus 52%; $p = .01$) compared with the control group in patients between 50 and 75 years of age. This benefit was not seen in those older than 75 years of age. The authors suggested that the combination of increasing DO_2 and maintaining the oxygen extraction ratio (O_2ER) below 25% without a changing VO_2 may be helpful in maintaining or improving the reserve of the body to meet the oxygen demands. This may be true particularly in older patients who have a lower baseline VO_2 . In the second study, the same intervention revealed a significant reduction in 60-day survival in high-risk elderly surgical patients randomized to have their DO_2 increased to the preceding levels.¹⁷ Thus it remains unclear that the mechanism of benefit of supranormal DO_2 in these patients is prevention and reversal of tissue hypoxia. A recent review of alternative potential mechanisms of beneficial effect of supranormal DO_2 suggests that catecholamines exert anti-inflammatory actions by modulating cytokine response.¹⁸ In general, catecholamines inhibit the inflammatory cytokine (e.g., tumor necrosis factor α [TNF- α]) production and may enhance anti-inflammatory cytokine (e.g., interleukin-6 and interleukin-10) production.¹⁸ The actions of epinephrine on these cytokines are blocked by propranolol and thus are mediated by adrenergic β -receptors. These data must be interpreted with caution because most studies have used animal or cell models of sepsis, have pretreated patients with vasopressors prior to endotoxin infusion, and have used doses that may not always be clinically relevant. A further problem with goal-directed therapy to supranormal oxygen transport values is the fact that the apparent linear relationship between DO_2 and VO_2 has been questioned because both share variables and that this so-called mathematical coupling can produce artifactual relationships between variables. The DO_2 and VO_2 indexed parameters are calculated as follows:

$$\text{DO}_2 = \text{CI} \times \text{CaO}_2$$

$$\text{VO}_2 = \text{CI} \times (\text{CaO}_2 - \text{CvO}_2)$$

where CI is the cardiac index, CaO_2 is the arterial oxygen content, and CvO_2 is the mixed venous oxygen content.

However, variable relationships between DO_2 and VO_2 have been observed when VO_2 was measured independently by indirect calorimetry. A linear relationship between DO_2 and VO_2 therefore may be the result of mathematical coupling or flow-dependent VO_2 . Currently available data do not support the concept that patient outcome or survival may be altered by treatment measures directed toward achieving supranormal DO_2 and VO_2 values.¹⁵ In fact, a recent consensus conference concluded that although pulmonary artery catheterization is useful to guide therapy, routinely increasing cardiac index to

predetermined supranormal values does not improve outcome.³ Furthermore, achievement of a supranormal DO_2 does not ensure parallel improvements in regional organ blood flow and oxygenation.¹⁹ The VO_2/DO_2 ratio (oxygen extraction ratio, or O_2ER) can be used to assess adequacy of perfusion and metabolic response. Patients who are able to increase VO_2 when DO_2 is increased show improved survival. However, low VO_2 and O_2ER values are indicative of poor oxygen utilization and lead to greater mortality.¹⁵ Another approach that may decrease the effect of mathematical coupling and provide individualized therapy may lie in titrated therapy, with sequential measurements of DO_2 and VO_2 to achieve VO_2 flow independency along with normalization of blood lactate and hemodynamic parameters.

2 The most recent data regarding goal-directed therapy in the hemodynamic support of sepsis relates to the importance of achieving predetermined parameters early in the management of sepsis. In a meta-analysis of early (defined as 8 to 12 hours postoperatively or before the development of organ failure) versus late (defined as after the onset of organ failure) resuscitative efforts in patients stratified according to severity of illness [determined by the control group mortality as greater than 20% (12 studies) or less than 15% (9 studies)] and targeting to supranormal oxygen transport variables, the data suggest that timing of resuscitation matters.²⁰ Early goal-directed therapy reduces both mortality and the development of organ failure in studies in which patients were more severely ill and when therapeutic interventions produced differences in oxygen delivery. Moreover, outcome was not improved significantly in less severely ill patients (control mortalities group less than 15% and normal oxygen delivery values as goals) or when therapy did not improve oxygen delivery.²⁰

2 In a recent prospective, randomized, controlled sepsis trial, Rivers and colleagues¹² demonstrated a significant improvement in survival (30.5% versus 46.5%; $p < .001$) in patients with severe sepsis and septic shock randomized to receive therapy based on goal-directed hemodynamic end points for at least 6 hours in the emergency department. They used a strategy of administering fluids rapidly to achieve a central venous pressure of 8 to 12 mm Hg, maintain a hematocrit above 30%, and use of dobutamine to achieve an ScvO_2 of greater than 70%. This approach demonstrates the benefits of initiating therapy early in the course of sepsis and directs therapy toward clearly defined goals in a consistent manner.

BLOOD LACTATE

Lactate is a metabolic product of pyruvate, and its production is increased under anaerobic conditions, such as may occur during shock. Blood lactate concentrations are used as a diagnostic and prognostic tool in sepsis; they are also used to measure the repayment of oxygen debt to tissues.¹¹ It is a useful tool to be used together with DO_2 and VO_2 because these measures change independently of one another.¹⁴ Serial lactate concentrations may show better correlation with outcome than oxygen transport parameters and may be superior to hemodynamic markers in determining adequacy of restoration of systemic oxygenation.¹¹ However, there are several caveats to guide the use of lactate concentrations in septic patients. First, lactate may accumulate in patients with other conditions, such as significant liver dysfunction or acute respiratory distress syndrome, who are not in shock. Second, both well-perfused and poorly perfused tissues contribute to arterial and mixed venous lactate concentrations and therefore are not reflective of regional perfusion. Third, although increased lactate concentrations have been correlated with increased mortality, the utility of blood lactate measurements in guiding therapy

has not been demonstrated clearly. Serial blood lactate measurements are more useful than single isolated measurements.

REGIONAL PERFUSION MONITORING

GASTROINTESTINAL TONOMETRY

Blood pressures, cardiac output, blood lactate, and global oxygen homeostasis parameters do not offer information as to individual organ function. The measurement of regional perfusion to detect inadequate tissue oxygenation has focused on the splanchnic circulation because it is sensitive to changes in blood flow and oxygenation for several reasons. First, the normally large majority of blood flow to the gut mucosa is redistributed toward the serosa and muscularis. Second, the gut may have a higher critical DO_2 threshold than other organs. Third, the tip of the villus has a countercurrent oxygen-exchange mechanism, rendering it very sensitive to reduction in regional blood flow and oxygenation.¹¹ Gastric tonometry measures gut luminal PCO_2 at equilibrium by placing a saline- or air-filled gas-permeable balloon in the gastric lumen. Assuming that CO_2 permeates freely among tissues and that the arterial bicarbonate (HCO_3^-) concentration is equal to that of the gut mucosa, the intramucosal pH (pHi) may be calculated using the Henderson-Hasselbalch equation:

$$\text{pHi} = 6.1 \log (\text{HCO}_3^-) 0.03 \times \text{PCO}_2$$

Increases in mucosal PCO_2 and calculated decreases in pHi are associated with mucosal hypoperfusion and perhaps increased mortality.²¹ The calculation of pHi can be confounded by increases in luminal PCO_2 , such as may occur when buffering antacids are used. Histamine-2-receptor antagonists or proton pump inhibitors may be used instead. The presence of respiratory acid-base disorders, systemic bicarbonate administration, arterial blood gas measurement errors, enteral feeding solutions, blood, or stool in the gut may confound pHi determinations.²² Gastric tonometry may be performed using either a saline- or air-filled balloon. The time delay (30 minutes) associated with equilibration of saline inside the balloon makes this method inconvenient for routine bedside monitoring. An air-filled balloon requires a shorter equilibrium time, is simpler to use, and is equally accurate.²³

The clinical utility of gastric tonometry, however, remains uncertain. Clinical trials of pHi-directed therapy have not been able to show consistently that it reduces mortality in critically ill patients.²¹ However, patients with a normal pHi (>7.35) on ICU admission who subsequently received pHi-guided treatment to increase DO_2 experienced a 38% reduction in mortality. The incidence of multiple organ failure and mortality were not statistically different between the groups, although this may have been due to a small sample size. Many clinicians believe that gastric mucosal PCO_2 may be more accurate than pHi. Furthermore, because mucosal PCO_2 is influenced by arterial PCO_2 , consensus is that the mucosal-arterial PCO_2 difference (PCO_2 gap) is likely the optimal measurement.²¹

Recent evidence suggests that the most proximal part of the gastrointestinal (GI) tract, the sublingual mucosa, may be an acceptable location to monitor regional perfusion and PCO_2 . One device recently has gained Food and Drug Administration (FDA) approval and consists of a catheter placed sublingually for the determination of sublingual PCO_2 (Psl CO_2). A small study of 22 critically ill patients with and without sepsis and septic shock attempted to validate the usefulness of sublingual capnography. They measured simultaneous gastric and sublingual PCO_2 , along with traditional hemodynamic parameters. The sublingual PCO_2 correlated well with mucosal PCO_2 ; however,

the initial sublingual-to-arterial PCO_2 gap was a better predictor of mortality than mucosal-to-arterial PCO_2 gap. This pilot study needs to be expanded before this technology becomes part of routine practice, but it offers the possibility of a noninvasive measurement of regional perfusion.²⁴

VASOPRESSORS AND INOTROPES

Vasopressors and inotropes in septic shock are required when volume resuscitation fails to maintain adequate blood pressure (mean arterial pressure [MAP] ≥ 65 mm Hg), when the PAOP is optimized to 12 to 15 mm Hg, and organs and tissues remain hypoperfused. However, vasopressors may be needed temporarily in the presence of inadequate filling pressures to treat life-threatening hypotension.³ The clinician must decide on the choice of agent, therapeutic end points, and the safe and effective doses of vasopressors and inotropes to be used. This section reviews adrenergic receptor pharmacology, exogenous catecholamine use, and alterations in receptor function in the critically ill. It also provides guidelines for the clinical use of adrenergic agents, optimization of pharmacotherapeutic outcomes, and minimization of adverse effects in critically ill patients with septic shock.

It should be noted that agents other than catecholamines have been used as inotropes and vasopressors in shock states. These include phosphodiesterase III inhibitors, naloxone, nitric oxide synthase inhibitors, calcium sensitizers, and vasopressin. However, the focus of this chapter is on catecholamines.

RECEPTOR PHARMACOLOGY

Comparative receptor activity of endogenous and exogenously administered catecholamines is summarized in Table 23–2. Endogenous catecholamines are responsible for regulation of vascular and bronchiolar smooth muscle tone and myocardial contractility. These effects are mediated by sympathetic adrenergic receptors of the autonomic nervous system located in the vasculature, myocardium, and bronchioles. Postsynaptic adrenoceptors are located at or near the synaptic junction. These receptors can be activated by naturally circulating or exogenous catecholamines (e.g., norepinephrine, epinephrine, and phenylephrine), whereas presynaptic adrenoceptors are stimulated by locally released neurotransmitters (e.g., norepinephrine) and are controlled by a negative-feedback mechanism.

Figure 23–2 depicts adrenoceptor–G protein interaction. β - and dopamine (DA)₁-adrenoceptor agonists activate the stimulatory G protein, G_s, which dissociates from the receptor and activates membrane-bound adenylyl cyclase (AC). α_2 - and DA_2 -agonists activate the inhibitory G protein, G_i, which dissociates from the receptor and blocks AC. AC converts adenosine triphosphate (ATP) to cyclic adenosine monophosphate (cAMP), which stimulates protein kinases, resulting in alterations in cellular functions.

The heart contains primarily postsynaptic β_1 -receptors, which cause increased rate and force of contraction when stimulated. This effect appears to be mediated by activation of adenylyl cyclase and subsequent generation and accumulation of cAMP. Stimulation of postsynaptic cardiac α_1 -receptors causes a significant increase in contractility without an increase in rate, an effect apparently not mediated by cAMP. The increased contractility is more pronounced at lower heart rates and has a slower onset and longer duration in comparison with β_1 -mediated inotropic response. Presynaptic α_2 -adrenoceptors also are found in the heart and appear to be activated by norepinephrine released by the sympathetic nerve itself. Their activation inhibits further norepinephrine release from the nerve terminal.

TABLE 23–2. Adrenergic and Dopaminergic Receptor Pharmacology and Organ Distribution

| Effector Organ | Receptor Subtype | Physiologic Response |
|----------------------------------|--|--|
| Heart | | |
| SA node | β_1, β_2 | Increased heart rate |
| Atria | β_1, β_2 | Increased contractility Increased conduction velocity |
| AV node | β_1, β_2 | Increased automaticity Increased conduction velocity |
| His-Purkinje system | β_1, β_2 | Increased automaticity Increased conduction velocity |
| Ventricles | $\beta_1, \beta_2, \alpha_1$ | Increased contractility Increased conduction velocity Increased automaticity Increased rate idioventricular pacemaker cells |
| Arterioles | | |
| Coronary | $\alpha_1, \alpha_2; \beta_2, DA_1$ | Constriction, dilatation |
| Skin and mucosa | α_1, α_2 | Constriction |
| Skeletal muscle | $\alpha_1; \beta_2$ | Constriction, dilatation |
| Cerebral | α_1 | Constriction (slight) |
| Pulmonary | $\alpha_1; \beta_2$ | Constriction, dilatation |
| Abdominal viscera (mesentery) | $\alpha_1; \beta_2, DA_1$ | Constriction, dilatation |
| Renal | $\alpha_1, \alpha_2; \beta_1, \beta_2, DA_1$ | Constriction, dilatation |
| Veins (systemic) | $\alpha_1, \alpha_2; \beta_2$ | Constriction, dilatation |
| Lungs | | |
| Trachial/bronchial smooth muscle | β_2 | Relaxation |
| Bronchial glands | $\alpha_1; \beta_2$ | Decrease, increase secretion |
| Stomach | | |
| Motility & tone | $\alpha_1, \alpha_2; \beta_2$ | Decrease (usually) |
| Sphincter | α_1 | Contraction (usually) |
| Intestine | | |
| Motility and tone | $\alpha_1, \alpha_2; \beta_1, \beta_2$ | Decrease |
| Sphincters | α_1 | Contraction |
| Secretions | α_2 | Inhibition (?) |
| Kidney | | |
| Renin secretion | α_1 | Decrease |
| Skeletal muscle | β_2 | Increased contractility, glyconeogenesis, K^+ uptake |
| Liver | α_1, β_2 | Glycogenolysis and gluconeogenesis |

Adapted from refs. 104 and 105.

Both presynaptic and postsynaptic adrenoceptors are present in the vasculature. Postsynaptic α_1 - and α_2 -receptors mediate vasoconstriction, whereas postsynaptic β_2 -receptors induce vasodilation. Presynaptic α_2 -receptors inhibit norepinephrine release in the vasculature as well. Presynaptic β_1 -adrenoceptors promote neurotransmitter release. Stimulation of peripheral DA_1 -receptors produces renal, coronary, and mesenteric vasodilation and a natriuretic response. Stimulation of DA_2 -receptors inhibits norepinephrine release from sympathetic nerve endings and prolactin release and may induce nausea and vomiting. DA_1 - and DA_2 -receptor stimulation also

suppresses peristalsis and may precipitate ileus. Cloning techniques have identified novel DA_1 - and DA_2 -like receptors, but their function beyond positive and negative AC coupling to the α -subunit of the G proteins has yet to be determined.

ALTERED ADRENOCEPTOR FUNCTION: IMPLICATIONS FOR THE CRITICALLY ILL

Most of the work describing receptor function and associated clinical pharmacology has been done either in animal models or human volunteers. In critically ill septic patients, derangements in adrenergic receptor activity may result in resistance to exogenous catecholamine administration.^{25,26} This “desensitization” frequently is characterized by myocardial and vascular hyporesponsiveness to high dosages of inotropes and vasopressor agents. Prolonged exposure of vascular endothelial tissue to vasopressor drugs (α -adrenergic agonists) or hormones (catecholamines) may produce this attenuation in response. Increased endogenous catecholamine concentrations have been reported in endotoxic and other critically ill patients, suggesting an acquired β -adrenergic receptor defect and desensitization of β -adrenergic receptors and alteration in voltage-sensitive calcium channels.^{25,26} Although the problem in critically ill patients may lie in decreased β -receptor activity or density, in patients with septic shock, the catecholamine concentrations are even higher, and thus abnormalities in β -adrenergic receptor function are greater, with associated reductions in myocardial cyclic monophosphate concentrations. The worsened receptor abnormality may be explained by defects distal to the receptor site, such as an uncoupling of the β -adrenergic receptor from AC or a dysfunction in the regulatory G protein unit of the AC system.^{25,26}

Mediators other than catecholamines (e.g., circulating cytokines) may be responsible for these distal alterations. Macrophage-derived interleukin-1 (IL-1) and TNF- α produce impaired coupling of β -adrenergic receptors to adenylate cyclase.^{25,26} Septic shock patients have exhibited impaired β -adrenergic receptor stimulation of cAMP

associated with myocardial hyporesponsiveness to various vasopressors and inotropes.^{25,26} However, increased chronotropic sensitivity to β -adrenergic stimulation with hypersensitivity of the adenylate cyclase system to isoproterenol stimulation also has been reported in animal models of bacteremia and endotoxemia. In the presence of intrinsic myocardial dysfunction and increased metabolic demands, this dysfunctional adrenergic system is incapable of mobilizing functional cardiac reserve to maintain adequate myocardial performance.^{25,26} Functional adrenergic receptor changes have been reported at various stages of sepsis, and thus adrenergic receptor sensitivity may be time-dependent during progression of sepsis to septic shock. The findings are not always consistent in various animal models of sepsis and in critically ill septic patients. For example, in an in vivo rodent model of sustained endotoxemia (48 hours) and continuous parenteral nutrition simulating advanced critical illness, Dickerson and colleagues showed no difference in α_1 -adrenergic maximal responsiveness (in MAP) to phenylephrine.²⁷ Time-dependent alterations in the production of endothelium-derived nitric oxide, a potent vasodilator, may explain the apparent differences in vascular reactivity to phenylephrine during the phases of endotoxemia.²⁷ These findings suggest that the clinical response to vasopressor and inotropic agents is variable during the stages of hemodynamic, myocardial, and peripheral vascular derangements of septic shock. In contrast, in critically ill septic patients in the ICU (24 to 48 hours from hospital admission), β -adrenergic receptor changes were already present, although the progression of desensitization of receptors earlier in sepsis was not quantified.²⁶ In summary, α - and β -adrenergic receptor derangements may vary among patients and during each bacteremic insult, and therefore, doses of catecholamines vary from patient to patient and during the insult. For these reasons, these drugs should be dosed to clinical end points and not arbitrary maximal doses.

CLINICAL PHARMACOLOGY OF CATECHOLAMINES

4 The receptor selectivity of clinically used vasopressors and inotropes and hemodynamic effects are listed in Table 23–3. In general, these drugs are rapidly acting with short durations of action. As such, these drugs are given as continuous infusions. Careful monitoring and calculation of infusion rates are advised because dosing adjustments are made frequently, and varying admixtures and concentrations are used in volume-restricted patients.

Dopamine often is recommended as the initial catecholamine in sepsis because it increases blood pressure by increasing myocardial contractility and vasoconstriction. Dopamine has been described to have dose-related receptor activity at DA₁-, DA₂-, β_1 -, and α_1 -receptors. Unfortunately, this dose-response relationship has not been confirmed in critically ill patients. In patients with septic shock, there is a great overlap of hemodynamic effects even at doses as low as 3 mcg/kg per minute.²⁸ Tachydysrhythmias are common owing to the release of endogenous norepinephrine by dopamine entering the sympathetic nerve terminal. Dopamine may increase the PAOP through pulmonary vasoconstriction.²⁹ This drug also may depress ventilation and worsen hypoxemia in patients dependent on the hypoxic ventilatory drive.

Dobutamine, a synthetic catecholamine, is primarily a selective β_1 -agonist with mild β_2 - and vascular α_1 activity, resulting in strong positive inotropic activity without concomitant vasoconstriction. In comparison with dopamine, dobutamine produces a larger increase in cardiac output and is less arrhythmogenic.³⁰ Ruffolo and colleagues³¹ showed that α_1 -adrenoceptors in the heart are directly stimulated by the (–) isomer of dobutamine and that the β_1 - and β_2 -agonist activity resides in the (+) isomer.³¹ This suggests that the strong inotropic action of dobutamine is a function of its structure, the additive effect of the cardiac α_1 - and β_1 -agonist activity, and a relatively weak chronotropic effect limited to the (+) isomer action on the β -receptors. Clinically, the increased myocardial contractility and subsequent reflex reduction in sympathetic tone leads to a decrease in systemic vascular resistance (SVR). Even though dobutamine is used optimally for low cardiac output states with high filling pressures or in cardiogenic shock, vasopressors may be needed to counteract arterial vasodilation.

Norepinephrine is a combined α - and β -agonist but mainly produces vasoconstriction primarily via its more prominent α effects on all vascular beds, thus increasing SVR. Norepinephrine administration generally produces either no change or some increase in cardiac output.^{32,33}

Phenylephrine is a pure α_1 -agonist and is believed to increase blood pressure through vasoconstriction. Given the presence of cardiac α_1 -receptors, phenylephrine also may increase contractility and cardiac output.³⁴

Epinephrine exerts combined α - and β -agonist effects. At the high epinephrine infusion rates used in septic shock, predominantly

TABLE 23–3. Receptor Pharmacology of Selected Inotropic and Vasopressor Agents Used in Septic Shock*

| Agent | α_1 | α_2 | β_1 | β_2 | DA [†] |

α -adrenergic effects are seen, and SVR and MAP are increased. Epinephrine traditionally has been reserved as the vasopressor of last resort owing to peripheral vasoconstriction, particularly in the splanchnic and renal beds.^{35,36}

CLINICAL USE OF VASOPRESSORS AND INOTROPES

5 Traditionally, a few vasopressors and inotropes have been used for hemodynamic support: dopamine, dobutamine, epinephrine, norepinephrine, and phenylephrine. Optimizing MAP as the goal of vasopressor therapy does not uniformly correlate with a decrease in mortality in septic shock.¹³ Historically, significant concerns about the adverse effects of the vasopressors limited their use. The recent focus on goal-directed therapy, with optimization of oxygen transport variables to supranormal values, also has yielded poor results in patients with septic shock.¹⁵ In fact, normalization of systemic DO_2 and VO_2 , whether spontaneously or by design, is associated with improved outcome and is not dependent on administration of vasopressor agents. Part of our inability to detect an improvement with vasopressor or inotrope therapy may result from our limited ability to quantify regional tissue perfusion. However, use of early aggressive goal-directed therapy to a SvCO_2 value of greater than 70% has been shown to reduce mortality in patients with sepsis and septic shock.¹²

6 **7** Dose titration and monitoring of vasopressor and inotropic therapy should be guided by the “best clinical response.” Clinically effective dosing of vasopressors and inotropes in septic shock often requires much larger doses than those recommended by the manufacturer. These large infusion rates must be tempered with the development of adverse effects. The goal is to use the minimally effective infusion rate while minimizing evidence of myocardial ischemia (e.g., tachydysrhythmias, electrocardiographic changes), renal (decreased glomerular filtration rate and/or urine output), splanchnic/gastric (low pHi, bowel ischemia), or peripheral (cold extremities) hypoperfusion, and worsening of PaO_2 , PAOP, and other hemodynamic variables.

11 Therapy with vasopressors and inotropes is continued until the myocardial depression and vascular hyporesponsiveness (i.e., blood pressure) of septic shock improve, usually measured in hours to days. Discontinuation of vasopressor or inotropic therapy should be executed slowly; therapy should be “weaned” to avoid a precipitous worsening in regional and systemic hemodynamics. Careful monitoring of global and regional end points also should be geared toward discontinuation of vasopressors and inotropes as soon as the patient is hemodynamically stable. This requires moment-by-moment observation. Because vasopressors and inotropes often are started while the patient is not yet optimally volume-resuscitated, clinicians should reevaluate the intravascular volume status continuously in order to be able to wean the patient from the vasopressor as soon as possible. Doses should be titrated carefully downward approximately every 10 minutes to determine if the patient is able to tolerate gradual withdrawal and eventual discontinuation of the vasopressor and/or inotrope. Discontinuation of the agents may occur only minutes to hours after their initiation or may take days to weeks. Septic shock requiring vasopressor and/or inotropic support usually resolves within a week.

ADVERSE EFFECTS

4 Catecholamine vasopressors may result in adverse peripheral vasoconstrictive, metabolic, and dysrhythmogenic effects that limit or outweigh their positive effects on the central circulation.³⁷ Norepinephrine, phenylephrine, and epinephrine can produce a lactic acidosis secondary to excessive constriction in peripheral arterioles,

enhanced glycogenolysis, or as a result of mobilization of lactate from peripheral tissues as a result of improved oxygenation. Additionally, excessive peripheral vasoconstriction may cause ischemia or necrosis of already poorly perfused areas such as the skin and the mesenteric and splanchnic circulations.^{35,38} Some of these profound vasoconstrictive effects have been compounded by the use of epinephrine and phenylephrine in septic shock patients, who are significantly hypovolemic. These agents are used in the context of late septic shock, where hypotension is refractory to less selective vasoconstrictors (e.g., norepinephrine or dopamine) such that very large doses of epinephrine or phenylephrine are required with little or no benefit. Myocardial ischemia and dysrhythmias may occur in patients with CAD, atherosclerosis, cardiomyopathies, LV hypertrophy, congestive heart failure, and underlying dysrhythmias owing to their inability to tolerate β_1 cardiac stimulation that mediates increases in cardiac output. The effect is usually the opposite, however, in healthy myocardium and in young patients. β_1 cardiac stimulation is well tolerated, ventricular filling pressures decrease, and cardiac output and DO_2 increase, with a resulting increase in peripheral perfusion. An extensive review of the dysrhythmogenic potential of the catecholamine vasopressors reveals a variety of resulting atrial and ventricular arrhythmias.³⁰ Sympathomimetic vasopressors also have been found to occupy neutrophil β_2 -receptors (e.g., epinephrine) and directly scavenge oxygen free radicals (e.g., dopamine and dobutamine).³⁹ These effects may be either beneficial or deleterious by dampening harmful effects of oxygen free radical-mediated tissue injury or by reducing neutrophilic defense against bacteria. At clinically relevant concentrations, dopamine inhibits in vitro endothelial adhesion molecule expression of E-selectin.⁴⁰ This and other adhesion molecules mediate leukocyte interaction with and adherence to endothelial cells, which is implicated in enhancing sepsis-induced multiple-organ failure and lung injury in many animal models.^{39,40} Epinephrine, dopamine, and other β -adrenergic agonists can inhibit production of $\text{TNF-}\alpha$ by neutrophils or expression of cellular adhesion molecules such as E-selectin by increasing cAMP, but the mechanism is more complex than previously thought.^{40,41}

Vasopressor catecholamines have the potential to cause extravasation-associated tissue damage if infusions infiltrate during peripheral administration. In the event of infiltration, an α -receptor antagonist such as phentolamine (10 mg in 10 mL saline) should be injected intradermally to reverse local vasoconstriction. As such, it is recommended to administer vasopressor drugs into a large central vein.

DOPAMINE

Dopamine is frequently the initial vasopressor used in septic shock. Doses of 5 to 10 mcg/kg per minute are initiated to improve MAP. Most studies in patients with septic shock have shown that at these doses dopamine increases CI by improving contractility and heart rate, resulting primarily from its β_1 effects. It increases arterial pressure and SVR as a result of both the increased cardiac output and, at higher doses (> 10 mcg/kg per minute), as a result of the α_1 effects.

6 The clinical utility of dopamine as a vasopressor in the setting of septic shock is limited because large doses frequently are necessary to maintain cardiac output and blood pressure. At doses exceeding 20 mcg/kg per minute, there is limited further improvement in cardiac performance and regional hemodynamics. Its clinical use frequently is hampered by tachycardia and tachydysrhythmias, which may lead to myocardial ischemia. Although tachydysrhythmias theoretically should not be expected to occur until 5 to 10 mcg/kg per minute of dopamine, these β_1 effects are observed with doses as low as 3 mcg/kg per minute. They seem to be more prevalent in patients

who are inadequately resuscitated (hypovolemic), in the elderly, in those who have preexisting or concurrent cardiac ischemia or dysrhythmias, and in patients currently receiving other dysrhythmogenic agents, including vasopressors and inotropes.

8 Other adverse effects limiting the use of dopamine in patients with septic shock are increases in PAOP, pulmonary shunting, and decreases in PaO₂.²⁹ The increase in PAOP may be due to changes in diastolic volumes from decreased cardiac compliance or increased venous return to the heart by α -adrenergic receptor-mediated vasoconstriction. This may affect gas exchange and decrease PaO₂. The increase in pulmonary shunting also may result from acute enhancement of pulmonary blood flow to nonhomogeneous lung regions. Thus dopamine should be used with caution in patients with elevated preload because the drug may worsen pulmonary edema. In the instance of high filling pressures, tachycardia, or tachydysrhythmias in the presence or absence of refractory hypotension, dopamine should be replaced by another vasopressor or inotrope such as norepinephrine, dobutamine, phenylephrine, or epinephrine, depending on the desired effect. Lastly, immune suppression of T-cell proliferation and pituitary hormone secretion and blunting of growth and thyroid hormones and prolactin secretion are also potentially clinically significant unwanted neuroendocrine effects of dopamine.

The effect of dopamine on global oxygen transport variables parallels the hemodynamic effects. Although dopamine improves global DO₂ in septic patients, it appears to compromise tissue oxygen extraction in the splanchnic and mesenteric circulations by α_1 -mediated vasoconstriction. Indeed, despite increasing systemic DO₂ and VO₂, large doses of dopamine worsen pHi and the PCO₂ gap. This is reflected by a decrease or lack of change in regional VO₂ and a decrease in tissue O₂ER. Dopamine at low or pressor doses impairs gastric motility in critical illness⁴² and may aggravate gut ischemia in septic shock.^{35,43,44} Jakob and colleagues⁴⁵ evaluated the effects of dopamine on systemic and regional blood flow and metabolism in 9 septic and 11 cardiac surgery patients. Dopamine was started at 1 mcg/kg per minute and increased until the cardiac output increased by 25%. Systemic and splanchnic hemodynamics and oxygen transport were measured at baseline and 90 minutes after increasing the cardiac output. Dopamine infusion at a mean dose of 4 mcg/kg per minute increased splanchnic blood flow in the cardiac surgery and septic patients. Splanchnic VO₂ increased in cardiac surgery patients but decreased in septic patients. The reduction in splanchnic oxygen consumption by dopamine in sepsis suggests an impairment of hepatosplanchnic metabolism despite an increase in regional perfusion.

Although splanchnic blood flow and DO₂ may increase with dopamine, there is no preferential increase in the splanchnic perfusion as a fraction of cardiac output and systemic increases in DO₂.^{46,47} One study found an inverse relationship between fractional splanchnic flow at baseline and the change in fractional splanchnic blood flow such that dopamine was effective in increasing the fractional splanchnic blood flow in those in whom it was normal but worsened it in those with high baseline values, such as occurs with redistribution of regional blood flow in septic shock.⁴⁶ Clinically, it is difficult to distinguish prospectively either subset of patients.

8 Currently, there is insufficient evidence to promote the use of dopamine as a first-line agent because regional hemodynamics, oxygen transport variables, and functional parameters of improved organ perfusion are not improved in a sustained manner and may be negatively impaired. The negative findings of using low-dose dopamine (see below) and the deleterious effects of inotropic and vasopressor doses of dopamine on regional hemodynamics and oxygen transport are raising a controversy over whether dopamine should be considered the first-line vasopressor agent in patients with severe sepsis or

septic shock.^{35,48} It still may be reasonable to use dopamine empirically in a hypotensive patient in whom a pulmonary arterial catheter has not been inserted and in whom the cause of hypotension—low cardiac output or vasodilation—is yet undetermined.³

LOW-DOSE DOPAMINE

In the critical care setting, low doses (1 to 3 mcg/kg per minute) of dopamine sometimes are used in patients with septic shock receiving vasopressors with or without oliguria. The goal of therapy is to prevent or reverse renal vasoconstriction caused by other pressors, to prevent oliguric renal failure, or to convert it to nonoliguric renal failure. Dopamine has been shown to increase renal blood flow and increased urine output owing to either its dopaminergic effect at low doses, its natriuretic effects (inhibition of the Na⁺/K⁺-adenosine triphosphate of renal tubular cells), or an increase in CI.^{49,50} In normal volunteers, the addition of dopamine to incremental doses of norepinephrine may blunt norepinephrine-induced renal vasoconstriction, thereby maintaining renal blood flow, natriuresis, urine output,^{28,51} and in one study, glomerular filtration.⁵¹ In oliguric patients, dopamine may increase fractional excretion of sodium and increase urine output. These effects also have been observed during the course of dopamine administration in nonseptic oliguric patients,⁵² as well as in oliguric^{46,53} and nonoliguric^{36,47,49} patients with septic shock. For this reason, dopamine is sometimes added in low doses to other vasopressors or inotropes (e.g., norepinephrine). Despite this practice, evidence supporting low-dose dopamine in preserving kidney function in oliguria with or without septic shock or in reversing vasopressor-induced vasoconstriction in septic shock is lacking and limited to small underpowered studies.^{36,49,50,53–56}

Furthermore, tolerance to the vasodilatory effects of dopamine after 24 to 48 hours is evident in nonoliguric patients with sepsis syndrome and has been reported in others.^{56,57} The lack of response to dopamine in septic shock patients on vasopressors and the tolerance that develops in responders to low-dose dopamine may be explained in part by time- and disease-dependent desensitization of the dopamine receptors^{56,57}; this may not occur in those with sepsis syndrome⁵⁶ or normal volunteers.²⁸ Furthermore, differences in the extent of preexisting vasodilation and the pathophysiology of renal dysfunction in oliguric and septic shock patients also may contribute to the inconsistent responses seen to the administration of low doses of dopamine.

Two recent studies, however, help put to rest the debate surrounding low-dose dopamine. Kellum and colleagues⁵⁸ performed a meta-analysis to determine if low-dose dopamine reduces the incidence or severity of acute renal failure, need for dialysis, or mortality in patients with critical illness. Among 17 randomized clinical trials ($n = 854$), low-dose dopamine did not prevent mortality (relative risk 0.90; 95% confidence interval 0.44–1.83; $p = .92$), onset of acute renal failure (relative risk 0.81; 95% confidence interval 0.55–1.19; $p = .34$), or need for dialysis (relative risk 0.83; 95% confidence interval 0.55–1.24; $p = .42$). There was sufficient statistical power to exclude any large (>50%) effect of dopamine on the risk of acute renal failure or need for dialysis. One adequately designed prospective, controlled trial has been conducted with low-dose dopamine in oliguric renal failure in critically ill patients. This study was not cited in the aforementioned meta-analysis owing to the lag in publication. Bellomo and colleagues⁵³ randomized 328 critically ill patients with early renal dysfunction to either low-dose dopamine (2 mcg/kg per minute) or placebo, with the primary end point being peak SCr. At the end of the study, there were no differences in peak SCr or other renal outcomes such as increase in SCr, need for renal replacement

therapies, improvement in urine output, time to recovery of normal renal function or survival, ICU stay, hospital stay, or development of arrhythmias. On the basis of available evidence, it can be concluded that low-dose dopamine for the treatment or prevention of acute renal failure cannot be justified and should be eliminated from routine clinical use.^{53,58}

NOREPINEPHRINE

Norepinephrine was first used three decades ago for the treatment of hypotensive states prior to the development of the newer synthetic catecholamines dopamine and dobutamine. Traditionally, norepinephrine was viewed as causing significant peripheral tissue vasoconstriction, which could selectively impair regional flow and thus DO_2 to the renal and splanchnic beds. However, recent clinical studies of norepinephrine support the primary use of norepinephrine to restore blood pressure in septic shock.^{32,59} In fact, in a retrospective study of 100 ICU patients treated with norepinephrine for severe hypotension and evidence of end-organ hypoperfusion unresponsive to both fluid resuscitation and dopamine treatment, early norepinephrine administration was associated with the lowest mortality rate.⁶⁰ However, in patients with increased sequential organ failure assessment (SOFA) scores and associated multiorgan failure, treatment with norepinephrine no longer offered an advantage. Early aggressive vasopressor support may be key to a positive outcome in septic shock.

In clinical practice, however, norepinephrine often is initiated after vasopressor doses of dopamine (4 to 20 mcg/kg per minute) alone or in combination with dobutamine (5 mcg/kg per minute) fail to achieve desired goals.³ Doses of dopamine and dobutamine are kept constant or stopped altogether, or in some instances, dopamine is kept at low doses for purported renal protection. It may be more rational to use norepinephrine because it is more potent than dopamine and is more effective at increasing MAP. It has combined strong α_1 activity and less potent β_1 -agonist effects while maintaining the vasodilatory effects of β_2 -receptor stimulation.

Norepinephrine infusions may be titrated to preset goals of MAP (usually >70 mm Hg), improvement in peripheral perfusion (to restore urine output or decrease blood lactate), and/or achievement of desired oxygen transport variables while not compromising cardiac index. Norepinephrine 0.01 to 2 mcg/kg per minute reliably and predictably improves hemodynamic parameters to “normal” or “supranormal” values in most patients with septic shock. As with other vasopressors, norepinephrine doses that exceed those recommended by the manufacturer are needed in critically ill patients with septic shock to achieve predetermined goals. A significant increase in MAP generally is accompanied by an increase in SVR. In contrast to dopamine, heart rate generally does not increase significantly with norepinephrine because of diminished stimulation of cardiac β_1 -receptors in septic shock.^{33,61} In a study of 10 patients with septic shock in whom norepinephrine doses were increased to 23, 31, and 47 mcg/min to maintain MAPs of 65, 75, and 85 mm Hg, the mean heart rates at these doses were 95, 101, and 105 beats per minute, respectively.³³ Norepinephrine has been shown to produce no change or some increase in the cardiac index in septic shock.³² In the same study by LeDoux and colleagues,³³ the increasing doses of norepinephrine required for the three levels of MAP resulted in a progressive increase in the cardiac index (mean values 4.7, 5.3, and 5.5 L/m² per minute, respectively).³³ In contrast to dopamine, with norepinephrine, there is no change in PAOP.⁶²

Whereas the effects on MAP, SVR, cardiac index, and heart rate appear to be desirable and more predictable, the effect of norepinephrine on urine output may depend on concurrently administered

vasoactive agents.⁶² Concurrent inotropic support with dobutamine and dopamine or low doses of dopamine precludes attributing any beneficial effects to norepinephrine alone. An increase in urine output may be due to increased renal perfusion pressure secondary to the increases in MAP and the SVR index, especially given that norepinephrine has a greater vasoconstrictive effect on the efferent arteriole of the kidney than on the afferent arteriole.

The effect of norepinephrine on oxygen transport parameters is variable and depends on baseline values and concurrently administered vasoactive agents. In most of the studies, either an increase or no change in DO_2 is seen with no change in O_2ER , particularly when mean DO_2 values were “supranormal” prior to therapy.⁶³ In all but one study,⁶⁴ patients had received dobutamine and/or dopamine prior to initiation of goal-directed therapy with norepinephrine. Martin and colleagues⁶⁴ found norepinephrine alone to be superior to dopamine in achieving and maintaining for at least 6 hours preset hemodynamic and oxygen transport variables (93% versus 31% of patients, $p < .001$). The authors suggested that differences between the two agents resulted from norepinephrine’s combined increase in VO_2 and decrease in lactate concentrations owing to correction of splanchnic ischemia and efficient hepatic clearance of lactate or owing to a preferential increase in DO_2 to areas of greatest oxygen demand, thus optimizing O_2ER .

Recently, Martin and colleagues,⁵⁹ in a prospective, observational cohort study of 97 adult patients with septic shock, determined that the use of norepinephrine to provide hemodynamic support was associated with a significant decrease in hospital mortality [day 7: 28% versus 40% ($p < .005$); day 28: 55% versus 82% ($p < .001$), and hospital discharge: 62% versus 84% ($p < .001$)].⁵⁹ Using stepwise logistic regression analysis, norepinephrine was found to be the only factor associated with significantly improved survival ($p = .03$). Despite the drawback of lack of randomization, this is the first study to demonstrate a survival benefit with any vasopressor. In a subsequent interventional study, Martin and colleagues³² showed that the addition of norepinephrine in patients with dobutamine-resistant septic shock resulted in significant improvements (40%) in cardiac index and stroke volume index during a 4-hour study period.³² This occurred despite an increase in LV afterload, suggesting that either a positive inotropic effect or the LV correction of systemic hypotension was responsible. The authors further speculated that older patients may benefit from a combined α - and β -vasopressor versus a pure β -agonist (i.e., dobutamine) given the higher incidence of coronary disease and compromised ventricles. By virtue of restored MAP and hence coronary perfusion, cardiac index is increased in older patients, whereas in younger patients with less coronary artery disease and a higher cardiac index at baseline, norepinephrine acts primarily as a vasopressor. In younger patients in this study, norepinephrine did not significantly increase cardiac index or stroke volume index.

Taken together, these recent data suggest that norepinephrine potentially should be repositioned as the vasopressor of choice in patients in septic shock because of its multiple benefits: (1) It may decrease mortality in septic shock, (2) it attenuates inappropriate vasodilation and low global oxygen extraction, (3) it attenuates myocardial depression at unchanged or increased cardiac output and increased coronary blood flow, (4) it improves renal perfusion pressure and renal filtration, (5) it improves splanchnic perfusion, and (6) it is less likely than other vasopressors to cause tachycardias and tachydysrhythmias.^{59,61,65}

DOBUTAMINE

Dobutamine is an inotrope with vasodilatory properties (a so-called inodilator), and it is used in the treatment of septic and cardiogenic

shock to increase cardiac index. In septic shock, LV ejection fraction (EF) and right ventricular function are depressed despite a high cardiac index, whereas ventricular volumes and compliance are increased. Stroke index is maintained by an increased heart rate and ventricular dilatation. In survivors, the myocardial depression is reversible and normalizes at 5 to 10 days after the onset of sepsis.⁶⁶ Dobutamine has been shown to increase stroke index, left ventricular stroke work index (LVSWI), and thus cardiac index and DO_2 without increasing PAOP in septic shock in animals, in human volunteers, and in controlled studies of human septic shock.⁶³

Most prospective, randomized, controlled studies of goal-directed therapy with dobutamine were performed for septic shock in surgical and medically critically ill patients refractory to concurrently administered vasopressors (dopamine and/or norepinephrine).⁶³ The oxygen transport effects may not be significant or may be transient, particularly during prolonged infusions. It appears that achievement of supranormal oxygen transport values with dobutamine in hyperdynamic septic shock refractory to fluid resuscitation and vasopressors is of little value as compared with treatment to normal values. In addition, administration of dobutamine to achieve these high values has resulted in an unchanged or an increased mortality and a greater incidence of adverse effects,⁶⁷ with the exception of a study in older nonseptic high-risk surgical patients.¹⁷ Results in medical and surgical patients may differ owing to differences in time of starting dobutamine infusion, the duration of the infusion, and dosages administered. Subgroups of patients with septic shock (6% to 34%) among critically ill, high-risk trauma and surgical patients have small and insignificant changes in DO_2 , VO_2 , O_2ER , and cardiac index.⁶⁸ The lack of response may be related to late treatment (>72 hours after surgery) resulting in irreversible changes owing to hypoperfusion and hypoxia. In a group of medical patients, the lack of sustained effect may have been attributed to the fact that very large doses were needed to achieve the desired effects over a longer treatment period (72 hours). The requirement for vasopressor support with dopamine may have decreased the oxygen extraction ratio (O_2ER) and negated the beneficial effects of increased delivery with dobutamine. Oxygen extraction ratio, mixed venous oxygen tension, and relative changes in SVR were not reported. In populations of medical and surgical patients, dobutamine did not increase the likelihood of patients achieving supranormal oxygen transport variables.⁶³ Continuation of dobutamine until death or resolution of acute illness resulted in an increased mortality despite an increase in the mean area under the DO_2 curve.⁶⁷ This is explained in part by the fact that no change in VO_2 was seen, and thus O_2ER decreased. Also, much higher doses of dobutamine were used in this study as compared with the previous study (5 to 200 versus 5 to 20 mcg/kg per minute). Seventeen of the 50 patients in the experimental group received 50 mcg/kg per minute or more of dobutamine at some time during the study. Despite these high doses, 35 of 50 patients (70%) were unable to achieve the predetermined goals. Infact, dose increments of dobutamine were limited by complications in half the dobutamine patients in the treatment group, with tachycardia, ischemic changes on ECG, hypertension, and tachydysrhythmias, despite the absence of preexisting cardiac abnormalities.⁶⁷

Recent studies have focused on the effects of dobutamine on gastric mucosal flow and the splanchnic circulation. The addition of dobutamine (held constant at 5 mcg/kg per minute) to norepinephrine improves gastric mucosal perfusion without increasing cardiac index.⁶⁹ This is consistent with findings that dobutamine may improve pH_i and mucosal perfusion in septic patients.⁷⁰ The addition of dobutamine to epinephrine-treated patients has been shown to improve gastric mucosal perfusion, as measured by improvements in pH_i, arterial lactate concentrations, and PCO_2 gap.⁷¹ Duranteau and colleagues'

findings likely were related to a blood flow redistribution toward gastric mucosal.⁶⁹ This effect may be due to either an increase in the fraction of the cardiac output that was distributed to the global hepatosplanchnic blood flow⁷¹ and/or to a redistribution of blood flow within gastric wall layers toward mucosal by "stealing" blood away from the muscularis potentially owing to the greater β_2 -mediated vasodilatation attributable to norepinephrine. This hypothesis is supported by two other recent investigations.^{72,73}

In these studies, a constant dose of dobutamine (5 mcg/kg per minute) was added to norepinephrine and compared with either epinephrine and norepinephrine alone to determine comparative effects on systemic and regional hemodynamics and oxygen transport variables.^{72,73} At the same increase in MAP, there was no significant difference in the systemic hemodynamic variables between the treatment groups. The combination of dobutamine-norepinephrine resulted in a lower increase in heart rate compared with the other groups. There was no difference among each group in DO_2I . Arterial lactate concentrations dropped significantly with norepinephrine-dobutamine as compared with dopamine and epinephrine infusions. Norepinephrine-dobutamine infusion was associated with a higher pH_i compared with epinephrine infusion, but the differences were not statistically different. The difference between gastric and arterial PCO_2 with norepinephrine-dobutamine tended to be lower compared with those obtained with dopamine, epinephrine, and norepinephrine alone. The authors concluded that for the same level of MAP as the therapeutic goal in patients with septic shock, norepinephrine-dobutamine improved gastric mucosal perfusion and tissue oxygen utilization.

6 Dobutamine should be started with doses ranging 2.5 to 5 mcg/kg per minute. Although generally a dose response may be seen, recent evidence suggests that doses in excess of 5 mcg/kg per minute may provide limited beneficial effects on oxygen transport values and hemodynamics and may increase adverse cardiac effects.⁷⁴ If given to patients who are intravascularly depleted, dobutamine will result in hypotension and a reflexive tachycardia. Pathophysiologic factors influence dosing requirements and pharmacokinetic parameters over the time course of the illness and the duration of the infusion. Decreases in PaO_2 and increases in PVO_2 , as well as myocardial adverse effects such as tachycardia, ischemic changes on electrocardiogram, tachydysrhythmias, and hypotension, are seen.⁶⁷ Thus infusion rates should be guided by clinical end points. Dobutamine, like other inotropes, usually is given until there is an improvement in myocardial function with resolution of the septic episode or when dose-limiting side effects are seen.

PHENYLEPHRINE

Despite its purported use in refractory septic shock, very little information is published regarding the clinical efficacy of phenylephrine. Nevertheless, it is an attractive agent for use in sepsis owing to its selective α -agonism and primarily vascular effects and its rapid onset **6** and short duration of action. It is generally initiated at dosages of 0.5 mcg/kg per minute and may be titrated quickly to desired effect.

There are three clinical trials using phenylephrine in septic shock evaluating 38 patients. Phenylephrine (0.5 to 9 mcg/kg per minute), when used alone or in combination with dobutamine or low doses of dopamine, improves blood pressure and myocardial performance in fluid-resuscitated septic patients.⁷⁵ Incremental doses of phenylephrine over 3 hours result in linear dose-related increases in MAP, SVR, heart rate, and stroke index when administered as a single agent in stable, nonhypotensive but hyperdynamic, volume-resuscitated

surgical ICU patients. In septic shock, phenylephrine did not impair cardiac index, PAOP, or peripheral perfusion.^{34,76} Yamazaki and colleagues⁷⁵ showed that although its administration resulted in improved myocardial performance in hyperdynamic, normotensive septic patients, phenylephrine worsened it in cardiac controls.⁷⁵ At a dosage of 70 mcg/min, phenylephrine improved cardiac index and MAP by increasing venous return to the heart (increase in CVP and stroke index) and by acting as a positive inotrope because SVR did not change. There was a clinically insignificant decrease in heart rate (3 beats per minute). However, in cardiac patients, myocardial performance worsened as a result of an increase in MAP and SVR and a decrease in cardiac index with no change in heart rate. Although these results suggest caution, it is noteworthy that the cardiac indices of the two groups were not comparable at baseline.

In septic shock, phenylephrine appears to increase global tissue oxygen use, although there is conflicting information regarding the relationship of the oxygen-transport variables with increases in MAP and cardiac index.^{34,76} Increases in VO_2 appear to be dissociated from DO_2 , representing an increase in O_2ER because the cardiac index remains unchanged. Increases in VO_2 may result from redistribution of blood flow to previously underperfused areas, improving oxygen use as a result of changes in MAP and SVR. With phenylephrine administration, no organ dysfunction was documented, and evidence of globally improved peripheral tissue perfusion was seen as the lactic acid concentration fell or remained unchanged, and urine output increased significantly at increased or maximal VO_2 . An increased O_2ER may contribute to improved tissue use.^{34,76} In one small study, measured DO_2 and VO_2 values paralleled MAP in most patients.⁷⁶ As with epinephrine, phenylephrine doses (1.3 to 3.7 mcg/kg per minute) required to achieve goals of therapy were significantly higher than those traditionally recommended for use. When phenylephrine (0.5 mcg/kg per minute) was titrated to a plateau in VO_2 or the appearance of adverse cardiac effects, there was a greater than 15% increase in DO_2 and VO_2 . When combined with dobutamine, phenylephrine resulted in a more consistent and statistically significant increase in both DO_2 and VO_2 . However, these observations may be biased because baseline DO_2 and VO_2 values were somewhat higher in patients who did not require dobutamine (5 of 11). In a second study, Flancbaum and colleagues³⁴ evaluated the use of phenylephrine as a single agent without another cardiotoxic agent in 10 septic, hyperdynamic surgical ICU patients.³⁴ Eight patients had a clinically significant increase (>15%) in VO_2 with variable doses of phenylephrine, whereas DO_2 increased in only three patients. Phenylephrine predictably increased MAP but not VO_2 in a dose-dependent fashion in the surgical patient population.

There are very few data regarding the effect of phenylephrine on regional hemodynamics and oxygen-transport variables. When phenylephrine replaced norepinephrine in patients with septic shock, it selectively reduced splanchnic blood flow and thus splanchnic DO_2 and splanchnic lactate uptake rate without changing the overall splanchnic VO_2 .⁷⁷ Because all these parameters normalized when norepinephrine was reinstated, these data suggest that exogenous β -adrenergic stimulation (norepinephrine) may determine hepatosplanchnic perfusion and oxygen availability but not utilization in septic shock. This study also demonstrated that while the phenylephrine-induced reduction in splanchnic DO_2 reduced the *de novo* synthesis of glucose (a highly oxygen-dependent pathway in the periportal region), it did not affect the formation of MEGX, a metabolite of lidocaine (a cytochrome P450-dependent pathway in the perivenous region), suggesting that the latter metabolic activity is not so dependent on oxygen and is retained in septic shock, reflecting the heterogeneity of metabolic function in different areas of the liver.⁷⁷

The available data on hemodynamics, oxygen-transport variables, and mortality with phenylephrine in septic shock patients may not be generalizable owing to the small numbers of patients evaluated. Adverse effects such as tachydysrhythmias are notably infrequent with phenylephrine, particularly when it is used as a single agent or with higher doses, and this is due to the fact that phenylephrine does not exert any activity on β_1 -adrenergic receptors. It is unclear, however, how sustained the beneficial effects may be with longer administrations of phenylephrine.³⁴ In an experimental animal model, however, sustained endotoxemia (48 hours) does not result in desensitization of α_1 -adrenergic responsiveness when phenylephrine is used.²⁷ Other mechanisms may be responsible for the ineffectiveness of vasopressors during advanced sepsis. Phenylephrine may be a particularly useful alternative in patients who cannot tolerate tachycardia or tachydysrhythmias with dopamine or norepinephrine, in patients with known underlying myocardial dysfunction, and in patients who are refractory to dopamine or norepinephrine (owing to β -adrenergic receptor desensitization). As with other vasopressors, phenylephrine is continued until resolution of the hemodynamic instability associated with the septic episode and is weaned when patients are stable clinically.

EPINEPHRINE

By convention, epinephrine has been reserved as a last-line agent in hemodynamic support of sepsis. There are very few objective data evaluating its comparative efficacy in early sepsis, with most studies examining the effects of epinephrine in refractory septic shock.⁶³ Despite this, epinephrine is an acceptable choice as a single agent owing to its combined vasoconstrictor and inotropic effects. Epinephrine infusion rates of 0.04 to 1 mcg/kg per minute alone increase hemodynamic and oxygen-transport variables to “supranormal” values without adverse effects in patients without CAD. In 69 patients evaluated in five studies, epinephrine alone or combined with either dobutamine or low doses of dopamine achieved the desired outcomes.^{27,63} Large doses (0.5 to 1 mcg/kg per minute) often were required when epinephrine was added to other agents. Smaller doses (0.10 to 0.50 mcg/kg per minute) are effective if dobutamine and dopamine infusions are kept constant potentially owing to exposure to less β -receptor stimulation and thus less receptor desensitization. The same holds true when epinephrine is used as a first-line agent and when it is used in younger patients. A linear dose-response curve is seen, with a rapid improvement of hemodynamic variables and oxygen delivery. Although DO_2 increases mainly as a function of consistent increases in cardiac index and a more variable increase in SVR, VO_2 may not increase, and O_2ER may fall. A transient fall in pH_i may be seen during the epinephrine administration, and this impairment in gastric mucosal perfusion can be counteracted in part by dobutamine. Furthermore, lactate concentrations may rise during the first few hours of epinephrine therapy; however, they normalize over the ensuing 24 hours in survivors.⁶³ The increase in lactate may be a result of worsened oxygen delivery to the liver (and subsequent anaerobic metabolism) or to the hepatosplanchnic circulation or, alternatively, may be due to a direct increase by epinephrine in calorogenesis and breakdown of glycogen and lactate production. There is evidence, however, to suggest that epinephrine, in contrast to dopamine, may increase the proportion of total cardiac output delivered to the splanchnic circulation, although VO_2 is not increased sufficiently to increase O_2ER . In contrast, when epinephrine is compared with a short infusion (2 hours) of a combination of norepinephrine and dobutamine, it preferentially decreases splanchnic oxygen delivery, worsens pH_i, and increases systemic lactate concentration without increasing

VO₂. Methodologic limitations of many of these studies included nonrandomized crossover periods, potentially leading to pharmacologic carry-over; failure of patients to achieve a steady state before crossover, and the use of time-dependent response measures. It is also unclear whether patients were comparable at baseline—whether they had received the same or other vasoactive agents before the study period and for how long.⁷⁸

Since data on the effects of vasopressors on splanchnic circulation in humans are limited and are confounded by the use of multiple agents used concurrently, DeBacker and colleagues³⁸ conducted a study in which regional hemodynamic effects of three catecholamine vasopressors were evaluated individually in septic shock patients. A convenience sample of 20 patients with septic shock was divided into two groups: moderate shock, in which the MAP was >65 mm Hg with dopamine at doses between 10 and 20 mcg/kg per minute, and a severe group, in which MAP was less than 65 mm Hg. Following a stable dose of dopamine, patients were randomized either to norepinephrine or epinephrine initially and then the other agent following a period of at least 45 minutes with each agent. Systemic and regional measurements were taken for each drug. The moderate shock group revealed minimal differences between the agents. However, in the severe shock group, epinephrine resulted in a higher DO₂ and VO₂ but a lower absolute and fractional splanchnic blood flow. Although the PCO₂ gap was not different, indocyanine green (ICG) clearance was lower with epinephrine compared with norepinephrine. No detrimental effects on the splanchnic circulation were found with dopamine. This study concluded that epinephrine titrated to blood pressure in patients with severe septic shock causes deterioration in splanchnic circulation and induces changes in splanchnic metabolism. Given that these changes are likely deleterious, high-dose epinephrine should be avoided in severe septic shock patients.³⁸

Three other recent studies compared epinephrine with either norepinephrine alone or norepinephrine in combination with dobutamine to determine their comparative effects on systemic and regional hemodynamics and oxygen-transport variables.^{69,72,73} The first study was a prospective, randomized study of two parallel groups. Sequin and colleagues⁷² compared epinephrine with the combination of norepinephrine-dobutamine on gastric perfusion, systemic and pulmonary hemodynamics, hepatic function, and blood gases in 22 patients with septic shock. Epinephrine or norepinephrine was started at a dose of 0.1 mcg/kg per minute and increased by 0.2 mcg/kg per minute every 5 minutes to reach an MAP of 70 to 80 mm Hg. Dobutamine was infused continuously at 5 mcg/kg per minute. At the same increase in MAP, there was no significant difference in the systemic or pulmonary hemodynamic and blood gas variables between the treatment groups. Epinephrine tended to induce greater increases in cardiac index and oxygen transport compared with norepinephrine-dobutamine. Epinephrine also significantly increased gastric mucosal blood flow compared with norepinephrine-dobutamine without modifying ICG clearance. The effects seen with epinephrine were mostly likely the result of an increase in the cardiac index.

The two other studies are prospective, randomized crossover studies performed in dopamine-resistant volume-replete patients with septic shock.^{69,73} The design and results of the two studies are fairly similar. In the study by Duranteau and colleagues,⁶⁹ epinephrine and norepinephrine were titrated to an MAP of 70 to 80 mm Hg. Epinephrine and the combination of norepinephrine and dobutamine both produced a significant increase in heart rate compared with norepinephrine alone. Epinephrine also significantly increased the cardiac index and oxygen delivery compared with norepinephrine alone. Oxygen consumption and oxygen extraction did not change throughout the study. For the same level of MAP, epinephrine and

the combination of norepinephrine-dobutamine induced a greater increase in mucosal perfusion than did norepinephrine alone. The same ratio between gastric mucosal perfusion and DO₂ was observed with norepinephrine-dobutamine and with epinephrine or norepinephrine alone, but because the pH_i and PCO₂ improved more with norepinephrine-dobutamine than with epinephrine or norepinephrine alone, the differences were not statistically different. These results can be explained by the vasodilatory effect of dobutamine on gastric mucosal microcirculation resulting in a redistribution of blood flow toward the mucosa.⁶⁹ The results of this study suggest that epinephrine does not have beneficial effects on the gastric mucosa.

In the third study, dosages of dopamine, epinephrine, norepinephrine, and norepinephrine-dobutamine also were adjusted to an MAP of >70 mm Hg.⁷³ Epinephrine induced a significant increase in heart rate compared with the other three groups and a higher cardiac index compared with norepinephrine alone as well as with norepinephrine-dobutamine. There was no difference among the groups in DO₂ index. However, O₂ER values were lower with epinephrine infusion compared with the other three groups. Arterial lactate concentrations dropped significantly with norepinephrine-dobutamine as compared with dopamine and epinephrine infusions. Norepinephrine-dobutamine infusion was associated with a higher pH_i compared with epinephrine infusion, but the differences were not statistically significant. The difference between gastric and arterial PCO₂ with norepinephrine-dobutamine tended to be lower than that with dopamine, epinephrine, or norepinephrine alone. The authors concluded that for the same level of MAP as the therapeutic goal in patients with septic shock, the administration of dopamine, norepinephrine, epinephrine, or norepinephrine-dobutamine improved systemic hemodynamics effectively. However, epinephrine and dopamine had deleterious effect on oxygen metabolism, and similar to the study by Duranteau and colleagues, norepinephrine-dobutamine improved gastric mucosal perfusion and tissue oxygen utilization. Again, this study reinforces some undesirable effects of epinephrine on regional hemodynamics and oxygen utilization.

6 It is important to note that despite the large doses used in all the studies discussed, clinically important dysrhythmias or cardiac ischemia were reported rarely in patients of any age or underlying cardiac status. Nevertheless, caution must be exercised before considering epinephrine in managing hypoperfusion in hypodynamic patients with CAD, in whom ischemia, chest pain, and myocardial infarction may result. Based on the current evidence, epinephrine should be avoided in septic shock. Although it effectively increases cardiac output and oxygen delivery, it has deleterious effects on the splanchnic circulation. If it is used as a second-line agent in septic shock, factors that may influence successful therapy with epinephrine may include the time from the onset of septic shock to effective therapy and the age of the population.

EXPERIMENTAL THERAPIES

NITRIC OXIDE SYNTHASE INHIBITORS

Nitric oxide (NO) is a short-acting, potent vasodilator derived from the enzymatic oxidation of arginine. Its production is under control of nitric oxide synthase (NOS). This enzyme is present (expressed) in two forms: a constitutive form (eNOS) and an inducible form (iNOS). Small amounts of NO normally are produced by the vascular endothelium under the control of eNOS for the physiologic control of vascular tone and blood flow distribution. Under pathophysiologic

conditions such as stimulation by lipopolysaccharide or cytokines, iNOS becomes diffusely expressed, producing large amounts of NO. The latter has been implicated in the cardiovascular failure of septic shock.^{79,80}

Pharmacologic inhibition of NO production has been investigated as an adjunct to standard therapies of septic shock. L-Arginine analogs such as monomethyl-L-arginine (L-NMMA) and L-arginine-methylester (L-NAME) are competitive inhibitors of NOS and have been shown to increase blood pressure and partially restore vascular reactivity in experimental and human septic shock.⁸¹ However, because these arginine analogs nonselectively block eNOS and iNOS, their use has been associated with extensive vasoconstriction, decreased cardiac output, and regional hypoperfusion, thus promoting organ failure and mortality.^{79,80} Some *S*-substituted thiourea derivatives have demonstrated both in vitro and in vivo (rodent) dose-dependent selectivity for iNOS inhibition. Recently, Rosselet and associates⁷⁹ demonstrated that low doses (0.1 mg/kg per hour) of *S*-methyl-isothiourea (SMT), a selective inhibitor of NO, were superior to norepinephrine in the treatment of rat endotoxic shock. These doses of SMT prevented hypotension by maintaining cardiac index without increasing the SVR index, as did norepinephrine. However, only low doses of SMT limited the development of lactic acidosis.

CORTICOSTEROIDS

The use of corticosteroids in the treatment of septic shock has been a topic of controversy for many years. A meta-analysis of early studies of steroids in sepsis demonstrated a lack of benefit and potential harm in sepsis and septic shock.^{82,83} There is a renewed interest in corticosteroid use because of the increased awareness of adrenocortical insufficiency in critically ill patients with septic shock.⁸⁴ Relative adrenal insufficiency has been defined as a poor adrenal response [<250 nmol/L (9 mcg/dL) irrespective of the initial serum cortisol level] to a dose of synthetic adrenocorticotropic hormone (ACTH), indicating a low functional reserve of the adrenal cortex.⁸⁴ Although absolute insufficiency is rare, relative adrenocortical insufficiency in the presence of normal or high cortisol concentrations at baseline is present in 30% to 50% of patients with septic shock and is associated with a poor outcome.⁸⁵

Since the two meta-analyses in 1995, five prospective, randomized, controlled trials of low-dose corticosteroids in vasopressor-dependent septic shock patients ($n = 505$) have been published.^{86–90} These studies used moderate physiologic doses (200 to 300 mg/day) of hydrocortisone. A meta-analysis of these studies showed that steroid therapy was associated with an overall improvement in survival rate (odds ratio [OR] 1.52, 95% confidence interval [CI] 1.03–2.27; $p = .036$) and shock reversal (OR 4.79, 95% CI 2.07–11.11; $p = .001$). These effects were beneficial in both responders and nonresponders to corticotrophin stimulation testing ($p = .63$ and $p = .75$, respectively).⁹¹ These studies also showed that low-dose corticosteroid administration improves hemodynamics and reduces the duration of vasopressor support.^{86–90} All these studies differ from earlier studies in that steroids were administered later in septic shock (23 hours versus less than 2 hours; $p = .02$). In these studies, steroids were administered longer (6 days versus 1 day; $p = .004$), doses were tapered, lower doses were used (hydrocortisone equivalents 1209 mg versus 23,975 mg; $p = .01$), all patients received high doses of catecholamine vasopressors, and control groups had higher mortality rates (mean 57% versus 34%; $p = .03$).⁹¹ Since only one of the five studies showed a mortality benefit of low-dose steroids in septic shock, further research is required to confirm this finding.⁹⁰

In order to understand further the interaction between vasopressors and corticosteroids, Bellissant and colleagues⁹² evaluated the hydrocortisone-phenylephrine MAP dose-response relationship in 12 septic shock patients within 3 hours of ICU admission and in normal controls.⁹² The hyporesponsiveness to phenylephrine was related to alterations in vascular and not central activity (no alteration in baroreflex sensitivity). The corticosteroid effects were deemed not to be related to sympathetic or renin-angiotensin system activation nor to NO pathways because no significant relationship was found between pharmacodynamic parameters and circulating catecholamines, renin, aldosterone, or nitrite/nitrate concentrations. More indirect mechanisms or effect on adrenergic receptor activity could not be excluded by the methods used by the investigators. Current proposed mechanisms of the vasoconstrictor effect of corticosteroids may include increasing the number and stimulating the function of α_1 - and β -adrenergic receptors. In addition, corticosteroids may attenuate the production of mediators responsible in part for the vasodilatation and hyperdynamic state of sepsis (perhaps indirectly through inducible NO inhibition and/or improved binding affinity of the cortisol receptor).⁹³

Given the current data, corticosteroids may be administered to patients with septic shock on high doses of vasopressors for prolonged periods of time if (1) reversible causes of hypotension are eliminated, (2) relative/absolute corticosteroid deficiency is determined with corticotropin stimulation testing, and (3) corticosteroids are used for at least 5 to 7 days and then are reduced progressively.⁸⁴

VASOPRESSIN

Vasopressin is emerging as a potentially useful therapy in the hemodynamic support of vasodilatory septic shock. Case series and small clinical trials have reported its use in patients who remain hypotensive on vasopressors.^{94,95} Arginine vasopressin has little pressor activity in normal subjects but markedly increases blood pressure when sympathetic nerve function is impaired, including in septic shock. Unlike the catecholamine vasopressors, vasopressin is a direct vasoconstrictor agent and does not have inotropic or chronotropic effects. As a result, it may decrease cardiac output and hepatosplanchnic flow. In fact, studies of vasopressin in septic shock generally do not enroll patients with a cardiac index of less than 2 to 2.5 L/m² per minute.

The term *relative vasopressin deficiency* is used to describe the fact that vasopressin concentrations appear to be elevated early in septic shock and then fall to normal or low concentrations as shock progresses.⁹⁶ Normally, in the presence of hypotension, vasopressin concentrations would be expected to be elevated. Thus vasopressin administration in low “replacement” doses (0.01–0.04 unit/min) to patients with vasodilatory septic shock receiving high doses and long courses of norepinephrine successfully increases arterial blood pressure and SVR index. In addition, vasopressin has been shown to increase urine flow rates most likely owing to increased renal perfusion and arterial pressure. In the majority of patients in case series, vasopressor therapy (e.g., norepinephrine or dopamine) was tapered successfully and discontinued early. No clinical or laboratory signs of cardiac or mesenteric ischemia were observed, nor was PAOP or oxygenation adversely affected.⁹⁵ In a double-blinded, placebo-controlled trial in vasodilatory shock in trauma patients requiring vasopressors, a vasopressin infusion (0.04 unit/min) significantly improved arterial pressure owing to peripheral vasoconstriction and permitted the withdrawal of catecholamine vasopressors (norepinephrine, phenylephrine, and/or dopamine).⁹⁷ All patients receiving vasopressin survived the 24-hour study period and had all other

catecholamine vasopressors withdrawn and blood pressure maintained solely with a low-dose vasopressin infusion.

Although vasopressin may be a useful agent in the treatment of refractory septic shock in low doses, it should not be used in doses exceeding 0.04 unit/min and/or in patients with hypovolemia, cardiogenic shock, or septic shock with myocardial depression because cardiac output may be adversely affected, including the development of myocardial ischemia and cardiac arrest.^{94,97–99} There is concern that vasopressin may have deleterious effects on the hepatosplanchnic circulation in humans.³ In addition, there are no randomized, blinded, placebo-controlled trials showing improvement in long-term outcomes such as mortality and length of hospital stay. The Canadian Critical Care Trials Group is conducting such a study, and results are expected in 2005. Until further safety data and larger efficacy trials are completed, vasopressin is not recommended as a replacement for norepinephrine or dopamine in septic shock but may be considered in patients who are refractory to catecholamine vasopressors despite adequate fluid resuscitation and should be administered in doses not exceeding 0.01–0.04 unit/min.⁴

TERLIPRESSIN

Terlipressin, a prodrug converted into lysine vasopressin, has been used recently in septic shock patients.¹⁰⁰ This drug has a half-life of 6 hours and acts via vascular V_{1a} receptors and renal tubular V_2 receptors.³⁷ In one report, terlipressin 1 mg was given intravenously to 15 patients with norepinephrine-resistant septic shock.¹⁰¹ Terlipressin was shown to increase MAP at 30 minutes, which lasted for 24 hours. Despite a decrease in cardiac output, terlipressin increased gastric mucosal perfusion, urine output, and creatinine clearance. These preliminary findings suggest that a clinical trial should be conducted that evaluates mortality, in addition to hemodynamic effects.

LEVOSIMENDAN

Levosimendan is a novel inotropic calcium-sensitizing drug. In advanced congestive heart failure, it improves cardiac contractility by sensitizing troponin C to calcium. It has been used recently in a porcine model of endotoxin-induced septic shock, in which pretreatment with levosimendan improved cardiac output and systemic and gut oxygen delivery.¹⁰² There are currently two ongoing clinical trials of levosimendan in septic shock. The role of levosimendan in the supportive management of circulatory failure in sepsis remains to be determined.

GENERAL CONCLUSIONS AND RECOMMENDATIONS

The choice of vasopressor or inotropic agent in septic shock should be made according to the needs of the patient (Fig. 23–3). The traditional algorithm suggests a stepwise approach first using dopamine and then norepinephrine; dobutamine is added for low cardiac output states, and occasionally, epinephrine and phenylephrine are used when necessary. Although this approach is empirical, it is used broadly in clinical practice and has been justified by a desire to avoid strong vasoconstriction and by the sense of safety resulting from graded doses of dopamine. This dose-response relationship, however, has never been established in the critically ill. In addition, recent observations of improved outcomes with norepinephrine and decreased regional perfusion with dopamine are calling into question the use of dopamine as a first-line agent.

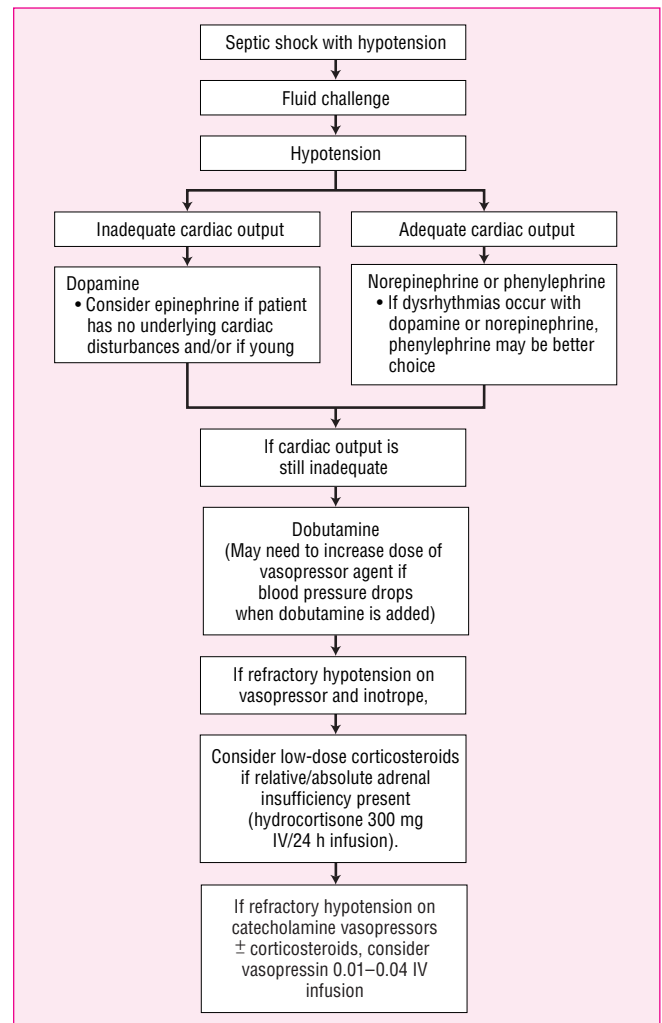

FIGURE 23–3. Algorithmic approach to the use of vasopressors and inotropes in septic shock. Algorithmic approach is intended to be used in conjunction with clinical judgment, hemodynamic monitoring parameters, and therapy end points, as discussed in the text. (Modified from ref. 3.)

Although goal-directed therapies to supranormal values cannot be recommended, developing a strategy to titrate therapy early in the course of illness to normal values is an acceptable approach. For all catecholamine vasopressors, larger doses than those recommended traditionally are required for goal-directed therapy to MAP and for normalization of oxygen-transport variables, DO_2 , and VO_2 . Attainment of supranormal DO_2 and VO_2 values is difficult in most patients, even if large doses are used. Patients who develop supranormal DO_2 and VO_2 values have a lower mortality, but whether this is achieved intrinsically or with exogenous administration of vasopressors/inotropes appears inconsequential. Goal-directed therapy to supranormal oxygen-transport variables therefore cannot be recommended because little or no benefit has been demonstrated to date. Further work is required to better elucidate the differential effects of vasopressors on regional hemodynamic and oxygen-transport values as measures of local tissue perfusion.

The algorithmic approach (see Fig. 23–3) that we recommend regarding the use of vasopressors and inotropes in the hemodynamic support of critically ill septic patients is consistent with the recommendations made in the Surviving Sepsis Campaign⁴ and the

American College of Critical Care Medicine's guidelines for the hemodynamic support of adult patients with sepsis.¹⁰³ Although difficult to demonstrate, there may be true differences in clinical outcomes as a result of differences in the pharmacologic activity of vasopressors and inotropes. For example, recent evidence suggests that when used appropriately with fluid replenishment, norepinephrine is safe and effective in treating septic shock; it decreases mortality, particularly when started early in the course of septic shock. It is effective in optimizing hemodynamic variables and improving systemic and regional (e.g., renal, gastric mucosal, and splanchnic) perfusion likely owing to its β_2 vasodilatory effects. Epinephrine causes a greater increase in cardiac index and DO_2 and increases gastric mucosal flow but may not preserve splanchnic circulation adequately owing to its predominant vasoconstrictive α effects. Epinephrine may cause a short-lived increase in lactic acid. This resolves in 24 hours, and no difference in clinical outcome has been documented. Epinephrine may be particularly useful when used earlier in the course of septic shock in young patients and in those who do not have any known cardiac abnormalities. Unlike epinephrine, dopamine does not preferentially increase the proportion of cardiac output that preferentially goes to the splanchnic circulation. The ability of dopamine to increase cardiac output by no more than 35% accompanied by a tachycardia or tachydysrhythmias limits its utility. Dopamine, as opposed to norepinephrine, has been shown to worsen splanchnic VO_2 and O_2ER and to be of limited value in improving urine output. Low-dose dopamine has not been shown consistently to increase the glomerular filtration rate, does not prevent renal failure, and indeed worsens splanchnic tissue oxygen utilization. Low-dose dopamine should not be used. Phenylephrine should be used when a pure vasoconstrictor is desired in patients who may not require or do not tolerate the β effects of dopamine or norepinephrine with or without dobutamine. In patients with a high filling pressure and hypotension, the combination of phenylephrine and dobutamine may be useful.

Shortcomings of study methodology, however, prevent the establishment of definitive conclusions. The consequences are that published guidelines for the management of severe sepsis and septic shock use many grade E (expert and consensus opinion, case series, case reports) recommendations. Short infusions (not exceeding 2 hours) during studies may show differences that are not clinically significant at 24 hours or more, as demonstrated for epinephrine and dobutamine. Clinically, vasopressors and inotropes are used for hours to days. Also, variable times at which a study is initiated with respect to the stage of sepsis or septic shock, the inherent differences in circulating catecholamine concentrations, and changes in receptor activity all may be confounding factors, as may be the prestudy duration and type of exogenous catecholamine administration.

Recent data with moderate doses of corticosteroids (200 to 300 mg/day) infused over 5 to 7 days may reverse septic shock and dependency on vasopressor agents, particularly in patients with relative adrenal insufficiency. Data are still needed regarding optimal dosing and the effect on outcomes such as mortality. Initial uncontrolled studies with vasopressin suggest a potential role in the management of vasopressor-refractory septic shock patients, although further data are needed.

Further pharmacotherapeutic and outcomes studies are still required to elucidate the place in therapy that individual vasopressors and inotropes or their combinations occupy in the supportive care of patients with bacteremia or septic shock. As supportive therapy, it is imperative that primary therapy aimed at the source of (antimicrobials) and consequences of (anticytokines) infection be initiated quickly to afford the patient the best chance of survival. Once this is accomplished, then we will need to direct our efforts to pharmacoeconomics and the cost-effectiveness of these therapies.

ABBREVIATIONS

cAMP: cyclic adenosine monophosphate
 CaO_2 : arterial oxygen content
 CI: cardiac index
 CvO_2 : venous oxygen content
 CHF: congestive heart failure
 DO_2 : oxygen delivery
 LVEF: left ventricular ejection fraction
 LVSWI: left ventricular stroke work index
 MAP: mean arterial pressure
 O_2ER : oxygen extraction ratio
 PaO_2 : arterial oxygen tension
 $PaCO_2$: arterial carbon dioxide tension
 (M)PAP: (mean) pulmonary artery pressure
 PAOP: pulmonary artery occlusion pressure
 PEEP: positive end-expiratory pressure
 SVR: systemic vascular resistance
 TNF- α : tumor necrosis factor α
 VO_2 : oxygen consumption

HYPOVOLEMIC SHOCK

Brian L. Erstad

Learning Objectives and other resources can be found at www.pharmacotherapyonline.com.

KEY CONCEPTS

- 1 Plasma does not have to be lost from the body for hypovolemic shock to occur.
- 2 Patients may die from hypovolemic shock despite having normal serum electrolyte concentrations.
- 3 While the Starling equation of fluid transport is useful for understanding the factors involved in fluid shifting between compartments, it is not a practical tool for use in the clinical setting.
- 4 Patients may have complications and death owing to reperfusion injury, as well as the initial insult.
- 5 The clinical presentation of patients with hypovolemic shock can vary substantially depending on concomitant disease states, medications, and cause of hypovolemia.
- 6 The initial monitoring of a patient with suspected volume depletion always should include vital signs, urine output, mental status, and physical examination.
- 7 The need for intravenous rehydration in children is often overestimated.
- 8 Crystalloid (sodium-containing) solutions should be used for most forms of circulatory insufficiency that are associated with hemodynamic instability.
- 9 Crystalloid solutions are preferred over colloid solutions for circulatory insufficiency owing to decreased plasma volume.
- 10 With adequate fluid administration, medications usually are not needed for the patient with circulatory insufficiency owing to decreased plasma volume.

This chapter discusses the assessment and management of hypovolemic shock. Depending on the classification scheme being used for shock, spinal and anaphylactic shock may be considered separately from hypovolemic shock because fluid loss from the body is not necessary for their occurrence. For example, there are distributive forms of shock, such as spinal shock resulting from loss of sympathetic activity, and anaphylactic shock, resulting from increased vascular permeability.¹ Although these forms of shock are not discussed in detail, it is important to note that the initial therapy for both is the same as for hypovolemic shock (i.e., adequate volume replacement) because circulating volume is decreased. In this regard, adequate fluid resuscitation to maintain circulating blood volume is a common principle in managing all forms of shock.

EPIDEMIOLOGY

It is estimated that approximately 1 million deaths per year occur in the United States in patients with shock.² The number is much higher when one considers that all causes of death ultimately result in circulatory failure (i.e., the last stage of shock). It is much more difficult to estimate the number of patients with reversible organ dysfunction or patients with end-organ damage who survived an episode of hypovolemic shock. Part of the problem is defining when progressive circulatory insufficiency results in the loss of normal compensatory responses by the body, which could reverse the processes leading to irreversible organ dysfunction. This loss of appropriate compensation varies from patient to patient and is not always readily apparent during the initial patient presentation.

ETIOLOGY

1 Hypovolemic shock may result from a number of problems, including plasma loss, sequestered fluid within a compartment in the body (e.g., third-spacing), thermal injury, and various forms of dehydration. Plasma loss may occur from hemorrhage or from sustained gastrointestinal or urinary losses that are insufficiently replaced. In some cases, such as in postoperative patients, a number of these problems may occur at the same time. For example, a patient may have had blood loss secondary to trauma or surgery, with additional fluid being third-spaced postoperatively. The third-spaced fluid may occur as tissue edema in the gastrointestinal tract with a concomitant ileus. As the example of third-spaced fluid indicates, fluid (i.e., plasma) does not have to be lost from the body for a person to develop hypovolemic shock.

Dehydration may result from primary water deficiency, usually because of decreased intake, but in some instances (e.g., diabetes insipidus) it may result from increased losses of water. In general, the term *dehydration* implies intracellular and interstitial fluid depletion, in contrast to *volume depletion*, which implies extracellular, and particularly intravascular, sodium and water loss. In the case of primary water deficit, cell dehydration occurs, with delayed circulatory failure from decreased circulatory volume with ongoing losses.³ Initially, the patient may be thirsty and possibly have some mental status changes, such as confusion. If the cellular dehydration occurs slowly, intracellular substances, referred to as *idiogenic osmols*, develop that limit progressive complications (e.g., cerebral edema or coma). With combined water and salt deficiencies, such as might occur with gastrointestinal

losses (e.g., diarrhea), interstitial and intravascular depletion is an early occurrence. Fortunately, dehydration is relatively easy to prevent with routine vigilance and water replacement compared with some of the other causes of shock.

PATHOPHYSIOLOGY

2 Hypovolemic shock is often described in terms of monitoring parameters such as lowered blood pressure, but patients with shock may die despite normal surrogate markers of circulatory insufficiency. Therefore, an appropriate definition should mention the underlying problem, which is inadequate tissue perfusion resulting from circulatory failure. In the case of hypovolemic shock, the cause of the altered perfusion is fluid (or volume) depletion resulting from trauma, surgery, thermal injury, or some form of dehydration. Figure 24–1 provides a simplified view of the pathophysiology of circulatory insufficiency. Cell damage and death may occur from the primary insult or from reperfusion injury. The latter problem is associated most frequently with trauma and blood loss that cause the release of a multitude of mediators of inflammation and injury that have complex interactions. Cells have varying responses to hypoxia, ranging from astrocytes that quit functioning almost immediately to hepatic cells that may function for several hours after injury.³ Left unmitigated, cell death occurs.

The body attempts to compensate for volume depletion beginning with autoregulatory changes involving smaller blood vessels. When the cause of circulatory insufficiency continues unabated, local mechanisms eventually fail to provide adequate compensation, and macrocirculatory changes ensue. Approximately 75% of blood volume is contained in venous capacitance vessels, with gravity being the major impediment to flow back to the heart.³ With increasing volume depletion, blood flow to the heart (preload) is decreased, with subsequent activation of baroreceptors and chemoreceptors leading to sympathetic discharge. Also, fluid shifting from the interstitial space to the intravascular space occurs through a phenomenon known as *transcapillary refill*, and hormones (e.g., adrenocorticotropic hormone, angiotensin, catecholamines, and vasopressin) that cause sodium and water retention by the kidneys are released. The phenomenon of transcapillary refill means that the body can have fluid losses exceeding normal plasma volume. These responses cause alterations in stroke volume, heart rate, and peripheral vascular resistance so that blood pressure and hence tissue perfusion can be maintained.

The microcirculatory changes associated with shock are complex and difficult to study. Although some mediators such as endothelin-1 cause vasoconstriction, other mediators, such as adenosine and nitric oxide, yield vasodilation.⁴ These changes result in hypoperfusion or hyperperfusion depending on the area. As these microcirculatory changes fail to maintain adequate organ perfusion, more widespread sympathetic nervous system activation and vasoconstriction ensue.

The factors involved in fluid shifting between the intravascular and interstitial spaces are described by the modified Starling equation:

$$J_v = K_{f,c} [(P_c - P_t) - \sigma(\pi_c - \pi_t)]$$

where J_v = net transvascular flow rate (cannot be measured in the clinical setting)

$K_{f,c}$ = capillary filtration coefficient for fluids (cannot be measured in the clinical setting)

P_c = capillary hydrostatic pressure (indirectly estimated in the clinical setting, e.g., pulmonary artery occlusive pressure)

P_t = tissue hydrostatic pressure (cannot be measured in the clinical setting)

σ = reflection coefficient for proteins (cannot be measured in the clinical setting)

π_c = plasma colloid osmotic pressure (not usually measured in the clinical setting, but technology is available)

π_t = tissue colloid osmotic pressure (cannot be measured in the clinical setting)

Proteins act as oncotic agents in each of these spaces to attract fluid, whereas hydrostatic forces push fluid into or out of the vessels. The equation has distinct permeability values for water and protein because each crosses the vascular membrane at a different rate.

3 Although the Starling equation is useful to practitioners in terms of understanding the factors involved in fluid shifting between compartments, the rate and direction of transvascular flow cannot be calculated accurately in the clinical setting because most factors cannot be measured directly.

The body’s compensatory mechanisms may have beneficial and harmful consequences. For example, if preload is not substantially decreased, cardiac output can be increased approximately fivefold by increases in stroke volume or heart rate.¹ Although this may be useful for providing blood flow to inadequately perfused tissues, it may cause large (e.g., fourfold) increases in oxygen consumption by the heart that could aggravate preexisting ischemia in patients with underlying coronary artery disease (CAD). Another example is the sympathetic nervous system–mediated vasoconstriction that causes blood to shift

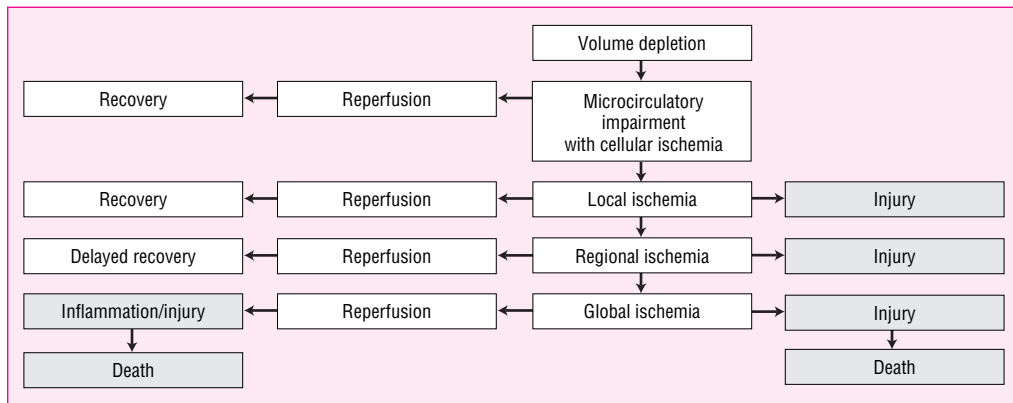

FIGURE 24–1. Pathophysiology of circulatory insufficiency.

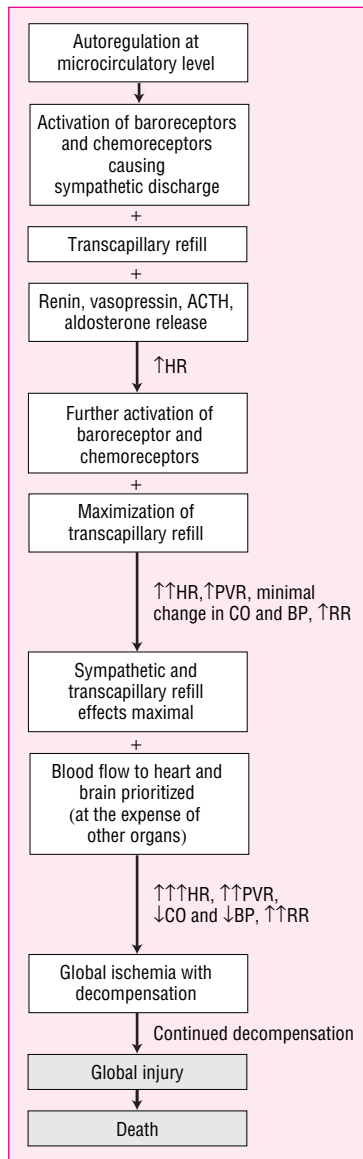

FIGURE 24–2. Activation of compensatory mechanisms with loss of circulatory volume. Certain stages may be absent depending on a number of factors, such as age, preexisting disease states, and cause of circulatory insufficiency. BP = blood pressure; CO = cardiac output; HR = heart rate; PVR = peripheral vascular resistance; RR = respiratory rate.

from the skin, skeletal muscle, and some internal organs such as the kidneys and gastrointestinal tract to organs (e.g., heart and brain) that are less tolerant of inadequate flow. If the vasoconstriction continues unabated, the hypoperfused organs eventually become damaged. Figure 24–2 provides an overview of the compensatory changes that occur with a loss of circulating blood volume.

4 In addition to the more acute implications of hypovolemia and attendant complications, reperfusion damage is likely to occur particularly after prolonged resuscitation attempts. In addition to oxygen free radical damage of cell membranes, a number of cellular (e.g., white blood cells and platelets) and humoral (e.g., procoagulants, anticoagulants, complement, and kinins) components are activated, causing the release of other inflammatory mediators.⁴ The resulting reperfusion injury may range from readily reversible organ dysfunction to multiple-organ failure and death.

Although the basic pathophysiology is similar for the various causes of hypovolemic shock, there are unique considerations relative to each. For example, whereas isolated head injuries associated with trauma typically do not result in substantial blood loss or shock, pelvic fractures may sequester several liters of blood as hematoma formation.⁵ Patients with traumatic or thermal injuries, as well as postoperative patients, may have substantial fluid accumulation in sites where it cannot be readily transferred back into blood vessels (i.e., third-spaced fluid) for maintaining pressure. With these types of injuries, prompt control of compressible bleeding sources with rapid patient transfer to the hospital for definitive treatment may preclude the cascade of events leading to shock. Indeed, with trauma patients, a “scoop and run” approach is used in most urban hospitals that places a priority on rapid transport to a hospital.⁶

In the case of hemorrhagic shock, prompt attention must be given to cell, as well as plasma, losses. Red blood cells lost during the bleeding episode may lead to ischemic damage in vital organs. Packed red blood cell transfusions may be needed to increase the oxygen-carrying capacity of the blood because oxygen transport is a function not only of cardiac output but also of hemoglobin concentration and saturation and of hemoglobin affinity for oxygen.

Clotting factors and platelets are also lost in hemorrhage. The resulting bleeding problems may be aggravated by the dilutional effect of fluid resuscitation on clotting factor activity. Fresh-frozen plasma that contains necessary clotting factors and platelets is often needed in massive blood loss to restore adequate coagulation. On the other hand, trauma patients are at increased risk for deep venous thrombosis and pulmonary embolism caused by multiple factors, including vessel damage, abnormal blood flow patterns, and the hypercoagulable state associated with injury. Therefore, some form of venous thromboembolism prophylaxis usually is indicated in multiple-trauma patients or patients with severe single-system injuries (e.g., spinal cord damage).

The pathophysiology becomes more complicated if the severity of shock is sufficient to require admission to the intensive care unit (ICU) after initial resuscitation or surgery. Most patients admitted to the ICU have a systemic inflammatory response syndrome (SIRS), which is the body’s response to injury. This syndrome is defined by a number of hypermetabolic changes reflected in the patient’s temperature, white blood cell count and differential, and respiratory and heart rates. The stress response involves complex interactions between the nervous system and immunomodulating substances and has similar (if not the same) harmful and helpful consequences described with reperfusion following shock.⁷ If the underlying problems are left untreated, the patient with SIRS may develop multiple-organ dysfunction syndrome (MODS) during the final stages of illness.

CLINICAL PRESENTATION

5 The initial presentation of patients with suspected volume depletion can vary markedly depending on factors such as age, concomitant disease states and medications, and the etiology and rapidity of depletion (see Clinical Presentation box at the end of this chapter). Intravascular depletion as a consequence of blood loss is signified by postural vital sign changes, and such measurements should be performed unless the diagnosis is obvious, as in the case of bleeding associated with trauma.⁸ Early signs and symptoms of dehydration and intravascular depletion caused by gastrointestinal or urinary losses often are relatively nonspecific. Plasma volume losses of less than 10 mL/kg of body weight usually are associated with minor signs

TABLE 24–1. Acute Circulatory Insufficiency: Initial Presentation and Therapy*

| | Mild | Severe |
|--------------------------------------|---|--|
| Plasma/blood loss | 10 mL/kg adult 20 mL/kg child | 30 mL/kg adult 35 mL/kg child |
| Mental status/level of consciousness | None—small changes (e.g., anxious, irritable) | Marked changes (e.g., confusion to unconscious) |
| Vital signs/orthostatic changes | Minor changes | Marked changes |
| Therapy | 20 mL/kg lactated Ringer's IV* over 10–15 min Unlikely to need blood cell replacement even if hemorrhagic loss | Lactated Ringer's IV as rapidly as possible until response in adult, then decrease rate of infusion 20 mL/kg lactated Ringer's IV in child (repeat quickly if minimal response); likely to need blood cell replacement and surgery if hemorrhagic |

*Patients may have intermediate degrees of volume loss in addition to those listed, but the amount of loss is often difficult to quantify. The presentations may also vary greatly in patients with similar amounts of loss (young athlete vs sedentary, elderly person). Refer to text for a more in-depth discussion of some of the guidelines in this table.

and symptoms of distress. Larger losses are not likely to be well tolerated (Table 24–1), particularly in patients older than 65 years of age. An 18-year-old athlete and a 65-year-old sedentary individual are likely to have a much different response to a similar amount of fluid loss. The young patient may lose one-fourth of his or her circulating blood volume with minimal changes in arterial blood pressure and a relatively low heart rate. However, the elderly patient may have orthostatic changes in blood pressure that are not well tolerated by organs such as the kidneys.³ Unfortunately, this same elderly patient may not have common signs and symptoms of volume depletion such as skin turgor changes or thirst but instead may have more subtle changes (e.g., mental status alterations).⁹

CLINICAL PRESENTATION OF HYPOVOLEMIC SHOCK

GENERAL

- The initial presentation of adult patients with suspected volume depletion could vary markedly depending on factors such as age, concomitant disease states and medications, and the etiology and rapidity of depletion.
- Plasma volume losses of less than 10 mL/kg of body weight usually are associated with minor signs and symptoms of distress.

SYMPTOMS

- Patients may present with thirst, nausea, anxiousness, weakness, light-headedness, and dizziness.
- Patients may report scanty urine output and dark-yellow-colored urine.

SIGNS

With more severe volume loss:

- Patients would have marked increases in heart rate (e.g., >120 beats per minute) and respiratory rate (e.g., >30 breaths per minute).
- Blood pressure would be decreased (e.g., systolic blood pressure < 90 mm Hg).
- Mental status changes or unconsciousness may occur.

- Agitation may be present if the patient is conscious.
- Body temperature would be low or normal [e.g., 36° to 37°C (96.8° to 98.6°F)] in the absence of concomitant infection.

LABORATORY TESTS

- The sodium and chloride concentrations are usually high with acute depletion but may be low or normal depending on type of fluid intake.
- The blood urea nitrogen (BUN) to creatinine ratio is likely to be elevated initially, but the creatinine would increase as renal dysfunction occurs.
- The complete blood count should be normal in the absence of concomitant disease states such as infection; in hemorrhagic shock, the red cell count, hemoglobin, and hematocrit would decrease over time.
- With more severe volume depletion, other organs may become dysfunctional, which may be reflected in laboratory testing (e.g., elevated transaminases with hepatic dysfunction).

OTHER DIAGNOSTIC TESTS

- Urine output would be decreased to less than 0.5 to 1 mL/hour.

The diagnosis of dehydration and intravascular depletion in children is complicated by difficulties in obtaining an accurate history. In younger children, parental observations are important for estimating fluid deficits and deciding whether hospitalization is necessary. Fortunately, there are prospective data that suggest that parental histories are predictive of acidosis and the need for hospitalization.¹⁰

6 Regardless of patient age or preexisting conditions, the initial monitoring of a patient with suspected volume depletion should include the following noninvasive parameters: vital signs, urine output, mental status, and physical examination (Fig. 24–3).

While the presenting signs and symptoms of circulatory insufficiency are variable, patients usually will have decreased blood pressure, increased heart and respiratory rates, and a normal or low-normal temperature (e.g., 36° to 37°C [96.8° to 98.6°F]) in the absence of infection, exposure to extremes of temperature, and medications that

FIGURE 24-3. Noninvasive assessment of circulatory insufficiency.

impair thermoregulation. As mentioned earlier, recordings of vital signs must be interpreted in light of known or suspected baseline conditions. For example, alcohol, β -blockers, butyrophenones such as haloperidol, diuretics, and medications with anticholinergic effects may impair thermoregulation.¹¹ Medications such as β -blockers and calcium channel blockers may alter resting blood pressure and heart rate, as well as the subsequent response to therapeutic interventions.

Although a blood pressure reading of 110/70 mm Hg (systolic/diastolic) may be acceptable in many patients, it may be inadequate in a patient with preexisting hypertension who normally has a blood pressure of 170/105 mm Hg. At the other extreme, patients with very low blood pressure may have inaudible or inaccurate determinations with cuff (sphygmomanometric) measurements. Chapter 13 details

blood pressure measurement (e.g., cuff size, position). In this case, intraarterial monitoring is indicated. As a noninvasive tool, the respiratory rate may correlate better than the heart rate with volume loss, but respiratory rate often is not used.³ The respiratory rate may be elevated because of anxiety or as a compensatory mechanism for the metabolic acidosis caused by lactic acidosis associated with poor tissue perfusion.

Although the kidneys continually produce urine, the bladder stores the urine for intermittent elimination. For the initial diagnosis and management of acute circulatory insufficiency, a catheter can be inserted into the bladder for measuring urine output. In contrast to thirst, which is a relatively insensitive indicator of volume depletion, urine output is generally diminished with inadequate fluid administration and increases with appropriate resuscitation. This presumes, of course, that acute renal failure or medications such as diuretics are not altering the expected response. Adults should produce at least 0.5 to 1 mL/kg per hour of urine, whereas children up to 12 years of age should produce at least 1 mL/kg per hour (2 mL/kg per hour if younger than 1 year of age).⁵

Mental status changes associated with volume depletion, if present, may range from subtle fluctuations in mood to unconsciousness. Although the latter finding typically is indicative of more severe depletion, less dramatic findings should not be interpreted as indicating mild fluid deficits. Losses of 4 L of plasma volume may be associated only with lassitude in an otherwise healthy adult patient.³ Similar interpretation difficulties must be considered when performing the initial physical examination. An orderly progression from warm, reddish skin with appropriate capillary refill (rapid return of blood flow to the extremity after removal of compression) to cold, cyanotic discoloration with impaired refill may not occur. Also, dry mucous membranes in elderly patients may be caused by mouth breathing or anticholinergic medications and not by fluid depletion.⁹

► TREATMENT: Hypovolemic Shock

■ DESIRED OUTCOME

The desired outcomes of therapy for circulatory insufficiency that has led to hypovolemic shock are to prevent further progression of the disease with subsequent organ damage and, to the extent possible, to reverse organ dysfunction that has already taken place.

■ GENERAL APPROACH TO TREATMENT

Milder forms of volume depletion may be managed in outpatient settings. For example, supplemental fluids can be added to the usual estimated daily requirements of 30 to 35 mL/kg in patients older than 12 years of age with dehydration. Commercially available carbohydrate/electrolyte drinks generally are more palatable than water and may promote earlier recovery.⁹ When the dehydration involves substantial losses of salt as well as water, additional sodium may need to be added to these drinks because they usually contain 50 mEq/L or less of sodium. This is less than the amounts of sodium (e.g., 90 to 120 mEq/L) generally recommended for rehydration.¹² The additional sodium will increase osmolarity, but this does not appear to delay gastric emptying.¹³ Also, guidelines for oral rehydration of children with acute diarrhea are available, which, if used appropriately, may prevent future hospitalization.¹⁴ Intravenous rehydration of

children in outpatient settings has been accomplished, but patients must be selected carefully.¹⁵ Outpatient rehydration of children usually is recommended for those with uncomplicated (e.g., vomiting less than 48 hours) acute gastroenteritis and relatively mild dehydration after the exclusion of more severe illnesses such as bowel obstruction.

◀ The need for intravenous rehydration often is overestimated. In a randomized trial conducted in a pediatric emergency department, children receiving oral rehydration for acute gastroenteritis had shorter lengths of stay than those receiving intravenous rehydration (225 versus 358 minutes; $p < .01$).¹⁶ Furthermore, there was a trend toward decreased hospital admissions in the oral compared with the intravenous rehydration group (11% versus 25%; $p = .2$).

Hospitalization is indicated in more severe forms of circulatory insufficiency. If access to the circulatory system for fluids and medication administration was not obtained prior to hospitalization, this should be a priority. Venous access generally is obtained during the preliminary examination process that includes the ABCs of life support (i.e., airway, breathing, and circulation), assessment of vital signs and mental status, and determination of urine output after catheterization. Whenever large-volume fluid resuscitation is expected, as in hemorrhagic shock, it is desirable to have at least two intravenous catheters. Because flow is a function of tubing length and catheter diameter, large-bore peripheral intravenous lines are preferred over longer central lines. Unfortunately, vascular access in some patients may be problematic, and other routes (e.g., intraosseous infusion in children) may be necessary.⁵ One interesting method of fluid

administration that has been investigated in elderly patients is subcutaneous infusion, or hypodermoclysis. This route of administration is not used commonly probably because of concerns of adverse effects that were found in early studies that used excessively hypotonic or hypertonic solutions. Although alternative methods of fluid administration, such as hypodermoclysis are desirable, there is a need for well-conducted trials before such methods can be recommended for routine use.

PHARMACOLOGIC THERAPY

8 Dextrose-in-water solutions may be appropriate for uncomplicated dehydration caused by water deprivation, but crystalloid (sodium-containing) solutions should be used for forms of circulatory insufficiency that are associated with hemodynamic instability. In the latter situation, intravenous solutions with sodium concentrations approximating normal serum sodium values usually are indicated because they cause more expansion of the intravascular and interstitial spaces compared with dextrose solutions (Table 24–2). Lactated Ringer’s and normal saline solutions are examples of such crystalloid solutions, although lactated Ringer’s solution is the preferred solution according to some published guidelines (see Advanced Trauma Life Support Guidelines) because it is unlikely to cause the hyperchloremic metabolic acidosis that is seen with infusion of large amounts of normal saline⁵ (Table 24–3). A “large” amount of fluid does not mean the typical bolus volumes used as fluid challenges in critically ill patients. Isolated boluses (e.g., 500 mL in patients older than 18 years of age) are unlikely to cause substantial changes in blood pressure or acid-base balance.¹⁷

Although lactated Ringer’s solution does contain lactate, it does not cause substantial elevations in circulating lactate concentrations

TABLE 24–3. Adverse Effects of Plasma Expanders: Crystalloids

| |
|---|
| Normal saline |
| Primarily extensions of pharmacologic actions (e.g., fluid overload, dilutional coagulopathy) |
| Hyperchloremic metabolic acidosis (has 154 mEq/L of chloride) |
| Hypnatremia (has 154 mEq/L of sodium) |
| Lactated Ringer’s |
| Primarily extensions of pharmacologic actions (e.g., fluid overload, dilutional coagulopathy) |
| Hyponatremia (has 130 mEq/L of sodium) |
| Aggravation of preexisting hyperkalemia (has 4 mEq/L of potassium) |
| Hypertonic saline |
| Primarily extensions of pharmacologic actions (e.g., fluid overload; dilutional coagulopathy; intracellular volume depletion) |
| Hypertatremia (has 513 mEq/L of sodium) |
| Hyperchloremia (has 513 mEq/L of chloride) |

when used as a resuscitation solution.¹⁸ However, blood samples for lactate determinations drawn through catheters (arterial and venous) that have not been cleared appropriately may have spurious increases or decreases in lactate concentrations because of retained lactated Ringer’s and nonlactated solutions (e.g., varying concentrations of dextrose-in-water or sodium chloride), respectively.¹⁹ Therefore, blood samples for lactate concentration determinations should be drawn from a catheter that has been cleared adequately (e.g., 5 mL) of infusate after temporarily stopping the fluid infusion.

While a number of pharmacologic therapies show promise in animal models of shock, few demonstrate success in subsequent trials involving patients with shock. In large part this is a result of the lack of acceptable animal models of shock that mimic the pathophysiology of patients.²⁰ In cases in which a relevant animal model is available, care

TABLE 24–2. Fluid Distribution and Major Indications^a

| Fluid | Intracellular | Interstitial | Intravascular | Major Indication |
|------------------------------------|---------------|--------------|-----------------------|---|
| Normal saline or lactated Ringer’s | None | 750 mL | 250 mL | Intravascular repletion in symptomatic patients |
| 3% sodium chloride | → | 750 mL+ | 250 mL+ | Small amounts (e.g., 250 mL) have been used in conjunction with normal saline or lactated Ringer’s for severe intravascular depletion in adults |
| 5% dextrose/0.45% sodium chloride | 333 mL | 500 mL | 167 mL | Maintenance fluid in euvolemic or dehydrated (sodium and water loss) patients with mild signs/symptoms of volume depletion |
| 5% dextrose | 667 mL | 250 mL | 83 mL | Dehydration (primarily water loss) in patients with mild signs/symptoms of volume depletion |
| 5% albumin | None | None | 1000 mL ^b | Intravascular repletion in symptomatic patients |
| 25% albumin | → | → | 1000 mL+ ^b | Smaller amounts (e.g., 50–100 mL or by continuous infusion in adults) titrated to response in hypovolemic patients with excess total body water |

^aBased on the administration of 1 L of each solution (which may not be an appropriate amount for clinical use); numbers are approximations; arrows indicate direction of fluid shift and plus signs indicate fluid retention in that compartment.

^bAfter distribution, 60% of albumin (and associated fluid) is in interstitial compartment and 40% is in intravascular compartment.

must be taken in extrapolating the information to forms of shock other than the one under study. This may be the problem with naloxone, which has been shown to raise blood pressure in some studies of shock but not in others.²¹ In light of the lack of other demonstrated pharmaceutical interventions, fluids remain the mainstay of therapy, although their use is not devoid of controversy.

Larger-molecular-weight solutions (i.e., >30,000) known as *colloids* have been recommended in conjunction with or as replacements for crystalloid solutions. Examples of colloids used as plasma expanders include albumin, hetastarch, and dextran. Albumin is known as a *monodisperse colloid* because all its molecules are of the same molecular weight (~67,000), whereas hetastarch and dextran solutions are *polydisperse compounds* with molecules of varying molecular weights [average molecular weights of 450,000 (range 10,000 to 1 million) for hetastarch and 40,000 (range 10,000 to 90,000) or 70,000 to 75,000 (range 20,000 to 200,000) for dextran-40 or dextran-70 or -75, respectively]. This has important implications for the distribution of the products because lower-molecular-weight substances are retained in the intravascular space for a shorter period of time as a result of more rapid leakage across the vessel membrane. The theoretical usefulness of colloids is based on their increased molecular weight (average molecular weight in the case of hetastarch and dextran) that corresponds to increased intravascular retention time in the absence of increased capillary permeability compared with crystalloids. Even in patients with intact capillary permeability, the colloid molecules eventually will leak through the membrane. In the case of albumin, approximately 60% of the albumin molecules (and associated fluid) are contained in the interstitial space within 5 days of exogenous administration. In patients with altered permeability (e.g., acute respiratory distress syndrome), the leakage of albumin from the intravascular to the interstitial space may occur within hours, not days.

Albumin is available in 5% and 25% concentrations. Plasma protein fraction has oncotic actions similar to a 5% albumin solution, which is not surprising because albumin is the predominant protein in this product. When given in equipotent amounts, albumin is much more costly than crystalloid solutions. Additionally, the 5% and 25% albumin solutions typically are priced in such a way that there is no cost savings associated with dilution of the 25% product to make a 5% concentration. The 5% albumin solution is relatively *iso-oncotic*, which means that it does not pull fluid into the compartment in which it is contained. In contrast, 25% albumin is referred to as *hyperoncotic* albumin because it tends to pull fluid into the compartment containing the albumin molecules. In general, the 5% albumin solution is used for hypovolemic states. The 25% solution should not be used for acute circulatory insufficiency unless it is used in combination with other fluids or unless it is being used in patients with excess total body water but intravascular depletion as a means of pulling fluid into the intravascular space. An example of the latter condition would be cirrhosis with ascites in which total body water is substantially increased, but the patient is hypotensive as a consequence of lack of intravascular volume. This use of hyperoncotic albumin presumes that there is evidence of adverse effects associated with this excess water such as interstitial fluid accumulation in the lungs. Although appealing theoretically, improved outcomes related to the fluid shifting associated with hyperoncotic albumin have not been documented in randomized, controlled trials. Additionally, the effect is temporary because the albumin crosses the vascular membrane over time.

Hetastarch 6% has comparable plasma expansion to a 5% albumin solution but is usually less expensive, which accounts for much of its use. Most of the trials comparing albumin with hetastarch for volume expansion have found no significant differences in clinically important outcomes (e.g., mortality). Few trials have directly

compared hetastarch with crystalloid solutions for intravascular expansion. Although hetastarch often is stated as being contraindicated in bleeding disorders, it has been most studied in patients with blood loss (e.g., trauma and perioperative patients). Hetastarch should be avoided in situations in which short-term impairments in hemostasis could have dire consequences, such as in patients undergoing cardiopulmonary bypass surgery and patients with intracranial bleeding. Hetastarch may aggravate bleeding through mechanisms specific to this colloid (e.g., decreased factor VIII activity). These mechanisms have not been well elucidated and often are difficult to distinguish from the dilutional effects on clotting factors caused by all plasma expanders. Hetastarch may cause elevations in serum amylase concentrations but does not cause pancreatitis.

Dextran-40, dextran-70, and dextran-75 are available for use as plasma expanders in the United States. The numbers refer to the average molecular weight of the solutions. In general, dextran solutions are not used as often as albumin or hetastarch solutions for plasma expansion possibly because of concerns related to aggravation of bleeding (i.e., anticoagulant actions related to inhibiting stasis of microcirculation) and anaphylaxis that is more likely to occur with the higher-molecular-weight solutions. However, both these concerns can be reduced if proper attention is paid to patient selection and, in the case of bleeding, published dosing guidelines with regard to the amounts of these products that should be infused. There are few comparative trials involving the dextran solutions, but the intravascular expansion within hours after infusion is approximately equal to the amount of dextran infused.

The crystalloid versus colloid debate was intensified when a meta-analysis by a well-respected group (Cochrane) found an overall increase in mortality associated with albumin using pooled results of randomized investigations.²² The meta-analysis involved 30 randomized trials with 1419 patients (relative risk of death with albumin versus no administration or crystalloid administration 1.68, 95% confidence interval 1.26–2.23). For hypovolemia (caused by blood loss in the majority of studies), the risk of death associated with albumin administration was not quite statistically significant (relative risk 1.46, 95% confidence interval 0.97–2.22). However, the most comprehensive meta-analysis to date did not find increased mortality attributable to albumin when looking at overall mortality (relative risk of death 1.11, 95% confidence interval 0.95–1.28) or for any category of indications.²³ Furthermore, a landmark investigation involving almost 7000 critically ill patients (conducted after the previously mentioned meta-analyses) did not find statistically significant differences in 28-day mortality between patients resuscitated with either normal saline or 4% albumin.²⁴ This multicenter, randomized, double-blind investigation, referred to as the Saline versus Albumin Fluid Evaluation (SAFE) study, involved a heterogeneous group of ICU patients, so clinicians must be cautious when extrapolating the results to more specific patient populations. With this caution in mind, this trial provides strong evidence that crystalloid solutions should be considered first-line therapy in patients with hypovolemic shock.

■ SPECIAL POPULATIONS

■ Trauma/Perioperative Patients

The need for the immediate treatment of hemorrhagic circulatory insufficiency with plasma expanders (i.e., crystalloids or colloids) seems obvious, but no large, well-controlled trials in humans have been conducted that support this practice. To the contrary, there is evidence to suggest that fluid resuscitation beyond minimal levels (i.e., mean

arterial pressure > 40–60 mm Hg) is harmful. One prospective study involving 598 adult patients with gunshot or stab wound injuries to the torso and systolic blood pressure measurements of 90 mm Hg or less found that delayed fluid resuscitation until operation was associated with increased survival and discharge from the hospital ($p = .04$).²⁵ Although concerns were expressed about the comparability of the immediate and delayed resuscitation groups, particularly because true randomization did not take place, a follow-up randomized trial was conducted to verify the findings. There were no differences in survival (four deaths in each group) in the second trial regardless of whether systolic blood pressure was titrated to greater than 100 mm Hg or to 70 mm Hg.²⁶ Both studies were conducted in populated urban areas with approximately 2 hours from the time of injury to operation. Therefore, the results may not be applicable to rural areas with extended transport times. There is also a concern in applying the results of these investigations to patients with certain kinds of single-system injuries, particularly head trauma, where cerebral perfusion pressure is of primary importance. While the applicability of these studies to other populations and settings is debatable, the *presumption* of benefits from immediate plasma expansion in all preoperative patients with circulatory insufficiency caused by hemorrhage is no longer valid. Instead, the initial priority should be surgical control of the bleeding source.

Despite the studies suggesting that vigorous prehospital resuscitation is not helpful and possibly harmful, hypertonic solutions have several characteristics that make them attractive for acute resuscitation. The intravascular and interstitial expansion resulting from the administration of these solutions is much greater than the volume infused by emergency personnel.

CLINICAL CONTROVERSY

Some clinicians believe that hypertonic solutions should be used for the resuscitation of patients with head injuries who have concomitant circulatory insufficiency.

By causing redistribution (i.e., pulling fluid) from the intracellular space, hypertonic solutions cause rapid expansion of the intravascular compartment, which is essential for vital organ perfusion. In head-injured patients, this redistribution should decrease intracranial pressure because the vessels of the brain are more impermeable to sodium ions than vessels in other areas of the body.²⁷ Additionally, hypertonic saline solutions have beneficial immunomodulating actions when compared with more isotonic solutions in experiments with animals.^{28,29}

Potential adverse effects associated with hypertonic fluid administration for circulatory insufficiency include cellular crenation and damage caused by the dramatic fluid shifts, as well as peripheral vein destruction from their high osmolality. Also, in the case of hypertonic sodium chloride solutions, there are the possibilities of neurologic damage from hypernatremia and hyperchloremic metabolic acidosis from hyperchloremia. In the limited number of studies conducted in humans to date, such adverse effects have been uncommon and apparently of little clinical importance.^{30,31}

Unfortunately, beneficial outcome data attributable to administration of these hypertonic solutions also have been lacking.³² Most of these studies were conducted in prehospital and emergency department settings using 250 mL 7.5% sodium chloride with or without 6% dextran-70. A meta-analysis of randomized, controlled trials found no statistical difference between the survival rates of patients receiving the hypertonic saline solutions and those receiving standard isotonic crystalloid solutions.³³ Part of the explanation for this finding may

be related to supplemental crystalloid fluids that were given routinely to patients in both the treatment and control groups, which probably would increase the number of patients needed to demonstrate a statistically significant difference in mortality. Until the concerns regarding efficacy and toxicity of these solutions have been resolved, normal saline could be considered as an alternative for head-injured patients when a hypertonic solution is desirable because it contains 154 mmol/L of both sodium and chloride. Given their relatively poor intravascular expansion and association with poor outcome in animal models of closed head injury, hypotonic solutions should be avoided in this population.³⁴

In addition to crystalloid solutions, colloids have been used for plasma expansion in patients with hemorrhagic circulatory insufficiency. In the United States, albumin and starch (i.e., hetastarch) derivatives are used most commonly, although dextran solutions also are available commercially.

CLINICAL CONTROVERSY

Some clinicians believe that colloid solutions have advantages beyond crystalloid solutions that justify their use for patients with hypovolemic shock.

The theoretical advantage of these compounds is their prolonged intravascular retention time compared with crystalloid solutions. In contrast to isotonic crystalloid solutions that have substantial interstitial distribution within minutes of intravenous administration, colloids remain in the intravascular space for hours or days depending on factors such as capillary permeability.

The colloids, in particular albumin, are expensive solutions. Therefore, it is difficult to justify the additional cost of colloidal products unless the benefit-to-risk ratio is substantially greater than that associated with inexpensive crystalloid solutions. This does not appear to be the case based on randomized, controlled studies and meta-analyses comparing colloid and crystalloid solutions for acute circulatory insufficiency.³⁵ Because other colloids, such as hetastarch, almost always have been compared with albumin and not with crystalloid solutions in published clinical studies (with no clinically important differences being found), there is no reason to suspect that these other colloids have any unique advantages as volume expanders. Adverse effects associated with colloids appear to be uncommon and generally are extensions of their pharmacologic activity (Table 24–4),  but this is also true of crystalloids. The benefit-to-risk ratio appears to be similar for colloids and crystalloids; thus, based on cost, crystalloids are preferred for initial treatment of circulatory insufficiency.

The preceding discussion has dealt primarily with acute circulatory insufficiency, but there are other considerations with regard to fluid replacement in elective surgical procedures. Preoperative fluid deficits may be associated with increased perioperative morbidity, some of which (e.g., drowsiness, dizziness) may be reduced by appropriate fluid administration prior to surgery.³⁶ However, care must be taken to avoid overhydration in the perioperative period because excess fluid will lead to weight gain and decreased pulmonary function.³⁷ There is some evidence to suggest that fluid restriction on the day of surgery may reduce postoperative morbidity. In one randomized, multicenter trial, use of a restricted intraoperative and postoperative intravenous fluid protocol led to significantly fewer cardiopulmonary (7% versus 24%; $p = .007$) and wound (16% versus 31%; $p = .04$) complications.³⁸

Another consideration in the patient with injuries or surgery is the potential need for blood product administration (Table 24–5) to

TABLE 24–4. Adverse Effects of Plasma Expanders: Colloids

| |
|---|
| Albumin |
| Primarily extensions of pharmacologic actions (e.g., fluid overload; dilutional coagulopathy; crystalloids are usually needed with 25% albumin in hypovolemic states to prevent intracellular volume depletion and renal failure) |
| Amino acid profile and catabolism alterations (clinical significance?); potential protein overload if given with exogenous protein (e.g., parenteral nutrition) |
| Anaphylactoid/anaphylaxis (life-threatening reactions rare; higher in patients with IgA deficiency) |
| Infectious complications (all reported cases have been associated with improper handling by manufacturer or institution; no reported cases of HIV or hepatitis transmission) |
| Interactions with medications and nutrients (clinical significance varies) |
| Metal loading, particularly aluminum (long-term administration in patients with renal failure) |
| Negative inotropic effect, reductions in ionized calcium concentrations? |
| Pyrogenic reactions? |
| Hetastarch |
| Primarily extensions of pharmacologic actions (e.g., fluid overload; dilutional coagulopathy) |
| Bleeding (decreases factor VIII/C activity; not recommended in patients with severe bleeding conditions such as subarachnoid hemorrhage) |
| Macroamylase formation may cause elevation in blood amylase that leads to inaccurate diagnosis of pancreatitis |
| Dextrans |
| Primarily extensions of pharmacologic actions (e.g., fluid overload; dilutional coagulopathy) |
| Anaphylaxis (increased incidence with increased molecular weight) |
| Bleeding (sometimes used for anticoagulant activity so not recommended in patients with severe bleeding) |

replace oxygen-carrying and clotting functions. Although a small group of trauma patients responds to the initial fluid bolus and remain stable, most patients respond initially and then deteriorate.⁵ The latter patients, as well as patients undergoing blood loss associated with surgery, frequently need blood components such as packed red blood cells. In the case of the latter component, red blood cells contain hemoglobin that delivers oxygen to tissues. Neither crystalloids nor colloids perform this function.

Blood products are not risk-free. For example, there is the rare but important risk of virus transmission (e.g., HIV, hepatitis). The administration of blood products has its own risks. For example, citrate that is added to stored blood to prevent coagulation may bind to

calcium, resulting in hypocalcemia. In contrast, potassium and phosphate concentrations are often elevated in stored blood, particularly when hemolysis has occurred during storage. Additionally, administration of excessive blood products may be counterproductive. In the case of red blood cells, attempts to raise the hematocrit to high-normal or supranormal concentrations may decrease oxygen delivery by increasing blood viscosity.³ Although there is no optimal hematocrit value for all patients, a minimum hematocrit concentration of 30% (equivalent to a hemoglobin concentration of 10%) traditionally has been used as the threshold for transfusion, particularly in patients at risk for ischemia, such as those with CAD. The use of a more liberal transfusion strategy has been called into question with the publication of a randomized, multicenter trial involving critically ill patients that found 30-day mortality to be similar whether patients were transfused at a hemoglobin concentration of 7 or 10 g/dL (18.7% versus 23.3%, respectively; $p = .11$).³⁹ The mortality during hospitalization was significantly lower in the restrictive group (22.2% versus 28.1%; $p = .05$). While the investigators were cautious about extrapolating the results of this investigation to patients with myocardial ischemia, the study does question the use of a liberal transfusion strategy for critically ill patients.

Other issues that must be considered with blood product administration include monitoring for transfusion-related reactions and attention to appropriate warming, particularly when large volumes are given to pediatric patients, because hypothermia is associated with increased fluid requirements and mortality.⁴⁰

The periodic shortages, high costs, and adverse effect concerns related to blood products have prompted investigations of alternative “bloodless” strategies. In addition to the use of more restrictive transfusion thresholds, as mentioned previously, these strategies have included hemoglobin-based oxygen carriers and perfluorocarbon compounds to deliver oxygen to tissues.⁴¹ Other strategies have aimed at reducing blood loss through the use of improved procedural and surgical techniques, as well as the administration of hemostatic medications.^{42,43}

TABLE 24–5. General Indications for Blood Products in Acute Circulatory Insufficiency Due to Hemorrhage*

| |
|--|
| Packed red blood cells |
| Increase oxygen-carrying capacity of blood—usually indicated in patients with continued deterioration after volume replacement or obvious exsanguination; needs to be warmed, particularly when used in children |
| Fresh-frozen plasma |
| Replacement of clotting factors—generally overused; indicated if ongoing hemorrhage in patients with PT/PTT > 1.5 times normal, severe hepatic disease, or other bleeding diathesis |
| Platelets |
| Used for bleeding due to severe thrombocytopenia (i.e., platelet count < 10,000 mcL) or rapidly dropping platelet counts as would occur with massive bleeding |
| Other products |
| Components such as cryoprecipitate and factor VIII are generally not indicated in acute hemorrhage, but rather are used after specific deficiencies are identified |

* Although whole blood could be used for large-volume blood loss, most hospitals use component therapy, and use crystalloids or colloids for plasma expansion. PT, prothrombin time; PTT, partial thromboplastin time.

■ Patients with Thermal Injuries

There are a number of formulas for estimating fluid requirements in thermally injured patients, but there is little reason to choose one over another based on well-controlled studies. In general, the amount of loss corresponds to the size of the thermal injury.³ Approximately 3 to 4 mL/kg of isotonic fluid (lactated Ringer's solution) for each percent burn can be used for calculating the expected fluid requirements for the first 24 hours after the burn. For example, a 60-kg person with 30% body surface area (BSA) burns is expected to require 5400 to 7200 mL of fluid over the initial 24 hours. Regardless of the calculated deficit, fluids should be administered until adequate tissue perfusion has been documented or adverse effects (e.g., pulmonary edema) occur. Crystalloids are preferred as initial therapy for burn victims because there is no substantial evidence that colloids mobilize edematous fluid, and there is a theoretical concern that extravascular fluid accumulation might be prolonged by the oncotic actions of albumin and other colloid products that have leaked through vessel walls.⁴⁴ Additionally, there is no evidence that colloids reduce mortality in patients with thermal injuries.²² Some novel therapies for thermal resuscitation are currently under study. For example, in a prospective study involving patients with more than 30% BSA burns, antioxidant therapy with extremely high doses on intravenous vitamin C (66 mg/kg per hour for 24 hours) reduced resuscitation fluid requirements and wound edema.⁴⁵ The proposed mechanism is reduction in free radical-induced increases in capillary permeability.

CLINICAL CONTROVERSY

The appropriate use of invasive hemodynamic monitoring tools such as right-sided heart catheterization in patients with hypovolemic shock is controversial.

■ ONGOING MONITORING

Although the monitoring of patients in the emergency department is relatively straightforward, it becomes much more controversial in other settings such as the ICU. This is particularly true with regard to the value of right-sided heart catheterization (also known as pulmonary artery or Swan-Ganz catheterization). However, most clinicians would agree that certain forms of monitoring are important because patients in the postresuscitation phase of management are at risk for various complications secondary to ischemia. A more complete discussion of invasive and noninvasive hemodynamic monitoring is found in Chapter 23.

One form of monitoring that may take place in the emergency and operating rooms, as well as in the ICU, requires placement of a central venous pressure (CVP) line. Monitoring of CVP provides the clinician with an indirect and insensitive yet useful estimate of the relationship between increased right atrial pressure and cardiac output.⁵

A number of laboratory tests are indicated for the subacute monitoring of shock. These include a renal battery for assessing possible electrolyte alterations and kidney perfusion (e.g., blood urea nitrogen and creatinine). Among other things, a complete blood count will enable assessment of possible infection (white blood cell count), oxygen-carrying capacity of the blood (hemoglobin, hematocrit), and ongoing bleeding (hemoglobin, hematocrit, and platelet count). The

prothrombin time (PT) and partial thromboplastin time (PTT) will give an indication of the ability of the blood to clot because, in the case of hemorrhagic shock, clotting factors are lost and diluted. An increasing lactate concentration (arterial, mixed venous, or central venous)⁴⁶ and base deficit are consistent with inadequate perfusion leading to anaerobic metabolism with accumulation of lactic acid. These tests often are considered the optimal end points of resuscitation in certain populations such as trauma patients.⁴⁷ Additionally, lactate clearance is a useful predictor of survival in children and adults.^{48,49} Other tests may be indicated if organ dysfunction is likely. For example, when blood flow to the liver is interrupted because of sustained hypotension, a condition known as *shock liver* may occur. In this condition, the transaminases on a liver panel may be markedly elevated in the first couple of days after marked hypotension, although the concentrations should decrease over time.³ Along with laboratory testing, a more extensive history can be obtained during the subacute monitoring period.

The value of pulmonary artery catheters has been debated hotly since their introduction. Such catheters are placed to obtain various oxygen-transport variables, some of which cannot be determined reliably from peripheral or other central vessels.⁵⁰ The debate was intensified when early studies suggested improved outcomes when cardiac output and other oxygen-transport variables were raised to supranormal levels, the monitoring of which required placement of a pulmonary artery catheter. Subsequent studies using similar monitoring parameters associated with pulmonary artery catheterization gave conflicting results.⁵¹

The controversy led to consensus conferences⁵² and workshops,⁵³ the development of organizational guidelines,⁵⁴ and the publication of a meta-analysis (which found a statistically significant reduction in *morbidity* using pulmonary artery catheters to guide therapy).⁵⁵ Ultimately, a large randomized, controlled trial involving pulmonary artery catheters was conducted in high-risk surgical patients.⁵⁶ The trial involved 1994 patients. The mortality was almost identical for the catheter and control groups (7.8% versus 7.7%, 95% confidence interval 2.3 to 2.5). There were no episodes of pulmonary embolism in the catheter group and eight episodes in the control group ($p = .004$). This trial is important not only because of the implications for high-risk surgical patients but also because it allows future trials to be conducted in other patient populations without some of the ethical issues raised about such trials in the past.

Part of the concern regarding pulmonary artery catheterization relates to interpretation of its results by inexperienced practitioners. Studies in both Europe and the United States found that one of two physicians incorrectly interpreted a tracing from a pulmonary artery catheter.⁵⁷ This could explain some of the results of studies finding no benefits to pulmonary artery catheterization or, in some cases, worse outcomes in the pulmonary artery catheterization group by actions taken as a result of inaccurate measurements or misinterpretation of information obtained from the monitoring process.

Complications related to pulmonary artery catheter insertion, maintenance, and removal include damage to vessels and organs during insertion, arrhythmias, infections, and thromboembolic damage. To avoid the complications associated with pulmonary artery catheterization, other less invasive tools were developed to obtain similar information. For example, cardiac output determinations have been made by Doppler, bioimpedance, dye, and ionic dilution techniques, although such measurements would not provide other data that are obtained routinely with pulmonary artery catheters (e.g., left-sided heart-filling pressure).⁵⁸ Additionally, advances in

pulmonary artery catheter technology that expand the information obtained from such monitoring (e.g., mixed venous oxyhemoglobin) are under investigation.⁵⁹ However, given the lack of well-defined outcome data associated with pulmonary artery catheterization, its use is best reserved for complicated cases of shock not responding to conventional fluid and medication therapies.

Commonly measured and calculated hemodynamic and oxygen-transport indices associated with invasive monitoring are primarily global indicators of tissue perfusion. There have been attempts to find regional and local indicators of hypoperfusion so that circulatory insufficiency could be treated before overt shock occurs. One focus of recent research has been monitoring modalities involving the gastrointestinal tract.

Although the literature is fairly consistent concerning low pHi values (gastric intramucosal pH) being predictive of death, pHi-guided therapy to decrease mortality has not been demonstrated.⁶⁰ Additionally, there are a number of technical considerations that remain to be resolved when using pHi or, more recently, capnometry (luminal Pco₂ tonometry) for monitoring and therapy.⁶¹ Despite these concerns, measures of regional tissue oxygenation continue to be investigated through a variety of novel monitoring techniques.⁶²

In addition to regional monitoring of tissue perfusion, local methods of monitoring are also being studied. For example, subcutaneous measurement of tissue oxygen pressure shows promise in preliminary investigations. It is unlikely that regional and local measurements will replace more global indicators of perfusion but rather that the methods will complement each other.

ONGOING MANAGEMENT

Proper attention to plasma expansion must be continued into the intraoperative and postoperative periods. A number of neurohormonal changes take place that affect urine output, and patients may have substantial third-spacing of fluid depending on the operation and the pre-existing condition of the patient. Furthermore, postoperative patients are prone to hyponatremia from renal generation of electrolyte-free water and from antidiuretic hormone release.⁶³ As in acute resuscitation, the administration of hypotonic solutions in the perioperative period does not prevent the decrease in extracellular volume that often occurs. Therefore, although excess fluid administration is to be avoided in the perioperative setting, isotonic crystalloid solutions should be used when fluids are indicated to prevent intravascular depletion and circulatory insufficiency.

Of the randomized studies comparing albumin with crystalloid solutions in the perioperative period, the majority found no statistically significant differences between groups.⁶⁴ The significant differences that have been found have involved isolated hemodynamic or respiratory variables with no obvious clinical correlates (e.g., duration of mechanical ventilation). Therefore, albumin (and other colloids) cannot be recommended for the prevention or initial treatment of circulatory insufficiency, although their use may be appropriate in

patients who are not responding to crystalloids and are developing problems such as interstitial fluid accumulation. Practice guidelines published by a consortium of academic medical centers reflect this recommendation, but colloids continue to be used widely.⁶⁵

In general, medications are not indicated in the initial therapy of hypovolemic shock. With hypovolemia, the body's natural response is to increase cardiac output and to constrict blood vessels to maintain blood pressure. There is no reason why most patients should need inotropic or vasoactive agents, assuming that fluid therapy is adequate. For that matter, there is no evidence that these medications improve outcome in patients with hypovolemic shock. However, once the cause of acute circulatory insufficiency has been stopped or treated and fluids have been optimized, some patients continue to have signs and symptoms of inadequate tissue perfusion. This may be caused by reperfusion injury. Although the search for a cryptogenic source (e.g., intraabdominal bleeding in a trauma patient) should continue, the clinician may need to administer medications to improve perfusion.

Pressor agents such as norepinephrine and high-dose dopamine are to be avoided, if possible, because they may increase blood pressure at the expense of peripheral tissue ischemia. Some sources use stronger language and state that vasopressors are contraindicated in certain forms of shock (e.g., hemorrhagic).⁵ This does not help the clinician who is treating a patient with unstable blood pressure despite massive fluid replacement and increasing interstitial fluid accumulation. In such situations, inotropic agents such as dobutamine are preferred if blood pressure is adequate (e.g., systolic blood pressure \geq 90 mm Hg) because they should not aggravate the existing vasoconstriction. The inotropic agents are justified by presumed inadequate cardiac output for the specific situation, although the measured values may be in the normal range.³

When pressure cannot be maintained with inotropic agents, or when inotropic agents with vasodilatory properties cannot be used because of inadequate blood pressure concerns, pressors may be required as a last resort. In general, the need for pressors is predictive of the development of MODS and increased length of hospital stay.⁶⁶ Although the response to pressor agents may be variable in hypovolemic shock, there does not appear to be resistance as a consequence of altered receptor response, as is sometimes seen in patients with septic shock.³ Potent vasoconstrictors such as norepinephrine and phenylephrine should be given through central veins because of the possibility of extravasation and necrosis with peripheral administration.

A number of interesting treatments for shock are under investigation, including autotransfusion for removing harmful cytokines from the body. Various alternatives to conventional blood components are also being studied, such as stroma-free hemoglobin and perfluorocarbon compounds, as virus-free alternatives to red blood cell transfusion. Hopefully, these will be useful adjuncts to adequate volume replacement, which is the primary therapeutic intervention in managing acute circulatory insufficiency owing to volume depletion.

PHARMACOECONOMIC CONSIDERATIONS

The primary therapy for hypovolemic shock is fluid replacement. The institutional cost of 1 L of most crystalloid solutions is less than \$1. Assuming that such fluids are used, it is the associated costs of personnel and equipment that become the primary economic considerations in the resuscitation of patients with hypovolemic shock. However,

as mentioned, many clinicians recommend that colloid plasma expanders (e.g., albumin, hetastarch, or dextrans) be used to replace some or all of the standard crystalloid solutions. Although the costs of these solutions vary depending on contractual arrangements as might occur with purchasing groups, in general, albumin solutions are more expensive than hetastarch and dextran products. All these solutions are markedly more costly than crystalloid solutions; in some cases,

there are 50- to 100-fold differences, even when used in equipotent amounts.

The only recent trial that investigated albumin use on a large-scale basis was an observational study involving 15 academic medical centers in the United States. Based on previously published guidelines, 62% of albumin use was defined as inappropriate at a cost of \$124,939.⁶⁷ Presuming equal efficacy and toxicity (as available studies indicate) between crystalloid and colloid solutions, cost-minimization analysis clearly indicates the economic advantages of the crystalloids.

Because medications are not simply alternatives to crystalloids but rather are used when crystalloid therapy has been optimized, there is little reason to compare medication and fluid therapies from an economic perspective. Furthermore, there are no economic comparisons

of the various inotropic and vasopressor medications used in the treatment of hypovolemic shock.

EVALUATION OF THERAPEUTIC OUTCOMES

Figure 24–4 is an algorithm that summarizes many of the treatment principles discussed in this chapter. The algorithm is an example of one approach to the adult patient presenting with hypovolemic shock. It presumes that initial rehydration attempts (i.e., outpatient or prehospital) were unsuccessful in restoring circulation. Obviously, modifications may be needed for patient-specific forms of hypovolemic shock. Other limitations of the algorithm should be recognized, particularly the decisions to add or to substitute colloid or

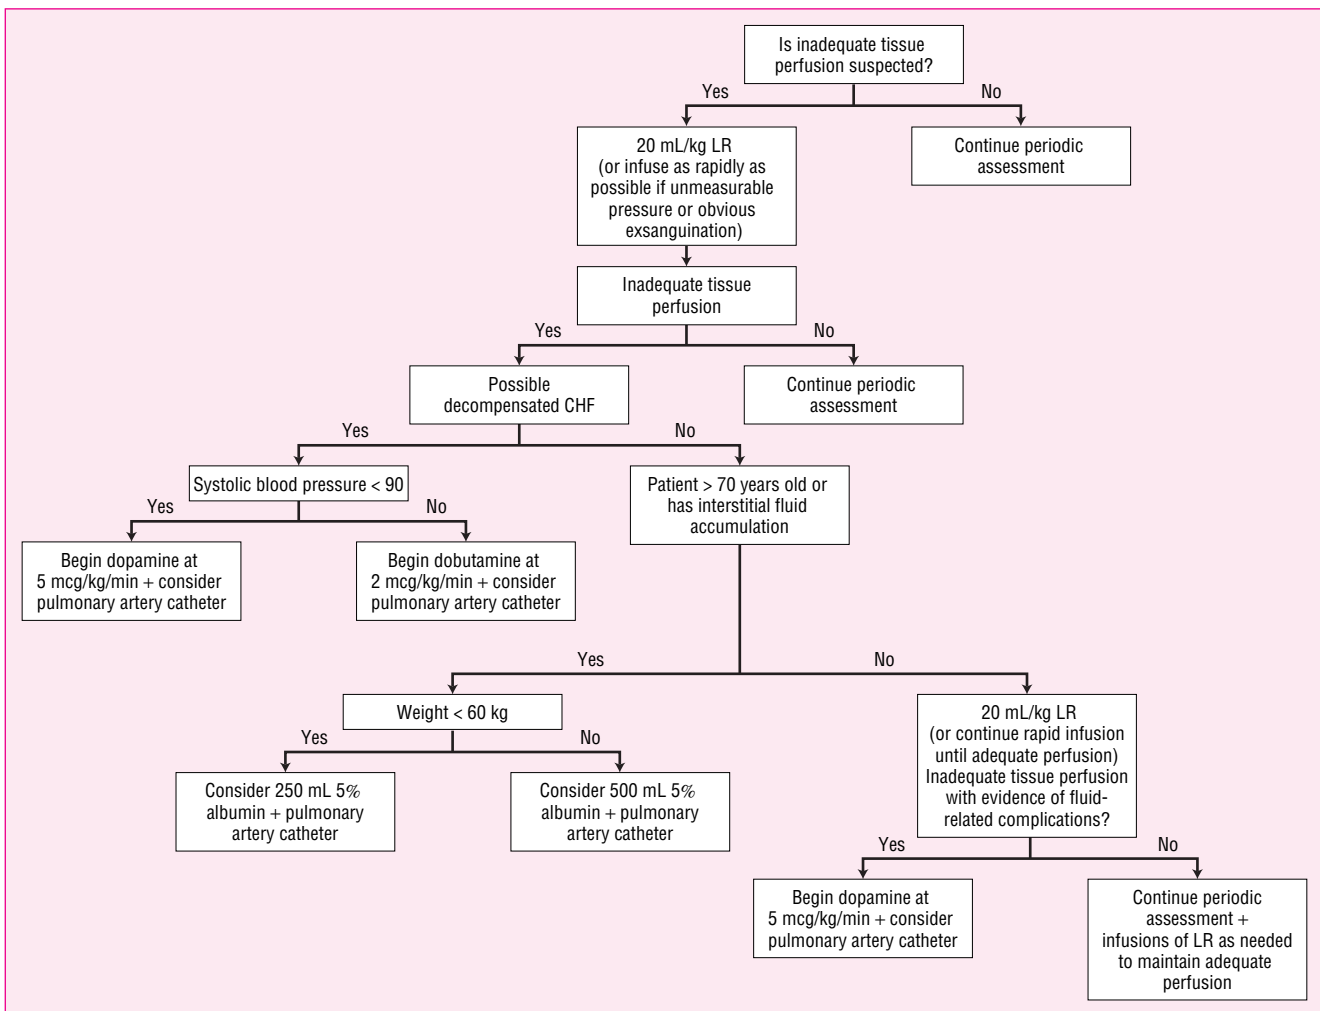

FIGURE 24–4. Hypovolemia protocol for adults. This protocol is not intended to replace or delay therapies such as surgical intervention or blood products for restoring oxygen-carrying capacity or hemostasis. If available, some measurements may be used in addition to those listed in the algorithm, such as mean arterial pressure or pulmonary artery catheter recordings. The latter may be used to assist in medication choices (e.g., agents with primary pressor effects may be desirable in patients with normal cardiac outputs, whereas dopamine or dobutamine may be indicated in patients with suboptimal cardiac outputs). Lower maximal doses of the medications in this algorithm should be considered when pulmonary artery catheterization is not available. CHF = congestive heart failure; LR = lactated Ringer’s solution. Colloids that may be substituted for albumin are hetastarch 6% and dextran-40. See text for an in-depth discussion of these and other issues involved in this protocol.

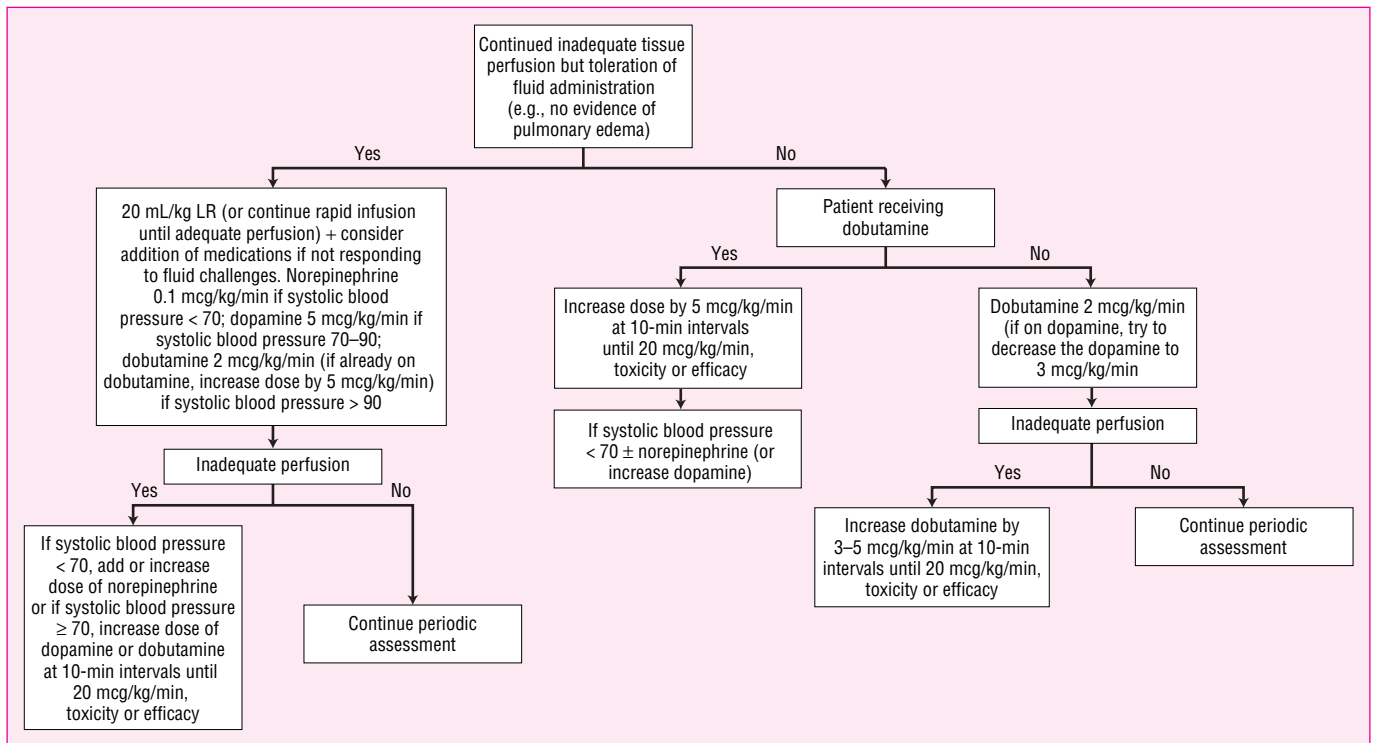

FIGURE 24-5. Ongoing management of inadequate tissue perfusion. CHF = congestive heart failure; LR = lactated Ringer's solution.

medication therapies when crystalloid solutions are not yielding desired results and when to perform pulmonary artery catheterization for more invasive monitoring. Medications become more important for the ongoing management of hypovolemic shock, particularly when the patient is unresponsive to fluids (Fig. 24-5). Additionally, it is hoped that the options for more complicated cases of hypovolemic shock do not detract from the primary effective resuscitative measure for most patients—fluid.

ABBREVIATIONS

SIRS: systemic inflammatory response syndrome
 MODS: multiple-organ dysfunction syndrome
 CAD: coronary artery disease
 BSA: body surface area
 CVP: central venous pressure
 PT: prothrombin time
 PTT: partial thromboplastin time
 pHi: gastric intramucosal pH

INTRODUCTION TO PULMONARY
FUNCTION TESTING

Jay I. Peters and Stephanie M. Levine

Learning Objectives and other resources can be found at www.pharmacotherapyonline.com.

KEY CONCEPTS

- 1 Normal ventilation-perfusion ratio. The function of the lung is to maintain P_{O_2} and P_{CO_2} within the normal range. This is accomplished by matching 1 mL mixed venous blood with 1 mL fresh air ($\dot{V}/\dot{Q} = 1$). Normally, there is less ventilation (\dot{V}) than perfusion (\dot{Q}), and the \dot{V}/\dot{Q} ratio is 0.8.
- 2 The air in the lung is divided into four compartments: tidal volume—the air exhaled during quiet breathing; inspiratory reserve volume—the maximal air inhaled above tidal volume; expiratory reserve volume—the maximum air exhaled below tidal volume; and residual volume—the air remaining in the lung after maximal exhalation. The sum of all four components is called the total lung capacity.
- 3 Obstructive lung disease is defined as an inability to get air out of the lung and is identified on spirometry when the FEV_1/FVC (amount of air forcefully exhaled in 1 second/total amount of air that can be exhaled during a forced exhalation) is less than 70% to 75%.
- 4 Reversible airway obstruction is common in asthma and chronic obstructive pulmonary disease (COPD). An increase in FEV_1 after an inhaled β -agonist of 12% and greater than 0.2 L suggests an acute bronchodilator response.
- 5 Restrictive lung disease is defined as an inability to get air into the lung. It is best defined as a reduction in total lung capacity (TLC) but is suspected when the forced vital capacity (FVC) is low and the FEV_1/FVC is normal.
- 6 Restrictive lung disease can be produced by a number of defects: increased elastic recoil (interstitial lung disease), respiratory muscle weakness (myasthenia gravis), mechanical restrictions (pleural effusion), and poor effort.

The primary function of the respiratory system is to maintain normality of arterial blood gases, that is, the P_{aO_2} and P_{aCO_2} (the arterial pressure of oxygen and carbon dioxide). To accomplish this task, several processes must be accomplished, including alveolar ventilation, pulmonary perfusion, ventilation-perfusion matching, and gas transfer across the alveolar-capillary membrane. Alveolar ventilation is achieved by the cyclic process of air movement in and out of the lung. During inspiration, the inspiratory muscle contracts and generates negative pressure in the pleural space. This pressure gradient between the mouth and the alveoli draws fresh air (tidal volume) into the lung. Approximately one-third of the inspired gas stays in the conducting airways (dead space), whereas two-thirds reaches the alveoli.

1 The human lung contains a series of branching, progressively tapering airways that originate at the glottis and terminate in a matrix of thin-walled alveoli. Coursing through this matrix of alveoli is a rich network of capillaries that originates from the pulmonary arterioles and terminates in the pulmonary venules. The adequacy of respiration in each gas exchange unit depends on the opposition of a thin film of mixed venous blood with just the right amount of fresh alveolar gas. During “ideal” gas exchange, there is uniform

blood flow and uniform ventilation; accordingly, there is no alveolar-arterial P_{O_2} difference [$P(A-a)O_2$ gradient, sometimes called the $A-a$ gradient]. Gas exchange is not perfect, however, even in the normal lung. Normally, there is less alveolar ventilation than pulmonary blood flow, and the overall ventilation-perfusion ratio is 0.8 (not 1.0).

Normal expiration is a passive process, and when the inspiratory muscles end their contraction, the elastic recoil of the lung pulls the lung back to its original size and shape. This process makes the alveolar pressure positive relative to the pressure at the mouth, and air flows out of the lung. During inspiration, the respiratory muscles must overcome the elastic properties of the lung (elastic recoil) and the resistance to airflow by the airways. During expiration, the flow of air is determined primarily by the elastic recoil and airway resistance.

Different pulmonary function tests (PFTs) are used to evaluate the physiologic process of the respiratory system. Physiologic abnormalities that can be measured by pulmonary function testing include obstruction to airflow, restriction of lung size, and decrease in the transfer of gas across the alveolar-capillary membrane. Abnormal values on PFTs are those outside the range of values obtained from a group of normal individuals matched according to age, height, sex, and race. A PFT is labeled abnormal when the results fall outside the

range in which 95% of people the same age, height, and sex would be found (95% confidence interval). This definition is arbitrary and may misclassify a small percentage of normal individuals as having lung dysfunction, as well as missing some patients with mild pulmonary disease. Therefore, clinical correlation and serial pulmonary function testing may be necessary for optimal interpretation of PFTs.

Potential uses of pulmonary function testing include the evaluation of patients with known or suspected lung disease; the evaluation of symptoms such as chronic cough, dyspnea, or chest tightness; monitoring the effects of exposure to dust, chemicals, or pulmonary toxic drugs; risk stratification prior to surgery; monitoring of the effectiveness of therapeutic interventions; and objective assessment of impairment or disability.¹

DEFINITIONS OF LUNG VOLUMES AND EXPIRATORY FLOWS

2 The air within the lung at the end of a forced inspiration can be divided into four compartments or lung volumes (Fig. 25-1). The volume of air exhaled during normal quiet breathing is termed *tidal volume* (V_T). The maximal volume of air inhaled above tidal volume is called the *inspiratory reserve volume* (IRV), and the maximal air exhaled below tidal volume is called the *expiratory reserve volume* (ERV). The *residual volume* (RV) is the amount of air remaining in the lungs after a maximal exhalation.

The combinations or sums of two or more lung volumes are termed *capacities* (see Fig. 25-1). *Vital capacity* (VC) is the maximal amount of air that can be exhaled after a maximal inspiration. It is equal to the sum of the IRV, V_T , and ERV. When measured on a forced expiration, it is called the *forced vital capacity* (FVC). When measured over an exhalation of at least 30 seconds, it is called the *slow vital capacity* (SVC, VC). The VC is approximately 75% of the *total lung capacity* (TLC), and when the SVC is within the normal range, a significant restrictive disorder is unlikely. Normally, the values for SVC and FVC are very similar unless airway obstruction is present.

The TLC is the volume of air in the lung after the maximal inspiration and is the sum of the four primary lung volumes (IRV, V_T , ERV, and RV). Its measurement is difficult because the amount

of air remaining in the chest after maximal exhalation (RV) must be measured by indirect methods. The definition of restrictive lung disease is based on a reduction in TLC (i.e., an inability to get air into the lung or restriction to air movement on inhalation).

The *functional residual capacity* (FRC) is the volume of air remaining in the lungs at the end of a quiet expiration. FRC is the normal resting position of the lung and occurs when there is no contraction of either inspiratory or expiratory muscles and is normally 40% of TLC. *Inspiratory capacity* (IC) is the maximal volume of air that can be inhaled from the end of a quiet expiration and represents the sum of V_T and IRV.

The FVC, which represents the total amount of air than can be exhaled, can be expressed as a series of timed volumes. The *forced expiratory volume in 1 second* (FEV_1) is the volume of air exhaled during the first second of the FVC maneuver. Although the FEV_1 is a volume, it conveys information on obstruction because it is measured over a known time interval. The FEV_1 depends on the volume of air within the lung and the effort during exhalation; therefore, it can be diminished by a decrease in TLC or by a lack of effort. A more sensitive way to measure obstruction is to express the FEV_1 as a ratio of FVC. This ratio is independent of the patient's size or the TLC; therefore, the FEV_1/FVC is a specific measure of airway obstruction with or without restriction. Normally, this ratio is 75% or greater, and any value below 70% to 75% suggests obstruction.

Because *flow* is defined as the change in volume with time, forced expiratory flow may be determined graphically by dividing the volume change by the time change. The *forced expiratory flow* (FEF) *during 25% to 75% of FVC* ($FEF_{25\%-75\%}$) represents the mean flow during the middle half of the FVC. The $FEF_{25\%-75\%}$, formerly called the *maximal midexpiratory flow* (MMEF), is reported frequently to assess small airways. The 95% confidence limit is so wide that the $FEF_{25\%-75\%}$ has limited utility in the early diagnosis of small airways disease in an individual subject. The *peak expiratory flow* (PEF), also called *maximum forced expiratory flow* (FEF_{max}), is the maximum flow obtained during the FVC. This measurement is used often in the outpatient management of asthma because it can be measured with inexpensive peak flow meters.

SPIROMETRY/FLOW-VOLUME LOOP

Spirometry is the most widely available and useful PFT. It takes only 15 to 20 minutes, carries no risks, and provides information about obstructive and restrictive disease. Spirometry allows for the measurement of all lung volumes and capacities except RV, FRC, and TLC and allows assessment of FEV_1 and $FEF_{25\%-75\%}$. Spirometry measurements can be reported in two different formats—standard spirometry (Fig. 25-2) and the flow-volume loop (Fig. 25-3). In standard spirometry, the volumes are recorded on the vertical (y) axis and the time on the horizontal (x) axis. In flow-volume loops, volume is plotted on the horizontal (x) axis, and flow (derived from volume/time) is plotted on the vertical (y) axis. The shape of the flow-volume loop can be helpful in differentiating obstructive and restrictive defects and in the diagnosis of upper airway obstruction (Fig. 25-4). This curve gives a visual representation of obstruction because the expiratory descent becomes more concave with worsening obstruction.

LUNG VOLUMES

Spirometry measures three of the four basic lung volumes but cannot measure RV (residual volume). RV must be measured to determine the TLC. TLC should be measured anytime there is a reduced VC. In

FIGURE 25-1. Lung volumes and capacities. ERV = expiratory reserve volume; FRC = functional residual capacity; IC = inspiratory capacity; IRV = inspiratory reserve volume; RV = residual volume; TLC = total lung capacity; VC = vital capacity; V_T = tidal volume.

FIGURE 25-2. Standard spirometry. Curve 1 is for a normal subject with a normal FEV_1 ; curve 2 is the FEV_1 in a patient with mild airways obstruction; curve 3 is for a patient with moderate airways obstruction; curve 4 is a patient with severe airways obstruction; BPTS = body temperature saturated with water vapor.

the setting of chronic obstructive pulmonary disease (COPD) with a low VC, measurement of TLC can help to determine whether there is a superimposed restrictive disorder. There are four methods to measure TLC: helium dilution, nitrogen washout, body plethysmography, and chest x-ray measurement (planimetry). The first two methods are called *dilution techniques* and only measure lung volumes in communication with the upper airway. In patients with airway obstruction who have trapped air, dilution techniques will underestimate the actual volume of the lungs. Planimetry measures the circumference of the lungs on the posteroanterior view and lateral views of a chest x-ray and estimates the total lung volume.

Body plethysmography, or body box, is the most accurate technique for lung volume determinations. It measures all the air in the lungs, including trapped air. The principle of the measurement of the body box is Boyle's gas law ($P_1V_1 = P_2V_2$): A volume of gas in a closed system varies inversely with the pressure applied to it. The changes in alveolar pressure are measured at the mouth, as well as pressure changes in the body box. The volume of the body box is known. Lung volumes can be determined measuring the changes in pressures caused by panting against a closed shutter.² The measurement of lung volumes provides useful information about elastic recoil of the lungs. If elastic recoil is increased (as in interstitial lung disease),

FIGURE 25-3. Normal flow-volume loop. Flows are measured on the vertical (y) axis, and lung volumes are measured on the horizontal (x) axis. FVC can be read from the tracing as the maximal horizontal deflection. Instantaneous flow (V_{max}) at any point in FVC also can be measured directly. FVC = forced vital capacity.

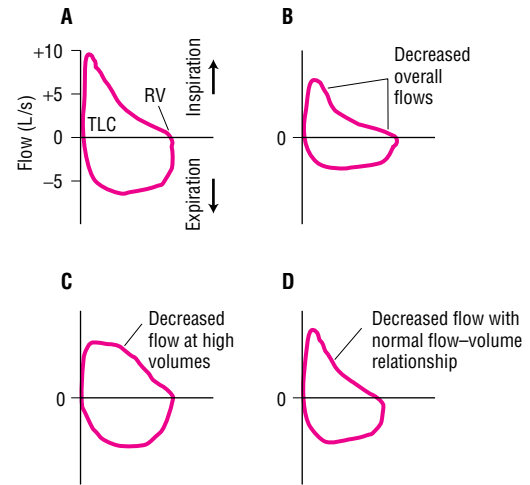

FIGURE 25-4. A. Flow-volume loop depicting mild obstruction characterized by decrease flow at low lung volumes. B. Moderate airflow obstruction characterized by a more concave curve. C. Variable intrathoracic obstruction in which peak flow is decreased at higher lung volumes with normalization of curve at lower lung volumes. D. Restrictive lung disease with a curve that is decreased in width but with a normal shape.

the lung volumes (TLC) are reduced. When the elastic recoil is reduced (as in emphysema), the lung volumes are increased.

CARBON MONOXIDE DIFFUSING CAPACITY

The diffusing capacity of the lungs (D_L) is a measurement of the ability of a gas to diffuse across the alveolar-capillary membrane. Carbon monoxide is the usual test gas because it is not normally present in the lungs and is much more soluble in blood than in lung tissue. When the diffusing capacity is determined with carbon monoxide, the test is called the *carbon monoxide diffusing capacity* (D_{LCO}). Because the D_{LCO} is directly related to the alveolar volume (V_A), it is frequently normalized to this value (D_L/V_A), which allows for its interpretation in the presence of abnormal lung volumes (e.g., after surgical lung resection).

The diffusing capacity will be reduced in all clinical situations in which there is impairment of gas transfer from the alveoli to capillary blood.^{2,3} Common conditions that reduce the D_{LCO} include lung resection, emphysema (loss of functioning alveolar-capillary units), and interstitial lung disease (thickening of the alveolar-capillary membrane). Normal PFTs with a reduced D_{LCO} should suggest the possibility of pulmonary vascular disease (e.g., pulmonary embolus) but also can be seen with anemia, early interstitial lung disease, and mild *Pneumocystis carinii* (PCP) infection in AIDS patients.

OBSTRUCTIVE LUNG DISEASE

3 Obstructive lung disease implies a reduced capacity to get air through the conducting airways and out of the lungs. This reduction in airflow may be caused by a decrease in the diameter of the airways (bronchospasm), a loss of their integrity (bronchomalacia), or a reduction in the elastic recoil (emphysema) with a resulting decrease in the driving pressure. The most common diseases associated with obstructive pulmonary functions are asthma, emphysema, and chronic bronchitis; however, bronchiectasis, infiltration of the bronchial wall by tumor or granuloma, aspiration of a foreign body, and bronchiolitis

also cause obstructive PFTs. The standard test used to evaluate airway obstruction is the forced-expiratory spiogram.

Standard spirometry and flow-volume loop measurements include many variables; however, according to American Thoracic Society guidelines, the diagnosis of obstructive and restrictive ventilatory defects should be made using the basic measurements of spirometry.³ A reduction in FEV₁ (with a normal FVC) establishes the diagnosis of obstruction. When both the FEV₁ and FVC are reduced, the FEV₁ cannot be used to assess airway obstruction because such patients may have either obstruction or restriction. In restrictive lung disease, the patient has an inability to get air into the lung, which results in a reduction of all expiratory volumes (FEV₁, FVC, and SVC). In obstructed patients, a better measurement is the ratio of the FEV₁ to FVC. Patients with restrictive lung disease have a reduced FEV₁ and a reduced FVC, but the FEV₁/FVC ratio remains normal. Although a normal FEV₁/FVC ratio is above 70% to 75%, the ratio is age-dependent, and slightly lower values may be normal in older patients. Caution should be used in interpreting obstruction when the ratio of FEV₁/FVC is below normal but the FEV₁ and FVC are both within the normal range because this pattern can be seen with healthy, athletic subjects. In screening spirometry, performed in office practice, the FEV₆ (the amount of air forcefully exhaled in 6 seconds) may be used in place of the FVC. The FEV₆ is a more reproducible number when obtained by less skilled personnel. The measurement of FEF_{25%–75%} is also abnormal in patients with obstructive airways disease. In general, this test has so much variability that it adds little to the measurement of FEV₁ and FEV₁/FVC ratio. The FEF_{25%–75%} has been of value in monitoring lung transplant patients for graft rejection,⁴ and a reduced value may be an early indicator of acute rejection.

Although there is no standardization for interpretation of severity of obstruction, most pulmonary laboratories state that an FEV₁/FVC ratio of less than 70% of the predicted value is diagnostic for obstruction, and the degree of obstruction then is based on the percent predicted of the FEV₁. An FEV₁ of less than 60% of the predicted value is moderate obstruction, and less than 40% of the predicted value is severe obstruction. In patients with obstruction, a dose of a bronchodilator (e.g., albuterol or isoproterenol) by metered-dose inhaler is given during the initial examination. An increase in the FEV₁ of more than 12% and greater than 0.2 L suggest an acute bronchodilator response.³ Because bronchodilator responsiveness is variable over time, the lack of an acute bronchodilator response should not preclude a 6- to 8-week trial of bronchodilators and/or corticosteroids.

Although all patients with obstructive lung disease of any etiology will have reduced flow rates on forced exhalation, the pattern on PFTs may be helpful in differentiating among the various etiologies (Table 25–1). Asthma is characterized by variable obstruction that often improves or resolves with appropriate therapy. Since asthma is an inflammatory disorder of the airways (predominantly large airways), the diffusing capacity of carbon monoxide (D_{LCO}) is normal. Most patients with acute asthma have a bronchodilator response of over 15% to 20%; however, this response is also seen in 20% of patients with COPD. These patients are said to have asthmatic bronchitis. Chronic bronchitis may be limited to the airways, but the vast majority of patients with chronic bronchitis and airway obstruction have a mixture of bronchitis and emphysema and have a reduction in D_{LCO}. Therefore, D_{LCO} is the best PFT in separating asthma from COPD.

After the diagnosis of obstructive airways disease is established, the course and response to therapy are best followed by serial spirometry. The multicenter Lung Health Study demonstrated an abnormally rapid decline (90–150 mL/year) in patients with COPD who continue

TABLE 25–1. Specific Patterns of Pulmonary Function in Patients with Chronic Obstructive Pulmonary Disease (COPD)

| | Asthma | COPD | |
|---------------------------------|--------|--------------------|----------------|
| | | Chronic Bronchitis | Emphysema |
| Decreased FEV ₁ | ++++ | ++++ | ++++ |
| Decreased FEV ₁ /FVC | ++++ | ++++ | ++++ |
| Increased airway resistance | ++++ | ++++ | + |
| Decreased D _{LCO} | — | –/++ ^a | ++++ |
| Response to bronchodilators | ++++ | + ^b | – ^b |

^aMost smokers with chronic bronchitis have reduced D_{LCO}.

^bTwenty percent of patients with COPD have large (++++) bronchodilator response.

D_{LCO} = diffusing capacity of carbon monoxide; FEV₁ = forced expiratory volume after 1 second; FVC = forced vital capacity.

to smoke.⁵ Smoking cessation often resulted in an increase in FEV₁ during the first year and a near-normal rate of decline (30–50 mL/year) in subsequent years.

AIRWAY HYPERREACTIVITY

4 Airway hyperreactivity or hyperresponsiveness is defined as an exaggerated bronchoconstrictor response to physical, chemical, or pharmacologic stimuli. Individuals with asthma, by definition, have hyperresponsive airways. Recently, the Lung Health Study Group⁶ observed nonspecific hyperresponsiveness in a significant number of patients with COPD. This group of patients with airway hyperreactivity appears to have a worse prognosis and an accelerated rate of decline in FEV₁.

Some patients with asthma (especially cough-variant asthma) present with no history of wheezing and normal PFTs. The diagnosis of asthma still can be established by demonstrating hyperresponsiveness to provocative agents. The two agents used most widely in clinical practice are methacholine and histamine. Other agents used for bronchial provocation include distilled water, cold air, and exercise. During a typical bronchoprovocation test, a baseline FEV₁ is measured after the inhalation of isotonic saline, and then increasing doses of methacholine are given at set intervals. Hyperresponsiveness is defined by a decline in FEV₁ of 20% or greater and by reversibility of obstruction to bronchodilators. The result can best be expressed as the provocative concentration necessary to cause a fall in FEV₁ of 20% (PC₂₀). A test is considered positive if either methacholine or histamine demonstrate a PC₂₀ for FEV₁ at 8 mg/mL or less or fewer than 60 to 80 cumulative breath units.⁷ This test is used most frequently to establish a diagnosis of asthma in patients with normal PFTs but may be useful in following patients with occupational asthma, establishing the severity of asthma, and assessing the response to treatment.

UPPER AIRWAY OBSTRUCTION

Obstruction of airflow by abnormalities in the upper airway often go undiagnosed or misdiagnosed because of improper interpretation of the PFTs. The patients have obstructive physiology and often are misclassified as having asthma or COPD. The shape of the flow-volume

FIGURE 25-5. Maximum expiratory flow-volume curves from patients with fixed obstruction, variable extrathoracic obstruction, and variable intrathoracic obstruction. RV = residual volume; TLC = total lung capacity.

loop, which includes inspiratory and expiratory flow-volume curves, and the ratio of the expiratory and inspiratory flow at 50% of vital capacity ($FEF_{50\%}/FIF_{50\%}$) may be useful in the diagnosis of upper airway obstruction.⁸

The shape of the flow-volume curve differs depending on whether the obstruction is fixed or variable (Fig. 25-5). Fixed lesions, as in strictures from previous intubations or tracheostomy, cause a uniform caliber of the airway during inspiration and expiration. With variable lesions, however, the airway caliber changes with changes in intrathoracic pressure. Variable lesions are subclassified into variable intrathoracic and variable extrathoracic. If the lesion is intrathoracic, as with tumors of the trachea, the negative pressure generated during inspiration opens the obstruction, whereas the positive pressure during expiration worsens the obstruction. If there is variable extrathoracic obstruction, as with vocal cord dysfunction, the negative pressure within the airways will pull the vocal cord toward the midline and potentiate the obstruction. In this case, there will be a plateau on the inspiratory limb on the flow-volume loop, and the $FEF_{50\%}/FIF_{50\%}$ will be greater than 1. Typical flow-volume curves from upper airway obstruction are shown in Figure 25-4.

Another test used to distinguish upper airway obstruction from COPD and asthma is the $FEV_1/FEV_{0.5}$ (FEV at 1 second/ FEV at 0.5 second). This ratio is usually greater than 1.5 in patients with upper airway obstruction.⁹ This is so because the $FEV_{0.5}$ is proportionately more reduced in upper airway obstruction because forced expiration measured at 0.5 second better reflects obstruction at high lung volumes. The abnormality seen on the flow-volume loop has been referred to as “straightening” of the curve during early expiration.

RESTRICTIVE LUNG DISEASE

5 *Restrictive lung disease* is defined as an inability to get air into the lungs and to maintain normal lung volumes. Restrictive lung disease reduces all the subdivisions of lung volumes (IRV, V_T , ERV, and RV) without reducing airflow. These patients have normal airway resistance, and their FEV_1/FVC ratio is greater than 75%.

Although *restriction* could be defined as a reduction in vital capacity (VC or FVC) with a normal FEV_1/FVC ratio, poor effort also will reduce FVC with a normal FEV_1/FVC ratio. A reduction in the TLC is the most accurate measurement of restrictive lung function. As mentioned previously, TLC can be measured by various techniques. The gas dilution methods (i.e., helium dilution and nitrogen washout) are unable to measure gas trapped in cysts or bullae and may underestimate the true lung volume. Therefore, TLC is best measured by plethysmography. Most restrictive lung disease is associated with impairment or destruction of the alveolar capillary membrane, and therefore, the D_{LCO} is reduced in most patients with restrictive lung disease. The reduction in D_{LCO} may occur prior to a reduction in lung volumes and is used as a marker of early interstitial (restrictive)

lung disease. The D_{LCO} may be abnormal even with a normal chest x-ray, and thin-cut computed tomographic (CT) scans of the chest may be required to diagnose early interstitial lung disease. Because peribronchiolar inflammation and fibrosis occur in patients with restrictive parenchymal lung disease, the $FEF_{25\%-75\%}$ may be reduced and fail to respond to bronchodilators.

The severity of restrictive disease has not been standardized; however, many laboratories classify patients with a reduced TLC into mild ($TLC \leq 80\%$), moderate ($TLC \leq 65\%$), and severe ($TLC \leq 50\%$). These definitions are completely arbitrary because a patient with obstructive lung disease may start with a TLC of 120% and subsequently develop a moderately severe restrictive lung disease while maintaining a TLC within the normal range. On flow-volume loop, patients with restrictive disease have normal-shaped curves with a reduction in the height and width of the curve because the peak expiratory flow rate (PEFR) and VC both depend on the amount of air within the lung prior to performing expiratory maneuvers (see Fig. 25-3).

6 Restrictive lung function can be produced by increased elastic recoil of the lung parenchyma (interstitial lung disease), respiratory muscle weakness, mechanical restrictions (chest wall deformities), and/or poor effort. Table 25-2 lists common causes of restrictive lung disease.

Restrictive lung function from parenchymal lung disease usually can be differentiated from processes causing mechanical

TABLE 25-2. Causes of Restrictive Lung Disease

| |
|-------------------------------|
| Interstitial lung diseases |
| Idiopathic pulmonary fibrosis |
| Sarcoidosis |
| Collagen vascular disease |
| Pneumoconiosis |
| Drug-induced lung disease |
| Pulmonary edema |
| Infiltrative lung diseases |
| Granulomatosis |
| Tumor |
| Pleural diseases |
| Pleural effusion |
| Fibrothorax |
| Pneumothorax |
| Chest wall diseases |
| Kyphoscoliosis |
| Ankylosing spondylitis |
| Neuromuscular disease |
| Miscellaneous causes |
| Obesity |
| Pregnancy |
| Ascites |
| Paralyzed diaphragm |
| Lung resection |

TABLE 25–3. Patterns of Pulmonary Function

|-----------------------|--------------------------|---------|--------------------------|-----------------------|
| | Asthma | COPD | Parenchymal Disease | Chest Bellows Disease |
| FVC | NI or I | NI or I | D | D |
| FEV ₁ | D | D | D | D |
| FEV ₁ /FVC | <75% | <75% | ≥75% | ≥75% |
| TLC | NI or I | NI or I | D | D |
| RV/TLC | NI or I | NI or I | NI | I |
| Airway resistance | I | I | NI | NI |
| D _{LCO} | NI | D | D | NI |

D = decreased; I = increased; NI = normal.

restriction as a result of chest bellows malfunction (Table 25–3). Restrictive parenchymal diseases are associated with a reduction in alveolar volume and an increase in lung elastic recoil. All lung volumes, as well as the D_{LCO}, are reduced. The RV/TLC ratio (normal ≤ 30%) and measurements of maximal inspiratory pressure (MIP; normal = –75 cm H₂O males, –50 cm H₂O females) remain normal. In addition, these patients exhibit mild resting hypoxemia that worsens with exercise. Monitoring gas exchange during exercise may be the most sensitive test for detecting progression of interstitial lung disease.¹⁰

Mechanical restriction caused by chest bellows malfunction may result from chest wall or skeletal deformity, loss of neuromuscular function, fibrosis of the pleural space, and abdominal overdistension causing upward displacement of the diaphragm, as well as decreased diaphragm movement. The most common pulmonary function pattern seen in these patients is a decrease in TLC and VC with only a slight decrease in RV. The RV is maintained in these diseases because lung compliance remains normal. The D_{LCO} is normal or only minimally reduced, and the D_{LCO}/V_A (corrected for alveolar volume) is normal. The RV/TLC ratio is often increased in patients with restrictive chest bellows disease. Patients with neuromuscular disease also have reduced respiratory muscle function with a reduction in their MIP.

PULMONARY GAS EXCHANGE

The essential function of the lungs is to maintain blood gas homeostasis. Arterial blood gas measurement plays an important role in the diagnosis and management of patients with pulmonary disease and should be ordered whenever hypoxemia, hypercapnia (CO₂ retention), and/or acid-base disorders are suspected clinically. Every time arterial blood gas determinations are ordered, the A–a gradient (the difference between the partial pressure of oxygen in the alveolus and the partial pressure of oxygen in arterial blood) should be calculated. This is done by computer on all automated blood gas machines, and a normal P(A–a)O₂ can be approximated for sea level breathing room air by multiplying the age by 0.3. The presence of hypoxemia with a normal A–a gradient usually implies alveolar hypoventilation (e.g., sedative overdose). Most patients develop hypoxemia secondary to mismatching of ventilation and perfusion, and the P(A–a)O₂ will be significantly elevated.

Pulse oximetry is used widely in clinical practice to monitor arterial saturation (SpO₂). A pulse oximeter is a small battery-operated device that is placed on the finger or the earlobe. This device emits and reads the reflected light from capillary blood, estimating the

saturation. Although very useful clinically, SpO₂ is only an estimate of the arterial saturation, and the actual arterial oxygen saturation (SaO₂) can be ±4% of the oximetry reading. The error may be even greater with a saturation of less than 88%. Pulse oximeters do not measure carboxyhemoglobin, and the SpO₂ may be overestimated significantly in patients with smoke inhalation or recent smokers. An initial validation of pulse oximetry with direct measurement of SaO₂ is recommended in any critically ill patient.

EXERCISE TESTING

Cardiopulmonary exercise testing allows for assessment of the multiple organs involved in exercise and has benefits over the assessment of either the cardiac or pulmonary system alone. The major indications for exercise testing are dyspnea on exertion, evaluation of exercise-induced bronchospasm, and suspected arterial desaturation during exercise.^{11,12} Exercise testing also can be useful in the evaluation of ventilatory or cardiovascular limitations to work, assessment of general fitness or conditioning, evaluation of disability, establishment of safe levels for exercise, evaluation of drug therapy, determining the need and liter flow for supplemental oxygen therapy during exercise, assessment of the effects of a rehabilitation program, and as a preoperative assessment before lung resection.^{11–13}

Tests for general fitness include the 6-minute walking distance and the Harvard step test.^{11,13} For the 6-minute walking distance, the subject simply walks a predetermined route or circuit as fast as possible for 6 minutes. The greater the distance covered, the better are the patient's general fitness and exercise tolerance. For the Harvard step test, the subject steps up and down on a 20-in step at a set rate for 5 minutes. A 1-minute rest period is followed by measurement of the subject's recovery heart rate. The lower the recovery heart rate, the better is the subject's general fitness.

Exercise testing sometimes is done to determine if exercise results in arterial oxygen desaturation (SaO₂ < 90%).^{12,13} This may be useful to quantify the level of exertion the patient can perform during the activities of daily living, as well as in determining appropriate levels of supplemental oxygen therapy. Typically, this test is done using a treadmill or cycle ergometer. A baseline measurement of arterial blood gas values or pulse oximetry is followed by up to 6 minutes of exercise, during which time the patient is monitored for oxygen desaturation using pulse oximetry. If significant desaturation occurs (saturation ≤88% to 90%), the test is terminated. In the event of oxygen desaturation, the test may be repeated to determine the level of supplemental oxygen therapy needed to compensate for the desaturation that otherwise would occur.

TABLE 25–4. Indications and Contraindications for Exercise Testing

Indications

- Dyspnea upon exertion
- Exercise-induced bronchospasm
- Suspected arterial desaturation with exercise
- Evaluation of ventilatory limitations to exercise
- Evaluation of cardiac limitations to exercise
- Assessment of general fitness or conditioning
- Evaluation of cardiopulmonary disability
- Establishment of safe levels for exercise
- Evaluation of drug therapy
- Determining appropriate use of supplemental oxygen therapy
- Assessment of the effect of a rehabilitation program
- Evaluation of specific disease states or conditions (e.g., asthma; COPD; interstitial lung disease; pulmonary vascular disorders; coronary artery disease; other vascular disorders; neuromuscular disorders; obesity; anxiety-induced hyperventilation)
- Assessment before resection

Contraindications

- Pao₂ less than 40 mm Hg on room air
- Paco₂ greater than 70 mm Hg
- FEV₁ less than 30% of predicted
- Recent (within 4 weeks) myocardial infarction
- Unstable angina pectoris
- Second- or third-degree heart block
- Rapid ventricular/atrial arrhythmias
- Orthopedic impairment
- Severe aortic stenosis
- Congestive heart failure
- Uncontrolled hypertension
- Limiting neurologic disorders
- Dissecting/ventricular aneurysms
- Severe pulmonary hypertension
- Thrombophlebitis or intracardiac thrombi
- Recent systemic or pulmonary embolus
- Acute pericarditis

Exercise tolerance tests or cardiopulmonary stress testing may include the measurement of oxygen consumption ($\dot{V}O_2$), carbon dioxide production ($\dot{V}CO_2$), minute volume ($\dot{V}E$), oxygen saturation via pulse oximeter (SpO_2), heart rate, blood pressure, and recording or monitoring of the subject’s electrocardiogram (ECG). During exercise, oxygen consumption ($\dot{V}O_2$) increases with workload in a linear fashion until a maximum oxygen consumption level is reached ($\dot{V}O_{2,max}$). Consequently, $\dot{V}O_{2,max}$ is a measure of an individual’s muscular work capacity.^{11–13} Normal $\dot{V}O_{2,max}$ is about 1700 mL/min for a

sedentary person and up to 5800 mL/min in a trained athlete.¹³ This compares with a resting $\dot{V}O_2$ of about 250 mL/min. Ventilatory equivalents for oxygen and carbon dioxide and O₂ pulse are often calculated. Ventilatory equivalent for oxygen is a measure of the efficiency of the ventilatory pump at various workloads^{11,13} and is calculated as follows:

$$\text{Ventilatory equivalent for } O_2 = \dot{V}E/\dot{V}O_2$$

A normal ventilatory equivalent for oxygen is 20 to 30.^{11,13}

O₂ pulse is an estimate of oxygen consumption per cardiac cycle and may be decreased with cardiac problems. O₂ pulse can be calculated as follows:

$$O_2 \text{ pulse} = (\dot{V}O_2 \times 1000)/\text{heart rate}$$

A normal O₂ pulse is 2.5 to 4.0 mL per beat at rest, increasing to 10 to 15 mL per beat during strenuous exercise.^{11,13}

The anaerobic threshold is the point during strenuous exercise at which anaerobic metabolism and lactic acid production begin.^{11,13} Carbon dioxide production ($\dot{V}CO_{2,max}$) increases with exercise at about the same rate as $\dot{V}O_2$, until the subject’s anaerobic threshold is reached. From that point on, $\dot{V}CO_2$ increases faster than $\dot{V}O_2$, and this change can be used to estimate the anaerobic threshold. A breath-by-breath plot of the ventilatory equivalents for O₂ and CO₂ also can be used to determine the anaerobic threshold. Anaerobic threshold is a measure of fitness in normal subjects, and aerobic training can delay the anaerobic threshold.^{11,13}

For exercise-tolerance testing, the subject typically is subjected to either a constant work load (steady-state tests) or an increasing work load (progressive multistage tests) using a cycle ergometer or treadmill.^{11,13} With the progressive multistage tests, the subject is exercised until exhaustion or the occurrence of an adverse reaction, at which point the test is stopped. Safety during exercise testing is of major importance, and rigorous guidelines for the termination of the test should be followed. Both types of tests can be used to determine $\dot{V}O_{2,max}$. A limit to exercise, as indicated by a decrease in $\dot{V}O_{2,max}$, can be as a result of (1) poor conditioning, (2) a pulmonary limitation, (3) a cardiac limitation, or (4) poor effort. In the case of poor conditioning, SpO_2 and O₂ pulse will be normal. With a pulmonary limitation to exercise, SpO_2 will be reduced, and O₂ pulse will be normal. With a cardiac limitation to exercise, SpO_2 will be normal, and O₂ pulse reduced. Table 25–4 summarizes the indications and contraindications for exercise testing. Table 25–5 summarizes the findings during maximum exercise associated with poor conditioning, pulmonary limitations to exercise, and cardiac limitations to exercise.

Review Questions and other resources can be found at www.pharmacotherapyonline.com.

TABLE 25–5. Typical Findings During Maximum Exercise with Poor Conditioning, Pulmonary Limitations to Exercise, and Cardiac Limitations to Exercise

| Test Parameter | Poor Conditioning | Pulmonary Limitation | Cardiac Limitation |
|--|-------------------|----------------------|--------------------|
| $\dot{V}O_{2,max}$ | ↓ | ↓ | ↓ |
| SpO_2 | N | ↓ | N |
| O ₂ pulse | N or ↓ | N or ↓ | ↓ |
| Anaerobic threshold | ↓ or N | ↓ or N | ↓ |
| Ventilatory reserve* (MVV- $V_{E,max}$) | N | ↓ | N or ↑ |

*Ventilatory reserve = Maximum voluntary ventilation (MVV) – minute volume during maximum exercise ($V_{E,max}$).
N = normal.

ASTHMA

H. William Kelly and Christine A. Sorkness

Learning Objectives and other resources can be found at www.pharmacotherapyonline.com.

KEY CONCEPTS

- 1 Asthma is a disease of increasing prevalence that is a result of genetic predisposition and environmental interactions.
- 2 Asthma is primarily a chronic inflammatory disorder of the airways of the lung characterized by T-helper cell type 2 (Th2)–lymphocyte–mediated immune response for which there is no known cure or primary prevention.
- 3 Asthma is characterized by either the intermittent or persistent presence of highly variable degrees of airway obstruction from airway wall inflammation and bronchial smooth muscle constriction.
- 4 The inflammatory process in asthma is treated most effectively with corticosteroids, with the inhaled corticosteroids having the greatest efficacy for persistent asthma.
- 5 Bronchial smooth muscle constriction is prevented or treated most effectively with inhaled β_2 -adrenergic receptor agonists.
- 6 Variability in response to medications requires individualization of therapy within existing evidence-based guidelines for management.
- 7 Ongoing patient education, including avoidance of triggers and self-management techniques, is essential for optimal patient outcomes.

Asthma has been known since antiquity, yet it is a disease that still defies precise definition. The word *asthma* is of Greek origin and means “panting.” More than 2000 years ago, Hippocrates used the word *asthma* to describe episodic shortness of breath; however, the first detailed clinical description of the asthmatic patient was made by Aretaeus in the second century.¹ An expert panel of the National Institutes of Health, the National Asthma Education and Prevention Program (NAEPP), has provided the following working definition of asthma²:

Asthma is a chronic inflammatory disorder of the airways in which many cells and cellular elements play a role, in particular, mast cells, eosinophils, T-lymphocytes, macrophages, neutrophils, and epithelial cells. In susceptible individuals, this inflammation causes recurrent episodes of wheezing, breathlessness, chest tightness, and coughing, particularly at night or in the early morning. These episodes are usually associated with widespread but variable airflow obstruction that is often reversible either spontaneously or with treatment. The inflammation also causes an associated increase in the existing bronchial hyperresponsiveness to a variety of stimuli.

This definition encompasses the important heterogeneity of the clinical presentation of asthma by describing the scientific and clinically accepted characteristics of asthma.

EPIDEMIOLOGY

- 1 An estimated 14 to 15 million persons in the United States have asthma (about 5% of the population).³ Asthma is the most common chronic disease among children in the United States, with

approximately 5 million children affected. Over the past two decades in the United States, the prevalence of asthma has increased by 75%, whereas the rate in children younger than age 5 has increased 160%.³ In the United States, as in other Western industrialized countries, the prevalence of asthma has reached epidemic proportions. Asthma accounts for 1.6% of all ambulatory care visits (13.7 million) and results in more than 470,000 hospitalizations and 2 million emergency department visits per year.³ Asthma is the third leading cause of preventable hospitalization in the United States, and hospitalizations for asthma among children 0 to 17 years of age have increased 4.5% per year, whereas total hospitalizations for all causes in children actually decreased.⁴ Children have the highest prevalence of asthma, at 68.6 per 1000 population younger than 18 years of age. Asthma accounts for more than 10 million missed school days per year.⁴ The prevalence of disabling asthma in children has increased 232% over the past 20 years compared with a 113% increase from all other chronic conditions in childhood. In young children (0 to 10 years of age), the risk of asthma is greater in boys than in girls, becomes about equal during puberty, and then is greater in women than in men.³

Ethnic minorities continue to share the burden of asthma disproportionately. African-Americans and Hispanics have a higher prevalence than whites, but this appears to be a result of urbanization and not race or socioeconomic status.⁵ African-Americans are three times as likely to be hospitalized and approximately 2.5 times more likely to die from asthma.³ In addition, African-Americans and Puerto Ricans living in inner cities are four times more likely to experience emergency department visits than whites.³ These patterns are likely a result of poor access to care.

The estimated cost of asthma in the United States in 1998 was \$12.6 billion.⁶ The average societal burden of asthma (including both

direct and indirect medical expenditures) in the United States averages \$640 per patient per year, with direct medical expenditures accounting for 40% to 50% of total costs.⁶ Emergency care of acute asthma exacerbations makes up the largest portion of direct medical costs. In 1997, an estimated cost of \$1 billion dollars per year in lost productivity accrued from parents staying home to care for their children.⁶

The natural history of asthma is still not well defined. Although asthma can occur at any time, it is principally a pediatric disease, with most patients being diagnosed by 5 years of age and up to 50% of children having symptoms by 2 years of age.² Between 30% and 70% of children with asthma will improve markedly or become symptom-free by early adulthood; chronic disease persists in about 30% to 40% of patients, and generally 20% or less develop severe chronic disease.² Atopic status is the strongest indicator of a poor prognosis, although initial severity also predicts severity as an adult.⁷ Diminished lung growth may occur in children with uncontrolled severe asthma. Low lung function and increased bronchial hyperresponsiveness are independent risk factors for low lung function in early adulthood.⁸

In adults, most longitudinal studies have suggested a more rapid rate of decline in lung function in asthmatics than in normal volunteers, primarily reflected in forced expiratory volume in 1 second (FEV₁).⁷ However, the annual decline in FEV₁ is less than in smokers or in patients with a diagnosis of emphysema. In general, asthmatics with less frequent attacks and normal lung function on initial assessment have higher remission rates, whereas smokers have the lowest remission and highest relapse rates.⁷ The level of bronchial hyperresponsiveness (BHR) tends to predict the rate of decline in FEV₁, with a greater decline with high levels of BHR.⁸ Thus airways obstruction in asthma not only may become irreversible but also may worsen over time owing to airway remodeling (see below).⁹

Although both the prevalence and the morbidity from asthma are increasing, the death rate from asthma in the United States appears to have reached a plateau of about 5000 deaths per year and may be on the decline.³ Despite the relatively low number of asthma deaths, 80% to 90% are preventable.² Most deaths from asthma occur outside the hospital, and death is rare after hospitalization. The most common cause of death from asthma is inadequate assessment of the severity of airways obstruction by the patient or physician and inadequate therapy. The most common cause of death in hospitalized patients is also inadequate or inappropriate therapy. Thus the key to prevention of death from asthma, as advocated by the NAEPP, is education.²

ETIOLOGY

▶ Asthma is at least a partially heritable complex syndrome that requires a gene-by-environment interaction for phenotypic expression. Epidemiologic studies strongly support the concept of a genetic predisposition to the development of asthma.¹⁰ Genetic factors account for 35% to 70% of the susceptibility. Asthma represents a complex genetic disorder in that the asthma phenotype is likely a result of polygenic inheritance or different combinations of genes. Initial searches were focused on establishing links between atopy (genetically determined state of hypersensitivity to environmental allergens) and asthma, but more recent genome-wide searches have found linkages with genes for metalloproteinases (e.g., *ADAM33*).^{10,11} Thus, although genetic predisposition to atopy is a significant risk factor for developing asthma, not all atopic individuals develop asthma, nor do all asthmatics exhibit atopy.

▶ Environmental risk factors for the development of asthma include socioeconomic status, family size, exposure to second-hand tobacco smoke in infancy and in utero, allergen exposure, urbanization, and decreased exposure to common childhood infectious agents.¹² Currently, the so-called hygiene hypothesis that proposes that genetically susceptible individuals develop allergies and asthma by allowing the allergic immunologic system (Th2-lymphocytes) to develop instead of the immunologic system used to fight infections (Th1-lymphocytes) is being used to explain the increase of asthma in Western countries.^{9,10} The first 2 years of life appear to be most important for the exposures to produce an alteration in the immune response system. Support for the hygiene hypothesis for asthma comes from studies demonstrating a lower risk for asthma in children who live on farms and are exposed to high levels of bacteria, in those with a large number of siblings, in those with early enrollment into child care, in those with exposure to cats and dogs early in life, or in those with exposure to fewer antibiotics.^{10,12}

Risk factors for early (<3 years of age) recurrent wheezing associated with viral infections include low birth weight, male gender, and parental smoking. However, this early pattern is due to smaller airways, and these risk factors are not necessarily risk factors for asthma in later life.⁷ Atopy is the predominant risk factor for children to have continued asthma.⁷ Asthma can occur in adults later in life. Occupational asthma in previously healthy individuals emphasizes the effect of environment on the development of asthma.¹³ The heterogeneity of the asthma phenotype appears most obvious when listing the diverse triggers of bronchospasm in asthmatic subjects^{2,10} (Table 26–1). The various triggers have relative degrees of importance from patient to patient. This variety should serve as ample evidence that asthma is likely to be as complex genetically.

Environmental exposures are the most important precipitants of severe asthma exacerbations^{2,10} (see Table 26–1). Epidemics of severe asthma in cities have followed exposures to high concentrations of aeroallergens.² Viral respiratory tract infections remain the single most significant precipitant of severe asthma in children and are an important trigger in adults as well.^{2,10} Other possible factors include air pollution, sinusitis, food preservatives, and drugs.

TABLE 26–1. List of Agents and Events Triggering Asthma

| | |
|-----------------------|--|
| Respiratory infection | Respiratory syncytial virus (RSV), rhinovirus, influenza, parainfluenza, <i>Mycoplasma pneumoniae</i> |
| Allergens | Airborne pollens (grass, trees, weeds), house-dust mites, animal danders, cockroaches, fungal spores |
| Environment | Cold air, fog, ozone, sulfur dioxide, nitrogen dioxide, tobacco smoke, wood smoke |
| Emotions | Anxiety, stress, laughter |
| Exercise | Particularly in cold, dry climate |
| Drugs/preservatives | Aspirin, NSAIDs (cyclooxygenase inhibitors), sulfites, benzalkonium chloride, β -blockers |
| Occupational stimuli | Bakers (flour dust); farmers (hay mold); spice and enzyme workers; printers (arabic gum); chemical workers (azo dyes, anthraquinone, ethylenediamine, toluene diisocyanates, polyvinyl chloride); plastics, rubber, and wood workers (formaldehyde, western cedar, dimethylethanolamine, anhydrides) |

FIGURE 26-1. Representative illustration of the pathology found in the asthmatic bronchus compared with a normal bronchus (*upper right*). Each section demonstrates how the lumen is narrowed. Hypertrophy of the basement membrane, mucus plugging, smooth muscle hypertrophy, and constriction contribute (*lower section*). Inflammatory cells infiltrate, producing submucosal edema, and epithelial desquamation fills the airway lumen with cellular debris and exposes the airway smooth muscle to other mediators (*upper left*).

PATHOPHYSIOLOGY

2 The major characteristics of asthma include a variable degree of airflow obstruction (related to bronchospasm, edema, and hypersecretion), BHR, and airways inflammation (Fig. 26-1). Evidence of inflammation arose from the studies of nonspecific BHR, bronchoalveolar lavage (BAL), bronchial biopsies, and induced sputum, as well as from postmortem observations of patients with asthma who died from an attack of asthma or from other causes. To understand the pathogenetic mechanisms that underlie the many variants of asthma, it is critical to identify factors that initiate, intensify, and modulate the inflammatory response of the airways and to determine how these immunologic and biologic processes produce the characteristic airways abnormalities. Immune responses mediated by IgE antibodies are of foremost importance.

ACUTE INFLAMMATION

Inhaled allergen challenge models contribute most to our understanding of acute inflammation in asthma.¹⁴ Inhaled allergen challenge in allergic patients leads to an early-phase allergic reaction that, in some cases, may be followed by a late-phase reaction. The activation of cells bearing allergen-specific IgE initiates the early-phase reaction. It is characterized primarily by the rapid activation of airway mast cells and macrophages. The activated cells rapidly release proinflammatory mediators such as histamine, eicosanoids, and reactive oxygen species that induce contraction of airway smooth muscle, mucus secretion, and vasodilatation.¹⁴ The bronchial microcirculation has an essential role in this inflammatory process. Inflammatory mediators induce microvascular leakage with exudation of plasma in the airways.¹⁴ Acute plasma protein leakage induces a thickened, engorged, and edematous airway wall and a consequent narrowing of the airway lumen. Plasma exudation may compromise epithe-

lial integrity, and the presence of plasma in the lumen may reduce mucus clearance.¹⁴ Plasma proteins also may promote the formation of exudative plugs mixed with mucus and inflammatory and epithelial cells. Together these effects contribute to airflow obstruction (Fig. 26-1).

The late-phase inflammatory reaction occurs 6 to 9 hours after allergen provocation and involves the recruitment and activation of eosinophils, CD4+ T cells, basophils, neutrophils, and macrophages.¹⁴ There is selective retention of airway T cells, the expression of adhesion molecules, and the release of selected proinflammatory mediators and cytokines involved in the recruitment and activation of inflammatory cells.¹⁴ The activation of T cells after allergen challenge leads to the release of T-helper cell type 2 (Th2)-like cytokines that may be a key mechanism of the late-phase response.¹⁴ The release of preformed cytokines by mast cells is the likely initial trigger for the early recruitment of cells. This cell type may recruit and induce the more persistent involvement by T cells.¹⁴ The enhancement of nonspecific BHR usually can be demonstrated after the late-phase reaction but not after the early-phase reaction following allergen or occupational challenge.

CHRONIC INFLAMMATION

Airways inflammation has been demonstrated in all forms of asthma, and an association between the extent of inflammation and the clinical severity of asthma has been demonstrated in selected studies.⁷ It is accepted that both central and peripheral airways are inflamed.

In asthma, all cells of the airways are involved and become activated (Fig. 26-2). Included are eosinophils, T cells, mast cells, macrophages, epithelial cells, fibroblasts, and bronchial smooth muscle cells. These cells also regulate airway inflammation and initiate the process of remodeling by the release of cytokines and growth factors.¹⁵

EPITHELIAL CELLS

Bronchial epithelial cells traditionally have been considered as a barrier, participating in mucociliary clearance and removal of noxious agents. However, epithelial cells also participate in inflammation by the release of eicosanoids, peptidases, matrix proteins, cytokines, and nitric oxide (NO). Epithelial cells can be activated by IgE-dependent mechanisms, viruses, pollutants, or histamines. In asthma, especially fatal asthma, extensive epithelial shedding occurs. The functional consequences of epithelial shedding may include heightened airways responsiveness, altered permeability of the airway mucosa, depletion of epithelial-derived relaxant factors, and loss of enzymes responsible for degrading proinflammatory neuropeptides. The integrity of airway epithelium may influence the sensitivity of the airways to various provocative stimuli. Epithelial cells also may be important in the regulation of airway remodeling and fibrosis.^{15,16}

EOSINOPHILS

Eosinophils play an effector role in asthma by release of proinflammatory mediators, cytotoxic mediators, and cytokines.¹⁵ Circulating eosinophils migrate to the airways by cell rolling, through interactions with selectins, and eventually adhere to the endothelium through the binding of integrins to adhesion proteins (vascular cell adhesion molecule 1 [VCAM-1] and intercellular adhesion molecule 1 [ICAM-1]). As eosinophils enter the matrix of the membrane, their survival is prolonged by interleukin 5 (IL-5) and

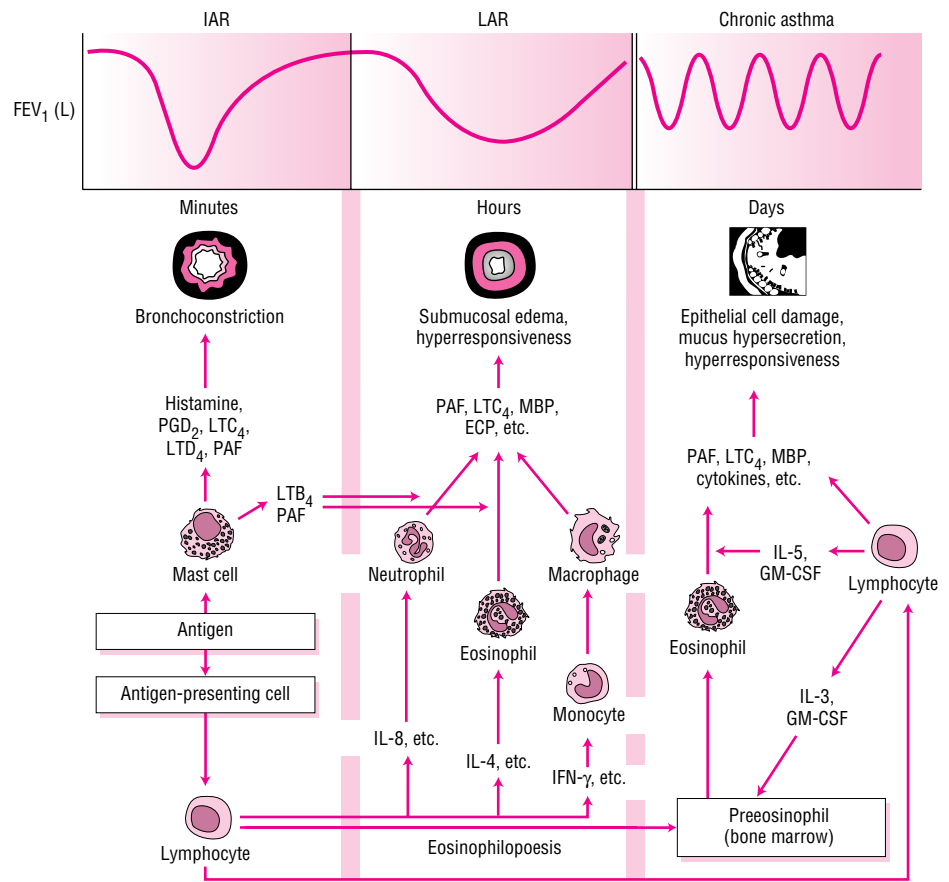

FIGURE 26–2. Diagrammatic presentation of the relationship between inflammatory cells, lipid and preformed mediators, inflammatory cytokines, and proposed pathogenesis and clinical presentation in asthma. See text for details. PG = prostaglandin; LT = leukotriene; PAF = platelet-activating factor; IL = interleukin; MBP = major basic protein; GM-CSF = granulocyte-macrophage colony-stimulating factor.

granulocyte-macrophage colony-stimulating factor (GM-CSF). On activation, eosinophils release inflammatory mediators such as leukotrienes and granule proteins to injure airway tissue.¹⁵

LYMPHOCYTES

Mucosal biopsy specimens from patients with asthma contain lymphocytes, many of which express surface markers of inflammation. There are two types of T-helper CD4⁺ cells. Type 1 T-helper (Th1) cells produce IL-2 and interferon- γ (IFN- γ), both essential for cellular defense mechanisms. Th2 cells produce cytokines (IL-4, -5, -6, -9, and -13) that mediate allergic inflammation. It is known that Th1 cytokines inhibit the production of Th2 cytokines, and vice versa. It is hypothesized that allergic asthmatic inflammation results from a Th2-mediated mechanism (an imbalance between Th1 and Th2 cells).¹⁵

TH1 AND TH2 CELL IMBALANCE

It has been postulated that the Th1/Th2 imbalance contributes to the cause and evolution of atopic diseases, including asthma. The T-cell population in the cord blood of newborn infants is skewed toward a Th2 phenotype.^{7,15} The extent of the imbalance between Th1 and Th2 cells (as indicated by diminished IFN- γ production) during the neonatal phase may predict the subsequent development of allergic disease, asthma, or both. It has been suggested that infants at high risk of asthma and allergies should be exposed to stimuli that upregulate Th1-mediated responses in order to restore the balance during a critical time in the development of the immune system and the lung.⁷

The basic premise of the hygiene hypothesis is that the newborn's immune system is skewed toward Th2 cells and needs timely

and appropriate environmental stimuli to create a balanced immune response. Factors that enhance Th1-mediated responses include infection with *Mycobacterium tuberculosis*, measles virus, and hepatitis A virus; increased exposure to infections through contact with older siblings; attendance at day care during the first 6 months of life; and a reduction in the production of IFN- γ . Restoration of the balance between Th1 and Th2 cells may be impeded by frequent administration of oral antibiotics, with concomitant alterations in gastrointestinal flora. Other factors favoring the Th2 phenotype include Western lifestyle, urban environment, diet, and sensitization to house dust mites and cockroaches. Immune "imprinting" may begin in utero by transplacental transfer of allergens and cytokines. The validity of the hygiene hypothesis has been challenged and will continue to generate intense debate.⁷

MAST CELLS

Mast cell degranulation is important in the initiation of immediate responses following exposure to allergens.² Mast cells are found throughout the walls of the respiratory tract, and increased numbers of these cells (three- to fivefold) have been described in the airways of asthmatics with an allergic component. Once binding of allergen to cell-bound IgE occurs, mediators such as histamine; eosinophil and neutrophil chemotactic factors; leukotrienes C₄, D₄, and E₄; prostaglandins; platelet-activating factor; and others are released from mast cells (see Fig. 26–2). Histologic examination has revealed decreased numbers of granulated mast cells in the airways of patients who have died from acute asthma attacks, suggesting that mast cell degranulation is a contributing factor in the progression of

the disease. Mast cell degranulation is believed to be an integral cause of exercise-induced bronchospasm (EIB) following either drying or cooling of the airways.¹⁵

ALVEOLAR MACROPHAGES

The primary function of alveolar macrophages in the normal airway is to serve as “scavengers,” engulfing and digesting bacteria and other foreign materials. They are found in large and small airways, ideally located for affecting the asthmatic response. A number of mediators produced and released by macrophages have been identified, including platelet-activating factor, leukotriene B₄, leukotriene C₄, and leukotriene D₄.¹⁵ Additionally, alveolar macrophages are able to produce neutrophil chemotactic factor and eosinophil chemotactic factor, which, in turn, further the inflammatory process.

NEUTROPHILS

The role of neutrophils in the pathogenesis of asthma remains somewhat unclear because they normally may be present in the airways and usually do not infiltrate tissues showing chronic allergic inflammation despite the potential to participate in late-phase inflammatory reactions. However, high numbers of neutrophils have been reported to be present in the airways of patients who died from sudden-onset fatal asthma.⁷ This suggests that neutrophils may play a pivotal role in the disease process, at least in the sudden-onset fatal cases and in some patients with long-standing or corticosteroid-dependent asthma. The neutrophil also can be a source for a variety of mediators, including platelet-activating factor, prostaglandins, thromboxanes, and leukotrienes, that contribute to BHR and airway inflammation.

FIBROBLASTS AND MYOFIBROBLASTS

Fibroblasts are found frequently in connective tissue. Human lung fibroblasts may behave as inflammatory cells on activation by IL-4 and IL-13. The myofibroblast may contribute to the regulation of inflammation via the release of cytokines and to tissue remodeling. In asthma, myofibroblasts are increased in numbers beneath the reticular basement membrane, and there is an association between their numbers and the thickness of the reticular basement membrane.¹⁶

INFLAMMATORY MEDIATORS

Associated with asthma for many years, histamine is capable of inducing smooth muscle constriction and bronchospasm and is thought to play a role in mucosal edema and mucus secretion.² Lung mast cells are an important source of histamine. The release of histamine can be stimulated by exposure of the airways to a variety of factors, including physical stimuli (such as exercise) and relevant allergens.² Histamine is involved in acute bronchospasm following allergen exposure; however, other mediators such as leukotrienes are also involved.

Besides histamine release, mast cell degranulation releases interleukins, proteases, and other enzymes that activate the production of other mediators of inflammation. Several classes of important mediators, including arachidonic acid and its metabolites (i.e., prostaglandins, leukotrienes, and platelet-activating factor), are derived from cell membrane phospholipids.

Once arachidonic acid is released, it can be broken down by the enzyme cyclooxygenase to form the prostaglandins. A further breakdown product, prostaglandin D₂, has been well characterized and is a potent bronchoconstricting agent. It is unlikely that prostaglandin D₂ can produce sustained effects on airway function or inflammation; however, its role in asthma remains to be determined. Sim-

ilarly, prostaglandin F_{2 α} is a potent bronchoconstrictor in patients with asthma and can enhance the effects of histamine.² However, its pathophysiologic role in asthma is unclear. Another cyclooxygenase product, prostacyclin (prostaglandin I₂), is known to be produced in the lung. It is unclear whether prostaglandin I₂ is important as a bronchoconstricting agent in humans; however, it may contribute to inflammation and edema owing to its effects as a vasodilator.

Thromboxane A₂ is produced by alveolar macrophages, fibroblasts, epithelial cells, neutrophils, and platelets within the lung.¹⁵ Indirect evidence from animal models suggests that thromboxane A₂ may have several effects, including bronchoconstriction, involvement in the late asthmatic response, and involvement in the development of airway inflammation and BHR. Potent and specific thromboxane synthetase inhibitors will be crucial tools for understanding the role of thromboxanes in asthma.

The 5-lipoxygenase pathway of arachidonic acid breakdown is responsible for production of the class of compounds called *cysteinyl leukotrienes* (LTs).¹⁵ Leukotrienes C₄, D₄, and E₄ (cysteinyl LTs) constitute the slow-reacting substance of anaphylaxis (SRS-A). These leukotrienes are liberated during inflammatory processes in the lung. Leukotrienes D₄ and E₄ share a common receptor (LTD₄ receptor) that, when stimulated, produces bronchospasm, mucus secretion, microvascular permeability, and airway edema.

Thought to be produced by macrophages, eosinophils, and neutrophils within the lung, platelet-activating factor (PAF) is involved in the mediation of bronchospasm, sustained induction of BHR, edema formation, and chemotaxis of eosinophils.¹⁵

ADHESION MOLECULES

An important step in the inflammatory process is the adhesion of the various cells to each other and the tissue matrix to facilitate infiltration and migration of these cells to the site of inflammation. To promote this, cell membranes express a number of glycoproteins, or adhesion molecules. Adhesion molecules have additional functions involved in the inflammatory process aside from promoting cell adhesion, including activation of cells and cell-cell communication, and promoting cellular migration and infiltration.² The many adhesion molecules are divided into families on the basis of their chemical structure. These families are the integrins, cadherins, immunoglobulin supergene family, selectins, vascular adhesion molecules, and carbohydrate ligands.¹⁵ Those thought to be important in inflammation include the integrins, immunoglobulin supergene family, selectins, and carbohydrate ligands, including ICAM-1 and VCAM-1.¹⁵ Adhesion molecules are found on a variety of cells, such as neutrophils, monocytes, lymphocytes, basophils, eosinophils, granulocytes, platelets, endothelial cells, and epithelial cells, and can be expressed or activated by the many inflammatory mediators present in asthma.¹⁵

CLINICAL CONSEQUENCES OF CHRONIC INFLAMMATION

Chronic inflammation is associated with nonspecific BHR and induces asthma exacerbations. Exacerbations are characterized by symptoms or worsening of asthma over a period of days or even weeks. Although the inflammatory nature of chronic asthma is not completely understood, corticosteroids remain the most potent anti-inflammatory drugs for use in the treatment of asthma.

Hyperresponsiveness of the airways to physical, chemical, and pharmacologic stimuli is a hallmark of asthma.² BHR also occurs in some patients with chronic bronchitis and allergic rhinitis.² Normal healthy subjects also may develop a transient BHR after viral

respiratory infections or exposure to ozone. However, the degree of BHR is quantitatively greater in asthmatic patients than in other groups. Bronchial responsiveness of the general population fits a unimodal distribution that is skewed toward increased reactivity. Patients with clinical asthma represent the extreme end of the distribution. The degree of BHR within asthmatics correlates with the clinical course of their disease and medication requirement necessary to control symptoms.² Patients with mild symptoms or in remission demonstrate lower levels of responsiveness, although still greater than the normal population.

Our current understanding recognizes that the increased BHR seen in asthma is at least in part owing to an inflammatory response within the airways. Early investigations found correlations with inflammatory cells in BAL fluids and degree of BHR.² Newer evidence suggests that airways remodeling, subepithelial fibrosis, or collagen deposition correlates with BHR.¹⁶ Although the precise link is not known, BHR is in part related to the extent of inflammation in the airways.

REMODELING OF THE AIRWAYS

Acute inflammation is a beneficial, nonspecific response of tissues to injury and generally leads to repair and restoration of the normal structure and function. In contrast, asthma represents a chronic inflammatory process of the airways followed by healing. The end result may be an altered structure referred to as a *remodeling of the airways*.¹⁶ Repair involves replacement of injured tissue by parenchymal cells of the same type and replacement by connective tissue and its maturation into scar tissue. In asthma, the repair process can be followed by complete or altered restitution of airways structure and function, presenting as fibrosis and an increase in smooth muscle and mucus gland mass.¹⁶

The precise mechanisms of remodeling of the airways are under intense study. Airways remodeling is of concern because it may represent an irreversible process that can have more serious sequelae such as the development of chronic obstructive pulmonary disease (COPD).² Recent observations in children with asthma (aged 5 to 12 years) suggest that prevention of the progressive loss of lung function in childhood may require recognition and treatment of the disease during the first 5 years of life.⁷ Whether there is a mechanistic link between this loss of airway function and structural remodeling of the airway in early life is unknown.

MUCUS PRODUCTION

The mucociliary system is the lung's primary defense mechanism against irritants and infectious agents. Mucus, composed of 95% water and 5% glycoproteins, is produced by bronchial epithelial glands and goblet cells.⁷ The lining of the airways consists of a continuous aqueous layer controlled by active ion transport across the epithelium in which water moves toward the lumen along the concentration gradient. Catecholamines and vagal stimulation enhance the ion transport and fluid movement. Mucus transport depends on the viscoelastic properties of the mucus. Mucus that is either too watery or too viscous will not be transported optimally. The exudative inflammatory process and sloughing of epithelial cells into the airway lumen impair mucociliary transport. The bronchial glands are increased in size and the goblet cells are increased in size and number in asthma. Expecto-rated mucus from patients with asthma tends to have a high viscosity. The mucus plugs in the airways of patients who died in status asthmaticus are tenacious and tend to be connected by mucous strands to the goblet cells. Asthmatic airways also may become plugged with

casts consisting of epithelial and inflammatory cells. Although it is tempting to speculate that death from asthma attacks is a result of the mucus plugging resulting in irreversible obstruction, there is no direct evidence for this. Autopsies of asthmatics who died from other causes have shown similar pathology. In addition, some subjects who have died of sudden severe asthma did not show the characteristic mucus plugging on necropsy.⁷

AIRWAY SMOOTH MUSCLE

The smooth muscle of the airways does not form a uniform coat around the airways but is wrapped around in a connecting network best described as a spiral arrangement.¹⁵ The muscle contraction displays a sphincteric action that is capable of completely occluding the airway lumen. The airway smooth muscle extends from the trachea through the respiratory bronchioles. When expressed as a percentage of wall thickness, the smooth muscle represents 5% of the large central airways and up to 20% of the wall thickness in the bronchioles. Total smooth muscle mass decreases rapidly past the terminal bronchioles to the alveoli, so the contribution of smooth muscle tone to airway diameter in this region is relatively small. In the large airways of asthmatics, smooth muscle may account for 11% of the wall thickness. It is possible that the increased smooth muscle mass of the asthmatic airways is important in magnifying and maintaining BHR in chronic asthma. However, it appears that the hypertrophy and hyperplasia are secondary processes caused by chronic inflammation and are not the primary cause of BHR.⁷

NEURAL CONTROL/NEUROGENIC INFLAMMATION

The airway is innervated by parasympathetic, sympathetic, and non-adrenergic inhibitory nerves.² Parasympathetic innervation of the smooth muscle consists of efferent motor fibers in the vagus nerves and sensory afferent fibers in the vagus and other nerves.¹⁵ The normal resting tone of human airway smooth muscle is maintained by vagal efferent activity. Maximum bronchoconstriction mediated by vagal stimulation occurs in the small bronchi and is absent in the small bronchioles. The nonmyelinated C fibers of the afferent system lie immediately beneath the tight junctions between epithelial cells lining the airway lumen.¹⁵ These endings probably represent the irritant receptors of the airways. Stimulation of these irritant receptors by mechanical stimulation, chemical and particulate irritants, and pharmacologic agents such as histamine produces reflex bronchoconstriction.¹⁵

The nonadrenergic, noncholinergic (NANC) nervous system has been described in the trachea and bronchi. Substance P, neurokinin A, neurokinin B, and vasoactive intestinal peptide (VIP) are the best characterized neurotransmitters in the NANC nervous system.¹⁵ VIP is an inhibitory neurotransmitter in the system. Inflammatory cells in asthma can release peptidases that can degrade VIP, producing exaggerated reflex cholinergic bronchoconstriction. NANC excitatory neuropeptides such as substance P and neurokinin A are released by stimulation of C-fiber sensory nerve endings. The NANC system may play an important role in amplifying inflammation in asthma by releasing nitric oxide (NO).

NITRIC OXIDE

NO is produced by cells within the respiratory tract. It has been thought to be a neurotransmitter of the NANC nervous system.¹⁷ Endogenous NO is generated from the amino acid L-arginine by the enzyme NO synthase.¹⁷ There are three isoforms of NO synthase.

One isoform is induced in response to proinflammatory cytokines, inducible NO synthase (iNOS), in airway epithelial cells and inflammatory cells of asthmatic airways.¹⁷ NO produces smooth muscle relaxation in the vasculature and bronchials; however, it appears to amplify the inflammatory process and is unlikely to be of therapeutic benefit. Recent investigations measuring exhaled NO concentrations have suggested that it may be a useful measure of ongoing lower airways inflammation in patients with asthma and for measuring effectiveness of therapy.¹⁷

CLINICAL PRESENTATION

CHRONIC ASTHMA

3 Classic asthma is characterized by episodic dyspnea associated with wheezing; however, the clinical presentation of asthma is as diverse as the number of triggering events (see Clinical Presentation 1). Although wheezing is the characteristic symptom of asthma, the medical literature is replete with the warning that “not all that wheezes is asthma.” A wheeze is a high-pitched, whistling sound created by turbulent airflow through an obstructed airway, so any condition that produces significant obstruction can result in wheezing as a symptom. In addition, “all of asthma does not wheeze” is an equally justifiable warning. Patients may present with a chronic persistent cough as their only symptom.²

CLINICAL PRESENTATION CHRONIC AMBULATORY ASTHMA

GENERAL

Asthma is a disease of exacerbation and remission, so the patient may not have any signs or symptoms at the time of exam.

SYMPTOMS

The patient may complain of episodes of dyspnea, chest tightness, coughing (particularly at night), wheezing, or a whistling sound when breathing. These often occur in association with exercise, but also occur spontaneously or in association with known allergens.

SIGNS

Expiratory wheezing on auscultation, dry hacking cough, or signs of atopy (allergic rhinitis and/or eczema) may occur.

LABORATORY

Spirometry demonstrates obstruction (FEV_1/FVC less than 80%) with reversibility following inhaled β_2 -agonist administration (at least a 12% improvement in FEV_1).

OTHER DIAGNOSTIC TESTS

A fall in FEV_1 of at least 20% following 6 minutes of near maximal exercise. Elevated eosinophil count and IgE concentration in blood. Elevated FeNO (greater than 12ppb). Positive methacholine challenge (PC_{20} FEV_1 less than 12.5 mg/mL).

There is no single test that can diagnose asthma. The diagnosis is based primarily on a good history² (Table 26–2). The patient may have a family history of allergy or asthma or have symptoms of allergic rhinitis.² Reversibility of airways obstruction following administration of an inhaled short-acting β_2 -agonist provides confirmation but is not by itself diagnostic. Patients with normal values of spirometry can be challenged by exercise or substances that produce

TABLE 26–2. Sample Questions^a for the Diagnosis and Initial Assessment of Asthma

A “yes” answer to any question suggests that asthma diagnosis is likely. In the past 12 months, . . .

- Have you had a sudden severe episode or recurrent episodes of coughing, wheezing (high-pitched whistling sounds when breathing out), or shortness of breath?
- Have you had colds that “go to the chest” or take more than 10 days to get over?
- Have you had coughing, wheezing, or shortness of breath during a particular season or time of the year?
- Have you had coughing, wheezing, or shortness of breath in certain places or when exposed to certain things (e.g., animals, tobacco smoke, perfumes)?
- Have you used any medications that help you breathe better? How often?
- Are the symptoms relieved when the medications are used?

In the past 4 weeks, have you had coughing, wheezing, or shortness of breath . . .

- At night that has awakened you?
- In the early morning?
- After running, moderate exercise, or other physical activity?

^aThese questions are recommended by the NAEPP but have not been formally validated.

bronchoconstriction, such as methacholine, to determine if they have hyperresponsive airways, but again, positive challenges are not diagnostic. Newer tests of inflammation in the airways such as induced sputum eosinophil counts and fraction of exhaled nitric oxide (FeNO) are consistent with but not diagnostic of asthma.

Asthma has a widely variable presentation from chronic daily symptoms to only intermittent symptoms. The intervals between symptoms can be days, weeks, months, or years. Asthma also can vary as to its severity. The NAEPP has provided a means of classifying asthma that is presented in Table 26–3.² The intermittent and/or chronic nature of symptoms does not necessarily determine the severity of symptoms during exacerbations. The severity is determined by lung function and symptoms prior to therapy, as well as by the amount of medication required to control the patient’s symptoms. Patients can present with a range from mild intermittent symptoms that require no medications or only occasional use of short-acting inhaled β_2 -agonists to severe chronic asthma symptoms despite receiving multiple medications. In addition, patients can change severity classifications based on exposures to triggering substances.

SEVERE ACUTE ASTHMA

Uncontrolled asthma, with its inherent variability, can progress to an acute state where inflammation, airways edema, excessive accumulation of mucus, and severe bronchospasm result in a profound airways narrowing that is poorly responsive to usual bronchodilator therapy^{2,10} (see Clinical Presentation 2). Although this progression is the most common scenario, some patients experience rapid onset or hyperacute attacks.^{2,10} Hyperacute attacks are associated with neutrophilic as opposed to eosinophilic infiltration and resolve rapidly with bronchodilator therapy, suggesting that smooth muscle spasm is the major pathogenic mechanism.¹⁰ In most cases, emergency department visits for severe acute asthma represent the failure of an adequate therapeutic regimen for chronic asthma. Underutilization of anti-inflammatory drugs and excessive reliance on short-acting inhaled β_2 -agonists are

TABLE 26–3. Classification of Asthma Severity: Clinical Features Before Treatment

| | Symptoms | Lung Function ^a |
|-------------------------------|--|--|
| Step 1 Mild Intermittent | Daytime ≤ 2 times/wk Asymptomatic between exacerbations Exacerbations brief (from a few hours to a few days); intensity may vary Nocturnal ≤ 2 times/mo | FEV ₁ or PEF $\geq 80\%$ PEF variability $< 20\%$ |
| Step 2 Mild Persistent | Daytime > 2 times/wk but < 1 time/day Exacerbations may affect activity Nocturnal > 2 times/mo | FEV ₁ or PEF $\geq 80\%$ PEF variability 20% to 30% |
| Step 3 Moderate Persistent | Daily symptoms Daily use of inhaled, short-acting β_2 -agonists Exacerbations affect activity Exacerbations ≥ 2 times/wk; may last days Nocturnal > 1 time/wk | FEV ₁ or PEF $> 60\%$ to $< 80\%$ PEF variability $> 30\%$ |
| Step 4 Severe Persistent | Continual symptoms Limited physical activity Frequent exacerbations Nocturnal frequent | FEV ₁ or PEF $\leq 60\%$ PEF variability $> 30\%$ |

^aThe presence of one of the features of severity is sufficient to place a patient in that category. An individual should be assigned to the most severe grade in which any feature occurs. The characteristics noted are general and may overlap because asthma is highly variable. Furthermore, an individual's classification may change over time. Patients at any level of severity can have mild, moderate, or severe exacerbations. Some patients with intermittent asthma experience severe and life-threatening exacerbations separated by long periods of normal lung function and no symptoms.

CLINICAL PRESENTATION SEVERE ACUTE ASTHMA

GENERAL

An episode can progress over several days or hours (usual scenario) or progresses rapidly over 1 to 2 hours.

SYMPTOMS

The patient is anxious in acute distress and complains of severe dyspnea, shortness of breath, chest tightness, or burning. The patient is only able to say a few words with each breath. Symptoms are unresponsive to usual measures (inhaled β_2 -agonist administration).

SIGNS

Signs include expiratory and inspiratory wheezing on auscultation (breath sounds may be diminished with very severe obstruction), dry hacking cough, tachypnea, tachycardia, pale or cyanotic skin, hyperinflated chest with intercostal and supraclavicular retractions, hypoxic seizures if very severe, normal or slightly elevated temperature.

LABORATORY

PEF and/or FEV₁ less than 50% of normal predicted values. Decreased arterial oxygen (PaO₂), and O₂ saturations by pulse oximetry (SaO₂ less than 90% on room air is moderate to severe). Decreased arterial or capillary CO₂ if mild, but in the normal range or increased in moderate to severe obstruction.

OTHER DIAGNOSTIC TESTS

Blood gases to assess metabolic acidosis (lactic acidosis) in severe obstruction. Complete blood count if there are signs of infection (fever and purulent sputum). Serum electrolytes as therapy with β_2 -agonist and corticosteroids can lower serum potassium and magnesium and increase glucose. Chest radiograph if signs of consolidation on auscultation.

the major risk factors for severe exacerbations.² A blunted perception of airway obstruction may predispose certain asthmatics to fatal attacks.² This may occur more commonly in patients who have labile asthma (fluctuation of daily peak flows of 50% or greater).

EXERCISE-INDUCED BRONCHOSPASM

During vigorous exercise, pulmonary functions (FEV₁ and peak expiratory flow [PEF]) in asthmatic patients increase during the first few minutes but then begin to decrease after 6 to 8 minutes (Fig. 26–3).¹⁸ Exercise-induced bronchospasm (EIB) is defined as a drop in FEV₁ of greater than 15% to 20% of baseline (pre-exercise value).^{2,18} Most

FIGURE 26–3. Typical responses to exercise in a normal subject and an asthmatic subject. Note the initial bronchodilation. PEF = peak expiratory flow rate.

studies suggest that 70% to 90% of asthmatics experience EIB.² exact pathogenesis of EIB is unknown, but heat loss and/or water loss from the central airways appears to play an important role.¹⁸ EIB is provoked more easily in cold, dry air, and warm, humid air can blunt or block it.¹⁸ A number of studies have demonstrated increased plasma histamine and tryptase concentrations during EIB, suggesting a role for mast cell degranulation.¹⁸

A refractory period following EIB lasts up to 3 hours after exercise. During this period, repeat exercise of the same intensity produces either no decrease in pulmonary function or a drop of less than 50% of the initial response.¹⁸ The refractory period is thought to be caused by an acute depletion of mast cell mediators and time required for their repletion. Patients with known refractoriness to exercise will still respond to histamine, so acute hyporesponsiveness of airway smooth muscle does not appear to be a factor.¹⁸

Exercise-induced bronchospasm is believed to be a reflection of the increased BHR of asthmatics. A correlation, though not perfect, exists between EIB and reactivity to histamine and methacholine.¹⁸ Other patient groups with bronchial hyperresponsiveness (e.g., after viral infection, cystic fibrosis, or allergic rhinitis) show bronchoconstriction after exercise to a lesser degree (5% to 10%) than asthmatics (20% to 40%).¹⁸ Patients will not always demonstrate the same sensitivity. During periods of remission, they often have a decreased sensitivity to the same degree of exercise. Finally, a number of children and adults with EIB are otherwise normal, without symptoms or abnormal pulmonary function except in association with exercise. Elite athletes have a higher prevalence of EIB than the general population.¹⁸

NOCTURNAL ASTHMA

3 Worsening of asthma during sleep is referred to as *nocturnal asthma*. Patients with nocturnal asthma exhibit significant falls in pulmonary function between bedtime and awakening.^{2,10} Typically, their lung function reaches a nadir at 3 to 4 A.M. Although the pathogenesis of this phenomenon is unknown, it has been associated with diurnal patterns of endogenous cortisol secretion and circulating epinephrine.¹⁰ Direct evidence for an inflammatory component to nocturnal asthma includes increased circulating histamine and activated eosinophils and leukotriene excretion at night associated with increased hyperresponsiveness to methacholine.¹⁰

Numerous other factors that may affect nocturnal worsening of asthma, including allergies and improper environmental control, gastroesophageal reflux, and sinusitis, also must be considered when evaluating these patients.² Most experts consider nocturnal asthma to be a sign of inadequately treated persistent asthma.^{2,10}

FACTORS CONTRIBUTING TO ASTHMA SEVERITY

VIRAL INFECTIONS

Viral infections are primarily responsible for exacerbations of asthma.² Viral upper respiratory tract infections are a major precipitant of acute asthma in children, being involved in up to 20% to 40% of acute episodes.² Infants are particularly susceptible to airways obstruction and wheezing with viral infections because of their small airways. The most common cause of exacerbations in both children and adults is the common rhinovirus.² Other viruses isolated include respiratory syncytial virus (RSV), parainfluenza virus, coronavirus, and influenza viruses. The inflammatory response to viral infection is thought to be associated directly with the increasing BHR. Certain viruses (RSV and parainfluenza virus) are capable of inducing spe-

cific IgE antibodies, and rhinovirus can activate eosinophils directly in asthmatics. The increase in asthma symptoms and BHR that occurs may last for days or weeks following resolution of the symptoms of the viral infection. The NAEPP recommends annual influenza vaccinations for patients with asthma.²

ENVIRONMENTAL AND OCCUPATIONAL FACTORS

Agents and events and the mechanisms that are known to trigger asthma are listed in Table 26–1.^{2,10} The general mechanisms are unknown but presumably are the result of epithelial damage and inflammation in the airway mucosa. Ozone and sulfur dioxide, common components of air pollution, have been used to induce BHR in animals. Exposure to 0.2 ppm ozone for 2 to 3 hours can induce bronchoconstriction and increase BHR in asthmatics.^{2,10} Sulfur dioxide in the ambient atmosphere is highly irritating. It presumably induces bronchoconstriction through mast cell or irritant-receptor involvement.¹⁰ Asthma produced by repeated prolonged exposure to industrial inhalants is a significant health problem. It has been estimated that occupational asthma accounts for 2% of all asthmatic persons.¹³ Persons with occupational asthma have the typical symptoms of asthma with cough, dyspnea, and wheeze. Typically, the symptoms are related to work and improve on weekends and during vacations.¹³ In some instances, symptoms may persist even after termination of exposure.¹³

PSYCHOLOGICAL FACTORS

Emotions and stress rarely can precipitate attacks of asthma but more commonly worsen an attack in progress.² Bronchoconstriction from psychological factors appears to be mediated primarily through excess parasympathetic input. Atropine has been shown to block experimental psychogenic bronchoconstriction. It is most important to emphasize to patients and to parents of asthmatic children that asthma is not an emotional disease; however, calming influences and relaxation techniques may benefit the patient who becomes severely emotionally distraught during an asthma attack.

SINUSITIS AND RHINITIS

Disorders of the upper respiratory tract, particularly sinusitis and rhinitis, have been linked with asthma for many years. As many as 40% to 50% of asthmatics have abnormal sinus radiographs.² However, chronic sinusitis may just represent a nonbacterial coexisting condition with allergic asthmatics because the histologic changes in the paranasal sinuses are similar to those seen in the lung and nose.² Some studies have shown that asthma symptoms improve with treatment of sinusitis. The mechanism by which sinusitis aggravates asthma is unknown. The treatment of allergic rhinitis with inhaled corticosteroids and cromolyn but not antihistamines will reduce BHR in asthmatic patients.² It has been postulated that transport of mucus chemotactic factors and inflammatory mediators from nasal passages during allergic rhinitis into the lung may accentuate BHR.

GASTROESOPHAGEAL REFLUX

Gastroesophageal reflux has been associated with asthma for many years.^{2,10} Nocturnal asthma may be associated with nighttime reflux.¹⁰ Reflux of acidic gastric contents into the esophagus is thought to initiate a vagally mediated reflex bronchoconstriction.¹⁰ Also of concern is that most medications that decrease airways smooth muscle tone have a relaxant effect on gastroesophageal sphincter tone as well. The

therapeutic approach most commonly taken for patients with gastroesophageal reflux and asthma is to initiate standard antireflux therapy and observe the asthma symptoms.²

MENSTRUATION-RELATED ASTHMA

Premenstrual worsening of asthma has been reported in as many as 30% to 40% of women in some studies, whereas worsening of pulmonary functions has been reported even in women not aware of worsening symptoms.¹⁹ The pathophysiology is uncertain because estrogen replacement in postmenopausal women has been shown to worsen asthma, whereas estradiol and progesterone administration have been variably reported to improve or have no effect on asthma in women with premenstrual asthma.^{19,20} Studies would indicate that, in general, bronchial responsiveness and symptoms improve in asthmatics during pregnancy.¹⁰ The clinical significance of menstruation-related asthma is still unclear because some studies have reported that up to 50% of emergency department visits by women were premenstrual, whereas others have reported no association with menstrual phase.^{19,21}

FOODS, DRUGS, AND ADDITIVES

Documentation in the literature of food allergens as triggers for asthma is not available.¹⁰ However, additives, specifically sulfites used as preservatives, can trigger life-threatening asthma exacerbations. Beer, wine, dried fruit, and open salad bars in particular have high concentrations of metabisulfites.² Severe oral corticosteroid-dependent patients should be warned about ingesting foods processed with sulfites. Another additive producing bronchospasm is benzalkonium chloride, which is found as a preservative in some nebulizer solutions of anti-asthmatic drugs.²²

Aspirin and other nonsteroidal anti-inflammatory drugs can precipitate an attack in up to 20% of adults with asthma.²³ The mechanism is related to cyclooxygenase inhibition, and 5-lipoxygenase inhibition can prevent the symptoms.²³ The prevalence increases with age. The greatest frequency occurs in severe corticosteroid-dependent asthmatics in their fourth and fifth decades who also have perennial rhinitis and nasal polyposis (presence of several polyps).²³ Other drugs that do not precipitate bronchospasm but which prevent its reversal are the β -blocking agents.^{2,10}

► TREATMENT: Asthma

■ AEROSOL THERAPY FOR ASTHMA

4 **5** Aerosol delivery of drugs for asthma has the advantage of being site-specific and thus enhancing the therapeutic ratio.^{2,24} Inhalation of short-acting β_2 -agonists provides more rapid bronchodilation than either parenteral or oral administration, as well as the greatest degree of protection against EIB and other challenges.²⁵ Inhaled corticosteroids produce a greater reduction of BHR than corticosteroids administered systemically.² Specific agents (e.g., cromolyn, nedocromil, formoterol, salmeterol, and ipratropium) are only effective by inhalation.^{2,24} Given the international ban on the pro-

duction and use of chlorofluorocarbons (CFCs), the manufacturers of CFC-propelled metered-dose inhalers (MDIs) are developing new devices for delivering topically active medication.^{2,24} Therefore, an understanding of aerosol drug delivery is essential to optimal asthma therapy. Table 26-4 lists the factors determining lung deposition of therapeutic aerosols.

■ DEVICE DETERMINANTS OF DELIVERY

Devices used to generate therapeutic aerosols include jet nebulizers, ultrasonic nebulizers, MDIs, and dry-powder inhalers (DPIs).

TABLE 26-4. Factors Determining Lung Deposition of Aerosols

| Device | Device Factors | Patient Factors |
|------------------------------|--|---|
| Metered-dose inhaler (MDI) | Canister held inverted Formulation (CFC, HFA, solution, suspension) Actuator cleanliness Addition of a spacer device | Inspiratory flow (slow, deep) Breath-holding Coordinating actuation with inhalation Priming and shaking the device |
| Dry-powder inhaler (DPI) | Device cleanliness Resistance to inhalation Humidity | Inspiratory flow (deep, forceful) Tilting head back Maintaining parallel to ground once activated |
| Jet nebulizer (small volume) | Volume fill (3–6 mL) Gas flow (6–12 L/min) Dead-space volume Open versus closed system Thumb-activating valve | Inspiratory flow (slow, deep) Breath-holding Tapping nebulizer |
| Ultrasonic nebulizer | Mouthpiece versus facemask Volume fill Not effective for suspensions Mouthpiece versus facemask | Inspiratory flow (slow, deep) Breath-holding Tapping nebulizer |
| Spacer device | Volume (≥ 650 mL) One-way valves Holding chamber versus opened-ended Metal versus plastic Mouthpiece versus facemask | Inspiratory flow (slow, deep) Time between actuation and inhalation (<5 s) Cleaning with detergent to reduce static Multiple actuations decrease delivery Coordination of actuation and inhalation for the simple open-tube spacers |

The single most important device factor determining the site of aerosol deposition is particle size.²⁴ Devices for delivering therapeutic aerosols generate particles with aerodynamic diameters from 0.5 to 35 microns.²⁴ Particles larger than 10 microns deposit in the oropharynx, particles between 5 and 10 microns deposit in the trachea and large bronchi, particles 1 to 5 microns in size reach the lower airways, and particles smaller than 0.5 microns act as a gas and are exhaled. In asthma, the airways, not the alveoli, are the target for delivery. Respirable particles are deposited in the airways by three mechanisms: (1) inertial impaction, (2) gravitational sedimentation, and (3) Brownian diffusion.²⁴ The first two mechanisms are the most important for therapeutic aerosols and probably are the only factors that can be manipulated by patients.

Each delivery device within a classification generates specific aerosol characteristics, so extrapolation of delivery data from one device cannot be done for the other devices in the class. For instance, MDIs can deliver 5% to 50% of the actuated dose; DPIs, 10% to 30% of the labeled dose; and nebulizers, 2% to 15% of the starting dose.²⁴ MDIs and DPIs are portable and convenient, unlike nebulizers. MDIs consist of a pressurized canister with a metering valve; the canister contains active drug, low-vapor-pressure propellants such as chlorofluorocarbon (CFC) or hydrofluoroalkane (HFA), cosolvents, and/or surfactants.²⁴ With any change in these components, the Food and Drug Administration (FDA) considers it to be a new drug that requires stability, safety, and efficacy studies prior to approval. The drug is either in solution or a suspended micronized powder. In order to disperse the suspension for accurate delivery, the canister must be shaken. The metering chamber measures a liquid volume, and therefore, the device must be held with the valve stem downward so that the chamber is covered with liquid²⁴ (Fig. 26–4). When the canister is actuated, the device releases the propellant and drug in a forceful spray whose particles are large (mass median aerodynamic diameter [MMAD] = 45 microns)²⁴ (see Fig. 26–4). As evaporation occurs, the particle size is reduced to a final MMAD of 0.5 to 5.5 microns depending on the MDI. The aerosol cloud of a CFC-propelled MDI extends at least 10 in beyond the MDI at the lowest MMAD, and that of an HFA-propelled MDI extends about 6 in.²⁴

The breath-actuated MDI Autohaler, is cocked with a lever to “load” the dose of medication, a baffle is opened by inspiratory pressure, and the dose is expelled from the canister metering chamber.²⁴ While the need for hand-lung coordination for proper actuation is reduced significantly with breath-actuated MDIs, these devices do not allow the use of a spacer device.

FIGURE 26–4. Illustration of a metered-dose inhaler demonstrating the particle size difference as the aerosol cloud extends outward.

Spacer devices are used frequently with an MDI to decrease oropharyngeal deposition and enhance lung delivery.^{2,26} However, not all spacer devices produce similar effects. The design of spacers varies from simple open-ended tubes that separate the MDI from the mouth to holding chambers with one-way valves that open during inhalation (the preferred system). The purpose of a spacer is to allow evaporation of the propellant prior to inhalation. Use of a spacer allows inhalation after actuation of the device, obviating the need for good hand-lung coordination, and permits a greater number of drug particles to achieve a respirable droplet size.²⁶ Additionally, the large particles that normally would deposit in the oropharynx “rain out” in the spacer.²⁶ All the available spacers significantly reduce oropharyngeal deposition from MDIs, with the holding-chamber devices being superior to the open-ended tubes.²⁶ This reduction in oropharyngeal deposition is an important factor in reducing local adverse effects (i.e., hoarseness and thrush) from inhaled corticosteroids.²⁴ The change in lung delivery depends on both the MDI and the drug, where one spacer device may enhance delivery with one MDI preparation and decrease delivery with others.²⁶ Finally, over time, holding chambers can build up static electricity that attracts small particles to the sides of the chamber, significantly reducing aerosol availability. It is recommended that spacers be washed weekly with household detergent, with a single rinse, and allowed to drip dry.²⁴

Dry micronized powders can be inhaled directly into the lung. Four DPIs for asthma are available for use in the United States (i.e., Diskus, Rotahaler, Turbuhaler, and Aerolizer), with others under development.²⁴ Each has unique characteristics with advantages and disadvantages (Table 26–5). The primary advantage of DPIs is that they are breath-actuated and require minimal hand-lung coordination.²⁶ Some DPIs are more flow-dependent than others.²⁶ Thus, similar to MDIs and spacers, delivery data from one DPI cannot be extrapolated to another.

Nebulizers come in two basic types, the jet nebulizer and the ultrasonic nebulizer. Jet nebulizers produce an aerosol from a liquid solution or suspension placed in a cup. A tube connected to a stream of compressed air or oxygen flows up through the bottom and draws the liquid up an adjacent open-ended tube.²⁴ The air and liquid strike a baffle, creating a droplet cloud that is then inhaled.²⁴ Ultrasonic nebulizers produce an aerosol by vibrating liquid lying above a transducer at speeds of about 1 MHz.²⁴ Both produce similar degrees of lung deposition, with the exception that ultrasonic nebulizers are ineffective for nebulizing micronized suspensions.²⁶ The aerosol output and lung delivery vary significantly among the commercially available jet nebulizers even when operated in the same manner.²⁴ Increasing fill volume will increase the total amount of drug delivered; however, it also will take longer for the patient to nebulize the dose.²⁴ The MMAD of the droplets is related directly to the gas flow, with flows of 5 to 12 L/min providing an aerosol cloud with an MMAD of 4 to 8 microns for most jet nebulizers.²⁶

■ PATIENT DETERMINANTS OF DELIVERY (See Table 26–4)

6 The most important patient factor determining aerosol deposition is inspiratory flow.^{2,24} High inspiratory flows increase the degree of deposition owing to impaction of particles of any size, thereby increasing deposition centrally (i.e., throat and large airways) and decreasing peripheral deposition. Holding chambers enhance the clinical efficacy in patients with poor hand-lung coordination but may offer no advantage in patients who can use an MDI optimally alone.²⁴ Optimal inspiratory flow for most MDIs is slow and deep (approximately 30 L/min).²⁴ In general, DPIs require

TABLE 26–5. Characteristics of Various Inhalation Devices

| Device | Drugs | Breath-Activated | Dose Counter | Other Excipients | Disadvantages |
|--------------------------|--|------------------|-----------------------------|--------------------------------------|---|
| CFC MDI | All classes | No | No | Propellants, surfactants | Requires coordination of actuation and inhalation Large pharyngeal deposition Difficult to teach |
| HFA-MDI | Albuterol | No | No | Propellants, surfactants, cosolvents | Same as CFC MDI |
| Autohaler MDI | Beclomethasone Pirbuterol | No Yes | No No | CFC propellant, surfactant | Requires rapid inhalation to activate |
| MDI plus holding chamber | All classes | No | No | | More expensive than MDI alone; less portable; some payers will not pay; inconsistent effect on delivery |
| Jet nebulizers | All classes except long-acting β_2 -agonists | No | — | Preservatives in some solutions | Significant interbrand variability; expensive and time-consuming; less efficient than MDIs; contamination possible; preparations may be light- and temperature-sensitive (short shelf-life) |
| Ultrasonic nebulizer | Cromolyn solution short acting β_2 -agonist solutions | No | — | Preservatives in some solutions | Same as for jet nebulizers plus cannot be used for suspensions |
| Rotahaler | Albuterol | Yes | — | Lactose filler | Single-dose capsule; requires high inspiratory flow |
| Turbuhaler | Budesonide | Yes | Indicator for last 20 doses | No | Requires high inspiratory flow (60 L/min). Pharyngeal deposition. Not approved for <6 years of age |
| Diskus | Fluticasone Salmeterol Fluticasone/salmeterol | Yes | Yes | Lactose filler | Not approved for <4 years of age |
| Aerolizer | Formoterol | Yes | — | Lactose filler | Single-dose capsules. Not approved for <5 years of age Requires high inspiratory flow (≥ 60 L/min) |
| Twisthaler | Mometasone | Yes | Yes | Lactose filler | Not approved for <12 years of age |

higher inspiratory flows (≥ 60 L/min) and a change in inhalation technique (i.e., deep, forceful inspiration) for optimal actuation, which, in turn, increases the amount of drug delivered to the larger central airways.²⁶ However, this difference in delivery may not produce clinically significant differences.²⁴ Patients should be cautioned not to exhale into DPIs because this causes loss of dose and moistens the dry powder, causing aggregation into larger particles. Patient factors that cannot be controlled include interpatient variability in airway geometry (particularly the differences between children and adults)²⁶ and the effects of bronchospasm, edema, and mucus hypersecretion. Mild obstruction increases aerosol deposition; however, severe obstruction probably leads to increased central deposition from impaction.²⁴ The absolute delivery to the lung is not as important as consistency of delivery, assuming that a sufficient dose to produce the desired therapeutic effect is achieved. No single inhalation device is the best for all patients. Table 26–5 lists the differing characteristics of inhalation devices.

Appropriate inhalation technique is essential to achieve optimal drug delivery and therapeutic effect.^{2,10} The components are illustrated in Figure 26–5. Approximately 50% to 80% of a dose from MDIs and DPIs impacts on the oropharynx and is then swallowed;

the rest is either left in the device or exhaled.²⁶ It is important that actuation occurs during inhalation, although the time during inspiration is unimportant.^{2,26} Although radiolabeled studies indicate improved delivery by holding the actuator 2 to 3 cm in front of an open mouth to allow more evaporation and less impaction, physiologic studies with bronchodilators have failed to document an advantage for this method.²⁴ Many patients do not use their MDIs optimally, and patient instruction with demonstration is the most effective means of improving inhaler technique.^{2,24,26} Even with instruction, up to 30% of patients, particularly young children and the elderly, cannot master the use of an MDI. For these patients, attachment of a holding-chamber device to the MDI or use of a breath-actuated MDI can improve efficacy significantly.^{2,24} Mouth rinsing following treatment with MDI- and DPI-inhaled corticosteroids is important to minimize local effects and oral absorption.²⁶

Delivery from high-resistance DPIs is more flow-dependent than from low-resistance DPIs. The Turbuhaler device has a greater flow dependency than the Aerolizer and the Diskus.^{24,26} Children 6 to 12 years of age received approximately one-half the dose of radiolabeled budesonide via Turbuhaler than those older than 12 years of age, whereas children younger than 6 years of age received

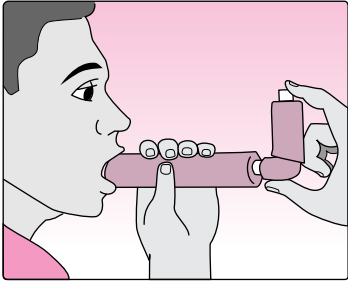

Steps for Using Your Inhaler

Please demonstrate your inhaler technique at every visit.

1. Remove the cap and hold inhaler upright.
2. Shake the inhaler.
3. Tilt your head back slightly and breathe out slowly.
4. Position the inhaler in one of the following ways (A or B is optimal, but C is acceptable for those who have difficulty with A or B. C is required for breath-activated inhalers):

A Open mouth with inhaler 1 to 2 inches away.

B Use spacer/holding chamber (that is recommended especially for young children and for people using corticosteroids).

C In the mouth. Do not use for corticosteroids.

D NOTE: Inhaled dry powder capsules require a different inhalation technique. To use a dry powder inhaler, it is important to close the mouth tightly around the mouthpiece of the inhaler and to inhale rapidly.

5. Press down on the inhaler to release medication as you start to breathe in slowly.
6. Breathe in slowly (3 to 5 seconds).
7. Hold your breath for 10 seconds to allow the medicine to reach deeply into your lungs.
8. Repeat puff as directed. Waiting 1 minute between puffs may permit second puff to penetrate your lungs better.
9. Spacers/holding chambers are useful for all patients. They are particularly recommended for young children and older adults and for use with corticosteroids.

Avoid common inhaler mistakes. Follow these inhaler tips:

- Breathe out *before* pressing your inhaler.
- Inhale *slowly*.
- Breathe in through your mouth, not your nose.
- Press down on your inhaler at the *start* of inhalation (or within the first second of inhalation).
- Keep inhaling as you press down on inhaler.
- Press your inhaler only *once* while you are inhaling (one breath for each puff).
- Make sure you breathe in evenly and deeply.

NOTE: Other inhalers are becoming available in addition to those illustrated above. Different types of inhalers require different techniques.

FIGURE 26–5. Instructions for inhaler use from the NAEPP Expert Panel Report 2.²

one-quarter of the dose.²⁶ The Aerolizer and the Diskus deliver about 15% of the dose to the airways, and this appears to be similar at both

30 and 60 L/min inspiratory flows; both have been approved for children aged 5 and 4 years, respectively.^{7,26}

► TREATMENT: Severe Acute Asthma

The primary goal is prevention of life-threatening asthma by early recognition of signs of deterioration and early intervention. As such, the principal goals of treatment include²

- Correction of significant hypoxemia
- Rapid reversal of airflow obstruction
- Reduction of the likelihood of recurrence of severe airflow obstruction
- Development of a written action plan in case of a further exacerbation

These goals are best achieved by early initiation of treatment and close monitoring of objective measures of oxygenation and lung function.² Early response to treatment as measured by the improvement in FEV₁ at 30 minutes following inhaled β_2 -agonists is the best predictor of outcome.²⁷ Providing adequate oxygen supplementation to maintain oxygen (O₂) saturations above 90% (or above 95% in pregnant women) is essential. In children younger than 6 years of

age, in whom lung function measures are difficult to obtain, a combination of objective (e.g., oxygen saturation, capillary CO₂, respiratory rate, and heart rate) and subjective measures may be used to assess severity.^{2,10}

The primary therapy of acute exacerbations is pharmacologic, which includes inhaled short-acting β_2 -agonists and, depending on the severity, systemic corticosteroids and O₂ (Figs. 26–6 and 26–7). It is important that therapy not be delayed, so the initial history and physical examination should be obtained while initial therapy is being provided. Patients at risk for life-threatening exacerbations require special attention. Risk factors include a history of previous severe asthma exacerbations (e.g., hospitalizations, intubations, or hypoxic seizures), complicating illnesses (e.g., cardiac disease, diabetes, illicit drug use, or psychosis), use of more than two canisters per month of short-acting inhaled β_2 -agonists, and current intake of oral corticosteroids or recent withdrawal from oral corticosteroids.¹⁰

A complete blood count may be appropriate for patients with fever or purulent sputum, but many patients will have a leukocytosis

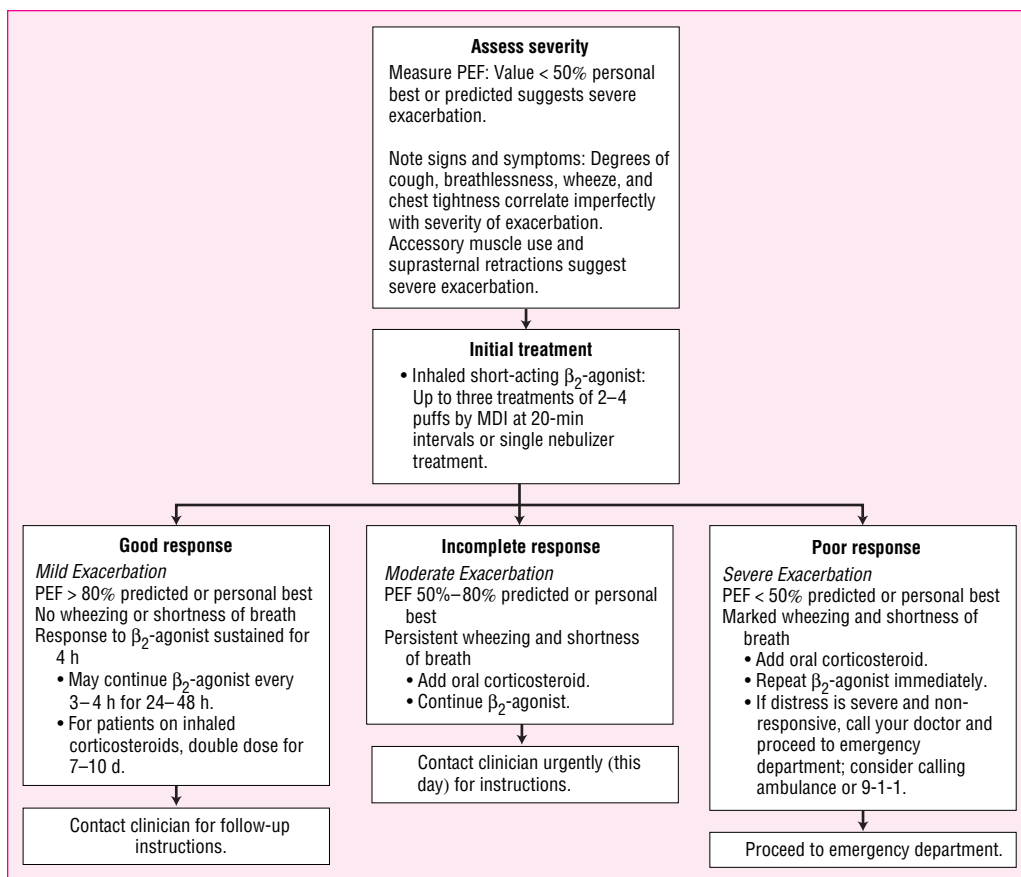

FIGURE 26-6. Home management of acute asthma exacerbation. Patients at risk for asthma-related death should receive immediate clinical attention after initial treatment. Additional therapy may be required. (From ref. 2.)

from a viral infection or secondary to corticosteroid administration. Routine chest radiographs have not been shown to be of value unless physical findings suggestive of consolidations or pneumothoraces are present.² Serum electrolytes should be monitored if high-dose continuous inhaled or systemic β_2 -agonists are to be used because they can produce transient decreases in potassium, magnesium, and phosphate.²⁷ The combination of high-dose β_2 -agonists and systemic corticosteroids occasionally may result in excessive elevations of glucose.²⁷

Initial response should be achieved within minutes, and most patients experience significant improvement within the first 30 to 60 minutes of therapy, with most patients doubling their FEV₁ or PEF.²⁸ In patients ultimately admitted to the hospital, only a 10% to 20% predicted improvement is seen within the first 2 hours. Hypoxemia, primarily a result of ventilation-perfusion mismatch, is immediately correctable by low-flow oxygen.² While reversal of lung function into the normal range may take 12 to 24 hours, complete restoration takes much longer—up to 3 to 7 days.^{10,27} A strategy to  prevent recurrence such as systemic corticosteroids and PEF monitoring should be used.^{2,10} It is essential to provide the patient with a self-management plan that includes a written action plan for dealing with exacerbations. Patients at risk for severe exacerbations should be taught how to use a peak-flow meter and monitor morning peak flows at home.^{2,10} In young children, an increased respiratory rate, increased heart rate, and inability to speak more than one or two words between breaths are signs of severe obstruction.² Oxygen saturations by pulse oximetry and peak flows should be measured in all patients not

completely responding to initial intensive inhaled β_2 -agonist therapy. Initially, on admission, the peak flows or clinical symptoms should be monitored every 2 to 4 hours. Prior to discharge from the emergency department or hospital, the patient should be given a sufficient supply of prednisone, taught the purpose of the medications and proper inhaler technique, and given an appointment for a follow-up visit.²

 Early recognition of deterioration and aggressive treatment are the keys to successful treatment of acute asthma exacerbations. Thus patient and/or parent education teaching self-management skills and written action plans for early institution of therapy for acute exacerbations improve outcomes.⁷ For more moderate to severe patients, this therapeutic plan also may include the availability of oral prednisone to begin at home.² Easy access by telephone to health care providers is also needed. Because of the rapid progression to severe asthma that can occur, patients and parents should be encouraged to communicate promptly with their asthma care provider during an exacerbation. Systemic corticosteroids and aggressive use of inhaled β_2 -agonists continue to be the cornerstones of therapy for acute severe asthma exacerbations.²

Figures 26-6 and 26-7 illustrate the recommended therapies for the treatment of acute asthma exacerbations in home and emergency department/hospital settings, respectively.² The dosages of the drugs for acute severe asthma are provided in Table 26-6.^{2,7} Institutions should strongly consider developing critical-pathways/treatment algorithms for their emergency departments because their implementation has been shown to improve outcomes and decrease the cost of care.²⁷

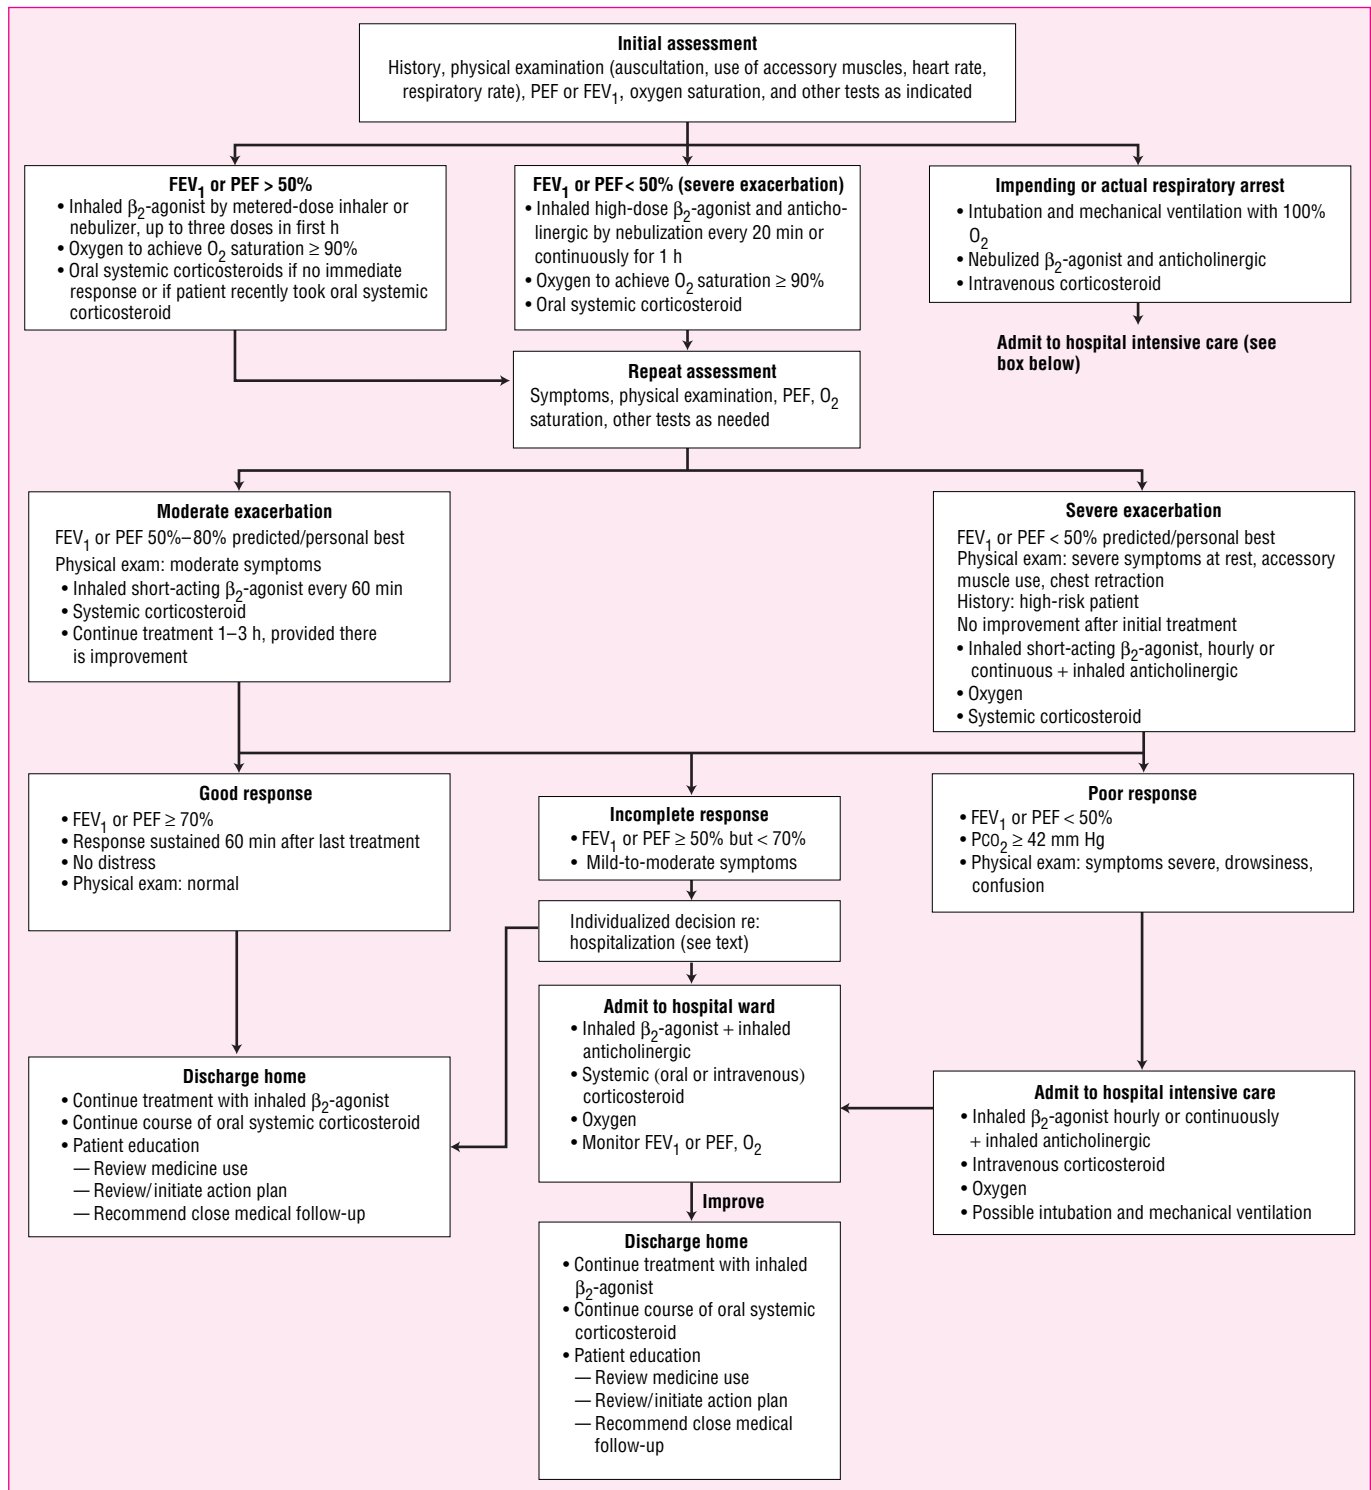

FIGURE 26–7. Emergency department and hospital care of acute asthma exacerbations. (From ref. 2.)

NONPHARMACOLOGIC THERAPY

Infants and young children may be mildly dehydrated owing to increased insensible loss, vomiting, and decreased intake.² Unless dehydration has occurred, increased fluid therapy is not indicated in acute

asthma management because the capillary leak from cytokines and increased negative intrathoracic pressures may promote edema in the airways.² Correction of significant dehydration is always indicated, and the urine specific gravity may help to guide therapy in young children, in whom the state of hydration may be difficult to determine.²⁷ Chest physical therapy and mucolytics are not indicated in the

TABLE 26–6. Dosages of Drugs of Acute Severe Exacerbations of Asthma in the Emergency Department or Hospital

| Medications | Dosages | | Comments |
|--|---|---|---|
| | >6 Years Old | ≤6 Years Old | |
| Inhaled β-agonists | | | |
| Albuterol nebulizer soln. (5 mg/mL) | 2.5–5 mg every 20 min for 3 doses, then 2.5–10 mg every 1–4 h as needed, or 10–15 mg/h continuously | 0.15 mg/kg (minimum dose 2.5 mg) every 20 min for 3 doses, then 0.15–0.3 mg/kg up to 10 mg every 1–4 h as needed, or 0.5 mg/kg/h by continuous nebulization | Only selective β_2 -agonists are recommended For optimal delivery, dilute aerosols to minimum of 4 mL at gas flow of 6–8 L/min |
| Albuterol MDI (90 mcg/puff) | 4–8 puffs every 30 min up to 4 h, then every 1–4 h as needed | 4–8 puffs every 20 min for 3 doses, then every 1–4 h as needed | In patients in severe distress, nebulization is preferred; use holding-chamber-type spacer |
| Levalbuterol nebulizer soln. | Give at one-half the mg dose of albuterol above | Give at one-half the mg dose of albuterol above | The single isomer of albuterol is likely to be twice as potent |
| Bitolterol nebulizer soln. (2 mg/mL) | See albuterol dose | See albuterol dose; thought to be as potent to one-half as potent as albuterol on a microgram basis | Has not been studied in acute severe asthma; do not mix with other drugs |
| Pirbuterol MDI (200 mcg/puff) | See albuterol dose | See albuterol dose; one-half as potent as albuterol on a microgram basis | Has not been studied in acute severe asthma |
| Systemic β-agonists | | | |
| Epinephrine 1:1000 (1 mg/mL) | 0.3–0.5 mg every 20 min for 3 doses SQ | 0.01 mg/kg up to 0.5 mg every 20 min for 3 doses SQ | No proven advantage of systemic therapy over aerosol |
| Terbutaline (1 mg/mL) | 0.25 mg every 20 min for 3 doses SQ | 0.01 mg/kg every 20 min for 3 doses, then every 2–6 h as needed SQ | Not recommended |
| Anticholinergics | | | |
| Ipratropium Br. nebulizer soln. (0.25 mg/mL) | 500 mcg every 30 min for 3 doses, then every 2–4 h as needed | 250 mcg every 20 min for 3 doses, then 250 mcg every 2–4 h | May mix in same nebulizer with albuterol; do not use as first-line therapy; only add to β_2 -agonist therapy |
| Ipratropium Br. MDI (18 mcg/puff) | 4–8 puffs as needed every 2–4 h | 4–8 puffs as needed every 2–4 h | Not recommended because dose in inhaler is low and has not been studied in acute asthma |
| Corticosteroids | | | |
| Prednisone, methylprednisolone, prednisolone | 60–80 mg in 3 or 4 divided doses for 48 h, then 30–40 mg/day until PEF reaches 70% of personal best | 1 mg/kg every 6 h for 48 h, then 1–2 mg/kg/day in 2 divided doses until PEF is 70% of normal predicted | For outpatient “burst” use 1–2 mg/kg/day, max. 60 mg, for 3–7 days; it is unnecessary to taper course |

Note: No advantage has been found for very-high-dose corticosteroids in acute severe asthma, nor is there any advantage for intravenous administration over oral therapy. The usual regimen is to continue the frequent multiple daily dosing until the patient achieves an FEV₁ or PEF of 50% of personal best or normal predicted value and then lower the dose to twice-daily dosing. This usually occurs within 48 hours. The final duration of therapy following a hospitalization or emergency department visit may be from 7 to 14 days. If patients are then started on inhaled corticosteroids, studies indicate there is no need to taper the systemic steroid dose. If the follow-up therapy is to be given once daily, studies indicate there may be an advantage to giving the single daily dose in the afternoon at around 3 PM.

therapy of acute asthma.² Sedatives should not be given because anxiety may be a sign of hypoxemia, which could be worsened by central nervous system depressants. Antibiotics also are not indicated routinely because viral respiratory tract infections are the primary cause of asthma exacerbations.^{2,7} Antibiotics should be reserved for patients who have signs and symptoms of pneumonia (e.g., fever, pulmonary consolidation, and purulent sputum from polymorphonuclear leukocytes). *Mycoplasma* and *Chlamydia* are infrequent causes of severe asthma exacerbations but should be considered in patients with high oxygen requirements.⁷

Respiratory failure or impending respiratory failure as measured by rising PaCO₂ (>45 mm Hg) or failure to correct hypoxemia with supplemental oxygen therapy is treated with intubation and mechanical ventilation. In order to prevent barotrauma and pneumothoraces from excess positive pressure, it is recommended that controlled hypoventilation or permissive hypercapnia be used (correcting the hypoxemia, PaO₂ > 60 mm Hg, but allowing the PaCO₂ to rise to the high 60 mm Hg range).

■ PHARMACOTHERAPY

■ β_2 -AGONISTS

4 The short-acting inhaled β_2 -agonists are the most effective bronchodilators and the treatment of first choice for the management of severe acute asthma.² Up to 66% of adults presenting to an emergency department require only three doses of 2.5 mg nebulized albuterol to be discharged.²⁸ Most well-controlled clinical trials have demonstrated equal to greater efficacy and greater safety of aerosolized β_2 -agonists over systemic administration regardless of the severity of obstruction.²⁷ Systemic adverse effects, hypokalemia, hyperglycemia, tachycardia, and cardiac dysrhythmias are more pronounced in patients receiving systemic β_2 -agonist therapy. Children younger than 2 years of age achieve clinically significant responses from nebulized albuterol.^{2,27} Effective doses of aerosolized β_2 -agonists can be delivered successfully through mechanical ventilator circuits to infants, children,

and adults in respiratory failure secondary to severe airways obstruction.²⁶

Frequent administration of inhaled β_2 -agonists (every 20 minutes or continuous nebulization) has been found to be superior to the same dosage administered at 1-hour intervals.²⁷ In the subset of more severely obstructed patients, continuous nebulization decreases the hospital admission rate, provides greater improvement in the FEV₁ and PEF, and reduces duration of hospitalization when compared with intermittent (hourly) nebulized albuterol in the same total dose.²⁹ Thus continuous nebulization is recommended for patients having an unsatisfactory response (achieving less than 50% of normal FEV₁ or PEF) following the initial three doses (every 20 minutes) of aerosolized β_2 -agonists and potentially for patients presenting initially with PEF or FEV₁ values of less than 30% of predicted normal.²⁷

The doses of inhaled β_2 -agonists for severe acute asthma (see Table 26–6) have been derived empirically. The β_2 -agonists follow a log-linear dose-response curve.²⁵ In addition, the dose-response curve is shifted to the right by more severe bronchospasm or by increased concentrations of bronchospastic mediators, which is characteristic of functional antagonists.³⁰ The ability to increase the dose of the short-acting aerosolized β_2 -agonists by as much as five- to tenfold over doses producing adequate bronchodilation in chronic stable asthmatics is what contributes to their efficacy in reversing the bronchospasm of acute severe asthma.²⁷ The nebulizer dose of inhaled β_2 -agonists for children often is listed on a weight basis (milligrams per kilogram). However, a fixed minimal dose (2.5 mg albuterol or equivalent), as opposed to a weight-adjusted dose, is more appropriate in younger children because children younger than 5 years of age receive a lower lung dose.²⁶ Adults dosed on a weight basis demonstrate excessive cardiac stimulation, so they have fixed maximal doses²⁷ (see Table 26–6). Initial doses of inhaled β_2 -agonists can produce vasodilation, worsening ventilation-perfusion mismatch, slightly lowering oxygen saturation or Pao₂. High-doses of inhaled β_2 -agonists can produce a decrease in serum potassium concentration, an increase in heart rate, and an increase in serum glucose concentration. However, both children and adults receiving continuously nebulized β_2 -agonists have demonstrated decreased heart rates as their lung function improves.^{27,29} Thus an elevated heart rate is not an indication to use lower doses or to avoid using inhaled β_2 -agonists.

Some controversy exists concerning the most cost-effective delivery system (MDI plus holding chamber versus nebulization) to be used in treating severe acute asthma in the emergency department and hospital (see below).^{24,31} The DPIs are currently not indicated for the treatment of severe acute asthma exacerbations. Patients with more severe obstruction may not be able to generate sufficient peak inspiratory flows for adequate delivery.²⁷

■ CORTICOSTEROIDS

Systemic corticosteroids are indicated in all patients with acute severe asthma not responding completely to initial inhaled β_2 -agonist administration (every 20 minutes for three to four doses).² Intravenous therapy offers no therapeutic advantage over oral administration.² This therapy usually is continued until hospital discharge. Tapering the dose in acute asthma following discharge from the hospital appears unnecessary, provided that patients are prescribed inhaled corticosteroids for outpatient therapy.² Most patients achieve 70% of predicted normal FEV₁ within 48 hours and 80% of predicted by 6 days after plateauing by day 3. Thus, maintaining systemic corticosteroid courses for 10 to 14 days may be unnecessarily long in

some patients. Indeed, many patients not admitted to the hospital respond to 3- to 5-day courses of systemic corticosteroids. Short courses of oral prednisone (3 to 10 days) have been effective in preventing hospitalizations in infants and young children.² It is recommended that a full dose of the corticosteroid be continued until the patient's peak flow reaches 80% of predicted normal or personal best.²

Multiple daily dosing of systemic corticosteroids for the initial therapy of acute asthma exacerbations appears warranted because receptor-binding affinities of lung corticosteroid receptors are decreased in the face of airway inflammation.²⁷ However, patients with less severe exacerbations may be treated adequately with once-daily administration. High-dose and very-high-pulse-dose corticosteroid regimens have not been shown to enhance the outcomes in severe acute asthma but are associated with a higher likelihood of side effects.²⁷

A recommended practice is to increase or double the dose of inhaled corticosteroids in patients who are experiencing a deterioration of their asthma control to prevent an exacerbation that requires emergency care.² Studies of inhaled corticosteroids (ICSs) in acute exacerbations of asthma have provided conflicting results. Currently, there is insufficient evidence supporting efficacy in the emergency department setting.³² However, there is some evidence that prescribing ICSs on discharge from the emergency department reduces the risk of relapse.¹⁰ This policy seems like a reasonable recommendation because inflammation is the underlying cause of deterioration in most cases.

■ ANTICHOLINERGICS

Inhaled ipratropium bromide generally produces a further improvement in lung function of 10% to 15% over inhaled β_2 -agonists alone. In children and adults, multiple-dose ipratropium bromide added to initial therapy also produced a reduced hospitalization rate in the subset of patients with an FEV₁ of less than 30% of predicted at baseline.^{33,34} Ipratropium bromide, a quaternary amine, is poorly absorbed and produces minimal or no systemic effects. Care should be used when administering ipratropium bromide by nebulizer. If a tight mask or mouthpiece is not used, the ipratropium bromide that deposits in the eyes may produce pupillary dilatation and difficulty in accommodation. Ipratropium bromide is not a vasodilator, so unlike β_2 -agonists it will not worsen ventilation-perfusion mismatch.²⁷

■ ALTERNATIVE THERAPIES

The emergency department use of aminophylline, a moderate bronchodilator, for acute asthma has not been recommended for a number of years.² Clinical trials of aminophylline in adults and children hospitalized with acute asthma have not reported sufficient evidence of efficacy (improvement in lung function and reduced hospital stay) but have reported an increased risk of adverse effects.²⁷ However, two studies of aminophylline in children with severe disease suggested a possible small benefit in reducing intensive care unit admissions.²⁷ Adverse effects of theophylline include nausea and vomiting and potentiation of the cardiac effects of the inhaled β_2 -agonists.

Magnesium sulfate is a moderately potent bronchodilator that is similar to aminophylline, producing relaxation of smooth muscle and central nervous system depression.³⁵ The use of intravenous magnesium sulfate in patients presenting to the emergency department is

controversial (see below).³⁵ The adverse effects of magnesium sulfate include hypotension, facial flushing, sweating, nausea, loss of deep tendon reflexes, and respiratory depression.²⁷ Patients have required dopamine to treat the hypotension.²⁷

Helium is an inert gas of low density with no pharmacologic properties that can lower resistance to gas flow and increase ventilation because the low density decreases the pressure gradient needed to achieve a given level of turbulent flow, converting turbulent flow to laminar flow.²⁷ Helium is given as a mixture of helium and oxygen (heliox), usually 60% to 70% helium with 30% to 40% oxygen.²⁷ As with a number of experimental approaches, heliox was reported to be efficacious in initial nonrandomized clinical trials. However, the small number of randomized, controlled trials completed to date have failed to document efficacy.³⁶ Although heliox is free of adverse effects, its use is limited to patients with a low inspired oxygen requirement because the decrease in density generally is insignificant clinically with less than 60% helium.²⁷

The inhalational anesthetics halothane, isoflurane, and enflurane all have been reported to have a positive effect in children and adults with severe asthma that is unresponsive to standard medical therapy.²⁷ The proposed mechanisms for inhalational anesthetics include direct action on bronchial smooth muscle, inhibition of airway reflexes, attenuation of histamine-induced bronchospasm, and interaction with β_2 -adrenergic receptors.²⁷ Well-controlled trials with these agents have not been completed. Potential adverse effects include myocardial depression, vasodilation, arrhythmias, and depression of mucociliary function. In addition, the practical problem of delivery and scavenging these agents in the intensive care environment as opposed to the operating room is a concern. The use of volatile anesthetics cannot be recommended based on insufficient evidence of efficacy.

Ketamine has been recommended for rapid induction of anesthesia in patients with asthma who require intubation and mechanical ventilation.²⁷ Ketamine is thought to produce bronchodilation from a combination of an increase in circulating catecholamines, direct smooth muscle relaxation, and inhibition of vagal flow.²⁷ Anecdotal reports have suggested that ketamine is useful as a short-term adjunct in severe acute asthma; controlled trials have not provided sufficient evidence of efficacy, however. Ketamine has several significant adverse effects, including the anesthesia emergence reaction, which can alter mood and cause delirium. These emergence phenomena occur in at least 25% of patients over 16 years of age; the incidence seems to be much lower in younger patients.²⁷ Other risks include an increase in heart rate, arterial blood pressure, and cerebral blood flow because of its sympathetic effects.²⁷

SPECIAL POPULATIONS

6 Infants and children younger than 4 years of age may be at greater risk of respiratory failure than older children and adults. Although treated with the same drugs, these younger children require the use of a facemask as opposed to a mouthpiece for delivery of aerosolized medication. Use of the facemask reduces delivery of drug to the lung by one-half so that a minimal dose is recommended as opposed to a weight-adjusted dose.²⁶ The facemask should be sized appropriately and should fit snugly over the nose and mouth. Use of the “blow by” method, where the therapist or parent places the mask or extension tubing near the child’s nose and mouth, should be discouraged because holding the mask as few as 2 cm from the patient’s face reduces lung delivery of the aerosol by 80%.²⁶

DRUG CLASS INFORMATION

SHORT-ACTING β_2 -AGONISTS

5 6 The β_2 -agonists are the most effective bronchodilators available. The β_2 -adrenergic receptors are transmembrane proteins consisting of clusters of seven helices of amino acids that form the ligand-binding core.³⁰ The human β_2 -adrenergic receptors are polymorphic in structure, with the most common polymorphisms in the amino terminus of the receptor at amino acid positions 16 (encoding either arginine [Arg] or glycine [Gly]) and 27 (encoding either glutamine [Gln] or glutamic acid [Glu]).³⁷ Some of the polymorphisms determine responsiveness to β_2 -agonists, whereas others may act as disease modifiers (see below).³⁷ Stimulation of β_2 -adrenergic receptor activates cytoplasmic G proteins, which, in turn, activate adenylyl cyclase to produce cyclic adenosine monophosphate (cAMP), generally thought to be responsible for the bulk of activity through activation of various proteins by cAMP-dependent protein kinase (PKA).³⁷ This activation, in turn, decreases unbound intracellular calcium, producing smooth muscle relaxation, mast cell membrane stabilization, and skeletal muscle stimulation.²⁵ Despite the fact that β_2 -agonists are potent inhibitors of mast cell degranulation in vitro, they do not inhibit the late asthmatic response to allergen challenge or the subsequent bronchial hyperresponsiveness.^{2,25} Long-term administration of β_2 -agonists does not reduce BHR, confirming a lack of significant anti-inflammatory activity.²⁵ β_2 -Adrenergic stimulation also activates Na^+ , K^+ -ATPase, produces gluconeogenesis, and enhances insulin secretion, resulting in a mild to moderate decrease in serum potassium concentration by driving potassium intracellularly.²⁵ The chronotropic response to β_2 -agonists is mediated in part by baroreceptor reflex mechanisms as a result of the drop in blood pressure from vascular smooth muscle relaxation, as well as by direct stimulation of cardiac β_2 -receptors and some β_1 stimulation at high concentrations.²⁵ Table 26–7 lists the pharmacologic effects of adrenergic receptor stimulation. Because β_1 -receptor stimulation produces excessive cardiac stimulation, resulting in cardiac arrhythmias, and because the inotropic effect enhancing myocardial oxygen consumption leads to myocardial necrosis, there

TABLE 26–7. Pharmacologic Responses to Sympathomimetic Agonists

| Tissue | Receptor Type | Response |
|-------------|----------------------|---|
| Airways | β_2 | Smooth muscle relaxation (bronchodilation), increased ciliary beat, increased serous secretion, and inhibition of mast cell degranulation |
| | α | Smooth muscle contraction (bronchoconstriction?) |
| Heart | β_1 | Inotropic and chronotropic |
| Vasculature | β_2 | Chronotropic |
| | β_2 | Vasodilation, decrease microvascular leakage |
| Skeletal | α | Vasoconstriction |
| | β_2 | Increased neuromuscular transmission (tremor and increased strength of contraction) |
| Uterus | β_2 | Relaxation (tocolysis) |
| Metabolic | α , β_1 | Glycogenolysis, lipolysis |
| | β_2 | Gluconeogenesis, hypokalemia, increased lactate production |

is no rationale for using non- β_2 -selective agonists in the treatment of asthma.²⁵

Table 26–8 compares the various β -adrenergic agonists used in asthma in terms of selectivity, potency, oral activity, and duration of action. The β_2 -agonists are functional or physiologic antagonists in that they relax airway smooth muscle regardless of the mechanism for constriction.³⁰ When administered in equipotent doses, all the short-acting drugs produce the same intensity of response; the only differences are in duration of action and cardiac toxicity.^{2,25} The catecholamine derivatives all have the disadvantage of rapid inactivation of their 3,4-hydroxyl catechol group from catechol-*O*-methyltransferase found in the gastrointestinal tract, rendering them orally inactive. In addition, catecholamines are taken up rapidly into tissues by secondary uptake mechanisms that limit their receptor occupancy and thus have a shorter duration of action.²⁵ All the β_2 -agonists are more bronchoselective when administered by the aerosol route.²⁵ Aerosol administration of the short-acting β_2 -agonists provides more rapid response and greater protection against provocations that induce bronchospasm such as exercise and allergen challenges than does systemic administration.²⁵ Differences in myocardial effects are discernible between selective and nonselective agents even when administered as aerosols, particularly at the higher doses used for severe acute asthma. The β_2 -agonists also differ in efficacy or ability to activate the β_2 -adrenergic receptors. Full agonists include the catecholamines, metaproterenol, and formoterol.³⁰ Partial agonists include albuterol, terbutaline, pirbuterol, and salmeterol.³⁰ The principal differences between full and partial agonists is that full agonists require a lower fraction of receptor occupancy to produce their maximum effect and more easily produce receptor desensitization.³⁰

All synthetic β_2 -agonists are 1:1 racemic mixtures of two mirror images (enantiomers) owing to an asymmetric or chiral carbon.^{30,38} Since most physiologic functions (receptor occupancy and activation and enzymatic metabolism) are stereoselective, the (*R*)-enantiomers of the β_2 -agonists are the most pharmacologically active isomer.³⁷ While it was felt initially that the (*S*)-enantiomers were essentially inactive owing to the 1000-fold potency difference between the enantiomers, studies in animal models and isolated in vitro tissue preparations have suggested that the (*S*)-enantiomers may be proinflammatory and could induce BHR.³⁹ However, evidence that this occurs consistently in humans or is clinically relevant is lacking (see below).³⁸ The pharmacokinetics are stereoselective as well, although not as predictable. (*R*)-Albuterol is metabolized more rapidly than (*S*)-albuterol, which could lead to accumulation of (*S*)-albuterol with continued dosing.³⁸ This accumulation is more exaggerated with oral

dosing, as would be expected from a drug with a high first-pass effect.³⁰ On the other hand, (*S*)-terbutaline is eliminated more rapidly than (*R*)-terbutaline.³⁰

Both the intensity and duration of response are dose-dependent, and more important, the dose-response relationship is dynamic.²⁵ At increasing levels of baseline bronchoconstriction (irrespective of the stimulus), the dose-response curve is shifted to the right, and the duration of bronchodilation is decreased.³⁰ This shift is reflected in the need for higher, more frequent doses in acute asthma exacerbations; the duration of protection against significant provocation is much less than the duration of bronchodilation in chronic stable asthma²⁵ (see Table 26–8).

Chronic administration of β_2 -agonists leads to downregulation (decreased number of β_2 receptors) and a decreased binding affinity for these receptors.^{25,30} Systemic corticosteroid therapy can both prevent and partially reverse this phenomenon.^{2,25} However, the use of inhaled corticosteroids appears to have minimal ability to prevent tolerance to β_2 -agonists.³⁰ The homozygous Gly-16 form of the receptor downregulates to a much greater extent compared with the homozygous Arg-16 form of the receptor.³⁷ The heterozygous Arg-16/Gly-16 is intermediately desensitized compared with the homozygous Gly-16 form. On the other hand, glutamate substitution at codon 27 (Glu-27) protects against downregulation compared with the glutamine form (Gln-27) of the receptor.³⁷ However, the Gly-16 overcomes any protective effect of Glu-27.³⁷ Tolerance primarily reduces duration of bronchodilation as opposed to peak response. A significantly greater tolerance develops in other tissues (e.g., lymphocytes and cardiac and skeletal muscle) compared with the lung primarily as a result of the surplus β_2 receptors found in respiratory smooth muscle.²⁵ Tolerance to the extrapulmonary effects (cardiac stimulation and hypokalemia) may account for a lack of significant cardiac effects with retention of the bronchodilator response despite chronic inhaled β_2 -agonist therapy, whereas tolerance to mast cell stabilization may be a drawback to chronic use.²⁵ Thus chronic β_2 -agonist administration produces a tolerance of minimal clinical significance that is overcome easily by increasing the dose or by administering corticosteroids.^{2,25} Most of the tolerance occurs within a week of regular administration and does not worsen with continued administration. As would be expected from a receptor phenomenon, tolerance is a cross-tolerance to all β_2 -agonists.^{25,30} Whether or not regular use of short-acting inhaled β_2 -agonists produces worsening of asthma in a subset of patients remains controversial (see below), but it does not appear to occur in the entire population.⁴⁰ However, regular treatment (four times daily) does not improve symptom control over as-needed use.⁴¹

TABLE 26–9. Pharmacodynamic/Pharmacokinetic Comparison of the Corticosteroids

| Systemic | Anti-inflammatory Potency | Mineralcorticoid Potency | Duration of Biologic Activity (h) | Elimination Half-Life (h) |
|--------------------|---------------------------|--------------------------|-----------------------------------|---------------------------|
| Hydrocortisone | 1 | 1.0 | 8–12 | 1.5–2.0 |
| Prednisone | 4 | 0.8 | 12–36 | 2.5–3.5 |

In conclusion, the inhaled short-acting selective β_2 -agonists are indicated for the treatment of intermittent episodes of bronchospasm. They are the first treatment of choice for acute severe asthma and exercise-induced bronchospasm.^{2,25} They inhibit EIB in a dose-dependent fashion and provide complete protection for a 2-hour period following inhalation with varying levels of patient-dependent protection over 4 hours.²⁵ Although the regular administration of β_2 -agonists slightly decreases the effect, two inhalations prior to exercise still essentially blocks exercise-induced bronchospasm completely (1% versus 5% drop in FEV₁).⁴²

SYSTEMIC CORTICOSTEROIDS

4 The corticosteroids are the most effective anti-inflammatories available to treat asthma.^{2,7,10} Actions useful in treating asthma include (1) increasing the number of β_2 -adrenergic receptors and improving the receptor responsiveness to β_2 -adrenergic stimulation, (2) reducing mucus production and hypersecretion, (3) reducing BHR, and (4) preventing and reversing airway remodeling.^{9,10} The glucocorticoid receptor is found in the cytoplasm of most cells throughout the body, explaining the multiple effects of systemic corticosteroids. There is no difference between glucocorticoid receptors found throughout the body; however, genetic differences between glucocorticoid receptors from different individuals may determine some of the variations in response.⁴³ The corticosteroids are lipophilic, readily cross the cell membrane, and combine with the glucocorticoid receptor. The activated complex then enters the nucleus, where it acts as a transcription factor leading to gene activation or suppression.⁴⁴ This leads to specific mRNA production, resulting in increased production of anti-inflammatory mediators; suppression of several proinflammatory cytokines such as IL-1, GM-CSF, IL-3, IL-4, IL-5, IL-6, and IL-8, reducing inflammatory cell activation, recruitment, and infiltration; and decreasing vascular permeability.⁴⁴ In addition, the activated glucocorticoid receptor complex can act directly with cytoplasmic transcription factors, nuclear factor κ B, and activating protein 1 to prevent the action of proinflammatory cytokines on the cell.⁴⁴

Owing to the mechanism that modifies gene expression, the time required to see the particular effect depends on the time required for new protein synthesis, decreased formation of the particular mediator,

and resolution of the inflammatory response.⁴⁴ Generally, the cellular and biochemical effects are immediate, but varying amounts of time are required to produce a clinical response. β_2 -Receptor density increases within 4 hours of corticosteroid administration.⁴⁴ Improved responsiveness to β_2 -agonists occurs within 2 hours.²⁷ In severe acute asthma, 4 to 12 hours may be required before any clinical response is noted.²⁷ Reversal of seasonally increased BHR requires at least 1 week of therapy.⁴⁴ The chronic use of corticosteroids does not induce a state of corticosteroid dependence. Nor is there evidence of tolerance produced by chronic administration.

The corticosteroids used in asthma are compared in Table 26–9.⁴⁵ Besides acute severe asthma, systemic corticosteroids are also recommended for the treatment of impending episodes of severe asthma unresponsive to bronchodilator therapy.^{2,10} The effects of corticosteroids in asthma are dose- and duration-dependent. This pattern is true for the adverse effects as well (Table 26–10). The clinician must balance the toxicity of chronic systemic corticosteroid therapy continually with control of asthma symptoms. Because short-term (1 to 2 weeks) high-dose corticosteroids (1 to 2 mg/kg per day of prednisone) do not produce serious toxicities, the ideal use is to administer the systemic corticosteroids in a short “burst” and then to maintain the patient on appropriate long-term control therapy with inhaled corticosteroids (discussed below).^{2,10} In general, therapy for more than 5 days at doses that exceed the usual physiologic endogenous cortisol

TABLE 26–10. Adverse Effects of Chronic Systemic Glucocorticoid Administration

| | |
|--|---|
| Hypothalamic–pituitary–adrenal suppression | Hypertension |
| Growth retardation | Skin striae |
| Skeletal muscle myopathy | Impaired wound healing |
| Osteoporosis/fractures | Inhibition of leukocyte and monocyte function |
| Aseptic necrosis of bone | Subcutaneous tissue atrophy |
| Pancreatitis | Glaucoma |
| Pseudotumor cerebri | Posterior subcapsular cataracts |
| Psychiatric disturbances | Moon facies |
| Sodium and water retention | Central redistribution of fat |
| Hypokalemia/hyperglycemia | |

production will cause temporary aberration in adrenal cortisol release.²⁷ However, this hypothalamic-pituitary-adrenal (HPA) axis suppression is short-lived (1 to 3 days) and readily reversible following short bursts (10 days or less) of pharmacologic doses.²⁷ A maximum number of short bursts that a patient can receive probably exists, after which chronic corticosteroid side effects occur. Patients receiving at least eight bursts (≥ 10 days each) were shown to have a similar decrease in trabecular bone density as patients on daily or alternate-day corticosteroids over 1 year.²⁷ Children who received four or more bursts of prednisone exhibited a subnormal response to hypoglycemic stress or adrenocorticotropic hormone (ACTH) administration.²⁷ Very short courses (3 to 5 days) have been effective in reducing hospitalization from acute exacerbations.^{2,10} Use of the shorter-acting corticosteroids such as prednisone will produce less adrenal suppression than the longer-acting dexamethasone.

ANTICHOLINERGICS

The anticholinergic agents have a long history of use for asthma, but they do not have a Food and Drug Administration (FDA)-approved indication for asthma.^{2,10} Anticholinergics are competitive inhibitors of muscarinic receptors.⁴⁶ Unlike β_2 -agonists, they are not functional antagonists; they only reverse cholinergic-mediated bronchoconstriction.³³ Normal bronchial tone is maintained through parasympathetic innervation of the airways via the vagus nerve. A

number of the triggers and mediators of asthma (i.e., histamine, prostaglandins, sulfur dioxide, exercise, and allergens) produce bronchoconstriction in part through vagal reflex mechanisms.² Studies of asthmatics consistently demonstrate that anticholinergics are effective bronchodilators, although not as effective as β_2 -agonists. Anticholinergics attenuate but do not block allergen-induced asthma in a dose-dependent fashion and have no effect on BHR.²

Ipratropium bromide is a nonselective muscarinic receptor blocker, and blockade of inhibitory muscarinic receptors theoretically could result in an increased release of acetylcholine and overcome the block on the smooth muscle receptors (M_3).⁴⁶ Only the quaternary ammonium derivatives such as ipratropium bromide should be used because they have the advantage of poor absorption across mucosae and the blood-brain barrier. This results in negligible systemic effects with a prolonged local effect (i.e., bronchodilation). In addition, the quaternary compounds do not appear to produce a decrease in mucociliary clearance.⁴⁶ Ipratropium bromide has a duration of action of 4 to 8 hours. Both intensity and duration of action are dose-dependent. Time to reach maximum bronchodilation is considerably slower than from aerosolized short-acting β_2 -agonists (2 hours versus 30 minutes). However, this is of little clinical consequence because some bronchodilation is seen within 30 seconds, 50% of maximum response occurs within 3 minutes, and 80% of maximum is reached within 30 minutes.⁴⁶ Ipratropium bromide is only indicated as adjunctive therapy in severe acute asthma not completely responsive to β_2 -agonists alone because it does not improve outcomes in chronic asthma.^{2,10}

PHARMACOECONOMICS

The number of emergency department visits for asthma exceeds the number of hospitalizations by approximately four times, yet the annual expenditures for emergency department visits (\$478.6 million) is significantly less than the estimated \$1.8 billion spent on inpatient hospital services for patients with acute severe asthma.⁶ Thus, reducing the number of patients requiring hospitalizations is a primary goal of therapy. Inpatient services have declined as a percentage of total medical expenditures primarily as a result of decreasing duration of hospitalizations.⁶ Since the primary drugs used to treat severe acute asthma are available generically, drug costs account for only a small portion of the overall costs of care. Few of the therapies used in the management of acute severe asthma have been evaluated formally for their pharmacoeconomic impact. One evaluation based on a meta-analysis of inhaled anticholinergics added to inhaled β_2 -agonists in children with acute severe asthma suggested that this approach was cost-effective and would reduce overall costs by reducing hospitalizations.⁴⁷ In children with acute severe asthma admitted to an intensive care unit, the use of continuously nebulized albuterol resulted in a decreased cost of care compared with intermittent nebulization.²⁷

CLINICAL CONTROVERSIES

Some clinicians believe that intravenous magnesium sulfate is effective for the treatment of severe acute asthma unresponsive to standard doses of inhaled β_2 -agonists in the emergency department. This is based on subset analyses of two studies showing that patients with the most severe obstruction following initial inhaled β_2 -agonists decreased hospitalizations with magnesium treatment compared with placebo.³⁵ However, the subset with severe obstruction is the one demon-

strating an improved response to the addition of ipratropium bromide and continuous nebulization of inhaled β_2 -agonists. Listed as experimental by the NAEPP,² the Global Initiative in Asthma (GINA) guidelines state that it can be considered for use in patients with severe episodes with a poor response to initial inhaled β_2 -agonists.¹⁰

Numerous studies have shown that the inhaled β_2 -agonists administered by MDI plus holding chamber provide a similar outcome in severe acute asthma as administration by jet nebulizers.³¹ Proponents of administration by MDI plus holding chambers argue that it is more cost-effective and so should replace nebulizer therapy. However, appropriate cost analyses have yet to be performed.²⁴ Nor have there been comparisons in the most severe subsets, where combination therapy and continuous nebulization are recommended.²⁷ Current practice should be based on the comfort level of the clinical staff until sufficient data are available to warrant a wholesale recommendation of one method.

EVALUATION OF THERAPEUTIC OUTCOMES

Figures 26-6 and 26-7 provide the monitoring parameters for severe acute asthma. Lung function, either spirometry or peak flows, should be monitored 5 to 10 minutes after each treatment.² Oxygen saturations can be easily monitored continuously with pulse oximetry. For young children and infants, pulse oximetry, lung auscultation, and observation of the presence of supraclavicular retractions is useful.^{2,27} The majority of patients will respond within the first hour of initial inhaled β_2 -agonists regardless of history of home administration of drug. Patients not achieving an initial response should be monitored every 0.5 to 1 hour. Depending on whether there is a standard emergency department or a special unit for severe acute asthma, the

decision to admit to the hospital should be made within 4 to 6 hours of entry to the emergency department. The mean duration of hospitalization following admission is 2 to 3 days. Frequency of monitoring

depends on the severity of the exacerbation. With mild exacerbations, monitor lung function every 2 to 3 hours and severe exacerbations every 0.5 to 1 hour.

► TREATMENT: Chronic Asthma

The diagnosis of chronic asthma is made primarily by history and confirmatory spirometry (see Clinical Presentation above).^{2,10} The NAEPP has provided a list of questions that would lead to the diagnosis of asthma² (see Table 26–2). In the older child and adult patient in whom spirometric evaluations can be performed, failure of pulmonary functions to improve acutely does not necessarily rule out asthma. Patients with long-standing disease or substantial inflammation may require an intensive, prolonged course of bronchodilators and glucocorticoids before reversibility is detected.^{2,10} If baseline spirometry is normal, challenge testing with exercise, histamine, or methacholine can be used to elicit BHR.² Patients with significant symptoms and/or an FEV₁ of less than 65% of predicted normal should not be challenged. Studies for atopy such as serum IgE and sputum and blood eosinophil determinations are not necessary to make the diagnosis of asthma, but they may help differentiate asthma from chronic bronchitis in adults. Clinically, this distinction is often difficult to make. Some patients with chronic bronchitis may have a reversible component, and some patients with long-standing severe chronic asthma may have significant irreversible damage and obstruction. Very high peripheral blood eosinophil counts may point to the diagnosis of allergic bronchopulmonary aspergillosis (ABPA) or other hyper eosinophilic syndromes.¹⁰ Skin testing is of no value in diagnosing asthma but is useful in identifying triggers.² In small infants unable to perform spirometry, the diagnosis is more difficult. They may demonstrate hyperinflation on the chest roentgenogram.² Radiologic examination is helpful in ruling out other causes of wheezing (e.g., foreign-body aspiration, parenchymal lung disease, cardiac disease, and congenital anomalies).² In place of pulmonary functions, the parents should be given a diary card to record symptoms and precipitating events.

■ GOALS OF MANAGEMENT

The NAEPP has provided the following goals for chronic asthma management²:

1. Maintain normal activity levels (including exercise and other physical activity).
2. Maintain (near) normal pulmonary functions.
3. Prevent chronic and troublesome symptoms (e.g., coughing or breathlessness in the night, in the early morning, or after exertion).
4. Prevent recurrent exacerbations of asthma, and minimize the need for emergency department visits or hospitalizations.
5. Provide optimal pharmacotherapy with minimal or no adverse effects.
6. Meet patients' and families' expectations of satisfaction with asthma care.

Toward these goals, every effort should be made to decrease the patient's baseline BHR and prevent it from increasing.

■ NONPHARMACOLOGIC THERAPY

Although the mainstay of the management of asthma is pharmacologic therapy, it is likely to fail without attending to the nonpharmacologic therapy issues. Figure 26–8 depicts the stepwise approach to asthma therapy recommended in the newest update by the NAEPP.⁷ It is important to note that the nonpharmacologic aspects of therapy are incorporated into the steps. The guidelines were designed to give primary health care providers a framework with which to develop the proper approach to the individualized therapy of patients. The heterogeneity of asthma demands an individualized approach to therapy with the basic goals of therapy as primary outcome measures.^{2,7}

The knowledge that inflammation plays a primary role in the pathogenesis of asthma has led to the conviction that the focus of therapy is the prevention and suppression of the underlying inflammation.^{2,7,10} Thus current therapeutic options in asthma consist of acute reliever medications used for acute exacerbations and long-term control medications used for the prevention of symptoms and exacerbations and the suppression of inflammation.² The currently accepted approach is to use drugs that suppress the inflammatory response as primary long-term control therapy, thereby reducing the degree of BHR and improving long-term control and outcomes in asthma by preventing airway remodeling.^{2,7,10}

7 The development of a partnership in care through patient education and the teaching of patient self-management skills should be the cornerstone of any treatment program.^{2,10} There are a number of published self-management programs for children and adults available through local American Lung Association chapters, as well as asthma treatment centers, and nationally through the NAEPP and the Asthma and Allergy Foundation of America.^{2,10} Asthma self-management programs have been shown to improve patient adherence to medication regimens, improve self-management skills, and improve use of health care services.^{2,7} The objective of these programs is to develop a partnership relationship between the patient and the health care provider. Table 26–11 lists the key educational messages recommended by the NAEPP.²

Self-management programs instruct patients in the pathogenesis of asthma and the appropriate use of their medications but focus principally on teaching patients to recognize triggers for their asthma and how to recognize early signs of deterioration. Use of objective measurement of airflow obstruction with a home peak-flow meter is integral to many of the programs.^{2,10} However, routine peak-flow monitoring in and of itself does not improve patient outcomes.⁷

The NAEPP now advocates the use of peak-flow meters only for patients with moderate and severe persistent asthma.² The NAEPP also has recommended a system based on a traffic light scenario (based on percentage of normal predicted values or personal best values): The green zone is equal to 80% to 100%, the yellow zone is equal to 50% to 79%, and the red zone is less than 50%. The yellow zone is cautionary and requires increasing as-needed bronchodilator use and either increasing the anti-inflammatory dose or beginning prednisone

| Classify Severity: Clinical Features Before Treatment or Adequate Control | | Medications Required to Maintain Long-Term Control | |
|--|--|---|--|
| | Symptoms/Day Symptoms/Night | PEF or FEV ₁ PEF Variability | Daily Medications |
| STEP 4 Severe Persistent | Continual Frequent | ≤60% >30% | <ul style="list-style-type: none"> • Preferred treatment: <ul style="list-style-type: none"> – High-dose inhaled corticosteroids AND – Long-acting inhaled β₂-agonists AND, if needed, – Corticosteroid tablets or syrup long term (2 mg/kg/day, generally do not exceed 60 mg per day). (Make repeat attempts to reduce systemic corticosteroids and maintain control with high-dose inhaled corticosteroids.) |
| STEP 3 Moderate Persistent | Daily >1 night/week | >60% – <80% >30% | <ul style="list-style-type: none"> • Preferred treatment: <ul style="list-style-type: none"> – Low-to-medium dose inhaled corticosteroids and long-acting inhaled β₂-agonists. • Alternative treatment (listed alphabetically): <ul style="list-style-type: none"> – Increase inhaled corticosteroids within medium-dose range OR – Low- to medium-dose inhaled corticosteroids and either leukotriene modifier or theophylline. <p>-----</p> <p>If needed (particularly in patients with recurring severe exacerbations):</p> <ul style="list-style-type: none"> • Preferred treatment: <ul style="list-style-type: none"> – Increase inhaled corticosteroids within medium-dose range and add long-acting inhaled β₂-agonists. • Alternative treatment: <ul style="list-style-type: none"> – Increase inhaled corticosteroids within medium-dose range and add either leukotriene modifier or theophylline. |
| STEP 2 Mild Persistent | >2/week but < 1x/day >2 nights/month | ≥80% 20–30% | <ul style="list-style-type: none"> • Preferred treatment: <ul style="list-style-type: none"> – Low-dose inhaled corticosteroids. • Alternative treatment (listed alphabetically): cromolyn, leukotriene modifier, nedocromil, OR sustained release theophylline to serum concentration of 5–15 mcg/mL. |
| STEP 1 Mild Intermittent | ≤2days/week ≤2 nights/month | ≥80% <20% | <ul style="list-style-type: none"> • No daily medication needed. • Severe exacerbations may occur, separated by long periods of normal lung function and no symptoms. A course of systemic corticosteroids is recommended. |
| Quick Relief All Patients | <ul style="list-style-type: none"> • Short-acting bronchodilator: 2–4 puffs short-acting inhaled β₂-agonists as needed for symptoms. • Intensity of treatment will depend on severity of exacerbation; up to 3 treatments at 20-minute intervals or a single nebulizer treatment as needed. Course of systemic corticosteroids may be needed. • Use of short-acting β₂-agonists >2 times a week in intermittent asthma (daily, or increasing use in persistent asthma) may indicate the need to initiate (increase) long-term-control therapy. | | |
| <p>↓ STEP DOWN Review treatment every 1 to 6 months; a gradual stepwise reduction in treatment may be possible.</p> <p>Goals of Therapy: Asthma Control</p> <ul style="list-style-type: none"> • Minimal or no chronic symptoms day or night • Minimal or no exacerbations • No limitations on activities; no school/work missed <p>Note</p> <ul style="list-style-type: none"> • The stepwise approach is meant to assist, not replace, the clinical decisionmaking required to meet individual patient needs. • Classify severity: assign patient to most severe step in which any feature occurs (PEF is % of personal best; FEV₁ is % predicted). • Gain control as quickly as possible (consider a short course of systemic corticosteroids); then step down to the least medication necessary to maintain control. • Minimize use of short-acting inhaled β₂-agonists. Over reliance on short-acting inhaled β₂-agonists (e.g., use of short-acting inhaled β₂-agonist everyday, increasing use or lack of expected effect, or use of approximately one canister a month even if not using it every day) indicates inadequate control of asthma and the need to initiate or intensify long-term control therapy. • Provide education on self-management and controlling environmental factors that make asthma worse (e.g., allergens and irritants). • Refer to an asthma specialist if there are difficulties controlling asthma or if step 4 care is required. Referral may be considered if step 3 care is required. | | <p>↑ STEP UP If control is not maintained, consider step up. First, review patient medication technique, adherence, and environmental control.</p> | |

FIGURE 26–8. Stepwise approach for managing asthma in adults and children older than 5 years of age. (From ref. 2.)

TABLE 26–11. Key Educational Messages for Patients**Basic facts about asthma**

- The contrast between asthmatic and normal airways
- What happens to the airways in an asthma attack

Roles of medications

- How medications work
 - Long-term control: medications that prevent symptoms, often by reducing inflammation
 - Quick relief: short-acting bronchodilator relaxes muscles around airways
- Stress importance of long-term-control medications and not to expect quick relief from them

Skills

- Inhaler use (patient demonstrate)
- Spacer and holding chamber use
- Symptom monitoring, peak flow monitoring, and recognizing early signs of deterioration

Environmental control measures

- Identifying and avoiding environmental precipitants or exposures

When and how to take rescue actions

- Responding to changes in asthma severity (daily self-management plan and action plan)

if not improved, whereas the red zone warrants contacting the patient's health care provider.² This approach can assist the patient and health professional in determining the next level of therapy.

Patient education is essential before monitoring can be effective. Patient education has proved successful regardless of the health professional who provided the information (physician, nurse, or pharmacist). The NAEPP advocates significant involvement of the primary health care provider in the educational process. The provision of written treatment plans enhances the success of education and peak-flow monitoring and is considered an essential component of care.² Samples of clinically tested written action plans are available from the NAEPP Expert Panel Report 2.²

In patients with known allergic triggers for their asthma, allergen avoidance has resulted in an improvement in symptoms, a reduction in medication use, and a decrease in BHR.^{2,10} Relatively simple environmental controls for patients with house dust mite allergy such as removing carpeting from bedrooms, washing sheets in hot water (>130°F), and using plastic pillow and mattress covers can reduce symptoms and need for medications.^{2,10} Obvious environmental triggers (i.e., warm-blooded animals, cockroaches), if the patient is sensitive, should be avoided; however, there is very little evidence that extensive environmental controls (i.e., home air-filtering systems and chemicals for killing house dust mites) are of any value.² Although allergen avoidance has proved beneficial, immunotherapy (allergy shots) is not efficacious in asthma, although a proven and accepted therapy for allergic rhinitis.^{2,10}

Patients who smoke should be encouraged to stop. Parents of children with asthma should stop or at least not smoke around their children.^{2,10}

■ PHARMACOLOGIC THERAPY

The current NAEPP recommendations for therapy of chronic asthma are illustrated in Figure 26–8.⁷ Regardless of the long-term control therapy, all patients need to have quick-relief medication in the form of short-acting inhaled β_2 -agonists available for acute

symptoms. The inhaled corticosteroids are considered the preferred long-term control therapy for persistent asthma in all patients.^{7,10} This new recommendation follows an evidence-based report by the NAEPP.⁷ Low- to medium-dose inhaled corticosteroids reduce BHR, improve lung function, and reduce severe exacerbations leading to emergency department visits and hospitalizations. They are more effective than either cromolyn, nedocromil, theophylline, or the leukotriene antagonists.⁷ In addition, the inhaled corticosteroids are the only therapy that reduces the risk of dying from asthma.⁴⁸

In the low to medium doses recommended by the NAEPP guidelines (Table 26–12), inhaled corticosteroids have been proved to be safe for long-term administration.⁴³ The principal adverse effect at low to medium doses is delayed growth in children that appears to be about 1 to 2 cm in the first year of therapy, is not progressive, and does not appear to prevent attainment of predicted adult height.⁴³ The inhaled corticosteroids do not appear to increase the risk of osteoporosis in the elderly or glaucoma and cataracts except at high doses^{7,43} (see Table 26–12). It is unknown whether the inhaled corticosteroids can reduce airway remodeling and loss of lung function found in some patients with persistent asthma. Studies demonstrating a reduction in some aspects of airway remodeling used high doses of inhaled corticosteroids.⁹ They do not enhance lung growth in children 5 to 12 years of age when administered for 4 to 6 years, nor do they induce remission of asthma because BHR and other measures of inflammation return to pretreatment levels on discontinuation of therapy.⁴⁹

Although short-term studies of the alternative long-term control therapies (e.g., cromolyn, leukotriene antagonists, nedocromil, and theophylline) demonstrate improvement in symptoms, lung function, and as-needed short-acting inhaled β_2 -agonist use, they do not reduce BHR, suggesting minimal anti-inflammatory activity.⁷ Few of these therapies have been assessed in long-term clinical trials. The evidence suggests minimal to no differences in efficacy between these alternatives. Therefore, the NAEPP lists them in alphabetical order to show no preference of one over the other.⁷ Of interest, the GINA guidelines, established in cooperation with the National Institutes of Health and the World Health Organization, list the alternatives based on costs because the World Health Organization is concerned with providing therapies to third world countries.¹⁰ As a result, theophylline is listed first as the least expensive and leukotriene antagonists last as the most expensive.¹⁰

The most significant change in the NAEPP guidelines update in 2002 is the recommendation that the combination of inhaled corticosteroids and long-acting inhaled β_2 -agonists is the preferred treatment for step 3 moderate persistent asthma.⁷ This change is based on strong evidence of superiority of the combination over doubling the dose of inhaled corticosteroids. In addition, this combination has been shown to be superior to the adding of leukotriene antagonists to inhaled corticosteroids.⁷ The addition of theophylline to inhaled corticosteroids is no more effective than doubling the dose of the inhaled corticosteroids on lung function and not as effective at reducing severe asthma exacerbations.⁷ The combination of inhaled corticosteroid and long-acting inhaled β_2 -agonists is more effective at reducing severe asthma exacerbations than doubling the dose of inhaled corticosteroids in moderate persistent asthma; however, increasing the dose of inhaled corticosteroid fourfold into the high-dose range also will result in a significant reduction in exacerbations.⁵⁰ However, doses of inhaled corticosteroids in the high range significantly enhance the risk of toxicity. Thus high doses of inhaled corticosteroids plus long-acting inhaled β_2 -agonists are reserved for patients with step 4 severe persistent asthma.⁷

TABLE 26–12. Available Inhaled Corticosteroid Products, Lung Delivery, and Comparative Doses

| ICS | Product | Lung Delivery ^a |
|-----------------------------------|---|----------------------------|
| Beclomethasone dipropionate (BDP) | 42 mcg/actuation CFC MDI, 200 actuations | 4–10% |
| | 40 and 80 mcg/actuation HFA MDI, 120 actuations | 55–60% |
| Budesonide (BUD) | 200 mcg/dose DPI, Turbuhaler, 200 doses | 32% (16–59%) |
| | 200 and 500-mcg ampules, 2 mL each | 6% |
| Flunisolide (FLU) | 250 mcg/actuation CFC MDI, 100 actuations | 32% |
| Fluticasone propionate (FP) | 44, 110, and 220 mcg/actuation CFC MDI, 120 actuations | 26–30% |
| | 50, 100, and 250 mcg/dose DPI, Rotadisk, 4 doses | 15% (13–18%) |
| | 50, 100, and 250 mcg/dose DPI, Diskus, 60 doses | 15% |
| Mometasone furoate (MF) | 200 and 400 mcg/dose DPI, Twisthaler, 14, 30, 60, and 120 doses | Unknown |
| Triamcinolone acetonide (TAA) | 100 mcg/actuation CFC MDI, 240 actuations with spacer | 22% |

| | Comparable Daily doses (mcg) | | |
|--------------|------------------------------|--------------------------|------------------------|

^aLung delivery from in vivo radiolabel scintigraphy or pharmacokinetic studies.

Although the addition of a third controller medication is often used clinically in patients requiring step 4 therapy, there are few studies evaluating this practice.⁷ Leukotriene antagonists added to high-dose inhaled corticosteroids and long-acting inhaled β_2 -agonists do not improve outcomes.⁷ None of the other long-term controllers has been evaluated in this scenario. Omalizumab or anti-IgE has received FDA approval for use in corticosteroid-dependent, severe asthma. Thus patients with severe asthma and atopy with an elevated IgE concentration would be candidates for omalizumab.⁵¹

SPECIAL POPULATIONS

6 Children 5 years of age and younger have not been studied adequately. Thus many of the recommendations in this age group are based on extrapolation of data from older children and adults.⁷ The few studies of inhaled corticosteroids in this younger group are supportive. The nebulized formulation of budesonide gained FDA approval from three pivotal efficacy and safety trials.⁷ The FDA approval for montelukast in children younger than age 6 was based on safety and pharmacokinetic studies establishing doses but not on efficacy trials.⁷ Not all trials of cromolyn in this younger group have demonstrated efficacy.⁷ Theophylline has not been evaluated adequately, except for pharmacokinetics.⁷ Combination therapy of any kind has not been studied except for a small number of patients down to 4 years of age on inhaled corticosteroids plus long-acting inhaled β_2 -agonists.⁷ The FDA approval of the Advair Diskus 100/50 in patients 4 to 11 years of age was based on extrapolation of efficacy data from patients older than 12 years of age and by safety and efficacy data from a study of the Advair Diskus 100/50 in children with asthma aged 4 to 11 years.

The recommendations for children 5 years of age and younger differ slightly from the recommendations for older children and adults. For step 3 therapy, both medium-dose inhaled corticosteroids as monotherapy and the combination of inhaled corticosteroids plus long-acting inhaled β_2 -agonists are considered preferred.⁷ However, there is no more evidence for a significant dose-response to the inhaled corticosteroids in this age group than there is for combination therapy.

Owing to the increased risk of osteoporosis in the elderly, patients requiring high doses of inhaled corticosteroids should have their bone mineral density determinations followed and appropriate therapies for osteoporosis instituted if necessary.⁴³

Asthma affects 7% of pregnant women, making it potentially the most common serious medical condition to complicate pregnancy.⁵² Maternal asthma has been reported to increase the risk of perinatal mortality, preeclampsia, preterm birth, and low-birth-weight infants.⁵² More severe asthma is associated with increased risks, whereas better-controlled asthma is associated with decreased risks.

A systematic review of the evidence on the safety of asthma medications has been conducted by drug class.⁵² This review concluded that it is safer for pregnant women with asthma to be treated with asthma medications than for them to have asthma exacerbations.⁵² Proper monitoring and control of asthma should enable a woman with asthma to maintain a normal pregnancy with little or no risk to her or her fetus.

A stepwise approach to managing asthma during pregnancy and lactation has been published, with low-dose inhaled corticosteroids recommended as preferred treatment for step 2 and the addition of long-acting β -agonists added in step 3 and step 4.⁵² Budesonide is considered the preferred inhaled corticosteroid to initiate because it has the greatest safety data from the Swedish Birth Registry.⁵² Albuterol is considered the preferred rescue therapy.⁵²

■ DRUG CLASS INFORMATION

■ INHALED CORTICOSTEROIDS

The mechanism of action of the corticosteroids has been reviewed (see above). The principal advantage of the inhaled corticosteroids (ICSs) is their high topical potency to reduce inflammation in the lung and low systemic activity.^{43–45} The ICSs have high anti-inflammatory potency, approximately 1000-fold greater than endogenous cortisol, and differ from each other by as much as four- to sixfold.⁴⁴ However, potency differences, which are simply a measure of binding affinity to the receptor, can be overcome simply by giving different microgram dosages of drug. Aerosol delivery of the preparations is remarkably variable, ranging from 10% to 60% of the nominal dose (i.e., that dose which leaves an actuator for an MDI or, in the case of a DPI, that which is released on actuation of the inhaler).^{24,45} Different devices for the same chemical entity may result in twofold differences in delivery, such as with fluticasone propionate and budesonide, or as much as eightfold with beclomethasone dipropionate (BDP) preparations.⁴⁵ Thus the delivery method can make a significant difference in the relative comparable dose.^{2,45}

The ICSs beclomethasone dipropionate, budesonide, flunisolide, fluticasone propionate, and triamcinolone acetonide that are currently available for use are compared and listed in Table 26–12. The ICSs have pharmacokinetic differences that result in different topical/systemic activity.^{44,45} Most evidence is consistent with log-linear dose-response curves for both indirect and direct responses.⁴³ The log-linear nature of the dose-response curve for corticosteroid activity raises the issue of how much of a difference in dose (or lung delivery) or potency is detectable. The dose-response curves for the ICSs are relatively flat primarily because all the measures used to assess efficacy (lung function, BHR, symptoms, and as-needed short-acting inhaled β_2 -agonist use) are downstream events from the anti-inflammatory activity.⁴⁴ In general, it takes a fourfold difference in potency or dose to detect clinically significant differences. The table of comparative doses (see Table 26–12) is based on extensive comparative clinical trials.⁷ Clinical comparative doses take into consideration potency differences as well as lung delivery differences from the various devices.

Since the glucocorticoid receptors within the various tissues are the same, differences in the pharmacokinetic profile are required to produce differences in the topical-systemic effect ratio (therapeutic index).⁴³ Pharmacokinetic properties that enhance improved topical selectivity include rapid systemic clearance, poor oral bioavailability, and long residence time in the lung.⁴³ Owing to their high lipophilicity, systemic clearance of the available ICSs is very rapid, approaching the rate of liver blood flow.⁴³ However, the ICSs differ markedly in their oral bioavailability, although they all undergo rather extensive first-pass metabolism to less active substances when absorbed⁴⁵ (see Table 26–9). The ICSs produce dose-dependent systemic effects from a combination of the orally absorbed fraction and the fraction absorbed from the lung^{43–45} (Table 26–13). Essentially all the drug that reaches the lung is absorbed systemically; thus a slow absorption from the lung results in an apparent long elimination half-life and enhances topical selectivity by lowering the systemic concentration.⁴⁵ The potential advantage of the drugs with low oral bioavailability is obviated by using a spacer device with the MDI for the drugs with higher oral bioavailability because appropriate spacers reduce the oral dose by 80%.²⁴ The use of holding chambers also can increase systemic activity by increasing lung delivery of drugs not absorbed significantly orally.⁴³ If this increase in lung deposition is twofold or less, it will increase systemic activity without producing a clinically important

TABLE 26–13. Effects of Inhaled Corticosteroids

| Beneficial Effects | Potential Adverse Effects |
|--|---|
| Decrease eosinophil numbers | Growth retardation, skeletal muscle myopathy |
| Decrease mast cell numbers | Osteoporosis, fractures and aseptic necrosis of hip |
| Decrease T-lymphocyte cytokine production | Posterior subcapsular cataract formation and glaucoma |
| Inhibit transcription of inflammatory genes in airway epithelium | Adrenal axis suppression, immunosuppression |
| Reduce endothelial cell leak | Impaired wound healing, easy bruising, skin striae |
| Upregulate β_2 -receptor production | Hyperglycemia/hypokalemia, hypertension |
| Reduce airway epithelial subbasement membrane thickening | Psychiatric disturbances |

increase in efficacy, thus decreasing the therapeutic index.⁴³ Mouth rinsing and spitting also will reduce the oral availability and are particularly useful for DPI devices.^{2,24}

The response to ICSs is somewhat delayed. Most patients' symptoms will improve in the first 1 to 2 weeks of therapy and will reach maximum improvement in 4 to 8 weeks. Improvement in baseline FEV₁ and PEFs may require 3 to 6 weeks for maximum improvement, whereas improvement in BHR requires 2 to 3 weeks and approaches maximum in 1 to 3 months but may continue to improve over 1 year.⁴⁴ Most of the improvement in these parameters occurs at low to medium doses, and there is a large variability in response, with 10% of patients not demonstrating an improvement in either parameter.⁵³ Whether these nonresponders also show no improvement in rates of exacerbations is unknown. Maximum decrease in exhaled nitric oxide occurs within 2 to 3 weeks.⁵⁴ Sensitivity to exercise challenge decreases after 4 weeks of therapy.⁴⁴ Although single doses do not inhibit the immediate asthmatic response to antigen challenge, continued therapy for 1 week partially suppresses the response. These two latter effects are likely due to a reduction in mucosal mast cells.⁴⁴

Local adverse effects from ICSs include oropharyngeal candidiasis and dysphonia that are dose-dependent. The dysphonia appears to be due to a local corticosteroid-induced myopathy of the vocal cords.² The use of a spacer device can decrease oropharyngeal deposition and thus decrease the incidence and severity of local side effects.²⁴ In infants who require delivery through a facemask, the parent should clean the nasal-perioral area with a damp cloth following each treatment to prevent topical candidal infections.

Systemic adverse effects can occur with any of the ICSs given in a sufficiently high dose.⁴³ Long-term adverse effects of greatest concern include growth suppression in children, osteoporosis, cataracts, and adrenal insufficiency and crisis.⁴³ Of these, only growth retardation occurs in low to medium doses. However, the growth reduction appears to be transient in that growth velocity is reduced in the first 6 months to 1 year of therapy and then returns to normal.⁴³ The effect is small (1 to 2 cm total) and not cumulative, and current studies suggest that attainment of predicted adult height is not affected.^{7,43} The suppression of the hypothalamic-pituitary-adrenal axis and decreased bone mineralization are dose-dependent and do not appear to be significant clinically except at high doses.⁴³ The risks of these adverse effects are all dose-dependent and depend on the therapeutic index

of each ICS and its delivery device. The effect of delivery device is illustrated by fluticasone propionate, which has both the greatest therapeutic index when administered by DPI and the lowest therapeutic index when administered by MDI plus holding chamber.⁴³

Most patients with moderate disease can be controlled with twice-daily dosing of most ICSs.^{2,10} Twice-daily dosing produces less thrush than three- to four-times-daily dosing regimens. In milder asthma, once-daily dosing is often sufficient to maintain control.⁴⁴ Some of the newer products have gained once-daily dosing indications for step-down therapy once initial control is established.⁴⁴ Chronobiologic dosing studies have demonstrated that dosing at 3 to 5 P.M. improves efficacy and may decrease adverse effects; however, this is a very difficult time to achieve for working adults and school children.⁷ There does not appear to be any specific pharmacologic or pharmacokinetic aspect of the ICSs that allows for once-daily dosing because all the agents studied (both the older low-potency and newer high-potency ICSs) have been effective, provided that patients had relatively mild to moderate asthma.⁴⁵ More severe patients require multiple daily dosing. The inflammatory response of asthma has been shown to inhibit steroid-receptor binding.⁴⁵ This provides strong theoretical evidence for initially beginning patients on higher and more frequent doses and then tapering down once control has been achieved. This approach is recommended by the NAEPP.²

■ LONG-ACTING INHALED β_2 -AGONISTS

The two long-acting β_2 -agonists, formoterol and salmeterol, provide long-lasting bronchodilation (12 or more hours) when administered as aerosols³⁰ (see Table 26–8). Unlike the more water-soluble short-acting β_2 -agonists, the long-acting agents are lipid-soluble, readily partitioning into the outer phospholipid layer of the cell membrane.³⁰ Salmeterol is more β_2 -selective than albuterol and more bronchoselective by virtue of its property of remaining in the lung tissue cell membrane, which produces its longer duration.³⁰ However, both formoterol and salmeterol will produce dose-dependent systemic β_2 -agonist effects.³⁰

The principal differences between formoterol and salmeterol is that formoterol has a more rapid onset of action (similar to that of albuterol), and formoterol is a full agonist, whereas salmeterol is a partial agonist. These differences are unlikely to produce clinically significant differences because both are recommended for chronic therapy only in combination with ICSs.^{7,10} They are available singly and as fixed-dose combinations with ICSs (see below). Patients should be warned that salmeterol is ineffective for acute severe asthma because it can take up to 20 minutes for onset and 1 to 4 hours for maximum bronchodilation following inhalation.^{2,7} Patients need to be counseled to continue to use their short-acting inhaled β_2 -agonists for acute exacerbations while receiving the long-acting inhaled β_2 -agonists.

Long-acting inhaled β_2 -agonists are indicated as preferred therapy for step 3 as adjunctive therapy to low to medium doses of ICSs and for step 4 in combination with medium to high doses of ICSs.⁷ Combination treatment with both an ICS and a long-acting β_2 -agonist provides greater asthma control than increasing the dose of ICS alone while at the same time reducing the frequency and perhaps the severity of exacerbations.⁵⁵ Since they are devoid of anti-inflammatory activity, the long-acting inhaled β_2 -agonists should not be used as monotherapy for asthma. Recent evidence suggests that patients treated with monotherapy are at an increased risk for severe exacerbations.⁵⁶ Additionally, a large and so far unpublished study of the effect of adding salmeterol to usual treatment for asthma in the general population has been halted prematurely owing to poor trial enrollment

and an increased risk of asthma-related deaths in African-American patients receiving salmeterol. Whether this was due to greater asthma severity or undertreatment with inhaled corticosteroids was difficult to discern.⁵⁷

As with short-acting β_2 -agonists, tolerance is produced with chronic administration. Long-term trials have shown no diminution in bronchodilator response but a partial loss of the initial bronchoprotective effect against methacholine or histamine challenge by salmeterol.⁵⁵ In particular, the duration of protection against EIB following a single dose of salmeterol is up to 9 hours but is reduced to less than 4 hours following regular treatment.⁵⁵ Following regular treatment with salmeterol and formoterol, decreased protection against nonspecific bronchoprovocation with methacholine also occurs, although it provides greater protection than placebo.⁵⁵ Responsiveness to short-acting β_2 -agonists has been reported to be slightly decreased but easily overcome by increasing the dose (by approximately one puff) following chronic therapy with long-acting β_2 -agonists.⁵⁵

There is ample evidence that the use of a long-acting β_2 -agonist in combination with ICS therapy does not mask inflammation.^{50,55} A meta-analysis of studies comparing the addition of salmeterol to ICS therapy versus at least a doubling of ICS dose demonstrates that rather than increasing asthma exacerbations, the number of these events was reduced.⁵⁸ There are few data on the efficacy of long-acting β -agonists (LABAs) on asthma exacerbation rates in pediatric patients, but studies are ongoing.⁵⁹

■ METHYLXANTHINES

Methylxanthines have been used for asthma therapy for over 50 years but their use in recent years has declined markedly owing to the high risk of severe life-threatening toxicity and numerous drug interactions, as well as decreased efficacy compared with ICSs and long-acting inhaled β_2 -agonists. Theophylline, the primary methylxanthine of interest, is a moderately potent bronchodilator with mild anti-inflammatory properties.^{2,10} Like the β_2 -agonists, the methylxanthines are functional antagonists of bronchospasm; however, their clinical utility is limited by their low therapeutic index.² Theophylline as a sustained-release product is the preferred oral preparation, whereas its complex with ethylenediamine (aminophylline) is the preferred injectable product owing to increased solubility.⁶⁰

The mechanism by which theophylline produces bronchodilation appears to be through nonselective phosphodiesterase inhibition.⁶⁰ Inhibition of phosphodiesterase results in increased cAMP and cyclic guanosine monophosphate (cGMP) concentrations. The phosphodiesterase (PDE) isoenzymes currently thought to be important for theophylline's clinical effects are isoenzymes III, predominant in airway smooth muscle, and IV, important in inflammatory cell regulation such as mast cells, neutrophils, eosinophils, and T-lymphocytes.⁶⁰ Selective PDE isoenzyme IV inhibitors, however, have no significant effects in clinical asthma. Theophylline is a competitive antagonist of adenosine and stimulates endogenous catecholamine release.⁶⁰ These latter two effects are important determinants of toxic symptoms of excess theophylline.^{2,60}

Theophylline, like the β_2 -agonists, has a log-linear dose-response curve.⁶⁰ Most chronic stable asthmatics will obtain significant bronchodilation when the serum theophylline concentration reaches 5 mcg/mL, and most patients will have no toxic symptoms with serum concentrations of less than 15 mcg/mL.^{2,60} The percentage of patients experiencing adverse effects increases sharply as concentrations exceed 15 mcg/mL. As with the β_2 -agonists, the dose-response curves for smooth muscle relaxation by theophylline are

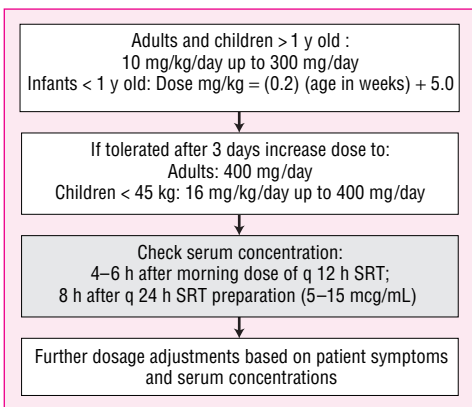

FIGURE 26–9. Algorithm for slow titration of theophylline dosage and guide for final dosage adjustment based on serum theophylline concentration measurement. For infants younger than 1 year of age, the initial daily dosage can be calculated by the following regression equation: Dose (mg/kg) = (0.2) (age in weeks) + 5.0. Whenever side effects occur, dosage should be reduced to a previously tolerated lower dose.

dynamic and shifted to the right in the face of increasing contractile stimuli.²⁷ This probably explains theophylline's relative lack of bronchodilatory effect in acute severe asthma.^{2,27} The severity of theophylline's toxicity precludes even doubling the usual dosage. Toxicities include caffeine-like effects of nausea, vomiting, tachycardia, jitteriness, and difficulty sleeping to more severe toxicities such as cardiac tachyarrhythmias and seizures. Death has occurred in children receiving their usual doses of theophylline during acute systemic viral illnesses.⁶⁰

Routine monitoring of serum concentrations is essential for the safe and effective use of theophylline.^{2,10} Theophylline is eliminated primarily by metabolism via the hepatic cytochrome P450 mixed-function oxidase microsomal enzymes (primarily the CYP1A2 and CYP3A3 isozymes), with 10% or less excreted unchanged in the kidney.⁶⁰ Theophylline clearance is age-dependent, with 1- to 9-year-olds having the highest systemic clearances and therefore requiring the largest dosages (on a weight basis). However, even within the same age groups, theophylline clearance can vary two- to threefold.⁶⁰ Figure 26–9 gives a dosing and monitoring schedule for theophylline. Factors affecting theophylline's hepatic metabolism are listed in Table 26–14.² Only drugs or diseases that produce a 20% or greater

inhibition or a 50% or greater induction of theophylline metabolism are likely to result in clinically significant interactions.⁶⁰

Sustained-release theophylline is less effective than ICSs and no more effective than oral sustained-release β_2 -agonists, cromolyn or leukotriene antagonists.⁷ The addition of theophylline to ICSs is similar to doubling the dose of the ICS and is overall less effective than the long-acting inhaled β_2 -agonists as adjunctive therapy.⁷

■ CROMOLYN SODIUM AND NEDOCROMIL SODIUM

Cromolyn sodium and nedocromil sodium are pharmacologically similar.² They are classified as mast cell stabilizers, and the principal difference appears to be potency, with 4 mg nedocromil by MDI equivalent to 10 mg cromolyn.^{2,61} However, there is no apparent difference in the clinical efficacy between these two drugs.² They inhibit the early and late asthmatic response to allergen challenge, as well as inhibit exercise-induced bronchospasm.^{2,10} Treatment prevents the usual rise in bronchial hyperresponsiveness with specific pollen seasons, but long-term treatment produces minimal to no change in baseline bronchial hyperresponsiveness.^{7,61} They inhibit neurally mediated bronchoconstriction, through C-fiber sensory nerve stimulation in the airways, although neither drug has a bronchodilatory effect.¹⁰

Cromolyn and nedocromil are only effective by inhalation and are available as MDIs, whereas cromolyn also is available as a nebulizer solution. The pharmacokinetics of both drugs are very similar. They are not bioavailable orally, but the portion of the dose that reaches the lung is absorbed completely.⁶¹ Absorption from the airway is significantly slower than elimination (hours versus minutes). The short duration in the lung likely limits their efficacy. Both the intensity and duration of protection against various challenges are dose-dependent.⁶¹ Higher doses produce greater and more prolonged protection.

Both drugs are remarkably nontoxic. No evidence of mutagenesis or teratogenesis has been found for cromolyn. Cough and wheeze have been reported following inhalation of each, and bad taste and headache following nedocromil are reported.² The taste from nedocromil is sufficiently bad in some patients (approximately 20%) to preclude them from taking the drug.⁶¹ Tolerance to cromolyn or nedocromil has not been demonstrated. Neither are ICS-sparing agents.

Cromolyn and nedocromil are no more or less effective than theophylline or the leukotriene antagonists for persistent asthma.⁷

TABLE 26–14. Factors Affecting Theophylline Clearance

| Decreased Clearance | % Decrease | Increased Clearance | % Increase |
|---|------------|-----------------------|------------|
| Cimetidine | –25 to –60 | Rifampin | +53 |
| Macrolides | –25 to –50 | Carbamazepine | +50 |
| Erythromycin, TAO, clarithromycin | | Phenobarbital | +34 |
| Allopurinol | –20 | Phenytoin | +70 |
| Propranolol | –30 | Charcoal-broiled meat | +30 |
| Quinolones | –20 to –50 | High-protein diet | +25 |
| Ciprofloxacin, enoxacin, pefloxacin | | Smoking | +40 |
| Interferon | –50 | Sulfinpyrazone | +22 |
| Thiabendazole | –65 | Moricizine | +50 |
| Ticlopidine | –25 | Aminoglutethimide | +50 |
| Zileuton | –35 | | |
| Systemic viral illness | –10 to –50 | | |

Neither cromolyn nor nedocromil is as effective as the ICSs for controlling persistent asthma.^{7,49} Neither is as effective as the inhaled β_2 -agonists for preventing exercise-induced bronchospasm but can be used in conjunction for patients not responding completely to the inhaled β_2 -agonists.¹⁸

Most patients will experience an improvement in 1 to 2 weeks, but it may take longer to achieve maximum benefit. Patients initially should receive cromolyn or nedocromil four times daily, and then only after stabilization of symptoms may the frequency be reduced to two times daily for nedocromil and three times daily for cromolyn. Only the nebulizer solution should be used for children younger than 5 years of age.²

■ LEUKOTRIENE MODIFIERS

Two clinically distinct cysteinyl leukotriene receptor antagonists (zafirlukast and montelukast) and one inhibitor of leukotriene synthesis (zileuton) have been available in the United States since 1996 for both children and adults with persistent asthma.⁶² In challenge studies, they reduce allergen-, exercise-, cold-air hyperventilation-, irritant-, and aspirin-induced asthma.⁶³ Clinical use of zileuton is limited owing to the need for four-times-daily dosing, the potential for elevated liver enzymes (especially in the first 3 months of therapy), and the potential inhibition of drugs metabolized by the CYP3A4 isoenzymes.^{62,63}

In clinical trials, the LTD₄ receptor antagonists (zafirlukast and montelukast) have demonstrated efficacy in adults and children with persistent asthma. These drugs improve pulmonary function tests (FEV₁ and PEF), decrease nocturnal awakenings and β_2 -agonist use, and improve asthma symptoms.^{62,63} A major advantage is that they are effective orally, administered once or twice a day, and contribute to patient adherence and satisfaction with therapy.⁶² However, they are less effective in asthma than low doses of ICSs, although some patients (even those with severe disease) may have useful clinical improvement.⁶⁴ For example, in 533 patients (>15 years old) with persistent asthma, treatment with fluticasone 176 mcg by MDI twice daily improved mean morning FEV₁ at end point by 22.9% versus montelukast 10 mg daily improvements of 14.5% ($p < .001$).⁶⁴ All other asthma outcomes were improved to a greater extent by fluticasone therapy. It is not yet possible to predict which patients respond best to leukotriene modifiers, although there is some evidence that patients with aspirin-sensitive asthma do well, as predicted by studies showing increased cysteinyl leukotriene production in these patients.⁶³ It is possible that genetic polymorphisms in the 5-lipoxygenase (5-LO) or LTC₄ synthase pathways or in cys-LT₁ receptors might predict better responders in the future.⁶³ Antileukotrienes also have modest efficacy in allergic rhinitis.

In general, the LTD₄ receptor antagonists are well tolerated and do not appear to have serious class-specific effects. In the early 6-month zafirlukast trials, nonrespiratory or laboratory abnormalities did not occur with greater frequency in the treatment group than in the placebo groups. However, postmarketing surveillance reports include elevations in serum aminotransferase concentrations and clinical hepatitis (thought to be rare).⁶⁵ An idiosyncratic syndrome similar to the Churg-Strauss syndrome, with marked circulating eosinophilia, heart failure, and associated eosinophilic vasculitis, has been reported in a small number of patients treated with zafirlukast or montelukast.⁶⁵ The majority of these patients had been receiving high-dose inhaled or oral corticosteroids and were able to reduce the dose as a consequence of the LTD₄ receptor antagonists. It is unclear whether the increased reports are due to increased case findings among patients

with asthma prescribed a new drug or whether the syndrome is related to glucocorticoid dose reduction or an idiosyncratic effect of leukotriene modifiers in general. Whatever the cause, it appears to be a rare syndrome, with an estimated incidence of fewer than 1 case per 15,000 to 20,000 patient-years of treatment.⁶⁵ Montelukast has been prescribed widely worldwide owing to its approval for use in young children. Churg-Strauss syndrome has not been reported in children, and the drug has been very well tolerated and palatable (4- and 5-mg chewable cherry tablets).⁶⁵

■ COMBINATION CONTROLLER THERAPY: ICS/LABA VERSUS ICS/LT RECEPTOR AGONISTS

Whereas ICS therapy is considered the most effective anti-inflammatory treatment, in cases of moderate to severe persistent asthma, the addition of a second long-term control medication to ICS therapy is one recommended treatment option. A combination-product inhaler (Advair) was developed to treat both the inflammatory and bronchoconstrictive components of asthma by delivering a dose of fluticasone (100, 250, or 500 mcg) with a fixed dose of salmeterol (50 mcg). Advair, in a variety of clinical trials in persistent asthma, was superior to the individual components at the same doses, comparable with concurrent therapy at the same doses, had a rapid onset of effect (within 1 week), and demonstrated clinical benefits that improved over the duration of the studies. Importantly, salmeterol therapy allows reduction in ICS dosage by 50% in patients with persistent asthma.^{7,55} Further, salmeterol plus low-dose fluticasone has been found to be more effective than higher-dose fluticasone alone in reducing asthma exacerbations in patients with persistent asthma.⁵⁵ The ability to detect deteriorating asthma and the severity of exacerbation were similar between groups.

Leukotriene receptor agonists also have been found to be successful as additive therapy in patients inadequately controlled on ICS alone and as ICS-sparing therapy.⁷ However, the magnitude of these benefits is less than those reported with the addition of long-acting β_2 -agonists (LABAs).⁷

■ ANTI-IGE (OMALIZUMAB)

Omalizumab is the first anti-IgE antibody approved for the treatment of asthma not well controlled on high doses of ICSs.⁶⁶ Omalizumab is a composite of 95% human and 5% antihuman murine IgE sequences. The mouse protein becomes part of the receptor complex and thus is shielded from exposure to the immune system and presents a low risk for an anaphylactic response.⁶⁶

Omalizumab is administered subcutaneously and has a slow absorption rate; peak serum concentration is achieved in 3 to 14 days.⁶⁶ It is eliminated primarily through the reticuloendothelial system and has an elimination half-life of 17 to 22 days; serum free IgE levels return to baseline in about 3 weeks.⁶⁶

The dosage of omalizumab is determined by the patient's baseline total serum IgE level (international units per milliliter) and body weight (kilograms).⁶⁶ Doses range from 150 to 375 mg and are given at either 2- or 4-week intervals. No further adjustments for variations in total serum IgE are required, and patients receive a consistent dose for the duration of treatment.⁶⁶ Omalizumab has been studied in patients aged 12 to 74 years and appears to be safe and efficacious.⁶⁶ It is only indicated for corticosteroid-dependent atopic patients requiring oral corticosteroids or on high-dose ICSs with continued symptoms and high IgE levels.

MISCELLANEOUS THERAPIES

METHOTREXATE

Low-dose methotrexate (15 mg/week) used for inflammatory diseases, psoriatic and rheumatoid arthritis, and polymyositis has been used to reduce the systemic steroid dose in patients with severe steroid-dependent asthma.⁶⁷ Double-blind, placebo-controlled trials have given decidedly mixed results, with half the studies showing no effect.⁶⁸ A meta-analysis determined that a statistically significant reduction (mean 4.37 mg/day prednisone, or 23% of the original dose) can be achieved.⁶⁷ The mechanism of action is unknown but may be anti-inflammatory or immunomodulatory effects. Methotrexate inhibits chemotaxis of neutrophils, inhibits leukotriene B₄-induced adherence to endothelium, and inhibits the proinflammatory activity of IL-1. Low-dose weekly methotrexate is not without hazard. Both hepatotoxicity and pulmonary fibrosis have been reported in patients receiving similar therapy for psoriasis and rheumatoid arthritis.⁶⁷ No evidence for induction of asthma remission exists because patients' corticosteroid requirement returns on discontinuation of the methotrexate. Methotrexate still should be considered experimental and should be reserved for only severe steroid-dependent asthmatics under the care of specialties. Patients require careful monitoring, including periodic liver biopsies. Owing to the marginal effect of methotrexate, the risk-benefit should be evaluated carefully prior to institution.

PHARMACOECONOMIC CONSIDERATIONS

Of the estimated \$12.6 billion cost of asthma in the United States in 1998, direct medical expenditure accounted for 58% of the total, with emergency care (emergency department and inpatient hospital care) reaching \$2.5 billion and prescription medications (\$3.2 billion) as the single largest direct medical expenditure.⁶ A cost-of-illness approach takes in all measurable costs; both indirect costs or costs to society and direct medical costs are considered. Using this approach, the cost per patient per year in 1994 in the United States was \$756, a slight decrease in inflation-adjusted expenditures over the past 10 years.⁶ Indirect costs such as lost work and death accounted for two-thirds of these expenditures.

The medication cost increase over the past 10 years resulted from a doubling of prescribed medications, as well as a 169% increase in unit cost per medication, presumably owing to a shift to more expensive anti-inflammatory drugs consistent with the recommendations of the NAEPP guidelines.² Asthma severity obviously has an impact on cost of care. Studies from health-maintenance organizations suggest that up to 45% of the cost of asthma is accrued by 10% of the patients, primarily as a result of emergency care.⁷⁰

Numerous studies have demonstrated the cost-effectiveness of patient education programs for asthma, particularly those providing guided self-management.⁷⁰ Several studies have reported positive results from pharmacist interventions reducing overall cost of care.⁷⁰ Similar studies have demonstrated the cost-effectiveness of specialist care compared with generalist care. However, the results of these trials may be confounded by changes in prescribing as part of the overall program. Indeed, use of ICSs reduces both morbidity, particularly hospitalizations, and mortality in asthma patients.^{48,71}

The NAEPP recommendations provide numerous alternatives for long-term controllers in mild to moderate persistent asthma, and few studies have compared their relative cost-effectiveness. This is important because outside the realm of randomized clinical trials that

OTHER AGENTS

As a result of the inflammatory nature of asthma and the risk of toxicities from corticosteroids, a number of the drugs with anti-inflammatory or immunomodulatory activity such as hydroxychloroquine, dapsone, gold, intravenous gamma-globulin, cyclosporine, and colchicine have been studied in severe steroid-dependent asthma with mixed results.^{2,67}

FUTURE THERAPIES

Agents that are now in development for asthma focus on the treatment of allergic inflammation.^{68,69} Examples include inhibitors of eosinophilic inflammation, drugs that may inhibit allergen presentation, and inhibitors of Th2 cells. Multiple cytokines have been implicated in allergic inflammation, and several possible inhibiting approaches are being explored. These range from drugs that inhibit cytokine synthesis (cyclosporin A and tacrolimus), humanized blocking antibodies to cytokines or their receptors, soluble receptors to mop up secreted cytokines, receptor antagonists, and drugs that block the signal-transduction pathways activated by cytokines.⁶⁸ Specifically, humanized monoclonal antibodies to IL-5 and nebulized soluble IL-4 receptors have been tested but have been disappointing to date.^{68,69}

evaluate efficacy, other factors such as concern about adverse effects and adherence to therapy may alter the overall clinical effectiveness. Use of ICSs in children has produced a cost of \$9.45 per symptom-free day gained and in adults \$5.00 per symptom-free day.⁷⁰ More recently, retrospective analyses of large managed-care-linked pharmacy claims and health care utilization databases has allowed direct comparisons of the various long-term controllers in a general population to assess clinical effectiveness and cost-effectiveness. These studies have confirmed comparative randomized clinical trials showing ICSs to be significantly more cost-effective than leukotriene antagonists despite slightly better compliance with the leukotriene antagonists.^{72,73} In addition, the combination of long-acting inhaled β_2 -agonists and ICSs lowers health care utilization and total health care costs compared with the combination of a leukotriene antagonist and an ICS.⁷⁴

CLINICAL CONTROVERSY

The potential for chronic use of inhaled β_2 -agonists to worsen asthma has been a concern for over 30 years. Large multicenter double-blind, placebo-controlled trials with both mild and moderate persistent asthma did not show that regular administration short-acting inhaled β_2 -agonists worsened asthma.^{10,41} However, recent studies genotyping patients at the β -receptor suggest that homozygous Arg-16 patients (who make up about 16% of the population) are predisposed to worsening asthma with regular administration as measured by lower morning PEFs.^{40,75} This phenomenon does not appear to occur with as-needed therapy with short-acting β_2 -agonists. It is yet unknown if regular treatment with long-acting inhaled β_2 -agonists is of similar concern. These patients still respond acutely to the β_2 -agonists, so whether they should avoid all β_2 -agonists is speculative. Since the use of short-acting inhaled β_2 -agonists does not improve control of symptoms, they should be used only as needed for symptoms.²

EVALUATION OF THERAPEUTIC OUTCOMES

The desired outcomes have been described previously. Control of asthma is defined as achieving a minimal need for “rescue” short-acting β_2 -agonists (ideally none), no acute episodes, no limitations on activity, no emergency care visits, no nocturnal symptoms, normal (or near-normal) pulmonary functions (FEV₁ and PEF), minimal to no medication side effects, and satisfaction of the patient and family with asthma care. Depending on the severity of the patient’s asthma, compromises from the ideal control are made, and the best possible outcome balancing disease control and possible adverse effects from the drugs is attempted.

Monitoring consists of quantitating the use of inhaled short-acting β_2 -agonists, days of limited activity, and number of symptoms (especially nocturnal). The NAEPP recommends yearly spirometric studies. In moderate to severe persistent asthma, once-daily (on awakening) peak-flow monitoring is recommended. Patients also should be asked about exercise tolerance. All patients on inhaled drugs should have their inhalation delivery technique evaluated periodically—monthly initially and then every 3 to 6 months.

Following initiation of anti-inflammatory therapy or an increase in dosage, most patients should begin experiencing a decrease in symptoms in 1 to 2 weeks and achieve maximum symptomatic improvement within 4 to 8 weeks. The use of higher doses or more potent ICS agents may accelerate the process. Improvement in FEV₁ and PEF should follow a similar time frame; however, a decrease in BHR, as measured by morning PEF, PEF variability, and exercise tolerance, may take longer and improve over 1 to 3 months.² Patients should be informed that following a viral respiratory infection, they may experience increased exercise intolerance for up to 4 weeks.

Initial visits with the patient should focus on the patient’s concerns, expectations, and goals of treatment. Basic education should focus on asthma as a chronic lung disease, the types of medications, and how they are to be used. Inhaler technique is taught, as is when to seek medical advice. Written action plans should be provided. The first follow-up visit should be in 2 to 4 weeks. At that time, the educational messages of the first visit should be repeated, as well as questions about the patient’s current medications and any difficulties related to the therapy.

CONCLUSION

Asthma is a complicated disease with a multitude of clinical presentations. The exact defect in asthma has not been defined, and it may be that asthma is a common presentation of a heterogeneous group of diseases. Asthma is defined and characterized by excessive reactivity of the bronchial tree to a wide variety of noxious stimuli. The reaction is characterized by bronchospasm, excessive mucus production, and inflammation. The central role of inflammation in inducing and maintaining BHR is now becoming widely appreciated and studied. The goal of asthma therapy is to normalize, as much as possible, the patient’s life and prevent chronic irreversible lung changes. Drugs are the mainstay of asthma therapy. The goal of drug therapy is to use the minimum amount of medications possible to completely control the disease. In chronic asthma, therapy should be aimed at both bronchospasm and inflammation in order to produce the best results. Patients should be followed and monitored diligently for toxicities. Although death from asthma is an uncommon event, the most common cause of death is underassessment of the severity of obstruction either by the patient or by the clinician; the next common cause is

undertreatment. A cornerstone of any therapy is education and the realization that most asthma deaths are avoidable.

ABBREVIATIONS

ABPA: allergic bronchopulmonary aspergillosis
 ACTH: adrenocorticotrophic hormone
 Arg: arginine
 BAL: bronchoalveolar lavage
 BHR: bronchial hyperresponsiveness
 CFC: chlorofluorocarbon
 cAMP: cyclic adenosine monophosphate
 CYP: Cytochrome P450
 DPI: dry powder inhaler
 EIB: exercise-induced bronchospasm
 FDA: Food and Drug Administration
 FeNO: fraction of exhaled nitric oxide
 FEV₁: forced expiratory volume in 1 second
 FVC: forced vital capacity
 GINA: Global Initiative for Asthma
 Gln: glutamine
 Glu: glutamic acid
 Gly: glycine
 GM-CSF: granulocyte-macrophage colony-stimulating factor
 HFA: hydrofluoroalkane
 ICAM-1: intercellular adhesion molecule 1
 ICSs: inhaled corticosteroids
 IgE: immunoglobulin E
 IL: interleukin
 iNOS: inducible nitric oxide synthase
 MDI: metered-dose inhaler
 MMAD: mass median aerodynamic diameter
 NAEPP: National Asthma Education and Prevention Program
 NANC: nonadrenergic, noncholinergic
 NO: nitric oxide
 PAF: platelet-activating factor
 PEF: peak expiratory flow
 PKA: protein kinase
 RSV: respiratory syncytial virus
 T cells: thymically derived lymphocytes
 VCAM-1: vascular cell adhesion molecule 1
 VIP: vasoactive intestinal peptide

CHRONIC OBSTRUCTIVE PULMONARY DISEASE

Sharya V. Bourdet and Dennis M. Williams

Learning Objectives and other resources can be found at www.pharmacotherapyonline.com.

KEY CONCEPTS

- 1 Chronic obstructive pulmonary disease (COPD) is a progressive disease characterized by airflow limitation that is not fully reversible and is associated with an abnormal inflammatory response of the lungs to noxious particles or gases.
- 2 COPD includes the terms *chronic bronchitis* and *emphysema*. Chronic bronchitis is defined in clinical terms, whereas emphysema is defined in terms of anatomic pathology. Because most patients exhibit some features of each disease, the current emphasis of COPD pathophysiology is on small airway disease and parenchymal damage that contributes to chronic airflow limitation.
- 3 Mortality from COPD has increased steadily over the past three decades; it currently is the fourth leading cause of death in the United States.
- 4 The primary cause of COPD is cigarette smoking. Other risks include a genetic predisposition, environmental exposures (including occupational dusts and chemicals), and air pollution.
- 5 Smoking cessation is the only management strategy proven to slow progression of COPD.
- 6 Oxygen therapy has been shown to reduce mortality in selected patients with COPD. Oxygen therapy is indicated for patients with a resting PaO₂ of less than 55 mm Hg or a PaO₂ of less than 60 mm Hg and evidence of right-sided heart failure, polycythemia, or impaired neurologic function.
- 7 Bronchodilators are the mainstay of drug therapy for COPD. Pharmacotherapy is used to relieve patient symptoms and improve quality of life. The selection of bronchodilator therapy should be based on patient-specific factors.
- 8 The role of inhaled corticosteroid therapy in COPD is not well established. Patients with severe COPD and frequent exacerbations may benefit from inhaled corticosteroids.
- 9 Treatment of acute exacerbations of COPD include intensification of bronchodilator therapy and a short course of systemic corticosteroids.
- 10 Antimicrobial therapy should be used during acute exacerbations of COPD if the patient exhibits at least two of the following: increased dyspnea, increased sputum volume, and increased sputum purulence.

Chronic obstructive pulmonary disease (COPD) is a chronic disease of the airways characterized by the gradual progressive loss of lung function. The prevalence and mortality of COPD have increased over the past two decades. Currently, COPD is the fourth leading cause of death in the United States. Although treatment guidelines for the management of COPD have been available for many years, concerns have been expressed that the recommendations were largely opinions and were not evidenced-based.

In order to standardize the care of patients with COPD and present evidence-based recommendations, the National Heart, Lung, and Blood Institute (NHLBI) and the World Health Organization (WHO) launched the Global Initiative for Chronic Obstructive Lung Disease (GOLD) in 2001.¹ This report was updated in August 2003. The goals of the GOLD organization are to increase awareness of COPD and reduce morbidity and mortality associated with the disease. The consensus group has proposed the following working definition for COPD:

- 1 *Chronic obstructive pulmonary disease* is a disease state characterized by airflow limitation that is not fully reversible. The airflow limitation is usually both

progressive and associated with an abnormal inflammatory response of the lungs to noxious particles or gases.¹

The most common conditions comprising COPD are chronic bronchitis and emphysema. Chronic bronchitis is a condition with chronic or recurrent excessive mucus secretion into the bronchial tree with cough that is present on most days for at least 3 months of the year for at least 2 consecutive years in a patient in whom other causes of chronic cough have been excluded.² While chronic bronchitis is defined in clinical terms, emphysema is defined in terms of anatomic pathology. Emphysema classically was defined on histologic examination at autopsy. Because this histologic definition is of limited clinical value, emphysema also has been defined as abnormal permanent enlargement of the airspaces distal to the terminal bronchioles accompanied by destruction of their walls yet without obvious fibrosis.²

- 2 The new consensus guidelines have moved away from chronic bronchitis and emphysema as descriptive subsets of COPD. This is based on the observation that the majority of COPD is caused by a common risk factor (cigarette smoking), and most patients exhibit features of both chronic bronchitis and emphysema. Therefore, emphasis is currently placed on the pathophysiologic features of small airways

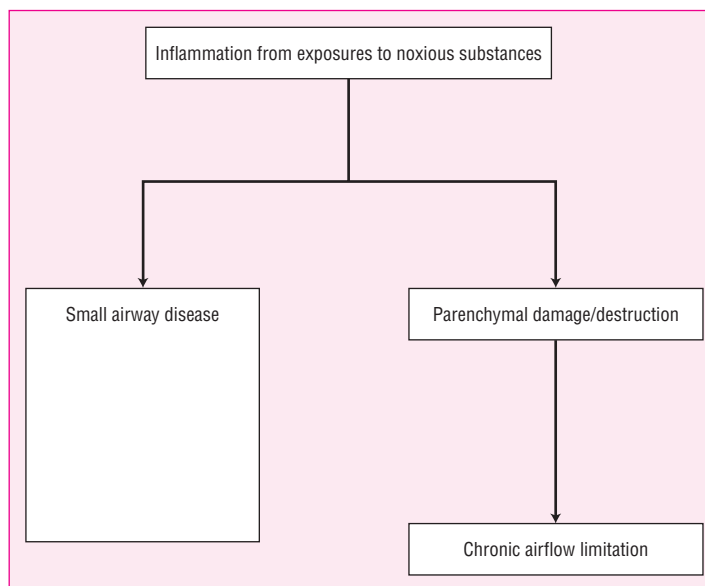

FIGURE 27–1. Mechanisms for developing chronic airflow limitation in COPD. (From ref. 1.)

disease and parenchymal destruction as contributors to chronic airflow limitation. Most patients with COPD demonstrate features of both problems. Chronic inflammation affects the integrity of the airways and causes damage and destruction of the parenchymal structures. This results in the chronic airflow limitation that characterizes COPD (Fig. 27–1).

EPIDEMIOLOGY

Data from the National Health Interview Survey in 2001 indicate that 12.1 million people over age 25 years in the United States have COPD.³ Over 9 million of these individuals have chronic bronchitis; the remaining number have emphysema or a combination of both diseases. However, there is evidence that this estimate is low. According to national surveys, the true prevalence of people with symptoms of chronic airflow obstruction may exceed 24 million.⁴

3 COPD is the fourth leading cause of death in the United States, exceeded only by cancer, heart disease, and cerebrovascular accidents. In 2000, over 119,000 deaths in the United States and 2.74 million deaths worldwide were attributed to COPD. It is the only leading cause of death to increase over the last 30 years and is projected to be the third leading cause by 2020.⁵ Overall, the mortality rate is higher in males; however, the female death rate has doubled over the last 25 years, and the number of female deaths exceeded male deaths in 2000. The mortality rate is higher in whites compared with blacks.⁵

Cigarette smoking is the primary cause of COPD, and although the prevalence of cigarette smoking has declined compared with 1965, approximately 25% of individuals in the United States currently smoke. The trend of increasing COPD mortality likely reflects the long latency period between smoking exposure and complications associated with COPD.

The mortality of COPD is significant; however, morbidity associated with the disease has significant impact on patients, their families, and the health care system. COPD represents the second leading cause of disability in the United States. Individuals with COPD have approximately double the number of hospital stays, days of restricted activity, and days of being confined to bed compared with people

without COPD.⁵ In 2000, there were over 15 million physician office visits, 1.5 million emergency room visits, and 726,000 hospitalizations due to COPD. Comparison of these data with those of recent years reflects a steady continuing increase.⁶

According to the NHLBI, the economic impact of COPD was \$23 billion in 2000 and \$32 billion in 2002, including \$18 billion in direct costs.⁵ It is estimated that by 2020, COPD will be the fifth most burdensome disease, as measured by disability-adjusted life years lost due to illness.

ETIOLOGY

Cigarette smoking is the primary modifiable risk factor for the development of COPD; however, the disease can be attributed to a combination of risk factors that results in lung injury and tissue destruction. The risk factors associated with the development of COPD can be divided into host factors and environmental factors (Table 27–1), and commonly, the interaction between these risks leads to expression of the disease. Host factors, such as genetic predisposition, may not be modifiable but are important for identifying patients at high risk of developing the disease. Environmental factors, such as tobacco smoke and occupational dust and chemicals, are modifiable factors that, if avoided, may reduce the risk of disease development.

Environmental exposures associated with COPD are particles that are inhaled by the individual and result in inflammation and cell injury. Exposure to multiple environmental toxins increases the risk of COPD. In such cases, it is helpful to assess an individual's total

TABLE 27–1. Risk Factors for Development of Chronic Obstructive Pulmonary Disease (COPD)

| Exposures | Host Factors |
|----------------------------------|---|
| Environmental tobacco smoke | Genetic predisposition (AAT deficiency) |
| Occupational dusts and chemicals | Airway hyperresponsiveness |
| Air pollution | Impaired lung growth |

burden of inhaled particles. For example, an individual who smokes and works in a textile factory has a higher total burden of inhaled particles than an individual who smokes and has no occupational exposure.

4 Cigarette smoking is the most common risk factor among industrialized countries and accounts for 85% to 90% of cases of COPD.¹ Components of tobacco smoke activate inflammatory cells, which produce and release the inflammatory mediators characteristic of COPD. Although the risk is lower in pipe and cigar smokers, it is still higher than in nonsmokers. Age of starting, total pack-years, and current smoking status are predictive of COPD mortality. However, only 15% to 20% of all smokers go on to develop COPD, and not all smokers who have equivalent smoking histories develop the same degree of pulmonary impairment, suggesting that other host and environmental factors contribute to the degree of lung dysfunction. Nevertheless, the rate of loss of lung function is determined primarily by smoking status and history.² Children and spouses of smokers are also at increased risk of developing significant pulmonary dysfunction by passive smoking, also known as *environmental tobacco smoke* or *secondhand smoke*.

Occupational exposures are also important risk factors for COPD and, in nonindustrialized countries, may be more common than cigarette smoking. These exposures include dust and chemicals such as vapors, irritants, and fumes. Reduced lung function and deaths from COPD are higher for individuals who work in gold and coal mining, in the glass or ceramic industries with exposure to silica dust, and in jobs that expose them to cotton dust or grain dust, toluene diisocyanate, or asbestos. Other occupational risk factors include chronic exposure to open cooking or heating fires.

It is unclear whether or not air pollution alone is a significant risk factor for the development of COPD in smokers and nonsmokers with normal lung function. However, in individuals with existing pulmonary dysfunction, significant air pollution worsens symptoms. As evidence for this, emergency department visits are increased during higher-intensity periods of air pollution.

Individuals exposed to the same environmental risk factors do not have the same chance of developing COPD, suggesting that host factors play an important role in pathogenesis.^{1,2} While many not yet identified genes may influence the risk of developing COPD, the best documented genetic factor is a hereditary deficiency of α_1 -antitrypsin (AAT). AAT-associated emphysema is an example of a pure genetic disorder inherited in an autosomal recessive pattern. The consequences of AAT deficiency are discussed in the pathophysiology section below as protease-antiprotease imbalance. True AAT deficiency accounts for less than 1% of COPD cases.²

AAT is a plasma protein that protects cells, especially those in the lung, from destruction by elastase released by neutrophils. In individuals with the most common allele (M), plasma levels of AAT are approximately 30 micromolar (150 mg/dL). The protective effect of AAT in the lungs is significantly diminished when plasma levels are less than 10 micromolar.⁷ AAT is an acute-phase reactant, and the serum concentration can be quite variable. Typically, reference range concentrations are 80–200 mg/dL (16–40 micromolar).

Several types of AAT deficiency have been identified and are due to mutations in the AAT gene. Two main gene variants, S and Z, have been identified. In patients who are homozygous with the S variant, AAT levels are at least 60% of those of normal individuals. These patients usually do not have an increased risk of COPD compared with normal individuals. Patients with homozygous Z deficiency (ZZ) have AAT levels that are 10% of those of normal individuals, while patients with heterozygous Z variant (SZ) have levels closer to 40% of those of normal individuals. Homozygous Z patients have a higher

risk of developing COPD compared with heterozygous Z patients.⁸ A history of cigarette smoking increases this risk. A small number of patients have a null, null phenotype and are at high risk for developing emphysema because they produce virtually no AAT.

Patients with AAT deficiency develop COPD at an early age (20 to 50 years) primarily owing to an accelerated decline in lung function. Compared with an average annual decline in forced expiratory volume in 1 second (FEV₁) of 25 mL/year in healthy nonsmokers, patients with homozygous Z deficiency have been reported to have declines of 54 mL/year for nonsmokers and 108 mL/year for current smokers.⁸ Patients developing COPD at an early age or those with a strong family history of COPD should be screened for AAT deficiency. If the concentration is low, phenotype testing (DNA) should be performed.

Two additional host factors that may influence the risk of COPD include airway hyperresponsiveness and lung growth. Individuals with airway hyperresponsiveness to various inhaled particles may have an accelerated decline in lung function compared with those without airway hyperresponsiveness. Additionally, individuals who do not attain maximal lung growth owing to low birth weight, prematurity at birth, or childhood illnesses may be at risk for COPD in the future.¹

PATHOPHYSIOLOGY

COPD is characterized by chronic inflammatory changes that lead to destructive changes and the development of chronic airflow limitation. The process involves not only the airways but also extends to the pulmonary vasculature and lung parenchyma. The inflammation of COPD is often referred to as neutrophilic in nature, but macrophages and CD8+ lymphocytes also play major roles.^{9,10} The inflammatory cells release a variety of chemical mediators, of which tumor necrosis factor α (TNF- α), interleukin 8 (IL-8), and leukotriene B₄ (LTB₄) play major roles.^{1,11} The actions of these cells and mediators are complementary and redundant, leading to the widespread destructive changes. The stimulus for activation of inflammatory cells and mediators is an exposure to noxious particles and gas through inhalation. The most common etiologic factor is exposure to environmental tobacco smoke, although other chronic inhalational exposures can lead to similar inflammatory changes.

Other processes that have been proposed to play a major role in the pathogenesis of COPD include oxidative stress and an imbalance between aggressive and protective defense systems in the lungs (proteases and antiproteases).⁹ These processes may be the result of ongoing inflammation or occur as a result of environmental pressures and exposures (Fig. 27–2).

An altered interaction between oxidants and antioxidants present in the airways is responsible for the increased oxidative stress present in COPD. Increases in markers (e.g., hydrogen peroxide and nitric oxide) of oxidants are seen in the epithelial lining fluid.¹ The increased oxidants generated by cigarette smoke react with and damage various proteins and lipids, leading to cell and tissue damage. Oxidants also promote inflammation directly and exacerbate the protease-antiprotease imbalance by inhibiting antiprotease activity.

The consequences of an imbalance between proteases and antiproteases in the lungs was described over 40 years ago when the hereditary deficiency of the protective antiprotease AAT was discovered to result in an increased risk of developing emphysema prematurely. This enzyme (AAT) is responsible for inhibiting several protease enzymes, including neutrophil elastase. In the presence of

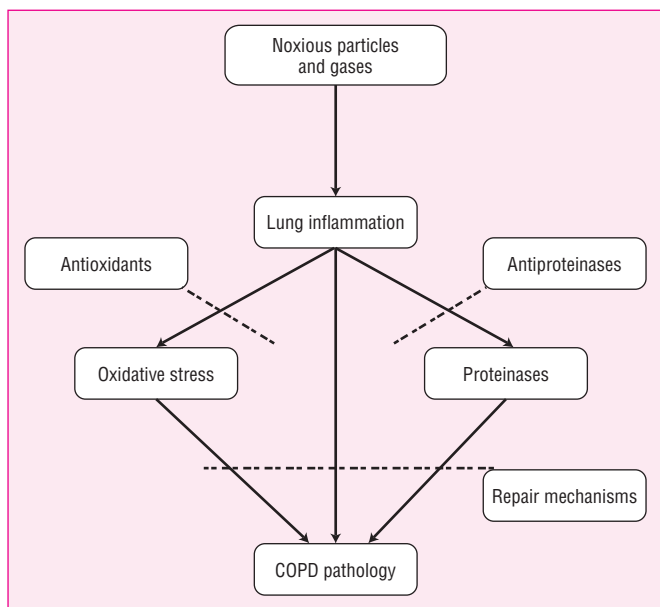

FIGURE 27-2. Pathogenesis of COPD. (From ref. 1.)

unopposed activity, elastase attacks elastin, a major component of alveolar walls.¹

In the inherited form of emphysema, there is an absolute deficiency of AAT. In cigarette smoking-associated emphysema, the imbalance is likely associated with increased protease activity or reduced activity of antiproteases. Activated inflammatory cells release several proteases other than AAT, including cathepsins and metalloproteinases (MMPs). In addition, oxidative stress reduces antiprotease (or protective) activity.

It is helpful to differentiate inflammation occurring in COPD from that present in asthma because the response to anti-inflammatory therapy differs. The inflammatory cells that predominate differ between the two conditions, with neutrophils playing a major role in COPD and eosinophils and mast cells in asthma. Mediators of inflammation also differ with LTB₄, IL-8, and TNF- α predominating in COPD, compared with LTD₄, IL-4, and IL-5 among the numerous mediators modulating inflammation in asthma.¹ Characteristics of inflammation for the two diseases are summarized in Table 27-2.

Pathologic changes of COPD are widespread, affecting large and small airways, lung parenchyma, and the pulmonary vasculature.¹ An inflammatory exudate is often present that leads to an increase in the number and size of goblet cells and mucus glands. Mucus secretion is increased, and ciliary motility is impaired. There is also a thickening of smooth muscle and connective tissue in the airways. Inflammation is present in central and peripheral airways. The chronic inflammation results in a repeated injury and repair process that leads to scarring and fibrosis. Diffuse airway narrowing is present and is more prominent in smaller peripheral airways.

Parenchymal changes affect the gas-exchanging units of the lungs, including the alveoli and pulmonary capillaries. The distribution of destructive changes varies depending on the etiology. Most commonly, smoking-related disease results in centrilobular emphysema that primarily affects respiratory bronchioles. Panlobular emphysema is seen in AAT deficiency and extends to the alveolar ducts and sacs.

The vascular changes of COPD include a thickening of pulmonary vessels and often are present early in the disease. These changes can be attributed to chronic inflammation and may lead to endothelial dysfunction of the pulmonary arteries. Later, structural changes lead to an increase in pulmonary pressures, especially during exercise. In severe COPD, secondary pulmonary hypertension leads to the development of right-sided heart failure.

Mucus hypersecretion is present early in the course of the disease and is associated with an increased number and size of mucus-producing cells. The presence of chronic inflammation perpetuates the process, although the resulting airflow obstruction and chronic airflow limitation may be reversible or irreversible. The various causes of airflow obstruction are summarized in Table 27-3.

Airflow limitation is assessed through spirometry, which represents the “gold standard” for diagnosing and monitoring COPD. The hallmark of COPD is a reduction in the ratio of FEV₁ to forced vital capacity (FVC) to less than 70%.^{1,12} The FEV₁ generally is reduced, except in very mild disease, and the rate of FEV₁ decline is greater in COPD patients compared with normal subjects.

The impact of the numerous pathologic changes in the lung perturbs the normal gas-exchange and protective functions of the lung. Ultimately, these are exhibited through the common symptoms of COPD, including dyspnea and a chronic cough productive of sputum. As the disease progresses, abnormalities in gas exchange lead to hypoxemia and/or hypercapnia; although there often is not a strong relationship between pulmonary function and arterial blood gas results.

TABLE 27-2. Features of Inflammation in COPD Compared with Asthma

| | COPD | Asthma |
|-----------------------|---|--|
| Cells | Neutrophils Large increase in macrophages Increase in CD8+ T lymphocytes | Eosinophils Small increase in macrophages Increase in CD4+ Th2 lymphocytes Activation of mast cells |
| Mediators | LTB ₄ IL-8 TNF- α | LTD ₄ IL-4, IL-5 (Plus many others) |
| Consequences | Squamous metaplasia of epithelium Parenchymal destruction Mucus metaplasia Glandular enlargement | Fragile epithelium Thickening of basement membrane Mucus metaplasia Glandular enlargement |
| Response to treatment | Glucocorticosteroids have variable effect | Glucocorticosteroids inhibit inflammation |

From ref. 1.

TABLE 27-3. Etiology of Airflow Limitation in COPD**Reversible**

Presence of mucus and inflammatory cells and mediators in bronchial secretions

Bronchial smooth muscle contraction in peripheral and central airways

Dynamic hyperinflation during exercise

Irreversible

Fibrosis and narrowing of airways

Reduced elastic recoil with loss of alveolar surface area

Destruction of alveolar support with reduced patency of small airways

Significant changes in arterial blood gases usually are not present until the FEV₁ is less than 1 L.¹ In these patients, hypoxemia and hypercapnia can become chronic problems. Initially, when hypoxemia is present, it usually is associated with exercise. However, as the disease progresses, hypoxemia at rest develops. Patients with severe COPD can have a low arterial oxygen tension (PaO₂ = 45 to 60 mm Hg) and an elevated arterial carbon dioxide tension (PaCO₂ = 50 to 60 mm Hg). The hypoxemia is attributed to hypoventilation (\dot{V}) of lung tissue relative to perfusion (\dot{Q}) of the area. This low \dot{V}/\dot{Q} ratio will progress over a period of several years, resulting in a consistent decline in the PaO₂. Some COPD patients lose the ability to increase the rate or depth of respiration in response to persistent hypoxemia. Although this is not completely understood, the decreased ventilatory drive may be due to abnormal peripheral or central respiratory receptors responses. This relative hypoventilation subsequently leads to hypercapnia. In this case, the central respiratory response to a chronically increased PaCO₂ can be blunted. These changes in PaO₂ and PaCO₂ are subtle and progress over a period of many years; as a result, the pH usually is nearly normal because the kidneys compensate by retaining bicarbonate. If acute respiratory distress develops, such as might be seen in pneumonia or a COPD exacerbation with impending respiratory failure, the PaCO₂ may rise sharply, and the patient presents with an uncompensated respiratory acidosis.

The consequences of long-standing COPD and chronic hypoxemia include the development of secondary pulmonary hypertension that progresses slowly if appropriate treatment of COPD is not initiated. Pulmonary hypertension is the most common cardiovascular complication of COPD and can result in cor pulmonale, or right-sided heart failure.¹³

The elevated pulmonary artery pressures are attributed to vasoconstriction (in response to chronic hypoxemia), vascular remodeling, and loss of pulmonary capillary beds. If elevated pulmonary pressures are sustained, cor pulmonale can develop, characterized by hypertrophy of the right ventricle in response to increases in pulmonary vascular resistance.

The risks of cor pulmonale include venous stasis with the potential for thrombosis and pulmonary embolism. Another important systemic consequence of COPD is a loss of skeletal muscle mass and general decline in the overall health status.

PATHOPHYSIOLOGY OF EXACERBATION

The natural history of COPD is characterized by recurrent exacerbations associated with increased symptoms and a decline in overall health status. Because many patients experience chronic symptoms, the diagnosis of an exacerbation is based, in part, on subjective mea-

asures and clinical judgment. A working definition of a COPD exacerbation is a sustained worsening of the patient's condition from the stable state and beyond normal day-to-day variations that is acute in onset and necessitates a change in regular medication.¹⁴

There are limited data about pathology during exacerbations owing to the nature of the disease and the condition of patients; however, inflammatory mediators including neutrophils and eosinophils are increased in the sputum. Chronic airflow limitation is a feature of COPD and may not change remarkably even during an exacerbation.¹

The primary physiologic change is often a worsening of arterial blood gas results owing to poor gas exchange and increased muscle fatigue. In a patient experiencing a severe exacerbation, profound hypoxemia and hypercapnia can be accompanied by respiratory acidosis and respiratory failure.

CLINICAL PRESENTATION

The diagnosis of COPD is made based on the patient's symptoms, including cough, sputum production, and dyspnea, and a history of exposure to risk factors such as tobacco smoke and occupational exposures. Patients may have these symptoms for several years before dyspnea develops and often will not seek medical attention until dyspnea is significant. The common features noted at presentation are summarized in Table 27-4.

The presence of airflow limitation should be confirmed with spirometry. Spirometry represents a comprehensive assessment of lung volumes and capacities. The hallmark of COPD is an FEV₁/FVC ratio of less than 70%, which indicates airway obstruction, and a postbronchodilator FEV₁ of less than 80% of predicted confirms the presence of airflow limitation that is not fully reversible.¹ An improvement in FEV₁ of less than 12% following inhalation of a rapid-acting bronchodilator is considered to be evidence of irreversible airflow obstruction. Reversibility of airflow limitation is measured by a bronchodilator challenge, which is described in Table 27-5. The use of peak expiratory flow measurements is not adequate for the diagnosis of COPD owing to low specificity and the high degree of effort dependence; however, a low peak expiratory flow is consistent with COPD. A comprehensive discussion about spirometry can be found in Chapter 25.

Use of accessory respiratory muscles

Diagnostic Tests

Spirometry with reversibility testing

Radiograph of chest

Arterial blood gas (not routine)

TABLE 27–5. Procedures for Reversibility Testing**Preparation**

Tests should be performed when patients are clinically stable and free from respiratory infection.

Patients should not have taken inhaled short-acting bronchodilators in the previous 6 hours, long-acting β -agonists in the previous 12 hours, or sustained-release theophylline in the previous 24 hours.

Spirometry

FEV₁ should be measured before bronchodilator is given.

Bronchodilators can be given by either metered-dose inhaler or nebulization.

Usual doses are 400 mcg of β -agonist, 80 mcg of anticholinergic, or the two combined.

FEV₁ should be measured again 30–45 minutes after bronchodilator is given.

Results

An increase in FEV₁ that is both greater than 200 mL and 12% above the prebronchodilator FEV₁ is considered significant.

From ref. 1.

Spirometry is also used to determine the severity of the disease, along with an assessment of symptoms and the presence of complications. Currently, the GOLD consensus guidelines suggests a five-stage classification system, which includes patients at risk for developing COPD (Table 27–6).

Patients at risk (stage 0) have normal spirometry but experience chronic symptoms of cough or sputum production and a history of exposure to risk factors. Patients in the remaining four stages of classification all exhibit the hallmark finding of airflow obstruction, i.e., a reduction in the FEV₁/FVC ratio to less than 70%. FVC is the total amount of air exhaled after a maximal inhalation. The extent of reduction in FEV₁ further defines the patient with mild, moderate, severe, or very severe disease.¹

Most patients who present in the milder stages of COPD will have a normal physical examination. In later stages of the disease, when airflow limitation is severe, patients may have cyanosis of mucosal

TABLE 27–6. Classification of COPD Severity**Stage 0: At Risk**

May have one or more symptoms of chronic cough, sputum production, or dyspnea

Exposure to risk factors

Normal spirometry

Stage I: Mild

FEV₁/FVC < 70%

FEV₁ \geq 80%

With or without symptoms

Stage II: Moderate

FEV₁/FVC < 70%

50% < FEV₁ < 80%

With or without symptoms

Stage III: Severe

FEV₁/FVC < 70%

30% < FEV₁ < 50%

With or without symptoms

Stage IV: Very Severe

FEV₁/FVC < 70%

FEV₁ < 30% or <50% with presence of chronic respiratory failure or right heart failure

From ref. 1.

membranes, development of “barrel chest” due to hyperinflation of the lungs, an increased respiratory rate and shallow breathing, and changes in breathing mechanics such as pursing of the lips to help with expiration or use of accessory respiratory muscles.

PROGNOSIS

The average rate of decline of FEV₁ is the most useful objective measure to assess the course of COPD. The average rate of decline in FEV₁ for healthy, nonsmoking patients owing to age alone is 25 to 30 mL/year. The rate of decline for smokers is steeper, especially for heavy smokers compared with light smokers. The decline in pulmonary function is a steady curvilinear path. The more severely diminished the FEV₁ at diagnosis; the steeper is the rate of decline. Greater numbers of years of smoking and number of cigarettes smoked also correlate with a steeper decline in pulmonary function.¹⁵ Conversely, the rate of decline of blood gases has not been shown to be a useful parameter to assess progression of the disease. Patients with COPD should have spirometry performed at least annually to assess disease progression.

The survival rate of patients with COPD is highly correlated to the initial level of impairment in the FEV₁ and age. Other less important factors include degree of reversibility with bronchodilators, resting pulse, perceived physical disability, diffusing capacity (D_{LCO}), cor pulmonale, and blood gas abnormalities. A rapid decline in pulmonary function tests indicates a poor prognosis. Median survival is approximately 10 years when the FEV₁ is 1.4 L, 4 years when the FEV₁ is 1.0 L, and about 2 years when the FEV₁ is 0.5 L.

While arterial blood gas (ABGs) measurements are important, they do not carry the prognostic value of pulmonary function tests. Measurement of arterial blood gases is more useful in patients with severe disease and is recommended for all patients with an FEV₁ of less than 40% of predicted or those with signs of respiratory failure or right-sided heart failure.¹

CLINICAL PRESENTATION OF COPD EXACERBATION

Because of the subjective nature of defining an exacerbation of COPD, the criteria used among clinicians varies widely; however, most rely on a change in one or more of the following clinical findings: worsening symptoms of dyspnea, increase in sputum volume, or increase in sputum purulence. Common presentation features are listed in Table 27–7. Patients using rapid-acting bronchodilators may report an

TABLE 27–7. Clinical Presentation of COPD Exacerbation**Symptoms**

Increased sputum volume

Acutely worsening dyspnea

Chest tightness

Presence of purulent sputum

Increased need for bronchodilators

Malaise, fatigue

Decreased exercise tolerance

Physical Examination

Fever

Wheezing, decreased breath sounds

Diagnostic Tests

Sputum sample for Gram stain and culture

Chest radiograph to evaluate for new infiltrates

TABLE 27–8. Staging Acute Exacerbations of COPD^a

| | |
|-------------------|--|
| Mild (type 1) | One cardinal symptom ^a plus at least one of the following: URTI ^b within 5 days, fever without other explanation, increased wheezing, increased cough, increase in respiratory or heart rate >20% above baseline |
| Moderate (type 2) | Two cardinal symptoms ^a |
| Severe (type 3) | Three cardinal symptoms ^a |

^aCardinal symptoms include worsening of dyspnea, increase in sputum volume, and increase in sputum purulence.

^bURTI = upper respiratory tract infection.

increase in the frequency of use. Exacerbations are commonly staged as mild, moderate, or severe according to the criteria summarized in Table 27–8.¹⁶

An important complication of a severe exacerbation is acute respiratory failure. In the emergency department or hospital, an ABG usually is obtained to assess the severity of an exacerbation. The diagnosis of acute respiratory failure in COPD is made on the basis of an acute change in the ABGs. Defining acute respiratory failure

as a PaO₂ of less than 50 mm Hg or a PaCO₂ of greater than 50 mm Hg often may be incorrect and inadequate because these values may not represent a significant change from a patient's baseline values. A more precise definition is an acute drop in PaO₂ of 10 to 15 mm Hg or any acute increase in PaCO₂ that decreases the serum pH to 7.3 or less.¹⁷ Additional acute clinical manifestations of respiratory failure include restlessness, confusion, tachycardia, diaphoresis, cyanosis, hypotension, irregular breathing, miosis, and unconsciousness.

PROGNOSIS

COPD exacerbations are associated with significant morbidity and mortality. While mild exacerbations may be managed at home, mortality rates are higher for patients admitted to the hospital. In one study of patients hospitalized with COPD exacerbations, in-hospital mortality ranged from 6% to 8% but increased to 23% to 35% for the first year after hospital discharge.¹⁸ Many patients experiencing an exacerbation do not have a return to their baseline clinical status for several weeks, significantly affecting their quality of life. Additionally, as many as half the patients originally hospitalized for an exacerbation are readmitted within 6 months.¹⁹

► TREATMENT: Chronic Obstructive Pulmonary Disease

■ DESIRED OUTCOMES

Given the nature of COPD, a major focus in health care should be on prevention. However, in patients with a diagnosis of COPD, the primary goal is to prevent or minimize progression. Specific goals of management are listed in Table 27–9.

Optimally, these goals can be accomplished with minimal risks or side effects. The therapy of the patient with COPD is multifaceted and includes pharmacologic and nonpharmacologic strategies. Appropriate measures of effectiveness of the management plan include continued smoking cessation, symptom improvement, reduction in FEV₁ decline, reduction in the number of exacerbations, improvements in physical and psychological well-being, and reduction in mortality, hospitalizations, and days lost from work.

Unfortunately, most treatments for COPD have not been shown to improve survival or to slow the progressive decline in lung function. However, many therapies do improve pulmonary function and quality of life and reduce exacerbations and duration of hospitalization. Several disease-specific quality-of-life measures are available to assess the overall efficacies of therapies for COPD, including the Chronic Respiratory Questionnaire (CRQ) and the St. George's Respiratory Questionnaire (SGRQ). These questionnaires measure the impact of various therapies on such disease variables as severity of dyspnea and level of activity; they do not measure impact of therapies on survival. While early studies of COPD therapies focused primarily on

TABLE 27–9. Goals of COPD Management

| |
|---------------------------------|
| Prevent disease progression |
| Relieve symptoms |
| Improve exercise tolerance |
| Improve overall health status |
| Prevent and treat exacerbations |
| Prevent and treat complications |
| Reduce morbidity and mortality |

improvements in pulmonary function measurements such as FEV₁, there is a trend toward greater use of these disease-specific quality-of-life measures to evaluate the benefits of therapy on larger clinical outcomes.

■ GENERAL APPROACH TO TREATMENT

To be effective, the clinician should address four primary components of management: Assess and monitor the condition, avoidance of or reduced exposure to risk factors, manage stable disease, and treat exacerbations. These components are addressed through a variety of nonpharmacologic and pharmacologic approaches.

■ NONPHARMACOLOGIC THERAPY

Patients with COPD should receive education about their disease, treatment plans, and strategies to slow progression and prevent complications.¹ Advice and counseling about smoking cessation are essential, if applicable. Because the natural course of the disease leads to respiratory failure, the clinician should address end-of-life decisions and advanced directives prospectively with the patient and family.²⁰

■ SMOKING CESSATION

5 A primary component of COPD management is avoidance of or reduced exposure to risk factors. Exposure to environmental tobacco smoke is a major risk factor, and smoking cessation is the most effective strategy to reduce the risk of developing COPD and to slow or stop disease progression. The cost-effectiveness of smoking-cessation interventions compares favorably with interventions made for other major chronic diseases.²¹ The importance of smoking

TABLE 27–10. Treating Tobacco Use and Dependence: Public Health Service Report (2000) Major Findings and Recommendations

Tobacco dependence should be recognized as a chronic condition requiring repeated treatment until permanent abstinence is achieved.

Effective treatments for tobacco dependence are available and should be offered to all tobacco users.

Clinicians and health care systems should ensure mechanisms to identify, document, and treat all tobacco users in the system.

Brief treatment interventions for tobacco dependence should be offered to all tobacco users at a minimum.

There is a strong dose-response relationship between the intensity of tobacco dependence counseling and its effectiveness.

The most effective types of counseling and behavioral therapies are (1) practical counseling employing problem solving and skills training, (2) social support as part of treatment, and (3) social support outside of treatment.

Numerous pharmacotherapies have been proven to be effective for smoking cessation and should be offered in the absence of contraindications. These include sustained-release bupropion, nicotine gum, nicotine inhaler, nicotine nasal spray, and nicotine patch.

Tobacco dependence treatments are effective and cost-effective compared with other medical and disease-prevention measures.

cessation cannot be overemphasized. Smoking cessation leads to decreased symptomatology and slows the rate of decline of pulmonary function even after significant abnormalities in pulmonary function tests have been detected ($FEV_1/FVC < 60\%$).¹⁵ As confirmed by the Lung Health Study, smoking cessation is the only intervention proven at this time to affect long-term decline in FEV_1 and slow the progression of COPD.²² In this 5-year prospective trial, smokers with early COPD were randomly assigned to one of three groups: smoking-cessation intervention plus inhaled ipratropium three times a day, smoking-cessation intervention alone, or no intervention. Smokers who underwent smoking-cessation intervention had fewer respiratory symptoms and a smaller annual decline in FEV_1 compared with smokers who had no intervention. However, this study also demonstrated the difficulty in achieving and sustaining successful smoking cessation.

Every clinician has a responsibility to assist smokers in smoking-cessation efforts. A clinical practice guideline for treating tobacco dependence from the U.S. Public Health Service (PHS) was updated in 2000.²³ The major findings and recommendations of that report are summarized in Table 27–10. In 2004, a report from the Surgeon General on the health consequences of smoking broadened the scope of the detrimental effects of cigarette smoking, indicating that “Smoking harms nearly every organ of the body, causing many diseases and reducing the health of smokers in general.”²⁴

TABLE 27–11. Five-Step Strategy for Smoking-Cessation Program (5 A’s)

| | |
|---------|--|
| Ask | Use systematic approach to identify all tobacco users. |
| Advise | Urge all tobacco users to quit. |
| Assess | Determine willingness to make a cessation attempt. |
| Assist | Provide support for the patient to quit smoking. |
| Arrange | Schedule follow-up and monitor for continued abstinence. |

All clinicians should take an active role in assisting patients with tobacco dependence in order to reduce the burden on the individual, his or her family, and the health care system. It is estimated that over 75% of smokers want to quit and that one-third have made a serious effort. Yet complete and permanent tobacco cessation is difficult.²² Counseling that is provided by clinicians is associated with greater success rates than self-initiated efforts.²³

The PHS guidelines recommend that clinicians take a comprehensive approach to smoking-cessation counseling. Advice should be given to smokers even if they have no symptoms of smoking-related disease or if they are receiving care for reasons unrelated to smoking. Clinicians should be persistent in their efforts because relapse is common among smokers owing to the chronic nature of dependence. Brief interventions (3 minutes) of counseling are proven effective. However, it must be recognized that the patient must be ready to stop smoking because there are several stages of decision making. Based on this, a five step intervention program is proposed (Table 27–11).

There is strong evidence to support the use of pharmacotherapy to assist in smoking cessation when counseling alone is not sufficient. Agents that are considered first line are listed in Table 27–12. Precautions to consider before using bupropion include a history of seizures or an eating disorder. Nicotine-replacement therapies are contraindicated in patients with unstable coronary artery disease, active peptic ulcers, or recent myocardial infarction or stroke. Nicotine patch, bupropion, and the combination of bupropion and the nicotine patch were compared with placebo in a controlled trial.²⁵ The treatment groups that received bupropion had higher rates of smoking cessation than the groups that received placebo or the nicotine patch. The addition of the nicotine patch to bupropion slightly improved the smoking-cessation rate compared with bupropion monotherapy. Second-line agents are less effective or associated with greater side effects; however, they may be useful in selected clinical situations. These therapies include clonidine and nortriptyline, a tricyclic antidepressant.

Behavioral modification techniques or other forms of psychotherapy also may be helpful in assisting in smoking cessation. Programs that address the many issues associated with smoking (i.e., learned behaviors, environmental influences, and chemical dependence) using a team approach are more likely to be successful. The

TABLE 27–12. First-Line Pharmacotherapies for Smoking Cessation

| Agent | Usual Dose | Duration | Common Complaints |
|----------------------|--|--------------------------|-------------------------|
| Bupropion SR | 150 mg orally daily for 3 days, then twice daily | 12 weeks, up to 6 months | Insomnia, dry mouth |
| Nicotine gum | 2–4 mg gum prn, up to 24 pieces daily | 12 weeks | Sore mouth, dyspepsis |
| Nicotine inhaler | 6–16 cartridges daily | Up to 6 months | Sore mouth and throat |
| Nicotine nasal spray | 8–40 doses daily | 3 to 6 months | Nasal irritation |
| Nicotine patches | Various, 7–21 mg every 24 hours | Up to 8 weeks | Skin reaction, insomnia |

role of alternative-medicine therapies in smoking cessation is controversial. Hypnosis may aid in improving abstinence rates when added to a smoking-cessation program but appears to give little benefit when used alone. Acupuncture has not been shown to contribute to smoking cessation and is not recommended.²

■ PULMONARY REHABILITATION

Exercise training is beneficial in the treatment of COPD to improve exercise tolerance and to reduce symptoms of dyspnea and fatigue.¹ Pulmonary rehabilitation programs are an integral component in the management of COPD and should include exercise training along with smoking cessation, breathing exercises, optimal medical treatment, psychosocial support, and health education. High-intensity training (70% maximal workload) is possible even in advanced COPD patients, and the level of intensity improves peripheral muscle and ventilatory function. Studies have demonstrated that pulmonary rehabilitation with exercise three to seven times per week can produce long-term improvement in activities of daily living, quality of life, and exercise tolerance in patients with moderate to severe COPD.²⁶ Programs using less intensive exercise regimens (two times per week) have not been shown to be of benefit.²⁷

■ IMMUNIZATIONS

Vaccines can be considered as pharmacologic agents; however, their role is described here in reducing risk factors for COPD exacerbations. Because influenza is a common complication in COPD that can lead to exacerbations and respiratory failure, an annual vaccination with the inactivated intramuscular influenza vaccine is recommended. Immunization against influenza can reduce serious illness and death by 50% in COPD patients.²⁸ Influenza vaccine should be administered in the fall of each year (October and November) during regular medical visits or at vaccination clinics. There are few contraindications to influenza vaccine except for a patient with a serious allergy to eggs. Oral anti-influenza agents (e.g., amantadine, rimantadine, and oseltamivir) can be considered for patients with COPD during an outbreak for patients who have not been immunized; however, these therapies are less effective and cause more side effects.²⁹

The polyvalent pneumococcal vaccine, administered one time, is widely recommended for people from 2 to 64 years of age who have chronic lung disease and for all people older than 65 years. Thus COPD patients at any age are candidates for vaccination. Although evidence for the benefit of the pneumococcal vaccine in COPD is not strong, the argument for continued use is that the current vaccine provides coverage for 85% of pneumococcal strains causing invasive disease and the increasing rate of resistance of pneumococcus to selected antibiotics. Currently, administering the vaccine remains the standard of practice and is recommended by the Centers for Disease Control and Prevention and the American Lung Association.³⁰ Repeated vaccination with the 23-valent product is not recommended for patients aged 2 to 64 years with chronic lung disease; however, revaccination is recommended for patients over 65 years of age if the first vaccination was more than 5 years earlier and the patient was younger than age 65.

■ LONG-TERM OXYGEN THERAPY

6 The use of supplemental oxygen therapy increases survival in COPD patients with chronic hypoxemia. Although long-term

oxygen has been used for many years in patients with advanced COPD, it was not until 1980 that data became available documenting its benefits. At that time, the Nocturnal Oxygen Therapy Trial Group published its data comparing nocturnal oxygen therapy (NOT; 12 h/day) with continuous oxygen therapy (COT; average of 20 h/day).³¹ Among patients who were followed for at least 12 months, the results revealed a mortality rate in the NOT group that was nearly double that of the COT group (51% versus 26%). Statistical estimates of the COT group suggest that COT may have added 3.25 years to a COPD patient's life. Additional data from the Nocturnal Oxygen Therapy Trial Group revealed that COT patients had fewer (but statistically insignificant) hospitalizations, improved quality of life and neuropsychological function, reduced hematocrit, and decreased pulmonary vascular resistance.³¹

The decline in mortality with oxygen therapy was further substantiated in 1981 in a study by the British Medical Research Council that compared 15 h/day of oxygen versus no supplemental oxygen in COPD patients.³² Patients receiving oxygen therapy for at least part of the day had lower rates of mortality than those not receiving oxygen. Recent analyses have shown that long-term oxygen therapy provides even more benefit in terms of survival after at least 5 years of use, and it improves the quality of life of these patients by increasing walking distance and neuropsychological condition and reducing time spent in the hospital.³³

Before patients are considered for long-term oxygen therapy, they should be stabilized in the outpatient setting, and pharmacotherapy should be optimized. Once this is accomplished, long-term oxygen therapy should be instituted if either of two conditions exists:

1. A resting PaO₂ of less than 55 mm Hg
2. Evidence of right-sided heart failure, polycythemia, or impaired neuropsychiatric function with a PaO₂ of less than 60 mm Hg

The most practical means of administering long-term oxygen is with the nasal cannula, at 1 to 2 L/min which provides 24% to 28% oxygen. The goal is to raise the PaO₂ above 60 mm Hg. Patient education about flow rates and avoidance of flames (i.e., smoking) is of the utmost importance.

There are three different ways to deliver oxygen, including (1) in liquid reservoirs, (2) compressed into a cylinder, and (3) via an oxygen concentrator. Although conventional liquid oxygen and compressed oxygen are quite bulky, smaller, portable tanks are available to permit greater patient mobility. Oxygen concentrator devices separate nitrogen from room air and concentrate oxygen. These are the most convenient and the least expensive method of oxygen delivery. Oxygen-conservation devices are available that allow oxygen to flow only during inspiration, making the supply last longer. These may be particularly useful to prolong the oxygen supply for mobile patients using portable cylinders. However, the devices are bulky and subject to failure.

■ ADJUNCTIVE THERAPIES

In addition to supplemental oxygen, adjunctive therapies to consider as part of a pulmonary rehabilitation program are psychoeducational care and nutritional support. Psychoeducational care (such as relaxation) has been associated with improvement in the functioning and well-being of adults with COPD.³⁴ The role of nutritional support in patients with COPD is controversial. Several studies have shown an association between malnutrition, low body mass index (BMI), and impaired pulmonary status among patients with COPD. However, in

a recent meta-analysis, the effect of nutritional support on outcomes in COPD was small and was not associated with improved anthropometric measures, lung function, or functional exercise capacity.³⁵

■ PHARMACOLOGIC THERAPY

Currently, there is no medication available for the treatment of COPD that has been shown to modify the progressive decline in lung function or prolong survival.¹ Thus a primary goal of pharmacotherapy is to control patient symptoms and reduce complications, including the frequency and severity of exacerbations and improving the overall the health status and exercise tolerance of the patient.

▶ Pharmacotherapy focuses on the use of bronchodilators to control symptoms. There are several classes of bronchodilators to choose from, and no single class has been proven to provide superior benefit over other available agents. The initial and subsequent choice of medications should be based on the specific clinical situation and patient characteristics. Medications can be used as needed or on a scheduled basis depending on the clinical situation, and additional therapies should be added in a stepwise manner depending on the response and severity of disease. Considerations should be given to individual patient response, tolerability, adherence, and economic factors. A stepwise approach to the management of COPD has been proposed based on the stage of disease severity (Fig. 27-3).

■ BRONCHODILATORS

Bronchodilator classes available for the treatment of COPD include β_2 -agonists, anticholinergics, and methylxanthines. There is no clear benefit to one agent or class over others, although inhaled therapy generally is preferred. In general, it can be more difficult for patients with COPD to use inhalation devices effectively compared with other populations owing to advanced age and the presence of other comorbidities. Clinicians should advise, counsel, and observe patient technique with the devices frequently and consistently.

Bronchodilators generally work by reducing the tone of airway smooth muscle, thus minimizing airflow limitation. In patients with COPD, the clinical benefits of bronchodilators include increased exercise capacity, decreased air trapping in the lungs, and relief of symptoms such as dyspnea. However, use of bronchodilators may not be associated with significant improvements in pulmonary function measurements such as FEV₁. In general, side effects of bronchodilator medications are related to their pharmacologic effects and are dose-dependent. Because COPD patients are older and more likely to have comorbid conditions, the risk for side effects and drug interactions is higher compared with patients with asthma.

■ Sympathomimetics (β_2 -Agonists)

A number of sympathomimetic agents are available in the United States. They vary in selectivity, route of administration, and duration of action. In COPD management, sympathomimetic agents with β_2 -selectivity, or β_2 -agonists, should be used as bronchodilators. β_2 -Agonists cause bronchodilation by stimulating the enzyme adenylyl cyclase to increase the formation of cyclic adenosine monophosphate (cAMP). cAMP is responsible for mediating relaxation of bronchial smooth muscle, leading to bronchodilation. In addition, they may improve mucociliary clearance. Although shorter-acting and less selective β -agonists are still used widely (e.g., metaproterenol, isoetharine, isoproterenol, and epinephrine), they should not be used owing to their shorter duration of action and increased cardiostimulatory effects. Selective β_2 -agonists such as albuterol, levalbuterol, bitolterol, formoterol, pirbuterol, salmeterol, and terbutaline are preferred for therapy.

Sympathomimetics are available in inhaled, oral, and parenteral dosage forms. The preferred route of administration is by inhalation. The use of oral and parenteral β -agonists in COPD is discouraged because they are no more effective than a properly used metered-dose inhaler (MDI) or dry-powder inhaler (DPI), and the incidence of systemic adverse effects such as tachycardia and hand tremor is greater. Administration of β_2 -agonists in the outpatient and emergency room settings via inhalers (MDIs or DPIs) is at least as effective as nebulization therapy and usually favored for reasons of cost and

convenience.^{36–38} Chapter 26 includes a complete description of the devices used for delivering aerosolized medication and a comparison β_2 -agonist therapies.

Albuterol is the most frequently used β_2 -agonist. It is available as an oral and inhaled preparation. Albuterol is a racemic mixture of (*R*)-albuterol that is responsible for the bronchodilator effect and (*S*)-albuterol that has no therapeutic effect. (*S*)-Albuterol is considered by some clinicians to be inert, whereas others believe that it may be implicated in worsening airway inflammation and antagonizing the response to (*R*)-albuterol. Levalbuterol is a single-isomer formulation of (*R*)-albuterol. A retrospective evaluation of levalbuterol versus albuterol use in patients with asthma and COPD concluded that levalbuterol offered significant advantages over albuterol for hospitalized patients.³⁹ Other clinicians feel that there are no significant differences between the products and that the use of levalbuterol is not justified owing to its higher acquisition cost.⁴⁰ The effects of a single dose of levalbuterol have been compared with those of albuterol and ipratropium plus albuterol in patients with COPD. No significant differences in pulmonary function improvements or adverse effects were noted.⁴¹

In COPD patients, β_2 -agonists exert a rapid onset of effect, although the response generally is less than that seen in asthma. Short-acting inhaled β_2 -agonists cause only a small improvement in FEV₁ acutely but may improve respiratory symptoms and exercise tolerance despite the small improvement in spirometric measurements.^{42–44} Patients with COPD can use quick-onset β_2 -agonists as needed for relief of symptoms or either short- or long-acting β_2 -agonists on a scheduled basis to prevent or reduce symptoms. The duration of action of short-acting β_2 -agonists is 4 to 6 hours.

Long-acting, inhaled β_2 -agonists offer the benefit of a long duration of action without loss of effectiveness. Salmeterol and formoterol can be dosed every 12 hours and provide bronchodilation throughout the dosing interval. Formoterol has an onset of action similar to albuterol, whereas salmeterol has a slower onset; however, both agents are indicated for sustained bronchodilation and not for acute relief of symptoms. In clinical studies, long-acting inhaled β_2 -agonists provide similar or superior improvements in lung function, exacerbation rates, and symptom improvements compared with short-acting bronchodilators.^{45–47} There is a growing body of literature to support the use of the long-acting agents in patient with frequent and persistent symptoms. For patients using β_2 -agonists on a scheduled basis, long-acting agents such as formoterol and salmeterol are more convenient because of reduced dosing frequency but are also more expensive.¹ The long-acting therapies should be considered when patients demonstrate a frequent need for short-acting agents.

■ Anticholinergics

When given by inhalation, anticholinergics such as ipratropium or atropine produce bronchodilation by competitively inhibiting cholinergic receptors in bronchial smooth muscle. This activity blocks acetylcholine, with the net effect being a reduction in cyclic guanosine monophosphate (cGMP), which normally acts to constrict bronchial smooth muscle. Muscarinic receptors on airway smooth muscle include M₁, M₂, and M₃ subtypes. Activation of M₁ and M₃ receptors by acetylcholine results in bronchoconstriction; however, activation of M₂ receptors inhibits further acetylcholine release.

Until recently, ipratropium has been the only available anticholinergic agent for COPD. Atropine has a tertiary structure and is absorbed readily across the oral and respiratory mucosa, whereas ipratropium has a quaternary structure that is absorbed poorly. The

lack of systemic absorption of ipratropium greatly diminishes the anticholinergic side effects such as blurred vision, urinary retention, nausea, and tachycardia associated with atropine. Ipratropium bromide is available as an MDI and a solution for inhalation. It provides a peak effect in 1.5 to 2 hours and has a duration of effect of 4 to 6 hours. Ipratropium has a slower onset of action and a more prolonged bronchodilator effect compared with standard β_2 -agonists. Because of the slower onset of effect (15 to 20 minutes compared with 5 minutes for albuterol), it may be less suitable for as-needed use; however, it is often prescribed in that manner. Clinicians differ about preference in choosing the initial short-acting bronchodilator therapy for the patient with COPD. Both a short-acting β_2 -agonist and ipratropium represent reasonable choices for initial therapy.

The role of inhaled anticholinergics in COPD is well established.^{48–52} However, results from the Lung Health Study showed that treatment with ipratropium did not affect the progressive decline in lung function.²² Studies comparing ipratropium with inhaled β_2 -agonists have generally reported similar improvements in pulmonary function. Others report a modest benefit with ipratropium, including a lower incidence of side effects such as tachycardia.^{49–51}

Although the recommended dose of ipratropium is 2 puffs four times a day, there is evidence for a dose-response, so the dose can be titrated upward often to 24 puffs a day. Ipratropium has been shown to increase maximum exercise performance in stable COPD patients with doses of 8 to 12 puffs prior to exercise but not with doses of 4 puffs or less.^{52–53} During sleep, ipratropium also has been shown to improve arterial oxygen saturation and sleep quality.⁵⁴ Ipratropium is well tolerated. The most frequent patient complaints are dry mouth, nausea, and an occasional metallic taste.

Tiotropium bromide, which was released in the United States in 2004, is a long-acting quaternary anticholinergic agent. This agent blocks the effects of acetylcholine by binding to muscarinic receptors in airway smooth muscle and mucus glands, blocking the cholinergic effects of bronchoconstriction and mucus secretion. Tiotropium dissociates slowly from M₁ and M₃ receptors, allowing prolonged bronchodilation. The dissociation from M₂ receptors is much faster, allowing inhibition of acetylcholine release. Binding studies of tiotropium in the human lung show that it is approximately 10-fold more potent than ipratropium and protects against cholinergic bronchoconstriction for greater than 24 hours.⁵⁵

When inhaled, tiotropium is minimally absorbed into the systemic circulation and results in bronchodilation within 30 minutes, with a peak effect in 3 hours. Bronchodilation persists for at least 24 hours. In the United States, it is delivered via the HandiHaler, a single-load, dry-powder, breath-actuated device. Because it acts locally, tiotropium is well tolerated, with the most common complaint being a dry mouth. Other anticholinergic side effects that are reported include constipation, urinary retention, tachycardia, blurred vision, and precipitation of narrow-angle glaucoma symptoms.

As a new therapy for COPD, tiotropium was evaluated as an addition to standard COPD medications in a 1-year, placebo-controlled, double-blind study involving over 900 subjects. Tiotropium 18 mcg/day improved the FEV₁ response an average of 12% (trough) to 22% (peak) when added to standard therapy.⁵⁶

The efficacy and safety of tiotropium administered via a DPI were compared with ipratropium administered four times daily by MDI in a multicenter, double-blind study that followed patients for 1 year.⁵⁷ Patients who received once-daily tiotropium demonstrated significantly greater improvements in lung function and selected quality-of-life scores, decreased dyspnea, and fewer exacerbations compared with patients who received ipratropium. There were no differences in side effects between the two agents.

As a newly available agent, tiotropium is expected to compete with long-acting inhaled β_2 -agonists for COPD management. Once-daily tiotropium has been compared with twice-daily salmeterol in two placebo-controlled trials of 6 months' duration. Tiotropium reduced asthma exacerbations and hospital admissions and improved quality of life, whereas both active treatments improved lung function and reduced dyspnea.⁵⁸ In another 6-month randomized, controlled trial of patients with COPD, patients were randomized to receive either tiotropium once daily by DPI, salmeterol twice daily by MDI, or placebo.⁵⁹ Patients receiving tiotropium had greater improvements in trough FEV₁ and dyspnea scores than those receiving salmeterol. Patients also were more likely to have improvements in quality-of-life indicators with tiotropium than with salmeterol. However, no differences in frequency of exacerbations were noted among the three groups.

Inhaled anticholinergic therapies have an important role in the management of COPD. Ipratropium is available as an MDI (individually and in combination with albuterol) delivering 18 mcg per puff and as a solution for nebulization at 200 mcg/mL. Tiotropium is available as a DPI at 18 mcg per dose. Tiotropium became available in mid-2004. However, based on efficacy and convenience, it likely will play a major role in COPD management.

■ Combination Anticholinergics and Sympathomimetics

Combination regimens of bronchodilators are used often in the treatment of COPD, especially as the disease progresses and symptoms worsen over time. Combining bronchodilators with different mechanisms of action allows the lowest possible effective doses to be used and reduces potential adverse effects from individual agents.¹ Combinations of both short- and long-acting β_2 -agonists with ipratropium have been shown to provide added symptomatic relief and improvements in pulmonary function.^{60–62}

A combination of albuterol and ipratropium (Combivent) is available as an MDI in the United States for chronic maintenance therapy of COPD. This product offers the obvious convenience of two classes of bronchodilators in a single inhaler. Future combination inhalation products may contain long-acting β_2 -agonists with tiotropium to reduce the need for frequent dosing. In a preliminary single-dose study, the combination of tiotropium and formoterol resulted in a faster and greater improvement in FEV₁ compared with either treatment alone.⁶³

■ Methylxanthines

Methylxanthines, including theophylline and aminophylline, have been available for the treatment of COPD for at least five decades and at one time were considered first-line therapy. However, in the past 20 years, with the advent of long-acting inhaled β_2 -agonists and inhaled anticholinergics, they are no longer considered first-line therapy. Inhaled bronchodilator therapy is preferred for COPD. Because of the risk for drug interactions and the significant inpatient and outpatient variability in dosage requirements, theophylline therapy generally is considered in patients who are intolerant or unable to use an inhaled bronchodilator.

The methylxanthines may produce bronchodilation through numerous mechanisms, including (1) inhibition of phosphodiesterase, thereby increasing cAMP levels, (2) inhibition of calcium ion influx into smooth muscle, (3) prostaglandin antagonism, (4) stimulation of

endogenous catecholamines, (5) adenosine receptor antagonism, and (6) inhibition of release of mediators from mast cells and leukocytes.⁶⁴

Chronic theophylline use in patients with COPD has been shown to exert improvements in lung function, including vital capacity (VC), FEV₁, minute ventilation, and gas exchange.⁶⁵ Subjectively, theophylline has been shown to reduce dyspnea, increase exercise tolerance, and improve respiratory drive in COPD patients.^{65,66} Other nonpulmonary effects of theophylline that may contribute to improved overall functional capacity in patients with COPD include improved cardiac function and decreased pulmonary artery pressure.⁶⁵

Although theophylline is available in a variety of oral dosage forms, sustained-release preparations are most appropriate for the long-term management of COPD. These products have the advantages of improving patient compliance and achieving more consistent serum concentrations over rapid-release theophylline and aminophylline preparations. However, caution must be used in switching from one sustained-release preparation to another because there are considerable variations in sustained-release characteristics.⁶⁶ Aside from intravenous aminophylline, there is no need to use any of the various salts forms of theophylline.

Regular use of methylxanthines has not been shown to have either a beneficial or a detrimental effect on the progression of COPD. However, methylxanthines may be added to the treatment plan of patients who have not achieved an optimal clinical response to ipratropium and an inhaled β_2 -agonist. Studies suggest that adding theophylline to a combination of albuterol and ipratropium provides added benefit for stable COPD patients, supporting the hypothesis that there is a synergistic bronchodilator effect.^{67–69} The efficacy of combination therapy with salmeterol and theophylline for patients with COPD was reported to improve pulmonary function and reduce dyspnea better than either treatment alone.⁷⁰ Combination treatment also was associated with a reduced number of exacerbations only when compared with the theophylline group, suggesting that the salmeterol component was responsible for this beneficial effect.

As is the case with other bronchodilator therapy, parameters other than objective measurements, such as FEV₁, should be monitored to assess efficacy of theophylline in COPD. Subjective parameters, such as perceived improvements in symptoms of dyspnea, and exercise tolerance, become increasingly important in assessing the acceptability of methylxanthines for COPD patients. Although objective improvement may be minimal, patients may experience an improvement in clinical symptoms, and thus benefit to the individual may be meaningful.

The role of theophylline in COPD is as maintenance therapy in the non-acutely ill patient. Therapy can be initiated at 200 mg twice daily and titrated upward every 3 to 5 days to the target dose. Most patients required daily doses of 400 to 900 mg. Dosage adjustments generally should be made based on serum concentration results. Traditionally, the therapeutic range of theophylline was identified as 10 to 20 mcg/mL; however, because of the frequency of dose-related side effects and the relatively minor benefit of higher concentrations, a more conservative therapeutic range of 8 to 15 mcg/mL often is targeted. This is especially preferable in the elderly. When concentrations are measured, trough measurements are most appropriate.

Once a dose is established, serum concentrations should be monitored once or twice a year unless the patient's disease worsens, medications that interfere with theophylline metabolism are added to therapy, or toxicity is suspected. The most common side effects of theophylline therapy are related to the gastrointestinal system, the cardiovascular system, and the central nervous system. Side effects are dose-related; however, there is overlap in side effects between the therapeutic and toxic ranges. Minor side effects include

dyspepsia, nausea, vomiting, diarrhea, headache, dizziness, and tachycardia. More serious toxicities, especially at toxic concentrations, include arrhythmias and seizures.

Factors that decrease theophylline clearance and lead to reduced maintenance-dose requirements include advanced age, bacterial or viral pneumonia, left or right ventricular failure, liver dysfunction, hypoxemia from acute decompensation, and use of drugs such as cimetidine, macrolides, and fluoroquinolone antibiotics. Factors that may enhance theophylline clearance and result in the need for higher maintenance doses include tobacco and marijuana smoking, hyperthyroidism, and the use of such drugs as phenytoin, phenobarbital, and rifampin.

■ CORTICOSTEROIDS

Corticosteroid therapy has been studied and debated in COPD therapy for half a century; however, owing to the poor risk-benefit ratio, chronic systemic corticosteroid therapy should be avoided if possible.¹ Because of the potential role of inflammation in the pathogenesis of the disease, clinicians hoped that corticosteroids would be promising agents in COPD management. However, their use continues to be debated, especially in the management of stable COPD.

The anti-inflammatory mechanisms whereby corticosteroids exert their beneficial effect in COPD include (1) reduction in capillary permeability to decrease mucus, (2) inhibition of release of proteolytic enzymes from leukocytes, and (3) inhibition of prostaglandins. Unfortunately, the clinical benefits of systemic corticosteroid therapy in the chronic management of COPD are often not evident, and the risk of toxicity is extensive and far-reaching. Currently, the appropriate situations to consider corticosteroids in COPD include (1) short-term systemic use for acute exacerbations and (2) inhalation therapy for chronic stable COPD.

The role of oral steroid use in chronic stable COPD patients was evaluated in a meta-analysis over a decade ago.⁷¹ Investigators concluded that only a small fraction (10%) of COPD patients treated with steroids showed clinically significant improvement in baseline FEV₁ (increase of 20%) compared with those treated with placebo. While a small number of COPD patients are considered responders to oral steroids, many of these patients actually may have an asthmatic, or reversible, component to their disease. The best predictors for response to oral steroids is the presence of eosinophils on sputum examination ($\geq 3\%$) and a significant response on pulmonary function tests to sympathomimetics.⁷² Both the presence of eosinophils in sputum and the responsiveness to sympathomimetics suggest an asthmatic component to the disease process and thus may explain the clinical benefit seen with steroids.

Long-term adverse effects associated with systemic corticosteroid therapy include osteoporosis, muscular atrophy, thinning of the skin, development of cataracts, and adrenal suppression and insufficiency. The risks associated with long-term steroid therapy are much greater than the clinical benefits. If a decision to treat with long-term systemic corticosteroids is made, the lowest possible effective dose should be given once per day in the morning to minimize the risk of adrenal suppression. If therapy with oral agents is required, an alternate-day schedule should be used.

Previously, a common clinical practice was to administer a short course (2 weeks) of oral corticosteroids as a trial to predict which patients would benefit from chronic oral or inhaled corticosteroids. There is now sufficient evidence suggesting that this practice is not effective in predicting a long-term response to inhaled corticosteroid and should not be recommended.⁷³

The use of chronic inhaled corticosteroid therapy has been of interest for the past decade. Inhaled corticosteroids have an improved risk-benefit ratio compared with systemic corticosteroid therapy. Using the model for asthma, it was hoped that the inhalation of potent corticosteroid would result in high local efficacy and limited systemic exposure and toxicity.

In the latter part of the 1990s, several large international trials were initiated to evaluate the effect on inhaled corticosteroids in COPD. Unfortunately, the results of these major clinical trials failed to demonstrate any benefit from chronic treatment with inhaled corticosteroids in modifying long-term decline in lung function that is characteristic of COPD. Therefore, the role of inhaled corticosteroids in COPD continues to be debated in the literature, unlike asthma, where their use is clearly advocated. Much of the debate centers on the appropriate outcome measures in this population of patients.

During the last decade, several studies of inhaled corticosteroids in COPD were designed to detect a benefit on slowing the progressive loss of lung function, but the results were disappointing.^{74–80} None of the large national or international trials were able to demonstrate a benefit of high-dose inhaled corticosteroid therapy on this primary outcome. However, inhaled corticosteroids have been associated with other important benefits in some patients, including a decrease in exacerbation frequency and improvements in overall health status.^{76,80} Clinicians continue to debate the most appropriate and  relevant outcome measure to evaluate in COPD studies. Based on the results of clinical trials, consensus guidelines suggest that inhaled corticosteroid therapy should be considered for symptomatic patients with stage III or IV disease (FEV₁ <50%) who experience repeated exacerbations.^{1,81} These are the patients who demonstrated benefit in clinical trials and in whom a trial of inhaled corticosteroid therapy is warranted. There are also data from epidemiologic studies that suggest that chronic treatment with inhaled corticosteroids is associated with a lower risk of rehospitalization for a broader group of patients with COPD. Thus the debate about the appropriate role for this anti-inflammatory therapy continues.

Although a dose-response relationship for inhaled corticosteroids has not been demonstrated in COPD, the major clinical trials employed moderate to high doses for treatment. Side effects of inhaled corticosteroids are relatively mild compared with the toxicity from systemic therapy. Hoarseness, sore throat, oral candidiasis, and skin bruising have been reported in the clinical trials. Severe side effects, such as adrenal suppression, osteoporosis, and cataract formation, have been reported less frequently than with systemic corticosteroids, but clinicians should monitor patients who are receiving high-dose chronic therapy.^{82,83}

■ COMBINATION THERAPY: BRONCHODILATORS AND INHALED CORTICOSTEROIDS

Following the disappointing results of chronic inhaled corticosteroid studies and the progressive decline in lung function, investigators became interested in the combination of potent anti-inflammatory therapies and long-acting bronchodilators. Subsequently, several studies have shown an additive benefit with long-acting bronchodilators.^{84–87} In various studies, combination therapy with salmeterol plus fluticasone or formoterol plus budesonide was associated with greater improvements in clinical outcomes such as FEV₁, health status, and frequency of exacerbations compared with inhaled corticosteroids or long-acting bronchodilators alone. The availability of combination inhalers (e.g., salmeterol plus fluticasone) makes administration of both inhaled corticosteroids and long-acting bronchodilators more

convenient for patients and decreases the total number of inhalations needed daily. Most of these studies were performed and published after the large international corticosteroid trials. Further clinical investigations are warranted; however, the combination therapies are prescribed increasingly in clinical practice, and additional products that combine these two therapeutic classes are anticipated.

■ α_1 -ANTITRYPSIN REPLACEMENT THERAPY

In patients with inherited AAT deficiency–associated emphysema, treatment focuses on reduction of risk factors such as smoking, symptomatic treatment with bronchodilators, and augmentation therapy with replacement AAT. Augmentation therapy consists of weekly infusions of pooled human AAT to maintain AAT plasma levels over 10 micromolar. Clinical evidence for slowing lung function decline or improving outcomes with augmentation therapy is sparse. One observational study followed patients in the National Registry of Severe AAT Deficiency over a period of several years and documented clinical outcomes. In this study, patients who received weekly aug-

mentation therapy with purified AAT had slower declines in FEV₁ and decreased mortality compared with patients who never received augmentation therapy.⁸ However, this was an observational study of patients, not a randomized, placebo-controlled trial, so direct cause-and-effect relationships cannot be concluded. One randomized, placebo-controlled study of patients with severe AAT deficiency (ZZ phenotype) did show a significant reduction in lung tissue loss and destruction as measured by computed tomographic (CT) scan in patients receiving augmentation therapy.⁸⁸ Other measures of lung function and mortality were not recorded.

The recommended dosing regimen for replacement AAT is 60 mg/kg administered intravenously once a week at a rate of 0.08 mL/kg per minute, adjusted to patient tolerance. It has been estimated that this form of augmentation therapy will have an annual cost of \$20,000 to \$30,000 per patient.⁸⁹ There have been repeated problems with supply of this biologic replacement therapy (derived from pooled blood donors) related to production difficulty and contamination issues. Currently, there are three products available (Prolastin, Aralast, and Zemaira), which should minimize this problem in the future.

► TREATMENT: COPD Exacerbation

■ DESIRED OUTCOMES

The goals of therapy for patients experiencing exacerbations of COPD are (1) prevention of hospitalization or reduction in hospital stay, (2) prevention of acute respiratory failure and death, and (3) resolution of exacerbation symptoms and a return to baseline clinical status and quality of life. Various therapeutic options are summarized in  Table 27–13. Pharmacotherapy consists of intensification of bronchodilator therapy and a short course of systemic corticosteroids. Antimicrobial therapy is indicated in the presence of selected symptoms. Since the frequency and severity of exacerbations are closely related to each patient's overall health status, all patients should receive optimal chronic treatment, including smoking cessation, appropriate pharmacologic therapy, and preventative therapy such as vaccinations.

■ NONPHARMACOLOGIC THERAPY

■ CONTROLLED OXYGEN THERAPY

Oxygen therapy should be considered for any patient with hypoxemia during an exacerbation. Caution must be used, however, because many patients with COPD rely on mild hypoxemia to trigger their drive to breathe. In normal, healthy individuals, the drive to breathe is triggered by carbon dioxide accumulation. In patients with COPD who retain carbon dioxide as a result of their disease progression, hypoxemia rather than hypercapnia becomes the main trigger for their respiratory drive. Overly aggressive administration of oxygen to patients with chronic hypercapnia may result in respiratory depression and respiratory failure. Oxygen therapy should be used to achieve a PaO₂ of greater than 60 mm Hg or oxygen saturation of greater than

TABLE 27–13. Therapeutic Options for Acute Exacerbations of COPD

| Therapy | Comments |
|------------------------------------|---|
| Antibiotics | Recommended if two or more of the following are present: Increased dyspnea Increased sputum production Increased sputum purulence |
| Corticosteroids | Oral or intravenous therapy may be used. If intravenous is used, it should be changed to oral after improvement in pulmonary status. If continued longer than 14 days, then the dose should be tapered to avoid HPA axis suppression. |
| Bronchodilators | MDIs and DPIs equal in efficacy to nebulization. β -Agonists also may increase mucociliary clearance. Long-acting β -agonists should not be used for quick relief of symptoms or on an as-needed basis. |
| Controlled oxygen therapy | Titrate oxygen to desired oxygen saturation (>90%). Monitor arterial blood gas for development of hypercapnia. |
| Noninvasive mechanical ventilation | Consider for patients with acute respiratory failure. Not appropriate for patients with altered mental status, severe acidosis, respiratory arrest, or cardiovascular instability. |

90%. However, an ABG should be obtained after oxygen initiation to monitor carbon dioxide retention owing to hypoventilation.

■ NONINVASIVE MECHANICAL VENTILATION

Noninvasive positive-pressure ventilation (NPPV) provides ventilatory support with oxygen and pressurized airflow using a face or nasal mask with a tight seal but without endotracheal intubation. There have been numerous trials reporting the benefits of NPPV in patients with acute respiratory failure due to COPD exacerbations. In one meta-analysis of eight studies, NPPV was associated with lower mortality, lower intubation rates, shorter hospital stays, and greater improvements in serum pH in 1 hour compared with treatment with usual care alone.⁹⁰ The benefits seen with NPPV generally can be attributed to a reduction in the complications that often arise with invasive mechanical ventilation. Not all patients with COPD exacerbations are appropriate candidates for NPPV. Patients with altered mental status may not be able to protect their airway and thus may be at increased risk for aspiration. Patients with severe acidosis (pH <7.25), respiratory arrest, or cardiovascular instability should be not be considered for NPPV. Patients failing a trial of NPPV or those considered poor candidates may be considered for intubation and mechanical ventilation.

■ PHARMACOLOGIC THERAPY

■ BRONCHODILATORS

During exacerbations, intensification of bronchodilator regimens is used commonly. The doses and frequency of bronchodilators are increased to provide symptomatic relief. Short-acting β_2 -agonists are preferred owing to rapid onset of action. Anticholinergic agents may be added if symptoms persist despite increased doses of β_2 -agonists. In fact, combinations of these agents are employed often, although data are lacking about the benefit versus higher doses of one agent. Bronchodilators may be administered via MDIs or nebulization with equal efficacy. Nebulization may be considered for patients with severe dyspnea who are unable to hold their breath after actuation of an MDI. Clinical evidence supporting the use of theophylline during exacerbations is lacking, and thus theophylline generally should be avoided. However, addition of one of these agents may be considered for patients not responding to other therapies. The risk of adverse effects such as cardiac arrhythmias should be considered and serum levels monitored closely.

■ CORTICOSTEROIDS

Until recently, the literature supporting the use of corticosteroids in acute exacerbations of COPD was sparse. However, since 1996, five studies have been performed that document the value of systemic corticosteroids in exacerbations of COPD.^{91–95} The Systemic Corticosteroids in Chronic Obstructive Pulmonary Disease Exacerbations (SCCOPE) trial evaluated three groups of patients hospitalized for exacerbations of COPD.⁹¹ The first group received an 8-week course of corticosteroids given as methylprednisolone 125 mg intravenously every 6 hours for 72 hours, followed by once-daily oral prednisone (60 mg on days 4 through 7, 40 mg on days 8 through 11, 20 mg on days 12 through 43, 10 mg on days 44 through 50, and 5 mg on days 51 through 57). The second group received a 2-week course given as

methylprednisolone 125 mg intravenously every 6 hours for 72 hours, followed by oral prednisone (60 mg on days 5 through 7, 40 mg on days 8 through 11, and 20 mg on days 12 through 15) and placebo on days 16 through 57. The third group received placebo for all 57 days of study. Rates of treatment failure and hospital stay were significantly higher in the placebo group than in either treatment group at 30 and 90 days. Groups randomized to corticosteroid treatment also had a significantly shorter length of hospital stay compared with the placebo group. The 8-week regimen was not found to be superior to the 2-week regimen. Significant treatment benefits were no longer evident at 6 months.

Davies and colleagues⁹² evaluated the oral use of corticosteroids in hospitalized patients with acute exacerbations of COPD. Patients received either 30 mg/day oral prednisolone or placebo for 14 days. Patients who were treated with corticosteroids had a significantly more rapid improvement in FEV₁ and a shorter hospital stay than did patients who received placebo. There was no significant difference between groups at 6-week follow-up.

In total, results from these trials suggest that patients with acute exacerbations of COPD should receive a short course of intravenous or oral corticosteroids. However, because of the large variability in dosage ranges, the optimal dose and duration of corticosteroid treatment are not known. It appears that short courses (9 to 14 days) are as effective as longer courses and have a lower risk of associated adverse effects owing to less time of exposure. Several trials used high initial doses of steroids before tapering to a lower maintenance dose. Adverse effects such as hyperglycemia, insomnia, and hallucinations may occur at higher doses. Depending on the clinical status of the patient, treatment may be initiated at a lower dose or tapered more quickly if these effects occur. If steroid treatment is continued for greater than 2 weeks, a tapering oral schedule should be employed to avoid hypothalamic-pituitary-adrenal (HPA) axis suppression.

■ ANTIMICROBIAL THERAPY

Most acute exacerbations of COPD are thought to be caused by viral or bacterial infections. However, as many as 30% of exacerbations are caused by unknown factors.¹ A meta-analysis of nine studies evaluating the effectiveness of antibiotics in treating exacerbations of COPD determined that patients receiving antibiotics had a greater improvement in peak expiratory flow rate than those who did not.⁹⁶

◀ This meta-analysis concluded that antibiotics are of most benefit and should be initiated if at least two of the following three symptoms are present: increased dyspnea, increased sputum volume, and increased sputum purulence. The utility of sputum Gram stain and culture is questionable because some patients have chronic bacterial colonization of the bronchial tree between exacerbations.

The emergence of drug-resistant organisms has mandated that antibiotic regimens be chosen judiciously. Selection of empirical antimicrobial therapy should be based on the most likely organism(s) thought to be responsible for the infection based on the individual patient profile. The most common organisms for any acute exacerbation of COPD are *Hemophilus influenzae*, *Moraxella catarrhalis*, *Streptococcus pneumoniae*, and *Hemophilus parainfluenzae*. More virulent bacteria may be present in patients with more complicated acute exacerbations of COPD, including drug-resistant pneumococci, β -lactamase-producing *H. influenzae* and *M. catarrhalis*, and enteric gram-negative organisms, including *Pseudomonas aeruginosa*. Table 27–14 summarizes recommended antimicrobial therapy for exacerbations of COPD and the most common organisms based on patient presentation.⁹⁷

TABLE 27–14. Recommended Antimicrobial Therapy in Acute Exacerbations of COPD

| Patient Characteristics | Likely Pathogens | Recommended Therapy |
|---|--|---|
| Uncomplicated exacerbations < 4 exacerbations per year No comorbid illness FEV ₁ > 50% of predicted | <i>S. pneumoniae</i> <i>H. influenzae</i> <i>M. catarrhalis</i> <i>H. parainfluenzae</i> Resistance uncommon | Macrolide (azithromycin, clarithromycin) Second- or third-generation cephalosporin Doxycycline Therapies not recommended ^a : TMP/SMX, amoxicillin, first-generation cephalosporins, and erythromycin |
| Complicated exacerbations Age ≥ 65 > 4 exacerbations per year FEV ₁ < 50% but > 35% of predicted | As above plus drug-resistant pneumococci, β-lactamase-producing <i>H. influenzae</i> and <i>M. catarrhalis</i> | Amoxicillin/clavulanate Fluoroquinolone with enhanced pneumococcal activity (levofloxacin, gatifloxacin, moxifloxacin) |
| Complicated exacerbations with risk of <i>P. aeruginosa</i> Chronic bronchial sepsis ^b Need for chronic Corticosteroid therapy Resident of nursing home > 4 exacerbations per year FEV ₁ > 35% of predicted | Some enteric gram-negatives As above plus <i>P. aeruginosa</i> | Fluoroquinolone with enhanced pneumococcal and <i>P. aeruginosa</i> activity (levofloxacin, gatifloxacin, moxifloxacin) IV therapy if required: β-lactamase resistant penicillin with antipseudomonal activity Third- or fourth-generation cephalosporin with antipseudomonal activity |

^aTMP/SMX should not be used due to increasing pneumococcal resistance; amoxicillin and first-generation cephalosporins are not recommended due to β-lactamase susceptibility; and erythromycin is not recommended due to insufficient activity against *H. influenzae*.

^bIn sepsis, double antipseudomonal coverage should be considered (e.g., addition of aminoglycoside).

Adapted from ref. 87.

Therapy with antibiotics generally should be continued for at least 7 to 10 days. Studies evaluating shorter treatment courses (usually 5 days) with the fluoroquinolones, second- and third-generation cephalosporins, and macrolide antimicrobials have demonstrated comparable efficacy with the longer treatment regimens.⁹⁸ If the patient deteriorates or does not improve as anticipated, hospitalization may be necessary, and more aggressive attempts should be made to identify potential pathogens responsible for the exacerbation.

■ COMPLICATIONS

■ COR PULMONALE

Cor pulmonale is right-sided heart failure secondary to pulmonary hypertension. Long-term oxygen therapy and diuretics have been the mainstays of therapy for cor pulmonale. Increasing the PaO₂ above 60 mm Hg with supplemental oxygen therapy decreases pulmonary hypertension and thus decreases the force against which the right ventricle has to work. While diuretics may help decrease fluid overload, caution should be used because patients with significant right-sided heart failure are highly dependent on preload for cardiac output. Therefore, the decision to use diuretics must be based on a risk-benefit ratio. Digitalis glycosides have no role in the treatment of cor pulmonale.

Other pharmacologic agents that have been investigated to treat cor pulmonale include hydralazine, calcium channel blockers,

angiotensin-converting enzyme inhibitors, and angiotensin II antagonists. However, there is insufficient evidence to offer guidelines for the role of these agents in COPD patients with cor pulmonale.

■ POLYCYTHEMIA

Polycythemia secondary to chronic hypoxemia in COPD patients can be improved by either oxygen therapy or periodic phlebotomy if oxygen therapy alone is not sufficient. COT was shown by the Nocturnal Oxygen Therapy Trial Group to reduce hematocrit values in treated patients.³¹ Acute phlebotomy is indicated if the hematocrit is above 55% to 60% and the patient is experiencing central nervous system effects suggestive of sludging from high blood viscosity. Long-term oxygen then can be used to maintain a lower hematocrit.

■ OTHER PHARMACOLOGIC CONSIDERATIONS

A number of other treatments have been explored over the years. Among these therapies, there is either insufficient evidence to warrant recommending their use, or they have been proven to not be beneficial in the management of COPD. A brief summary is provided because the clinician likely will encounter patients who are receiving or inquire about these treatments.

■ SUPPRESSIVE ANTIMICROBIAL AGENTS

Because COPD patients often are colonized with bacteria and experience recurrent exacerbations of their condition, a common practice employed in the past has been the use of low-dose antimicrobial therapy as preventative or prophylaxis against these acute exacerbations. However, clinical studies over the past 40 years have failed to demonstrate any benefit from this practice.¹ The role of antimicrobial therapy is limited to acute exacerbations of COPD meeting specific criteria.

■ EXPECTORANTS AND MUCOLYTICS

Adequate water intake generally is acceptable to maintain hydration and assist in the removal of airway secretions. Beyond this, the regular use of mucolytics or expectorants for COPD patients has no proven benefit.⁹⁹ This includes the use of saturated solutions of potassium iodide, ammonium chloride, acetylcysteine, and guaifenesin.

■ RESPIRATORY STIMULANTS

There is no role for respiratory stimulants in the long-term management of COPD.¹ Agents that have shown some utility in the acute setting include amiltrine and doxapram. However, amiltrine is available only in Europe, and its usefulness is limited by neurotoxicity. Doxapram is available for intravenous use only and may be no better than intermittent NPPV.

■ SURGICAL INTERVENTION

Recent trials have evaluated the effect of bilateral lung volume reduction surgery (LVRS) for management of severe COPD. Short-term trials comparing the effects of pulmonary rehabilitation plus LVRS with pulmonary rehabilitation alone reported that the combination of treatments resulted in greater improvements in lung function, gas exchange, and quality of life at 3 months.

Only recently have data evaluating the long-term effect of LVRS compared with pulmonary rehabilitation been published. The National Emphysema Treatment Trial (NETT), a prospective, randomized trial evaluating the long-term effects of LVRS plus pulmonary rehabilitation compared with pulmonary rehabilitation alone, followed 1218 patients for 3 years.¹⁰⁰ The primary end points for the study were mortality and maximal exercise capacity 2 years after randomization. Secondary end points included pulmonary function, distance walked in 6 minutes, and quality-of-life measurements. At an interim analysis, patients with an FEV₁ of less than 20% of predicted or a carbon monoxide diffusing capacity of less than 20% of predicted were noted to be at high risk of death after surgery and subsequently were excluded from the study. Results of the study showed no mortality benefit

with LVRS compared with pulmonary rehabilitation alone. Patients undergoing surgery had improved exercise capacity, lung function, and quality of life at 2 years, but these patients also had a higher risk of short-term morbidity and mortality associated with the surgery. A subgroup analysis of the study noted that patients with predominantly upper-lobe emphysema and low exercise capacity undergoing surgery had lower mortality rates at 2 years compared with patients treated with medical therapy alone. Because of the costs and risks associated with LVRS, more studies are needed to better determine the ideal surgical candidates and identify subgroups of patients that would benefit most from surgery.

■ DIETARY SUPPLEMENTS

There has been increasing interest in the role of antioxidants, including vitamins E and C and β -carotene, in reducing the frequency of exacerbations. It is postulated that they may be beneficial in COPD as a result of an imbalance between oxidants and antioxidants that has been considered in the pathogenesis of smoking-induced lung disease. However, there is no good evidence that antioxidant therapies improve COPD symptoms or slow disease progression.

■ INVESTIGATIONAL THERAPIES

Based on the knowledge about the importance of neutrophilic inflammation in COPD and potential therapeutic benefit of inhibition of neutrophil activity, a number of anti-inflammatory compounds are being explored. Specifically, agents inhibiting leukotriene B₄, neutrophil elastase, and phosphodiesterases currently are being evaluated. To date, studies evaluating leukotriene-modifying therapies have been disappointing. Further studies are needed to evaluate the clinical benefit of such inhibitors in patients with COPD.

Phosphodiesterase 4 (PDE4) is the major phosphodiesterase found in airway smooth muscle cells and inflammatory cells and is responsible for degrading cAMP. Inhibition of PDE4 results in relaxation of airway smooth muscle cells and decreased activity of inflammatory cells and mediators such as TNF- α and IL-8. Two PDE₄ inhibitors have reached clinical trials, cilomilast and roflumilast. Cilomilast has been evaluated in several human trials and has been shown to improve expiratory airflow as measured by FEV₁ in patients with COPD when given at a dose of 15 mg twice daily for 6 weeks. Future studies of cilomilast should evaluate its effects on other clinical outcomes such as health status, exacerbation frequency, and progression of disease.

Neutrophil elastase is implicated in the induction of bronchial disease, causing structural changes in lungs, impairment of mucociliary clearance, and impairment of host defenses. Protease inhibitors, namely, inhibitors of neutrophil elastase, are being investigated currently for the treatment of COPD.

PHARMACOECONOMIC CONSIDERATIONS

The overall cost of therapy is an important consideration in contemporary medical practice. Meaningful cost analysis goes beyond the cost of the medication itself and incorporates the impact of a given therapeutic agent on overall health care cost. Because of the relative lack of benefit among objective outcome measures in COPD

clinical trials, pharmacoeconomic studies can be useful in decision making about pharmacotherapy options. Pharmacoeconomic analyses in COPD, although limited, are available regarding antibiotic use in acute exacerbations and some therapies for management of chronic stable COPD.

Grossman and colleagues¹⁰¹ conducted a trial investigating the use of aggressive antimicrobial therapy (ciprofloxacin) compared with

usual antibiotic therapy (defined as any nonquinolone) in the treatment of acute exacerbations of COPD. Overall, the results indicated no preference for either treatment arm. However, in patients who were categorized as high risk (severe underlying lung disease, more than four exacerbations per year, duration of bronchitis greater than 10 years, elderly, significant comorbid illness), the use of aggressive antibiotic therapy was associated with improved clinical outcome, higher quality of life, and fewer costs. The results of this study are consistent with Table 27–14, which suggests that higher-risk patients are likely to have more resistant strains of organisms and thus require more aggressive antimicrobial treatment.

Friedman and colleagues¹⁰² conducted a post hoc pharmacoeconomic evaluation of two multicenter, randomized trials comparing the combination of ipratropium and albuterol with both drugs used as monotherapy. Patients who received a combination of ipratropium and albuterol had lower rates of exacerbations, lower overall treatment costs, and improved cost-effectiveness compared with either drug used alone. With the introduction of new bronchodilator therapies, and with no clearly consistent advantage of one class of agents over another, pharmacoeconomic analyses may be useful for clinicians in determining the most appropriate therapy for their patients.

CLINICAL CONTROVERSIES

Albuterol is one of the most commonly prescribed medications in the United States. Albuterol is a 50/50 racemic mixture of (*R*)-albuterol and (*S*)-albuterol, with the (*R*)-isomer responsible for all the therapeutic effect. A single-isomer product, levalbuterol, claims clinical superiority based on the absence of the (*S*)-isomer, which may have detrimental effects in the airway and antagonistic effects on the active isomer. However, the acquisition cost of levalbuterol is significantly higher than that of generic albuterol. The advantages of using the single-isomer product in clinical practice are not clear.

A combination product of a long-acting inhaled β -agonist (salmeterol) and an inhaled corticosteroid agent (fluticasone) is one of the most commonly prescribed medications for lung disease, including COPD. However, in expert guidelines, inhaled corticosteroids are indicated only for patients with more severe disease who experience frequent exacerbations. Many patients now receiving therapy with the combination inhaler may be candidates for bronchodilator therapy alone.

The role of systemic corticosteroids for acute exacerbations of COPD has been clarified in recent years. However, the appropriate dosage regimen is not well established. Regimens range from initial high doses (methylprednisolone 125 mg every 6 hours) to more conservative dosing (prednisone 40–60 mg/day).

Consensus guidelines indicate that bronchodilator therapy is the focus of pharmacotherapy for COPD. However, there is no clear choice for the initial agent. For patients with daily but not persistent symptoms, either ipratropium or albuterol offers advantages as initial therapy. Both also have limitations if chosen as the initial therapy.

EVALUATION OF THERAPEUTIC OUTCOMES

To evaluate therapeutic outcomes of COPD effectively, the practitioner must first delineate between chronic stable COPD and acute exacerbations. In chronic stable COPD, pulmonary function tests should be assessed periodically and with any therapy addition, change

in dose, or deletion of therapy. Because objective improvements often are minimal, subjective assessments are important. Other outcome parameters are commonly evaluated, including dyspnea score, quality-of-life assessments, and exacerbation rates, including visits to the emergency department or hospitalization. In acute exacerbations of COPD, white blood cell count, vital signs, chest x-ray, and changes in frequency of dyspnea, sputum volume, and sputum purulence should be assessed at the onset and throughout treatment of an exacerbation. In more severe exacerbations, ABGs and oxygen saturation also should be monitored. As with any drug therapy, patient adherence to therapeutic regimens, side effects, potential drug interactions, and subjective measures of quality of life also must be evaluated.

ACUTE RESPIRATORY DISTRESS SYNDROME

Peter Gal and J. Laurence Ransom

Learning Objectives and other resources can be found at www.pharmacotherapyonline.com.

KEY CONCEPTS

- 1 Neonatal respiratory distress syndrome (RDS) is predominantly a disease of surfactant deficiency.
- 2 Antenatal steroids markedly reduce the incidence of neonatal RDS and some other complications of prematurity.
- 3 Surfactant prophylaxis and replacement therapy markedly reduce RDS-related pulmonary morbidity and mortality.
- 4 Acute respiratory distress syndrome (ARDS) is a syndrome presenting with bilateral pulmonary infiltrates, high oxygen requirements ($\text{PaO}_2/\text{FiO}_2 < 200$ mm Hg), and noncardiogenic pulmonary edema.
- 5 Acute lung injury (ALI) is similar to ARDS but with milder gas exchange abnormalities (i.e., $\text{PaO}_2/\text{FiO}_2 < 300$ mm Hg).
- 6 Causes of ARDS may be pulmonary or extrapulmonary, and responses to interventions may differ with etiology.
- 7 Mechanical ventilation is the foundation for treatment and prevention of ARDS.
- 8 For both RDS and ARDS, ventilator maneuvers to minimize barotrauma and volutrauma are critical to management. Ventilator management remains more an art than a science.
- 9 Anti-inflammatory therapies (pharmacologic and nutrition) offer theoretical therapeutic advantages for managing ARDS, but compelling evidence describing when and how to use them is not yet available.

This chapter addresses the problems of acute respiratory distress syndromes in neonates, children, and adults. Abbreviations are used throughout the text, and a glossary for physiology, diseases, and drugs is presented in Table 28–1. Descriptions of ventilator-related terms are provided in Tables 28–2 and 28–3. Because the physiology of neonatal respiratory distress syndrome (RDS) and acute respiratory distress syndrome (ARDS) has some differences, these diseases will be discussed separately.

NEONATAL RESPIRATORY DISTRESS SYNDROME (RDS)

1 RDS, historically known as *hyaline membrane disease* (HMD), is more appropriately termed *surfactant-deficiency RDS*. RDS is associated with considerable morbidity and mortality. Before 35 weeks' gestation, the risk of RDS and the severity of disease increase with greater degree of prematurity and, in the absence of appropriate antenatal interventions, occurs in over 50% of newborns of 30 weeks' or less gestation. The Vermont Oxford Network experience for 1999 describes over 27,000 neonates below 1500 g from 325 neonatal intensive care unit (NICU) sites.¹ The annual report noted that RDS occurred in over 80% of premature infants below 1000 g and that there was a gradual decline to about 42% of neonates with birth weights between 1400 and 1500 g.

RDS is attributed primarily to insufficient formation and differentiation of type II pneumocytes with consequent impaired production and release of surfactant. Pulmonary surfactant contains phospholipids that function at the air-liquid interface in the alveolus to lower surface tension, thus preventing alveolar collapse. In the face

of surfactant deficiency, atelectasis and impaired gas exchange occur. Additionally, alveolar transudation of protein-rich fluid forms a hyaline membrane, giving rise to the term *hyaline membrane disease*.²

Epithelial sodium channel (ENaC) maturation also appears important in RDS. In utero, fluid is actively secreted into lungs via chloride channels. At birth, the ENaC takes over, and fluid is actively reabsorbed from the lungs. In premature infants, immaturity of the ENaC results in failure to reabsorb lung fluid, with consequent pulmonary edema.³ In term infants, this conversion occurs at birth in response to circulating catecholamines. Failure of the conversion to occur in preterm infants results in an inability to clear alveolar fluid and consequent pulmonary edema.³

Measurement of lung maturation in amniotic fluid using biochemical markers of surfactant deficiency is an important consideration in preventive and therapeutic interventions, as well as in predicting the likelihood of developing RDS. Measurement of surfactant components in amniotic fluid using either the ratio of lecithin to sphingomyelin (L/S ratio) or phosphatidylglycerol (PG) have been particularly useful for confirming lung maturity. PG is the better test because, unlike the L/S ratio, it is reliable in the presence of blood, meconium, or maternal diabetes. Also, turnaround time for PG is more rapid.⁴ A positive PG test or L/S ratio is associated with a sensitivity of 95% to 99% and a positive predictive value of 97% to 98%. Both tests suffer from limited specificity (50% to 70%) and limited negative predictive value (54% to 56%). Thus a test result indicating immaturity does not ensure development of RDS, but a test indicating maturity makes RDS very unlikely.⁴ RDS severity and risk are made worse by a variety of perinatal factors, including perinatal hypoxia or asphyxia, acidosis, cold stress, patent ductus arteriosus, and maternal diabetes mellitus. These factors may further compromise

TABLE 28–1. Glossary of Terms and Abbreviations

| | |
|-------------------|--|
| ENaC | Epithelial sodium channel |
| L/S ratio | Lecithin/sphingomyelin ratio |
| PG | Phosphatidylglycerol |
| CXR | Chest x-ray |
| RDS | Neonatal respiratory distress syndrome |
| HMD | Hyaline membrane disease |
| PIE | Pulmonary interstitial emphysema |
| BPD | Bronchopulmonary dysplasia |
| IVH | Intraventricular hemorrhage |
| PVL | Periventricular leukomalacia |
| PDA | Patent ductus arteriosus |
| NEC | Necrotizing enterocolitis |
| ARDS | Acute respiratory distress syndrome |
| ALI | Acute lung injury |
| PCWP | Pulmonary capillary wedge pressure |
| CO | Cardiac output |
| TRH | Thyrotropin releasing hormone |
| SRT | Surfactant replacement therapy |
| PFC | Perfluorocarbon |
| NO | Nitric oxide |
| ABG | Arterial blood gas |
| PaO ₂ | Arterial blood gas oxygen |
| PaCO ₂ | Arterial blood gas carbon dioxide |
| SaO ₂ | Oxygen saturation |
| MvO ₂ | Mixed venous saturation |
| ECMO | Extracorporeal membrane oxygenation |
| VILI | Ventilator-induced lung injury |
| MODS | Multiple organ dysfunction syndrome |

pulmonary blood supply, consequently causing death of an already limited number of type II alveolar cells and limiting surfactant production.

Chronic intrauterine stress, on the contrary, lowers the risk of RDS by promoting lung maturation, perhaps by increasing endogenous glucocorticoid concentrations.²

CLINICAL PRESENTATION

The presentation of neonatal RDS is summarized in Table 28–4 and is illustrated in Fig. 28–1. A number of neonatal disorders may mimic

and be indistinguishable from RDS, the most important being sepsis caused by group B β -hemolytic *Streptococcus*, pneumococcus, or gram-negative bacilli. Sepsis is a common concurrent problem with RDS and may alter the response to therapy.⁵ All neonates with suspected RDS should be evaluated for sepsis. Antibiotics should be used until sepsis can be ruled out or a full therapeutic course is completed. Other etiologies for RDS include transient tachypnea of the newborn, spontaneous pneumothorax, congenital cyanotic heart disease, and diaphragmatic hernia.

PREVENTION

Several perinatal/antenatal interventions can be adopted to prevent or minimize the severity of RDS. These include optimizing care at labor and delivery and control of maternal diseases to avoid factors known to predispose to RDS. Additionally, drug therapy to delay premature delivery (tocolytics) or to assist with lung maturation (steroids) can be instituted (Fig. 28–2). Early initiation of antibiotics to treat bacterial vaginosis and trichomoniasis also has been associated with significant reduction in preterm births.^{6,7}

Tocolysis can be expected to delay delivery for 2 to 7 days.⁶ However, this may provide sufficient time to resolve a reversible etiology or promote fetal lung maturation. Up to 80% of women with presumptive preterm labor will not have a preterm delivery. Recently it was suggested that measuring fetal fibronectin to identify patients unlikely to have a preterm delivery may be better than treating all patients with symptoms of preterm labor or waiting for cervical changes that will reduce the likelihood of successful inhibition of labor.⁶ Contraindications to tocolytic therapy include fetal death or lethal abnormality, eclampsia, abruptio placentae, and proven chorioamnionitis. Relative contraindications are preeclampsia, severe chronic hypertension, renal disease, heart disease, fetal distress, and fetal growth retardation. Of the tocolytics commonly used (i.e., β -sympathomimetics, calcium channel blockers, magnesium sulfate, and nonsteroidal anti-inflammatory drugs [NSAIDs]), none has clear advantages over the others, but different profiles for maternal and fetal toxicities must be considered.^{6,8} Only short courses of tocolytics can be justified to allow time to control the cause of preterm labor or to administer antenatal corticosteroids. Prolonged maintenance therapy has the same results as placebo.^{6,8}

TABLE 28–2. Glossary of Terms for Ventilator Settings and Management

| | |
|-------------------|---|
| Et | Expiratory time; in the ventilatory cycle, the amount of time devoted to exhalation. |
| It | Inspiratory time; in the ventilatory cycle, the amount of time devoted to inspiration. |
| I:E | Ratio of inspiratory time to expiratory time; in a normal, spontaneously breathing patient, this is 1:1.5. |
| PaO ₂ | Partial pressure of oxygen present in arterial blood; normal level for adults is 80–100 mm Hg; normal level for premature babies is 50–70 mm Hg. |
| PaCO ₂ | Partial pressure of carbon dioxide present in arterial blood; normal is 35–45 mm Hg, but higher levels are acceptable to minimize ventilator support. |
| PEEP | Positive end-expiratory pressure; positive pressure at the end of exhalation designed to prevent alveoli from collapsing during expiration. |
| PIP | Peak inspiratory pressure; the maximum level of pressure achieved by the ventilator during inspiration. |
| IMV | Intermittent mandatory ventilation; a mode of ventilation designed to deliver a preset inspiratory rate; continuous flow of gas is available for patient's spontaneous breaths. |
| FiO ₂ | Fraction (percentage) of inspired oxygen. |
| TV | Tidal volume; volume of gas delivered during a single inspiration. |
| MAP | Mean airway pressure; a constant distending pressure. |
| Hz | Hertz; normally described as cycles per second, this is the number of breaths per minute. |
| FRC | Functional residual capacity; the volume of air remaining in the lung after normal expiration. |
| Amp | Amplitude; a wavelike change in pressure centered around a mean airway pressure. |
| Sigh | A breath that recruits and maintains alveolar patency, used in HFJV; similar to pressure provided with PIP. |
| CWF | Chest wiggle factor; a clinical observation ensuring appropriate chest wall movement with HFOV. |
| BPM | Breaths per minute. |

TABLE 28–3. Mechanical Ventilator Types and Modes of Ventilation

| | |
|-------|---|
| CMV | Controlled mechanical ventilation; a ventilator mode in which RR + TV are under machine, rather than, patient control. |
| AC | Assist control; mode in which patient receives a full TV if the patient breathes over the ventilator. |
| PC | Pressure control; ventilator delivers a TV until a certain pressure is achieved. |
| SIMV | Synchronized intermittent mandatory ventilation; a ventilator breath “synchronized” with patient’s inspiratory effort. |
| PS | Pressure support; pressure on inspiration designed to assist generation of tidal volume. |
| IRV | Inverse ratio ventilation; ventilator mode in which inspiratory time is prolonged in comparison to expiration time. Used to decrease plateau pressure and improve oxygenation. |
| HFOV | High-frequency oscillatory ventilation; a mechanical diaphragm produces oscillations superimposed on a constant gas flow. Can provide from 180 to 900 breaths per minute. Both inspiration and expiration are actively promoted. |
| HFJV | High-frequency jet ventilation; small volumes of air are released in a pulsating fashion through a jet nozzle, and directed down the airway in a patient simultaneously receiving conventional ventilation. Can provide from 240 to 660 breaths per minute. Inspiration is active, but expiration is passive, predisposing to air trapping. |
| HFFI | High-frequency flow interruption; similar to HFJV, but air pulses are delivered at lower pressures and volumes. |
| HFPPV | High-frequency positive-pressure ventilation; conventional mechanical ventilation at faster-than-usual rates. |
| PPAV | Patient proportional assist ventilation; a collective term describing ventilators using patient-controlled rates and tidal volumes. |
| OH | Oxygen hood; a clear plastic enclosure placed over a nonintubated infant to allow humidification of room air (21% F _O ₂ or increased F _O ₂). |

3 Fetal lung maturation can be accelerated with antenatal corticosteroids. The National Institutes of Health (NIH) consensus conference in 1994 concluded that all fetuses between 24 and 34 weeks’ gestation at risk for preterm delivery should receive corticosteroids regardless of gender, race, maternal infection, and availability of surfactant. A report by the National Institutes of Child Health and Development Neonatal Research Network noted that antenatal steroid use was associated with fewer pulmonary problems and mortality.⁹ Many women who are appropriate candidates are

still untreated.⁹ Treatment with three or more courses of antenatal steroids is discouraged because of concerns for impaired fetal growth and long-term neurodevelopmental delays, although further studies to evaluate the validity of this conclusion are needed.¹⁰ Use of one or two courses of antenatal steroid therapy is relatively devoid of toxicity and markedly improves neonatal morbidity and mortality. Betamethasone appears to provide superior benefits to dexamethasone.¹¹ The odds ratio (95% confidence interval [CI]) for developing RDS is reduced to 0.49 (95% CI 0.41–0.6) if steroids are started 24 hours to 7 days before

TABLE 28–4. Presentation of Neonatal RDS**General**

The patient will appear in acute respiratory distress, which will worsen progressively to respiratory failure. Fluid retention, edema, and oliguria are common in the first 48 hours of untreated RDS.

Signs and Symptoms

Within the first few hours of life the patient will have expiratory grunting, intercostal respiratory retractions, use of accessory neck muscles, paradoxical seesaw respirations, tachycardia, pallor, cyanosis, and progressively increased oxygen requirements.

Laboratory Tests

Obstetricians may obtain amniotic fluid to measure the lecithin-sphingomyelin (L/S) ratio or phosphatidylglycerol (PG) to determine fetal lung maturity.

Since infection may cause RDS, a sepsis work-up is needed, i.e., WBC with differential, and blood culture. Arterial blood gases and oxygen saturation monitors can be used to evaluate for adequate oxygenation.

Other

Chest x-ray consistent with RDS shows a characteristic reticulogranular (ground-glass) pattern to the peripheral lung fields. The collapse of small airspaces around the large airways traps air in the large airways, making them easily visible. These are called *air bronchograms*. In severe RDS, lungs may appear as a total whiteout. Progression of RDS should be monitored with repeat chest x-rays. If echocardiography is performed to evaluate for presence of a patent ductus arteriosus, the elevated pulmonary pressure may cause shunting right to left through the ductus arteriosus.

**FIGURE 28–1.** Chest x-ray demonstrating surfactant-deficient respiratory distress syndrome with ground glass appearance and air bronchograms.

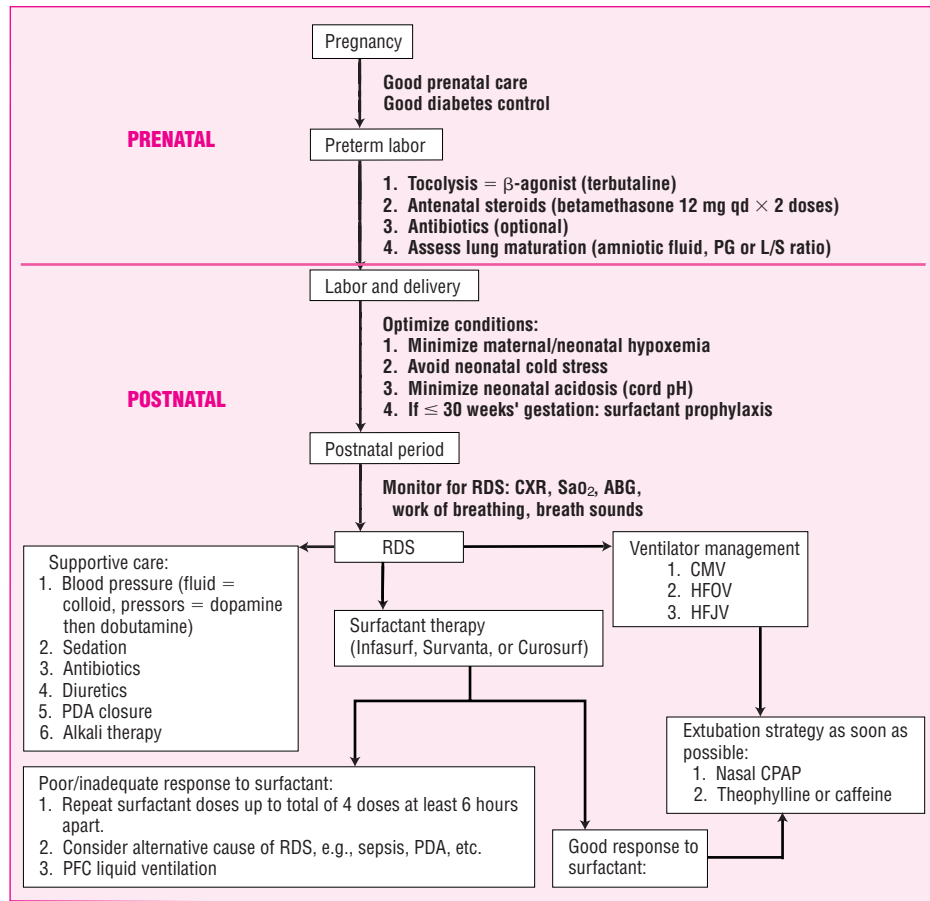

FIGURE 28–2. Algorithm for prevention and treatment of neonatal RDS.

delivery. Even if treatment is started less than 24 hours or more than 7 days from delivery, risk is still reduced (odds ratio [OR] 0.69, 95% CI 0.50–0.94).¹⁰ Antenatal steroids also reduced the risk of intraventricular hemorrhage (OR 0.5, 95% CI 0.3–0.9), necrotizing enterocolitis (OR 0.35, 95% CI 0.18–0.68), and neonatal mortality (OR 0.6, 95% CI 0.5–0.8).^{9,10} An estimated number of patients needed to treat (NNT) to prevent RDS in one preterm infant of less than 30 weeks' gestation, where RDS occurs in 50% of untreated cases, is 6 patients.^{10,11} One report estimated that over \$3000 was saved per treated neonate and that if treatment rates increased to 60%, annual savings in health care costs from initial hospitalization alone would exceed \$157 million. Even an incomplete course of betamethasone has been proven to provide benefits, primarily in the areas of reduced need for vasopressors and lower rates of intraventricular hemorrhage and death.¹¹

Use of thyrotropin-releasing hormone (TRH) as an adjunct to antenatal corticosteroids was thought to further accelerate fetal lung maturation.¹² However, the Australian Collaborative Trial of Antenatal Thyrotropin-Releasing Hormone (ACTOBAT) study failed to show additional benefits from TRH 200 mcg every 12 hours. The frequencies of RDS (relative risk [RR] 1.17, 95% CI 1.00–1.36) and need for ventilation (RR 1.15, 95% CI 1.01–1.31) were not reduced, and treatment was associated with maternal nausea, vomiting, and light-headedness. Of more concern was the 12-month follow-up report in which TRH treatment was associated with motor delays (OR 1.51, 95% CI 1.11–2.05), sensory impairment (OR 2.00, 95% CI 1.06–3.74), social delays (OR 1.41, 95% CI 1.01–1.95), and severe neurodevelopmental impairment (OR 1.75, 95% CI 1.07–2.87).¹³ At this point, antenatal TRH treatment cannot be advised.

► TREATMENT: Neonatal Respiratory Distress Syndrome

■ GENERAL APPROACH TO TREATMENT

Recently, treatment options for RDS have advanced significantly. Effective drug therapies include surfactant and perfluorocarbons (PFCs). Nitric oxide and extracorporeal membrane oxygenation (ECMO) have been used as final resorts. Supportive therapies such as mechanical ventilation, management of acidosis, and diuresis are also important. An algorithm for prevention and treatment of neonatal RDS is presented in Fig. 28–2.

■ NONPHARMACOLOGIC THERAPY

■ VENTILATOR THERAPY

8 Positive-pressure ventilation (PPV) provides vital support to maintain adequate ventilation and oxygenation during the acute phase of RDS. Effective PPV is accomplished by generating a pressure that exceeds the “closing” pressure of the lung. Ventilation modes delivering this positive pressure are conventional mechanical ventilation (CV), high-frequency ventilation (HFV), patient proportional

TABLE 28–5. Ventilator Management and Considerations in RDS

| Ventilator Type | Setting | Normal Initial Settings | | Advantages | Disadvantages |
|-----------------|----------------------------|-------------------------|---------|--|---|
| | | <1500 g | >1500 g | | |
| CMV | PIF (cm H ₂ O) | 18–20 | 20–22 | High inspiratory pressures allow “popping open” of alveoli | Larger tidal volumes and inspiratory pressures causing lung injury |
| | Target TV (mL/kg) | 4–6 | 6–8 | | |
| | PEEP (cm H ₂ O) | 4 | 4–5 | | |
| | IMV (bpm) | 40–60 | 40–60 | | |
| CPAP | (cm H ₂ O) | 5–7 | 6–8 | Little barotrauma/volutrauma | Lack of tidal volume |
| HFOV | MAP (cm H ₂ O) | 7–10 | 8–12 | Less risk of volutrauma/barotrauma | Risk for IVH/PVL? |
| | | | | Increased alveolar recruitment | Unable to give aerosolized respiratory medications |
| | | | | Approved for air-leak syndromes | Hypotension |
| | | | | Simple to operate | Increased mucostasis? |
| HFJV | Amplitude Hz | To appropriate CWF | | Increased CO ₂ removal | Risk for IVH/PVL? Two machines Increased gas trapping Unable to give respiratory medicines |
| | | 15 | 15 | | |
| | PIP (cm H ₂ O) | 18–20 | 20–22 | | |
| PPAV SIMV | PEEP (cm H ₂ O) | 4–5 | 4–5 | Less barotrauma due to “synchronizing” with patient’s own breath Patient-sensitive Reduced need for sedation | Lack of clinical experience |
| | Sigh rate (bpm) | 5–10 | 5–10 | | |
| | Rate (bpm) | 420 | 420 | | |
| | Rate (bpm) | 20–30 | 10–20 | | |
| | Volume (mL/kg) | 8–15 | 10–15 | | |

assist ventilation (PPAV), synchronized intermittent mandatory ventilation (SIMV), and continuous positive airway pressure (CPAP).² As ventilator technology advances, hybrids of the different ventilation modes also have been tried. A comprehensive review describing these modes of ventilation is beyond the scope of this chapter, and we recommend the reader to an excellent text.¹⁴

The increased neonatal survival seen today can be credited, in part, to the extensive technological advances in respiratory care, including mechanical ventilation. CV, employed since the early 1970s, is based on delivering a volume of air (tidal volume [TV]) by using inspiratory and expiratory pressures (positive inspiratory pressure/positive end-expiratory pressure [PIP/PEEP]) at a specific rate (intermittent mandatory ventilation [IMV]).¹⁵ Although successful, CV-induced lung morbidity has required continual assessment of ventilator modes that decrease baro- and volutrauma. A summary of these ventilation modes is given in Table 28–5, with the range of typical initial settings listed. Evidence is not yet compelling to recommend a preferred ventilator mode. The improved outcomes in premature infants also can be attributed to better understanding of neonatal physiology, most notably oxygen delivery optimization and cerebral protective effects of carbon dioxide. The oxygen-hemoglobin dissociation curves in neonates are shifted to the left as compared with adults, resulting in target PaO₂ values of 50 to 75 mm Hg and SaO₂ values greater than 90%. Whether oxygen saturation targets of 70% to 90% will become more acceptable is an area of future debate. One study of preterm infants of 28 or fewer weeks’ gestation compared neonates ventilated to target oxygen saturations of 70% to 90% with those targeted to 88% to 98%.¹⁷ Survival rates and cerebral palsy rates at 1 year were the same, but the lower saturation group had an average of 17 fewer days on mechanical ventilation and 56 fewer days on supplemental oxygen. In addition, complications of retinopathy of prematurity requiring

cryotherapy were one-fourth as frequent. This approach needs additional studies before it can be applied more broadly.

Allowing PaCO₂ to exceed 50 or even 60 mm Hg (called *permissive hypercapnia*) is a good strategy, provided that the blood pH remains acceptable, because it means that less aggressive ventilator pressures are needed. Too aggressive ventilation can result in hypocarbia, which is associated with periventricular leukomalacia and consequent neurodevelopmental delays. The more comprehensive understanding of neonatal physiology allows the clinician to use improved ventilator technologies and select strategies that allow for the most appropriate fit for the circumstance. For example, although CV remains a good choice for many neonates, those with pulmonary air leaks probably are managed more safely with high-frequency oscillatory ventilation (HFOV). Increasingly, HFOV using a “high volume” strategy, which avoids atelectasis, is being considered the preferred first-line ventilator therapy. This must be tempered by an inability of studies to show differences in outcomes between CV and HFOV. Since rapid and early ventilator weaning is becoming popular, and given that the optimal approach to weaning from HFOV is unknown, the pendulum may shift back to CV when prophylactic surfactant is used, and rapid advancement to extubation is anticipated.

The goals of CV are to achieve appropriate arterial blood gas parameters (PaO₂ of 50 to 75 mm Hg, PaCO₂ of 40 to 60 mm Hg, pH of 7.28 to 7.40), chest expansion (diaphragm position on an inspiratory film at ribs eight to nine), and avoidance of toxicities. Often a tradeoff of either higher FIO₂ or higher PIP must be made. Using permissive hypercapnea so that less aggressive ventilator pressures are needed appears the safer approach, but data proving this bias are lacking.

Such decisions thus involve clinician bias and the “art” of medicine rather than being based on a strong scientific basis.

Early conversion from ventilator modes requiring endotracheal intubation to nasal CPAP, even in infants as young as 25 weeks' gestation, is associated with reduced chronic lung disease at 28 days (NNT = 6).¹⁵ This is aided markedly by concurrent use of methylxanthines to increase respiratory drive (NNT = 3.7 in infants < 1000 g).¹⁶

CLINICAL CONTROVERSY

Clinicians disagree on the best ventilator approach for managing RDS while avoiding chronic lung disease. There is consensus, however, that all modes of positive-pressure ventilation damage lungs and that patients should be extubated as soon as possible.

PHARMACOLOGIC THERAPY

SURFACTANT THERAPY

Surfactant replacement therapy (SRT) is widely accepted as the most clinically acceptable and cost-effective approach to the treatment of RDS. Clinical trials have been carried out worldwide using an array of artificial, modified natural, and natural surfactants. Natural surfactants are either processed extracts of minced lungs or extracts of lavaged surfactant, which affects the surfactant protein makeup of the preparation. The differences in preparations can be discerned from key components and dosing strategies, which are summarized in Table 28–6.

Natural human surfactant contains 85% phospholipids, 10% neutral lipids, and 5% surfactant proteins or apolipoproteins. Animal surfactants have similar protein and lipid content. Surfactant is synthesized in type II pneumocytes in the alveoli. After secretion, the major

route of clearance is via reuptake by type II cells. Small quantities are removed by absorption into the lymphatics and clearance by alveolar macrophages. After reuptake into the type II cells, the phospholipids are either recycled for secretion or degraded and reused to synthesize new phospholipids.^{18,19}

Most exogenous surfactants incorporate dipalmitoyl phosphatidylcholine (DPPC), which constitutes 45% to 70% of endogenous lung surfactant and is the major phospholipid causing the low surface tension of surfactant. Other phospholipids, mainly phosphatidyl ethanolamine, phosphatidyl glycerol, phosphatidylinositol, and sphingomyelin, are responsible for adsorbing to the air-liquid interface. Four surfactant proteins (SP-A, SP-B, SP-C, and SP-D) comprise 2% to 5% of the weight of natural surfactant.^{18,19} SP-A appears to regulate pulmonary surfactant turnover, formation of tubular myelin, and immune regulation. Since natural surfactant products undergo an organic solvent extraction procedure, no substantial quantities of SP-A are present in these products. SP-B appears to be involved in the formation of tubular myelin. It is also the most active hydrophobic protein in improving the surface activity of surfactant, perhaps by increasing the lateral stability of the phospholipid layer. Increasing SP-B content of surfactant preparations is associated with increased activity and resistance to inactivation by various endogenous substances. Genetic deficiency of SP-B in full-term infants results in death from respiratory failure. SP-C is speculated to be involved in the spreadability and surface activity of surfactant by increasing the adsorption of DPPC and other phospholipids to the air-liquid interface. SP-D function is unknown, but it has the structure of lectins and proteins responsible for bacterial opsonization.^{18,19}

When given in the delivery room as prophylaxis, natural surfactant can be given as a single bolus down the endotracheal tube, although the manufacturers still recommend divided doses using the same procedure as for treatment.²⁰ For neonates with established RDS

TABLE 28–6. Exogenous Surfactants Used for the Treatment of Neonate with Respiratory Distress Syndrome

| Surfactant Type Dose (mg/kg)/Volume (mL/kg) | Source | Components | Concentration (g/L) | Initial Dose (mg/kg) |
|--|---|---|------------------------|-------------------------|
| Artificial surfactants | | | | |
| Pulmactant (ALEC) 100/1.2 | Synthetic | DPPC, unsaturated phosphatidylglycerol | 100 | 100 |
| Colfosceril palmitate (Exosurf) 67.5/5 | Synthetic | DPPC, hexadecanol, tyloxapol | 13.5 | 67.5 |
| Human surfactants | | | | |
| Human 60/3 | Aminotic fluid whole surfactant | Surfactant lipids, SP-A, SP-B (2.0–5.0%), SP-C, SP-D | 20 | 60–70 |
| Animal surfactants | | | | |
| Calfactant (Infasurf) 100/3 | Calf lung lavage | Surfactant lipids, SP-B (1.7%), SP-C | 25 | 100 |
| CLSE 100/3 | Calf lung lavage | Surfactant lipids, SP-B (1.7%), SP-C | 30 | 90 |
| SFRI 1 (Alveofact) 50/1.2 | Cow lung lavage | Surfactant lipids, SP-B (1.7%), SP-C | 45 | 50 |
| Poractant alfa (Curosurf) Dose 1: 200/2.5 Doses 2–4 100/1.25 | Minced pig lung extract purified by chromatography | Lung phospholipids, SP-B (0.2%), SP-C | 80 | 200 |
| Surfacten (Surfactant-TA) 100/4 | Minced cow lung extract + synthetic lipids | Lung lipids + DPPC, tripalmitin, palmitic acid | 30 | 100 |
| Beractant (Survanta) 100/4 | Minced cow lung extract + synthetic lipids acid, | Lung lipids + DPPC, tripalmitin, palmitic acid, SP-B (<0.1%), SP-C | 25 | 100 |

ALEC = artificial lung expanding compound; CLSE = calf lung surfactant extract; DPPC = dipalmitoyl phosphatidylcholine; SP-A = surfactant protein A; SP-B = surfactant protein B; SP-C = surfactant protein C. Doses reported per milligram of phospholipid and milliliter of surfactant product.

who are stabilized on the ventilator, surfactant is best administered via a sideport in the endotracheal adapter in two bolus fractional doses at a 45-degree upward tilt angled to the right and then left.²⁰ Animal studies confirm that the bolus technique delivers and distributes surfactant evenly. Use of the slow infusion technique delivered surfactant primarily to the upper lobes,¹⁸ and nebulized surfactant concentrated in select pockets of each lobe, resulting in areas of hypo- and hyperinflation.¹⁸

Several issues have been addressed in the Cochrane Database Systematic Reviews and other useful publications to help direct optimal therapeutic approaches. These include synthetic versus natural surfactants, comparison of available natural surfactants, optimal timing for initiating surfactant therapy, and single versus multiple dosing strategies.^{2,18,19,21–26} Outcome measures examined during surfactant trials include oxygen and ventilator requirements, severity of RDS, RDS mortality, total mortality, pneumothorax and other air-leak syndromes, pulmonary interstitial emphysema (PIE), bronchopulmonary dysplasia (BPD), and complications some investigators associate with surfactant therapy, such as intraventricular hemorrhage (IVH), pulmonary hemorrhage, and patent ductus arteriosus (PDA). In general, the primary benefits are more rapid resolution and milder course of RDS and lower risk of pneumothorax, death, or chronic lung disease (also referred to as *bronchopulmonary dysplasia*).

Several surfactant products are available currently in the United States. All represent natural surfactant preparations from different sources (Table 28–7). The only previously available synthetic surfactant in the United States was colfosceril (Exosurf). While there were clear therapeutic benefits to this product, it did not compare favorably with natural surfactant extracts.^{2,18,21} A meta-analysis of 11 direct-comparison trials showed that compared with synthetic surfactant, natural surfactant reduced the risk of: pneumothorax (RR 0.63, 95% CI 0.53 to 0.75) and mortality (RR 0.87, 95% CI 0.76 to 0.98). Risks for other important clinical or toxic end points were not increased with either preparation.²¹ Exosurf was withdrawn from the market because of insufficient efficacy. Comparisons of natural surfactants are more complex. Theoretically, the surfactant with the most surfactant proteins and fastest onset of action should be the best.¹⁸ This was demonstrated for prevention of death in an animal study. However, direct comparisons of beractant with the faster-acting calfactant failed to demonstrate differences in death at discharge. It is important to recognize that the study was powered to find a 25% difference, and smaller differences may have been missed.¹⁸ Benefits noted with calfactant in this comparison study in the prophylaxis arm were longer duration of effect, resulting in less frequent and fewer doses, and shorter duration of mechanical ventilation and supplemental oxygenation with prophylactic surfactant therapy. A larger multicenter trial repeating the earlier comparison trial is ongoing. At this point, no clear advantage can be advocated for the different surfactant products. Since onset

of effect and potency are not identical, the products should not be interchanged without earlier monitoring of arterial blood gases for calfactant and poractant to avoid overventilation and the associated risk of pulmonary damage, periventricular leukomalacia, and intraventricular hemorrhage.

The optimal time to initiate surfactant is also controversial. Options are RDS prophylaxis administration in the delivery room or later administration in the NICU when the diagnosis of RDS can be made clearly and the position of the endotracheal tube for surfactant delivery can be confirmed. The advantage of prophylaxis is that the drug is more evenly distributed in the lung, and excess ventilator support is avoided.^{2,18,19} Disadvantages to the use of prophylaxis are that administration errors are more likely owing to poor placement of the endotracheal tube and unnecessary exposure and costs for patients who would not have developed RDS. Alternatively, waiting for the diagnosis of RDS before treatment with surfactant results in unnecessary exposure to increased ventilator pressures and oxygen supplementation, which are associated with greater pulmonary damage and the costs associated with subsequent management.^{2,18} A meta-analysis of eight studies comparing RDS prophylaxis with treatment with surfactant demonstrated a benefit to prophylaxis in infants of fewer than 30 weeks' gestation. Benefits included a decrease in the incidence of neonatal mortality (RR 0.61, 95% CI 0.48 to 0.77), mortality prior to hospital discharge (RR 0.75, 95% CI 0.59 to 0.96), bronchopulmonary dysplasia (RR 0.87, 95% CI 0.77 to 0.97), pneumothorax (RR 0.62, 95% CI 0.42 to 0.89), and pulmonary interstitial emphysema (RR 0.54, 95% CI 0.36 to 0.82).²² If prophylactic surfactant therapy in the delivery room is used in favor of rescue therapy, the NNT to avoid one death prior to discharge is 20 patients. In reports of recent trials using surfactant rescue^{22,24} in newborns weighing 501 to 1500 g in over 5000 patients, only 45% actually required treatment. Alternatively, over 80% of neonates with birth weights below 1000 g had RDS in the 1999 Vermont Oxford Network experience reporting on over 27,000 neonates with birth weights below 1500 g. Neonates below 1000 g would be expected to benefit more from a prophylactic surfactant dosing approach. Any surfactant treatment approach provides multiple outcome benefits.

The optimal dose of exogenous surfactant remains uncertain. Controlled trials comparing single and multiple doses of surfactant have shown multiple doses to reduce the incidence of pneumothorax and neonatal mortality significantly.²⁵ Meta-analysis of studies comparing single to multiple doses of natural surfactant identified two studies. Multiple doses reduced the risk of pneumothorax (RR 0.51, 95% CI 0.30 to 0.88) and showed a trend toward reduced mortality (RR 0.63 95% CI 0.39 to 1.02). Both reports are in relatively larger newborns (mostly more than 30 weeks' gestation), and the benefits may be different in light of the increased use of antenatal steroids, which enhance surfactant response in preterm infants, and the predominant

TABLE 28–7. Relative Risks for Potential Beneficial and Adverse Effects of Synthetic and Natural Surfactants

| Outcome | Synthetic Surfactant | | | | Natural Surfactant | | | |
|-----------------|----------------------|------------------|-----|------------------|--------------------|------------------|-----|------------------|
| | No. | Prophylaxis | No. | Rescue | No. | Prophylaxis | No. | Rescue |
| Pneumothorax | 5 | 0.64 (0.49–0.89) | 3 | 0.52 (0.42–0.65) | 9 | 0.31 (0.22–0.44) | 12 | 0.34 (0.27–0.44) |
| BPD | 5 | 1.09 (0.80–1.47) | 3 | 0.68 (0.46–0.99) | 7 | 0.88 (0.67–1.17) | 10 | 1.01 (0.81–1.27) |
| Death | 7 | 0.67 (0.52–0.88) | 3 | 0.47 (0.30–0.74) | 9 | 0.60 (0.42–0.85) | 11 | 0.59 (0.47–0.74) |
| Death + BPD | 3 | 0.82 (0.63–1.08) | 2 | 0.65 (0.50–0.82) | 7 | 0.64 (0.49–0.84) | 10 | 0.66 (0.53–0.82) |
| All IVH | 4 | 0.94 (0.73–1.21) | 2 | 0.77 (0.62–0.97) | 8 | 0.95 (0.73–1.24) | 10 | 0.94 (0.76–1.15) |
| Severe IVH | | | | 1.05 (0.86–1.18) | | 0.91 (0.72–1.14) | | |
| PDA | 5 | 1.27 (1.03–1.57) | 3 | 0.73 (0.60–0.88) | 9 | 1.16 (0.89–1.50) | 12 | 0.96 (0.79–1.18) |
| Pulmonary bleed | 4 | 3.12 (1.54–6.32) | 3 | 1.49 (0.57–3.79) | 2 | 0.73 (0.31–1.69) | 2 | 1.25 (0.74–2.13) |

use of surfactant in neonates below 1000 g. The use of multiple doses makes physiologic sense because animal studies suggest that much of the initial surfactant dose is inhibited by soluble proteins and other factors in the small airways and alveoli. Multiple doses may overcome this initial inactivation. Many clinicians use up to four doses of natural surfactant based on clinical need. A typical strategy is repeating surfactant doses if after 6 hours or more from the previous dose the patient continues to require mechanical ventilation and the FiO_2 exceeds 30% or 40%, depending on the clinician's preference.

Despite the high success rates, 20% of neonates fail to respond to treatment. Factors associated with poor response include sepsis, pneumonia, PDA, congenital heart disease, pulmonary hypertension, meconium aspiration, and pulmonary hypoplasia.^{2,19} Whether retreatment of RDS with surfactant after resolution of these factors is useful is currently unknown.

Although surfactant appears to be generally well tolerated, some possible toxicities and associated problems include bradycardia, airway obstruction, and oxygen desaturation during administration; pulmonary hemorrhage; intraventricular hemorrhage (IVH); and the theoretical risk of allergy to natural surfactants,^{18,21,23,24} although antibodies were absent in over 1400 Survanta-treated neonates.²⁴

Problems during administration appear to be related to the volume of surfactant delivered, so surfactants using lower administration volumes may be better tolerated. Surfactant treatment is also associated with higher likelihood of clinically significant PDA. Pulmonary edema is associated with PDA. The pink respiratory secretions are thought to represent hemorrhagic pulmonary edema owing to capillary leakage of blood rather than the serious pulmonary hemorrhage seen in 10% to 45% of neonates with RDS in the presurfactant era.²³ Early closure of the PDA may minimize the risk of hemorrhagic pulmonary edema, as well as optimize surfactant response. While the relationship of IVH to surfactant use is controversial, cerebral blood flow velocity has been shown to be altered in some studies.¹⁸ The risks of surfactants causing periventricular leukomalacia (PVL), a marker of hypoxic-ischemic brain injury, is poorly understood, but two trials^{25,26} comparing calfactant and colfosceril found increased risk with calfactant (OR 2.03, 95% CI 1.09 to 3.80).²⁵ A theoretical basis for this is the more rapid and greater pulmonary beneficial effects with calfactant, resulting in overventilation and hypocarbia, because this is associated with decreased cerebral blood flow. If this is the correct cause, a more intense respiratory monitoring approach and aggressive ventilator weaning can avoid the problem. This trend needs to be assessed for all surfactants in additional studies that better measure this important prognostic marker for neurodevelopment.

■ Pharmacoeconomics of SRT

The pharmacoeconomic impact of SRT is examined in several reports.^{27–29} SRT has lowered RDS mortality by at least 30%. From 1989 to 1990 (when Exosurf was introduced), 80% of the decline in infant mortality nationwide was attributable directly to SRT.²⁷ The reduction in resource use resulted in projected savings (using 1991 dollars) of \$5800 in survivors and \$4400 in infants who died.²⁷ Survanta use was projected to save \$3300 in hospital resources for infants surviving to 28 days.²⁸ Savings as high as \$18,000 in total hospital charges per surviving infant were projected in one analysis.²⁹ Each RDS- or treatment-related adverse outcome confers cost to health care. Although new therapeutic approaches may improve RDS outcomes, it is unethical to perform placebo-controlled trials for RDS, so these estimates will be difficult to reconsider.

Although data are limited, the number of neonates with RDS needed to treat with SRT to avoid selected RDS-related complications is estimated in Table 28–7. Use of prophylactic surfactant in combination with new respiratory strategies to extubate neonates rapidly to nasal CPAP is not measured in these economic analyses, and it is likely that the economic savings are larger than reported in these studies if this strategy is applied to neonates born at 30 weeks or less of gestation.

CLINICAL CONTROVERSY

Most authors agree that surfactant prophylaxis is a good strategy for neonates below 30 weeks' gestational age. However, considerable disagreement exists for patients who are 30 to 32 weeks' gestation. If prophylaxis is not used, then early surfactant treatment of neonates developing RDS is necessary.

■ LIQUID VENTILATION WITH PERFLUORO-CHEMICALS

An investigational but highly promising approach to treating refractory RDS is the use of partial liquid ventilation, also called *perfluorocarbon-associated gas exchange* (PAGE).^{30,31} Studies with perflubron, a PFC, have reported a dramatic increase in partial pressure of oxygen in arterial blood (PaO_2) and dynamic lung compliance within 1 hour of starting therapy, and treatment resulted in prevention of RDS-associated deaths.³¹ PFCs are inert liquids in which oxygen and carbon dioxide are highly soluble. PFCs have low surface tension and are distributed evenly throughout the lung at low inflation pressures. The surface tension with PFCs at the alveolar air-liquid interface is markedly lower than seen with air ventilation, allowing for markedly lower ventilator pressures and a reduced risk of barotrauma.^{30,31} Clinically, PFCs have been dosed by instillation into the endotracheal tube through the sideport at a rate of 1 mL/kg per minute without interrupting mechanical gas ventilation until a column of fluid is welled up in the endotracheal tube. This volume of PFC is felt to represent the infant's liquid functional residual capacity (FRC). Fluid that evaporates is replaced hourly to maintain this liquid FRC.^{30,32}

In animal studies, PFCs also offered a vehicle for improved drug delivery via the lungs.^{30,32} Addition of exogenous surfactant to PFC ventilation appears to improve surfactant delivery and enhance response to PFCs and surfactant in animals,^{30,31} although studies in humans are unavailable. Adverse events associated with PFC use are mild and manageable, although long-term studies are lacking. Problems include endotracheal tube obstruction, hypoxic episodes, pneumothorax or fluorothorax (i.e., PFC leakage into the pleural space), and pulmonary hemorrhage.³⁰ These are not necessarily causal relationships, and overall, PFCs have been remarkably toxicity-free. The limited experience with PFCs and PAGE requires that this therapy be viewed as a promising but investigational option in RDS unresponsive to surfactant.

■ NITRIC OXIDE

Nitric oxide (NO) is a natural endothelium-derived relaxing factor that is important in regulating vascular tone, especially the pulmonary vasculature. Under normal physiologic conditions, NO is synthesized in endothelial cells and released into the vascular smooth muscle, where it stimulates cyclic GMP for vascular dilatation. At birth, NO helps in the transition from the markedly elevated pulmonary pressures in utero to normal pulmonary pressures and respiratory function.

Clinical studies have demonstrated the benefits of NO in persistent pulmonary hypertension of the newborn, meconium aspiration syndrome, and RDS.^{2,33,34} An exogenous NO product and delivery system was approved by the Food and Drug Administration (INOmax and INOvent; INO Therapeutics, Inc.). Dosages of 5 to 80 parts per million (ppm) usually are targeted. While inhaled NO therapy was effective in term and near-term infants with respiratory failure, it has not appeared beneficial in preterm neonates, although further studies are justified.^{2,33,34} Potential toxicities are few but include methemoglobinemia, inhibited platelet aggregation, and severe acute pulmonary edema secondary to the NO₂ oxidant metabolite. Further studies are needed to examine the clinical impact of this adjunctive therapy and the cost-benefit ratio as well.

■ SUPPORTIVE PHARMACOTHERAPY

Supportive pharmacotherapy in RDS is aimed at alleviating pain and discomfort, minimizing ventilator complications, and correcting any metabolic and/or fluid imbalance.

■ Narcotics/Benzodiazepines

Appropriate pharmacologic treatment is effective in alleviating pain and discomfort in neonates. Many ventilator-induced complications are secondary to asynchrony between ventilator rates and patient-driven respirations, resulting in pneumothorax and increased cerebral pressures that may promote IVH. Avoidance of these serious adverse effects can be accomplished by nonpharmacologic methods (e.g., positive-pressure assisted ventilation [PPAV]) or through the use of sedative and paralytic agents. A comprehensive review of sedation in neonates is available³⁵; therefore, the following discussion will be limited. The most commonly used analgesics and sedative agents are morphine, fentanyl, and lorazepam. Studies have shown a significantly greater percentage of ventilator time in synchrony and a decrease in catecholamine levels in neonates who receive narcotics routinely. A recent comparison of morphine and fentanyl in this patient population showed fentanyl to have a better side-effect profile at equivalent efficacy.³⁶ One concern is that studies examining fentanyl have shown an increase in ventilator support, tolerance, and physiologic dependence effects with long-term use.³⁶

All narcotics are expected to have this problem. The most common side effects demonstrated with narcotics include decreased gastrointestinal motility and risk of hypotension. Lorazepam is the preferred sedative agent in the absence of pain owing to its fast onset of action, its lack of hemodynamic toxicities, and its low risk of metabolite accumulation in comparison with diazepam. Midazolam continuous infusion is a reasonable alternative, although more costly and requiring additional fluid, which may be detrimental in a patient predisposed to PDA. Muscle paralysis has been used to reduce ventilator fighting and the consequent complications. However, its role in RDS has diminished owing to adverse effects (e.g., edema and hypoventilation). If paralysis is induced, assessment of sedation and seizures is confounded. Consequently, concurrent phenobarbital serum concentrations of 40 mg/L are recommended. Independent of

agent use, it is imperative to establish target sedation and pain scores to guide the clinical team in optimizing drug dosage. The use of sedation scores provides a mechanism to adjust drug dosing to effect, which maximizes effectiveness while limiting complications.

■ Acidosis

Acidosis is associated with a number of physiologic effects that increase the severity of RDS, including increased pulmonary vascular resistance, impaired synthesis of surfactant, reduced cardiac output, and depressed ventilation. Consequently, measures that reduce the risk of acidosis, such as prevention of hypoxemia, hypotension, and excessive blood loss through venipuncture and minimizing oxygen consumption through careful temperature control, are critical. Correction of metabolic acidosis with sodium bicarbonate or 0.3 M tromethamine (THAM) is recommended when blood pH falls below 7.25 and base excess is 5 or less. Patients should not receive sodium bicarbonate in congestive heart failure or any other conditions where sodium administration worsens the clinical condition. Patients receiving THAM should be monitored for episodes of apnea and bradycardia, which may worsen following administration. THAM should be avoided in uremic or anuric patients and should not be given via umbilical artery catheter.

■ Diuretics

Pulmonary edema is a prominent feature of RDS. The severity of RDS is correlated with the presence of factors that cause pulmonary edema. This is not unexpected because excess fluid in the alveolar and interstitial spaces impairs pulmonary gas exchange, lowers lung compliance, and reduces FRC. Prevention of fluid overload and pulmonary edema is critical to minimize the risk of opening the ductus arteriosus and the need for high ventilatory pressures. Pulmonary edema can benefit from PEEP because of redistribution of fluid from airspaces to interstitial tissue and improvement in gas exchange. Oliguria is well recognized during the early stages of RDS. A meta-analysis of six trials concluded that routine use of a diuretic, furosemide, to correct oliguria was not shown to improve markers of ventilation, oxygenation, or mortality.³⁷ The potential benefits of furosemide must be weighed against its risks, especially electrolyte imbalance. Furosemide also promotes prostaglandin synthesis, which may increase the risk of developing a PDA, although the meta-analysis did not document an increased risk.³⁷ The intermittent use of furosemide 1 to 2 mg/kg when pulmonary edema is thought to play a clinical role is justified and often beneficial clinically.

■ Methylxanthines

Extubation from mechanical ventilation as soon as possible is essential to minimize the toxicity of pressure and oxygen to lungs. Methylxanthines have been shown to facilitate successful extubation. In a meta-analysis of the benefits of methylxanthines, neonates weighing less than 1000 g were able to remain extubated more often if a methylxanthine was used concurrently with CPAP.¹⁸

CONCLUSIONS

Advances in prevention and reversal of RDS have had considerable impact on morbidity and mortality from RDS. Systematic reviews such as those published by the Cochrane Collaboration³⁹ provide fre-

quent revisions of the evidence for the therapeutic options to treat RDS. These allow implementation of best practices to minimize the incidence and severity of RDS and its sequelae. Nevertheless, chronic lung disease, although less severe, continues to occur in 10% to 45% of neonates depending on the institution studied. The challenge for

the future is to manage effectively the 20% of neonates with RDS responding poorly to surfactant. Institutions need to use multidisciplinary committees to enhance proficiency with therapies that will further reduce long-term pulmonary sequelae associated with RDS. Ensuring surfactant availability at all preterm deliveries so that prophylactic surfactant treatment can be used when appropriate, rapid extubation to nasal CPAP, and use of methylxanthines to facilitate extubation are useful NICU policies. Finally, if more than one surfactant is used in an institution, the pharmacodynamic differences between surfactants must be understood to optimize timing of arterial blood gas measurements to guide ventilator weaning and thus avoid serious sequelae from under- or overventilation.

ACUTE RESPIRATORY DISTRESS SYNDROME (ARDS)

Acute respiratory distress syndrome (formerly known as *adult respiratory distress syndrome*) was first described in 1967 in 12 patients presenting with acute respiratory distress, cyanosis refractory to oxygen therapy, decreased lung compliance, and diffuse infiltrates seen on chest x-ray.⁴⁰ Although the clinical description is similar to neonatal RDS, the underlying pathophysiology and ultimate morbidity and mortality differ considerably. A proper diagnostic definition of ARDS and acute lung injury (ALI) is necessary in order for clinical trials to include appropriate patients. Efforts to arrive at a standard definition were initially made in 1971, modified in 1988, and revised again in 1994.⁴⁰ Establishing epidemiologic data is influenced by the definition used. Comparing results across clinical trials has been confounded by the lack of a standardized definition. Designing a controlled, prospective study is difficult because there are so many variables and possible measures of response, although pulmonary morbidity and death are frequent end points. Limited patient numbers in clinical trials have resulted in insufficient power to detect potentially important but modest benefits of therapies. Recently, attention has focused on the systemic inflammatory response syndrome (SIRS) and the ablation of such response in limiting lung dysfunction, with mixed results.^{41–47} In this situation, biochemical markers of the disease process also may prove useful for comparisons of clinical and therapeutic interventions. Management of ARDS is still primarily supportive, with a general focus on ventilator management, prevention or limitation of pulmonary tissue damage, hemodynamic support, and prevention of multiorgan dysfunction syndrome (MODS).

EPIDEMIOLOGY AND ETIOLOGY

4 Accurate estimation of the incidence of ARDS has been confounded historically by variation in definition parameters. In an effort to standardize definitions, the 1994 American-European Consensus Conference (AECC) provided the clinical definition of ARDS: (1) acute onset of arterial hypoxemia with a $\text{PaO}_2/\text{FIO}_2$ ratio of less than 200 mm Hg, (2) bilateral infiltrates on frontal chest radiograph consistent with pulmonary edema, and (3) pulmonary wedge pressure of 18 mm Hg or less without clinical evidence of left atrial hypertension.^{40,46} A broader term attempting to encompass patients with milder gas exchange abnormalities ($\text{PaO}_2/\text{FIO}_2 < 300$ mm Hg) is ALI. The 1994 consensus definitions were designed to develop homogeneity for epidemiologic and clinical research aspects; however, it is now recognized that these definitions are a temporary solution for a complex disease state.⁴¹ While this definition has the advantages that it is easy to use and recognizes the spectrum of the clinical disorder, it fails to recognize the cause or the presence or absence of multiorgan dysfunction.⁴²

The most recent estimates, using the AECC criteria and data from the NIH-sponsored ARDS network, identified an incidence of

ALI/ARDS at the 20 hospitals studied of 2.2 cases per ICU bed per year (range 0.7 to 5.8) and 11.2 to 22.4 cases per 10^5 person-years.⁵² These data are extrapolated from the American Hospital Association national survey of hospitals registry of the number of adult ICU beds, burn ICU beds, and cardiac ICU beds.⁵² Alternatively, the incidence may be as high as 75 per 100,000.⁴⁰ In absolute terms, about 150,000 people in the United States develop ARDS or ALI annually.^{49,50}

6 Certain groups are predisposed to developing ARDS, and the risks vary within these groups. Patients with aspiration pneumonia or sepsis are at the highest risk for developing ARDS.⁵³ Other causes of ARDS include pneumonia, pulmonary contusion, fat emboli, inhalational injury, near-drowning, severe trauma with shock, multiple transfusions of blood products, acute pancreatitis, cardiopulmonary bypass, and drug overdose.⁴²

Mortality associated with ARDS typically has been 40% to 60% in case series but appears to be declining to 34% to 36% in more recent reports.^{40,54} The explanation for this is unclear.⁵⁴ Subgroup analysis suggests that patients with trauma-induced ARDS are more likely to survive than those with an infectious etiology.⁵⁴ The constellation of underlying pathophysiologic conditions and the individual response to the inflammatory cascade appears to place the underlying subgroups at higher or lower risks for mortality.⁵⁵

Morbidity in survivors appears to persist for several months. Pulmonary function appears to return to normal by 6 months, but muscle wasting and fatigue persist for at least 12 months, especially in the patients with more complications and requiring systemic glucocorticoids during the critical illness.⁴⁵

PATHOPHYSIOLOGY

Damage to the alveolar epithelium and the microvascular endothelium compromises the alveolar-capillary barrier and results in influx of protein-rich edema fluid during the acute phase of ALI and ARDS. The extent of alveolar epithelial injury is predictive of outcome. Epithelial injury is thought to predispose to progression of the disease process in five ways: (1) increased fluid permeability resulting in alveolar flooding, (2) type II pneumocyte damage impairing removal of edema fluid from alveoli, (3) type II pneumocyte injury reducing surfactant production, (4) damaged epithelial barrier predisposing to systemic infection, and (5) disorganized or insufficient epithelial repair possibly leading to fibrosis.^{40,42} After the acute phase of ALI or ARDS, there may be rapid resolution of the disorder, or it may progress to a fibrosing alveolitis. This fibrotic process may begin early in the disease course and be detectable histologically as early as 5 days after onset of the disease. Proinflammatory cell mediators, especially interleukin 1 (IL-1)–receptor antagonist, soluble tumor necrosis factor receptor, and autoantibodies against IL-8, IL-10, and IL-11, are thought to stimulate this cascade of events.⁴⁰ The inflammatory process is thought to reflect a balance between proinflammatory cytokines and anti-inflammatory mediators.⁴⁰ Neutrophils predominate in the pulmonary edema fluid and bronchoalveolar fluid obtained from affected patients. Neutrophils release oxidants, proteases, leukotrienes, platelet-activating factor, and other proinflammatory molecules that may play a role in causing lung injury. However, the importance of neutrophils in this cascade of lung damage was called into question recently because ALI and ARDS also occur in neutropenic patients and do not occur more frequently in patients with pneumonia who are treated with therapies to increase the number of circulating neutrophils.⁴⁰ Cytokine-mediated proinflammatory response appears to be further enhanced in association with ventilator-induced lung injury (VILI). The cascade of proinflammatory cytokine release is thought to be stimulated by alveolar overdistension and possibly by

TABLE 28–8. Presentation of ARDS**General**

The patient will have a medical problem known to cause ARDS and exhibit refractory hypoxemia.

Signs and Symptoms

Progressive respiratory failure due to poor oxygenation.

Laboratory Tests

Arterial blood gas (ABG) and arterial blood oxygen saturation (SaO_2) monitoring are necessary.

$\text{PaO}_2/\text{FiO}_2$ ratio less than 200 (ARDS) or 300 (ALI).

Other

Pulmonary artery catheter to measure pulmonary wedge pressure, which should be normal (≤ 18 mm Hg).

Chest x-ray shows bilateral pulmonary infiltrates with pulmonary edema.

CT scan to detect underlying conditions and help to evaluate pulmonary response to ventilatory and positioning maneuvers.

cyclic opening and closing of atelectatic alveoli.^{40,57} This can result not only in local pulmonary effects but also in a systemic inflammatory response with multiple systemic organ failure.⁵⁸ No single mediator or clinical feature adequately predicts which patient will develop ARDS. One postulate is that a genetic predisposition for lung injury when combined with inflammatory mediators may contribute to this lack of predictive value.⁵⁶ Nonetheless, inflammatory mediators compromise the pulmonary endothelium, resulting in increased protein permeability across endothelial and epithelial cells. This results in arterial hypoxemia and bilateral radiographic infiltrates from a protein-rich edema that is a chemotactant for further inflammatory mediators. The “leakage” of fluid into the pulmonary interstitium results in three physiologic alterations: (1) an impairment of tissue integrity that compromises normal expansion of alveolar tissue, (2) a physical impairment of oxygen–carbon dioxide exchange on an alveolar level, and (3) inactivation of endogenous surfactant resulting in alveolar collapse and development of pulmonary ventilation–perfusion mismatch. Not all areas of the lung are equally affected. Fluid-filled alveoli, atelectasis, and consolidation occur primarily in

dependent lung zones, whereas other areas may be relatively spared.⁵⁹ This creates problems with mechanical ventilation because positive pressure can overdistend normal alveoli while trying to open other atelectatic alveoli.

CLINICAL PRESENTATION

Clinical and diagnostic assessment of ARDS is summarized in Table 28–8. The clinical presentation of ARDS is associated most often with concomitant factors that can complicate the differential diagnosis. As such, ARDS presents clinically as refractory hypoxemia (blood oxygen saturation $<90\%$) with bilateral pulmonary infiltrates on chest radiography. However, chest radiographs may be interpreted differently for the diagnosis of ARDS even among experienced intensivists.⁵⁸ To assist with the diagnosis of ARDS, computed tomography (CT) is being used with increased regularity to detect underlying conditions such as abscesses, surgical emphysema, and pneumothorax. Further, CT has been used to evaluate pulmonary response to ventilatory and positioning maneuvers.⁵⁹

► TREATMENT: Acute Respiratory Distress Syndrome

■ DESIRED OUTCOME

No effective therapy is available to treat the underlying pathophysiology of ARDS. Thus initial therapy is focused on maintaining adequate oxygenation and tissue perfusion. Identifying and appropriately managing the precipitating factors and minimizing nosocomial complications related to infection, ventilator management, and other interventions also play prominent roles. Prevention of MODS is important because studies have shown that mortality is linked to a variety of factors, including nonpulmonary organ dysfunction.^{42,61} Finally, investigational pharmacologic therapies to attenuate the inflammatory response may be a part of the clinician’s approach to the ARDS patient. Treatment options are outlined in Fig. 28–3.

■ VENTILATOR MANAGEMENT

7 The cornerstone for the treatment of ARDS is mechanical ventilation. This area of management is evolving rapidly owing to newer ventilator technologies and improved understanding of lung physiology and VILI. Traditionally, ventilator management has focused on giving patients a tidal volume sufficient to maintain normal

arterial blood gas values for PaCO_2 or pH. Often this has required supraphysiologic tidal volumes of 10 to 15 mL/kg of predicted ideal body weight (normal physiologic volume is 7 to 8 mL/kg).⁵⁰ It has become apparent that a “high volume” approach causes excessive distension of normally aerated portions of affected lungs with consequent release of inflammatory mediators. This is one mechanism thought to perpetuate ALI as well as nonpulmonary organ damage. Several investigators have tried a “low volume” strategy and administered tidal volumes of 6 mL/kg.^{42,61–64} The Acute Respiratory Distress Syndrome Network compared ventilator strategies using a traditional tidal volume approach, i.e., initial tidal volume of 12 mL/kg, and adjusted to give a plateau pressure (measured after a 0.5-second pause at the end of inspiration) of 45 to 50 cm H_2O , with a “low volume” strategy, i.e., initial tidal volume 6 mL/kg, and adjusted to give a plateau pressure of 25 to 30 cm H_2O .⁶¹ Both groups used a volume-assist-control ventilator mode until the patient was weaned from the ventilator or until day 28 of the study. The ratio for the duration of inspiration to the duration of expiration (I:E ratio) was set at 1.1 to 1.3. Ventilator settings were adjusted overall to achieve target goals for arterial blood pH of 7.3 to 7.45 and PaO_2 of 55 to 80 mm Hg or oxygen saturation of 88% to 95%. This study, which included over 400 patients in each treatment group, showed that the “low volume” strategy reduced mortality significantly (31.0% versus 39.8%), increased the percentage breathing without assistance by day 28 (65.7% versus 55.0%), reduced the

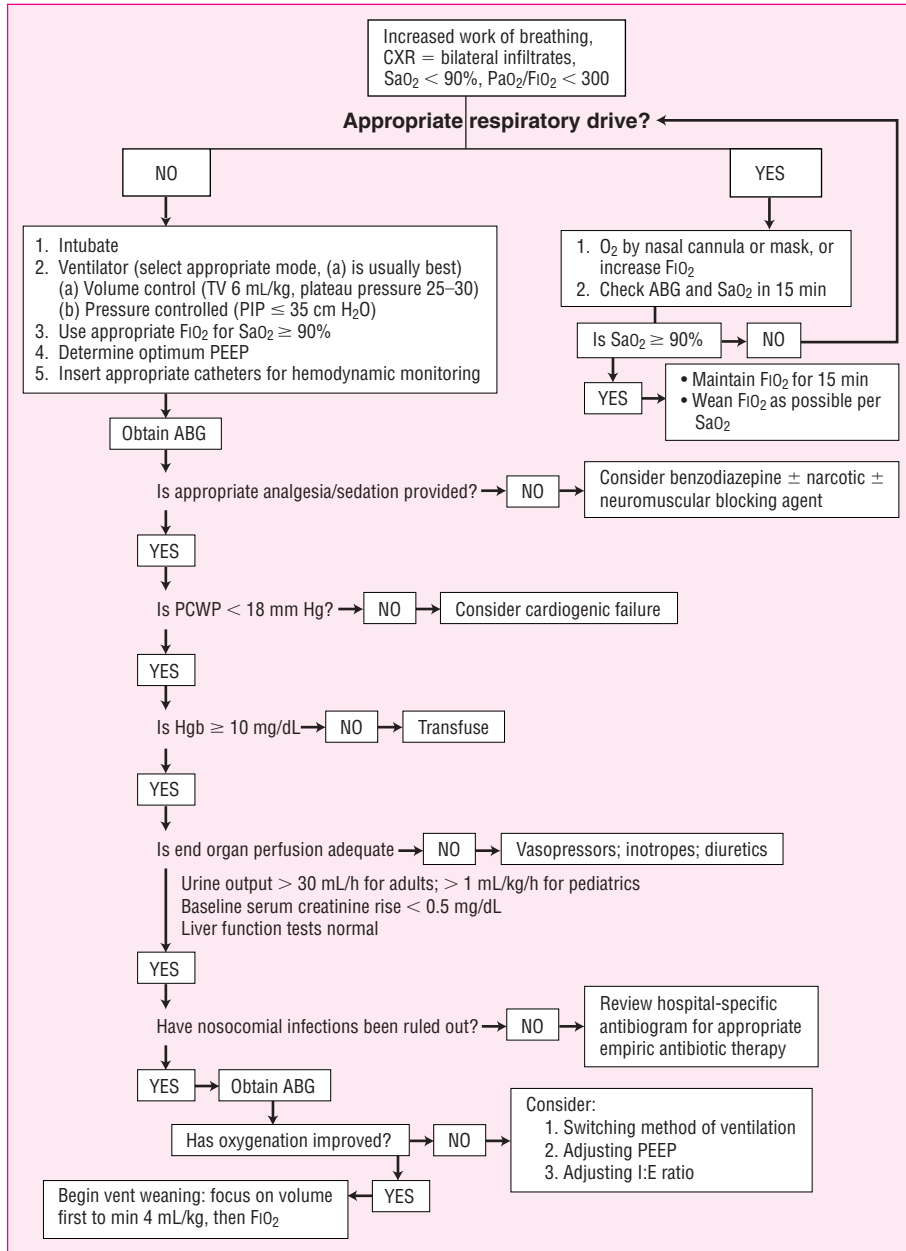

FIGURE 28-3. Algorithm for treatment of ARDS and ALI.

number of days without ventilator use during the first 28 days (12 ± 11 versus 10 ± 11), and reduced days without failure of nonpulmonary organs (15 ± 11 versus 12 ± 11). Day 3 IL-6 plasma concentrations were lower in the “low volume” strategy group, supporting the clinical findings.⁶¹ This approach using gentler ventilation with adjunctive therapies to maintain acceptable arterial blood oxygenation and pH also was embraced in the accompanying editorial.⁶⁴ Interpretation of the data using a “low volume” strategy is confounded by inconsistent results among the five published clinical trials comparing this approach with conventional ventilator approaches.⁷⁵ A meta-analysis of these studies indicated that positive results were noted in two trials with relatively high tidal volumes in the control groups (i.e., ≥ 10 mL/kg), but when tidal volumes more typical of clinical practice were applied (i.e., 8–9 mL/kg), no significant differences were found. The ethics of exposing control patients to unnecessarily high tidal volumes to study the value of the “high volume” versus “low volume”

strategies resulted in a serious controversy and delayed funding of other clinical trials proposed by the prestigious ARDS Network for an indefinite period.⁵⁰ The best way to proceed with subsequent clinical trials remains controversial, but most clinicians regard a “low volume” strategy as the current best practice. The risk with using a “low volume” strategy is that it may result in lung derecruitment, atelectasis, and promotion of inflammatory response. Also, this approach of using higher PEEP and lower tidal volumes with conventional ventilation may lead to hypoventilation and respiratory acidosis. This could lead to increased need for sedation or neuromuscular blockade.^{40,50} Myopathy and neuropathy are recognized increasingly as a concern with prolonged neuromuscular blocker use, especially when systemic steroids are used concurrently.

A new approach called the *alveolar recruitment maneuver* (ARM) has been used successfully in patients with extrapulmonary causes of ARDS but is less successful if the etiology is pulmonary.⁶⁰

ARM requires that the tidal volume be delivered in a prolonged manner as an extended sigh lasting about 1 minute and that PEEP be increased in a gradual and reciprocal manner with the tidal volume to keep the newly recruited alveoli open. This maneuver can improve oxygenation but also carries many risks related to lung damage and decreased cardiac output. Patient position is important because ARM is less effective when patients are in the prone position.⁶⁰ Prone position, however, generally may be the preferred position because PaO₂ is typically higher in ventilated patients, possibly due to better recruitment of alveoli. Since ventilator management is as much of an art as a science, only individuals experienced with ventilator modes and options should oversee selection of ventilator strategy and changes in ventilator settings in such a life-threatening situation.

Clinicians caring for critically ill patients must have a rudimentary understanding of the technical aspects of mechanical ventilation to optimize therapy. Therefore, the following section simply provides an overview of ventilator technology and issues. Mechanical ventilation management is based on evaluations of respiratory and hemodynamic measurements. Arterial blood gas (ABG) determination is a key component to the respiratory management of ARDS because it describes perfusion (pH), oxygenation (PaO₂), and degree of ventilation (PaCO₂). In addition, the ABG determination allows assessment of the acid-base balance of a patient to differentiate whether acidosis or alkalosis is from metabolic, respiratory, or mixed etiologies so that the appropriate management can be implemented. Acid-base disorders are discussed extensively in Chapter 53. Appropriate lung distension is evaluated by clinical observation of chest wall expansion and radiography, notably the chest x-ray. Chest x-rays also provide important information, including endotracheal tube placement, severity of lung disease, markers of pulmonary toxicity, presence of air leaks, and an estimation of heart size.

The goal of mechanical ventilation is to provide adequate oxygen delivery while promoting the removal of CO₂. The target SaO₂ traditionally has been greater than 90% on the lowest possible FIO₂. In light of the recent study using low-tidal-volume ventilator strategy, slightly lower oxygen saturation and more liberal use of the FIO₂ to avoid increased ventilator pressures should be tolerated. The use of ventilatory maneuvers that achieve these end points while minimally disrupting the anatomic and physiologic aspects of respiratory and hemodynamic function is another goal. For the purpose of this discussion, there are six main types of ventilator management. A brief explanation of each follows. In reality, a number of hybrids between different ventilator modes also exist.

■ CONTROL-MODE VENTILATION (CMV)

CMV administers a breath independent of the patient's efforts. Ventilator settings determine the end of inspiration and the beginning of expiration (the I:E ratio, normally 1:2). PEEP is used to prevent alveolar collapse at the end of expiration. The "best PEEP" is determined clinically by monitoring the patient's oxygenation and most often is between 10 and 15 cm H₂O. PEEP rarely should exceed 20 cm H₂O. The tidal volume associated with the breath is independent of the patient and is set between 6 and 15 mL/kg of ideal weight. However, if highly compliant endotracheal tubing is used, higher volumes may be warranted. Risk associated with this form of ventilation is overdistension with possible pneumothorax. Some clinicians advocate an I:E ratio of 1:1, which purportedly allows use of more PEEP without pushing up peak inspiratory pressure or plateau pressure. This is reasonable in patients unless they have chronic obstructive pulmonary disease (COPD).

■ ASSIST-CONTROL VENTILATION (ACV)

ACV uses a mechanically set rate for breaths per minute but does allow patient-initiated breaths. The ventilator senses a patient's "trigger" of an inspiratory phase by noting a change in pressure within the endotracheal tubing. After such a trigger, the patient receives a full-tidal-volume inspiration. In the absence of a patient's inspiratory effort, the machine will deliver a programmed number of breaths per minute. Disadvantages of ACV include discomfort in "conforming" to predetermined tidal volumes while being alert enough to generate an inspiratory effort. Another disadvantage associated with the delivery of a complete-tidal-volume breath is the increased likelihood of developing respiratory alkalosis.

■ INTERMITTENT MANDATORY VENTILATION (IMV)/ SYNCHRONIZED INTERMITTENT MANDATORY VENTILATION (SIMV)

Intermittent mandatory ventilation (IMV) is a form of mechanical ventilation that not only delivers a preset number of breaths per minute but also allows the patient to breathe spontaneously between mechanical breaths. Thus, as the patient begins to initiate an increasing number of breaths, the preset mechanical IMV number can be dialed down. This form of ventilation allows the patient to increase his or her work of breathing; thus it is ideal for patients who are weaning from mechanical ventilation. An evolution of IMV is SIMV, which allows for the mechanical breaths to coincide with the inspiratory effort generated by the patient. Although functionally similar, SIMV prevents the "stacking" of breaths that may lead to higher peak airway pressures and higher intrathoracic pressures. The use of SIMV for the initial phase of ARDS is not indicated because patients generally are unable to initiate an inspiratory effort nor maintain such effort for a prolonged period of time.

■ PRESSURE-CONTROL VENTILATION (PCV)

PCV is a time-cycled ventilation that limits inspiratory pressures, thereby maximizing alveolar pressure. Ventilation is independent of the patient's effort but depends on pulmonary compliance. Thus there is a reduced likelihood of overdistension and pulmonary tissue damage because inspiration is limited once the predetermined peak pressure is obtained. Thus it is assumed that VILI is reduced.

■ PRESSURE-SUPPORT VENTILATION (PSV)

PSV is a type of mechanical ventilation that uses a patient's inspiratory effort and supplements to a select level of positive airway pressure. The patient controls the ventilatory rate and inspiratory assist time, whereas the PSV supplements inspiratory flow and tidal volume. Because PSV is heavily reliant on the patient's effort, this form of ventilation may not be optimal in patients unable to generate sufficient effort. However, it is the modality of choice in patients who are unable to synchronize with other modes of support.

■ HIGH-FREQUENCY VENTILATION (HFV)

HFV has been mentioned as a ventilator option for neonatal RDS (see Table 28–2). The basic concept for its use in ARDS is that the pressure-volume curve in ARDS creates a narrow window of safety

for PPV. If staying between the points of low inflection (where atelectasis occurs) and high inflection (where overdistension occurs) is the goal, then theoretically HFV, which delivers small, frequent tidal volumes, should be an optimal ventilator strategy. However, initial clinical trials of HFV in patients with ARDS have failed to demonstrate superior outcomes, giving little incentive at this time for clinicians to switch from control-mode ventilation.⁶⁵ Advocates for HFV have noted several problems in the studies failing to find HFV superior to control-mode ventilation. The most serious flaw cited is that the studies lacked sufficient statistical power to recognize modest benefits. One recent editorial⁶⁵ noted that only 447 patients thus far had been included in all HFV studies combined. The authors point out that about 500 patients would be needed for each arm of the study (total 1000 patients) to detect a 10% reduction in mortality. Only the “low volume” strategy study with control-mode ventilation published by the ARDS Network⁷⁴ approaches this. Another criticism is that early studies used a “low pressure/low volume” strategy that permitted pressures below the lower inflection point, allowing for the shear stress associated with repeated collapse and opening of terminal airways. This strategy would promote inflammatory mediator release and would be unlikely to improve outcomes. Ventilation using sufficient PEEP to recruit alveoli above the lower inflection point combined with HFV to deliver small tidal volumes warrants an appropriately designed and powered clinical trial.⁶⁵ Finally, ventilator technology for HFV has been insufficient to support proper use of this ventilator mode in adults. High-frequency oscillatory ventilation (HFOV) seems most appropriate because it promotes expiration as well as inspiration and avoids air trapping. A newer high-frequency oscillatory ventilator (3100B Ventilator, SensorMedics) purportedly is able to provide the extended levels of continuous distending pressures needed to follow a “high volume” strategy necessary for HFOV to succeed in adults with ARDS.⁶⁵ HFOV is more established in infants and children with respiratory distress, where smaller endotracheal tube sizes are used. In adults, HFOV is recommended primarily when oxygen requirements exceed 60% and mean airway pressure is 20 cm H₂O or greater or PEEP is >15 cm H₂O.⁶⁵ Theoretically, this strategy would provide the most physiologic ventilator approach because both airway collapse and overdistension can be avoided while gradually recruiting and opening atelectatic alveoli. Clinical trials testing this ventilator are in progress. If HFOV is used, it is important to ensure no significant obstruction of the airway with blood or mucus because this greatly impedes delivery of the oscillatory waveform.⁶⁵

■ VILI AND OTHER COMPLICATIONS

Irreversible loss of disease control or serious ventilator-related toxicities through oxygen toxicity, barotrauma, and volutrauma can occur if ventilatory management is not monitored and optimized continuously.^{40,46,57} These ventilator-related toxicities may occur even with appropriate ventilator management, and minimizing these toxicities is one of the major goals of ventilator management.

Despite increasing evidence that pressure is more damaging to lungs than oxygen toxicity, oxygen supplementation remains a serious concern in ARDS as well as RDS. Toxicity occurs as a result of oxygen-derived free radicals. The combination of high O₂ concentrations with the underlying lung damage may create a proinflammatory condition that further worsens underlying lung damage. There does not appear to be a universally accepted duration of exposure or O₂ concentration that correlates with lung damage, thereby suggesting that disease severity and individual susceptibility are the most important factors.^{40,56} However, with the increasing attention to pressure-related

lung damage, oxygen toxicity may be the lesser evil if compromises must be made to achieve adequate oxygenation.

ARDS does not affect the lung uniformly; there are consolidated and necrotic areas not available for gas exchange, areas of collapse that may be recruited, and normal alveolar components. It has been reported that in severe cases of ARDS the inflation capacity of the lungs may be less than one-third normal.^{34,51} Although traditional ventilator management has described tidal volumes of 10 to 15 mL/kg, consolidated or collapsed areas of the lung volume will “shunt” to areas of least resistance, i.e., alveoli that are not collapsed. Thus areas of hyperinflation can be located next to hypoinflation within the lung field. Furthermore, these areas of altered ventilation may not be evident in gross examination of mean airway pressure because this parameter is calculated under passive inflation.⁴³ The volutrauma of ARDS is a result of regional overdistension of alveolar components and generally occurs in patients with a static pressure greater than 30 mm Hg. The risk of volutrauma occurs later in the course of ARDS presumably because of the uneven degradation of the lung structure creating areas of weakened tissue and increased risk for alveolar disruption.⁶⁶ As mentioned earlier, a low-tidal-volume strategy appears to be the safer course.

In addition to the damage incurred with tidal volume, barotrauma can ensue. The shearing force of a tidal volume associated with alveolar collapse and reinflation is an important aspect of VILI.⁵⁶ Thus the employment of PEEP can limit this barotrauma. In addition, PEEP can limit the FIO₂ needed for adequate oxygen saturation. PEEP is a pressure applied by the ventilator that prevents complete lung emptying at end expiration, increasing lung volume. This improved gas exchange redistributes (but does not decrease) lung water. The concept behind the ability of PEEP to reduce lung injury stems from the prevention of continued alveolar collapse and reopening with consequent inflammation and worsening ARDS.⁴² However, finding the “best PEEP” can be challenging because too much volume remaining in the alveoli can cause overdistension and damage, with possible hemodynamic effects. One additional adverse consequence of a ventilator strategy that uses a large tidal volume is the translocation of bacteria and endotoxins with subsequent systemic sequelae.^{67,68}

CLINICAL CONTROVERSY

The best ventilator approach for managing ARDS remains controversial. Most practitioners agree that lower tidal volumes are better, but the definition of *lower* is confusing. Furthermore, the proper, ethical way to study ventilator interventions for ARDS has been challenged and must be resolved before additional studies of ARDS interventions can continue.

■ PERFUSION MANAGEMENT

Tissue perfusion is a critical component of ARDS. In order to optimize oxygen dissociation on a cellular level, appropriate tissue perfusion is required. In addition, adequate perfusion supplies glucose and electrolytes while eliminating metabolic by-products. Clinical monitoring of the ARDS patient requires assessment of perfusion in two capacities: hemodynamic/fluid support and end-organ function.

■ HEMODYNAMIC AND FLUID MANAGEMENT

Theoretically, improving oxygen supply should improve oxygen delivery to the tissues. Although the validity of this direct relationship

TABLE 28–9. Hemodynamic and Fluid Support Decisions in ARDS

| PCWP | MAP | CO | Tissue Hypoxia | Therapeutic Maneuver |
|-----------|-----------|-----------|----------------|---|
| Decreased | Decreased | Decreased | Yes | Fluid bolus |
| Decreased | Decreased | Increased | Yes | Vasopressor ± fluid bolus |
| Decreased | Decreased | Increased | No | Vasopressor |
| Decreased | Increased | Increased | No | Diuresis and negative fluid balance |
| Decreased | Increased | Decreased | Yes | After-load reducer |
| Decreased | Increased | Decreased | No | After-load reducer and negative balance |

has been scrutinized, most clinicians optimize cardiac output in ARDS patients to ensure adequate perfusion by using fluids, blood transfusions, inotropic agents, and afterload-reducing agents. In addition to the ABG and hemoglobin determinations, hemodynamic parameters such as cardiac output, pulmonary artery obstruction pressure, and mean arterial pressure are monitored to determine which agent is most appropriate to improve perfusion. These parameters, combined with evaluation of tissue hypoxia, contribute extensively to the fluid-management decisions of ARDS (Table 28–9). The importance of appropriate fluid management cannot be overstated. Sufficient intravascular volume is needed for adequate perfusion. On the other hand, keeping patients relatively dry to avoid a persistent positive fluid balance is important to reduce the likelihood of pulmonary edema, which is associated with a poorer prognosis.⁴⁰ A clinical trial involving 19 treated and 18 control patients examined the value of 25 g albumin 25% given over 20 to 40 minutes plus furosemide 1 mg/mL given as a continuous infusion every 8 hours (dose titrated to weight loss) for 5 days given to hypoproteinemic patients with ALI.⁴⁹ This small double-blind trial demonstrated the albumin plus furosemide group to achieve significantly greater weight loss (10 versus 4.7 kg) and serum albumin (1.9 versus 0.7 g/dL), increases in oxygenation at 24 hours (89% versus 50%), with an apparent plateau effect by the third study day; and reversal of the diagnosis of ALI/ARDS (53% versus 11%). The study had too few patients to detect modest differences in major clinical outcomes such as ventilator dependence or mortality. An important caveat to these results was that most ALI cases were caused by an extrapulmonary etiology (mainly trauma), which the authors caution may be more associated with pulmonary edema and alveolar collapse and thus may be more amenable to diuretic therapy. Pressors also may offer theoretical benefits because catecholamines such as isoproterenol and dopamine may upregulate epithelial sodium channels and thus help to reduce pulmonary edema.⁶⁷ A randomized trial of restricted versus liberal fluid management was initiated by the National Institutes of Health ARDS Network.⁵⁰

■ PERFUSION AND PREVENTION OF END-ORGAN DAMAGE

Another marker of sufficient tissue perfusion can be clinical assessment of end-organ function. As mentioned previously, prevention of MODS is an important factor in reducing ARDS-associated mortality. Clinically, assessments of urine output and serum electrolytes are important aspects of renal function monitoring, whereas liver function tests (aminotransferases AST and ALT) are important laboratory parameters for monitoring hepatic function. Central nervous system assessment can be difficult in the ARDS patient and is confounded by concurrent drug therapies (e.g., sedatives, narcotics, etc.) that alter neurologic status.

Stress-induced gastrointestinal bleeding is another complication of ARDS. Mechanical ventilation, altered gastric blood flow, and

coagulopathy are indications for stress ulcer prophylaxis.⁴¹ However, considerable controversy exists as to the role of pH-altering drugs for stress prophylaxis and the relationship with nosocomial pneumonia. Given the considerable risk of mortality with gastrointestinal bleeding in patients with ARDS, it is our opinion that prophylactic agents should be used. There does not appear to be a uniform clinical advantage of either histamine antagonists or proton pump inhibitors; therefore, selection should be based on costs.

■ Nosocomial Pneumonia

Nosocomial pneumonia in ARDS patients causes mortality in 67% of patients versus 23% of patients without pneumonia. Prevention and early treatment are critical to decreasing ARDS mortality. Ventilator-associated pneumonia correlates directly with length of mechanical ventilation.⁶⁹ Diagnosis of ventilator-associated pneumonia is difficult because no diagnostic method, even protected specimen brush, correlates with microbiologic results on autopsy or affects mortality.⁷⁰ Mechanically ventilated patients are always colonized with pathogenic organisms. When clinical findings suggest ventilator-associated pneumonia, the causative organism correlates with the organism colonizing the upper airway and should be the target of antimicrobial therapy.⁷¹

Gastric colonization does not correlate with ventilator-associated pneumonia and mortality differences. Attempts to decontaminate the gastrointestinal tract have not become established norms.⁷¹ Antibiotic use carries the risk of acquiring multiresistant organisms, which can adversely affect hospital and community antibiograms. Based on the epidemiologic and financial costs of resistant organisms generated with such a procedure, its routine practice cannot be advocated.

■ Catheter-Related Infection

ARDS patients are also at risk for the development of catheter-related infections, especially bacteremia, which is life-threatening. Appropriate hospital hygiene and the standard use of sterile technique are of extreme importance in preventing infections. Catheter-related infections are dealt with elsewhere in this text (see Chap. 137). Diagnosis of catheter-related infections can be difficult, although most clinicians agree that semiquantitative cultures of removed catheters are helpful. Catheter-associated organisms usually are gram-positive bacteria, namely, *Staphylococcus* spp. Catheter removal and antimicrobial therapy are cornerstones of treatment.

■ Nutritional Support

Parenteral nutrition is often necessary in seriously ill ARDS patients because blood flow to the gastrointestinal tract is limited. Enteral

nutrition is preferred if tolerable, even in small amounts. The advantages of enteral feedings include decreased need for central catheter access, increased gastrointestinal access, increased gastrointestinal blood flow decreasing the risk of gut contamination, and decreased risk for ulceration. It is important for the clinician to remember that using a high amount of intravenous carbohydrates as the major source of caloric intake increases the production of carbon dioxide, which can further complicate management of the ARDS patient. Interest has increased in the potential benefits of selected enteral nutritional approaches. Use of an enteral formula containing eicosapentaenoic acid (EPA, fish oil), γ -linolenic acid (GLA, borage oil), and antioxidants was compared recently with a standard ready-to-feed high-fat, low-carbohydrate (corn oil base) formula.⁷² This preliminary trial reported that both formulas were well tolerated by most patients and resulted in fewer days on the ventilator and in the ICU and fewer instances of new organ failures. The authors speculated that the benefits were due to the anti-inflammatory effects of the EPA + GLA formulation. This formula contained polyunsaturated long-chain fatty acids (PUFAs) with an N-6:N-3 ratio of 1:1 (compared with 54:1 for the standard formulation). A subsequent trial with EPA + GLA (Oxepa) showed that patients fed this formula for 4 to 7 days had reduced inflammatory mediators and markers of inflammation in bronchoalveolar lavage fluid and increased oxygenation.⁷³ For patients who can tolerate enteral feedings, formulas with lipid content high in N-3 PUFAs are worth considering.

■ INVESTIGATIONAL THERAPIES

9 Various therapies have been evaluated to reverse or limit the pulmonary damage associated with ARDS. These entities range from inhibiting the underlying etiology (e.g., antidiotoxin immunotherapy) to altering inflammatory mediators (e.g., cyclooxygenase inhibitors) to directly improving oxygenation (e.g., NO and surfactant). To date, no single therapy has uniformly demonstrated benefits in clinical trials. These trials have been summarized in a comprehensive review.⁴¹ The failure to prove clinical benefits to the various therapies should not discourage further research on any approach. A subsequent editorial challenges the negative findings in these large trials and tries to reconcile the promising experimental evidence with the trial outcomes.⁷⁴ The author questions the definitions used for ARDS and the end point of death as perhaps issues to resolve. Most studies also suffer from problems with insufficient patient numbers to ensure the validity of negative findings, inappropriate selection of drug-delivery technique (as in the case of surfactant⁷⁶), and uncertainty about optimal dosing. Nevertheless, some recent studies performed by the National Institutes of Health ARDS Network and other multicenter groups involved large patient numbers and placebo-controlled trials. These studies failed to show improved outcomes for mortality, pulmonary and nonpulmonary organ morbidity, and measures of interleukins or other markers of inflammation.

At this juncture, despite laboratory experiments raising expectations of benefits and in some cases experiential reports favorable to the therapy, studies to date have failed to demonstrate substantial

benefits with systemic glucocorticoids, liposomal prostaglandin E₁, inhaled NO, ketoconazole, procysteine, and lisofylline.⁴¹

Synthetic surfactant (Exosurf) was studied in a placebo-controlled trial of patients with ARDS.^{75,77} While this therapy also failed to show benefits, the drug was aerosolized over 5 days to administer 240 mL Exosurf. Since aerosolized surfactant is poorly delivered and was shown recently to be ineffective in neonates with RDS, this trial cannot be considered of value in gauging the efficacy of surfactant for ARDS. Also, natural surfactants that also have surfactant proteins may be a better choice. Phase III studies using a recombinant SP-C-based surfactant showed reduced mortality for the subgroup of patients with ARDS secondary to direct insults, although no benefit was seen for the total study population.⁷⁷ It is important to consider etiologies for ARDS when future clinical trials are designed.

Systemic glucocorticoids have been tried for the prevention of ARDS in patients with septic shock, for accelerating resolution of acute ARDS, and for prevention of fibroproliferation.⁴² Short courses of high-dose systemic steroids generally have been ineffective in preventing ARDS in patients with septic shock or resolution of ARDS. In fact, a theoretical risk of a net proinflammatory state may be created in the setting of preformed and released inflammatory cytokines increasing cytokine receptors and resumption of cytokine production after steroids are withdrawn.⁴²

While apparently ineffective during the acute phase of ARDS, prolonged glucocorticoid therapy may have a role in patients with ARDS who remain unimproved for 7 days. Therapy at this point is targeting the fibrosing alveolitis phase of the disease.^{42,76} In a small trial, methylprednisolone was started at 2 mg/kg per day and tapered gradually over 32 days.⁴³ Treatment was associated with significant reduction in mortality, lung injury score, and multiorgan dysfunction. The prolonged high-dose methylprednisolone course differs from studies of glucocorticoids during the acute phase of ARDS. The study investigators challenge the negative findings for early steroid use on the basis of their findings. Ultimately, steroid use remains controversial but probably should be considered investigational and potentially harmful during the acute phase of ARDS.

Selective pulmonary vasodilation, particularly in patients with severe refractory hypoxemia, is being studied as an adjunctive therapy for ARDS.⁷⁸ Inhaled NO is the most studied. Studies using doses ranging from 1.25 to 80 ppm have demonstrated short-term benefits in oxygenation but no sustained improvement in outcomes such as days requiring mechanical ventilation or mortality.

In pediatric patients with ARDS, extracorporeal membrane oxygenation (ECMO) has been used.⁴⁶ These patients have been part of larger cohorts identified as respiratory failure. Anecdotally, practitioners observe the greatest benefit in the sickest patients. Prospective studies are needed to confirm clinical impression. The benefits of ECMO for adults with ARDS seem less optimistic.⁴⁶

A large number of additional therapies have been or are under review. These therapies include nonsteroidal anti-inflammatory agents, proinflammatory agents (GM-CSF), antiadhesion molecules, gene therapy, antidiotoxin therapy, and antioxidants (e.g., superoxide dismutase).⁴³ Therapies will continue to focus on the early interventions to prevent the progressive downward spiral of lung injury, inflammation, and hypoxemia.

EVALUATION OF OUTCOMES AND MONITORING PLANS

Mortality, ICU stay, and duration of mechanical ventilation are common outcome measures used in ARDS studies. However, there is

considerable debate not only on the definition of ARDS but also on the usefulness of these markers or other surrogate markers in determining efficacy of ARDS therapies.

Monitoring ventilatory parameters, ABGs, and oxygen saturation assists in determination of illness severity and provides

TABLE 28–10. Monitoring Parameters for ARDS

| Hemodynamic | Ventilator Status | Infection | End-Organ Damage |
|--|-------------------------|---------------------------------|----------------------|
| PCWP | FiO ₂ | White blood cells/differential | BUN |
| Cardiac output/index | PaO ₂ | Chest x-ray findings | Creatinine |
| Oxygen saturation (SaO ₂) | SaO ₂ | Temperature | Urine output |
| Mixed venous oxygenation (MvO ₂) | MvO ₂ | Cultures | Liver function tests |
| Hemoglobin/hematocrit | Plateau pressure | Changes in color/quality sputum | PT/PTT |
| Urine output | Respiratory effort/rate | New onset hypotension | |
| | | Abdominal examination | |
| | | Number of central catheter days | |

rudimentary end points of perfusion. For example, most clinicians agree that maintaining an oxygen saturation of more than 90% is important. Effects of inotropic agents, blood products, and vasopressors must be measured to optimize oxygenation. Thus appropriate monitoring of invasive hemodynamic parameters (i.e., pulmonary artery obstruction pressure) through a pulmonary artery catheter is critical in appropriate management of the ARDS patient. Radiographically, ARDS cannot be distinguished from cardiogenic pulmonary edema; therefore, a pulmonary artery catheter is almost essential. In addition, because ventilatory maneuvers can reduce cardiac output (excessive PEEP), appropriate hemodynamic monitoring can be essential for establishing appropriate ventilator settings. A summary of monitoring parameters for patients with ARDS can be found in Table 28–10.

CONCLUSIONS

ARDS-related mortality remains very high. Therapy is primarily supportive but requires extensive comprehension of the underlying pathophysiology to ensure optimal pharmacotherapy. Separation of the illness into pulmonary and extrapulmonary etiologies may become necessary to develop proper strategies for research and therapeutic interventions. Vigilance in monitoring ventilatory and hemodynamic end points to prevent MODS is the priority, with prevention of secondary complications such as pneumonia and catheter-related infections very significant. Designing research that is both ethically acceptable and clinically sound remains a difficult and controversial issue.

Learning Objectives and other resources can be found at www.pharmacotherapyonline.com.

KEY CONCEPTS

1 Select populations may be more susceptible to toxicities associated with specific agents.

2 Primary treatment is discontinuation of the offending agent and supportive care.

The manifestations of drug-induced pulmonary diseases span the entire spectrum of pathophysiologic conditions of the respiratory tract. As with most drug-induced diseases, the pathologic changes are non-specific. Therefore, the diagnosis is often difficult and, in most cases, is based on exclusion of all other possible causes. In addition, the true incidence of drug-induced pulmonary disease is difficult to assess as a result of the pathologic nonspecificity and the interaction between the underlying disease state and the drugs.

Considering the physiologic and metabolic capacity of the lung, it is surprising that drug-induced pulmonary disease is not more common. The lung is the only organ of the body that receives the entire circulation. In addition, the lung contains a heterogeneous population of cells capable of various metabolic functions, including *N*-alkylation, *N*-dialkylation, *N*-oxidation, reduction of *N*-oxides, and *C*-hydroxylation.

Evaluation of epidemiologic studies on adverse drug reactions provides a perspective of the importance of drug-induced pulmonary disease. In a 2-year prospective survey of a community-based general practice, 41% of 817 patients experienced adverse drug reactions.¹ Four patients, or 0.5% of the total respondents, experienced adverse respiratory symptoms. Respiratory symptoms occurred in 1.2% of patients experiencing adverse drug reactions. In a recent retrospective analysis of clinical case series in France, 898 patients had reported drug allergy, with a bronchospasm incidence of 6.9%. When these patients were rechallenged with the suspected drug, only 241 (17.6%) tested positive. The incidence of bronchospasm in patients with positive provocation test was 7.9%.²

Adverse pulmonary reactions are uncommon in the general population but are among the most serious reactions, often requiring intervention. In a study of 270 adverse reactions leading to hospitalization from two populations, 3.0% were respiratory in nature.³ Of the reactions considered to be life-threatening, 12.3% were respiratory. An early report on death caused by drug reactions from the Boston Collaborative Drug Surveillance Program indicated that 7 of 27 drug-induced deaths were respiratory in nature.⁴ This was confirmed in a follow-up study in which 6 of 24 drug-induced deaths were respiratory in nature.⁵

with chronic obstructive airway disease, alveolar hypoventilation, and chronic carbon dioxide retention have an exaggerated respiratory depressant response to narcotic analgesics and sedatives. In addition, the injudicious administration of oxygen in patients with carbon dioxide retention can worsen ventilation-perfusion mismatching, producing apnea.⁶ Although the benzodiazepines are touted as causing less respiratory depression than barbiturates, they may produce a profound additive or synergistic effect when taken in combination with other respiratory depressants. Combining intravenous diazepam with phenobarbital to stop seizures in an emergency department frequently results in admissions to an intensive care unit for a short period of assisted mechanical ventilation, regardless of the drug administration rate. Too rapid intravenous administration of any of the benzodiazepines, even without coadministration of other respiratory depressants, will result in apnea. The risk appears to be the same for the various available agents (diazepam, lorazepam, and midazolam). Respiratory depression and arrests resulting in death and hypoxic encephalopathy have occurred following rapid intravenous administration of midazolam for conscious sedation prior to medical procedures. This has been reported more commonly in the elderly and the chronically debilitated or in combination with opioid analgesics. Concurrent use of inhibitors of cytochrome P450 3A4 with benzodiazepines are likely to lead to greater risk of respiratory depression.

1 Prolonged apnea may follow administration of any of the neuromuscular blocking agents used for surgery, particularly in patients with hepatic or renal dysfunction. In addition, persistent neuromuscular blockade and muscle weakness have been reported in critically ill patients receiving neuromuscular blockers continuously for more than 2 days to facilitate mechanical ventilation.⁷ This has resulted in delayed weaning from mechanical ventilation and prolonged ICU stays. The prolonged neuromuscular blockade has been confined principally to pancuronium and vecuronium in patients with renal disease. Both agents have pharmacologic active metabolites that are excreted renally. The persistent muscular weakness is less well defined but appears to represent an acute myopathy.⁷ High-dose corticosteroids appear to produce a synergistic effect, supported by animal studies showing that corticosteroids at dosages greater than or equal to 2 mg/kg per day of prednisone produce atrophy in denervated muscle.⁸ The fluorinated corticosteroids (e.g., triamcinolone) appear to be more myopathic.⁹ Dose-dependent respiratory muscle weakness has been reported in chronic obstructive pulmonary

DRUG-INDUCED APNEA

Apnea may be induced by central nervous system (CNS) depression or respiratory neuromuscular blockade (Table 29–1). Patients

disease (COPD) and asthma patients receiving repeated short courses of oral prednisone in the previous 6 months.¹⁰

Respiratory failure has been known to occur following local spinal anesthesia. Apnea from respiratory paralysis and rapid respiratory muscle fatigue has followed the administration of polymyxin and aminoglycoside antibiotics.⁶ The mechanism appears to be related to the complexation of calcium and its depletion at the myoneural junction. Intravenous calcium chloride has been variably effective in reversing the paralysis.⁶ The aminoglycosides competitively block neuromuscular junctions. This has resulted in life-threatening apnea when neomycin, gentamicin, streptomycin, or bacitracin has been administered into the peritoneal and pleural cavities.⁶ The aminoglycosides will produce an additive blockade and ventilatory paralysis with curare or succinylcholine and in patients with myasthenia gravis or myasthenic syndromes.⁶ Intravenous administration of aminoglycosides has resulted in respiratory failure in babies with infantile botulism. Treatment consists of ventilatory support and administration of an anticholinesterase agent (neostigmine or edrophonium).⁶

DRUG-INDUCED BRONCHOSPASM

Bronchoconstriction is the most common drug-induced respiratory problem. Bronchospasm can be induced by a wide variety of drugs through a number of disparate pathophysiologic mechanisms (Table 29–2). Regardless of the pathophysiologic mechanism, drug-induced bronchospasm is almost exclusively a problem of patients with preexisting bronchial hyperreactivity (e.g., asthma, chronic obstructive lung disease).¹¹ By definition, all patients with nonspecific bronchial hyperreactivity will experience bronchospasm if given sufficiently high doses of cholinergic or anticholinesterase agents. Severe asthmatics with a high degree of bronchial reactivity may wheeze following the inhalation of a number of particulate substances, such as the

lactose in dry-powder inhalers (DPIs) and inhaled corticosteroids, presumably through direct stimulation of the central airway irritant receptors. Other pharmacologic mechanisms for inducing bronchospasm include β_2 -receptor blockade and nonimmunologic histamine release from mast cells and basophils.¹¹ A large number of agents are capable of producing bronchospasm through immunoglobulin (IgE)-mediated reactions.¹¹ These drugs can become a significant occupational hazard for pharmacists, nurses, and pharmaceutical industry workers.¹¹

ASPIRIN-INDUCED BRONCHOSPASM

Aspirin sensitivity or intolerance occurs in 4% to 20% of all asthmatics.¹² The frequency of aspirin-induced bronchospasm increases with age. Patients older than 40 years have a frequency approximately four times that of patients younger than 20 years.¹² The frequency increases to 14% to 23% in patients with nasal polyps.¹² Women predominate over men, and there is no evidence for a genetic or familial predisposition.¹³

The classic description of the aspirin-intolerant asthmatic includes the triad of severe asthma, nasal polyps, and aspirin intolerance. The typical patient experiences intense vasomotor rhinitis, which may or may not be associated with aspirin exposure, beginning during the third or fourth decade of life.¹⁴ Over a period of months, nasal polyps begin to appear, followed by severe asthma exacerbated by aspirin.

Bronchospasm typically begins within minutes to hours following ingestion of aspirin and is associated with rhinorrhea, flushing of the head and neck, and conjunctivitis.¹⁴ The reactions are severe and often life-threatening.

All aspirin-sensitive asthmatics do not fit the classic “aspirin triad” picture, and not all patients with asthma and nasal polyps develop sensitivity to aspirin.¹³ In most cases, aspirin-sensitive asthmatics are clinically indistinguishable from the general population of asthmatics except for their intolerance to aspirin and other nonsteroidal anti-inflammatory drugs (NSAIDs). Aspirin-induced asthmatics are not at higher risk of having fatal asthma if aspirin and other NSAIDs are avoided.¹⁵

Diagnosis of aspirin-induced asthma requires a detailed medical history. The definitive diagnosis is made by aspirin provocation tests, which may be done via different routes.^{13,16} An oral provocation test is used commonly where threshold doses of aspirin induce a positive reaction measured by a drop in forced expiratory volume in 1 second (FEV₁) and/or the presence of symptoms.^{16,17} A nasal provocation test is done by the application of one dose of lysine-aspirin, and aspirin sensitivity is manifested with clinical symptoms of watery discharge and a significant fall in inspiratory nasal flow.^{16,17} When lysine-aspirin bronchoprovocation was compared with oral aspirin provocation, both methods were equally sensitive.¹⁸

PATHOGENESIS

Aspirin-induced asthma is correctly classified as an idiosyncratic reaction in that the pathogenesis is still unknown. Patients with aspirin intolerance have increased plasma histamine concentrations after ingestion of aspirin and elevated peripheral eosinophil counts.^{13,14} All attempts to define an immunologic mechanism have been unsuccessful. Chemically similar drugs such as salicylamide and choline salicylate do not cross-react, whereas a large number of chemically dissimilar NSAIDs do produce reactions.^{13,14} Table 29–3 lists the analgesics that do and do not cross-react with aspirin.

TABLE 29–3. Tolerance of Anti-Inflammatory and Analgesic Drugs in Aspirin-Induced Asthma

^aA very small percentage (5%) of aspirin-sensitive patients react to acetaminophen and phenacetin.

The currently accepted hypothesis of aspirin-induced asthma is that aspirin intolerance is integrally related to inhibition of cyclooxygenase. This is supported by the following evidence: (1) All NSAIDs that inhibit cyclooxygenase produce reactions, (2) the degree of cross-reactivity is proportional to the potency of cyclooxygenase inhibition, and (3) each patient with aspirin sensitivity has a threshold dose for precipitating bronchospasm that is specific for the degree of cyclooxygenase inhibition produced, and once established, the dose of another cyclooxygenase inhibitor needed to induce bronchospasm can be estimated.¹⁴

The mechanism by which cyclooxygenase inhibition produces bronchospasm in susceptible individuals is unknown. Arachidonic acid metabolism through the 5-lipoxygenase pathway may lead to the excess production of leukotrienes C₄ and D₄.¹⁵ Leukotrienes C₄, D₄, and E₄ produce bronchospasm and promote histamine release from mast cells,¹⁴ whereas the administration of leukotriene receptor antagonists and 5-lipoxygenase inhibitors ablate the pulmonary and nonpulmonary responses to aspirin in aspirin-sensitive asthmatics.¹⁹ The precise mechanism by which augmented leukotriene production occurs is unknown, and available hypotheses do not explain why only a small number of asthmatic patients react to aspirin and NSAIDs.

DESENSITIZATION

Patients with aspirin sensitivity can be desensitized. The ease of desensitization correlates with the sensitivity of the patient.¹⁴ Highly sensitive patients who react initially to less than 100 mg aspirin require multiple rechallenges to produce desensitization.¹³ Desensitization usually persists for 2 to 5 days following discontinuance, with full sensitivity reestablished within 7 days.¹³ Cross-desensitization has been established between aspirin and all NSAIDs tested to date. Because patients may experience life-threatening reactions, desensitization should be attempted only in a controlled environment by personnel with expertise in handling these patients. In addition, there have been reports of patients who have failed to maintain a desensitized state despite continued aspirin administration.¹³ The chronic asthma symptoms have improved markedly in a number of aspirin-sensitive asthmatics who have undergone desensitization.¹³

CROSS-SENSITIVITY WITH FOOD AND DRUG ADDITIVES

Up to 80% of aspirin-sensitive asthmatics will have an adverse reaction to the yellow azo dye tartrazine (FD&C Yellow No. 5), which is used widely for coloring foods, drinks, drugs, and cosmetics.¹² However, the studies reporting high cross-reactivity were poorly controlled and often used only subjective criteria.^{12,20} In double-blind, placebo-controlled trials using pulmonary function testing, sensitivity to tartrazine has proved to be a rare event.²⁰ Tartrazine sensitivity appears to occur only in aspirin-intolerant patients at a prevalence of 2%.²⁰ Although rare, owing to the severity of reaction and widespread use of tartrazine, the Food and Drug Administration (FDA) has required labeling for the products containing this dye.²¹ The likely mechanism is dose-related histamine release, and the clinical presentation is the same as the reaction to aspirin in aspirin-sensitive patients.²¹

Reactions to other azo dyes, monosodium glutamate, parabens, and nonazo dyes have been reported much less frequently than reactions to tartrazine and have been equally difficult to confirm with controlled challenges.²⁰ Positive reactions to sodium benzoate, a food preservative, have been reported in as many as 23% of

aspirin-sensitive individuals.¹² Acetaminophen is a weak inhibitor of cyclooxygenase. As such, approximately 5% of aspirin-sensitive asthmatics will experience reactions to acetaminophen.¹² Most aspirin-sensitive asthmatics can use acetaminophen as a safe alternative to aspirin. There is a growing body of evidence that selective COX-2 inhibitors may be used safely in aspirin-sensitive patients,^{22–25} but long-term studies with these agents should be undertaken to confirm

their safe use in aspirin-sensitive patients. At this point, the package inserts of these agents state that they are contraindicated for aspirin-sensitive asthmatics.^{22–25} Sporadic cases of worsening bronchospasm and anaphylaxis have been reported in aspirin-sensitive asthmatics receiving intravenous hydrocortisone succinate, but such reactions have not been reported with use of other corticosteroids.¹³ It is not known whether it is the hydrocortisone or the succinate that is the problem.

► TREATMENT: Aspirin-Sensitive Asthma

2 Therapy of aspirin-sensitive asthmatics takes one of two general approaches: desensitization or avoidance. Avoidance of triggering substances seldom alters the clinical course of patients' asthma. The therapy of asthma has been nonspecific; however, in theory, 5-lipoxygenase inhibitors such as zileuton or leukotriene antagonists should provide specific therapy. A few studies have investigated use of leukotriene modifiers to prevent aspirin-induced bronchospasm in aspirin-sensitive asthmatic patients.^{26–28} Pretreatment with zileuton in eight aspirin-sensitive asthmatic patients protected them from the same threshold provoking doses of aspirin.²⁶ However, larger, escalating doses of aspirin above the threshold challenge doses were not examined in this study. Furthermore, when doses of aspirin were escalated above the threshold provocative doses, zileuton did not prevent formation of leukotrienes.²⁷ In a similar study, pretreatment with montelukast 10 mg/day did not protect patients when aspirin doses were increased above their threshold doses.²⁸ In a recent study, the mean provoking dose of aspirin did not differ in the asthmatics who were taking leukotriene modifiers and the control group (60.4 mg versus 70.3 mg, respectively).²⁹ Although initial studies suggested that

leukotriene modifiers blocked aspirin-induced reactions, it is now apparent that they merely shift the dose-response curve to the right, leaving the patient at risk at higher doses. Thus even patients who might benefit from leukotriene modifiers should avoid aspirin and all NSAIDs. A case of ibuprofen 400 mg–induced asthma was reported in an asthmatic patient on zafirlukast 20 mg twice daily.³⁰ Furthermore, most of the challenge studies are based on incremental doses of aspirin or NSAIDs, and exposure of patients to full clinical doses of aspirin or NSAIDs can overcome the antagonistic effect of leukotriene modifiers. The respiratory symptoms can be decreased but not prevented by pretreatment with antihistamines, cromolyn, and nedocromil.^{13,31} The long-term asthma control of patients with aspirin sensitivity does not differ from that for other asthmatics. There is no evidence to support that aspirin-sensitive asthmatics respond better to leukotriene modifiers. In a double-blind, randomized, placebo-controlled study, aspirin-sensitive asthmatic patients on montelukast showed a 10% improvement in FEV₁ compared with the placebo group.³² Similar results were reported when montelukast was compared with placebo in patients with intermittent or persistent asthma.³³

β-BLOCKERS

1 β-Adrenergic receptor blockers comprise the other large class of drugs that can be hazardous to a person with asthma. Even the more cardioselective agents such as acebutolol, atenolol, and metoprolol have been reported to cause asthma attacks.¹¹ Patients with asthma may take nonselective and β₁-selective blockers without incident for long periods; however, the occasional report of fatal asthma attacks resistant to therapy with β-agonists should provide ample warning of the dangers inherent in β-blocker therapy.¹¹

If a patient with bronchial hyperreactivity requires β-blocker therapy, one of the selective β₁-blockers (e.g., acebutolol, atenolol, metoprolol, or pindolol) should be used at the lowest possible dose. Celiprolol and betaxolol appear to possess greater cardioselectivity than currently marketed drugs.^{34,35} Fatal status asthmaticus has occurred with the topical administration of the nonselective timolol maleate ophthalmic solution for the treatment of open-angle glaucoma.³⁶ Early investigations with ophthalmic betaxolol suggest that it is well tolerated even in timolol-sensitive asthmatics.^{37,38}

SULFITES

Severe, life-threatening asthmatic reactions following consumption of restaurant meals and wine have occurred secondary to ingestion of the food preservative potassium metabisulfite.²⁰ Sulfites have been used for centuries as preservatives in wine and food. As antioxidants, they prevent fermentation of wine and discoloration of fruits and vegeta-

bles caused by contaminating bacteria.³⁹ Previously, sulfites had been given "generally recognized as safe" status by the FDA. Sensitive patients react to concentrations ranging from 5 to 100 mg, amounts that are consumed routinely by anyone eating in restaurants. Consumption of sulfites in U.S. diets is estimated to be 2 to 3 mg/day in the home with 5 to 10 mg per 30 mL of beer or wine consumed.²⁰ Anaphylactic or anaphylactoid reactions to sulfites in nonasthmatics are extremely rare. In the general asthmatic population, reactions to sulfites are uncommon. Approximately 5% of steroid-dependent asthmatics demonstrate sensitivity to sulfiting agents, but the prevalence is only around 1% in non-steroid-dependent asthmatic patients.³⁹

MECHANISM

Three different mechanisms have been proposed to explain the reaction to sulfites in asthmatic patients.³⁹ The first is explained by the inhalation of sulfur dioxide, which produces bronchoconstriction in all asthmatics through direct stimulation of afferent parasympathetic irritant receptors. Furthermore, inhalation of atropine or the ingestion of doxepin protects sulfite-sensitive patients from reacting to the ingestion of sulfites. The second theory, IgE-mediated reaction, is supported by reported cases of sulfite-sensitive anaphylaxis reaction in patients with positive sulfite skin test. Finally, a reduced concentration of sulfite oxidase enzyme (the enzyme that catalyzes oxidation of sulfites to sulfates) compared with normal individuals has been demonstrated in a group of sulfite-sensitive asthmatics.

A number of pharmacologic agents contain sulfites as preservatives and antioxidants. The FDA now requires warning labels on

drugs containing sulfites. Most manufacturers of drugs for the treatment of asthma have discontinued the use of sulfites. In addition, labeling is required on packaged foods that contain sulfites at 10 ppm or more, and sulfiting agents are no longer allowed on fresh fruits and vegetables (excluding potatoes) intended for sale.

Pretreatment with cromolyn, anticholinergics, and cyanocobalamin have protected sulfite-sensitive patients.^{39,40} Presumably, pharmacologic doses of vitamin B₁₂ catalyze the nonenzymatic oxidation of sulfite to sulfate.

OTHER PRESERVATIVES

Both ethylenediamine tetraacetic acid (EDTA) and benzalkonium chloride used as stabilizing and bacteriostatic agents, respectively, can produce bronchoconstriction.⁴¹ In addition to producing bronchoconstriction, EDTA potentiates the bronchial responsiveness to histamine.⁴¹ These effects presumably are mediated through calcium chelation by EDTA. Benzalkonium chloride is more potent than EDTA, and its mechanism appears to be a result of mast cell degranulation and stimulation of irritant C fibers in the airways.⁴¹

The bronchoconstriction from benzalkonium chloride can be blocked by cromolyn but not the anticholinergic ipratropium bromide.⁴² Benzalkonium chloride is found in the commercial multiple-dose nebulizer preparations of ipratropium bromide and beclomethasone dipropionate marketed in the United Kingdom and Europe and is presumed to be in part responsible for paradoxical wheezing following administration of these agents.^{41–43} Benzalkonium chloride is also found in albuterol nebulizer solutions marketed in the United States and has been implicated as a possible cause of paradoxical wheezing in infants receiving this preparation.⁴¹ The effect of these agents on FEV₁ when used in the amount administered for treatment of acute asthma was evaluated in subjects with stable asthma.⁴⁴ Patients were assigned randomly to inhale up to four 600-mcg nebulized doses of EDTA and benzalkonium chloride and normal saline. The change in FEV₁ was not different between EDTA and the placebo group; however, benzalkonium chloride was associated with a statistically significant decrease in FEV₁ compared with placebo. It is important to consider that these agents are always used in combination with bronchodilators and β_2 -agonists, which are potent mast cell stabilizers, and the anecdotal reports have not yet been confirmed with controlled investigations.^{41,42}

CONTRAST MEDIA

Iodinated radiocontrast materials are the most common cause of anaphylactoid reactions producing bronchospasm.⁴⁵ The reader is referred to Chap. 86 for a discussion of this topic.

NATURAL RUBBER LATEX ALLERGY

Allergy to natural rubber latex, first reported in 1989 in the United States, is a common cause of occupational allergy for health care workers.⁴⁶ Natural rubber is a processed plant product from the commercial rubber tree, *Hevea brasiliensis*.⁴⁷ Latex allergens are proteins found in both raw latex and the extracts used in finished rubber products. Latex gloves are the largest single source of exposure to the protein allergens.⁴⁷

1 The reported prevalence of latex allergy depends on the sample population. In the general population, latex allergy is less than 1%; however, the prevalence increases in health care workers to 5% to 15%.⁴⁷ Risk factors for latex allergy include frequent exposure to rubber gloves, history of atopic disease, and presence or history of hand dermatitis. Patients with spina bifida are at an increased risk of latex allergy with incidence of 24% to 60% due to early and repeated exposure to rubber devices during the surgical procedures.⁴⁷

Clinical manifestations of latex allergy range from contact dermatitis and urticaria, rhinitis and asthma, and reported cases of anaphylaxis.^{46,47} The early manifestation of rubber allergy is contact urticaria, which is an IgE-mediated reaction to rubber proteins following direct contact with the medical devices: mainly rubber gloves.⁴⁷ Contact dermatitis may occur within 1 to 2 days. Contact dermatitis is a cell-mediated delayed-type hypersensitivity reaction to the additive chemical component of rubber products.⁴⁷ Rhinitis and asthma may follow inhalation of allergens by cornstarch powder used to coat the latex gloves. Asthma caused by occupational exposure is seen mostly in atopic patients with histories of seasonal and perennial allergies and asthma.⁴⁷ There are also isolated cases of wheezing secondary to latex exposure in patients without a history of asthma.⁴⁷

The diagnosis of latex allergy is based on the presence of latex-specific IgE, as well as symptoms consistent with IgE-mediated reactions.⁴⁸ The mainstay of therapy for latex allergy is avoidance. The FDA requires appropriate labeling for all medical devices containing natural rubber latex to ensure avoidance and a latex-free environment. The role of pretreatment with antihistamines, corticosteroids, and allergen immunotherapy remains to be determined.^{47,48} Two randomized, placebo-controlled clinical trials have evaluated the role of specific immunotherapy in the treatment of latex allergy.^{49,50} Although both studies have shown an improvement of cutaneous and rhinitis reactions, systemic reactions were observed, and bronchoconstriction did not improve. At this time, immunotherapy remains investigational for the treatment of latex allergy.

ANGIOTENSIN-CONVERTING ENZYME INHIBITOR-INDUCED COUGH

1 Cough has become a well-recognized side effect of angiotensin-converting enzyme (ACE) inhibitor therapy. According to spontaneous reporting by patients, cough occurs in 1% to 10% of patients receiving ACE inhibitors, with a preponderance of females. In a retrospective analysis, 14.6% of women had cough compared with 6.0% of the men on ACE inhibitors. It is suggested that women have a lower cough threshold, resulting in their reporting this adverse effect more commonly than men.⁵¹ Studies specifically evaluating cough caused by ACE inhibitors have reported a prevalence of 19% to 25%.^{52,53} Patients receiving ACE inhibitors had a 2.3 times greater likelihood of developing cough than a similar group of patients receiving diuretics.⁵² Patients with hyperreactive airways do not appear to be at greater risk.⁵³ African-Americans and Chinese have a higher incidence of cough.⁵¹ When different disease states were compared, 26% of patients with heart failure had ACE inhibitor-induced cough compared with 14% of those with hypertension.⁵¹ Cough can occur with all ACE inhibitors.⁵⁴

The cough typically is dry and nonproductive, persistent, and not paroxysmal.⁵⁴ The severity of cough varies from a “tickle” to a debilitating cough with insomnia and vomiting. The cough can begin within 3 days or have a delayed onset of up to 12 months following initiation of ACE inhibitor therapy.⁵⁴ The cough remits within 1 to

4 days of discontinuing therapy but rarely can last up to 4 weeks and recur with rechallenge.⁵⁴ Patients should be given a 4-day withdrawal to determine if the cough is induced by ACE inhibitors. The chest x-ray is normal, as are pulmonary function tests (spirometry and diffusing capacity). Bronchial hyperreactivity, as measured by histamine and methacholine provocation, may be worsened in patients with underlying bronchial hyperreactivity such as asthma and chronic bronchitis. However, bronchial hyperreactivity is not induced in others.^{54,55} The cough reflex to capsaicin is enhanced but not to nebulized distilled water or citric acid.⁵⁴

The mechanism of ACE inhibitor–induced cough is still unknown. ACE is a nonspecific enzyme that also catalyzes the hydrolysis of bradykinin and substance P (see Chap. 24) that produce or facilitate inflammation and stimulate lung irritant receptors.⁵⁴ ACE inhibitors also may induce cyclooxygenase to cause the production of prostaglandins. NSAIDs, benzonatate, inhaled bupivacaine, theophylline, baclofen, thromboxane A₂ synthase inhibitor,^{51,56} and cromolyn sodium all have been used to suppress or inhibit ACE inhibitor–induced cough.^{54,57} The cough generally is not responsive to cough suppressants or bronchodilator therapy. No long-term trials evaluating different treatment options for ACE inhibitor–induced cough exist. Cromolyn sodium may be considered first because it is the  most studied agent and has minimal toxicity.⁵¹ The preferred therapy is withdrawal of the ACE inhibitor and replacement with an alternative antihypertensive agent. Owing to their decrease in ACE inhibitor–induced side effects, angiotensin II receptor antagonists often are recommended in place of an ACE inhibitor; however, there are rare reports of this agent inducing bronchospasm.⁵⁸ The clinical trials suggest that angiotensin II receptor antagonists have the same incidence of cough as placebo. Furthermore, when angiotensin II receptor antagonists were compared with ACE inhibitors, cough occurred much less frequently. Reduction in the incidence of cough with angiotensin II receptor antagonists is likely due to the lack of effect on clearance of bradykinin and substance P.⁵⁹ The use of alternative therapies to treat ACE inhibitor–induced cough generally is not recommended.⁴

PULMONARY EDEMA

Pulmonary edema may result from the failure of any of a number of homeostatic mechanisms. The most common cause of pulmonary edema is an increase in capillary hydrostatic pressure because of left ventricular failure. Excessive fluid administration in compensated and decompensated heart failure patients is the most frequent cause of iatrogenic pulmonary edema. Besides hydrostatic forces, other homeostatic mechanisms that may be disrupted include the osmotic and oncotic pressures in the vasculature, the integrity of the alveolar epithelium, interstitial pulmonary pressure, and the interstitial lymph flow.⁶ The edema fluid in cardiogenic pulmonary edema contains a low amount of protein, whereas noncardiogenic pulmonary edema fluid has a high protein concentration.⁶ This indicates that noncardiogenic pulmonary edema results primarily from disruption of the alveolar epithelium. The reader is referred to Chap. 28 for a detailed discussion of this topic.

The clinical presentation of pulmonary edema includes persistent cough, tachypnea, dyspnea, tachycardia, rales on auscultation, hypoxemia from ventilation-perfusion imbalance and intrapulmonary shunting, widespread fluffy infiltrates on chest roentgenogram, and decreased lung compliance (stiff lungs). Noncardiogenic pulmonary edema may progress to hemorrhage; cellular debris collects in the

alveoli, followed by hyperplasia and fibrosis with a residual restrictive mechanical defect.⁶

NARCOTIC-INDUCED PULMONARY EDEMA

The most common drug-induced noncardiogenic pulmonary edema is produced by the narcotic analgesics⁶ (Table 29–4). Narcotic-induced pulmonary edema is associated most commonly with intravenous heroin use but also has occurred with morphine, methadone, meperidine, and propoxyphene use.^{6,60} There also have been a few reported cases associated with the use of the opiate antagonist naloxone and nalmefene, a long-acting opioid antagonist.^{61,62} The mechanism is unknown but may be related to hypoxemia similar to the neurogenic pulmonary edema associated with cerebral tumors or trauma or a direct toxic effect on the alveolar capillary membrane.⁶⁰ Initially thought to occur only with overdoses, most evidence now supports the theory that narcotic-induced pulmonary edema is an idiosyncratic reaction to moderate as well as high narcotic doses.⁶⁰

Patients with pulmonary edema may be comatose with depressed respirations or dyspnea and tachypnea. They may or may not have other signs of narcotic overdose. Symptomology varies from cough and mild crepitations on auscultation with characteristic radiologic findings to severe cyanosis and hypoxemia even with supplemental

oxygen. Symptoms may appear within minutes of intravenous administration but may take up to 2 hours to occur, particularly following oral methadone.⁶⁰ Hemodynamic studies in the first 24 hours have demonstrated normal pulmonary capillary wedge pressures in the presence of pulmonary edema.

Clinical symptoms generally improve within 24 to 48 hours and radiologic clearing occurs in 2 to 5 days, but abnormalities in pulmonary function tests may persist for 10 to 12 weeks. Therapy consists of naloxone administration, supplemental oxygen, and ventilatory support if required. Mortality is less than 1%.⁶⁰

OTHER DRUGS THAT CAUSE PULMONARY EDEMA

A paradoxical pulmonary edema has been reported in a few patients following hydrochlorothiazide ingestion but not any other benzthiazide diuretic.⁶ Acute pulmonary edema rarely has followed the injection of high concentrations of contrast medium into the pulmonary circulation during angiocardiology.⁶ Rare occurrences of pulmonary edema have followed the intravenous administration of bleomycin, cyclophosphamide, and vinblastine.⁶

The selective β_2 -adrenergic agonists terbutaline and ritodrine have been reported to induce pulmonary edema when used as tocolytics.⁶ This disorder commonly occurs 48 to 72 hours after tocolytic therapy.⁶² This has never occurred with their use in asthma patients, even in inadvertent overdosage. This reaction may result from excess fluid administration used to prevent the hypotension from β_2 -mediated vasodilation or the particular hemodynamics of pregnancy. In a review of 330 patients who received tocolytic therapy and were monitored closely for their fluid status, no episode of pulmonary edema was reported.⁶²

IL-2, a cytokine used alone or in combination with cytotoxic drugs, has been reported to induce pulmonary edema. Although other cytokines have been associated with pulmonary edema, the problem is most significant with IL-2. A weight gain of 2 kg has been reported after treatment with IL-2.⁶²

Pulmonary edema has occurred occasionally with salicylate overdoses. The serum salicylate concentrations are often greater than 45 mg/dL, and the patients have other signs of toxicity, although some cases have been associated with concentrations in the usual therapeutic range.⁶⁰

PULMONARY EOSINOPHILIA

Pulmonary infiltrates with eosinophilia (Loeffler's syndrome) have been associated with nitrofurantoin, *para*-aminosalicylic acid, methotrexate, sulfonamides, tetracycline, chlorpropamide, phenytoin, NSAIDs, and imipramine^{6,63} (Table 29–5). The disorder is characterized by fever, nonproductive cough, dyspnea, cyanosis, bilateral pulmonary infiltrates, and eosinophilia in the blood.⁶ Lung biopsy has revealed perivascularitis with infiltration of eosinophils, macrophages, and proteinaceous edema fluid in the alveoli. The symptoms and eosinophilia generally respond rapidly to withdrawal of the offending drug.

Sulfonamides were first reported as causative agents in users of sulfanilamide vaginal cream.⁶ *para*-Aminosalicylic acid frequently produced the syndrome in tuberculosis patients being treated with this agent.⁶ There have been nine reported cases associated with sulfasalazine use in inflammatory bowel disease.⁶³ The drug as-

sociated most frequently with this syndrome is nitrofurantoin.^{6,60} Nitrofurantoin-induced lung disorders appear to be more common in postmenopausal women.⁶⁰ Lung reactions made up 43% of 921 adverse reactions to nitrofurantoin reported to the Swedish Adverse Drug Reaction Committee between 1966 and 1976.⁶³ No apparent correlation exists between duration of drug exposure and severity or reversibility of the reaction.⁶³ Most cases occur within 1 month of therapy. Typical symptoms include fever, tachypnea, dyspnea, dry cough, and less commonly, pleuritic chest pain. Radiographic findings include bilateral interstitial infiltrates, predominant in the bases and pleural effusions 25% of the time. Although there are anecdotal reports that steroids are beneficial, the usual rapid improvement following discontinuation of the drugs brings the utility of steroids into question. Complete recovery usually occurs within 15 days of withdrawal.

A few cases of pulmonary eosinophilia have been reported in asthmatics treated with cromolyn.^{6,63} The significance of this is unknown in light of the occasional spontaneous occurrence of pulmonary eosinophilia in asthmatic patients. Cases of acute pneumonitis and eosinophilia have been reported to occur with phenytoin and carbamazepine therapy.⁶³ Patients have had other symptoms of hypersensitivity, including fever and rashes. The symptoms of dyspnea and cough subside following discontinuation of the drug.

OXYGEN TOXICITY

Because of the similarity to pulmonary fibrosis, oxygen-induced lung toxicity is reviewed briefly. More extensive reviews on this topic have been published.^{64,65}

The earliest manifestation of oxygen toxicity is substernal pleuritic pain from tracheobronchitis.⁶⁵ The onset of toxicity follows an asymptomatic period and presents as cough, chest pain, and dyspnea. Early symptoms usually are masked in ventilator-dependent patients. The first noted physiologic change is a decrease in pulmonary compliance caused by reversible atelectasis. Then decreases in vital capacity occur, followed by progressive abnormalities in carbon monoxide diffusing capacity.⁶⁵ Decreased inspiratory flow rates, reflected in the need for high inspiratory pressures in ventilator-dependent patients, occur as the fractional concentration of inspired oxygen requirement increases. The lungs become progressively stiffer as the ability to oxygenate becomes more compromised.

The fraction of inspired oxygen and duration of exposure are both important determinants of the severity of lung damage. Normal human volunteers can tolerate 100% oxygen at sea level for 24 to 48 hours with minimal to no damage.⁶⁴ Oxygen concentrations of

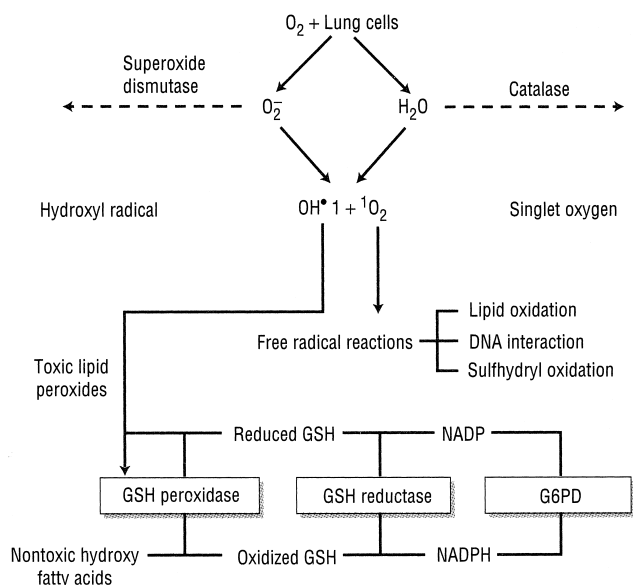

FIGURE 29-1. Schematic of the interaction of oxygen radicals and the antioxidant system. GSH = glutathione; G6PD = glucose-6-phosphate dehydrogenase; NADP = nicotinamide-adenine dinucleotide phosphate; NADPH = reduced NADP.

less than 50% are well tolerated even for extended periods. Inspired oxygen concentrations between 50% and 100% carry a substantial risk of lung damage, and the duration required is inversely proportional to the fraction of inspired oxygen.⁶⁴ Underlying disease states may alter this relationship. Lung damage may not be lasting and may improve months to years after the exposure.^{66,67}

Oxygen-induced lung damage generally is separated into the acute exudative phase and the subacute or chronic proliferative phase. The acute phase consists of perivascular, peribronchiolar, interstitial, and alveolar edema with alveolar hemorrhage and necrosis of pulmonary endothelium and type I epithelial cells.⁶⁴ The proliferative phase consists of resorption of the exudates and hyperplasia of interstitial and type II alveolar lining cells. Collagen and elastin deposition in the interstitium of alveolar walls then leads to thickening of the gas-exchange area and the fibrosis.⁶⁴

The biochemical mechanism of the tissue damage during hyperoxia is the increased production of highly reactive, partially reduced oxygen metabolites⁶⁵ (Fig. 29-1). These oxidants normally are produced in small quantities during cellular respiration and include the superoxide anion, hydrogen peroxide, the hydroxyl radical, singlet oxygen, and hypochlorous acid.⁶⁵ Oxygen free radicals normally are formed in phagocytic cells to kill invading microorganisms, but they also are toxic to normal cell components. The oxidants produce toxicity through destructive redox reactions with protein sulfhydryl groups, membrane lipids, and nucleic acids.⁶⁵

The oxidants are products of normal cellular respiration that are normally counterbalanced by an antioxidant defense system that prevents tissue destruction. The antioxidants include superoxide dismutase, catalase, glutathione peroxidase, ceruloplasmin, and α -tocopherol (vitamin E). Antioxidants are ubiquitous in the body. Hyperoxia produces toxicity by overwhelming the antioxidant system. There is experimental evidence that a number of drugs and chemicals produce lung toxicity through increasing production of oxidants (e.g., bleomycin, cyclophosphamide, nitrofurantoin, and paraquat) and/or by inhibiting the antioxidant system (e.g., carmustine, cyclophosphamide, and nitrofurantoin).^{68,69}

PULMONARY FIBROSIS

A large number of drugs have been associated with chronic pulmonary fibrosis with or without a preceding acute pneumonitis (Table 29-6). The cancer chemotherapeutic agents make up the largest group and have been the subject of numerous reviews.^{68,69} Although the mechanisms by which all the drugs produce pneumonitis and/or fibrosis are not known, the clinical syndrome, pulmonary function abnormalities, and histopathology present a relatively homogeneous pattern.⁶⁸ The histopathologic picture closely resembles oxidant lung damage, and in some experimental cases, oxygen enhances the pulmonary injury.⁶⁰ Although the terms *pulmonary fibrosis* or *interstitial pneumonitis* have been used widely to describe pneumonia after bone marrow transplantation, in 1991, a National Institutes of Health workshop recommended that the term *idiopathic pneumonia syndrome* (IPS) should be used to avoid histopathologic terms and to define the inherent heterogeneity of this disorder.⁷⁰ IPS accounts for more than 40% of deaths related to bone marrow transplantation.⁷⁰ Suggested causes of IPS include radiation or chemotherapy regimens prior to transplantation, graft-versus-host disease, unrecognized infections, and other inflammation-related lung injuries.^{71,72} IPS is characterized by dyspnea, hypoxemia, nonproductive cough, diffuse alveolar damage, and interstitial pneumonitis in the absence of lower respiratory infection. IPS has been reported early and late, up to 24 months after bone marrow transplantation.⁷²

The lung damage following ingestion of the contact herbicide paraquat classically resembles hyperoxic lung damage. Hyperoxia accelerates the lung damage induced by paraquat. Lung toxicity from paraquat occurs following oral administration in humans and aerosol administration and inhalation in experimental animals.⁶⁹ The pulmonary specificity of paraquat results in part from its active uptake into lung tissue. Paraquat readily accepts an electron from reduced nicotinamide-adenine dinucleotide phosphate and then is reoxidized rapidly, forming superoxide and other oxygen radicals.⁶⁹ The toxicity may be a result of nicotinamide-adenine dinucleotide phosphate depletion (see Fig. 29-1) and/or excess oxygen free-radical generation with lipid peroxidation. Treatment with exogenous superoxide dismutase has had limited and conflicting results.⁶⁹

A number of furans have been shown to produce oxidant injury to lungs.⁶⁹ Occasionally, patients with acute nitrofurantoin lung toxicity will progress to a chronic reaction leading to fibrosis, and

rarely, a patient may develop chronic toxicity without an antecedent acute reaction. Like paraquat, nitrofurantoin undergoes cyclic reduction and reoxidation that may produce superoxide radicals or deplete nicotinamide-adenine dinucleotide phosphate. In addition, nitrofurantoin inhibits glutathione reductase, an enzyme involved in the glutathione antioxidant system (see Fig. 29–1). Table 29–7 provides a list of possible nondrug causes of pulmonary fibrosis.

DRUGS ASSOCIATED WITH PULMONARY FIBROSIS

ANTINEOPLASTICS

A number of cancer chemotherapeutic agents produce pulmonary fibrosis. In an excellent review,⁶⁸ six predisposing factors for the development of cytotoxic drug–induced pulmonary disease were described: (1) cumulative dose, (2) increased age, (3) concurrent or previous radiotherapy, (4) oxygen therapy, (5) other cytotoxic drug therapy, and (6) preexisting pulmonary disease. Drugs that are directly toxic to the lung would be expected to show a dose-response relationship. Dose-response relationships have been established for bleomycin, busulfan, and carmustine (BCNU).⁶⁸ Bleomycin and busulfan exhibit threshold cumulative doses below which a very small percentage of patients exhibit toxicity, but carmustine shows a more linear relationship.⁶⁹ Older patients appear to be more susceptible, possibly as a result of a decrease in the antioxidant defense system.

Excessive irradiation produces a pneumonitis and fibrosis thought to be caused by oxygen free-radical formation.⁶⁸ Evidence for synergistic toxicity with radiation exists for bleomycin, busulfan, and mitomycin.⁶⁸ Hyperoxia has shown synergistic toxicity with bleomycin, cyclophosphamide, and mitomycin.⁶⁸ Carmustine, mitomycin, cyclophosphamide, bleomycin, and methotrexate all appear to show increased lung toxicity when they are part of multiple-drug regimens.

NITROSOUREAS

BCNU is associated with the highest incidence of pulmonary toxicity (20% to 30%).⁶⁸ The lung pathology generally resembles that

produced by bleomycin and busulfan. Unique to BCNU is the finding of fibrosis in the absence of inflammatory infiltrates. BCNU preferentially inhibits glutathione reductase, the enzyme required to regenerate glutathione, thus reducing glutathione tissue stores.^{68,69} The patients present with dyspnea, tachypnea, and nonproductive cough that may begin within a month of initiation of therapy but may not develop for as long as 3 years.⁶⁸ Most patients receiving BCNU develop fibrosis that may remain asymptomatic or become symptomatic any time up to 17 years after therapy.⁷³ The cumulative dose has ranged from 580 to 2100 mg/m².⁶⁹ The disease is usually slowly progressive with a mortality rate from 15% to greater than 90% depending on the study and period of follow-up. In a retrospective study, the risk factors for development of IPS and prognostic factors for outcomes were evaluated in 94 patients with relapsed Hodgkin's disease treated with BCNU containing high-dose chemotherapy and hematopoietic support. The risk factors for pulmonary fibrosis and mortality were female sex and dose of BCNU, with all deaths reported in those who received BCNU at doses of more than 475 mg/m².⁷⁴ Rapid progression and death within a few days occur in a small percentage of patients.⁶⁸ Corticosteroids do not appear to be effective in reducing damage.⁶⁸ Other nitrosoureas, lomustine, and semustine also have been reported to produce lung damage in patients receiving unusually high doses.⁶⁸

BLEOMYCIN

Bleomycin is the best-studied cytotoxic pulmonary toxin. Because of its lack of bone marrow suppression, pulmonary toxicity is the dose-limiting toxicity of bleomycin therapy. The incidence of bleomycin lung toxicity is about 4%, which may be affected by the following risk factors: bleomycin cumulative dose, age, high concentration of inspired oxygen, radiation therapy, and multidrug regimens, particularly those with cyclophosphamide.⁶² Age at the time of treatment with bleomycin may be a risk factor as well; patients younger than 7 years of age at the time of receiving bleomycin therapy are more likely to develop pulmonary toxicity compared with older subjects.⁶² The cumulative dose above which the incidence of toxicity significantly increases is 450 to 500 units.⁶⁸ However, rapidly fatal pulmonary toxicity has occurred with doses as low as 100 units.⁶⁸

Experimentally, bleomycin generates superoxide anions, and the lung toxicity is increased by radiation and hyperoxia.⁶⁸ Pretreatment with superoxide dismutase and catalase reduces toxicity in experimental animals.⁶⁸ Bleomycin also oxidizes arachidonic acid, which may account for the marked inflammation. Bleomycin also may affect collagen deposition by its stimulation of fibroblast growth.⁶⁸ Combination of bleomycin with other cytotoxic agents, particularly regimens containing cyclophosphamide, may predispose patients to pulmonary damage.

There are two distinct clinical patterns of bleomycin pulmonary toxicity. Chronic progressive fibrosis is the most common; acute hypersensitivity reactions occur infrequently. Patients present with cough and dyspnea. The first physiologic abnormality seen is a decreased diffusing capacity of carbon monoxide.⁶⁸ Chest radiographs show a bibasilar reticular pattern, and gallium scans show marked uptake in the involved lung.⁶⁸ Chest radiographic changes lag behind pulmonary function abnormalities. Spirometry tests before each bleomycin dose are not predictive of toxicity. The single-breath diffusing capacity of carbon monoxide is the most sensitive indicator of bleomycin-induced lung disease. Although it is not absolutely predictive, a drop of 20% or greater in the diffusing capacity of carbon monoxide is an indication for using alternative therapies.⁶⁸

The prognosis of bleomycin lung toxicity has improved due to early detection, but the mortality rate is approximately 25%. Mild cases respond to discontinuation of bleomycin therapy.⁶² Corticosteroid therapy appears to be helpful in patients with acute pneumonitis, although there have been no controlled trials. Patients with chronic fibrosis would be less likely to respond. Although corticosteroids have been used for a number of drug-induced pulmonary problems, a study in mice showing a potential for worsening of lung damage when administered early during the repair stage should sound a word of caution against their indiscriminate use.⁷⁵

MITOMYCIN

Mitomycin is an alkylating antibiotic that produces pulmonary fibrosis at a frequency of 3% to 12%.⁶⁸ The mechanism is unknown, but oxygen and radiation therapy appear to enhance the development of toxicity.⁶⁸ The clinical presentation and symptoms are the same as for bleomycin. The mortality rate is about 50%. Early withdrawal of the drug and administration of corticosteroids appear to improve the outcome significantly.

ALKYLATING AGENTS

A number of alkylating agents have been associated with pulmonary fibrosis (see Table 29–5). The incidence of clinical toxicity is around 4%, although subclinical damage is apparent in up to 46% of patients at autopsy. The mechanism of toxicity is unknown; however, epithelial cell damage that triggers the arachidonic acid inflammatory cascade may be the initiating event.⁶⁸ The clinical presentation is insidious, with 4 years being the average duration of therapy before the onset of symptoms.⁶⁸ Patients present with low-grade fever, weight loss, weakness, dyspnea, cough, and rales.⁶⁸ Pulmonary function tests initially show abnormal diffusion capacity followed by a restrictive pattern (low vital capacity). The histopathologic findings are nonspecific. The prognosis is one of slow progression with a mean survival of 5 months following diagnosis.⁶⁸ Although there is no direct dose-dependent correlation, patients receiving less than 500 mg busulfan do not develop the syndrome without concomitant radiation or use of other pulmonary toxic chemotherapeutic agents.⁶⁸ There are anecdotal reports of beneficial responses to corticosteroids, but no controlled studies have been done.

Cyclophosphamide infrequently produces pulmonary toxicity. More than 20 well-documented cases have been reported to date. In animal models, cyclophosphamide produces reactive oxygen radicals. High oxygen concentrations produce synergistic toxicity with cyclophosphamide. The duration of therapy before the onset of symptoms is highly variable, and there may be a delay of several months between the onset of symptoms and discontinuation of the drug.⁶⁸ Cyclophosphamide may potentiate carmustine lung toxicity.⁶⁸ Clinical symptoms usually consist of dyspnea on exertion, cough, and fever. Inspiratory crackles and the bibasilar reticular pattern typical of cytotoxic drug-induced radiographic changes are present. Histopathologic changes are also nonspecific. Approximately 60% of patients recover. Corticosteroid therapy has been reported to be beneficial; however, death despite corticosteroid administration also has been reported.

Chlorambucil, melphalan, and uracil mustard also have been associated with pulmonary fibrosis. Of the alkylating agents, only nitrogen mustard and thiotepa have not been reported to cause fibrotic pulmonary toxicity.⁶⁸

ANTIMETABOLITES

Methotrexate was first reported to induce pulmonary toxicity in 1969.⁶⁸ The pulmonary toxicity to methotrexate is unique in that discontinuation is not always necessary, and reinstatement of the drug may not produce recurrence of symptoms.⁶ Methotrexate pulmonary toxicity most commonly appears to result from hypersensitivity,⁶³ and it can occur 3 or more years following methotrexate therapy.⁷⁶ Age, sex, underlying pulmonary disease, duration of therapy, or smoking is not associated with an increased risk of pneumonitis with methotrexate.⁷⁶ Serial pulmonary function tests did not help to identify pneumonitis in patients receiving methotrexate before the onset of clinical symptoms.⁷⁶ Reductions in diffusing capacity of carbon monoxide and lung volumes are the most common manifestations of methotrexate lung toxicity.⁶² Pulmonary edema and eosinophilia are common, and fibrosis occurs in only 10% of the patients who develop acute pneumonitis.⁶⁸ Systemic symptoms of chills, fever, and malaise are common before the onset of dyspnea, cough, and acute pleuritic chest pain. Methotrexate also has been associated with granuloma formation.⁶⁸

The prognosis of methotrexate-induced pulmonary toxicity is good, with a 1% or less mortality rate.⁶³ Pulmonary toxicity has followed intrathecal as well as oral administration and has occurred after single doses as well as long-term daily and intermittent administration.⁶⁸ Pneumonitis has been reported to occur up to 4 weeks following discontinuation of therapy.⁶⁸ Numerous anecdotal reports have claimed dramatic benefit from corticosteroid therapy. It is unknown whether intermittent (weekly) dosing, as is done for rheumatoid arthritis, decreases the risk of methotrexate-induced pulmonary toxicity because pneumonitis has occurred with this form of dosing.

Rarely, azathioprine and its major metabolite 6-mercaptopurine have been reported to produce an acute restrictive lung disease. Procarbazine, a methylhydrazine associated more commonly with Loeffler's syndrome, rarely has been associated with pulmonary fibrosis.⁶³ The vinca alkaloids vinblastine and vindesine have been reported to produce severe respiratory toxicity in association with mitomycin. The incidence with the combination is 39% and may represent a true synergistic effect between these agents.⁶⁸

NONCYTOTOXIC DRUGS

Pulmonary fibrosis associated with the ganglionic-blocking agent hexamethonium was first reported in 1954⁶ (see Table 29–6). Patients developed extreme dyspnea after several months on the drug. Pathologic findings were consistent with bronchiectasis, bronchiolectasis, and fibrosis.⁶ This phenomenon has occurred occasionally with use of the other ganglionic blockers (i.e., mecamylamine and pentolinium).⁶

In 1959, radiographic changes characteristic of diffuse pulmonary fibrosis were reported in 87% of 31 patients who had taken phenytoin for 2 years or more.⁶⁰ Since then, studies have been conflicting. If phenytoin does produce chronic fibrosis, it would appear to be a relatively rare event.

Gold salts (sodium aurothiomalate) used in the treatment of rheumatoid arthritis have produced pulmonary fibrosis with cough, dyspnea, and pleuritic pain 5 to 16 weeks following institution of therapy.⁶⁰ Pulmonary function tests show a restrictive defect, and patients generally have an eosinophilia. The reactions improve on discontinuation of the gold therapy and recur promptly on reexposure. The pulmonary deficit may not resolve completely.

AMIODARONE

Amiodarone, a benzofuran derivative, produces pulmonary fibrosis when used for supraventricular and ventricular arrhythmias⁷⁷ (see Table 29–6). The duration of amiodarone therapy before the onset of symptoms has ranged from 4 weeks to 6 years.^{60,77} The estimated incidence is 1 in 1000 to 2000 treated patients per year. The clinical course is variable, ranging from acute onset of dyspnea with rapid progression into severe respiratory failure and death caused by slowly developing exertional dyspnea over a few months. Patients generally improve on discontinuation of the drug.⁷⁷ The majority of patients develop reactions while taking maintenance doses greater than 400 mg daily for more than 2 months or smaller doses for more than 2 years. The risk of amiodarone pulmonary toxicity is higher during the first 12 months of therapy even at a low dosage.⁷⁸ Other risk factors include cardiopulmonary surgery combined with the administration of high concentrations of oxygen.⁷⁸ Routine spirometry does not appear to be predictive of patients at risk.⁷⁹ Carbon monoxide diffusing capacity studies are sensitive indicators of amiodarone pulmonary toxicity but have only a 21% positive predictive value.⁷⁹ Clinical findings include exertional dyspnea, nonproductive cough, weight loss, and occasionally low-grade fever.^{60,79} Radiographic changes are nondiagnostic and consist of diffuse bilateral interstitial changes consistent with a pneumonitis. Pulmonary function abnormalities include hypoxia, restrictive changes, and diffusion abnormalities.

The mechanism of amiodarone-induced pulmonary toxicity is multifactorial. Amiodarone and its metabolite can damage lung tissue directly by a cytotoxic process or indirectly by immunologic reactions.⁷⁸ Amiodarone is an amphiphilic molecule that contains both a highly apolar aromatic ring system and a polar side chain with a positively charged nitrogen atom.⁷⁷ Amphiphilic drugs characteristically produce a phospholipid storage disorder in the lungs of experimental animals and humans.⁶⁹ Chlorphentermine, an anorectic, is the prototype amphiphilic compound. The mechanism is currently believed to be the inhibition of lysosomal phospholipases.⁶⁹ The inflammation and fibrosis are thought to be a late finding resulting from nonspecific inflammation following the breakdown of phospholipid-laden macrophages.⁷⁷

In a review of 39 cases, 9 patients died, and the remaining 30 patients had resolution of abnormalities after withdrawal of the drug.⁷⁷ Some patients have had resolution with lowering of the dosage, and therapy has been reinstated at lower doses without problems in others. Of the patients who died, one-half received corticosteroids. There have been reports of a protective effect with prophylactic corticosteroids and other reports of patients developing amiodarone lung toxicity while on corticosteroids.⁷⁷ At this time, any benefit of corticosteroids is unclear because most patients improve after stopping the drug.

PULMONARY HYPERTENSION

Pulmonary hypertension is a rare disorder, occurring with an approximate incidence of 1 to 2 cases per 1 million in the general population.⁸⁰ With progression of the disease, right ventricular afterload increases, and the ability to increase cardiac output with activity decreases. This progresses to right-sided heart failure and death.⁸¹

Patients with pulmonary hypertension often complain of exertional dyspnea, chest pain, and syncope. Due to the nonspecific nature of these symptoms and lack of a noninvasive diagnostic test for detecting pulmonary hypertension, there are often delays in the

diagnosis of the disease, frequently up to a year after the onset of symptoms.⁸¹

The factors leading to the development of pulmonary hypertension are unclear, although associations with portal hypertension and pregnancy have been detected. Obesity by itself may double the risk of pulmonary hypertension.⁸² Additionally, the use of cocaine or oral contraceptives, infection with the human immunodeficiency virus (HIV), the use of anorexic agents,⁸³ hepatic cirrhosis, genetic susceptibility, and female sex in the third to fourth decades of life also have been implicated as predisposing factors.⁸² Exposure of patients to fenfluramine or dexfenfluramine has been associated with 20% of all diagnosed cases of pulmonary hypertension.⁸²

The first reports of the association between pulmonary hypertension and the use of anorexic agents occurred in the late 1960s and early 1970s in western Europe when the drug aminorex was used for weight reduction.⁸⁴ The incidence of pulmonary hypertension returned to baseline after the drug was removed from the market. In the early 1990s, an association between fenfluramine use and pulmonary hypertension was established.⁸⁵ Shortly thereafter, the International Primary Pulmonary Hypertension Study Group investigated the potential role of anorexic agents in causing pulmonary hypertension.⁸³ Included in this multinational case-control study were 95 patients with pulmonary hypertension and 355 controls from general practices matched for gender and age. The use of anorexic agents, primarily fenfluramine and dexfenfluramine, within the last year was associated with an increased risk of pulmonary hypertension with an odds ratio of 10:1. When anorexic drugs were used for a total of more than 3 months, the odds ratio increased to 23:1.

In a 12-year observational study, 62 patients with fenfluramine-associated pulmonary hypertension were compared with 125 sex-matched patients with pulmonary hypertension unrelated to the use of fenfluramine derivatives. In most of the cases (81%), fenfluramine derivatives were used for at least 3 months. The time frame between the initiation of the therapy and the onset of dyspnea ranged from 27 days to 23 years. Both the fenfluramine-associated pulmonary hypertension group and the control group had similar levels of New York Heart Association functional class and symptoms, as well as an overall survival rate of 50% in 3 years.⁸⁶

The mechanism by which anorexic agents cause pulmonary hypertension is unknown. Studies have shown that fenfluramine, dexfenfluramine, and aminorex inhibit potassium channels in isolated pulmonary artery smooth muscle cells in rats, which results in vasoconstriction. Potassium channel activity is altered in pulmonary artery smooth muscle cells obtained from patients with pulmonary hypertension, leading to speculation that anorexic agents may cause vasoconstriction followed by vascular growth and remodeling.⁸¹ Another potential mechanism involves serotonin, which has been found in increased levels in patients with pulmonary hypertension.⁸¹ Serotonin can be stored in the platelet when serotonin plasma concentration is high. Serotonin acts as a pulmonary vasoconstrictor when it is released from the platelets.⁸²

Patients with pulmonary hypertension associated with anorexic use may experience a considerable improvement in their condition or possibly even remission within 1 to 3 months following discontinuation of the drug.^{82,87} Pharmacologic agents used in the treatment of pulmonary hypertension include high dosage of calcium channel blockers and anticoagulants.⁸⁰ Epoprostenol, also known as *prosta-cyclin*, a strong vasodilator of all vascular beds was approved for the long-term therapy of pulmonary hypertension in 1995.⁸⁸ Additionally, lung and heart lung transplantations have played a role in the treatment of pulmonary hypertension. However, the 4-year survival

rate is less than 60% in pulmonary hypertension patients receiving any transplant.⁸⁸ Bosentan, an endothelin receptor antagonist indicated for primary pulmonary hypertension, also may have a role, but currently, no studies exist describing its use.

In September 1997, the FDA requested the manufacturers of fenfluramine and dexfenfluramine to voluntarily withdraw their products from the market. This was done following case reports of valvular heart disease in patients taking either medication as monotherapy or in combination with another anorexic agent, phentermine. Because no association has been found between phentermine alone and valvular heart disease, it is still available. Isolated case reports of pulmonary hypertension and phentermine monotherapy have been reported,^{89,90} but present data do not support an association. Although fenfluramine and phentermine were both approved by the FDA to be used as anorectic agents, the combination therapy, “fen-phen,” was never approved.

MISCELLANEOUS PULMONARY TOXICITY

Drugs may produce serious pulmonary toxicity as part of a more generalized disorder. The pleural thickening, effusions, and fibrosis that occur as an extension of the retroperitoneal fibrotic reactions of methysergide and practolol or as part of a drug-induced lupus syndrome are the most common examples (Table 29–8).

Methysergide therapy for prophylaxis of poorly controlled migraine headache occasionally results in pulmonary toxicity associated with pleural effusions. The patients develop pleural pain, dyspnea, and fever. Chest radiography reveals a uniform hazy shadowing over the lower lung fields, and a loud pleural rub is heard on auscultation.⁶ The mechanism is unknown, and most patients improve with discontinuation of the drug. Pleural and pulmonary fibrosis has been reported in one patient taking pindolol, a β -blocker structurally similar to practolol, an agent known to produce fibrosis.⁶⁰ Acute pleuritis with pleural effusions and fibrosis is a prominent manifestation of drug-induced lupus syndrome. Procainamide is associated with the largest number of pulmonary reactions, with 46% of patients with the lupus

TABLE 29–8. Drugs That May Induce Pleural Effusions and Fibrosis

^aRelative frequency of reactions: F = frequent; I = infrequent; R = rare.

syndrome developing pulmonary complications.⁶ Symptoms include pleuritic pain and fever with muscle and joint pain. Chest radiographs show bilateral pleural effusions and linear atelectasis. Patients have a positive antinuclear antibody test. Symptoms usually resolve within 6 weeks of drug withdrawal.⁶

Hydralazine is the next most common cause of lupus syndrome. Most patients who develop pleuropulmonary manifestations have antecedent symptoms of generalized lupus.⁶ Other drugs that produce the lupus syndrome include isoniazid and phenytoin. Phenytoin also can produce hilar lymphadenopathy as part of a generalized pseudolymphoma or lymphadenopathy syndrome.⁶

MONITORING THERAPEUTIC OUTCOMES

Monitoring for drug-induced pulmonary diseases consists primarily of having a high index of suspicion that a particular syndrome may be drug-induced. Most hypersensitivity or allergic reactions (bronchospasm) occur rapidly, within the first 2 weeks of therapy with the offending agent, and reverse rapidly with appropriate therapy (e.g., withdrawal of the offending agent and administration of corticosteroids and bronchodilators). Dyspnea associated with Loeffler’s syndrome and acute pulmonary edema syndromes also improve rapidly in 1 to 2 days. However, some residual defect in diffusion capacity and the roentgenogram may persist for a few weeks. It is probably unnecessary to do follow-up spirometry or diffusion capacity determinations in these patients unless there is some concern that the syndrome will progress to pulmonary fibrosis (through the use of bleomycin or nitrofurantoin).

The routine monitoring of patients receiving known pulmonary toxins with dose-dependent toxicity such as amiodarone, bleomycin, or carmustine is still controversial. For chronic fibrosis, the diffusing capacity of carbon monoxide is the most sensitive test and may be useful in patients receiving bleomycin for detecting and preventing further deterioration of lung function with continued administration. Carmustine lung toxicity may be delayed up to 10 years following administration, and routine monitoring has not proved preventive. Monitoring patients receiving amiodarone in doses greater than 400 mg/day every 4 to 6 months may prove useful in detecting early disease that requires lowering the amiodarone or stopping the drug. Because there is no evidence of a cumulative dose effect once it has been established that the patient can tolerate the elevated dose, continued routine monitoring past the first year is unnecessary.

ABBREVIATIONS

ACE: angiotensin-converting enzyme
 CNS: central nervous system
 COPD: chronic obstructive pulmonary disease
 DPIs: dry-powder inhalers
 EDTA: ethylenediamine tetraacetic acid
 FDA: Food and Drug Administration
 FEV₁: forced expiratory volume in 1 second
 HIV: human immunodeficiency virus
 IPS: idiopathic pneumonia syndrome
 NSAIDs: nonsteroidal anti-inflammatory drugs

CYSTIC FIBROSIS

Gary Milavetz and Jeffrey J. Smith

Learning Objectives and other resources can be found at www.pharmacotherapyonline.com.

KEY CONCEPTS

- 1 Cystic fibrosis (CF) is a disorder of chloride ion transport in epithelial cells. It especially affects the cells that line the pulmonary and gastrointestinal systems, although the functions of other exocrine glands are also altered.
- 2 The chloride ion transport dysfunction results in thickened secretions that typically lead to obstruction, infection, and inflammation in the airways. These, in turn, lead to most of the morbidity and mortality associated with CF.
- 3 Thickened secretions from the pancreas lead to deficiencies of digestive enzymes and bicarbonate, which lead to maldigestion of foodstuffs. This maldigestion leads to malabsorption and malnutrition.
- 4 Treatment of the gastrointestinal component includes pancreatic enzyme replacement plus vitamin, nutrient, and caloric supplementation aimed at providing adequate nutritional needs.
- 5 Airway obstruction and pulmonary infection occur as a result of bacterial colonization and infection, thickened secretions, and inflammation.
- 6 Acute antibiotic treatment is aimed at bacterial eradication, whereas chronic treatment slows the progression of the disease. *Pseudomonas aeruginosa* is the most common pathogen found in patients with CF.
- 7 The progression of pulmonary disease is prevented by a two-pronged approach: (1) Reducing or eradicating inflammation to decrease cellular and tissue alterations. (2) Sterilizing the pulmonary tree to reduce the bacterial infection and colonization associated with the disease.
- 8 Gene therapy may be the treatment of the future, but it has not demonstrated beneficial effects yet.
- 9 The goal of therapy of CF is to slow or stop the progression of the disease and allow young patients to grow and develop normally. Although the pathophysiologic goal is similar in adulthood, the overall goal is to have as normal a lifestyle as possible.

Cystic fibrosis (CF) is the most common lethal genetic disease in the Caucasian population. The disease mainly involves the exocrine glands and thus affects a number of organ systems (Table 30–1). The more common manifestations of this disease involve the gastrointestinal and pulmonary systems, with premature mortality associated with the latter. Most of the pathology results from a defect in electrolyte transport caused by a loss of functional chloride channels in epithelial cells. The protean nature of this disease dictates that care be multidisciplinary with a wide variety of therapeutic interventions.

EPIDEMIOLOGY

CF is inherited through an autosomal (Mendelian) recessive mode. Of a couple with each parent being a carrier (heterozygous for the trait), a child has a one-in-four chance of having the disease, a one-in-two chance of being a carrier, and a one-in-four chance of being normal (having neither the disease nor the trait). The incidence of CF is greatest in the Caucasian population; it occurs in about 1 in every 2000 live births in the United States.¹ Thus the incidence of the trait (carrier state) in this group is about 5%. The frequency of this disease is considerably less in other races, occurring in about 1 in 17,000 blacks and 1 in 90,000 Asians.²

After years of intensive research, the cystic fibrosis gene was identified and cloned in 1989.^{3–5} The gene is located on the long arm of chromosome 7 and codes for a protein called the *cystic fibrosis transmembrane regulator* (CFTR). This membrane protein functions as a chloride channel involved in the transport of electrolytes and water. Over 1000 cystic fibrosis–associated mutations within the CF gene have been described, but the most common mutation involves a 3-base-pair deletion that results in the absence of a phenylalanine residue at position 508 of the CFTR protein.^{3–5} This common mutation, referred to as the ΔF_{508} allele, is present in about 70% of patients in the United States. The mutations have been divided into four classes: class I, defective protein production; class II, defective protein processing; class III, defective channel regulation; and class IV, defective channel conductance.⁶ Patients homozygous for the ΔF_{508} mutation, which falls primarily into class II, tend to be diagnosed at an earlier age owing to a greater frequency of pancreatic insufficiency (99% versus 72% in heterozygotes and 36% in patients with other genotypes).^{7,8}

PATHOPHYSIOLOGY

CF is a disease of epithelia, especially the cells lining the intestinal tract, pancreatic ducts, hepatobiliary tree, vas deferens, sweat ducts,

TABLE 30–1. Organ Involvement in Cystic Fibrosis

| Organ System/Organ | Abnormality | Consequence |
|--------------------|---|---|
| Gastrointestinal | | |
| Pancreas | Digestive enzyme deficiency Insulin deficiency | Maldigestion Malnutrition Glucose intolerance |
| Intestines | Viscous secretions | Obstruction |
| Liver | Biliary cirrhosis/fatty infiltration | Portal hypertension/ esophageal varices |
| Pulmonary | Viscous secretions Infection | Chronic obstruction Endobronchial infection |
| Sweat glands | Failure to reabsorb sodium | Hyponatremia |
| Reproductive | Obstruction of epididymis, vas deferens, and seminal vesicles Viscous cervical mucus | Aspermia Decreased fertility |
| Hematologic | Chronic disease? | Anemia |
| Bone and joint | Unknown | Arthritis, osteopenia |

and airway lumen. In the normal state, these epithelial cells can transport chloride through CFTR chloride channels, with sodium and water accompanying this ion flux. Chloride transport through CFTR channels is activated by protein kinases in response to an increase in the intracellular second messenger, cyclic adenosine 3',5'-monophosphate (cAMP).⁹ In cystic fibrosis, a loss of functional CFTR chloride channels leads to defective cAMP-stimulated chloride transport; in most epithelia this defect results in decreased chloride secretion and increased sodium absorption (Fig. 30–1). Defective electrolyte transport is thought to alter the volume or composition of the fluid secreted by the pancreas, hepatobiliary tree, reproductive tract, sweat gland, and airways.

GASTROINTESTINAL TRACT

The gastrointestinal tract may be involved in CF with either intestinal obstruction or deficient secretion of digestive enzymes by the pancreas. In 10% to 16% of CF patients, the first gastrointestinal manifestation of the disease is small bowel obstruction that is evident shortly after birth and known as *meconium ileus*. In these patients, the basic electrolyte transport defect is thought to cause abnormally tenacious meconium that cannot be evacuated. A similar condition, known as *distal intestinal obstruction syndrome* or *meconium ileus equivalent*, occurs in older CF patients; it is also thought to result from abnormally tenacious gastrointestinal secretions and fecal impaction. Other intestinal complications include intussusception, volvulus, gastroesophageal reflux, atresia, perforation, giant cystic meconium peritonitis, and rectal prolapse.

FIGURE 30–1. Electrolyte transport in the airway epithelial cell. CFTR is the cyclic-3',5'-AMP (cAMP)-dependent chloride channel.

A relative deficiency of pancreatic digestive enzymes (pancreatic achylia) is present with most genotypes and is apparent clinically in 85% of patients. Pancreatic lesions including fibrosis, fatty replacement, and cyst formation are secondary to obstruction of small pancreatic ducts by thickened secretions and cellular debris. Inspissated eosinophilic material may accumulate in the acini and ductules. As a result, the volume of pancreatic secretions and the concentration of pancreatic enzymes and bicarbonate are reduced. Affected enzyme concentrations include trypsin, chymotrypsin, carboxypeptidase, amylase, and lipase. This leads to a maldigestion of ingested nutrients, including fats and protein. Increased fecal losses of bile acids (binding to undigested fecal fat decreases enterohepatic recycling) also may contribute to fat maldigestion.

Because of the lipase deficiency, fat-soluble vitamin (A, D, E, and K) deficiencies may occur. Whether lipase activity or bile acids (e.g., in micelle formation) are involved in fat-soluble vitamin absorption with steatorrhea is unclear. Vitamin B₁₂ and zinc deficiencies also may occur as a result of pancreatic enzyme deficiency. Although pancreatic involvement is predominantly exocrine in nature, insulin deficiency with glucose intolerance also occurs in CF patients, especially as they advance in age. Carbohydrate intolerance is characterized by low insulin concentrations and enhanced peripheral sensitivity to insulin but not by the presence of islet cell or anti-insulin antibodies. Carbohydrate intolerance in CF is not usually associated with the ketosis as commonly occurs in type 1 diabetes. This complication involves an increase in the number of insulin receptors with decreased affinity for insulin. Despite a concomitant increase in tissue affinity for insulin, 8% of CF children over 12 years of age require insulin therapy.

The liver can be involved in CF. Biliary cirrhosis secondary to bile duct obstruction occurs in as many as 18% of patients, whereas fatty infiltration occurs in about 30% of patients in a pattern unrelated to nutritional status. Bile ducts may be obstructed by inspissated mucus, which may lead to focal or multilobar cirrhosis.¹⁰ Such hepatic involvement can occur at any age but is more common with advancing age and can lead to portal hypertension, esophageal varices, and hypersplenism. The most common laboratory abnormality associated with hepatic involvement is elevated serum hepatic isoenzymes (gamma-glutamyltranspeptidase, alanine aminotransferase, aspartate aminotransferase, and alkaline phosphatase).^{11,12}

PULMONARY SYSTEM

The pulmonary manifestations of CF result from an incompletely characterized defect in innate host defenses at the airway surface, including an exaggerated inflammatory response, defective bactericidal activity, and altered mucus clearance. It is unclear which step initiates the disease process, but it eventually leads to chronic airway infection, inflammation, and obstruction. The combination of persistent obstruction along with inflammation often leads to air trapping, atelectasis, and eventually bronchiectasis that progresses until respiratory insufficiency develops. The lung disease usually progresses from small airway obstruction to more generalized airway obstruction and finally toward a component of restrictive lung disease as individual segments become completely obstructed and nonfunctional. Hyperinflation or dilation of the airspaces is a common finding. Furthermore, persistent obstruction of the small airways with mucus, an excellent culture medium for microorganisms, may facilitate the growth of bacteria within an extracellular matrix or biofilm, making the infection relatively resistant to antibiotics. Although bacterial infections are thought to be a major contributor to CF airway disease, viruses and other nonbacterial pathogens also play an important pathologic role.^{13–15} Environmental factors, such as exposure to tobacco smoke, also may contribute.¹⁶

The three most common bacterial pathogens isolated from the respiratory secretions (sputum) of CF patients are *Staphylococcus aureus*, *Pseudomonas aeruginosa*, and *Hemophilus influenzae*, with *P. aeruginosa* usually predominating throughout life. *Proteus*, *Klebsiella* spp., and *Stenotrophomonas maltophilia* are observed less frequently. Mucoid strains (alginate producers) of *P. aeruginosa* commonly observed in CF may be particularly resistant to antibiotics,¹⁷ as are nonmotile forms. The isolation of *Burkholderia cepacia* from the sputum of CF patients has become more common at some CF centers. The significance of this contagious organism varies from one patient to the next. Three fairly distinct syndromes associated with this *B. cepacia* have been described, these being asymptomatic colonization, chronic deterioration with intermittent fever and weight loss, and rapid, usually fatal deterioration.¹⁸ The nature of the initially cultured oropharyngeal flora in patients younger than 2 years of age has prognostic significance. The finding of *P. aeruginosa* or *P. aeruginosa* plus *S. aureus* in initial cultures appears related to increased morbidity and mortality, respectively.¹⁹

The presence of these bacteria contributes to the destructive changes in the airways of CF patients by direct damage from bacterial toxins and the body's immune reaction to these bacteria. For example, *P. aeruginosa* expresses number of extracellular toxins, proteases, hemolysins, and exopolysaccharides that may be responsible for direct airway damage, increased mucin production by the airway epithelium, and the production of immune complexes (IgG and IgM) that may contribute to local damage. Elevated levels of such mediators as granulocyte elastase, tumor necrosis factor α , interleukins 1 and 2, and related complexes with associated inhibitors have been well documented in CF patients. One inflammatory mediator that clearly contributes to pulmonary pathophysiology is neutrophil elastase. Present in excess, it overwhelms and neutralizes native antiproteases (α_1 -antitrypsin and secretory leukocyte protease inhibitor [SLPI]), destroys structural fibers, and inhibits complement-mediated phagocytosis and antipseudomonal antibodies. Combined with other inflammatory mediators, a self-sustaining vicious cycle leading to progressive and often permanent tissue damage is established. The neutrophil influx that is part of this cycle results in release of neutrophil-derived DNA, which is thought to contribute to sputum viscosity. The occasional presence of *Aspergillus fumigatus* in the sputum of these patients also may contribute to the pulmonary pathology because it can induce a steroid-responsive allergic reaction.

The consequence of these pulmonary processes is a decrease in gas exchange by the lungs. The challenge of moving air through obstructed airways often requires the use of accessory muscles, resulting in an increased anteroposterior chest diameter (also referred to as *barrel chest*), a flattened diaphragm, and pulmonary hypertension. The increased work of breathing in these patients produces a relative exercise intolerance and increased resting energy expenditure. Hemoptysis secondary to bronchiectasis occurs but is seldom massive. Other respiratory complications include gastroesophageal reflux, pneumothorax, and right-sided heart failure (cor pulmonale) secondary to the pulmonary hypertension. Although seldom overt clinically, the findings of right ventricular hypertrophy, increased heart weight, and right atrial and right ventricular chamber dilatation usually are present at autopsy. Digital clubbing, a common finding in CF as well as other chronic pulmonary conditions, may be related to chronic hypoxia.

The upper respiratory tract is also involved commonly in CF. Sinusitis and nasal polyposis occur in 90% and 50% of patients, respectively.²⁰ Sinusitis is chronic in character, and acute symptoms are unusual. Although its etiology is not entirely clear, sinusitis may result from obstruction of the sinus ducts, thus preventing drainage. The bacteria generally isolated in these cases include *P. aeruginosa*, *H. influenzae*, streptococci, and anaerobes. Usually, the same strain

of *P. aeruginosa* found in the lungs is present in the upper airways (nasopharynx and sinuses), which may represent a reservoir for the pathogen.

SWEAT GLANDS

Abnormally high concentrations of sodium and chloride are found in the sweat of CF patients owing to defective chloride absorption across the water-impermeable sweat duct epithelium. This forms the basis for measuring sweat chloride concentration as a diagnostic test for CF. This defect in salt absorption rarely causes clinical symptoms except in warmer environments or during hot weather, when excessive sweating may lead to salt depletion; this clinical problem can be prevented by supplementing the diet with salt. In the sweat coil where salt and water are excreted into the gland lumen, sodium and chloride are not excreted at abnormally high concentrations in CF because chloride is secreted through chloride channels other than CFTR. However, as sweat progresses through the sweat duct toward the skin surface, chloride absorption across the water-impermeable epithelium is reduced because of a loss of CFTR chloride channels. Similar abnormalities can be seen in the excretions of the salivary glands.

REPRODUCTIVE SYSTEM

About 95% of males with CF are sterile because of obstruction of the epididymis, vas deferens, and seminal vesicles resulting in aspermia. There is late maturation of the reproductive system with delayed onset of puberty in both sexes. Females also have reduced fertility owing to the production of abnormal cervical mucus. Menstrual irregularity and oligomenorrhea are also common. Nonetheless, owing to greater life expectancy in these patients, increasing numbers are becoming mothers. In these individuals, the course and tolerance of pregnancy are related to the progravid nutritional and pulmonary status.

HEMATOLOGIC SYSTEM

Anemia is observed in some CF patients despite chronic hypoxia. The apparent deficient erythroid response occurs, at least in part, from disturbances in erythropoietin regulation and iron availability (impaired gastrointestinal absorption). Despite chronic hypoxia in some patients with CF, erythropoietin concentrations are normal or low. The condition is characterized by decreased hematocrit and serum ferritin, increased carboxyhemoglobin, and normal or low hemoglobin. Vitamin E concentrations may be normal. Many patients may have iron deficiency owing to decreased dietary intake, malabsorption, or blood loss.

BONES AND JOINTS

Arthritis may occur in CF and can take one of several forms.²¹ The arthritis may be either mono- or polyarticular and usually is non-destructive. An episodic form is most common and may be due to immune complexes formed in response to the chronic pulmonary infections. Hypertrophic osteoarthropathy occurs in CF, as it does in association with other pulmonary diseases. The incidence of arthritis may be increasing as median survival age increases. Osteopenia and osteoporosis also occur more frequently in adults with CF. The causes of the resulting bone demineralization are multifactorial and include vitamin D malabsorption, decreased vitamin D conversion (via sunlight), delayed puberty and endocrine development, poor nutrition, limited physical activity, and chronic acidosis.

CLINICAL PRESENTATION

The clinical findings of CF develop as a direct consequence of the pathophysiologic processes just described. Thus the clinical findings can be conveniently subdivided by organ system.

GASTROINTESTINAL SYSTEM

Intestinal symptoms usually are secondary to either intestinal obstruction or maldigestion of nutrients. Obstruction, manifested as meconium ileus, distal intestinal obstruction syndrome, or intussusception, causes abdominal distension, pain, vomiting, or a change in stool output.

More commonly, the gastrointestinal symptoms of CF are caused by maldigestion of food, causing steatorrhea and malnutrition. The stools are foul, odorous, bulky, greasy, and more frequent in number; rectal prolapse may occur, especially in the presence of excessive weight loss. The stool's high fat content results from a relative lipase deficiency. Perhaps the most significant consequence of maldigestion is malnutrition; that is, CF children characteristically fall below their age-related norms for both weight and height.

PULMONARY SYSTEM

The respiratory symptoms of CF usually are those of obstructive airway disease such as coughing, sputum production, labored breathing, wheezing, retractions, pleurisy, and cyanosis. Digital clubbing is a common finding thought to be associated with bronchiectasis. Increased anteroposterior chest diameter, a flattened diaphragm, and hyperaeration may be noted on chest roentgenogram.

The respiratory status usually follows a cyclic pattern from a state of relative well-being to one of acute pulmonary deterioration theoretically paralleling the course of the airway infection. There may be significant declines in pulmonary function, referred to as *acute respiratory exacerbations* and generally associated with symptoms of bacterial endobronchial infection. Common pathogens found in the lungs of a CF patient include: *S. aureus*, *H. influenzae*, and *P. aeruginosa*. Less common pathogens include: *S. maltophilia* and *B. cepacia*, which used to be referred to as *P. cepacia*. Increased coughing, increased sputum production, changes in sputum character (e.g., thicker and darker in color), tachypnea, dyspnea, increasing oxygen requirement, and a decrease in exercise tolerance are common. Symptoms of chronic sinusitis and nasal polyposis may include nasal obstruction, pain over affected sinuses, and anosmia.

Concomitantly, laboratory testing of peripheral blood may reveal an increased white blood count with increased polymorphonuclear leukocytes and immature forms consistent with an acute infection. Tests of pulmonary function often demonstrate both intermittent and persistent decreases in forced vital capacity (FVC) and forced expiratory volume at 1 second (FEV₁) and increased residual volume (RV). Tests of small airway function are more markedly affected as the pulmonary disease progresses. Arterial blood gases may reveal hypoxia or hypercapnia as the disease progresses.

OTHER SIGNS AND SYMPTOMS

The relative insulin deficiency observed in older CF patients is often asymptomatic and only detected during annual laboratory testing. However, CF-related diabetes may present as a recent decline in weight without the typical gastrointestinal symptoms of malabsorption. It also may present as untreated cases of diabetes mellitus type 2.

Cor pulmonale usually is not evident clinically unless signs of left-sided heart failure ensue, although enlargement in cardiac size may be noted on routine chest roentgenogram prior to that time. Signs and symptoms of anemia and arthritis in CF patients do not differ from those owing to other chronic diseases.

Excess losses of sodium and chloride in the sweat of CF patients seldom results in symptoms of heat prostration, but this phenomenon may cause a "salty" taste on the skin.

DIAGNOSIS

The diagnosis of CF usually is made on the basis of elevated sweat chloride concentrations (sweat chloride testing) and may be confirmed with CFTR mutational analysis. Another test, recording the potential difference across the nasal epithelium, usually is reserved for cases in which the results of sweat testing and mutational analysis are nondiagnostic.²² For sweat chloride determination, two samples of sweat are collected with the use of pilocarpine iontophoresis, and the concentration of chloride in each sample is measured. Duplicate sweat chloride concentrations of 60 mEq/L or more are considered diagnostic of CF. However, a number of disorders, such as adrenal insufficiency, hypothyroidism, protein-calorie malnutrition, anorexia nervosa, ectodermal dysplasia, mucopolysaccharidosis, nephrosis with edema, type 1 glycogen storage disease, familial hypoparathyroidism syndrome, fucosidosis, nephrogenic diabetes insipidus, and Mauriac syndrome, may be associated with elevated sweat chloride concentrations, but generally these conditions do not present a problem in the differential diagnosis of CF. Ninety-eight percent of CF patients will have a sweat chloride concentration 60 mEq/L or greater. The remaining 2% usually have sweat chloride concentrations between 50 and 60 mEq/L, and the test may have to be repeated one or more times to obtain definitive results. Nevertheless, the results of sweat testing alone may not be able to confirm the presence or absence of CF. The presence of chronic obstructive respiratory disease (COPD) or exocrine pancreatic insufficiency and/or a positive family history of the disease also may provide additional support for the diagnosis. Genetic (CFTR mutation) analysis and recording of nasal transepithelial potential difference may be helpful in making a diagnosis. Genetic (CFTR mutation) analysis may be used to confirm the diagnosis in utero or to detect heterozygotes (carriers), with obvious implications for genetic counseling. Newborn screening for the disease has been adopted in some states, although the benefits of making a presymptomatic diagnosis on long-term outcome are still being assessed.²³

COURSE

CF is a heterogeneous disease in terms of initial presentation, organ involvement, and clinical course. Some children are diagnosed at birth because of meconium ileus, which occurs in about 16% of people with CF. Neonatal screening programs are increasing, but the benefits of presymptomatic diagnosis are still being assessed; prenatal diagnosis is early in its implementation. Most patients are diagnosed by 1 year of age because of a history of steatorrhea and poor weight gain. The median age at diagnosis is 7 months, and most patients are diagnosed by 12 years of age.²⁴

The course of the disease after diagnosis varies from one patient to another. A patient may have a rapid downhill course from early pulmonary involvement, whereas another may suffer only from gastrointestinal complaints for many years without significant

pulmonary symptoms. Although the expected life span of CF patients has increased to over 30 years of age in the last two decades, some patients still die early in life secondary to a fulminant pulmonary process. Still others, owing to minimal involvement and a mild course, may not be diagnosed until their second decade of life. The increased

longevity now realized with early diagnosis and aggressive treatment may have led to an increase in formerly less common complications such as diabetes and hepatic disease. Two-year mortality rates above 50% are associated with an FEV₁ of less than 30% of predicted, a PaO₂ of <50 mm Hg, or a PCO₂ of >50 mm Hg.²⁵

► TREATMENT: Cystic Fibrosis

■ DESIRED OUTCOME

The desired pharmacotherapeutic outcomes for CF are both long and short term. In the long term, one obviously tries to halt or delay progression of the disease to allow for normal growth and development. In the short term, acute problems must be dealt with. The ultimate goal of pharmacotherapy for the gastrointestinal involvement of CF is optimal nutrition. On a day-to-day basis, normal bowel habits, continued weight gain, and normal vitamin levels are desirable. The goal of therapy for the pulmonary component is to reduce the signs and symptoms of airway infection, inflammation, and obstruction. Thus antibiotic, anti-inflammatory, bronchodilator, and mucolytic therapies are geared toward treating the complications that compromise lung function. For an acute pulmonary exacerbation, a return of pulmonary function to the preexacerbation status is the central goal of therapy.

■ GENERAL APPROACH TO TREATMENT

The Cystic Fibrosis Foundation has published clinical guidelines for the diagnosis and care of CF patients, including applicable pharmacotherapy.²⁶ The following information is generally in agreement with those guidelines, although it may contain more current information. The interested reader is referred to that publication for more detail on the drug treatment of CF and its various complications.

■ GASTROINTESTINAL SYSTEM

The treatment of gastrointestinal involvement ultimately is aimed at correcting the nutritional deficit present in many patients.²⁷ In addition to pancreatic enzyme replacement and other drug therapy described below, nutritional supplementation is employed frequently. Nutritional interventions range from behavioral modification to nocturnal feedings via gastrostomies.²⁸

■ Pancreatic Enzyme Supplementation

The backbone of gastrointestinal therapy in CF is pancreatic enzyme replacement or supplementation. The preferred products are microencapsulated pancreatic enzymes, although powders are marketed and are useful in patients unable to swallow capsules or to otherwise use the microencapsulated beads they contain. Microencapsulated products protect the contained enzymes from destruction by gastric acid and may be given in much lower doses than their predecessors, which were susceptible to acid breakdown. Most contemporary enzyme-replacement products vary mainly in enzyme content per capsule, with lipase content being the chief variable. Representative products and their contents are presented in Table 30–2. Infants are normally given 2000 to 4000 lipase units per 120 mL of formula or breast milk, which provides 450 to 900 lipase units per gram of ingested fat. In general, patients require 500 to 4000 lipase units per gram of ingested fat, with the average pediatric or adult patient requiring 1800 units per

TABLE 30–2. Pancreatic Enzyme Products

| Trade Name | Manufacturer | Enzyme Content (Units) | | | Form ^a |
|----------------|----------------|------------------------|----------|---------|-------------------|
| | | Lipase | Protease | Amylase | |
| Cotazym | Organon | 8000 | 30,000 | 30,000 | C |
| Cotazym-S | | 5000 | 20,000 | 20,000 | ECM |
| Creon | Reid-Rowell | 8000 | 13,000 | 30,000 | ECM |
| Ilozyme | Adria | 11,000 | 30,000 | 30,000 | T |
| Ku-Zyme | Schwarz Pharma | 8000 | 30,000 | 30,000 | C |
| Pancrease | McNeil | 4000 | 25,000 | 20,000 | ECM |
| Pancrease MT4 | | 4000 | 12,000 | 12,000 | ECM |
| Pancrease MT10 | | 10,000 | 30,000 | 30,000 | ECM |
| Pancrease MT16 | | 16,000 | 48,000 | 48,000 | ECM |
| Pancrelipase | Geneva | 4000 | 25,000 | 20,000 | ECM |
| Protilase | Rugby | 4000 | 25,000 | 20,000 | ECM |
| Ultrase MT12 | Scandipharm | 12,000 | 39,000 | 39,000 | ECM |
| Ultrase MT20 | | 20,000 | 65,000 | 65,000 | ECM |
| Ultrase MT24 | | 24,000 | 78,000 | 78,000 | ECM |
| Viokase | Robins | 8000 | 30,000 | 30,000 | T |
| Viokase | | 16,800 | 70,000 | 70,000 | P ^b |
| Zymase | Organon | 12,000 | 24,000 | 24,000 | ECM |

^aDosage form: C = capsule; ECM = enteric-coated microspheres or beads; T = tablet; P = powder.

^bViokase powder, units of enzymes per 700 mg.

gram of fat. Enzymes also may be dosed based on weight, with an initial dose of 1000 lipase units being administered per kilogram of body weight per meal. One-half that amount is administered with snacks.

Before the introduction of microencapsulated enzyme products, various maneuvers were used to circumvent or overcome the problem of acid breakdown. The most obvious of these was to administer large quantities of enzyme product. Enteric-coated (microencapsulated) pancreatic enzymes largely have solved this problem. The occasional patient may yet require large quantities of even the microencapsulated enzyme product. Whether such difficulties are caused by residual acid breakdown or perhaps low pH in the upper small intestine (secondary to deficient bicarbonate excretion by the pancreas) resulting in a failure to dissolve the coating of the microencapsulated beads is unknown. Defective enteric coating on some generic brands also has been described and led to Food and Drug Administration (FDA) reclassification of these products, which now require bioequivalence data. Histamine H₂-receptor antagonists and proton pump inhibitors have been used to reduce the enzyme dose when residual acid breakdown of enzymes or impaired neutralization of gastric acid is suspected. Another possible maneuver is to administer both microencapsulated and non-enteric-coated enzyme products (e.g., powder) concomitantly.

For patients who are unable to swallow capsules, the contents may be emptied into applesauce, jelly, or some other nonalkaline vehicle, provided that the patient does not chew the microencapsulated beads. Side effects of pancreatic enzyme products are uncommon. Perianal irritation resembling diaper rash may occur in infants fed excess quantities of enzyme powders. Hyperuricosuria also has been reported to occur secondary to pancreatic enzyme use, apparently related to their high purine content. Proximal colonic stricture (fibrosing colonopathy) is a dose-related side effect associated with lipase doses in excess of 24,000 units/kg per day.²⁹

■ Vitamin Supplementation

Patients should receive multivitamin tablets daily to provide adequate water-soluble vitamins along with reasonable amounts of vitamins D and K. While clinically evident fat-soluble vitamin deficiencies are unusual in patients taking adequate pancreatic enzymes and receiving a balanced diet, obvious vitamin K deficiency, manifested as bleeding diathesis, can occur. Demineralization of bone also has been described, and vitamin E deficiency has been related to neurologic dysfunction. In addition, appropriate laboratory tests (serum carotene, vitamin E, and cholecalciferol concentrations) often will help to document other deficiencies, leading to recommendations for additional supplementation of these vitamins. Water-miscibilized vitamin A, 4000 international units (IU) per day, and vitamin E, 100 to 400 IU/day, also should be administered either singly or in the form of a water-miscibilized combination product (containing vitamins A, D, E, and K). Vitamin K, in a dose of 5 mg twice weekly, should be given to patients with prolonged prothrombin times. It also should be noted that appropriately adjusted doses of fat-soluble preparations may be more cost-effective than their water-miscible counterparts (e.g., 800 IU fat-soluble vitamin E versus 200 IU water-miscible vitamin E).³⁰

■ Treating Meconium Ileus and Distal Intestinal Obstruction Syndrome

The treatment of meconium ileus or distal intestinal obstruction syndrome sometimes can be limited to the use of enemas with iso-osmolar

contrast material. Unfortunately, surgery (bowel resection and primary anastomosis) is often necessary to treat meconium ileus and prevent its complications. Distal intestinal obstruction syndrome usually responds to management by oral or nasogastric administration of electrolyte lavage solutions. The adequacy of pancreatic enzyme dosage also should be reassessed in the face of distal intestinal obstruction.

■ Prevention and Treatment of Cirrhosis

Ursodeoxycholic acid, a bile acid with choleric properties, has been shown to produce morphologic and functional improvement in affected patients. The effects are dose-related, and 15–20 mg/kg per day has been used, sometimes in combination with taurine supplementation.³¹ Administering this agent prophylactically to patients at risk for liver disease, if feasible, has been proposed.³²

■ CARDIOVASCULAR SYSTEM

Various modalities have been used in attempts to treat pulmonary hypertension and secondary cor pulmonale of CF. These treatments, which include the use of vasodilators, inotropic agents, and diuretics, all have resulted in limited and transient effects. This is most likely due to the fact that none of these modes of therapy addresses the underlying cause of the cor pulmonale—hypoxia. Likewise, supplemental (often nocturnal) oxygen treatment also has failed to affect mortality rates or disease progression, although it does appear to prevent oxygen desaturation that occurs with exercise, as well as that occurring during sleep. Thus the most beneficial approach may be to attempt to improve oxygenation with aggressive pulmonary therapy.

■ PULMONARY SYSTEM

Management of the pulmonary component of CF can be broken down into three general areas: anti-obstructive, anti-inflammatory, and anti-infective therapy.³³

■ Anti-Obstructive Therapy

The cornerstone of pulmonary therapy is percussion and postural drainage, which aids in the clearance of pulmonary mucus and is performed once or twice daily in “healthy” patients and as often as six times daily during acute pulmonary exacerbations. New flutter devices also may be useful adjuncts in this regard. A flutter device is a hand-held unit that produces vibrations in the airways when exhaled through. These vibrations loosen and facilitate the removal of mucus and secretions from the airways. Percussion is sometimes preceded by nebulizer therapy, during which nebulized sterile water or 0.9% sodium chloride solution is inhaled to liquefy pulmonary secretions. Bronchodilators may be added to the nebulizer solution to prevent bronchospasm, and mucolytic agents (e.g., *N*-acetylcysteine; Mucomyst, Mead Johnson) may be added to liquefy pulmonary secretions or enhance mucus clearance. The effects of bronchodilators administered by inhalation can be demonstrated with pulmonary function testing; however, the efficacy of mucolytic agents is not readily demonstrated. Moreover, many patients prefer not to use *N*-acetylcysteine because of its unpleasant taste and odor and because it may induce bronchospasm. Normal saline and sodium bicarbonate

solutions may be administered by aerosol as aids to sputum expectoration, but documentation of efficacy is elusive.

Recombinant human DNase has been approved for use in CF. When given by inhalation (2.5 mg once or twice daily), recombinant human (rh) DNase reduces the viscosity of CF sputum and leads to statistically significant, though modest, improvement in pulmonary function.³⁴ More important, the regular use of rhDNase may help to decrease the incidence of (or lengthen the time between) respiratory exacerbations and thereby improve quality of life and indirectly decrease the overall costs of care in patients with mild to moderate disease. Should these outcomes be borne out in additional long-term studies, especially before the onset of clinical symptoms, this therapy may be justified as a way to prevent or delay the progression of pulmonary disease.

Because some CF patients have a component of reactive airways disease that may contribute to their pulmonary disease, systemic bronchodilators such as theophylline and β -agonists may provide some benefit. Recurrent wheezing or dyspnea that improves with bronchodilators represents a legitimate indication for these agents. However, responsiveness to such agents (>15% improvement in FEV₁) should be documented before a protracted course is begun. Standard antiasthmatic doses of most bronchodilators should be appropriate for CF patients, but theophylline clearance may differ in CF fibrosis patients, and bioavailability of some products may be decreased, sometimes necessitating the use of higher-than-usual doses.³⁵ Because of the necessity of pharmacokinetic monitoring and its involvement in a number of common drug interactions, theophylline should be considered second-line bronchodilator therapy at most in these patients. Because CF patients are at high risk to develop complications from influenza, the influenza vaccine should be administered on a yearly basis, and amantadine prophylaxis or treatment may be indicated as well.

■ Anti-Inflammatory Therapy

In an attempt to block the consequences of the inflammatory component of this disease, corticosteroid therapy has been evaluated. Results of preliminary trials were encouraging, and a large, multicenter, placebo-controlled trial found that alternate-day prednisone treatment at 2 mg/kg had beneficial effects on pulmonary function, but it also had undesirable effects on linear growth and glucose metabolism.³⁶ Further analysis of the data from this same study suggested that the benefits of a 1 mg/kg dose might outweigh the risks.³⁷ Data concerning the efficacy of inhaled corticosteroids are scant. A long-term trial of oral ibuprofen indicates a beneficial effect in young CF patients with good lung function by slowing the rate of progression of pulmonary disease.³⁸ Unfortunately, therapeutic drug monitoring (periodic determination of ibuprofen serum concentrations) is required.

■ Antibiotic Therapy

Young children with CF have an extended period of time, perhaps months or years, when they have no evidence of airway infection. Later, they develop a mild airway infection or early bacterial colonization, often without associated symptoms. However, bronchoalveolar lavage fluid reveals evidence of infection and inflammation (high neutrophil count with a predominance of proinflammatory cytokines). Eventually, they develop a chronic airway infection that cannot be eradicated fully even with prolonged use of systemic or topical antibiotics. This scenario is best explained by the ability of bacteria such

as *P. aeruginosa* to achieve high-density growth within small airways, whereby they become organized into a community that grows more slowly and secretes an extracellular matrix that protects the bacteria from local host defenses and/or most antibiotics. This complex growth pattern is referred to as a *biofilm community*. Acute exacerbations of CF are thought to involve satellite foci of bacterial proliferation that stimulate mucus production in response to bacterial exoproducts, worsen airway obstruction, and suppress the appetite owing to the host's proinflammatory response.

Because of the complexities of bacterial infections in CF, antibiotics are used with three different goals in mind. First, before an infection develops, the primary goal is to detect infections early in their course so that treatment is successful at preventing the bacteria from developing into a biofilm community (bacterial eradication). Second, once biofilm growth has become established, the primary goal is to use antibiotics to prevent rapid bacterial proliferation (bacterial suppression) to avoid excess sputum production, decreased lung function, and the concomitant loss of appetite and weight. Finally, once an acute exacerbation has developed, the primary goal is to eliminate bacterial proliferation, reduce the bacterial load and the degree of sputum production, return lung function to the preexacerbation (target) value, improve nutritional intake, and correct any weight losses (treatment of acute exacerbations).

However, the use of antibiotics in CF is somewhat controversial and certainly challenging. Controversy exists because innate host defenses in CF certainly may be sufficient to eliminate most pathogens, including *P. aeruginosa*, from the airways. Without antibiotics, some patients with CF appear to go many years before they develop typical airway infections caused by *P. aeruginosa*. In addition, some CF patients have transiently positive throat and bronchoalveolar lavage (BAL) cultures for *P. aeruginosa* that resolve without exogenous antibiotics. Thus it is unclear when antibiotics actually are needed to help eradicate these pathogens. Moreover, once bacterial eradication with antibiotics is accomplished, will some other organism soon initiate another airway infection? In other words, are the early stages of bacterial colonization merely a marker for a decrease in host defenses? Does this decrease in host defense persist, suggesting that repeated courses of antibiotics will be required regardless of whether eradication therapy was successful? The answers to these questions remain unknown, and thus the use of antibiotics in CF lung disease is controversial.

The chronic use of antibiotics to suppress bacteria in CF is controversial because antibiotic resistance may be induced or enhanced. Suppressive therapy is prescribed with the intention of prolonging the time between acute exacerbations and to slow the rate of progression of lung disease. Although attractive intuitively, this practice is not supported by well-designed clinical trials.³⁹ Moreover, the practice of routine, quarterly administration of intravenous courses of antibiotics used at some European centers still lacks proof of efficacy.⁴⁰ Aerosolized tobramycin (TOBI) daily for 1 to 2 months has been shown to eradicate *P. aeruginosa* from the airways of recently infected patients with CF.

Antibiotic treatment for acute pulmonary exacerbations usually results in clinical improvement without eliminating bacteria from the sputum. In this case, the antibiotics are thought to lessen the bacterial burden within the airways and thereby inhibit the quantity of exotoxins produced or the degree of host inflammation against the bacteria or their exoproducts.⁴¹ The failure to eradicate the organism suggests that bacteria may be colonizing the airway surface rather than penetrating the tissues as a pathogen. The bacteria may remain viable within an environment protected from the antibiotics, such as enclosed within a biofilm community. It also suggests the possibility

that antibiotics may not be essential for the treatment of acute exacerbations. One study comparing antibiotic therapy with placebo indicated that antibiotics are not essential for recovery from an acute exacerbation.⁴² However, the study size was small and only included patients with mild to moderate disease; thus these results may not be applicable to all acute exacerbations. These results are also consistent with the notion that viral infections, air pollutants, irritants, allergens, or some other factors play a role in clinical exacerbations.

Finding known bacterial pathogens at high density in airway secretions, along with the clinical setting of increased cough, increased sputum production that is thicker and darker than baseline, and a significant decrease in lung function and loss of appetite and exercise tolerance, supports the addition of antibiotics to treat this clinical exacerbation. However, deciding to start antibiotic therapy leads to a number of other important, and sometimes perplexing, issues. These include the selection of the best antibiotic(s) for the individual patient, the optimal route of administration, the best dosage and dosage regimen to use (especially in light of altered pharmacokinetics in patients with CF and the potential emergence of antibiotic-resistant bacteria), and the identification of appropriate end points of therapy.

■ **Selection of Antibiotic.** Suppressive therapy may be accomplished with the use of common orally administered antibiotics such as trimethoprim-sulfamethoxazole, amoxicillin-clavulanic acid, or one of the many oral cephalosporins. Specific therapy for acute exacerbations is directed at proven or likely pathogens such as *P. aeruginosa* and *S. aureus* and usually includes aminoglycoside and extended-spectrum penicillin. Since most *S. aureus* encountered are β -lactamase producers, use of an extended-spectrum penicillin- β -lactamase inhibitor combination (e.g., ticarcillin-clavulanate) will help to avoid the necessity of triple-drug therapy. Single-agent therapy with newer antibiotics, especially on an outpatient basis, is employed frequently at some centers where significant resistance to these agents has not yet emerged. Such agents would include ceftazidime, aztreonam, and ciprofloxacin. However, the evidence supporting the clinical superiority of two-drug combinations over single-agent therapy leads many clinicians to always treat with combinations.^{43–46} The fact that such combinations are sometimes synergistic in vitro and the possibility that they may act to suppress or delay the emergence of resistance provides attractive rationale for their use. Further, in vitro synergism has been reported to persist even in the face of resistance to one of the single agents in a given combination.⁴⁷ Lastly, monodrug therapy has been met with rapid emergence of resistance.⁴⁸

Unlike other cases of lower respiratory tract infection, organism-specific drug treatment may be based on results from sputum cultures in CF patients because good agreement between sputum and thoracotomy cultures has been demonstrated.⁴⁹ Typically, such results will lead one to prescribe or recommend aminoglycoside-extended-spectrum penicillin combinations, although other antibiotics such as ciprofloxacin and older agents such as colistin also may play a role. While the complete eradication of *S. aureus* and *H. influenzae* is a practical goal or end point of antibiotic therapy, the total eradication of *Pseudomonas* spp. is infrequent and transient. Thus, once a patient has been colonized/infected with *P. aeruginosa*, it is prudent to assume that it is always present regardless of culture results. Consistent with these infectious phenomena, the complete resolution of pulmonary signs and symptoms becomes less and less likely as the disease progresses. *B. cepacia* and *S. maltophilia* generally are resistant to most antibiotics. These bacteria may be susceptible to trimethoprim-sulfamethoxazole or chloramphenicol. *B. cepacia* from CF patients frequently is susceptible to ceftazidime, whereas some

strains of *S. maltophilia* may be susceptible to other agents such as doxycycline and piperacillin.

■ **Selection of Dose-Altered Pharmacokinetics.** Although altered pharmacokinetics in CF are not limited to antibiotics (Table 30–3), this drug class has been the studied most extensively.⁵⁰ As is true for theophylline, many CF patients have increased total body clearance for many antibiotics, including the aminoglycosides, some of the β -lactams, and trimethoprim-sulfamethoxazole. Thus higher doses of these agents may be necessary to produce therapeutic concentrations (Table 30–4). Unfortunately, these alterations in pharmacokinetics are neither consistent nor predictable. Why the pharmacokinetics of these antibiotics are different in CF patients is unknown. It appears that for many β -lactam antibiotics, increased total body clearance could be accounted for by increased renal clearance. However, it should be pointed out that renal function, as reflected by glomerular filtration rate and renal blood flow, is not different in CF patients as compared with non-CF controls.⁵¹ Moreover, a concomitant increase in renal clearance does not completely explain the increase in total body clearance of aminoglycosides, leading some to speculate about extrarenal pathways for elimination. In any event, increased total body clearance dictates higher doses in many but not all patients. However, a range of dosage requirements should be expected, consistent with a range in the variation of pharmacokinetics in these patients. For example, experience with netilmicin revealed a dosage requirement range of 7–17 mg/kg per day to achieve peak concentrations (one-half hour after the end of a drug infusion) of 8 mcg/mL or greater.⁵² The mean dosage requirement in this study was approximately 12 mg/kg per day. Peak concentrations of this magnitude are felt to be necessary to treat pneumonia caused by gram-negative bacteria adequately.^{53,54} Variations in hepatic metabolic activity or in phenotypic distribution of metabolic polymorphisms may explain some pharmacokinetic differences in CF.^{55,56}

TABLE 30–4. Antibiotic Doses in Cystic Fibrosis

| Antibiotic | Dose (mg/kg/d) | Regimen | Adult Maximum Dose (g/d) |
|--|--------------------|---------|--------------------------|
| Parenteral Antibiotics | | | |
| Tobramycin, ^a gentamicin, ^a or netilmicin ^a | 6–9 | q8 h | NA |
| Amikacin ^a | 20–30 | q8 h | NA |
| Azlocillin | 400 | q4–6 h | 24 |
| Aztreonam | 200 | q6 h | 8 |
| Ceftazidime | 150 | q8 h | 6 |
| Colistin | 2.5–6 | q6–8 h | NA |

^aStarting doses; adjust to desired serum concentrations based on dose/serum concentration relationship.

^bAdult dose.

^cBased on trimethoprim.

Although alterations in pharmacokinetics of antibiotics may correlate with the severity of pulmonary disease,^{57,58} it is not possible to predict changes in antibiotic pharmacokinetics in CF patients based on markers of clinical status or disease progression. Attempts to correlate antibiotic pharmacokinetics with Shwachman score (a gross method for quantitation of disease status) have been unsuccessful.^{59,60} Attempts to guide aminoglycoside dosing often are based on measured serum concentrations during a course of therapy. However, this method also may meet with mixed success owing to changing pharmacokinetics of this family of antibiotics during an acute pulmonary exacerbation.⁶¹ This observation should not, however, deter one from attempts to adjust doses to desirable concentrations based on serum concentration determinations and subsequent pharmacokinetic calculations.

■ **Alternate Routes of Administration.** An additional route of antibiotic administration that is intuitively attractive in patients with CF is by inhalation of aerosolized solution. Such a route of administration should, theoretically, deliver the drug to the actual site of infection and perhaps avoid systemic toxicity. Certainly many classes of antibiotics including β -lactams, aminoglycosides, and polymyxins have been administered to CF patients in this fashion, often in conjunction with systemic antibiotics. However, until recently, no clear effect or advantage had been demonstrated consistently. Early studies suffered from lack of controls, small sample size, and a failure to ensure that the respiratory equipment used would, in fact, guarantee that drug is delivered to the small airways. In a subsequent placebo-controlled, multicenter trial, 600 mg tobramycin administered by aerosol three times daily was found to produce a small but statistically significant improvement in FEV₁, forced vital capacity (FVC), forced expiratory volume from 25% to 75% of vital capacity (FEF_{25%–75%}), *P. aeruginosa* density in sputum, and peripheral white blood cell count.⁶² This

being recognized, appropriate clinical circumstances for this form of therapy (type and condition of patient), length of therapy, and frequency of therapy remain to be clarified. One-half this dose is apparently also effective, and a 300-mg dose is the current norm. If such doses are to be used, preservative-free antibiotic preparations should be used. The efficacy of smaller doses of inhaled aminoglycosides remains unproven.

■ **Bacterial Resistance.** As already noted, emergence of antimicrobial resistance seems to follow the introduction and use of a new antibiotic.⁴⁸ *P. aeruginosa* can exhibit many resistance mechanisms, revealed as resistance to quinolones (altered DNA gyrase target site), β -lactams (production of Bush group 1 β -lactamase), aminoglycosides (decreased permeability and modifying enzymes), and carbapenems (decreased permeability). *B. cepacia* is inherently resistant to most antibiotics. Methicillin-resistant staphylococci are increasingly common in institutional settings and will become a more pervasive problem in CF populations. These phenomena require close attention to susceptibility reports in selecting therapy and the avoidance of unnecessary or unnecessarily protracted courses of antibiotic therapy.

■ **Recommendations for Antibiotic Therapy.** Despite these inherent difficulties, a number of recommendations regarding the use of systemic antibiotics in CF can be made. The selection of antibiotics should be based on specific culture and susceptibility results. When instituting empirical therapy in the absence of culture results, the clinician can be guided by the most recent laboratory data or institute therapy based on likely pathogens in the patient's age group. Aminoglycosides should be dosed initially at the upper end of the normal dosage range (e.g., 6 to 7.5 mg/kg per day for tobramycin), and serum concentrations should be determined so that dosage can

be adjusted appropriately to achieve peak concentrations of at least 8 mcg/mL. It should be kept in mind that aminoglycoside serum half-lives may lengthen during the course of treatment so that a constant relationship between dose and serum concentration may not exist. Upward adjustments in dosage therefore should be made with some degree of caution and should be followed with further determination of serum concentrations. Once-daily administration of aminoglycosides is gaining popularity, as in other settings. Obviously, such a dosing practice would result in much larger peak concentrations than those mentioned earlier. Comparative efficacy and safety of such dosing regimens in CF patients have not yet been elucidated fully, but this practice is likely to be employed increasingly as CF-specific data are generated.

β -Lactam antibiotics such as extended-spectrum penicillins should be prescribed with aminoglycosides to take advantage of their frequent synergy and to prevent the emergence of resistance. These agents should be prescribed in large doses to delay stepwise resistance. Ticarcillin, azlocillin, and piperacillin should be prescribed in a dose of at least 350 mg/kg per day divided into four to six doses. For patients with *P. aeruginosa* and *S. aureus*, the combination of an aminoglycoside and ticarcillin-clavulanate or piperacillin-tazobactam is appropriate. Selection among these agents should be based on local susceptibility patterns and cost considerations. The possible increased incidence of fever and exanthema with the newer penicillins should be kept in mind.⁶³ Aztreonam would be a safe and effective β -lactam to use in patients experiencing these serum sickness-like reactions to the penicillins.⁶⁴ In older patients with *P. aeruginosa* isolates with broad resistance patterns, the clinician should work closely with the microbiology laboratory to identify effective agents or combinations. The potential use of older agents with unique mechanisms of action, such as colistin, should not be overlooked.

Oral antibiotics may be prescribed in symptomatic outpatients with susceptible pathogens in their sputum. Agents with activity

against common pathogens such as *S. aureus* and *H. influenzae* are useful in this setting. These typically include such antibiotics as first-generation cephalosporins, trimethoprim-sulfamethoxazole, and amoxicillin-clavulanic acid. The use of such agents on a “prophylactic” basis is discouraged because the data available at present suggest that a beneficial effect does not outweigh the risk of development of resistance among the common bacterial pathogens of CF.⁶⁵ The 4-fluoroquinolone antibiotic ciprofloxacin possesses potent activity against most CF pathogens and has been evaluated in adult patients undergoing pulmonary exacerbations. Although not conclusive because of shortcomings in the studies, available data suggest that this oral agent is as effective as standard intravenous therapy.⁶⁶ The availability of a potent oral antipseudomonal agent poses a number of potential uses in the CF population. However, it should be kept in mind that repeated or long-term use likely will lead to resistance and that antibiotics play only a supportive role in the treatment of these patients. Thus oral antibiotic therapy, regardless of efficacy, does not negate the need for other forms of therapy, which are often best administered in the hospital setting. It also should be pointed out that although ciprofloxacin appears to be safe in patients less younger 18 years of age with little evidence of joint or cartilage toxicity,⁶⁷ this agent should be used with caution in the younger population.

■ Treatment of Other Pulmonary Complications

The drug and nondrug treatments of the most serious of pulmonary complications, including pulmonary hypertension, right-sided heart failure, respiratory failure, pneumothorax, and hemoptysis, are beyond the scope of this chapter. In general, the therapeutic approach does not vary substantively from that for other respiratory diseases.

EVALUATION OF THERAPEUTIC OUTCOMES

GASTROINTESTINAL

The patient’s nutritional status should be monitored closely on both short- and long-term bases. Height, weight, and BMI should be followed with time; anthropometric measurements give more precise information. The adequacy of pancreatic enzyme replacement can be assessed grossly by following stool patterns with the goal of normal number per day and normal consistency. Any evidence of steatorrhea may indicate suboptimal enzyme therapy. A more precise method would involve assessment of fat quantities in the stool. If a patient does not respond to normal doses of enzyme supplement, other factors that can cause similar symptoms (e.g., bloating, abdominal pain, and symptomatic steatorrhea) should be considered. These would include lack of adherence with directions for taking the enzymes, outdated enzymes, dietary factors such as excessive fruit juice consumption, high-fat meals, and concomitant gastrointestinal disease (e.g., enteric bacterial or parasitic infection, celiac disease, and inflammatory bowel disease). Vitamin status can be assessed through serum monitoring of fat-soluble vitamin concentrations.

PULMONARY

Pulmonary status can be monitored with a combination of clinical observation and examination and a variety of laboratory tests. Over

the long run, pulmonary function usually is followed with spirometry, lung volumes, and oxygenation. Physical examination should focus on signs and symptoms of upper and lower respiratory tract infection. In addition, exercise tolerance, recent character of sputum production, and oxygen requirements are key to long- and short-term assessment. With antibiotic and bronchodilator treatment of acute respiratory exacerbations, a return to preexacerbation clinical status, based on physical examination or pulmonary function testing, becomes a practical end point for antimicrobial treatment. Although the goal of bacterial eradication is desirable, other attainable end points may be more reasonable, as discussed earlier. Bacterial density in sputum, sputum DNA and protein content, and C-reactive protein all have proven value as monitoring parameters but may not be available at some centers. Of the objective parameters, pulmonary function tests correlate best with clinical observations and scoring systems.⁶⁸ Response to intravenous antibiotics and aggressive chest physiotherapy, as measured by FEV₁ at the end of 1 week of treatment, has been used to predict total length of therapy necessary. In patients whose FEV₁ had recovered more than 40% at the end of 1 week, a total of 2 weeks of therapy generally was sufficient.⁶⁹ Little has been done by way of pharmacodynamic studies in treating CF. Therefore, symptomatic improvement is largely relied on to assess the relative success of antibiotic therapy. Oral antibiotic therapy also should be limited in length with specific end points, such as decreased cough and/or improved pulmonary function, identified as treatment commences.

NEW DIRECTIONS IN THERAPY

Now that the gene and gene product of CF have been identified, gene therapy becomes an obvious potential for treatment.⁷⁰ Research to date has centered on introduction of the correct gene into affected tissues. Viral vectors, chiefly adenovirus, have been studied in animal models, and human trials are under way. Liposomes may represent another useful delivery mode to introduce the correct gene.

Other novel approaches to therapy are currently being investigated and, for the most part, are directed at the inflammatory component of the disease or the basic cellular defect. Protease inhibitors hold potential in this condition for reasons cited earlier. α_1 -Antitrypsin administered by aerosol shows promise, as does secretory leukocyte protease inhibitor (SLPI) and other antiproteases.^{71–73} Azithromycin, perhaps not functioning as an antibiotic, slow the rate of progression of lung disease in patients chronically infected with *P. aeruginosa*.⁷⁴ In an attempt to directly approach the cellular defect in CF, the diuretic amiloride had been shown to possess positive activity in improving respiratory secretion rheology and clearance,⁷⁵ presumably by blocking excessive sodium reabsorption, but was found to be no more effective than placebo in a large-scale, controlled trial. At a similar level, the secretagogues adenosine and uridine triphosphate (ATP and UTP) have been shown to increase chloride excretion in the epithelial cells of CF patients.⁷⁶ The combination of amiloride and UTP (thereby both blocking sodium absorption and stimulating chloride secretion) also may promote clearance of airway secretions.⁷⁷ Other experimental therapies interact with the defects in CFTR production or processing. Studies with phenylbutyrate (which increases the amount of functional protein that reaches the cell surface), 8-cyclopentyl-1,3-dipropylxanthine (CPX), milrinone (a phosphodiesterase inhibitor), and genistein (a tyrosine-kinase inhibitor), each of which activate mutant CFTR, and low-concentration gentamicin (which suppresses certain premature stop mutations in *CFTR*) are all active.

It is hoped that some, if not all, of these approaches will provide viable additions to our pharmacologic armamentarium for this disease. For older, more severely affected patients who may not be able to benefit from such advances, organ transplants (single-lung, double-lung, heart-lung) are more widely available and reasonably successful.⁷⁸

CONCLUSION

Pharmacotherapeutic intervention plays an important role in the management of these patients but is complex. The clinician is as yet faced with many unresolved issues in attempting to apply sound therapeutic principles in this population. Although close attention should be paid to pharmacologic treatment, the approach to these patients should be multifaceted and multidisciplinary in character. In addition to the involvement of such pediatric subspecialties as pulmonology, gastroenterology, pharmacology, and infectious diseases, contributions from such areas as nutrition support and social work should be a regular and ongoing part of the management effort.

ABBREVIATIONS

ATP: adenosine triphosphate
BAL: bronchoalveolar lavage
BMI: body mass index

CF: cystic fibrosis

CFTR: cystic fibrosis transmembrane regulator

FEF_{25%–75%}: forced expiratory volume from 25 to 75% of vital capacity

FEV₁: forced expiratory volume at 1 second

FVC: forced vital capacity

PaO₂: partial pressure of arterial oxygen

PaCO₂: partial pressure of arterial carbon dioxide

SLPI: secretory leukocyte protease inhibitor

UTP: uridine triphosphate

EVALUATION OF THE GASTROINTESTINAL TRACT

Marie A. Chisholm and Mark W. Jackson

KEY CONCEPTS

- 1 The patient history is key to evaluating GI problems and should include the problem onset, the setting in which it developed, and its presentation.
- 2 A complete physical exam should be performed with detailed attention to the overall condition of the patient and focused attention should be given to the patient's abdomen.
- 3 Contrast agents such as barium sulfate are effective in examining the GI tract for structural diseases.
- 4 The upper GI series involves radiographic visualization of the esophagus, stomach, and small intestine; whereas the lower GI series involves visualization of the colon and rectum.
- 5 Enteroclysis is used to evaluate the small bowel by introducing contrast agents by tube through the nose or mouth.
- 6 GI ultrasonography, computed tomography, and magnetic resonance imaging provide images of the gallbladder, liver, pancreas, and abdominal wall.
- 7 Radionuclide imaging is useful to visualize the liver, spleen, bile ducts, gallbladder, and gut.
- 8 The endoscope, an illuminated optical instrument, revolutionized the diagnosis and management of GI disorders with common endoscopic studies including esophagogastroduodenoscopy, colonoscopy, sigmoidoscopy, and endoscopic retrograde cholangiopancreatography.
- 9 There is an evolving role for capsule endoscopy (an encapsulated camera swallowed by the patient that takes pictures of the GI tract) in the assessment of the small bowel.

The gastrointestinal (GI) tract is composed of organs and tissues that have diverse forms and functions. It includes the esophagus, stomach, small intestine, large intestine, colon, rectum, biliary tract, gallbladder, liver, and pancreas. Despite the rapid proliferation of technology for the diagnosis of digestive diseases, the patient history and physical examination still hold central roles. When combined with a thorough patient history and physical examination, diagnostic procedures are essential in the evaluation of GI disorders. This chapter describes the most commonly used tools available in clinical practice to evaluate patients with GI diseases.

SYMPTOMS OF GASTROINTESTINAL DYSFUNCTION

A variety of symptoms can arise from GI dysfunction. Common GI symptoms include heartburn, abdominal pain, dyspepsia, nausea, vomiting, diarrhea, constipation, and gastrointestinal bleeding. Signs and symptoms of malabsorption, hepatitis, and GI infection are also commonly seen. The next sections describe methods that are commonly used to assess patients with GI complaints. For specific details concerning each GI disease state, please consult that particular chapter in this book.

PATIENT HISTORY

- 1 A comprehensive patient history is the cornerstone in the evaluation of a patient with digestive complaints. A clear, detailed, chronologic account of the patient's problems should be ascertained. This account should include the onset of the problem, the setting in which it developed, and its manifestations. The onset of the problem often provides important information that helps to confirm diagnosis. For example, biliary pain, such as that encountered with symptomatic gallstone disease, typically evolves over minutes and lasts for hours, but pain caused by pancreatitis evolves over hours and lasts for days. The setting is always relevant as it provides clues to the possible origin of the disorder. For example, is the patient an alcoholic (liver disease, esophageal varices, or pancreatitis)? Does the patient have severe atherosclerosis (mesenteric ischemia)? Is the patient immunosuppressed (opportunistic infection)? Also aiding in the differential diagnosis is identification of factors that alleviate or exacerbate the principal symptom. For instance, ingesting a meal often relieves the pain of duodenal ulcer, but worsens that of gastric ulcer. The health care professional should ask questions that address the potential etiologic possibilities, including motility disorders, structural diseases, malignancies, infections, psychosocial factors, dietary factors, and travel-associated diseases.^{1,2} Questions concerning past medical and

TABLE 31–1. General Questions in a Gastrointestinal History

1. Tell me about the problem that you are experiencing. When did it start?
2. Where is your pain located? Please point to the area where you feel pain. What were you doing when the pain occurred? How rapidly did the pain come on? Is your pain constant or intermittent? What factors exacerbate or alleviate your pain? Does the pain awaken you at night?
3. What medications are you taking to help the pain? How much do you take? Do these medications work?
4. What other medications are you currently taking? Why are you taking them?
5. Have you recently had a change in dietary intake? If so, please describe. Can you draw any correlation between the foods that you eat and your GI complaint?
6. Have you recently had a change in bowel habits? Have you experienced any diarrhea or constipation lately? Do you experience painful bowel movements?
7. Have you experienced any nausea or vomiting lately? If so, please describe conditions centered around this event.
8. Have you experienced any recent change in weight? Was this intentional? How many pounds have you gained or lost and over what time period did this occur? How has your appetite been?
9. Have you passed any blood from your rectum or vomited blood? Have you noticed any dark, tarry stools?
10. Have you had any acid indigestion?
11. Do you have difficulty swallowing?
12. Has anyone in your family experienced similar GI complaints? If so, please describe. Does anyone in your family have a history of GI disorders, including cancer of the GI tract?
13. Describe your past medical history, including illnesses and surgeries.
14. Please describe any past injuries that you have experienced.
15. Have you recently traveled outside of the United States? If so, where? When? How long did you stay? What kind of living conditions did you experience? What foods and drinks did you ingest?

family history detailing illnesses, surgeries, injuries, and habits are extremely valuable (Table 31–1). Because many drugs have been reported to cause GI injury, a patient’s medication history is also vital (Table 31–2).

PHYSICAL EXAMINATION

Because the organ systems of the body interact and may provide important data needed for diagnosis, it is necessary to perform a thorough physical examination.³ A global evaluation of the patient should be performed with notable attention to appearances and vital signs because they may suggest clues to the patient’s overall condition and stability. Careful examination of the abdomen is also an essential part of the work-up. Examination of the abdomen is classically approached by inspection, auscultation, percussion, and palpation. Inspection of the abdomen may reveal scars, hernias, bulges, or peristalsis. Auscultation is mainly focused on analysis of bowel sounds and identification of bruits. Percussion of the abdomen allows for detection of tympany, measurement of visceral organs, and detection of ascites. Palpation may allow the clinician to identify tenderness, rigidity, masses, and hernias. A digital rectal examination is used to detect masses, tenderness, and assess muscle tone. Stool on the examiner’s glove obtained during rectal examination is often subjected to hemocult testing for the indirect detection of occult blood.^{2,3}

TABLE 31–2. Drugs That May Commonly Cause Gastrointestinal Injury

| Gastrointestinal Mucosal Injury | Liver Damage (Continued) |
|---------------------------------------|------------------------------|
| Aspirin | Isoniazid |
| Bisphosphonates | Ketoconazole |
| Chemotherapeutic agents | Methotrexate |
| Corticosteroids | Methyldopa |
| Ethacrynic acid | Monoamine oxidase inhibitors |
| Ethanol | Niacin |
| Gentian violet | Nifedipine |
| Iron preparations | Nitrofurantoin |
| Isoproterenol | Phenytoin |
| Nonsteroidal anti-inflammatory agents | Propylthiouracil |
| Pancreas supplementation | Pyridium |
| Potassium chloride | Rifampin |
| Reserpine | Salicylates |
| Warfarin | Sulfonamides |
| Jaundice | Tetracycline |
| Acetohexamide | Verapamil |
| Androgens | Warfarin |
| Chlorpropamide | Zidovudine |
| Corticosteroids | Pancreatitis |
| Erythromycin | Azathioprine |
| Estrogens | Corticosteroids |
| Ethanol | Didanosine |
| Gold salts | Estrogens |
| Nitrofurantoin | Ethacrynic acid |
| Phenothiazines | Ethanol |
| Warfarin | Furosemide |
| Liver Damage | Metronidazole |
| Acetaminophen | Opiates |
| Allopurinol | Pentamidine |
| Aminosalicilyc acid | Sulindac |
| Dapsone | Sulfonamides |
| Erythromycin | Tetracycline |
| Ethanol | Thiazides |
| Glyburide | |

LABORATORY AND MICROBIOLOGIC TESTS

Laboratory and microbiologic tests may be used to (a) assess organ function, (b) screen for certain GI disorders, and (c) evaluate the effectiveness of therapy. To achieve an accurate diagnosis and provide the best care, it is important to assess the patient’s fluid and electrolyte status, nutritional status, and abdominal organ function. A serum chemistry panel provides clinicians with valuable information. For example, serum creatinine (S_{Cr}) and blood urea nitrogen (BUN) are often used as a measure of hydration status, as well as serving as indicators for renal function. Elevations in S_{Cr} and BUN may be indicative of renal dysfunction or dehydration, and bleeding from the GI tract may lead to elevations in BUN. Albumin levels can be used to assess the patient’s nutritional and hydration status and provide information concerning hepatic and renal function. Specifically, low albumin may be indicative of malnutrition, hepatic dysfunction, nephrotic syndromes, or protein-losing enteropathies such as Crohn’s disease and ulcerative colitis. Serum measurements of sodium, chloride, and potassium are useful to determine electrolyte abnormalities associated with diarrheal illnesses. A complete blood count (CBC) helps to provide information concerning infection, malignancy, bone marrow suppression, anemia, and blood loss.⁴

Specific laboratory blood tests are used as screening tools for certain GI disorders. For example, measurements of serum aspartate transaminase (AST) and alanine transaminase (ALT) are elevated in

most diseases of the liver, and serum alkaline phosphatase and bilirubin are often elevated in hepatobiliary disorders. Because prothrombin time is related to hepatocyte synthesis of vitamin K–dependent clotting factors, it serves as an indirect measure of hepatic function. When evaluating patients with suspected pancreatitis, serum and urine measurements of amylase and lipase are important, because these will be elevated in most patients with acute pancreatitis (see Chap. 39).

Microbiologic studies are useful in evaluating patients with unexplained diarrhea, abdominal pain, and suspected GI infections. Microbiologic studies of the stool may be used to detect the presence of bacteria and parasites. Pathogens most often responsible for infectious diarrhea and enteritis include bacteria such as *Shigella*, *Salmonella*, *Escherichia coli*, and *Yersinia*; viruses such as cytomegalovirus, especially in AIDS patients; and parasites such as *Entamoeba histolytica* and *Giardia lamblia*.⁵ Because *Helicobacter pylori* is a significant factor associated with peptic ulcer disease and gastritis, identification of this organism is critical in evaluating patients experiencing dyspepsia (see Chap. 33).

DIAGNOSIS

The patient history, physical examination, and routine laboratory tests are extremely useful in establishing a diagnosis, but frequently a more specific study is required to confirm or disprove a clinical suspicion. The most appropriate diagnostic test depends on the anatomic region involved, the suspected abnormality, patient preference, the patient's overall condition, and clinical manifestations of the patient. The next sections outline the most frequently used diagnostic studies and procedures and their roles in evaluating the GI tract.

RADIOLOGY

Radiologic procedures rely on the differential absorption of radiation of adjacent tissues to highlight anatomy and pathology. Radiologic procedures important in evaluating the GI tract include plain radiography, upper GI series, lower GI series, and enteroclysis.^{6,7}

PLAIN RADIOGRAPHY OF THE GI SYSTEM

Radiographic evaluation of the GI tract often starts with plain films of the abdomen, which are straightforward, uncontrasted radiographs.⁷ Specific abdominal structures that may be identified include the kidney, ureters, and bladder (KUB); esophagus; stomach; intestine; stones; and vessels. Plain films are often used to evaluate abdominal pain. Clinicians frequently employ plain radiographic fluoroscopy to guide and position other instruments that are used to evaluate and treat GI disorders; an example is the manipulation of dilation devices to treat esophageal strictures. Bowel obstruction and perforation are especially well identified by this technique.

CONTRAST AGENTS

3 Many different types of contrast agents are available. Two types of contrast agents commonly used to enhance visualization of the GI tract are barium sulfate and aqueous iodinated compounds. Barium sulfate is the contrast agent of choice for studying the esophagus, stomach, and intestine, except in special clinical situations.⁷ Barium sulfate is not generally absorbed, and constipation is the most frequent adverse effect reported with its use. Two widely used iodinated contrast agents for visualizing the GI tract are diatrizoate meglumine and diatrizoate sodium. Unlike barium, these agents are relatively nontoxic if inadvertently introduced into the peritoneal cavity; therefore the main indication for use of iodinated agents in GI radiography is

for suspected bowel perforation. Because iodinated contrast agents are hyperosmolar, they possess the potential to cause severe diarrhea, dehydration, and electrolyte imbalances. Nephrotoxicity associated with iodinated contrast agents may occur and is generally self-limited.^{7,8} Allergies and hypersensitivity reactions such as rashes associated with contrast agents are possible and should be monitored and treated accordingly.

UPPER GI SERIES

4 The upper GI series refers to the radiographic visualization of the esophagus, stomach, and small intestine. Patient preparation for an upper GI usually consists of instructing patients to refrain from eating or drinking 8 to 12 hours prior to testing, thereby allowing the upper GI tract to empty. A contrast agent such as barium sulfate is administered to the patient at the beginning of the study. The observed swallowing of the contrast agent permits visualization and monitoring of esophageal structural and motor functions. This phase of the procedure is most often referred to as a barium swallow. As the contrast medium flows into the stomach and small intestine, several regional radiographic films are taken in order to inspect these areas. This tracking of contrast agents through the small intestine is referred to as the small bowel follow-through. The upper GI series with the small bowel follow-through includes the examination of the esophagus to the distal end of the small intestine, and is useful to evaluate and detect obstructions, tumors, ulcers, and abnormal intestinal loops. The upper GI series with small bowel follow-through commonly uncovers gastric cancer, peptic ulcer disease, esophagitis, gastric outlet obstruction, and Crohn's disease (Fig. 31–1).

FIGURE 31–1. Upper GI series with small bowel follow-through demonstrating narrowed distal terminal ileum and separation of small bowel loops (arrow). These findings are consistent with Crohn's disease.

LOWER GI SERIES

The lower GI series is used to examine the colon and rectum. Patients complaining of lower abdominal pain, constipation, or diarrhea are often referred for a lower GI series. Before the procedure the colon is prepared by instructing the patient to refrain from eating or drinking 8 to 12 hours before the procedure, and by administering bowel-cleansing agents such as bisacodyl, magnesium citrate, magnesium hydroxide, or polyethylene glycol-electrolyte solution. During a lower GI series, a barium sulfate enema is given to contrast the terminal large intestine and rectum. The lower GI series is useful to detect and evaluate enterocolitis, obstructions, volvulus, and mucosal and structural lesions.⁷ The lower GI series is commonly used to diagnose Crohn's disease, ulcerative colitis, colon cancers, and diverticulitis.

SMALL BOWEL ENTEROCLYSIS

5 Enteroclysis or small bowel enema refers to the technique of direct small bowel introduction of a contrast agent through a tube inserted through the patient's mouth or nose. Intermittent radiographic films are taken of the small bowel as the contrast agent flows distally (Fig. 31-2). Because enteroclysis provides detailed imaging, it is an accurate method for evaluating the small bowel and for detecting small mucosal lesions that may be overlooked on the traditional small bowel follow-through.⁹ Methylcellulose is used to enhance the detail of the small intestine in enteroclysis, thereby improving visualization. Patient preparation for this procedure involves instructing patients to refrain from eating or drinking 8 to 12 hours before testing and administering bowel-cleansing agents. The most frequent disorder evaluated by enteroclysis is obscure GI bleeding.

IMAGING STUDIES

By using computer-assisted techniques, it is possible to generate cross-sectional radiographic images through the body. Ultrasonography, computed tomography, radionuclide scanning, and magnetic resonance imaging are frequently used imaging procedures for evaluating digestive disorders.

FIGURE 31-2. Normal small bowel enteroclysis. Contrast agents are instilled into the small bowel to highlight tumors, strictures, or other lesions. In this image, one can identify the normal circular folds.

ULTRASONOGRAPHY

6 Ultrasonography provides images of deeper structures such as the gallbladder, liver, pancreas, and abdominal wall. The clinician is able to image slices of the GI tract by directing a narrow beam of high-energy sound waves into the body and recording the reflections from the various organs and structures. Because ultrasonography is noninvasive, relatively inexpensive, requires no ionizing radiation, and can be performed with a portable unit, it is a well-accepted and useful technology. It accurately depicts gallstones and gallbladder, and hepatobiliary and pancreatic diseases (Fig. 31-3). When combined with Doppler technologies, ultrasonography may image GI vascularity. Ultrasonography is limited by the presence of bowel gas and excessive amounts of body fat.^{10,11}

COMPUTED TOMOGRAPHY

Computed tomography (CT) or computed axial tomography (CAT) scans provide detailed images of the GI system in which transverse

FIGURE 31-3. Abdominal ultrasound demonstrating a chronic pancreatic pseudocyst (arrows).

FIGURE 31-4. CT scan of the abdomen showing pancreatitis with calcification (*white arrow*) and pancreatic pseudocyst (*black arrows*).

planes of tissue are swept by a radiographic beam and a computer analysis of the variance in absorption produces a precise reconstructed image of that area.⁶ Contrast agents may be added in a CT procedure to illuminate specific hollow structures and vascularity of the GI tract. The abdominal CT displays organs from the diaphragm down to the pelvic brim, and is especially valuable for detecting GI diseases of the liver, pancreas, spleen, and colon. Patient preparation for CT includes refraining from eating or drinking for a minimum of 4 hours before the test. The remarkable detail that CT offers in imaging organs and tissues adds to its popularity for evaluation of the GI system. CT is useful in the identification of liver cancer, pancreatitis, pancreatic cancer, intra-abdominal abscesses, and cysts (Fig. 31-4).¹⁰ Unlike ultrasonography, patient body size or the presence of gas does not limit the quality of imaging with CT.

RADIONUCLIDE IMAGING

➤ Radionuclide imaging involves intravenous injections of a radiopharmaceutical imaging agent and the use of a computerized detection camera to gather images. Although the choice of a radiopharmaceutical agent depends on the specific organ or function being studied, the most commonly used agent is technetium (Tc-99m) tagged to a carrier molecule. Radiographic imaging is useful to visualize the liver and spleen (liver-spleen scan), bile ducts, gallbladder (HIDA [hepatoiminodiacetic acid] scan), and gut (bleeding scan).¹⁰ Cysts, abscesses, tumors, and obstructions are detected and displayed as areas of differential uptake of radioactivity (Fig. 31-5).⁶ Radionuclide bleeding scans may detect hemorrhages and may assist in localization.

MAGNETIC RESONANCE IMAGING

Magnetic resonance imaging (MRI) places the patient in close proximity to a high-strength magnetic field through which pulses of

FIGURE 31-5. HIDA scan demonstrating normal gallbladder (*arrow*).

radiofrequency radiation are projected, thereby exciting the nuclei of hydrogen, phosphorus, oxygen, and other elements. The radiofrequency signals are manipulated and recorded by a computer, and a two-dimensional image representing a section of the patient is produced.¹⁰ MRI has greater sensitivity to identify liver tumors than ultrasonography, CT, or radionuclide imaging. Although currently MRI is not as popular as other imaging techniques because of limited availability, expense, and problems associated with the use of powerful magnetic fields, its use is predicted to increase in the future.¹¹

ARTERIOGRAPHY

Arteriography of the gut depicts the configuration of visceral blood vessels after intravenous administration of a contrast medium. Arteriography may be employed for detecting tumors and bleeding lesions and therapeutic applications, including embolization of bleeding vessels, fistulas, and inoperable tumors.¹⁰

ENDOSCOPY

8 Refinement in optical engineering and fiber optics has made possible the development of the endoscope, which has revolutionized the management of GI disorders. An endoscope is an illuminated optical instrument designed to inspect the interior of the GI tract. Endoscopes enable the practitioner to inspect intraluminal mucosal lesions and to obtain biopsies and washings for cytology studies. Upper GI tract endoscopy (esophagogastroduodenoscopy) is capable of inspecting the esophagus, stomach, and proximal small bowel. Lower GI tract endoscopy of the rectum and colon may be accomplished by colonoscopy or sigmoidoscopy. Endoscopy can also be used to perform many therapeutic procedures.

Preparation for endoscopic examinations includes instructing patients to refrain from eating or drinking 8 to 12 hours prior to the endoscopic procedure. Bowel cleansing is necessary for colonoscopy and sigmoidoscopy. Topical pharyngeal anesthetics such as viscous lidocaine or benzocaine usually improve patient acceptance of the upper endoscopic tube. Intravenous sedating agents such as meperidine hydrochloride, diazepam, lorazepam, and midazolam hydrochloride are among the most common agents used to induce “conscious sedation” minutes prior to the endoscopy. These sedating agents tend to improve patient acceptance and ease of the procedure. With the development of flumazenil, a benzodiazepine antagonist, the use of benzodiazepines for mild sedation during GI procedures has increased. In addition, antimuscarinic agents such as atropine sulfate are occasionally used for their cardiovascular effects, such as increasing a patient’s heart rate, or for their antispasmodic effects, such as reducing duodenal and colonic motility. Because of its effectiveness at reducing bowel motility, glucagon is also often used. Endoscopy is contraindicated for patients with severe respiratory or cardiac failure, and for patients with suspected perforated viscera. The most commonly used endoscopic studies are upper endoscopy, colonoscopy, sigmoidoscopy, and endoscopic retrograde cholangiopancreatography.

ESOPHAGOGASTRODUODENOSCOPY

Esophagogastroduodenoscopy (EGD) is used to examine the esophagus, stomach, and duodenum. Patient preparation for EGD includes fasting for 6 to 8 hours prior to the procedure and the administration of sedatives and topical anesthetics. Common indications may be either diagnostic or therapeutic in nature, and include evaluating suspected upper GI bleeding, obstructions, upper abdominal pain,

FIGURE 31-6. Deep “punched out” gastric ulcers (arrows) as shown by EGD.

persistent vomiting, and radiographic abnormalities.¹² EGD commonly uncovers peptic ulcers and other lesions (Fig. 31-6).

COLONOSCOPY

Colonoscopy permits direct examination of the large intestine and rectum. To prepare for colonoscopy, the patient should fast for about 8 hours prior to the examination, and bowel cleansing should be completed. Agents such as midazolam and meperidine are usually given to produce conscious sedation. Similarly to upper GI endoscopy, indications for lower GI endoscopy can be either diagnostic or therapeutic in nature, and include evaluation and detection of abnormalities visualized by radiography, as well as GI hemorrhage, colonic lesions, volvulus, ulcerative colitis, Crohn’s disease, diverticulitis, and excision of colonic polyps.¹³

SIGMOIDOSCOPY

Sigmoidoscopy is used to evaluate the sigmoid colon and rectum (Fig. 31-7). Flexible sigmoidoscopy has virtually replaced rigid sigmoidoscopy because of increased patient comfort and superior performance. The major indication for this examination is to evaluate symptoms related to the colon or rectum, and to conduct screening of asymptomatic patients for colon polyps or cancer. Patient preparation involves instructing patients to abstain from eating or drinking 8 to 12 hours prior to the procedure and administering bowel-cleansing agents. Anoscopy is especially useful in evaluating the anus. The major indications for anoscopic examination include symptoms related to the anus and rectum, such as bleeding, protrusions or swelling, pain, and severe itching. Patients undergoing sigmoidoscopy or anoscopy generally do not require sedation.

ENDOSCOPIC RETROGRADE CHOLANGIOPANCREATOGRAPHY

Endoscopic retrograde cholangiopancreatography (ERCP) is an important procedure that is used to evaluate and treat diseases of the biliary tree and pancreas. By injecting contrast agents through a catheter

FIGURE 31-7. Sigmoidoscopic photograph revealing the light-raised lesions of antibiotic-associated pseudomembranous colitis.

placed in the pancreaticobiliary ducts during ERCP, abnormalities such as obstructions, calculi, and strictures can be examined. ERCP also allows for the use of therapeutic techniques such as the removal of ductal stones, stenting of strictures, and sphincterotomy. Preparation for ERCP consists of conscious sedation and glucagon to relax gut motility. Common reasons for ERCP include detection and evaluation of pancreatic malignancy, pancreatitis, biliary obstruction, bile duct stones, jaundice, and patients whose clinical presentation suggests biliary disease (Fig. 31-8).

CAPSULE ENDOSCOPY

9 Capsule endoscopy allows the visualization of the small intestine, and consists of a vitamin-pill-sized video camera that is

swallowed and acts as an endoscope. While the video capsule travels naturally through the digestive tract, images are transmitted to a recording device. Patients return the recording device to the practitioner so that the images can be downloaded to a computer and evaluated. Eventually, the camera is naturally excreted and not retrieved.¹⁴

MISCELLANEOUS TESTS

ESOPHAGEAL MANOMETRY

Esophageal manometry is used to evaluate diseases of the esophagus by assessing esophageal motor functions. Common indications for this procedure include dysphagia and obscure chest pain. A special catheter equipped with pressure transducers is placed into the esophagus to measure esophageal pressures and peristalsis. Provocative testing with pharmacologic agents such as edrophonium chloride, a cholinergic muscle stimulant, may be used to precipitate esophageal pain during this procedure. Typical indications for esophageal manometry include evaluating esophageal dysmotility, nonobstructive dysphagia, obscure chest pain, scleroderma, intestinal pseudo-obstruction, achalasia, and aiding in positioning instruments such as pH probes.

AMBULATORY pH MONITORING

Gastric fluid pH monitoring in patients who complain of gastroesophageal reflux may be necessary. Indications for pH monitoring include evaluating atypical chest pain and severe or unusual reflux disorders. Ambulatory 24-hour pH monitoring is an elegant way to link esophageal acid exposure, as detected by a probe in the esophagus, with patient symptoms. The pH probe is placed approximately 5 cm above the distal esophagus. Because intraesophageal pH is normally higher ($\text{pH} \geq 6$) than that of the stomach (pH approximately 1 to 3), the pH probe will record a decrease in pH if gastroesophageal reflux occurs. The ambulatory 24-hour pH study links the patient's symptom to an acid event (Fig. 31-9).

The Bernstein test, another procedure used to measure gastric fluid pH, is less expensive than ambulatory pH monitoring. This procedure requires inserting a nasogastric (NG) tube and administering

FIGURE 31-8. ERCP demonstrating a dilated, irregular pancreatic duct with areas of stricturing (*large arrow*). A pancreatic pseudocyst is visible immediately adjacent to the spine (*small arrows*).

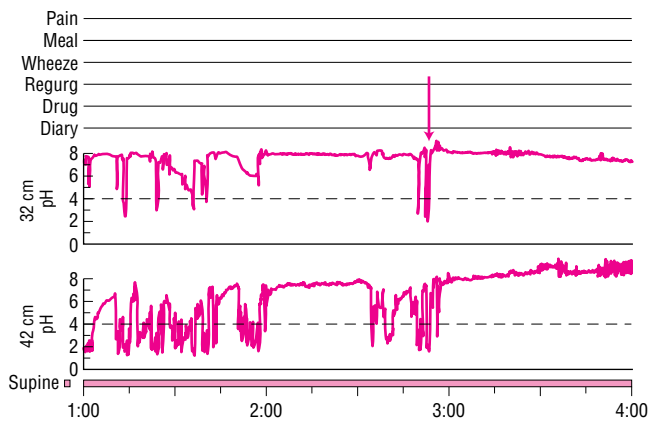

FIGURE 31-9. Ambulatory pH monitoring. The pH recordings from two esophageal probes are plotted over a 3-hour interval. Notice that the patient's symptom of regurgitation correlates with a low pH (<4) event (arrow).

alternating dripped solutions of normal saline and 0.1 N hydrochloric acid (HCl) into the esophagus via the NG tube. If patient symptoms are reproduced by the acid perfusion and not the saline, the study is considered abnormal and indicative of acid hypersensitivity.¹⁵

ENDOSCOPIC ULTRASONOGRAPHY

In recent years, endoscopic ultrasonography has emerged as a useful adjunct in the diagnosis and staging of gastroenterologic disorders. The instrument itself functions very much like a typical upper endoscope but with the added feature of an ultrasound transducer. The examiner is then able to see the regional anatomy and pathology beneath the mucosa. The major advantage of this procedure is its capability to deliver the ultrasound transducer to close proximity of deep tissues for enhanced image resolution. In clinical practice, endoscopic ultrasound is highly useful in detecting and defining gastrointestinal and pancreatic malignancies. It also plays a role in the diagnosis of submucosal lesions and small pancreatic malignancies. Endoscopic ultrasound guidance of fine-needle biopsy is increasingly performed.

LAPAROSCOPY

Laparoscopy uses a tube-like device with an elaborate optical system that permits distinct visualization of the peritoneal cavity. General anesthesia is often given and a surgical incision is made in the abdomen to allow the passage of the laparoscope. The exterior of the liver, gallbladder, spleen, peritoneum, diaphragm, and pelvic organs may be clearly examined during the laparoscopic examination. Similar to the other endoscopic techniques mentioned, biopsies and therapeutic interventions may be performed during the laparoscopy. Reasons for doing laparoscopy include evaluating patients with ascites, abdominal masses, chronic abdominal pain, abnormalities indicated

on liver-spleen scan, liver diseases, obstructive jaundice, and hepatic malignancy.

CONCLUSIONS

Evaluation of the GI tract begins with a careful history and comprehensive physical examination. It then proceeds in a deliberate and thoughtful manner to establish the correct diagnosis and appropriate management. Laboratory and microbiologic tests, radiography, ultrasonography, computed tomography, radionuclide scanning, magnetic resonance imaging, arteriography, endoscopy, esophageal manometry, pH monitoring, endoscopic ultrasonography, and laparoscopy have definite roles in diagnosing and evaluating GI disorders.

GASTROESOPHAGEAL REFLUX DISEASE

Dianne B. Williams and Robert R. Schade

Learning Objectives and other resources can be found at www.pharmacotherapyonline.com.

KEY CONCEPTS

- 1 Patients should be assessed for symptoms, such as heartburn, and for signs and symptoms of complications that require immediate medical attention, such as dysphagia or bleeding.
- 2 Endoscopy is used to evaluate mucosal damage from gastroesophageal reflux disease (GERD) and assess for the presence of Barrett's esophagus (BE); 24-hour ambulatory pH testing or a therapeutic trial of a proton pump inhibitor are useful for diagnosing GERD in patients with persistent symptoms or atypical symptoms; manometry is useful in evaluating motility and before antireflux surgery.
- 3 The goals of treatment of GERD are to alleviate symptoms, to decrease the frequency of recurrent disease, to promote healing of mucosal injury, and to prevent complications.
- 4 Treatment of GERD involves a stepwise approach determined by disease severity and includes lifestyle changes and patient-directed therapy (phase I); pharmacologic treatment with nonprescription and prescription medications (phase II); and interventional approaches such as antireflux surgery or endoluminal therapies (phase III).
- 5 Patients with typical GERD symptoms should be treated with lifestyle modifications and a trial of empiric acid-suppression therapy. Those who do not respond to empiric therapy or who have more complicated symptoms should undergo diagnostic tests.
- 6 Interventional approaches (antireflux surgery or endoluminal therapies) offer an alternative treatment for refractory GERD or when pharmacologic management is undesirable.
- 7 Acid suppression is the mainstay of GERD treatment. H₂-receptor antagonists in divided doses are effective in less severe GERD. Proton pump inhibitors provide the greatest relief of symptoms and highest rates of healing, especially in patients with erosive disease or moderate to severe symptoms.
- 8 Many patients with GERD will relapse if medication is withdrawn, so long-term maintenance treatment is required. A proton pump inhibitor is the drug of choice for maintenance of patients with moderate to severe GERD.
- 9 Patient medication profiles should also be reviewed for drugs that may aggravate GERD. Patients should be monitored for adverse drug reactions and potential drug-drug interactions of drugs used to treat GERD. Finally, patients should be assessed for compliance to their therapeutic regimen.

Gastroesophageal reflux disease (GERD) is a common medical disorder and patients with this condition are seen by clinicians from various specialties. GERD refers to any symptomatic clinical condition or histologic alteration that results from episodes of gastroesophageal reflux. Gastroesophageal reflux is the retrograde movement of gastric contents from the stomach into the esophagus. When the esophagus is repeatedly exposed to refluxed material for prolonged periods of time, inflammation of the esophagus (reflux esophagitis) occurs, and in some cases it can progress to erosion of the squamous epithelium of the esophagus (erosive esophagitis). Complications of long-term reflux may include the development of strictures, Barrett's esophagus, or adenocarcinoma of the esophagus. Gastroesophageal reflux associated with disease processes in organs other than the esophagus, such as the lungs, is referred to as atypical (or extra-esophageal) GERD.¹ Severe reflux symptoms associated with normal endoscopic findings are referred to as symptomatic GERD, nonerosive reflux disease (NERD), or endoscopy-negative reflux disease (ENRD).

Many patients suffering from mild GERD do not go on to develop erosive esophagitis and are often managed with lifestyle changes, antacids, and nonprescription histamine (H₂)-receptor

antagonists or nonprescription proton pump inhibitors. Those with more severe symptoms (with or without endoscopic findings) predictably follow a course of relapsing disease requiring more intensive treatment with acid-suppressive therapy followed by long-term maintenance therapy.² Interventional therapies including antireflux surgery and endoluminal therapies offer an alternative to medical management for those patients who fail therapy or for those patients in whom medical management is undesirable.

EPIDEMIOLOGY

Gastroesophageal reflux disease occurs in both adults and children. Although mortality associated with GERD is rare (1 death per 100,000 patients), GERD symptoms have a greater impact on quality of life than do duodenal ulcers, untreated hypertension, mild congestive heart failure, angina, or menopause.^{3,4}

The true prevalence and incidence of GERD is difficult to assess because (a) many patients do not seek medical treatment, (b) symptoms do not always correlate well with severity of disease,

and (c) there is no standardized definition or universal gold standard method for diagnosing the disease.³

Approximately 44% of the American population suffer from GERD symptoms monthly, and more than 20% suffer with symptoms on a weekly basis.⁵ Despite the prevalence of GERD, many patients choose not to seek medical help from a physician and self-treat with nonprescription medications or consult only with their pharmacist. This may be due to their lack of understanding of symptoms of GERD, including heartburn, or it may be due to some financial or personal reason. Heartburn is the hallmark symptom of GERD and is generally described as a substernal sensation of warmth or burning rising up from the abdomen that may radiate to the neck. It may be waxing and waning in character. Interestingly, as many as 46% of patients with mild disease will heal spontaneously with self-medication, and another 31% will show significant improvement, indicating a relatively benign process in patients with minimal symptoms.⁶

Conversely, the presence of symptoms in patients who do seek medical advice does not always correlate well with the presence of esophageal inflammation or erosion. Of the 20% to 40% of patients who experience heartburn, 30% to 79% of these patients will have evidence of esophagitis.⁷ On the other hand, many patients with esophageal damage may not experience symptoms, or they may present with atypical symptoms.⁸ Finally, the lack of a standardized definition and universal gold standard for diagnosing GERD presents another obstacle in assessing epidemiologic data.

The prevalence of GERD varies depending on the geographic region, but appears highest in Western countries.³ The prevalence increases in adults older than 40 years of age. Except during pregnancy and possibly nonerosive reflux disease, there does not appear to be a major difference in incidence between men and women. Heartburn is a common complaint during pregnancy. NERD may occur more commonly in women and in patients who are approximately a decade younger than patients who develop erosive disease. Although gender does not generally play a major role in the development of GERD, it is an important factor in the development of Barrett's esophagus (BE), a complication of GERD in which the normal squamous epithelium is replaced with specialized columnar epithelium. BE is most prevalent in caucasian adult males in Western countries.

PATHOPHYSIOLOGY

The key factor in the development of GERD is the retrograde movement of acid or other noxious substances from the stomach into the esophagus.⁹ In some cases, gastroesophageal reflux is associated with defective lower esophageal sphincter (LES) pressure or function. Patients may have decreased gastroesophageal sphincter pressures related to (a) spontaneous transient LES relaxations, (b) transient increases in intra-abdominal pressure, or (c) an atonic LES—all of which may lead to the development of gastroesophageal reflux. Problems with other normal mucosal defense mechanisms such as anatomic factors, esophageal clearance, mucosal resistance, gastric emptying, epidermal growth factor, and salivary buffering may also contribute to the development of GERD. Aggressive factors that may promote esophageal damage upon reflux into the esophagus include gastric acid, pepsin, bile acids, and pancreatic enzymes. Thus the composition and volume of the refluxate as well as duration of exposure are the most important aggressive factors in determining the consequences of gastroesophageal reflux. Rational therapeutic regimens in the treatment of gastroesophageal reflux are designed to maximize normal mucosal defense mechanisms and attenuate the aggressive factors.

Several complications may occur with gastroesophageal reflux, including esophagitis, esophageal strictures, Barrett's esophagus, and adenocarcinoma of the esophagus. Strictures are common in the distal esophagus and are generally 1 to 2 cm in length. The use of nonsteroidal anti-inflammatory drugs (NSAIDs) or aspirin has been implicated as an additional risk factor that may contribute to the development or worsening of esophageal strictures.¹⁰ Although GERD may lead to esophageal bleeding, the blood loss is usually chronic and low grade in nature, but can lead to anemia. In some patients, the reparative process leads to the replacement of the squamous epithelial lining of the esophagus by specialized columnar-type epithelium. This condition, known as Barrett's esophagus, is more likely to occur in those patients with a long history (years) of symptomatic reflux that in many cases improves without intervention.¹¹ Barrett's esophagus can be found in 3.5% to 12% of patients undergoing first-time endoscopy for reflux symptoms, and the prevalence is probably higher in patients with more severe or complicated disease.¹² Patients with BE have a greater than 30% incidence of esophageal stricture formation. Additionally, the risk of esophageal adenocarcinoma is 30 to 60 times higher in patients with BE as compared to the general population.¹³ Interestingly, the risk of esophageal adenocarcinoma could be increased in patients with long-standing frequently recurring reflux symptoms (heartburn and regurgitation) despite the presence or absence of BE.¹³

LOWER ESOPHAGEAL SPHINCTER PRESSURE

The LES is a manometrically defined zone at the distal esophagus with an elevated basal resting pressure. The sphincter is normally in a tonic, contracted state, preventing the reflux of gastric material from the stomach, but relaxes on swallowing to permit the free passage of food into the stomach.

Mechanisms by which defective LES pressure may cause gastroesophageal reflux are threefold. First, and probably most importantly, reflux may occur following spontaneous transient LES relaxations that are not associated with swallowing.¹⁴ Although the exact mechanism is unknown, esophageal distention, vomiting, belching, and retching have all been shown to cause relaxation of the LES. While not thought to contribute significantly to erosive esophagitis, these transient relaxations, which are normal postprandially, may play an important role in intermittent nonerosive reflux.² Transient decreases in sphincter pressure are responsible for approximately 65% of the reflux episodes in patients with GERD. The propensity to develop gastroesophageal reflux secondary to transient decreases in LES pressure is probably dependent on numerous factors, including the degree of sphincter relaxation, efficacy of esophageal clearance, patient position (more common in recumbent position), gastric volume, and intragastric pressure. Second, reflux may occur following transient increases in intra-abdominal pressure (stress reflux).⁹ An increase in intra-abdominal pressure such as that occurring during straining, bending over, coughing, eating, or a Valsalva maneuver may overcome a weak LES, and thus may lead to reflux. Third, the LES may be atonic, thus permitting free reflux as seen in patients with scleroderma, for instance. Although transient relaxations are more likely to occur when there is normal LES pressure, the latter two mechanisms are more likely to occur when the LES pressure is decreased by such factors as fatty foods, gastric distention, smoking, or certain medications.⁹ Table 32-1 lists medications and foods that affect lower esophageal sphincter pressures.¹⁵ Various foods aggravate esophageal reflux by decreasing LES pressure or by precipitating symptomatic reflux by direct mucosal irritation (e.g., spicy foods, orange juice, tomato juice, and coffee).

Pregnancy, treated achalasia, and scleroderma are conditions in which reflux is common. There are many postulated reasons for the

TABLE 32–1. Foods and Medications That May Worsen GERD Symptoms

| Decreased lower esophageal sphincter pressure | |
|--|----------------------------------|
| Foods | |
| Fatty meal | Garlic |
| Carminatives (peppermint, spearmint) | Onions |

Adapted from Weinberg and Kadish.¹⁵

increased incidence of heartburn during pregnancy, including hormonal effects on esophageal muscle, LES tone, and physical factors (increased intra-abdominal pressure) resulting from an enlarging uterus.¹⁶

A decrease in LES pressure resulting from any of the previously mentioned causes is not always associated with gastroesophageal reflux. Likewise, individuals who experience decreases in sphincter pressures, and subsequently reflux, do not always develop GERD. The other natural defense mechanisms (anatomic factors, esophageal clearance, mucosal resistance, and other gastric factors) must be evoked to explain this phenomenon.

ANATOMIC FACTORS

Proposed anatomic factors contributing to reflux can be categorized into valvular mechanisms, extrinsic compression, a segment of the esophagus in the chest, mucosal choke, and spiral stretch mechanisms. Disruption of the normal anatomic barriers by a hiatal hernia was once thought to be a primary etiology of gastroesophageal reflux and esophagitis. Now it appears that a more important factor related to the presence or absence of symptoms in patients with hiatal hernia is the LES pressure. The size of a hiatal hernia is proportional to the frequency of transient LES relaxations.¹⁷ Patients with hypotensive LES pressures and large hiatal hernias are more likely to experience gastroesophageal reflux following abrupt increases in intra-abdominal pressure, compared to patients with a hypotensive LES and no hiatal hernia. Although anatomic factors are still considered significant by some, the diagnosis of hiatal hernia is currently considered a separate entity with which gastroesophageal reflux may or may not simultaneously occur.

ESOPHAGEAL CLEARANCE

In many patients with GERD, the problem is not that they produce too much acid, but that the acid produced spends too much time in

contact with the esophageal mucosa. Approximately 50% of GERD patients with esophagitis have a prolonged acid clearance time from the esophagus.⁹ This is not surprising, because the symptoms and/or severity of damage produced by gastroesophageal reflux are partially dependent on the duration of contact between the gastric contents and the esophageal mucosa.¹⁸ This contact time is in turn dependent on the rate at which the esophagus clears the noxious material, as well as the frequency of reflux. The esophagus is cleared by primary peristalsis in response to swallowing, or by secondary peristalsis in response to esophageal distention and gravitational effects. Swallowing contributes to esophageal clearance by increasing salivary flow. Saliva contains bicarbonate that buffers the residual gastric material on the surface of the esophagus. The production of saliva decreases with increasing age, making it more difficult to maintain a neutral intra-esophageal pH. Therefore esophageal damage due to reflux occurs more often in the elderly, and similarly in patients with Sjögren's syndrome or xerostomia.¹⁹ Swallowing is also decreased during sleep, making nocturnal GERD a problem in many patients.

MUCOSAL RESISTANCE

Within the esophageal mucosa and submucosa there are mucus-secreting glands. The mucus secreted by these glands may contribute to the protection of the esophagus.²⁰ Bicarbonate moving from the blood to the lumen can neutralize acidic refluxate in the esophagus. When the mucosa is repeatedly exposed to the refluxate in GERD, or if there is a defect in the normal mucosal defenses, hydrogen ions diffuse into the mucosa, leading to the cellular acidification and necrosis that ultimately cause esophagitis.⁹ In theory, mucosal resistance may be related not only to esophageal mucus, but also to tight epithelial junctions, epithelial cell turnover, nitrogen balance, mucosal blood flow, tissue prostaglandins, and the acid-base status of the tissue.²⁰ Saliva is also rich in epidermal growth factor, stimulating cell renewal.

GASTRIC EMPTYING

Delayed gastric emptying can contribute to gastroesophageal reflux. An increase in gastric volume may increase both the frequency of reflux and the amount of gastric fluid available to be refluxed. Gastric volume is related to the volume of material ingested, rate of gastric secretion, rate of gastric emptying, and amount and frequency of duodenal reflux into the stomach. Factors that increase gastric volume and/or decrease gastric emptying, such as smoking and high-fat meals, are often associated with gastroesophageal reflux. This partially explains the prevalence of postprandial gastroesophageal reflux. Fatty foods may increase postprandial gastroesophageal reflux by increasing gastric volume, delaying the gastric emptying rate, and decreasing the LES pressure. Patients with gastroesophageal reflux, particularly infants, may have a defect in antral motility. The delay in emptying may promote regurgitation of feedings, which might in turn contribute to two common complications of GERD in infants (i.e., failure to thrive and pulmonary aspiration).²¹

COMPOSITION OF REFLUXATE

The composition, pH, and volume of the refluxate are the most important aggressive factors in determining the consequences of gastroesophageal reflux. In animals, acid has two primary effects when it refluxes into the esophagus. First, if the pH of the refluxate is less than 2, esophagitis may develop secondary to protein denaturation. In addition, pepsinogen is activated to pepsin at this pH and may also cause esophagitis. Duodenogastric reflux esophagitis or "alkaline" refers to

esophagitis induced by the reflux of biliary and pancreatic fluid. The term *alkaline esophagitis* may be a misnomer in that the refluxate may be either weakly alkaline or acidic in nature. An increase in gastric bile concentrations may be caused by duodenogastric reflux due to a generalized motility disorder, or slower clearance of the refluxate or following surgery.²²

Although bile acids have both a direct irritant effect on the esophageal mucosa and an indirect effect of increasing hydrogen ion permeability of the mucosa, symptoms are more often related to acid reflux than to bile reflux. Esophageal pH monitoring demonstrates that severity of disease is related to degree of esophageal acid exposure and not so much to bile exposure. Specifically, the percentage of time that the esophageal pH is below 4 is greater for patients with severe disease as compared to those with mild disease.^{23,24} However, esophageal pH monitoring in conjunction with 24-hour bile monitoring has been associated with a higher incidence of BE in patients with both acid and alkaline reflux.²² More study is needed to substantiate this finding. Nevertheless, the combination of acid, pepsin, and/or bile is a potent refluxate in producing esophageal damage.

The pathophysiology of gastroesophageal reflux is a complex cyclic process. It is difficult, if not impossible, to determine which occurs first: gastroesophageal reflux leading to defective peristalsis with delayed clearing, or an incompetent LES pressure leading to gastroesophageal reflux. Understanding the factors associated with the development of GERD provides insight into the treatment modalities currently used to manage a patient who suffers from the disease.

CLINICAL PRESENTATION

1 Patients with GERD may display symptoms described as (a) typical, (b) atypical, or (c) complicated. Table 32–2 summarizes each of these clinical presentations of GERD.¹¹ The severity of

TABLE 32–2. Clinical Presentation of GERD

Typical symptoms: May be aggravated by activities that worsen gastroesophageal reflux such as recumbent position, bending over, or eating a meal high in fat.

- Heartburn
- Water brash (hypersalivation)
- Belching
- Regurgitation

Atypical symptoms: In some cases, these extraesophageal symptoms may be the only symptoms present, making it more difficult to recognize GERD as the cause, especially when endoscopic studies are normal.

- Nonallergic asthma
- Chronic cough
- Hoarseness
- Pharyngitis
- Chest pain
- Dental erosions

Complicated symptoms: These symptoms may be indicative of complications of GERD such as Barrett's esophagus, esophageal strictures, or esophageal cancer.

- Continual pain
- Dysphagia
- Odynophagia
- Bleeding
- Unexplained weight loss
- Choking

From Schindlbeck et al.³⁰

the symptoms of gastroesophageal reflux does not always correlate with the degree of esophagitis, but it does correlate with the duration of reflux. It is important to distinguish GERD symptoms from those of other diseases, especially when chest pain or pulmonary symptoms are present. Interestingly, approximately 50% of patients presenting with chest pain who have a normal electrocardiogram have GERD.⁹ Similarly, 53% of patients with asthma have GERD.²⁵ Patients presenting with asthma (especially nocturnal asthma) that is poorly responsive to standard medical therapies should be evaluated to determine if GERD contributes to their symptoms.¹¹ Pulmonary symptoms result from either direct irritation of the vagus nerve when refluxed acid comes in contact with the esophageal mucosa, causing bronchospasm (the reflex theory); or less commonly from aspiration of the refluxate into the lungs, causing chemical irritation that manifests as pneumonia or pulmonary fibrosis (the reflux theory).²⁶

Patients who are not adequately treated for GERD may go on to develop complications from long-term acid exposure. Long-term, recurrent reflux symptoms that are not adequately treated may lead to the development of Barrett's esophagus and may be an independent risk factor for the development of esophageal adenocarcinoma.¹³ Esophageal strictures may be present in patients presenting with dysphagia. However, these symptoms may occur in other esophageal disorders such as esophageal diverticulum, achalasia, obstruction, esophageal spasm, esophageal infections, scleroderma, and malignancy. The presence of complicated symptoms should be further investigated to differentiate other diseases as the cause.

2 The tests that are useful in diagnosing GERD include endoscopy, 24-hour ambulatory pH monitoring, proton pump inhibitor administration as a diagnostic tool, and manometry.

The most useful tool in the diagnosis of gastroesophageal reflux is the clinical history, including both presenting symptoms and associated risk factors. Patients presenting with mild, typical symptoms of reflux (heartburn and regurgitation) do not usually require invasive esophageal evaluation. These patients generally benefit from an initial trial of lifestyle modifications and patient-directed nonprescription drug therapies. A clinical diagnosis of GERD can be assumed in patients who respond to appropriate therapy.²⁷

Endoscopy is the preferred technique for assessing the mucosa for esophagitis and for the presence of complications such as Barrett's esophagus.²⁷ It enables visualization and biopsy of the esophageal mucosa. Although less expensive than endoscopy, barium radiography lacks the sensitivity and specificity needed to accurately determine the presence of mucosal injury or to distinguish between BE and esophagitis.²⁷ For these reasons barium radiography has limited use in the routine diagnosis of GERD.²⁷

In patients with atypical symptoms, 24-hour ambulatory pH monitoring may be the only way to objectively prove the symptoms are reflux-related. Ambulatory pH monitoring may also be useful in patients who are on what is considered adequate therapy, but whose symptoms are not improving. However, GERD that is truly refractory to medical therapy is uncommon.²⁷ Continuous pH monitoring can be performed by passing a small pH probe intranasally and placing it approximately 5 cm above the LES.¹⁹ Patients keep a diary of symptoms and these are correlated with the pH measurement corresponding to the time the symptom was reported. In addition to correlating symptoms to abnormal esophageal acid exposure, 24-hour ambulatory pH monitoring also documents the percentage of time the intraesophageal pH is low and determines the frequency and severity of reflux.^{19,27} Problems with esophageal pH monitoring arise when different methods are used to perform the test or a patient's baseline differs significantly from the standard baseline. Additionally, pH monitoring is not readily available in many institutions. The empiric

TABLE 32-3. Endoscopic Classification of Esophagitis

| | |
|---------|--|
| Grade 0 | Normal esophageal mucosa |
| Grade 1 | Erythema or diffusely red mucosa and edema causing accentuated folds |
| Grade 2 | Isolated round or linear erosions extending from the gastroesophageal junction upwards, not involving the entire circumference |
| Grade 3 | Confluent erosions extending around the entire circumference or superficial ulceration without stenosis |
| Grade 4 | Complicated cases; erosions as above, plus deep ulcerations, strictures, or columnar epithelium-lined esophagus |

From Savary and Miller.³⁴

use of standard dose, or even double-dose, omeprazole as a therapeutic trial for diagnosing the presence of GERD may be as beneficial as ambulatory 24-hour pH monitoring in diagnosing GERD. This approach is less expensive, more convenient, and more readily available than ambulatory pH monitoring, and has shown promise in patients with typical and atypical symptoms of GERD as well.²⁸⁻³² It seems to be especially useful in those patients in whom other gastrointestinal disorders such as esophageal erosions, peptic ulcers, and carcinomas, have been ruled out by endoscopy, but symptoms are still present. Preliminary results have also been promising in patients with extraesophageal symptoms.³³ Problems with using a proton pump inhibitor as a diagnostic tool include lack of a standardized dosing regimen and duration of the diagnostic trial.

Esophageal manometry to evaluate motility should be performed in any patient who is a candidate for antireflux surgery.²⁷ Esophageal manometry is useful in determining which surgical procedure is best for the patient. To perform manometry, a multilumen tube is passed into the stomach and the pressures are measured as the tube is pulled back across the lower esophageal sphincter, esophagus, and pharynx.

Several systems have been used to classify severity of GERD; a common grading scale is shown in Table 32-3.³⁴ Although endoscopy is a highly specific test, it is not extremely sensitive. In mild cases of GERD, the esophageal mucosa may appear relatively normal; however, obtaining mucosal biopsies may increase diagnostic yield. In addition, noninflammatory GERD and major motor disorders may be missed by endoscopy.

▶ TREATMENT: Gastroesophageal Reflux Disease

■ GENERAL APPROACH TO TREATMENT

4 The treatment of GERD is categorized into one of the following modalities: (1) lifestyle changes and patient-directed therapy with antacids, nonprescription H₂-receptor antagonists, and/or nonprescription proton pump inhibitors; (2) pharmacologic intervention primarily with standard or high-dose acid-suppressing agents; (3) and interventional therapies (antireflux surgery or endoluminal therapies) (Table 32-4). The initial therapeutic modality used is in part dependent on the patient's condition (frequency of symptoms, degree of esophagitis, and presence of complications). Historically, a step-up approach has been used, starting with noninvasive lifestyle modifications and patient-directed therapy, and progressing to pharmacologic management or interventional approaches.^{6,8,9} A step-down approach, starting with a proton pump inhibitor given once or twice daily instead of an H₂-receptor antagonist, and then stepping down to

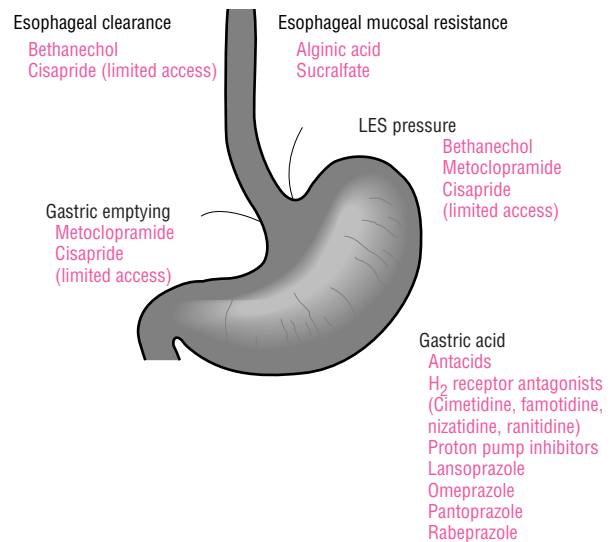

FIGURE 32-1. Therapeutic interventions in the management of gastroesophageal reflux disease. Pharmacologic interventions are targeted at improving defense mechanisms or decreasing aggressive factors. (LES, lower esophageal sphincter.)

TREATMENT

DESIRED OUTCOMES

3 Therapeutic modalities used in the treatment of gastroesophageal reflux are targeted at reversing the various pathophysiological abnormalities. The goals of treatment are to (a) alleviate or eliminate the patient's symptoms; (b) decrease the frequency or recurrence and duration of gastroesophageal reflux; (c) promote healing of the injured mucosa; and (d) prevent the development of complications. Therapy is directed at augmenting defense mechanisms that prevent reflux and/or decrease the aggressive factors that worsen reflux or mucosal damage (Fig. 32-1). Specifically, therapy is directed at (a) decreasing the acidity of the refluxate; (b) decreasing the gastric volume available to be refluxed; (c) improving gastric emptying; (d) increasing LES pressure; (e) enhancing esophageal acid clearance; and (f) protecting the esophageal mucosa.

the lowest degree of acid suppression needed to control symptoms, is also effective. Neither the "step-up" nor "step-down" approach has superior efficacy or cost effectiveness over the other. The clinician should determine the most appropriate approach for an individual patient.²⁷ Whichever method is used, every attempt should be made to aggressively control symptoms and to prevent relapses early in the course of the patient's disease in order to prevent the complications that are seen with long-standing symptomatic GERD.³⁵ In patients with moderate to severe GERD, starting with a proton pump inhibitor as initial therapy is advocated because of its superior efficacy over H₂-receptor antagonists.

Dietary and lifestyle modifications and education about factors that may worsen GERD symptoms should be discussed with the patient.²⁷ Table 32-5 lists many of the lifestyle changes that are included in phase I therapy.^{8,36} Although most patients do not respond to lifestyle changes alone, the importance of maintaining these lifestyle changes throughout the course of GERD therapy should

TABLE 32–5. Nonpharmacologic Treatment of GERD with Lifestyle Modifications

- Elevate the head of the bed (increases esophageal clearance). Use 6- to 8-inch blocks under the head of the bed. Sleep on a foam wedge
- Dietary changes
 - Avoid foods that may decrease lower esophageal sphincter pressure (fats, chocolate, alcohol, peppermint, and spearmint)
 - Avoid foods that have a direct irritant effect on the esophageal mucosa (spicy foods, orange juice, tomato juice, and coffee)
 - Include protein-rich meals in diet (augments lower esophageal sphincter pressure)
 - Eat small meals and avoid eating immediately prior to sleeping (within 3 h if possible) (decreases gastric volume)
 - Weight reduction (reduces symptoms)
- Stop smoking (decreases spontaneous esophageal sphincter relaxation)
- Avoid alcohol (increases amplitude of the lower esophageal sphincter, peristaltic waves, and frequency of contraction)
- Avoid tight-fitting clothes
- Discontinue, if possible, drugs that may promote reflux (calcium channel blockers, β -blockers, nitrates, theophylline)
- Take drugs that have a direct irritant effect on the esophageal mucosa with plenty of liquid if they cannot be avoided (tetracyclines, quinidine, and KCl, iron salts, aspirin, nonsteroidal anti-inflammatory drugs)

Compiled From Kitchin and Castell⁸ and Richter and Castell.³⁶

be stressed to the patient on a routine basis, no matter what other therapeutic modality is used. Patients with mild or infrequent symptoms may see improvement with the inexpensive nonprescription H₂-receptor antagonists, antacids, or alginic acid.

5 After 2 weeks, if patients are not responding to lifestyle changes and to patient-directed therapy, they are generally started on a pharmacologic treatment regimen consisting of an acid-suppressing agent. Acid-suppressing therapy with proton pump inhibitors or H₂-receptor antagonists are the mainstay of GERD treatment. Patients presenting with more severe symptoms (with or without esophageal erosions) or with erosive esophagitis should be started on a proton pump inhibitor as initial therapy, because it provides the most rapid symptomatic relief and healing of esophagitis in the highest percentage of patients.²⁷ H₂-receptor antagonists in divided doses are effective in patients with mild GERD.²⁷ Patients not responding to standard doses of H₂-receptor antagonists may require higher doses and/or more frequent dosing, because improvement correlates with the extent and duration of acid suppression.¹¹ Standard H₂-receptor antagonist doses may be increased to two to four times the normal dose. If this is necessary, it is more cost effective to switch to a proton pump inhibitor.

Prokinetic agents offer an alternative to standard doses of H₂-receptor antagonists in mild to moderate nonerosive GERD, but may not be as effective as acid-suppressing agents and can be more expensive. Combining prokinetic agents with acid-suppressing drugs offers only modest improvements in symptoms over standard doses of H₂-receptor antagonists and should not be routinely recommended. These agents improve defects related to esophagogastric motility, such as decreased LES pressure, decreased esophageal clearance, or delayed gastric emptying. Unfortunately, the availability of a prokinetic agent that has an acceptable adverse effect profile is lacking. Cisapride has been removed from the market for general use because of reports of cardiac arrhythmias (torsades de pointes) and is currently available

only through a limited access program from the manufacturer. For this reason, it is no longer routinely used in managing patients with GERD. The use of other prokinetic agents such as metoclopramide and bethanechol is limited by their adverse effect profile. Mucosal protectants such as sucralfate have a very limited role in the treatment of GERD.

Maintenance therapy is generally necessary to control symptoms and to prevent complications. In patients with more severe symptoms (with or without esophageal erosions), or in patients with other complications, maintenance therapy with a proton pump inhibitor is most effective. Routine use of combination therapy has no role in maintenance therapy of GERD. GERD that is refractory to adequate acid suppression is rare. In these cases, the diagnosis should be confirmed through further diagnostic tests before long-term, high-dose therapy or interventional approaches (antireflux surgery or endoluminal therapies) are considered.²⁷ Interventional approaches may also be considered a maintenance option in certain patients with established GERD.²⁷

NONPHARMACOLOGIC THERAPY

Nonpharmacologic treatment of GERD includes lifestyle modifications, which should be started initially and continued throughout the treatment course for GERD, and interventional approaches (antireflux surgery or endoluminal therapies).

LIFESTYLE MODIFICATIONS

The most common lifestyle changes that a patient should be educated about include (a) weight loss; (b) elevation of the head of the bed; (c) eating smaller meals and avoidance of eating 3 hours prior to sleeping; (d) avoidance of foods or medications that exacerbate GERD; (e) smoking cessation; and (f) avoidance of alcohol (see Table 32–5). Obese patients were 2.8 times more likely to experience GERD symptoms than patients who were not obese.³⁷ While there are limited data indicating that reflux occurs more often with obesity, it would seem logical that the increased intra-abdominal pressure and dietary habits of obese patients would predispose them to reflux.² Therefore weight loss and a low-fat diet is recommended. A meal high in fat will decrease LES pressure for 2 hours or more postprandially. In contrast, a high-protein, low-fat meal will elevate LES pressure. Elevating the head of the bed about 6 to 8 inches with a foam wedge under the mattress (not just elevating the head with pillows) decreases nocturnal esophageal acid contact time and should be recommended.⁹ Many foods may worsen the symptoms of GERD. Fats and chocolate can decrease LES pressure, while citrus juice, tomato juice, coffee, and pepper may irritate damaged endothelium. It is important to evaluate patient profiles and to identify potential medications that may exacerbate GERD symptoms. Medications, such as anticholinergics, barbiturates, calcium channel blockers, and theophylline decrease LES pressure. Other medications including aspirin, iron, NSAIDs, quinidine, potassium chloride, and bisphosphonates act as direct contact irritants to the esophageal mucosa.

Patients taking bisphosphonates (e.g., alendronate) should be instructed to drink 6 to 8 ounces of plain tap water and remain upright for at least 30 minutes following administration. Proper patient education can help prevent dysphagia or esophageal ulceration. Patients should be closely monitored for worsening symptoms when any of these medications are started. If symptoms worsen, alternative

therapies may be warranted. The clinician must weigh the risks and benefits of continuing a drug known to worsen GERD and esophagitis. Smoking can cause aerophagia, which leads to increased belching and regurgitation.² However, data are lacking to show that symptoms improve in patients who quit smoking. Nevertheless, patients with GERD should be encouraged to quit smoking. Alcohol, although not thought to play a role in severe disease, decreases LES pressure and may exacerbate symptoms such as heartburn.²

Many patients are noncompliant with lifestyle modifications, and even those who do comply generally continue to have symptoms requiring acid-suppression therapy. Nonetheless, it is important to regularly stress the value of lifestyle modification.

■ INTERVENTIONAL APPROACHES

■ Antireflux Surgery

6 Surgical intervention is a viable alternative for selected patients with well-documented GERD.²⁷ The goal of antireflux surgery is to re-establish the antireflux barrier, to position the lower esophageal sphincter within the abdomen where it is under positive (intra-abdominal) pressure, and to close any associated hiatal defect.³⁸ It should be considered in patients (a) who fail to respond to pharmacologic treatment; (b) who opt for surgery despite successful treatment because of lifestyle considerations, including age, time, or expense of medications; (c) who have complications of GERD (BE, strictures, or grade 3 or 4 esophagitis); or (d) who have atypical symptoms and reflux documented on 24-hour ambulatory pH monitoring.³⁸

Surgical procedures include Nissen, Belsey, Toupet, and Hill fundoplication operations. The procedure chosen depends on the surgeon's expertise and preference, as well as on anatomic considerations.³⁸ In general, 90% of patients have symptom resolution following successful open Nissen fundoplication. Because of the diminished surgical complications with the newer laparoscopic surgical procedures (Nissen fundoplication being one of the most commonly performed procedures), the role of surgery in the long-term management of GERD has become more appealing. The major complications with antireflux surgery include gas bloat syndrome (inability to belch or vomit), dysphagia, vagal denervation, splenic trauma, and very rarely, death.¹ In contrast, death has not occurred due to pharmacologic treatment with a proton pump inhibitor. Antireflux surgery has been found to be superior to medical management (with an H₂-receptor antagonist or prokinetic agent). However, similar comparisons with proton pump inhibitors are lacking. A preliminary study of 310 patients who were initially controlled on omeprazole 40 mg daily found antireflux surgery to be slightly superior to omeprazole 20 mg daily at 3 years.³⁹ Omeprazole doses of 40 to 60 mg were found to be equally efficacious to antireflux surgery. Long-term effectiveness of antireflux surgery ranges from 5 to 20 years.²⁷

CLINICAL CONTROVERSY

Some clinicians believe that patients should be offered the newer endoscopic interventions instead of proton pump inhibitors for long-term maintenance of GERD. While the newer endoscopic therapies provide good results and less recovery time than surgery, the long-term effects are still not known. Conversely, many patients prefer not to have to take medication indefinitely, and in some cases still complain of symptoms despite drug therapy.

■ Endoluminal Therapies

Several new endoluminal approaches to the management of GERD have recently been developed.⁴⁰ These techniques include endoscopic suturing to produce a plication, endoluminal application of radiofrequency heat energy resulting in tissue injury or nerve ablation (the Stretta procedure), and endoscopic injection of a biopolymer known as Enteryx at the gastroesophageal junction. These techniques are relatively new, and although FDA-approved, their exact role in the management of GERD has yet to be determined.

Endoscopic gastroplastic plication of folds of the gastroesophageal junction is accomplished using a suturing device introduced by mouth with endoscopic assistance, and it enhances the barrier function of the gastroesophageal junction. Preliminary reports suggest that following the procedure there is a significant reduction in symptoms of heartburn and regurgitation, and that the quality-of-life scores improve. There has been a reported reduction in the use of other acid-suppressing medications such as proton pump inhibitors in the population treated.

The Stretta device delivers radiofrequency energy through specialized needles placed into the submucosal tissue of the esophagus while monitoring esophageal mucosal surface temperatures. This results in tissue injury leading to increased collagen deposition and scarring at the gastroesophageal junction, potentially increasing LES pressure and reducing gastroesophageal reflux. Again, the primary outcome has been reduction in symptomatic heartburn and improvement in quality of life. Although acid exposure time was reduced, proton pump inhibitor use is continued in approximately 15% of patients at 6 months, and 30% of patients at 12 months. Because of the paucity of sufficient study data, it is unclear what the role of this device will be in the management of patients with symptomatic GERD.

Therapy of gastroesophageal reflux through injection of bulking agents into the gastroesophageal junction has been tried using bovine collagen or polytetrafluoroethylene. More recently, the injection of ethylene vinyl alcohol copolymer (Enteryx) has been approved by the FDA for the treatment of GERD. In this technique, the polymer is injected through a needle placed through the endoscope into the tissue at the esophagogastric junction. The exact mechanism of action for this technique is not known, although reduction in transient LES pressure has been demonstrated. The overall safety of this procedure has been excellent with no major complications being reported. Among the 70% to 80% of treated patients who responded, most were able to discontinue proton pump inhibitor use.

■ PHARMACOLOGIC THERAPY

■ ANTACIDS AND ANTACID-ALGINIC ACID PRODUCTS

Patients should be educated that antacids are an appropriate component of treating mild GERD, even though documentation of their efficacy in placebo-controlled clinical trials is lacking.⁶ Although the literature is somewhat controversial on the superiority of antacids to placebo, physicians and patients clearly consider antacids to be effective for immediate symptomatic relief, and antacids are often used concurrently with other acid-suppressing therapies. Maintaining the intragastric pH above 4 decreases the activation of pepsinogen to pepsin, a proteolytic enzyme. Also, neutralization of gastric fluid leads to increased LES pressure. Patients who require frequent use of antacids for chronic symptoms should be treated with prescription acid-suppressing therapy because their illness is considered more significant.

An antacid product combined with alginic acid is not a potent neutralizing agent and does not enhance LES pressure; however, it does form a highly viscous solution that floats on the surface of the gastric contents. This viscous solution is thought to serve as a protective barrier for the esophagus against reflux of gastric contents. It also reduces the frequency of the reflux episodes.⁴¹ The combination product usually relieves symptoms associated with reflux.^{42,43} Efficacy data indicating endoscopic healing are lacking.

Antacid or antacid combination products may cause gastrointestinal adverse effects (diarrhea or constipation, depending on the product), alterations in mineral metabolism, and acid-base disturbances. Aluminum-containing antacids may bind to phosphate in the gut and lead to bone demineralization. In addition, antacids interact with a variety of drugs by altering gastric pH, increasing urinary pH, adsorbing medications to their surfaces, providing a physical barrier to absorption, or forming insoluble complexes with other medications.⁴⁴ Antacids have clinically significant drug interactions with tetracycline, ferrous sulfate, isoniazid, quinidine, sulfonyleureas, and quinolone antibiotics. Antacid-drug interactions are influenced by composition, dose, and dosage schedule of the antacid, as well as by the formulation.

Dosage recommendations for antacids in the management of GERD are somewhat difficult to derive from the literature (see Table 32-4 for general dosing guidelines). Doses range from hourly to an as-needed basis. In general, antacids have a short duration of action, which necessitates frequent administration throughout the day to provide continuous neutralization of acid. Typical doses are two tablets or one tablespoonful four times daily—after meals and at bedtime. Taking antacids after meals can increase the duration of action from about 1 hour to about 3 hours; however, nighttime acid suppression cannot be maintained with bedtime doses.

■ ACID SUPPRESSION WITH H₂-RECEPTOR ANTAGONISTS (CIMETIDINE, FAMOTIDINE, NIZATIDINE, AND RANITIDINE)

◀ Acid-suppressing therapies are the mainstay of treatment of GERD. H₂-receptor antagonists in divided doses are effective in treating patients with mild to moderate GERD.²⁷ The majority of the trials assessing the efficacy of standard doses of H₂-receptor antagonists indicate that symptomatic improvement is achieved in an average of 60% of patients after 12 weeks of therapy.²⁷ However, endoscopic healing rates tend to be lower, an average of 50%.²⁷

The efficacy of H₂-receptor antagonists in the management of GERD is extremely variable and is frequently lower than desired. Response to the H₂-receptor antagonists appears to be dependent on the (a) severity of disease, (b) dosage regimen used, and (c) duration of therapy. These factors are important to keep in mind when comparing various clinical trials and/or assessing a patient's response to therapy.

The severity of esophagitis at baseline has a profound impact on the patient's response to H₂-receptor antagonists. For symptomatic relief of mild GERD, low-dose, nonprescription H₂-receptor antagonists may be beneficial. For nonerosive disease, H₂-receptor antagonists are generally given at standard doses twice daily. Patients not responding to standard doses may be hypersecretors of gastric acid, requiring higher doses.⁶ For these patients and those with erosive disease, higher doses and/or dosing four times daily (cimetidine 800 mg twice daily, famotidine 40 mg twice daily, nizatidine 150 mg four times daily, or ranitidine 150 mg four times daily) provide better acid control, especially after mealtime acid surges.² Although higher doses of H₂-receptor antagonists may provide higher symptomatic and

endoscopic healing rates, limited information exists regarding the safety of these regimens, and they can be less effective and more costly than once-daily proton pump inhibitors. Unlike duodenal ulcer disease, in which the duration of therapy is relatively short (e.g., 4 to 6 weeks), prolonged courses (8 weeks or more) of H₂-receptor antagonists are frequently required in the treatment of GERD.

Because all of the H₂-receptor antagonists have similar efficacy, selection of the specific agent to use in the management of GERD should be based on factors such as differences in pharmacokinetics, safety profile, and cost. In general, the H₂-receptor antagonists are well tolerated. The most common adverse effects are headache, somnolence, fatigue, dizziness, and either constipation or diarrhea. Patients should be monitored for the presence of adverse effects as well as potential drug interactions, especially when on cimetidine. Cimetidine may inhibit the metabolism of theophylline, warfarin, phenytoin, nifedipine, or propranolol, among others. An alternate H₂-receptor antagonist should be selected if the patient is on any of these medications.

■ ACID SUPPRESSION WITH PROTON PUMP INHIBITORS (ESOMEPRAZOLE, LANSOPRAZOLE, OMEPRAZOLE, PANTOPRAZOLE, AND RABEPRAZOLE)

Proton pump inhibitors are superior to H₂-receptor antagonists in treating patients with moderate to severe GERD. This includes not only those patients with erosive esophagitis or complicated symptoms (BE or strictures), but also those patients with nonerosive GERD who have moderate to severe symptoms. In these patient populations, relapse is common and long-term maintenance therapy is generally indicated. Comparable doses of proton pump inhibitors are omeprazole 20 mg = esomeprazole 20 mg = lansoprazole 30 mg = rabeprazole 20 mg = pantoprazole 40 mg per day. Symptomatic relief is seen in approximately 83% of patients treated with a proton pump inhibitor, while the endoscopic healing rate at 8 weeks is 78%.²⁷ All of the proton pump inhibitors are generally well tolerated, while the newer agents, esomeprazole, pantoprazole, and rabeprazole, appear less likely to cause significant drug interactions. In general, all of these agents are safe and effective and the choice of a particular agent will most likely be based on cost.

Proton pump inhibitors block gastric acid secretion by inhibiting gastric H⁺/K⁺-adenosine triphosphatase in gastric parietal cells.⁴⁵ This produces a profound, long-lasting antisecretory effect capable of maintaining the gastric pH above 4, even during acid surges seen postprandially.^{2,9} While the proton pump inhibitors have the same mechanism of action, there are slight differences in their actual binding to the cysteine residues in the proton pump.

A correlation appears to exist between the percentage of time the gastric pH remains above 4 during the 24-hour period and healing erosive esophagitis. Lansoprazole 15 mg and 30 mg daily, omeprazole 20 mg daily, and ranitidine 150 mg four times daily were compared in suppressing gastric acid secretion in 29 healthy men.⁴⁶ After 5 days, the mean 24-hour gastric pH values for lansoprazole 30 mg, 15 mg, omeprazole, and ranitidine were 4.53, 3.97, 4.02, and 3.59, respectively. The percentage of time the pH remained above 4 for the lansoprazole 30 mg, 15 mg, omeprazole, and ranitidine groups were 63%, 48%, 51%, and 38%, respectively. This difference was statistically different for the lansoprazole 30-mg group. A similar study also showed that lansoprazole 30 mg maintained a higher 24-hour gastric pH as compared with omeprazole 20 mg.⁴⁷

Rabeprazole appears to have a faster onset of action after the first dose and maintains the gastric pH >4 for a higher percentage of time during a 24-hour period as compared with omeprazole (45% vs

25%). The percentage of time the gastric pH values remained above 4 by day 8 was 60.3% and 50.4%, respectively. However, this was only significant on the first day of therapy.⁴⁸ Another study showed rabeprazole 20 mg and 40 mg increased mean gastric pH to 4.2 and 4.7, respectively. The percentage of time the esophageal pH was <4 was decreased and fewer reflux episodes were noted with both doses.⁴⁹

During a 5-day study of 38 GERD patients, esomeprazole 20 mg and 40 mg maintained intragastric pH >4 for a significantly longer time as compared to omeprazole 20 mg (13 hours, 18 hours, and 11 hours, respectively).⁵⁰ The 24-hour median intragastric pH was also significantly higher in both the esomeprazole 20 mg and 40 mg groups as compared with omeprazole 20 mg (4.1, 4.9, and 3.6, respectively).

Proton pump inhibitors are superior to H₂-receptor antagonists both in their ability to control symptoms and to heal esophagitis in patients with GERD.⁵¹ They are also more cost effective in patients with severe disease. A meta-analysis of 43 double-blind or single-blind trials with various drug classes in patients with erosive esophagitis found that healing was highest with proton pump inhibitors as compared with H₂-receptor antagonists (83.6% vs 51.9%).⁵¹ Symptom relief was achieved in 77% of patients on a proton pump inhibitor as compared with 48% of patients on an H₂-receptor antagonist. Both healing and symptom relief occurred almost twice as fast when a proton pump inhibitor was used. Even with mild esophagitis (grade 1 or 2), omeprazole was still superior to high-dose ranitidine.⁵² In a study of 446 patients with grade 1 or 2 esophagitis, omeprazole 20 mg daily was more effective at relieving symptoms than was ranitidine 150 mg four times daily. Sixty-one percent and 74% of patients were symptom-free at 4 weeks and 8 weeks, respectively, in the omeprazole group, as compared with 31% and 50% in the ranitidine group, respectively.

There are a few trials comparing proton pump inhibitors to each other. In general, healing rates at 4 weeks and 8 weeks are similar; lansoprazole and rabeprazole, however, may relieve symptoms faster after the first dose when compared to omeprazole. This is especially true when the higher dose of lansoprazole (30 mg daily) is compared to omeprazole 20 mg.⁵³ Both daytime and nighttime symptoms, as well as pain severity, were reported to be significantly better with lansoprazole 30 mg, as compared with omeprazole 20 mg or lansoprazole 15 mg, after the first dose. Healing rates at 4 weeks and 8 weeks were similar. Symptom relief was similar when a higher dose of omeprazole (40 mg daily) was compared with lansoprazole 30 mg.⁵⁴

Esomeprazole, is the S-isomer of omeprazole and may offer greater acid suppression and improved healing rates as compared with the other proton pump inhibitors. Esomeprazole was compared with omeprazole in 1960 patients with endoscopy-confirmed grade 2 reflux esophagitis.⁵⁵ The number of patients healed at 8 weeks were 94% (esomeprazole 40 mg), 90% (esomeprazole 20 mg), and 87% (omeprazole 20 mg) ($p < 0.05$). Healing at 4 weeks and improvement in heartburn was also considered superior in the esomeprazole 40 mg group as compared with the omeprazole 20 mg group. More experience with using this agent in clinical practice will clarify its role in the treatment of patients with GERD.

Rabeprazole 20 mg daily was compared with omeprazole 20 mg daily and found to be equally efficacious at 4 and 8 weeks in healing erosive esophagitis. Symptom relief (both frequency and intensity) was similar in both groups.⁵⁶

Similar results were seen when pantoprazole 40 mg was compared with omeprazole 20 mg in 286 patients with mild to moderate reflux esophagitis. Healing rates were 74% and 78%, respectively, after 4 weeks; and 90% and 94%, respectively, after 8 weeks of treatment. Symptom relief was similar for both groups.⁵⁷ More pub-

lished trials are needed with pantoprazole and rabeprazole, especially with long-term use.

Omeprazole (40 to 60 mg daily) and lansoprazole (30 to 60 mg daily) also appear to be effective in healing esophagitis and esophageal ulcers in patients with gastroesophageal reflux complications.^{58,59} When patients with complications of GERD (BE, strictures, or failed antireflux surgery) who were refractory to high-dose H₂-receptor antagonist therapy received omeprazole 40 mg daily, all patients were healed during 20 weeks of therapy.⁵⁸

Whether proton pump inhibitors can actually reverse BE remains a topic for debate. The use of high-dose omeprazole (40 mg twice daily) caused partial regression of BE, but no change was noted in patients receiving ranitidine 150 mg twice daily.⁶⁰ Others propose that these islands of normal squamous cells that appear in patients with BE after high-dose proton pump inhibitors may be covering gastric mucosa and may mask the development of cancerous changes in the mucosa.⁶¹ It is unknown whether regression of BE reduces the risk of adenocarcinoma in someone who already has BE, but aggressive therapy aimed at adequate suppression of acid reflux early in the course of a patient's disease may help to prevent the development of BE.

The proton pump inhibitors are usually well tolerated; however, potential adverse effects include headache, dizziness, somnolence, diarrhea, constipation, and nausea. The frequency of adverse events appears to be similar to that seen with the H₂-receptor antagonists. Concern and controversy regarding the safety of therapy with a proton pump inhibitor are based on the proton pump inhibitor's ability to cause hypergastrinemia and gastric carcinoid tumors in rats. After nearly a decade of experience with the proton pump inhibitors, gastric carcinoid tumors have not been directly linked to omeprazole use in humans.⁶

Drug interactions with the proton pump inhibitors vary with each agent. All proton pump inhibitors can decrease the absorption of drugs such as ketoconazole or itraconazole, which require an acidic environment to be absorbed. All proton pump inhibitors are metabolized by the cytochrome P450 system to some extent, specifically by the CYP2C19 and CYP3A4 enzymes. However, no interactions with lansoprazole, pantoprazole, or rabeprazole have been seen with CYP2C19 substrates such as diazepam, warfarin, or phenytoin.³⁵ Esomeprazole does not appear to interact with warfarin or phenytoin, and an interaction with diazepam is generally not considered clinically relevant. Pantoprazole is also metabolized by a cytosolic sulfotransferase and is therefore less likely to have significant drug interactions compared with the other proton pump inhibitors.⁶² While generally not causing major concern, omeprazole has the potential to inhibit the metabolism of warfarin, diazepam, and phenytoin; and lansoprazole may decrease theophylline concentrations.

Drug interactions with omeprazole are of particular concern in patients who are considered "slow metabolizers," as found in approximately 3% of the caucasian population. Unfortunately, it is unclear which patients have the polymorphic gene variation that makes them slow metabolizers.⁶² Like omeprazole, the metabolism of esomeprazole may also be altered in patients with this polymorphic gene variation. Rabeprazole increases digoxin trough concentrations by approximately 20%.⁶² Patients on potentially interacting drugs should be monitored closely for potential problems.

The proton pump inhibitors degrade in acidic environments and are therefore formulated in a delayed-release capsule or tablet formulation. Lansoprazole, esomeprazole, and omeprazole contain enteric-coated (pH-sensitive) granules in a capsule form. In patients unable to swallow the capsule or in pediatric patients, the contents of the capsule can be mixed in applesauce or placed in orange juice. If a patient has a nasogastric tube, the contents of an omeprazole capsule can

be mixed in 8.4% sodium bicarbonate solution. Esomeprazole can be mixed with water. Lansoprazole comes in a packet for oral suspension and a delayed-release orally disintegrating tablet. While these dosage forms are beneficial for those who cannot swallow the capsule, such as elderly or pediatric patients, it should not be placed through a nasogastric tube. Patients taking pantoprazole or rabeprazole should be instructed not to crush, chew, or split the delayed-release tablets. Pantoprazole is available in an intravenous formulation, which offers an alternative route of administration for patients unable to take an oral proton pump inhibitor. It should be emphasized that the intravenous product is not more efficacious than oral proton pump inhibitors and will be significantly more expensive. Careful patient selection will be necessary to avoid the tremendous cost anticipated from the use of this product. An injectable form of lansoprazole is expected to be approved within the year. Patients should be instructed to take their proton pump inhibitor in the morning, 15 to 30 minutes before breakfast to maximize efficacy, because these agents inhibit only actively secreting proton pumps.^{2,62} Food may decrease the absorption of lansoprazole. If dosed twice daily, the second dose should be administered approximately 10 to 12 hours after the morning dose and prior to a meal or snack.³⁵

■ PROKINETIC AGENTS

The efficacy of the prokinetic agents cisapride, metoclopramide, and bethanechol has been evaluated in the treatment of GERD. The inferior efficacy and side effect profiles associated with metoclopramide and bethanechol, as compared with cisapride, limit their use in the treatment of GERD. Cisapride, on the other hand, has comparable efficacy to H₂-receptor antagonists in treating patients with mild esophagitis. Unfortunately, cisapride is no longer available for routine use because of life-threatening arrhythmias when it is combined with certain medications and other disease states. Prokinetic agents have also been used as adjunctive therapy with an H₂-receptor antagonist. The only scenario in which this combination is appropriate is in a patient with GERD who has a known or suspected motility disorder, or in a patient who has failed high-dose proton pump inhibitor therapy.

■ Cisapride

The efficacy of cisapride appears similar to that of the H₂-receptor antagonists in patients with mild esophagitis. However, cisapride generally costs more than the H₂-receptor antagonists and offers no real advantage, especially in patients with normal GI motility. Because this agent is no longer available for routine use in GERD, an evaluation of clinical trials is not included. Three treatment protocols are available through the manufacturer, Janssen. One protocol is a pediatric outpatient study, the second protocol is an adult outpatient study, and the third protocol is an inpatient neonatal study. Physicians must register as investigators and patients must be enrolled just as with any other study protocol. More information can be obtained from the company.

■ Metoclopramide

Metoclopramide, a dopamine antagonist, increases LES pressure in a dose-related manner, and accelerates gastric emptying in gastroesophageal reflux patients. Unlike cisapride, however, metoclopramide does not improve esophageal clearance. Metoclopramide

provides symptomatic improvement for some patients with gastroesophageal reflux disease; however, substantial data indicating that metoclopramide provides endoscopic healing are lacking. In addition, metoclopramide's side effect profile and the incidence of tachyphylaxis with continued use limits its usefulness in treating many patients with GERD. The risk of adverse effects is much greater in patients with renal dysfunction because the drug is primarily eliminated by the kidneys. Contraindications include Parkinson's disease, mechanical obstruction, concomitant use of other dopamine antagonists, anticholinergic agents, and pheochromocytoma.

■ MUCOSAL PROTECTANTS

Sucralfate, a nonabsorbable aluminum salt of sucrose octasulfate, has very limited value in the treatment of GERD. Sucralfate has similar healing rates as H₂-receptor antagonists for patients with mild esophagitis.⁶³ However, sucralfate is less effective than higher doses of H₂-receptor antagonists in patients with refractory esophagitis.⁶³ Overall, the efficacy of sucralfate varies greatly among the studies. The wide range of response rates may in part be related to patient population, baseline degree of esophagitis, duration of treatment, dose used, or sucralfate formulation used. Sucralfate cannot be routinely recommended for use in the treatment of anything but the mildest cases of GERD.

■ COMBINATION THERAPY

Combination therapy with an acid-suppressing agent and a prokinetic agent or a mucosal protectant agent would seem logical given the multifactorial nature of the disease, particularly in light of the disappointing results seen with many monotherapy regimens. However, sufficient data to support combination therapy are limited, and this approach should not be routinely recommended unless a patient has esophagitis plus motor dysfunction occurring concurrently or if the patient has failed high-dose proton pump inhibitor therapy. Most studies suggest that combination therapy offers only modest improvements over standard doses of H₂-receptor antagonists alone. Therefore patients not responding to standard doses of H₂-receptor antagonists should have their dose of H₂-receptor antagonists increased or be switched to a proton pump inhibitor instead of adding a prokinetic agent. Monotherapy with a proton pump inhibitor is not only more efficacious in patients not responding to an H₂-receptor antagonist or prokinetic agent alone, but it also improves compliance with once-daily dosing and is ultimately more cost effective.

■ MAINTENANCE THERAPY

⚠ Although healing and/or symptomatic improvement may be achieved via many different therapeutic modalities, a large percentage of patients with gastroesophageal reflux will relapse following discontinuation of therapy, especially those with more severe disease.⁶⁴ Follow-up studies indicate that 70% to 90% of patients will relapse within 1 year of discontinuation of therapy, regardless of what therapeutic regimen had been used to induce remission.⁶⁴ Patients who have symptomatic relapse following discontinuation of therapy or lowering of dose, including patients with complications such as BE, strictures, or hemorrhage, should be considered for long-term maintenance therapy to prevent complications or worsening of esophageal function.⁹ The goal of maintenance therapy is to

improve quality of life by controlling the patient's symptoms and preventing complications.⁶ These goals cannot generally be achieved by decreasing the dose of the therapeutic modality used for initial healing or switching to a less potent acid-suppressing agent. Most patients will require standard doses to prevent relapses.⁶⁵ Patients should be counseled on the importance of complying with lifestyle changes and long-term maintenance therapy in order to prevent recurrence or worsening of disease.⁶

H₂-receptor antagonists may be effective maintenance therapy for patients with mild disease.² Although cisapride was an effective maintenance therapy, it is no longer an option unless it is obtained through the limited access program from the manufacturer. The proton pump inhibitors are the drugs of choice for maintenance treatment of moderate to severe esophagitis.⁶⁶ Lower doses of a proton pump inhibitor or alternate-day dosing may be effective in some patients with less-severe disease, thereby allowing titration in some cases.² Preliminary data with esomeprazole suggest that "on demand" maintenance therapy for patients with endoscopy-negative GERD may be effective.^{67,68} However, patients with more severe disease and/or complications should be maintained on omeprazole 20 mg daily, lansoprazole 30 mg daily, rabeprazole 20 mg daily, or esomeprazole 20 mg daily. Long-term chronic use of higher doses of proton pump inhibitors is not indicated unless the patient has complicated symptoms, has high-grade erosive esophagitis per endoscopy, or has had further diagnostic evaluation to determine the level of acid exposure. Many institutions allow the use of normal-dose proton pump inhibitors by all physicians, but limit the use of high-dose proton pump inhibitors to gastroenterologists. Antireflux surgery and other endoluminal procedures may also be considered a viable alternative to long-term drug therapy for maintenance of healing in patients who are candidates.

■ Maintenance Therapy with Proton Pump Inhibitors

In a comparison of maintenance regimens, omeprazole (20 mg daily) alone or in combination with cisapride (10 mg three times daily) was significantly more effective in preventing recurrence of erosive GERD than was ranitidine (150 mg three times daily) alone or cisapride (10 mg three times daily) alone.⁶⁶ Omeprazole was also effective in patients with complicated forms (grades 3 and 4) of esophagitis.

Omeprazole and lansoprazole in doses of 20 mg and 30 mg daily, respectively, decreased relapse rates significantly.^{65,66} At 1 year, relapse rates were 15% and 10%, respectively. Both omeprazole and lansoprazole were superior to H₂-receptor antagonists in maintaining Lansoprazole 15 mg daily was compared to lansoprazole 30 mg daily or ranitidine 300 mg twice daily in preventing recurrence of reflux esophagitis.⁶⁹ At 12 months, relapse rates were 31%, 20%, and 68% for lansoprazole 15 mg, 30 mg, and ranitidine 300 mg, respectively. Lansoprazole 15 mg and 30 mg daily were comparable in maintaining

treatment phase for grade 1 or 2 esophagitis, patients were randomized to receive maintenance therapy with omeprazole 10 mg daily or ranitidine 150 mg twice daily. At 1 year, 68% of patients on omeprazole were in remission, as compared with 39% of patients receiving ranitidine. Even at a lower dose, omeprazole was superior to ranitidine for maintenance therapy.

Preliminary placebo-controlled studies with esomeprazole indicate that maintenance of erosive esophagitis healing occurs in 54% to 94% of patients after 6 months of 10-mg to 40-mg doses of esomeprazole.^{70,71} Doses of 20 mg to 40 mg were superior to the 10-mg dose. Studies are needed comparing esomeprazole to the other proton pump inhibitors in maintenance therapy for GERD.

Omeprazole 20 mg (given on the weekend) was compared to omeprazole 20 mg daily and ranitidine 150 mg twice daily. The relapse rate at 12 months was 68%, 11%, and 75%, respectively, indicating that weekend regimens are ineffective in preventing recurrence.⁷² Long-term studies are needed with pantoprazole, but it should be effective as maintenance therapy for GERD.

Long-term use of the proton pump inhibitors indicates that they are safe, with no evidence of carcinoid tumors directly linked to their use. Prolonged hypergastrinemia leading to the development of colonic polyps, and potentially adenocarcinoma, was also a concern that has proven unfounded with long-term use of proton pump inhibitors.⁷³ However, the role of *Helicobacter pylori* status in patients with GERD is a concern. One study showed that patients treated with proton pump inhibitors had a higher incidence of atrophic gastritis that was linked to the development of gastric cancer.¹ In this study, 30% of patients treated with omeprazole over an average of 5 years developed atrophy, whereas none of a cohort group that received antireflux surgery developed atrophy within the same time frame.⁷⁴ Most of the patients who developed atrophic gastritis had concomitant *H. pylori* infection. On the other hand, the presence of *H. pylori* infection may actually have a protective effect against GERD, and clearing the infection may be associated with a worsening of GERD symptoms.⁷⁵ The FDA recently stated that there was insufficient evidence linking proton pump inhibitor use to atrophic gastritis, intestinal metaplasia, or gastric cancer.⁷⁶ As a consequence of the controversy surrounding *H. pylori* and GERD, specific guidelines on how to handle these patients are lacking. Most clinicians would probably opt to eradicate *H. pylori* infections once detected. Further studies are needed to determine the role of *H. pylori* in patients with GERD.

■ Maintenance Therapy with H₂-Receptor Antagonists

The studies evaluating the efficacy of the H₂-receptor antagonists in maintaining GERD patients in remission have been disappointing. Currently, ranitidine 150 mg twice daily is the only H₂-receptor antagonist regimen that is FDA approved for maintenance of healing of erosive esophagitis.

SPECIAL POPULATIONS CONSIDERATIONS

ATYPICAL GERD SYMPTOMS

Patients presenting with atypical symptoms may require higher doses and longer treatment courses as compared with patients with typical symptoms. These patients are best diagnosed with ambulatory pH testing or an empiric trial with a proton pump inhibitor.⁷⁷ In patients presenting with noncardiac chest pain, a short course (1 to 8 weeks) of

omeprazole 20 mg twice daily has been advocated.⁷⁷ In patients with asthma, antireflux medications have been shown to improve asthma symptoms and even to decrease antiasthma medication use, but were found to have little or no effect on lung function.⁷⁸ A trial of 3 months has been advocated using twice-daily proton pump inhibitor therapy for both asthma and laryngeal symptoms thought to be associated with GERD. Omeprazole doses as high as 60 mg daily have been used.⁷⁷ In patients with chronic cough, pH testing is the preferred approach for evaluation of GERD, when available.⁷⁹ Maintenance therapy is

generally indicated in patients who respond to the therapeutic trial or have endoscopic evidence of reflux.

Interventional management may be indicated in selected patients not responding to medical management.

ENDOSCOPY-NEGATIVE REFLUX DISEASE

While the integrity of the esophageal mucosa is best evaluated with endoscopy, it does not confirm whether or not the patient's symptoms are related to GERD.²⁷ In some cases, patients with typical symptoms and increased acid exposure have no evidence of esophageal damage. Many patients with persistent severe symptoms but normal endoscopy will require therapy similar to those with positive endoscopic findings. This condition is referred to as endoscopy-negative reflux disease.⁸⁰ Patients presenting with normal esophageal mucosa on endoscopy may undergo pH testing or a therapeutic trial with a proton pump inhibitor to further confirm the diagnosis of GERD. Remember, however, that even when ambulatory pH monitoring or a therapeutic trial is used, it does not absolutely rule GERD in or out. In more serious cases, both may be necessary to confirm the diagnosis.²⁷

Patients with normal endoscopy treated with omeprazole had improvement in symptoms, quality-of-life scores, and antacid use.⁸¹ Treatment with a proton pump inhibitor is more effective than treatment with an H₂-receptor antagonist in these patients, as demonstrated by several clinical trials.^{82,83}

PEDIATRIC PATIENTS WITH GERD

Gastroesophageal reflux occurs in approximately 18% of the infant population. Most have physiologic reflux with no clinical consequence.⁸⁴ Complications, although rare, include distal esophagitis, failure to thrive, esophageal peptic strictures, BE, and pulmonary disease.⁸⁵ Chronic vomiting associated with gastroesophageal reflux must be distinguished from other causes such as neurologic, metabolic, eating, and rumination disorders. Developmental immaturity of the LES is one suspected cause of gastroesophageal reflux in infants.⁸⁵ Like adults, transient LES relaxations seem to be the most common cause of gastroesophageal reflux in children. Other causes include impaired luminal clearance of gastric acid, neurologic impairment, and type of infant formula. Uncomplicated gastroesophageal reflux usually resolves without incident by 12 to 18 months of life, and usually responds to supportive therapy, including dietary adjustments, postural management, and reassurance for the parents.⁸⁵ Thickened feedings may be useful in milder cases. Smaller, more frequent feedings may also be beneficial. If there is no improvement, medical therapy may be indicated. Combined use of a prokinetic agent and an acid-suppressing agent seems to work the fastest.⁸⁵ Unfortunately, there is no longer a readily available prokinetic agent without major problems. H₂-receptor antagonists are commonly used. A dose of ranitidine 2 mg/kg twice daily is effective.⁸⁵

The use of proton pump inhibitors is becoming more common in pediatrics. Lansoprazole recently received FDA approval for treating symptomatic and erosive GERD in pediatric patients <1 year old. A dose of 15 mg once daily is recommended for children weighing ≤30 kg, and a dose of 30 mg once daily is recommended for those weighing >30 kg. While not FDA approved for use in children, there is evidence supporting the effectiveness of omeprazole in treating children with GERD. A common dose for treating esophagitis is 1 mg/kg per day (divided once or twice daily).⁸⁶ While no major adverse events have been noted in children receiving proton pump inhibitors for up to 7 years, the relative safety of prolonged proton pump inhibitor use in children remains unknown.⁸⁶ There are no

data involving the other proton pump inhibitors in the treatment of GERD.

ELDERLY PATIENTS WITH GERD

Many elderly patients have decreased host defense mechanisms such as saliva production. More aggressive therapy with a proton pump inhibitor may be warranted in patients with symptomatic GERD in patients older than 60 years of age.⁸⁷ Often these patients do not seek medical attention because they feel their symptoms are part of the normal aging process. They may present with atypical symptoms such as chest pain, asthma, hoarseness, coughing, wheezing, poor dentition, or jaw pain. Decreased GI motility is a common problem in elderly patients. Unfortunately, there are no good prokinetic agents available to these patients.

Cisapride is not available for general use and elderly patients are especially sensitive to the central nervous system effects of metoclopramide. They may also be sensitive to the central nervous system effects of H₂-receptor antagonists. Proton pump inhibitors appear to be the most useful treatment modality because they have superior efficacy and are dosed once daily, which is beneficial in all patients, but is especially beneficial in the elderly.

PHARMACOECONOMIC CONSIDERATIONS

In addition to the traditional clinical end points that demonstrate that a certain therapy is effective, we must also evaluate the cost-effectiveness of the therapy in relation to predicted outcomes and its effects on quality of life.² For GERD, one must consider the primary goals of treatment: to relieve symptoms, to heal injury, to prevent recurrence, and to prevent complications. These factors must be evaluated separately, because different costs are associated with achieving each end point. For example, patients with complications associated with GERD, such as strictures, would be more likely to use medical resources as a consequence of revisits and diagnostic tests.² Although effects on quality of life may be difficult to evaluate when your goal is preventing recurrence,² untreated GERD has a more negative impact on psychological well-being than untreated hypertension, mild heart failure, angina pectoris, or menopause.⁴ Improving a patient's quality of life is a measure of treatment success and may help decide which therapy a patient receives.²

The proton pump inhibitors are generally more expensive than the H₂-receptor antagonists or prokinetic agents. This is likely to be less of an issue now that omeprazole has become generically available and is also available over the counter. However, the most expensive therapy is the one that is ineffective.² This means that if the H₂-receptor antagonist does not accomplish the treatment goals, then it costs more because the patient must be retreated.

Patient compliance is another factor that will affect the outcome of drug therapy. Drug regimens that are easily managed will improve compliance, and therefore outcome for the patient. This can especially be a problem in patients who require high-dose therapy with H₂-receptor antagonists. Not only is the patient required to take the drug more often in higher doses, but there is also increased expense associated with such regimens. The patient may be unable to afford the drug. Choosing a drug that is least expensive and provides the greatest benefit related to dosing interval and number of tablets taken is the optimal regimen. Studies comparing various treatment strategies for GERD show that proton pump inhibitors are more cost effective than H₂-receptor antagonists, especially in patients with moderate to severe disease.⁸⁸⁻⁹⁰

Decision analysis has been used to evaluate the cost effectiveness of phase I therapy or phase I therapy combined with omeprazole 20 mg daily or ranitidine 150 mg twice daily for patients with persistent symptomatic GERD who failed phase I therapy. A complex model that evaluated the influence of empiric versus definitive therapy, compliance, and efficacy of the three treatment regimens was employed. Although the retail cost of omeprazole was highest among the treatments evaluated, it was the most cost-effective strategy and was associated with the lowest overall cost. Studies also show that proton pump inhibitors improve quality-of-life measures in symptomatic patients with erosive esophagitis.⁹¹ Additional studies are needed to evaluate the impact of various treatment regimens on quality-of-life issues, cost, and to compare long-term medical management with antireflux surgery and endoluminal approaches. At least one study showed that proton pump inhibitors were equally effective to antireflux surgery and slightly more cost effective at 5 years. However, the costs were similar after 10 years.⁹²

EVALUATION OF THERAPEUTIC OUTCOMES

9 The long-term benefits of treatment are difficult to assess because of the limited information known about the epidemiology and natural history of GERD. Therefore successful outcomes are generally measured in terms of three separate end points: (a) relieving symptoms, (b) healing the injured mucosa, and (c) preventing complications.

The short-term goal of therapy is to relieve symptoms such as heartburn and regurgitation to the point at which they do not impair the patient's quality of life. Patients should be educated regarding lifestyle modifications that should be adhered to throughout the course of therapy including smoking cessation, weight loss, raising the head of the bed, eating smaller meals, and avoiding eating prior to bedtime. Patients should also be instructed to avoid foods that aggravate GERD symptoms, such as fat and chocolate. In addition, the patient's drug profile should be reviewed to identify medications that may contribute to GERD symptoms. These agents should be avoided if possible. Table 32-6 has recommendations for providing pharmaceutical care to patients with GERD.

The clinician should take an active role in educating the patient about potential adverse effects and drug interactions that may occur with drug therapy. The frequency and severity of symptoms should be monitored and patients should be counseled on symptoms that suggest the presence of complications requiring immediate medical attention, such as dysphagia or odynophagia. Patients with persistent symptoms should be evaluated for the presence of strictures or other complications. Patients should also be monitored for the presence of atypical symptoms such as cough, nonallergic asthma, or chest pain. These symptoms require further diagnostic evaluation. Long-term maintenance treatment is indicated in patients who have strictures because they commonly recur if esophagitis is not treated.⁹³

The second goal is to heal the injured mucosa. Again, lifestyle modifications and the importance of complying with the therapeutic regimen chosen to heal the mucosa should be stressed. Patients should be educated about the risk of relapse and the need for long-term maintenance therapy to prevent recurrence or complications.

The final, more long-term goal of therapy is to decrease the risk of complications (esophagitis, strictures, and BE). A small subset of patients may continue to fail treatment despite therapy with high doses of H₂-receptor antagonists or omeprazole. Maintenance therapy with standard to higher doses of antisecretory agents may be indicated in these acid hypersecreters, because severe esophagitis that is not

TABLE 32-6. Recommendations for Providing Pharmaceutical Care to Patients with GERD

1. Assess the patient's symptoms to determine if patient-directed therapy is appropriate or whether they should be evaluated by a physician. Determine the type of symptoms, frequency, and exacerbating factors. Refer any patient with complicated or atypical symptoms to a physician for further diagnostic work-up.
2. Obtain a thorough history of prescription, nonprescription, and natural drug product use.
3. Counsel the patient on lifestyle modifications that will improve symptoms. These include avoiding foods and medications that worsen GERD, avoiding tight-fitting clothes, eating smaller meals, raising the head of the bed, losing weight, and avoiding tobacco use.
4. Recommend appropriate drug therapy based on patient presentation. Proton pump inhibitors are the drugs of choice for patients with moderate to severe symptoms.
5. Develop a plan to assess effectiveness of acid-suppressing therapy after an appropriate amount of time (8–16 weeks). Recommend alternative therapy if necessary.
6. Assess improvement in quality-of-life measures such as physical, psychological, and social functioning and well-being.
7. Evaluate the patient for the presence of adverse drug reactions, drug allergies, and drug interactions.
8. Stress the importance of compliance with the therapeutic regimen, including lifestyle modifications. Recommend a therapeutic regimen that is easy for the patient to accomplish.
9. Provide patient education with regard to disease state, lifestyle modifications, and drug therapy. Patients should be counseled on:
 - What causes GERD and what things to avoid (see #3)
 - When to take their medications
 - What potential adverse effects may occur
 - Which drugs may interact with their therapy
 - What warning signs they should report to their physician (dysphagia, odynophagia, unexplained weight loss, or bleeding)

adequately treated may lead to BE and its associated risk of adenocarcinoma. Unfortunately, data are lacking that show that effective treatment of esophagitis decreases the risk of developing adenocarcinoma in patients with BE. Patients should be monitored for the presence of continual pain, dysphagia, or odynophagia.

CONCLUSIONS

Gastroesophageal reflux disease is a common entity that classically presents as heartburn. The pathophysiology of reflux is complex, involving both aggressive factors (acid, pepsin, bile acids, pancreatic enzymes, and prostaglandins) and defense mechanisms (anatomic factors, LES pressure, esophageal clearance, and gastric emptying). Therapeutic modalities are designed to minimize the aggressive factors and/or augment defense mechanisms. The pharmacologic critical elements outlined should be considered when evaluating and treating a patient with GERD.

PEPTIC ULCER DISEASE

Rosemary R. Berardi and Lynda S. Welage

Learning Objectives and other resources can be found at www.pharmacotherapyonline.com.

KEY CONCEPTS

- 1 Patients with peptic ulcer disease should reduce psychological stress, cigarette smoking, and nonsteroidal anti-inflammatory drug (NSAID) use, and should avoid foods and beverages that exacerbate ulcer symptoms.
- 2 Eradication is recommended for all *Helicobacter pylori* (HP)-positive patients with an active ulcer, a documented history of a prior ulcer, or a history of ulcer-related complications.
- 3 Treatment with a conventional antiulcer drug (H₂-receptor antagonist, proton pump inhibitor, or sucralfate) may be an alternative to HP eradication, but is discouraged because of the high rate of ulcer recurrence and ulcer-related complications. Combining conventional antiulcer drugs adds to treatment costs without enhancing efficacy.
- 4 Maintenance therapy with a low-dose H₂-receptor antagonist or proton pump inhibitor is only indicated for high-risk patients who fail HP eradication, patients with severe complications, or those with HP-negative ulcers.
- 5 The selection of an HP eradication regimen should be based on efficacy, safety, antibiotic resistance, cost, and the likelihood of compliance. Treatment should be initiated with a proton pump inhibitor-based three-drug regimen. If a second course of HP therapy is required, the regimen should contain different antibiotics.
- 6 Standard proton pump inhibitor dosages reduce the risk of NSAID-related gastric and duodenal ulcers and are at least as effective as misoprostol cotherapy. Standard-dose H₂-receptor antagonists reduce the risk of NSAID-related duodenal ulcer, but higher dosages are needed to reduce the risk of gastric ulcer.
- 7 Standard dosages of a proton pump inhibitor and a non-selective NSAID appear to be as effective as a selective cyclooxygenase-2 (COX-2) inhibitor in reducing the risk of NSAID-induced ulcers and upper GI complications.
- 8 The eradication of HP improves clinical outcomes and decreases the use of health care resources when compared to conventional antisecretory therapy. Misoprostol cotherapy, proton pump inhibitor cotherapy, or switching to a selective COX-2 inhibitor is cost effective in patients with the highest risk for NSAID-related ulcers and upper GI complications.
- 9 Patients with peptic ulcer disease, especially those receiving HP eradication or misoprostol cotherapy, require patient education regarding their disease and drug treatment to successfully achieve a positive therapeutic outcome.
- 10 Patients with peptic ulcer disease who develop recurrent ulcer signs or symptoms of GI bleeding or perforation should be referred to a specialist. Assess reasons for therapeutic failure, including noncompliance to the drug regimen, antibiotic resistance (HP eradication), heavy smoking, NSAID use, and the need for HP eradication in a patient on conventional antiulcer medications.

Acid-related diseases (gastritis, erosions, and peptic ulcer) of the upper gastrointestinal (GI) tract require gastric acid for their formation.¹⁻⁴ Peptic ulcer disease (PUD) differs from gastritis and erosions in that ulcers typically extend deeper into the muscularis mucosa.¹ There are three common forms of peptic ulcers: *Helicobacter pylori* (HP)-associated, nonsteroidal anti-inflammatory drug (NSAID)-induced, and stress ulcers (Table 33-1). The term “stress-related mucosal damage” (SRMD) is preferred to stress ulcer or stress gastritis, because the mucosal lesions range from superficial gastritis and erosions to deep ulcers.

Chronic peptic ulcers vary in etiology, clinical presentation, and tendency to recur (see Table 33-1). HP-associated and NSAID-induced ulcers develop most often in the stomach and duodenum of ambulatory patients (Fig. 33-1). Occasionally, ulcers develop in the esophagus, jejunum, ileum, or colon. Peptic ulcers are

also associated with Zollinger-Ellison syndrome (ZES), radiation, chemotherapy, and vascular insufficiency (Table 33-2).^{1,4} In contrast, acute ulcers (SRMD) occur primarily in the stomach in critically ill hospitalized patients (see Table 33-1). This chapter focuses on chronic PUD associated with HP and NSAIDs. A brief discussion of ZES and upper GI bleeding related to PUD and SRMD is included.

The natural course of chronic PUD is characterized by frequent ulcer recurrence. Approximately 60% to 100% of ulcers recur within 1 year of initial ulcer healing with conventional antiulcer regimens.¹ The most important factors that influence ulcer recurrence are HP infection and NSAID use. Other factors include gastric acid hypersecretion, cigarette smoking, alcohol use, a long duration of PUD, ulcer-related complications, and patient noncompliance. The cause of ulcer recurrence is most likely multifactorial.

TABLE 33–1. Comparison of Common Forms of Peptic Ulcer

| Characteristic | <i>H. pylori</i> -induced | NSAID-induced | SRMD |
|-----------------|----------------------------|----------------------------|--|
| Condition | Chronic | Chronic | Acute |
| Site of damage | Duodenum > stomach | Stomach > duodenum | Stomach > duodenum |
| Intragastric pH | More dependent | Less dependent | Less dependent |
| Symptoms | Usually epigastric pain | Often asymptomatic | Asymptomatic |
| Ulcer depth | Superficial | Deep | Most superficial |
| GI bleeding | Less severe, single vessel | More severe, single vessel | More severe, superficial mucosal capillaries |

H. pylori, *Helicobacter pylori*; NSAID, nonsteroidal anti-inflammatory drug; SRMD, stress-related mucosal damage.

EPIDEMIOLOGY

Approximately 10% of Americans develop chronic PUD during their lifetime.¹ The incidence varies with ulcer type, age, gender, and geographic location. Race, occupation, genetic predisposition, and societal factors may play a minor role in ulcer pathogenesis, but are attenuated by the importance of HP infection and NSAID use. The prevalence of PUD in the United States has shifted from predominance in men to nearly comparable prevalence in men and women. Recent trends suggest a declining rate for younger men and an increasing rate for older women.¹ Factors that have influenced these trends include the declining smoking rates in younger men and the increased use of NSAIDs in older adults.

Since 1960, ulcer-related physician visits, hospitalizations, operations, and deaths have declined in the United States by more than 50%, primarily because of decreased rates of PUD among men.¹ The decline in hospitalizations has resulted from a reduction in hospital admissions for uncomplicated duodenal ulcer. However, hospitalizations of older adults for ulcer-related complications (bleeding and perforation) have increased.¹ Although the overall mortality from PUD has decreased, death rates have increased in patients older than 75 years of age, most likely a result of increased consumption of NSAIDs and an aging population. Patients with gastric ulcer have a higher mortality rate than those with duodenal ulcer because gastric ulcer is more prevalent in older individuals. Despite these trends, PUD remains one of the most common GI diseases, resulting in impaired quality of life, work loss, and high-cost medical care. To date, H₂-receptor antagonists (H₂RAs), proton pump inhibitors (PPIs), and drugs that promote mucosal defense have not altered PUD complication rates.¹

FIGURE 33–1. Anatomic structure of the stomach and duodenum and most common locations of gastric and duodenal ulcers.

ETIOLOGY AND RISK FACTORS

Most peptic ulcers occur in the presence of acid and pepsin when HP, NSAIDs, or other factors (see Table 33–2) disrupt normal mucosal defense and healing mechanisms.¹ Hypersecretion of acid is the primary pathogenic mechanism in hypersecretory states such as ZES.⁴ Ulcer location is related to a number of etiologic factors. Benign gastric ulcers can occur anywhere in the stomach, although most are located on the lesser curvature, just distal to the junction of the antral and acid-secreting mucosa (see Fig. 33–1). Most duodenal ulcers occur in the first part of the duodenum (duodenal bulb).

HELICOBACTER PYLORI

Helicobacter pylori infection causes chronic gastritis in all infected individuals and is causally linked to PUD, gastric cancer, and mucosa-associated lymphoid tissue (MALT) lymphoma (Fig. 33–2).^{1,5–7} However, only a small number of infected individuals will develop symptomatic PUD (about 20%) or gastric cancer (less than 1%).^{1,6} The pattern and distribution of gastritis correlates strongly with the risk of a specific gastrointestinal disorder. The development of atrophic gastritis and gastric cancer is a slow process that occurs over 20 to 40 years. Serologic studies confirm an association between HP and gastric cancer.^{1,6} Supportive evidence for PUD is based on the fact that most non-NSAID ulcers are infected with HP, and that HP eradication markedly decreases ulcer recurrence.^{5,6} Host-specific cofactors and HP strain variability play an important role in the pathogenesis of PUD and gastric cancer.^{5–7} Although an association between HP and PUD bleeding is less clear, eradication of HP decreases recurrent bleeding.⁸ No specific link has been established between HP and dyspepsia, nonulcer dyspepsia (NUD), or gastroesophageal reflux disease.^{9–11}

TABLE 33–2. Potential Causes of Peptic Ulcer

| |
|---|
| Common causes |
| <i>Helicobacter pylori</i> infection |
| Nonsteroidal anti-inflammatory drugs |
| Critical illness (stress-related mucosal damage) |
| Uncommon causes |
| Hypersecretion of gastric acid (e.g., Zollinger-Ellison syndrome) |
| Viral infections (e.g., cytomegalovirus) |
| Vascular insufficiency (crack cocaine-associated) |
| Radiation |
| Chemotherapy (e.g., hepatic artery infusions) |
| Rare genetic subtypes |
| Idiopathic |

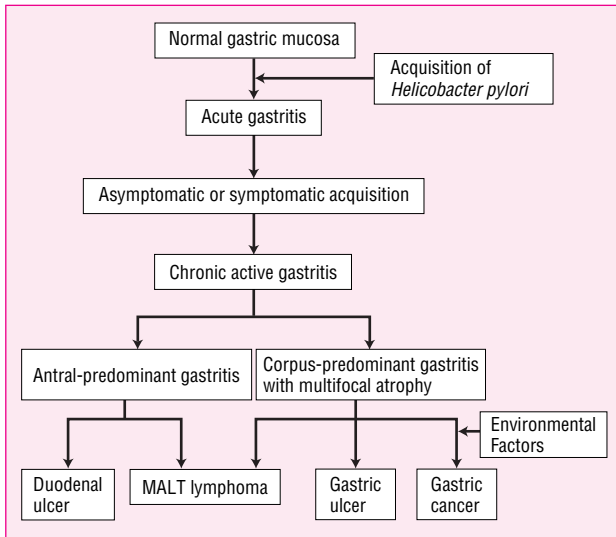

FIGURE 33–2. The natural history of *Helicobacter pylori* infection in the pathogenesis of gastric ulcer and duodenal ulcer, mucosa-associated lymphoid tissue (MALT) lymphoma, and gastric cancer.

Approximately 50% of the world's population is colonized by HP.⁶ The prevalence of HP varies by geographic location, socioeconomic conditions, ethnicity, and age. In developing countries, HP prevalence exceeds 80% in adults and correlates with lower socioeconomic conditions.⁵ In industrialized countries, the prevalence of HP in adults is between 20% and 50%.⁵ The prevalence of HP in the United States is 30% to 40%, but remains higher in ethnic groups such as African and Latin Americans.⁶ There is a decreasing frequency of infection, especially in regions with improving sanitation and socioeconomic conditions.⁶ In developed countries, there is an increased HP prevalence with age.^{1,6} However, this reflects a more intense transmission when older generations were children, as younger generations have been less likely to acquire the infection. Infection rates do not differ with gender or smoking status.

HP is transmitted person-to-person by three different pathways; fecal-oral, oral-oral, and iatrogenic.^{1,6} Transmission of the organism is thought to occur by the fecal-oral route, either directly from an infected person, or indirectly from fecal-contaminated water or food.¹ Members of the same household are likely to become infected when someone in the same household is infected.¹ Risk factors include crowded living conditions, a large number of children, unclean water, and consumption of raw vegetables.⁶ Transmission by the oral-oral route has been postulated because HP has been isolated from the oral cavity.⁶ Transmission of HP can occur iatrogenically when infected instruments such as endoscopes are used.¹

NONSTEROIDAL ANTI-INFLAMMATORY DRUGS

NSAIDs are one of the most widely prescribed classes of medications in the United States, particularly in individuals 60 years of age and older.¹ There is overwhelming evidence linking chronic nonselective NSAID (including aspirin) use to a variety of GI tract injuries (Table 33–3).^{1,12–14} Subepithelial gastric hemorrhages occur within 15 to 30 minutes of ingestion, and progress to gastric erosions with continued ingestion.^{1,12} These lesions heal within a few days with continued NSAID use and do not lead to GI complications. Gastroduodenal ulcers occur in 15% to 30% of regular NSAID users and may develop

TABLE 33–3. Selected Nonsteroidal Anti-Inflammatory Drugs (NSAIDs) and Cyclooxygenase-2 (COX-2) Inhibitors

| | |
|--|--|
| Nonsteroidal Anti-Inflammatory Drugs (NSAIDs) | |
| Nonsalicylates | |
| Nonselective (traditional) NSAIDs: indomethacin, piroxicam, ibuprofen, naproxen, sulindac, ketoprofen, ketorolac, flurbiprofen, diclofenac | |

| Salicylates | |
| Acetylated: aspirin | |
| Nonacetylated: salsalate, trisalicilate | |

within a week or with continued treatment (6 months or longer).¹² Gastric ulcers are most common, occur primarily in the antrum (see Fig. 33–1), and are of greater concern than erosions because of their potential to bleed or perforate (see Table 33–1). NSAID-induced ulcers may occur in the esophagus and colon, but are less common.^{1,15} Each year, nonselective NSAIDs account for at least 16,500 deaths and 107,000 hospitalizations in the United States.^{1,14} Clinically important upper GI events occur in 3% to 4.5% of arthritis patients taking NSAIDs, and 1.5% have a serious complication (major GI bleeding, perforation, or obstruction).¹²

The risk factors for NSAID-induced ulcers and GI-related complications are presented in Table 33–4. Combinations of factors confer an additive risk. The risk of NSAID complications is increased as much as 14-fold in patients with a previous history of an ulcer or ulcer-related bleeding.¹ Advanced age is an independent risk factor and increases linearly with the age of the patient.¹ The high incidence of ulcer complications in older individuals may be explained by age-related changes in gastric mucosal defense. The risk for NSAID-induced ulcers and complications is dose related, although both can occur with low dosages of nonprescription NSAIDs and the low dosages of aspirin taken for cardioprotective purposes (81 to 325 mg/day).^{1,12–14,16,17} The use of corticosteroids alone does not increase the risk of ulcer or complications, but ulcer risk is

| Alcohol consumption | |

^aCombinations of risk factors are additive.

Compiled from Del Valle et al,¹ Suerbaum and Michetti,⁵ Laine,¹² and Gleeson and Davis.¹⁵

increased twofold in corticosteroid users who are also taking concurrent NSAIDs.¹ The use of low-dose aspirin in combination with another NSAID increases the risk of upper GI complications to a greater extent than the use of either drug alone.^{1,17} The risk of bleeding is markedly increased when NSAIDs are used in combination with anticoagulants.¹ NSAID-related dyspepsia that is not relieved by antiulcer medications may indicate an ulcer or ulcer complication, but dyspepsia does not correlate directly with mucosal injury or clinical events. Whether HP infection is a risk factor for NSAID-induced ulcers remains controversial.^{18–20} Most evidence indicates that both HP and NSAIDs are independent risk factors and that HP does not potentiate the risk of ulcer formation in NSAID users.¹⁸ However, recent data suggest that HP may potentiate the effects of NSAIDs and low-dose aspirin with regard to ulcer bleeding.^{19,20} Cigarette smoking and alcohol ingestion contribute to increased ulcer risk but do not appear to be independent factors.¹

There is little evidence to support clinically important differences with regard to the frequency of ulcers and upper GI complications among most available nonaspirin, nonselective NSAIDs (see Table 33–3) when used in equipotent anti-inflammatory dosages.¹ However, the nonacetylated salicylates (e.g., salsalate) and newer NSAIDs (e.g., etodolac, nabumetone, and meloxicam) may be associated with a decreased incidence of GI toxicity.^{1,21,22} NSAIDs that selectively inhibit cyclooxygenase-2 (COX-2) decrease the incidence of gastroduodenal ulcers and related GI complications when compared to the nonselective NSAIDs.^{21,22} The use of buffered or enteric-coated aspirin confers no added protection from ulcer or GI complications.²³

CIGARETTE SMOKING

There is epidemiologic evidence that links cigarette smoking to PUD, impaired ulcer healing, and ulcer-related GI complications.¹ The risk is proportional to the number of cigarettes smoked and is modest when fewer than 10 cigarettes are smoked per day. Smoking does not increase ulcer recurrence after HP eradication. Death rates are higher among patients who smoke than among nonsmoking patients, although it is not known whether the increase in mortality reflects PUD or the cardiac and pulmonary sequelae of smoking. The exact mechanism by which cigarette smoking contributes to PUD remains unclear. Possible mechanisms include delayed gastric emptying of solids and liquids, inhibition of pancreatic bicarbonate secretion, promotion of duodenogastric reflux, and reduction in mucosal prostaglandin (PG) production. Although smoking increases gastric acid secretion, this effect is not consistent. It is uncertain whether nicotine or other components of smoke are responsible for these physiologic alterations. Cigarette smoking may provide a favorable milieu for HP infection.

PSYCHOLOGICAL STRESS

The importance of psychological factors in the pathogenesis of PUD remains controversial.¹ Clinical observation suggests that ulcer patients are adversely affected by stressful life events. However, results from controlled trials are conflicting and have failed to document a cause-and-effect relationship.¹ It is possible that emotional stress induces behavioral risks such as smoking and the use of NSAIDs, or alters the inflammatory response or resistance to HP infection. The role of stress and how it affects PUD is complex and probably multifactorial.

DIETARY FACTORS

The role of diet and nutrition in PUD is uncertain, but may explain regional variations.¹ Coffee, tea, cola beverages, beer, milk, and spices may cause dyspepsia, but do not increase the risk for PUD. Beverage restrictions and bland diets do not alter the frequency of ulcer recurrence. Although caffeine is a gastric acid stimulant, constituents in decaffeinated coffee or tea, caffeine-free carbonated beverages, beer, and wine are also responsible for increasing gastric acid secretion. In high concentrations, alcohol ingestion is associated with acute gastric mucosal damage and upper GI bleeding; however, there is insufficient evidence to confirm that alcohol causes ulcers.

DISEASES ASSOCIATED WITH PEPTIC ULCERS

There is epidemiologic evidence to suggest an increased prevalence of duodenal ulcers in patients with certain chronic diseases, but the pathophysiologic mechanisms of these associations are uncertain.¹ A strong association exists in patients with systemic mastocytosis, multiple endocrine neoplasia type 1, chronic pulmonary diseases, chronic renal failure, kidney stones, hepatic cirrhosis, and α_1 -antitrypsin deficiency. An association may exist in patients with cystic fibrosis, chronic pancreatitis, Crohn's disease, coronary artery disease, polycythemia vera, and hyperparathyroidism.

PATHOPHYSIOLOGY

Gastric and duodenal ulcers occur because of an imbalance between aggressive factors (gastric acid and pepsin) and mechanisms that maintain mucosal integrity (mucosal defense and repair).

GASTRIC ACID AND PEPSIN

The potential for producing mucosal damage is related to the secretion of gastric (hydrochloric) acid and pepsin. Hydrochloric acid is secreted by the parietal cells, which contain receptors for histamine, gastrin, and acetylcholine. Acid (as well as HP infection and NSAID use) is an independent factor that contributes to the disruption of mucosal integrity. Increased acid secretion has been observed in patients with duodenal ulcers and may be a consequence of HP infection.^{24,25} Patients with ZES (described later in the chapter) have gastric acid hypersecretion resulting from a gastrin-producing tumor.⁴ Patients with gastric ulcer usually have normal or reduced rates of acid secretion (hypochlorhydria).

Acid secretion is expressed as the amount of acid secreted under basal or fasting conditions, basal acid output (BAO); after maximal stimulation, maximal acid output (MAO); or in response to a meal.²⁴ Basal, maximal, and meal-stimulated acid secretion varies according to time of day and the individual's psychological state, age, gender, and health status. The BAO follows a circadian rhythm, with the highest acid secretion occurring at night and the lowest in the morning. An increase in the BAO:MAO ratio suggests a basal hypersecretory state such as ZES. A review of gastric acid secretion and its regulation can be found elsewhere.²⁴

Pepsinogen, the inactive precursor of pepsin, is secreted by the chief cells located in the gastric fundus (see Fig. 33–1). Pepsin is activated by acid pH (optimal pH of 1.8 to 3.5), inactivated reversibly at pH 4, and irreversibly destroyed at pH 7. Pepsin appears to play a role in the proteolytic activity involved in ulcer formation.²⁴

MUCOSAL DEFENSE AND REPAIR

Mucosal defense and repair mechanisms protect the gastroduodenal mucosa from noxious endogenous and exogenous substances.¹ Mucosal defense mechanisms include mucus and bicarbonate secretion, intrinsic epithelial cell defense, and mucosal blood flow.^{1,25} The viscous nature and near-neutral pH of the mucus-bicarbonate barrier protect the stomach from the acidic contents in the gastric lumen. Mucosal repair after injury is related to epithelial cell restitution, growth, and regeneration. The maintenance of mucosal integrity and repair is mediated by the production of endogenous prostaglandins. The term *cytoprotection* is often used to describe this process, but *mucosal defense* and *mucosal protection* are more accurate terms, as prostaglandins prevent deep mucosal injury and not superficial damage to individual cells. Gastric hyperemia and increased prostaglandin synthesis characterize adaptive cytoprotection, the short-term adaptation of mucosal cells to mild topical irritants. This phenomenon enables the stomach to initially withstand the damaging effects of irritants. Alterations in mucosal defense that are induced by HP or NSAIDs are the most important cofactors in the formation of peptic ulcers.

HELICOBACTER PYLORI

Helicobacter pylori is a spiral-shaped, pH-sensitive, gram-negative, microaerophilic bacterium that resides between the mucus layer and surface epithelial cells in the stomach, or any location where gastric-type epithelium is found.^{1,5,6} The combination of its spiral shape and flagellum permits it to move from the lumen of the stomach, where the pH is low, to the mucus layer, where the local pH is neutral. The acute infection is accompanied by transient hypochlorhydria, which permits the organism to survive in the acidic gastric juice.²⁵ The exact method by which HP initially induces hypochlorhydria is unclear. One theory is that HP produces large amounts of urease, which hydrolyzes urea in the gastric juice and converts it to ammonia and carbon dioxide.^{5,6} The local buffering effect of ammonia creates a neutral microenvironment within and surrounding the bacterium, which protects it from the lethal effect of acid.⁶ HP also produces acid-inhibitory proteins, which allows it to adapt to the low-pH environment of the stomach.²⁵ HP attaches to gastric-type epithelium by adherence pedestals, which prevent the organism from being shed during cell turnover and mucus secretion. Colonization of the corpus (body) of the stomach is associated with gastric ulcer (see Fig. 33–2). Antral organisms are hypothesized to colonize gastric metaplastic tissue (which is thought to arise secondary to changes in acid or bicarbonate secretion, products of HP, or host inflammatory responses) in the duodenal bulb, leading to duodenal ulcer.¹

A number of bacterial and host factors contribute to the ability of HP to cause gastroduodenal mucosal injury. Pathogenic mechanisms include: (a) direct mucosal damage, (b) alterations in the host immune/inflammatory response, and (c) hypergastrinemia leading to increased acid secretion.^{1,5} In addition, HP enhances the carcinogenic conversion of susceptible gastric epithelial cells.^{6,7}

Direct mucosal damage is produced by virulence factors (vacuolating cytotoxin, cytotoxin-associated gene protein, and growth-inhibitory factor), elaborating bacterial enzymes (lipases, proteases, and urease), and adherence.^{1,5} About 50% of HP strains produce a protein toxin (Vac A) that is responsible for cellular vacuole formation. Strains with cytotoxin-associated gene (cagA) protein are associated with duodenal ulcer, atrophic gastritis, and gastric cancer.^{1,5,7} Lipases and proteases degrade gastric mucus, ammonia produced by urease may be toxic to gastric epithelial cells, and bacterial adherence enhances the uptake of toxins into gastric epithelial cells. HP infection

alters the host inflammatory response and damages epithelial cells directly by cell-mediated immune mechanisms, or indirectly by activated neutrophils or macrophages attempting to phagocytose bacteria or bacterial products.^{1,5} HP infection may increase gastric acid secretion in patients with duodenal ulcer, or diminish acid output in patients with gastric cancer.¹ Antral-predominant infection is associated with hypergastrinemia and increased gastric acid secretion. Responsible mechanisms include cytokines, such as tumor necrosis factor- α released in HP gastritis; products of HP, such as ammonia; and diminished expression of somatostatin. Why somatostatin is diminished is unclear, but cytokines may be involved.¹ Corpus (body)-predominant infection promotes gastric atrophy and decreases acid output.^{1,6,7}

NONSTEROIDAL ANTI-INFLAMMATORY DRUGS

Nonselective NSAIDs including aspirin (see Table 33–3) cause gastric mucosal damage by two important mechanisms: (a) direct or topical irritation of the gastric epithelium and (b) systemic inhibition of endogenous mucosal prostaglandin synthesis.^{1,13,14} Although the initial injury is initiated topically by the acidic properties of many of the NSAIDs, systemic inhibition of the protective prostaglandins plays the predominant role in the development of gastric ulcer.^{1,13,14} Cyclooxygenase (COX) is the rate-limiting enzyme in the conversion of arachidonic acid to prostaglandins and is inhibited by NSAIDs (Fig. 33–3).

Two similar COX isoforms have been identified: cyclooxygenase-1 (COX-1) is found in most body tissue, including the stomach, kidney, intestine, and platelets; cyclooxygenase-2 (COX-2) is undetectable in most tissues under normal physiologic conditions, but its expression can be induced during acute inflammation and arthritis (Fig. 33–4).^{13,14} COX-1 produces protective prostaglandins that regulate physiologic processes such as GI mucosal integrity, platelet homeostasis, and renal function. COX-2 is induced (upregulated) by inflammatory stimuli such as cytokines, and produces prostaglandins involved with inflammation, fever, and pain. COX-2 is also constitutionally expressed in organs such as the brain, kidney, and reproductive tract. Adverse effects (e.g., GI toxicity or renal toxicity) of NSAIDs are associated with the inhibition of COX-1, whereas anti-inflammatory actions result from NSAID inhibition of COX-2.^{13,14} Nonselective NSAIDs including aspirin (see Table 33–3) inhibit both COX-1 and COX-2 to varying degrees.^{1,13,14} Aspirin irreversibly inhibits platelet COX-1 for as long as 18 hours, resulting in decreased platelet aggregation and prolonged

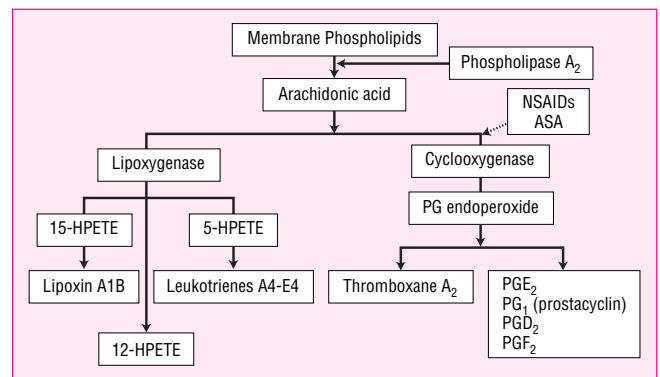

FIGURE 33–3. Metabolism of arachidonic acid after its release from membrane phospholipids. ASA, aspirin; HPETE, hydroperoxyeicosatetraenoic acid; NSAIDs, nonsteroidal antiinflammatory drugs; PG, prostaglandin. Broken arrow indicates inhibitory effects.

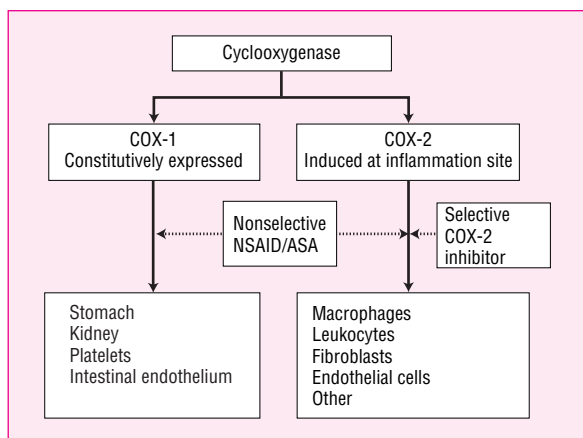

FIGURE 33–4. Tissue distribution and actions of cyclooxygenase (COX) isoenzymes. Nonselective nonsteroidal anti-inflammatory drugs (NSAIDs) including aspirin (ASA) inhibit COX-1 and COX-2 to varying degrees; COX-2 inhibitors inhibit only COX-2. Broken arrow indicates inhibitory effects.

bleeding times, which may potentiate upper and lower GI bleeding.¹ Similar effects are observed with the nonselective NSAIDs.

A number of other mechanisms may contribute to the development of NSAID-induced mucosal injury. Neutrophil adherence may damage the vascular endothelium and may lead to a reduction in mucosal blood flow, or may liberate oxygen-derived free radicals and proteases. Leukotrienes, products of lipoxygenase metabolism, are inflammatory substances that may contribute to mucosal injury through stimulatory effects on neutrophil adherence (see Fig. 33–3).

Topical irritant properties are predominantly associated with acidic NSAIDs (e.g., aspirin) and their ability to decrease the hydrophobicity of the mucous gel layer in the gastric mucosa.^{1,13,14} Most nonaspirin NSAIDs have topical irritant effects, but aspirin appears to be the most damaging. Although NSAID prodrugs, enteric-coated aspirin tablets, salicylate derivatives, and parenteral or rectal preparations are associated with less-acute topical gastric mucosal injury, they can cause ulcers and related GI complications as a result of their systemic inhibition of endogenous PGs.

COMPLICATIONS

Upper GI bleeding, perforation, and obstruction occur with HP-associated and NSAID-induced ulcers and constitute the most serious, life-threatening complications of chronic PUD.^{1,2,26} Bleeding is caused by the erosion of an ulcer into an artery and occurs in approximately 10% to 15% of patients.^{1,2} The bleeding may be occult (hidden) and insidious, or may present as melena (black-colored stools) or hematemesis (vomiting of blood). The use of NSAIDs (especially in older adults) is the most important risk factor for upper GI bleeding. Deaths occur primarily in patients who continue to bleed, or in those patients who rebleed after the initial bleeding has stopped (see section on upper GI bleeding).

Ulcer-related perforation into the peritoneal cavity occurs in about 7% of patients with PUD.¹ The incidence of perforation is increasing with the increased use of NSAIDs. Mortality is usually higher for perforated gastric ulcer than duodenal ulcer. The pain of perforation is usually sudden, sharp, and severe, beginning first in the epigastrium, but quickly spreading over the entire abdomen. Most patients experience ulcer symptoms prior to perforation. However, older patients who experience perforation in association with NSAID use may be asymptomatic. Penetration occurs when an ulcer burrows

into an adjacent structure (pancreas, biliary tract, or liver) rather than opening freely into a cavity.

Gastric outlet obstruction occurs in about 2% of patients with peptic ulcers.¹ Mechanical obstruction is caused by scarring or edema of the duodenal bulb or pyloric channel and can lead to gastric retention. Symptoms usually occur over several months and include early satiety, bloating, anorexia, nausea, vomiting, and weight loss. Perforation, penetration, and gastric outlet obstruction occur most often in patients with long-standing PUD.

Treatment of PUD has improved so dramatically that even the most virulent ulcers can be managed with medication. Intractability to drug therapy is now an infrequent manifestation of PUD and an infrequent indication for surgery.

CLINICAL PRESENTATION

SIGNS AND SYMPTOMS

The clinical presentation of PUD varies depending on the severity of abdominal pain and the presence of complications (Table 33–5).¹

TABLE 33–5. Presentation of Chronic Peptic Ulcer Disease

| | |
|------------------------|--|
| General | <ul style="list-style-type: none"> Mild epigastric pain or acute life-threatening upper gastrointestinal complications |
| Symptoms | <ul style="list-style-type: none"> Abdominal pain that is often epigastric and described as burning, but may present as vague discomfort, abdominal fullness, or cramping A typical nocturnal pain that awakens the patient from sleep (especially between 12 AM and 3 AM) The severity of ulcer pain varies from patient to patient, and may be seasonal, occurring more frequently in the spring or fall; episodes of discomfort usually occur in clusters lasting up to a few weeks followed by a pain-free period or remission lasting from weeks to years Changes in the character of the pain may suggest the presence of complications Heartburn, belching, and bloating often accompany the pain Nausea, vomiting, and anorexia, are more common in patients with gastric ulcer than with duodenal ulcer, but may also be signs of an ulcer-related complication |
| Signs | <ul style="list-style-type: none"> Weight loss associated with nausea, vomiting, and anorexia Complications, including ulcer bleeding, perforation, penetration, or obstruction |
| Laboratory tests | <ul style="list-style-type: none"> Gastric acid secretory studies Fasting serum gastrin concentrations are only recommended for patients unresponsive to therapy, or for those in whom hypersecretory diseases are suspected The hematocrit and hemoglobin are low with bleeding, and stool hemoccult tests are positive Tests for <i>Helicobacter pylori</i> (see Table 33–6) |
| Other diagnostic tests | <ul style="list-style-type: none"> Fiberoptic upper endoscopy (esophagogastroduodenoscopy) detects more than 90% of peptic ulcers and permits direct inspection, biopsy, visualization of superficial erosions, and sites of active bleeding Routine single-barium contrast techniques detect 30% of peptic ulcers; optimal double-contrast radiography detects 60% to 80% of ulcers |

Ulcer-related pain in duodenal ulcer often occurs 1 to 3 hours after meals and is usually relieved by food, but this is variable. In gastric ulcer, food may precipitate or accentuate ulcer pain. Antacids usually provide immediate pain relief in most ulcer patients. The abdominal pain usually diminishes or disappears during treatment; however, recurrence of pain after healing often suggests an unhealed or recurrent ulcer.

Abdominal pain does not always correlate with the presence or absence of acid or an ulcer. Asymptomatic patients may have an ulcer at endoscopy, and patients with endoscopically proven healed ulcers may have persistent symptoms. Many patients, particularly older adults, with an NSAID-induced ulcer-related complication may not have prior abdominal symptoms. The reasons for this are unclear, but may relate to the analgesic effect of the NSAID or differences in the way older individuals perceive pain.

Dyspepsia may or may not be associated with an ulcer, and in itself is of little clinical value when trying to identify subsets of patients who are most likely to have an ulcer. As many as 50% of patients who take NSAIDs report having dyspepsia.¹⁴ Patients with dyspeptic symptoms may have either uninvestigated (no upper endoscopy) dyspepsia or investigated (underwent upper endoscopy) dyspepsia. If an ulcer is not confirmed in a patient with ulcer-like symptoms at the time of endoscopy, the disorder is referred to as nonulcer dyspepsia.³

Ulcer-like symptoms may also occur in the absence of peptic ulceration in association with HP gastritis or duodenitis.

DIAGNOSIS

Routine laboratory tests are not helpful in establishing the diagnosis of uncomplicated PUD (see Table 33–5).¹

TESTS FOR *HELICOBACTER PYLORI*

The diagnosis of HP infection can be made using endoscopic or nonendoscopic tests (Table 33–6).^{1,5,27} The tests that require upper endoscopy are more expensive, uncomfortable, and require a mucosal biopsy for histology, culture, or detection of urease activity. Recommendations to maximize the diagnostic yield include taking at least three tissue samples from specific areas of the stomach, as patchy distribution of HP infection can lead to false-negative results. Because certain medications may decrease the sensitivity of these tests, antibiotics and bismuth salts should be withheld for 4 weeks and PPIs for 1 to 2 weeks prior to endoscopic testing.

The nonendoscopic tests (see Table 33–6) include serologic antibody detection tests, the urea breath test (UBT), and the stool antigen

TABLE 33–6. Tests for Detection of *Helicobacter pylori*

| Test | Description | Comments |
|---|---|---|
| Endoscopic tests | | |
| Histology | Microbiologic examination using various stains | Gold standard; >95% sensitive and specific; permits classification of gastritis; results are not immediate; not recommended for initial diagnosis; tests for active HP infection; antibiotics, bismuth, and PPIs may cause false-negative results |
| Culture | Culture of biopsy | Enables sensitivity testing to determine appropriate treatment or antibiotic resistance; 100% specific; results are not immediate; not recommended for initial diagnosis, but may be used after failure of second-line treatment; tests for active HP infection; antibiotics, bismuth, and PPIs may cause false-negative results |
| Biopsy (rapid) urease | HP urease generates ammonia, which causes a color change | Test of choice at endoscopy; >90% sensitive and specific; easily performed; rapid results (usually within 24 hours); tests for active HP infection; antibiotics, bismuth, and PPIs may cause false-negative results; test may yield false-negatives in active ulcer bleeding; available as gel tests, paper tests, and tablets |
| Nonendoscopic tests | | |
| Antibody detection (laboratory-based) | Detects antibodies to HP in serum; in the U.S., only FDA-approved anti-HP IgG antibody should be used | Quantitative; less sensitive and specific than endoscopic tests; more accurate than in-office or near-patient tests; unable to determine if antibody is related to active or cured infection; antibody titers vary markedly between individuals and take 6 months to 1 year to return to the uninfected range; not affected by PPIs or bismuth; antibiotics given for unrelated indications may cure the infection but antibody test will remain positive |
| Antibody detection (can be performed in office or near patient) | Detects IgG antibodies to HP in whole blood or fingerstick | Qualitative; quick (within 15 minutes); unable to determine if antibody is related to active or cured infection; most patients remain seropositive for at least 6 months to 1 year post HP eradication; not affected by PPIs, bismuth, or antibiotics |
| Urea breath test | HP urease breaks down ingested labeled C-urea, patient exhales labeled CO ₂ | Tests for active HP infection; 95% sensitive and specific; results take about 2 days; antibiotics, bismuth, PPIs, and H ₂ RAs may cause false-negative results; withhold PPIs or H ₂ RAs (1 to 2 weeks) and bismuth or antibiotics (2 to 4 weeks) before testing; may be used posttreatment to confirm eradication |
| Stool antigen | Identifies HP antigen in stool, leading to color change that can be detected visually or by spectrophotometer | Tests for active HP infection; sensitivity and specificity comparable to urea breath test when used for initial diagnosis; antibiotics, bismuth, and PPIs may cause false-negative results, but to a lesser extent than with the urea breath test; may be used posttreatment to confirm eradication |

test.^{1,5,27–29} These tests are more convenient and less expensive than the endoscopic tests. Serologic tests are of limited use in evaluating posttreatment eradication and are not reliable in young children.^{1,5,27} The UBT is based on HP urease activity. The ¹³carbon (nonradioactive isotope) and ¹⁴carbon (radioactive isotope) tests require that the patient ingest radiolabeled urea, which is then hydrolyzed by HP (if present in the stomach) to ammonia and radiolabeled bicarbonate. The radiolabeled bicarbonate is absorbed in the blood and excreted in the breath. A mass spectrometer is used to detect ¹³carbon, whereas ¹⁴carbon is measured using a scintillation counter. The stool antigen test is approved by the Food and Drug Administration (FDA), but availability in the United States is limited. It is less expensive and easier to perform than the UBT, and may be useful in children.²⁸ Although comparable to the UBT in the initial detection of HP, the stool antigen test is less accurate when used to confirm HP eradication posttreatment.²⁹ Salivary and urine antibody tests are under investigation.^{1,27}

Testing for HP is only recommended if eradication therapy is considered. If endoscopy is not planned, serologic antibody testing is a reasonable choice to determine HP status. Posttreatment evaluation to confirm eradication is unnecessary in most patients with PUD unless they have recurrent symptoms, complicated ulcer, MALT lymphoma, or gastric cancer.¹ The UBT is the preferred nonendoscopic method to verify HP eradication after treatment. To avoid confounding bacterial suppression with eradication, the UBT must be delayed at least 4 weeks after the completion of treatment. The term “eradication” or “cure” is used when posttreatment tests conducted 4 weeks after the end of treatment do not detect the organism. Quantitative antibody tests are considered impractical for posttreatment eradication as antibody titers remain elevated for long periods of time.

► TREATMENT: Peptic Ulcer Disease

■ DESIRED OUTCOME

The treatment of chronic PUD varies depending on the etiology of the ulcer (HP or NSAID), whether the ulcer is initial or recurrent, and whether complications have occurred (Fig. 33–5). Overall treatment is aimed at relieving ulcer pain, healing the ulcer, preventing ulcer recurrence, and reducing ulcer-related complications. The goal of therapy in HP-positive patients with an active ulcer, a previously documented ulcer, or a history of an ulcer-related complication, is to eradicate HP, heal the ulcer, and cure the disease. Successful eradication heals ulcers and reduces the risk of recurrence to less than 10% at 1 year.¹ The goal of therapy in a patient with a NSAID-induced ulcer is to heal the ulcer as rapidly as possible. Patients at high risk of developing NSAID ulcers should be switched to a COX-2 inhibitor or receive prophylactic drug cotherapy to reduce ulcer risk and ulcer-related complications. When possible, the most cost-effective drug regimen should be utilized.

■ GENERAL APPROACH TO TREATMENT

The treatment of PUD centers on the eradication of HP in HP-positive patients and reducing the risk of NSAID-induced ulcers and ulcer-related complications. Drug regimens containing antimicrobials such as clarithromycin, metronidazole, amoxicillin, and bismuth salts and antisecretory drugs such as the PPIs or H₂RAs are used to relieve

IMAGING AND ENDOSCOPY

The diagnosis of PUD depends on visualizing the ulcer crater either by upper GI radiography or endoscopy (see Table 33–5).¹ Because of its lower cost, greater availability, and greater safety, many physicians believe that radiography should be the initial diagnostic procedure in patients with suspected uncomplicated PUD. If complications are thought to exist, or if an accurate diagnosis is warranted, upper endoscopy is the diagnostic procedure of choice. If a gastric ulcer is found on radiography, malignancy should be excluded by direct endoscopic visualization and histology.

CLINICAL COURSE AND PROGNOSIS

The natural history of PUD is characterized by periods of exacerbations and remissions.¹ Ulcer pain is usually recognizable and episodic, but symptoms are variable, especially in older adults and in patients taking NSAIDs. Antiulcer medications, including the H₂RAs, PPIs, and sucralfate, relieve symptoms, accelerate ulcer healing, and prevent ulcers from recurring, but they do not cure the disease. Both duodenal ulcers and gastric ulcers recur unless the underlying cause (HP or NSAID) is removed. Successful HP eradication markedly decreases ulcer recurrence and complications. Prophylactic therapy or COX-2 inhibitors dramatically decrease the risk for ulcers and ulcer-related complications in high-risk patients taking NSAIDs. About 20% of patients with chronic PUD experience upper GI bleeding, perforation, or obstruction. Mortality in patients with gastric ulcer is slightly higher than in duodenal ulcer and the general population. The lifetime risk of gastric adenocarcinoma in HP-infected patients is less than 1%.^{1,6}

ulcer symptoms, heal the ulcer, and eradicate HP infection. Successful eradication will alter the natural history of PUD and cure the disease. PPIs, H₂RAs, and sucralfate are used to heal HP-negative NSAID-induced ulcers, but ulcer recurrence is likely in high-risk patients if the NSAID is continued. Prophylactic cotherapy with a PPI or misoprostol is used to decrease the risk of an ulcer and upper GI complications in patients taking nonselective NSAIDs. COX-2 inhibitors are often used in place of a nonselective NSAID to reduce the risk of ulcers and complications.

Dietary modifications may be important for some patients, especially those who are unable to tolerate certain foods and beverages. Lifestyle modifications such as reducing stress and decreasing or stopping cigarette smoking is often encouraged. Some patients may require radiographic or endoscopic procedures for a definitive diagnosis or for complications such as bleeding. Surgery may be necessary in patients with ulcer-related bleeding or other complications such as perforation.

■ NONPHARMACOLOGIC THERAPY

◀ Patients with PUD should eliminate or reduce psychological stress, cigarette smoking, and the use of nonselective NSAIDs (including aspirin). Although there is no “antiulcer diet,” the patient should avoid foods and beverages (e.g., spicy foods, caffeine, and alcohol) that cause dyspepsia or that exacerbate ulcer symptoms. If possible, alternative agents such as acetaminophen, nonacetylated

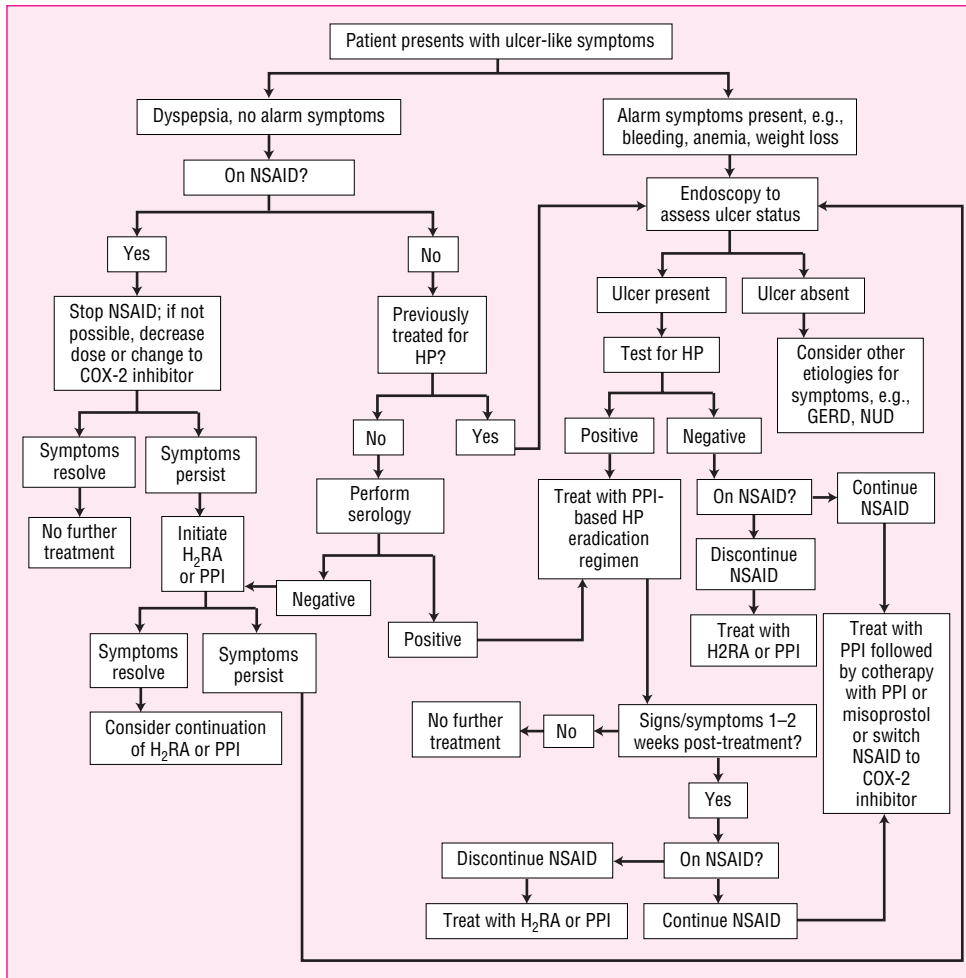

FIGURE 33-5. Algorithm: Guidelines for the evaluation and management of a patient who presents with dyspeptic or ulcer-like symptoms. COX-2, cyclooxygenase-2; GERD, gastroesophageal reflux disease; HP, *Helicobacter pylori*; H₂-RA, H₂-receptor antagonist; PPI, proton pump inhibitor; NSAID, nonsteroidal anti-inflammatory drug; NUD, nonulcer dyspepsia.

salicylate (e.g., salsalate), or COX-2 inhibitors should be used for relief of pain.

Elective surgery for PUD is rarely performed today because of highly effective medical management such as the eradication of HP and the use of potent acid inhibitors.³⁰ A subset of patients, however, may require emergency surgery for bleeding, perforation, or obstruction. In the past, surgical procedures were performed for medical treatment failures and included vagotomy with pyloroplasty or vagotomy with antrectomy.³⁰ Vagotomy (truncal, selective, or parietal cell) inhibits vagal stimulation of gastric acid. A truncal or selective vagotomy frequently results in postoperative gastric dysfunction and requires a pyloroplasty or antrectomy to facilitate gastric drainage. When an antrectomy is performed, the remaining stomach is anastomosed with the duodenum (Billroth I) or with the jejunum (Billroth II). A vagotomy is unnecessary when an antrectomy is performed for gastric ulcer. The postoperative consequences associated with these procedures include postvagotomy diarrhea, dumping syndrome, anemia, and recurrent ulceration.

■ PHARMACOLOGIC THERAPY

■ RECOMMENDATIONS

2 Guidelines for the eradication of infection in HP-positive individuals are presented in Table 33-7. Recommended HP

eradication regimens are presented in Table 33-8. First-line therapy should be initiated with a PPI-based three-drug regimen for a minimum of 7 days, but preferably 10 to 14 days. If a second course of treatment is required, the PPI-based three-drug regimen should contain different antibiotics or a four-drug regimen with bismuth subsalicylate, metronidazole, tetracycline, and a PPI should be used.

3 Treatment with a conventional antiulcer drug (H₂RA, PPI, or sucralfate) is an alternative to HP eradication, but is discouraged because of the high rate of ulcer recurrence and ulcer-related complications associated with these regimens. Concomitant therapy (e.g., an H₂RA and sucralfate or an H₂RA and a PPI) is not recommended because it adds to drug costs without enhancing efficacy. Maintenance therapy with a PPI or H₂RA is recommended for high-risk patients with ulcer complications, patients who fail eradication, or those with HP-negative ulcers.

4 Patients with NSAID-induced ulcers should be tested to determine their HP status. If HP-positive, treatment should be initiated with a PPI-based three-drug eradication regimen. If HP-negative, the NSAID should be discontinued and the patient treated with either a PPI, H₂RA, or sucralfate. If the NSAID must be continued, treatment should be initiated with a PPI (if HP-negative) or with a PPI-based three-drug eradication regimen (if HP-positive). Prophylactic cotherapy with a PPI or misoprostol or switching to a selective COX-2 inhibitor is recommended for patients at risk of developing ulcer-related upper GI complications (see Table 33-4). PPI cotherapy should be considered in high-risk patients taking a COX-2 inhibitor.

TABLE 33–7. Guidelines for the Eradication of *Helicobacter pylori* (HP) Infection in HP-Positive Individuals

■ TREATMENT OF *HELICOBACTER PYLORI*-ASSOCIATED ULCERS

The following discussion focuses on the eradication of HP in adults. Guidelines for the treatment of HP infection in older adults,^{31,32} children,^{33,34} and patients with chronic renal insufficiency³⁵ can be found elsewhere.

5 The goal of HP drug therapy is eradication of the organism. Treatment should be effective, well-tolerated, easy to comply with, and cost-effective. HP regimens should have eradication (cure) rates of at least 80% based on intention-to-treat analysis, or at least 90% based on per protocol analysis, and should minimize the potential for antimicrobial resistance.^{1,5,36,37} The use of a single antibiotic, bismuth salt, or antiulcer drug does not achieve this goal.^{1,5} However,

clarithromycin is the single most effective antibiotic.¹ Two-drug regimens that combine a PPI and either amoxicillin or clarithromycin have yielded marginal and variable eradication rates in the United States and are not recommended.^{1,5} In addition, the use of only one antibiotic is associated with a higher rate of antimicrobial resistance.³⁸

Eradication regimens (see Table 33–8) that combine two antibiotics and one antisecretory drug (triple therapy) or a bismuth salt, two antibiotics, and an antisecretory drug (quadruple therapy) increase eradication rates to an acceptable level and reduce the risk of antimicrobial resistance.^{1,5,36,38} When selecting a first-line eradication regimen, an antibiotic combination should be used that permits second-line treatment (if necessary) with different antibiotics. The antibiotics that have been most extensively studied and found to be effective in various combinations include clarithromycin, amoxicillin, metronidazole, and tetracycline.^{1,5} Although other antibiotics may be effective, they should not be used as part of the initial HP regimen. Because of insufficient data, ampicillin should not be substituted for amoxicillin, doxycycline should not be substituted for tetracycline, and azithromycin or erythromycin should not be substituted for clarithromycin. Amoxicillin should not be used in penicillin-allergic patients and metronidazole should be avoided if alcohol is consumed.³⁶ Bismuth salts have a topical antimicrobial effect.¹ Explanations as to why antisecretory drugs enhance the efficacy of antibiotics include increased activity or stability of the antibiotic at a higher intragastric pH and enhanced topical antibiotic concentration resulting from decreased intragastric volume.

■ PROTON PUMP INHIBITOR-BASED THREE-DRUG REGIMENS

Proton pump inhibitor–based three-drug regimens with two antibiotics (see Table 33–8) constitute first-line therapy for eradication of HP.^{1,5,36} A meta-analysis³⁹ of 666 studies indicates that PPI-based regimens that combine clarithromycin and amoxicillin, clarithromycin and metronidazole, or amoxicillin and metronidazole yield similar eradication rates (78.9% to 82.8%) using intent-to-treat analysis; however, other studies suggest that the amoxicillin-metronidazole combination is less effective.¹ Eradication rates were improved when the

TABLE 33–8. Drug Regimens to Eradicate *Helicobacter Pylori*^a

| Drug #1 | Drug #2 | Drug #3 | Drug #4 |
|---|---|--|--|
| <i>Proton pump inhibitor–based three-drug regimens</i> | | | |
| Omeprazole 20 mg twice daily or lansoprazole 30 mg twice daily or pantoprazole 40 mg twice daily or esomeprazole 40 mg daily or rabeprazole 20 mg daily | Clarithromycin 500 mg twice daily | Amoxicillin 1 g twice daily or metronidazole 500 mg twice daily | |
| <i>Bismuth-based four-drug regimens^b</i> | | | |
| Omeprazole 40 mg twice daily or lansoprazole 30 mg twice daily or pantoprazole 40 mg twice daily or esomeprazole 40 mg daily or rabeprazole 20 mg daily or Standard ulcer-healing dosages of an H ₂ -receptor antagonist taken for 4–6 weeks (see Table 33–9) | Bismuth subsalicylate 525 mg four times daily | Metronidazole 250–500 mg four times daily | Tetracycline 500 mg four times daily or amoxicillin 500 mg four times daily, or, clarithromycin 250–500 mg four times daily |

^aAlthough treatment is minimally effective if used for 7 days, 10–14 days of treatment is recommended. The antisecretory drug may be continued beyond antimicrobial treatment in the presence of an active ulcer.

^bIn the setting of an active ulcer, acid suppression is added to hasten pain relief.

clarithromycin dose was increased to 1.5 g/day, but increasing the dosage of the other antibiotics did not increase eradication rates.³⁹ Most clinicians prefer to initiate triple therapy with clarithromycin and amoxicillin rather than clarithromycin and metronidazole. Reserving metronidazole as an alternative or second-line agent leaves an effective back-up agent and reduces exposure and adverse effects from metronidazole. Alternatively, the PPI-clarithromycin-metronidazole regimen is an excellent alternative in penicillin-allergic patients (see Table 33–8).

An initial 7-day course of therapy provides minimally acceptable eradication rates and has been approved by the FDA and is recommended in Europe.^{1,5} The duration of therapy, however, remains controversial in the United States, as longer treatment periods (10-day and 14-day) favor higher eradication rates and are less likely to be associated with antimicrobial resistance.^{1,5,38,40} One meta-analysis reports a 7% to 9% increase in eradication rates with a 14-day treatment regimen when compared to a 7-day regimen.⁴⁰ A number of other antibiotics and antibiotic combinations have been evaluated as part of the PPI-based three-drug regimen with varying degrees of success.^{1,5,41}

The PPI is an integral part of the three-drug regimen and should be taken 15 to 30 minutes before a meal (see section on PPIs) along with the two antibiotics (see Table 33–8). Although gastric acid inhibition is necessary to influence HP eradication rates, the specific level of inhibition remains unknown. A single daily dose of a PPI may be less effective than a double dose when used as part of a triple-therapy HP eradication regimen.⁴² Substitution of one PPI for another is acceptable and does not appear to enhance or diminish HP eradication.⁴³ An H₂RA should not be substituted for a PPI, as better eradication rates have been demonstrated with a PPI.⁴⁴

CLINICAL CONTROVERSY

Some clinicians favor an initial 7-day HP regimen, while others favor a 10-day or 14-day treatment course. The duration of therapy is controversial, as shorter periods may enhance compliance, but longer treatment periods in compliant patients favor higher eradication rates and are less likely to be associated with antimicrobial resistance. Patients receiving a second course of therapy after an unsuccessful eradication should receive treatment for 14 days.

■ BISMUTH-BASED FOUR-DRUG REGIMENS

The bismuth-based four-drug regimens presented in Table 33–8 were originally used as first-line therapy to eradicate HP. Eradication rates for a 14-day regimen containing bismuth, metronidazole, tetracycline, and an H₂-receptor antagonist are similar to those achieved with PPI-based triple therapy.^{1,5,45} Increasing the duration of treatment to 1 month does not substantially increase eradication. Substitution of amoxicillin for tetracycline lowers the eradication rate and is usually not recommended.^{1,45} Substitution of clarithromycin 250 to 500 mg four times a day for tetracycline yields similar results, but increases adverse effects. The antisecretory drug is also used to hasten pain relief in patients with an active ulcer. Although the original bismuth-based four-drug regimen is effective and inexpensive, it is associated with frequent adverse effects and poor compliance. A capsule containing bismuth, metronidazole, and tetracycline is under investigation.

First-line treatment with quadruple therapy using a PPI (with bismuth, metronidazole, and tetracycline) in place of the H₂RA achieves

similar eradication rates as those of PPI-based triple therapy and permits a shorter treatment duration (7 days).^{1,45} Although evidence supports the efficacy of bismuth-based quadruple therapy as first-line treatment, it is often recommended as second-line treatment when a clarithromycin-amoxicillin regimen is used initially (see section on eradication regimens after initial treatment failure). All medications except the PPI (see section on PPIs) should be taken with meals and at bedtime.

■ ERADICATION REGIMENS AFTER INITIAL TREATMENT FAILURE

HP eradication is often more difficult after initial treatment fails and eradication rates are extremely variable.^{5,37} Because there are limited data on second attempts to eradicate HP, treatment failures should be handled on a case-by-case basis. Failure of first- and second-line regimens in primary care requires referral to a specialist.

Second-line empiric treatment should: utilize antibiotics that were not previously used during initial therapy; use antibiotics that do not have resistance problems; use a drug that has a topical effect such as bismuth; and the duration of treatment should be extended 10 to 14 days.⁴⁶ Thus after unsuccessful initial treatment with a PPI-amoxicillin-clarithromycin regimen, empiric second-line therapy should be instituted with bismuth subsalicylate, metronidazole, tetracycline, and a PPI for 10 to 14 days (see Table 33–8).^{5,46,47} When metronidazole resistance is suspected, metronidazole may be replaced by furazolidone (100 mg four times a day) in either the proton pump inhibitor-based three-drug regimen or the bismuth-based four-drug regimen.⁴⁶ When furazolidone is used, patients should be counseled not to ingest alcohol or monoamine oxidase inhibitors.¹ Other successful second-line regimens are discussed elsewhere.^{46,47}

■ FACTORS THAT CONTRIBUTE TO UNSUCCESSFUL ERADICATION

Factors that contribute to unsuccessful eradication include poor patient compliance, resistant organisms, low intragastric pH, and a high bacterial load.^{37,38,46,48} Poor patient compliance is an important factor influencing successful therapy. Compliance decreases with multiple medications, increased frequency of administration, increased length of treatment, intolerable adverse effects, and costly drug regimens. Although a longer treatment duration may contribute to noncompliance, missed doses in a 7-day regimen may also lead to failed eradication.⁴⁶ Tolerability varies with different regimens. Metronidazole-containing regimens increase the frequency of adverse effects (especially when the dose is >1 g/day). Other common adverse effects include taste disturbances (metronidazole and clarithromycin), nausea, vomiting, abdominal pain, and diarrhea. Antibiotic-associated colitis, a serious complication, occurs occasionally. Oral thrush and vaginal candidiasis may also occur.

An important determinant of successful HP eradication therapy is the presence of preexisting antimicrobial resistance.^{1,37,38,46,49} Metronidazole resistance is most common (10% to 60%), but varies depending on prior antibiotic exposure and geographic region.^{1,37,38,49} The clinical importance of metronidazole resistance in eradicating HP remains uncertain, as the synergistic effect of combining metronidazole with other antibiotics appears to render resistance to metronidazole less important. Primary resistance to clarithromycin is lower (10% to 15%) than with metronidazole, but it is more likely to affect

TABLE 33–9. Oral Drug Regimens Used to Heal Peptic Ulcers or Maintain Ulcer Healing

| Drug | Duodenal or Gastric Ulcer Healing (mg/dose) | Maintenance of Duodenal or Gastric Ulcer Healing (mg/dose) |
|---|---|--|
| <i>Proton pump inhibitors</i> | | |
| Omeprazole | 20–40 daily | 20–40 daily |
| Lansoprazole | 15–30 daily | 15–30 daily |
| Rabeprazole | 20 daily | 20 daily |
| Pantoprazole | 40 daily | 40 daily |
| Esomeprazole | 20–40 daily | 20–40 daily |
| <i>H₂-receptor antagonists</i> | | |
| Cimetidine | 300 four times daily | 400–800 at bedtime |
| | 400 twice daily | |
| | 800 at bedtime | |
| Famotidine | 20 twice daily | 20–40 at bedtime |
| | 40 at bedtime | |
| Nizatidine | 150 twice daily | 150–300 at bedtime |
| | 300 at bedtime | |
| Ranitidine | 150 twice daily | 150–300 at bedtime |
| | 300 at bedtime | |
| <i>Promote mucosal defense</i> | | |
| Sucralfate (g/dose) | 1 four times daily | 1–2 twice daily |
| | 2 twice daily | 1 four times daily |

the clinical outcome.^{1,38,46} Secondary resistance occurs in up to two-thirds of treatment failures. Resistance to tetracycline and amoxicillin is uncommon.¹ Resistance to bismuth has not been reported. The role of antibiotic sensitivity testing before initiating HP treatment has not been established.

■ TREATMENT OF NSAID-INDUCED ULCERS

Nonselective NSAIDs should be discontinued (when possible) if an active ulcer is confirmed. If the NSAID is stopped, most uncomplicated ulcers will heal with standard regimens of an H₂-receptor antagonist, PPI, or sucralfate (Table 33–9).^{1,12,14} PPIs are usually preferred because they provide more rapid ulcer healing than H₂RAs or sucralfate. If the NSAID must be continued in a patient despite ulceration, consideration should be given to reducing the NSAID dose, or switching to acetaminophen, a nonacetylated salicylate, a partially selective COX-2 inhibitor, or a selective COX-2 inhibitor (see Table 33–3). The PPIs are the drugs of choice when the NSAID must be continued, as potent acid suppression is required to accelerate ulcer healing.^{1,12,14} H₂RAs are less effective in the presence of continued NSAID use; sucralfate does not appear to be effective. If HP is present, treatment should be initiated with an eradication regimen that contains a PPI.^{1,12–14}

STRATEGIES TO REDUCE THE RISK OF NSAID-INDUCED ULCERS AND ULCER-RELATED UPPER GI COMPLICATIONS

A number of strategies are used to reduce the risk of NSAID-related ulcers and GI complications. Strategies aimed at reducing the topical irritant effects of nonselective NSAIDs—prodrugs, slow-release formulations, and enteric-coated products—do not prevent ulcers or GI complications such as bleeding or perforation. Medical cotherapy with misoprostol or a PPI decreases the risk of ulcers and GI complications in high-risk patients (see Table 33–3).^{1,12–14,21,50,51}

Switching to a selective COX-2 inhibitor also decreases ulcer risk and complications.^{1,12–14,21,50–52}

MISOPROSTOL COTHERAPY WITH A NONSELECTIVE NSAID

Misoprostol, 200 mcg four times a day, markedly reduces the risk of NSAID-induced gastric ulcer, duodenal ulcer, and ulcer-related GI complications, but diarrhea and abdominal cramping limit its use.^{12–14,21} Because a dosage of 200 mcg three times a day is comparable in efficacy to 800 mcg/day, the lower dosage should be considered in patients unable to tolerate the higher dose.^{1,12–14} Reducing the misoprostol dosage to 400 mcg/day or less to minimize diarrhea may compromise its prophylactic effects. A fixed combination of misoprostol 200 mcg and diclofenac (50 mg or 75 mg) is available and may enhance compliance, but the flexibility to individualize drug dosage is lost. A large double-blind clinical trial in rheumatoid arthritis patients receiving misoprostol 200 mcg four times a day provides the most compelling evidence that serious upper GI complications can be prevented, especially in high-risk patients.⁵³ However, the reduction in complications was less than the prevention of endoscopic lesions, indicating that it is not appropriate to extrapolate from ulcer prevention to a reduction in GI complications.

H₂-RECEPTOR ANTAGONIST COTHERAPY WITH A NONSELECTIVE NSAID

Standard H₂-receptor antagonist dosages (e.g., famotidine 40 mg/day) are effective in reducing the risk of NSAID-induced duodenal ulcer, but not gastric ulcer (the most frequent type of ulcer associated with NSAIDs).^{1,12–14,21} Therefore standard H₂RA dosages should not be used as cotherapy with a nonselective NSAID for prophylaxis. There is evidence that higher dosages (e.g., famotidine 40 mg twice daily, ranitidine 300 mg twice daily) reduce the risk for gastric ulcer and duodenal ulcer.^{1,21} However, there are no studies that have evaluated whether higher H₂RA dosages reduce the risk of ulcer-related upper

GI complications. The H₂RAs may be used when necessary to relieve NSAID-related dyspepsia.

PROTON PUMP INHIBITOR COTHERAPY WITH A NONSELECTIVE NSAID

Standard PPI dosages (e.g., omeprazole 20 mg/day and lansoprazole 30 mg/day) reduce the risk of NSAID-induced gastric ulcer and duodenal ulcer.^{1,12–14,21} In a large comparative multicenter trial, omeprazole 20 mg/day was superior to ranitidine 150 mg twice daily in preventing NSAID-induced gastroduodenal ulcers.⁵⁴ Two randomized controlled trials have compared PPIs with misoprostol and placebo. **6** In the first study,⁵⁵ omeprazole 20 mg/day was as effective as misoprostol 400 mcg/day in reducing the incidence of gastric ulcer; however, if a higher dosage of misoprostol had been used it might have been more effective. In the second study of HP-negative NSAID-users with a history of gastric ulcer,⁵⁶ misoprostol 800 mcg/day was more effective than lansoprazole (15 mg or 30 mg/day) and placebo. When withdrawals from the study (primarily related to the side effects of misoprostol) were regarded as “treatment failures,” lansoprazole and full-dose misoprostol were considered clinically equivalent. Although there are no large clinical studies to prove that PPIs decrease the risk for NSAID-related upper GI complications, two small studies have reported a reduction in serious upper GI complications in patients with a history of upper GI bleeding.^{57,58} Proton pump inhibitor cotherapy is considered an alternative to misoprostol in high-risk patients taking nonselective NSAIDs (including low-dose aspirin).

SELECTIVE COX-2 INHIBITORS

Of the oral selective COX-2 inhibitors now available in the U.S. (see Table 33–3) only celecoxib was investigated in arthritic patients, in a large, long-term, randomized controlled trial (named CLASS), that was specifically designed to evaluate upper gastrointestinal complications versus nonselective NSAIDs.^{59,60} Patients in the CLASS trial, were permitted to take low-dose aspirin for cardioprotection.⁵⁹ The initial analysis of the CLASS trial indicated that, when compared to nonselective NSAIDs, celecoxib had 50% fewer symptomatic ulcers and serious upper GI complications in patients not taking concomitant low-dose aspirin. However, in the CLASS trial, these benefits were negated in the aspirin users. Although a systematic review⁶¹ of celecoxib found that it is safer than nonselective NSAIDs, a re-evaluation of the CLASS data by the FDA concluded that celecoxib does not have a GI safety advantage over nonselective NSAIDs.^{21,52} The manufacturer of celecoxib argued (and the FDA acknowledged) that confounding factors in study design, including the use of low-dose aspirin, account for these discrepant results. Concerns about the cardiovascular safety of selective COX-2 inhibitors (e.g., thrombotic events and myocardial infarction) have arisen.^{21,52,60} GI effects such as dyspepsia and abdominal pain, fluid retention, hypertension, and renal toxicity can also occur with the COX-2 inhibitors.^{21,52}

7 Two small comparative trials in HP-negative patients with histories of NSAID-related ulcer complications suggested that a standard dosage of a PPI and a nonselective NSAID have a GI safety profile similar to that observed with a selective COX-2 inhibitor.^{62,63} However, the comparative benefits and cost effectiveness of these regimens remain controversial. Cotherapy with a PPI and a selective COX-2 inhibitor should be considered in patients with multiple or life-threatening risk factors.¹

CLINICAL CONTROVERSY

Some clinicians favor the use of a PPI and a nonselective NSAID, while others favor a selective COX-2 inhibitor when treating a patient at risk of NSAID-related GI complications. High-risk patients taking a nonselective NSAID should receive cotherapy with a PPI or be switched to a COX-2 inhibitor. The comparative benefits and cost effectiveness of these regimens remains controversial.

Some clinicians favor the concomitant use of an NSAID and low-dose aspirin in a high-risk patient, while others favor the use of a selective COX-2 inhibitor and low-dose aspirin. Ulcer risk is increased when a nonselective NSAID and aspirin are used concomitantly, but the benefit of the COX-2 inhibitor may be reduced in a patient taking low-dose aspirin. The comparative risks and benefits of these two methods to reduce ulcer complications has not been studied and remains controversial.

CONVENTIONAL TREATMENT OF ACTIVE DUODENAL AND GASTRIC ULCERS AND LONG-TERM MAINTENANCE OF ULCER HEALING

Conventional treatment with standard dosages of H₂-receptor antagonists or sucralfate relieves ulcer symptoms and heals the majority of gastric and duodenal ulcers in 6 to 8 weeks (see Table 33–9).^{1,64} Proton pump inhibitors provide comparable ulcer healing rates over a shorter treatment period (4 weeks).^{1,64} A higher daily dose or a longer treatment duration is sometimes needed to heal larger gastric ulcers. Antacids, although effective, are not used as single agents to heal ulcers because of the high volume and frequent doses required (100 to 144 mEq of acid-neutralizing capacity 1 hour and 3 hours after meals and at bedtime), as well as associated adverse effects.¹ When conventional antiulcer therapy is discontinued after ulcer healing, most HP-positive patients develop a recurrent ulcer within 1 year.^{1,5}

Continuous antiulcer therapy (see Table 33–9) is aimed at the long-term maintenance of ulcer healing and at preventing ulcer-related complications. Because HP eradication dramatically decreases ulcer recurrence (<10% at 1 year), continuous maintenance therapy has become largely obsolete.¹ However, maintenance therapy may be indicated for patients who have a history of ulcer-related complications, a healed refractory ulcer, failed HP eradication therapy, or who are heavy smokers or NSAID users. Long-term maintenance therapy with an H₂RA, PPI, or sucralfate is safe, but sucralfate should be avoided in renal impairment.

TREATMENT OF REFRACTORY ULCERS

Ulcers are considered refractory to therapy when symptoms, ulcers, or both persist beyond 8 weeks (duodenal ulcer) or 12 weeks (gastric ulcer) despite conventional treatment, or when several courses of HP eradication fail.¹ Poor patient compliance, antimicrobial resistance, cigarette smoking, NSAID use, gastric acid hypersecretion, or tolerance to the antisecretory effects of an H₂RA (see section on antiulcer agents) may contribute to refractory PUD. Patients with refractory ulcers should undergo upper endoscopy to confirm a nonhealing

ulcer, exclude malignancy, and assess HP status. HP-positive patients should receive eradication therapy (see section on treatment of HP-associated ulcers). In HP-negative patients, higher PPI dosages (e.g., omeprazole 40 mg/day) heal the majority of ulcers.¹ Continuous treatment with a PPI is often necessary to maintain healing, as refractory ulcers typically recur when therapy is discontinued or the dose is reduced. Switching from one PPI to another is not beneficial. Patients with refractory gastric ulcer may require surgery because of the fear of malignancy.

ANTIULCER AGENTS

A comprehensive review of the pharmacology, pharmacokinetics, pharmacodynamics, efficacy, drug interactions, and tolerability of the antiulcer agents can be found elsewhere.¹

PROTON PUMP INHIBITORS

The PPIs (omeprazole, esomeprazole, lansoprazole, rabeprazole, and pantoprazole) dose-dependently inhibit basal and stimulated gastric acid secretion.^{1,64–71} When PPI therapy is initiated, the degree of acid suppression increases over the first 3 to 4 days of therapy, as more and more proton pumps are inhibited. Upon discontinuation of therapy, full restoration of acid secretion takes 3 to 5 days.⁶⁶ Because PPIs inhibit only those proton pumps that are actively secreting acid, they are most effective when taken 15 to 30 minutes before meals.^{64,72}

The PPIs are formulated as enteric-coated pH-sensitive granules contained in gelatin capsules (omeprazole, esomeprazole, and lansoprazole), powders (lansoprazole), rapidly disintegrating tablets (lansoprazole), or as enteric-coated tablets (rabeprazole, pantoprazole and nonprescription omeprazole). Available intravenous products include pantoprazole, lansoprazole, and esomeprazole (pending FDA approval at time of application).^{64,73} The pH-sensitive enteric coating prevents degradation and premature protonation of the drug in stomach acid. The enteric coating dissolves in the duodenum at pH values above 6 and then the drug is systemically absorbed. The granules may be removed from the capsule and administered in acidic juices (e.g., orange or apple) by mouth, nasogastric tube, or gastrostomy tube; they can be sprinkled on applesauce; or a suspension can be prepared for nasogastric/nasoduodenal use by dissolving the granules in an 8.4% solution of sodium bicarbonate.^{64,74,75} Esomeprazole granules may be administered with water via a nasogastric tube.⁷⁵

All five PPIs provide similar ulcer-healing rates, maintenance of ulcer-healing rates, and relief of ulcer symptoms when used in recommended dosages (see Table 33–8).^{1,65–70} When higher dosages are indicated, the daily dose should be divided in order to obtain better 24-hour pH control.⁶⁶ A dosage reduction is not necessary in renal impairment or older adults, but should be considered in severe hepatic disease.^{1,71}

The short-term (<12 weeks) adverse effects of all five PPIs are similar and not unlike those observed with the H₂RAs (see the section on H₂RAs).^{1,64} Because PPIs increase intragastric pH, they may alter the bioavailability of orally administered drugs, such as ketoconazole, digoxin, or pH-dependent dosage forms.^{1,66} Omeprazole and esomeprazole selectively inhibit hepatic cytochrome P450 (CYP450) isoenzyme 2C19 and decrease the elimination of phenytoin, diazepam, and R-warfarin.^{1,64,66} Lansoprazole produces a slight

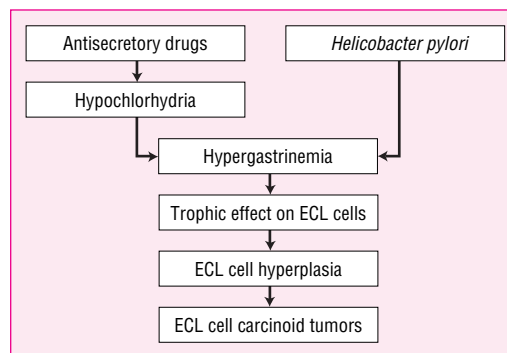

FIGURE 33–6. The gastrin hypothesis suggests that prolonged hypergastrinemia results in hyperplasia of the enterochromaffin-like (ECL) cells of the gastric fundus. The trophic influence of gastrin may be a risk factor for ECL cell carcinoid tumor formation.

increase in the metabolism of theophylline, presumably by inducing CYP1A.^{1,64,66} Rabeprazole, and pantoprazole do not significantly affect CYP metabolism and thus have a lower potential for CYP-mediated drug interactions.^{1,66}

Consequences of Prolonged Hypochlorhydria

All PPIs dose-dependently increase serum gastrin concentrations approximately two- to fourfold as a function of their potent acid-inhibitory effect (Fig. 33–6).^{1,76} Fasting gastrin elevations are usually within the normal range and return to baseline within 1 month of discontinuing the drug. A consequence of hypergastrinemia is its trophic effect on enterochromaffin-like (ECL) cells in the gastric epithelium, which has been associated with the development of gastric carcinoid tumors in female rats. In humans, use of PPIs may lead to ECL hyperplasia; however, there has been no evidence that these changes result in dysplasia, carcinoid tumors, or gastric adenocarcinoma.^{1,76} Long-term PPI therapy in HP-positive patients has been associated with progressive atrophic gastritis of the gastric body.^{1,76} At this time there is inadequate evidence to link the long-term use of PPIs with gastric cancer in HP-positive patients or to support an association between PPIs, colonic polyps, and colorectal cancer.¹ Although bacterial overgrowth occurs in the stomach as a consequence of hypochlorhydria and may lead to carcinogenic N-nitroso compounds in animals, it is unlikely to result in significant gastric nitrosation in humans.^{1,76} A decrease in vitamin B₁₂ was reported in patients receiving long-term PPI therapy, but it is not a major concern.⁷⁶

H₂-RECEPTOR ANTAGONISTS

Ulcer healing is comparable among H₂RAs (cimetidine, famotidine, nizatidine, and ranitidine) with equipotent multiple daily doses or a single full dose given after dinner or at bedtime (see Table 33–9), but tolerance to their antisecretory effect may occur. Twice-daily administration suppresses daytime acid and benefits patients with daytime ulcer pain. Cigarette smokers may require higher doses or a longer duration of treatment. H₂-receptor antagonists are eliminated renally and therefore a dosage reduction is recommended in patients with moderate to severe renal failure.

The short- and long-term safety of all four H₂RAs is similar.¹ Thrombocytopenia, the most common hematologic effect, is

reversible and occurs with all four H₂RAs. However, the propensity for H₂RAs to cause thrombocytopenia is likely overestimated.^{1,77} Cimetidine inhibits several CYP450 isoenzymes, resulting in numerous drug interactions (e.g., theophylline, lidocaine, phenytoin, and warfarin).¹ Ranitidine binds less avidly to hepatic CYP450 isoenzymes than does cimetidine, and thus has less potential for drug interactions. Famotidine and nizatidine do not interact with drugs metabolized by hepatic CYP450 isoenzymes. Because the H₂RAs decrease acid secretion and increase intragastric pH, they may alter the bioavailability of orally administered drugs such as ketoconazole or pH-dependent dosage forms. The effect of cimetidine, ranitidine, and nizatidine (but not famotidine) on serum alcohol is unlikely to be clinically important.⁷⁸

■ SUCRALFATE

Sucralfate should be taken on an empty stomach to prevent binding to dietary protein and phosphate. Deterrents to its use include multiple doses per day, large tablet size, and the need to separate the drug from meals and potentially interacting medications. Adverse effects are minor and occur in less than 5% of patients. Constipation is most common and develops in about 3% of patients.¹ Nausea, dry mouth, dizziness, and a metallic taste occur infrequently. Seizures may occur in dialysis patients who are also receiving aluminum-containing antacids. Hypophosphatemia may develop with long-term treatment (see section on antacids). Gastric bezoar formation has been reported. The concomitant use of sucralfate with oral fluoroquinolones, phenytoin, digoxin, theophylline, quinidine, amitriptyline, warfarin, and ketoconazole may reduce their bioavailability.^{1,79} The interaction is often minimized by giving the interacting drug at least 2 hours before sucralfate. Alternative antiulcer therapy may be warranted in patients taking oral fluoroquinolones.

■ PROSTAGLANDINS

Misoprostol, a synthetic prostaglandin E₁ analog, moderately inhibits acid secretion and enhances mucosal defense.¹ Antisecretory effects are dose-dependent over the range of 50 mcg to 200 mcg; cytoprotective effects occur in humans at doses of greater than 200 mcg. Because protective effects occur at higher doses, it is difficult to establish the protective effect independent of the antisecretory action. Although not recommended in the United States, a dose of 200 mcg four times daily or 400 mcg twice daily heals duodenal ulcers and gastric ulcers comparable to standard H₂RA or sucralfate regimens.¹

Diarrhea, the most troublesome adverse effect, is dose dependent and develops in 10% to 30% of patients.¹ Abdominal cramping, nausea, flatulence, and headache typically accompany the diarrhea. Antacids (other than magnesium) may be taken with misoprostol when needed for abdominal pain. Misoprostol is uterotrophic and produces uterine contractions that may endanger pregnancy; therefore the drug is contraindicated in pregnant women. If misoprostol is prescribed to women in their childbearing years, use of adequate contraceptive measures must be confirmed and a negative serum pregnancy test should be documented within 2 weeks of initiating treatment. Patients should be counseled about the GI effects and the need to avoid magnesium antacids, as they may increase the propensity for GI adverse effects. Young women should be warned about the importance of adequate contraception.

■ BISMUTH PREPARATIONS

Bismuth subsalicylate is currently the only available bismuth salt in the United States.¹ Possible ulcer-healing mechanisms include an antibacterial effect, a local gastroprotective effect, and stimulation of endogenous prostaglandins. Bismuth salts do not inhibit or neutralize acid. Bismuth subsalicylate is regarded as safe and has few adverse effects when taken in recommended dosages. Because renal insufficiency may decrease bismuth elimination, bismuth salts should be used with caution in older patients and in renal failure. Bismuth subsalicylate may cause salicylate sensitivity or bleeding disorders, and should be used with caution in patients receiving concurrent salicylate therapy. Patients should be advised that bismuth salts may impart a black color to the stool and possibly the tongue (liquid preparations).

■ ANTACIDS

Antacids neutralize gastric acid, inactivate pepsin, and bind bile salts. Aluminum-containing antacids also suppress HP and enhance mucosal defense.^{1,80,81} GI adverse effects are most common with antacids and are dose dependent.^{1,81} Magnesium salts cause an osmotic diarrhea, whereas aluminum salts cause constipation. Diarrhea usually predominates with magnesium/aluminum preparations. Aluminum-containing antacids (except aluminum phosphate) form insoluble salts with dietary phosphorus and interfere with phosphorus absorption.¹ Hypophosphatemia occurs most often in patients with low dietary phosphate intake (e.g., malnutrition or alcoholism). Combined treatment with sucralfate may amplify the hypophosphatemia and the potential for aluminum toxicity (see section on sucralfate).

Magnesium-containing antacids should not be used in patients with a creatinine clearance of less than 30 mL/min because magnesium excretion is impaired.⁸¹ Hypercalcemia may occur in patients with normal renal function taking more than 20 g/day of calcium carbonate, and in renal failure patients taking more than 4 g/day. The milk-alkali syndrome (hypercalcemia, alkalosis, renal stones, increased blood urea nitrogen, and increased serum creatinine concentration) occurs with high calcium intake in patients with systemic alkalosis produced by either ingestion of absorbable antacids (sodium bicarbonate) or prolonged vomiting. Antacids may alter the absorption and excretion of drugs when administered concomitantly.^{1,79,81} Important interactions may occur when antacids are administered with iron supplements, tetracycline, warfarin, digoxin, quinidine, isoniazid, ketoconazole, or the fluoroquinolones. Most interactions can be avoided by separating the antacid from the oral drug by 2 hours.

■ PHARMACOECONOMIC CONSIDERATIONS

8 The eradication of HP improves clinical outcomes and decreases the use of health care resources when compared to conventional antisecretory therapy.⁸² Thus the costs of continued treatment and recurrence far outweigh the cost of HP drug regimens. The cost effectiveness of misoprostol cotherapy is greatest in patients with the highest risk for NSAID-related GI complications.⁸³ The use of a PPI with a nonselective NSAID or switching to a selective COX-2 inhibitor has also been reported to be cost effective in high-risk patients.⁸⁴ However, the comparative cost effectiveness of these regimens requires further study. Whether cotherapy with a high-dose H₂RA is cost effective remains to be determined.

EVALUATION OF THERAPEUTIC OUTCOMES

10 Recommendations for treating and monitoring patients with PUD are presented in Table 33–10. Relief of epigastric pain should be monitored throughout the course of treatment in patients with either HP- or NSAID-induced ulcers. Ulcer pain typically resolves in a few days when NSAIDs are discontinued and within 7 days upon initiation of antiulcer therapy. Most patients with uncomplicated PUD will be symptom free after treatment with any one of the recommended antiulcer regimens. The persistence, or redevelopment, of symptoms after several weeks of treatment suggests failure of ulcer healing or HP eradication, or an alternative diagnosis such as gastroesophageal reflux disease. The majority of patients with

TABLE 33–10. Recommendations for Treating and Monitoring Patients with *Helicobacter pylori* (HP)-Associated and Nonsteroidal Anti-inflammatory Drug (NSAID)-Induced Ulcers

Helicobacter pylori-associated ulcer

1. Recommend drug treatment as presented in the chapter text.
2. Assess patient allergies to determine if allergic to penicillin (or other antibiotics) so that drug regimens that contain penicillin (or other antibiotics) can be avoided. Avoid regimens that contain tetracycline in children.
3. Assess patient use of alcohol or alcohol-containing products with metronidazole and oral birth control medications with antibiotics and counsel appropriately.
4. Assess likelihood of noncompliance to the drug regimen as a cause of treatment failure.
5. Recommend a different antibiotic combination if HP eradication fails and a second treatment is planned.
6. Inform the patient of change in stool color when bismuth salicylate is included in an HP eradication regimen.
7. Assess and monitor patients for potential adverse effects, especially those associated with metronidazole, clarithromycin, and amoxicillin.
8. Assess and monitor patients for potential drug interactions, especially those receiving metronidazole, clarithromycin, and cimetidine.
9. Monitor patients for salicylate toxicity, especially in patients receiving cotherapy with other salicylates, anticoagulants, or in patients with renal failure.
10. Provide patient education to patients who are receiving HP eradication therapy, including why antibiotic and antiulcer combinations are used, when and how to take medications, adverse effects, alarm symptoms, when to contact their health care provider, and the importance of compliance to drug treatment.

NSAID-induced ulcer

1. Recommend drug treatment as presented in the chapter text.
2. Assess risk factors for NSAID-induced ulcers and ulcer-related complications, and when indicated recommend appropriate strategies for reducing ulcer risk.
3. Recommend eradication treatment for HP-positive patients taking NSAIDs.
4. Monitor patients for signs and symptoms of NSAID-related upper GI complications.
5. Assess and monitor patients for potential drug interactions and adverse effects (especially misoprostol).
6. Provide patient education to patients at risk of NSAID-induced ulcers or GI-related complications, including why cotherapy is used with nonselective NSAIDs, when and how to take medications, adverse effects, alarm symptoms, when to contact their health care provider, and the importance of compliance to drug treatment.

uncomplicated HP-positive ulcers do not require confirmation of ulcer healing or HP eradication. When endoscopy is not indicated, the urea breath test is the preferred test to confirm HP eradication. Patient compliance should be assessed in patients who fail therapy.

High-risk patients on NSAIDs should be closely monitored for signs or symptoms of bleeding, obstruction, penetration, or perforation. Patients who remain symptomatic, have recurrent attacks, or who have ulcer-related complications should be referred to a specialist. Follow-up endoscopy can be justified in patients with frequent symptomatic recurrence, refractory disease, complications, or suspected hypersecretory states.

ZOLLINGER-ELLISON SYNDROME

ZES is characterized by gastric acid hypersecretion and recurrent peptic ulceration that results from a gastrin-producing tumor (gastrinoma).^{4,85} In the United States, ZES accounts for 0.1% to 1% of patients with duodenal ulcer; however, this may be an underestimation of the true incidence because of the heterogeneity of clinical manifestations.⁴ Gastrinomas are classified as those associated with multiple endocrine neoplasia type 1 (MEN 1) or sporadic tumors, which have a greater tendency to behave as malignant tumors. More than 90% of gastrinomas are located in the region of the pancreas, the most common site being the duodenum. Malignant gastrinomas occur in 30% to 50% of patients, with metastases to regional lymph nodes, liver, spleen, and bone.

A diagnosis of ZES should be considered in patients with multiple ulcers and recurrent or refractory PUD, often accompanied by esophagitis or ulcer complications.^{4,86} Ulcers occur most often in the duodenum, but may involve the stomach or jejunum. Diarrhea occurs in 30% to 50% of patients and results from high concentrations of acid that overwhelm the duodenum's buffering capacity and damage the mucosa.⁴ Intraluminal acid causes steatorrhea by inactivating pancreatic lipase and precipitating bile acids. Vitamin B₁₂ malabsorption may result from reduced intrinsic factor activity. Patients may have other symptoms when the parathyroid, pituitary, thyroid, or adrenal glands are involved. The diagnosis is established in patients with a basal acid output (BAO) greater than 15 mEq/h (without prior gastric surgery) and when the fasting serum gastrin is higher than 1000 pg/mL.^{4,85} Location of the tumor is essential as early surgical resection prior to liver metastases is often curative.^{4,86,87} Unfortunately, effective medical therapy may delay the recognition of the disease and adversely influence outcome. The widespread use of PPIs, although effective in reducing symptoms, may mask the clinical presentation and complicate the diagnosis.^{4,86} In addition, PPIs can cause hypergastrinemia, which may further complicate the diagnosis of ZES.⁸⁶

Treatment is based on the presence or absence of peptic ulcers, esophagitis, diarrhea, and a gastrinoma, which may be malignant. The PPIs are the oral drugs of choice for managing gastric acid hypersecretion. Treatment should be instituted with omeprazole 60 mg/day (or an equivalent dose of esomeprazole, lansoprazole, rabeprazole, or pantoprazole) and should be adjusted to individual patient response.^{4,64,85} Dividing the daily dose and giving the PPI every 8 to 12 hours is most effective in controlling acid output and relieving symptoms. Although doses as high as 360 mg/day of omeprazole have been administered, an average dose of 60 to 80 mg/day (40 to 80 mg/day of esomeprazole or rabeprazole; 30 to 90 mg/day of lansoprazole; or 40 to 120 mg/day of pantoprazole) reduces basal acid output to target levels. Patients should be evaluated every 6 to 12 months and the PPI dose adjusted accordingly. A gradual reduction in PPI dose is recommended after

the initial dose required for adequate control of gastric acid hypersecretion is achieved.⁴ Intravenous pantoprazole in dosages of 80 mg every 8 to 12 hours is safe and effective for rapid and prolonged acid suppression in patients unable to take oral PPIs.⁶⁹

Ocreotide directly inhibits gastric acid secretion and the release of gastrin.⁴ Although a subcutaneous dose of 100 to 250 mcg three times a day substantially reduces gastric acid secretion, ocreotide is not considered first-line treatment. The long-acting repeatable ocreotide formulation is efficacious in patients with gastrointestinal neuroendocrine tumors.⁸⁸ However, it is important to demonstrate that the patient tolerates ocreotide prior to converting to the long-acting product. An initial dose of 20 mg intramuscularly once monthly is subsequently titrated based on response. Patients with metastatic gastrinoma require tumor resection or treatment with chemotherapeutic agents.

UPPER GASTROINTESTINAL BLEEDING

Upper GI bleeding occurs in approximately 100 cases per 100,000 adults annually.⁸⁹ Despite a decreased incidence of PUD and improvements in the management of upper GI bleeding, the mortality rate associated with acute hemorrhage remains about 7%. Upper GI bleeding can be broadly categorized as variceal or nonvariceal bleeding. Two common types of nonvariceal bleeding are bleeding from chronic peptic ulcers and bleeding from SRMD (stress gastritis, stress ulcer, or stress erosions), both of which are acid-peptic complications.^{2,89} The presentation and pathophysiology of these two conditions are somewhat different, as bleeding associated with chronic PUD usually precedes hospital admission, whereas bleeding associated with SRMD develops in severely ill patients during hospitalization.^{1,90}

The underlying pathophysiology of bleeding from a peptic ulcer or from SRMD is similar in that impaired mucosal defense in the presence of gastric acid and pepsin leads to mucosal damage. In chronic PUD, HP infection and NSAID use are the most important etiologic factors, whereas the primary pathogenic factor in SRMD is thought to be mucosal ischemia resulting from reduced gastric blood flow. In contrast to chronic PUD, stress-related mucosal lesions are characteristically asymptomatic, multiple, located in the proximal stomach, and are unlikely to perforate (see Table 33–1). Bleeding from SRMD occurs from superficial mucosal capillaries, whereas bleeding associated with chronic PUD usually results from a single vessel. The mortality rate associated with stress-related mucosal bleeding (SRMB) approximates 50% and is related to the underlying severity of the patient population.⁹¹ In contrast, the mortality associated with chronic PUD-related bleeding is about 10%, but can increase dramatically in selected patient populations.^{89,92} Although the initial management of acute upper GI bleeding focuses on aggressive resuscitative measures and ensuring hemodynamic stability, and is the same for both PUD-related bleeding and SRMB, the medical management of each condition is distinctly different.^{89,90,92}

PEPTIC ULCER–RELATED BLEEDING

The degree of risk must be assessed to determine how aggressively to treat the patient with chronic PUD-related bleeding.^{89,92} Patients greater than 60 years of age, with comorbid conditions, low systolic blood pressure, high transfusion requirements, shock, ongoing blood loss, prolonged prothrombin time, and erratic mental status generally have poorer prognoses and usually require more aggressive intervention including admission to an intensive care unit (ICU). Diagnostic

endoscopy is usually performed to identify the source of the bleeding, assess the potential risk for rebleeding, and if appropriate, therapeutic interventions are employed to promote hemostasis.^{2,89,93} Several endoscopic treatment approaches (e.g., thermocoagulation, laser therapy, injection sclerotherapy, hemoclippping, and ligation) can be utilized. The appearance of the ulcer at the time of endoscopy is a prognostic indicator for the risk of rebleeding.^{89,92} Clean-based ulcers are most commonly seen and are associated with a low risk of rebleeding. In most cases, these patients can be immediately discharged after endoscopy on antiulcer therapy. Patients with an adherent clot overlying the ulcer base are at intermediate risk of rebleeding. Patients with a visible vessel or active bleeding are at high risk of rebleeding, and must be carefully managed, as rebleeding increases the mortality rate 10-fold.

Antisecretory therapy is often used as adjuvant therapy to prevent PUD rebleeding in high-risk patients because acid impairs clot stability. H₂-receptor antagonists are ineffective in preventing PUD rebleeding because they do not achieve an intragastric pH of 6 (which is needed to promote clot stability), and tolerance to their antisecretory effect develops rapidly.^{89,93–95} In contrast, high-dose continuous intravenous infusions of a PPI (omeprazole 80 mg loading dose, followed by 8 mg/h for 3 days) are effective in reducing the risk of rebleeding in patients who have undergone endoscopy hemostasis.^{89,93,95–97} Although therapy with the PPI may be started prior to endoscopic intervention, one study indicates that the combination of therapeutic endoscopy and a high-dose PPI continuous intravenous infusion is more beneficial than either strategy alone.⁹⁷ Studies that assessed the efficacy of intermittent intravenous infusions of omeprazole have generally shown poor results and are not recommended to reduce the risk of PUD rebleeding.^{89,95} A limited number of studies demonstrate the efficacy of high-dose oral therapy (omeprazole 80 mg/day for 5 days) in preventing PUD rebleeding.^{89,98,99} The risk of rebleeding is greatest within the first 72 hours (especially the first 24 hours) and it is during this time that antisecretory therapy to prevent rebleeding in high-risk patients should be employed.⁹⁶ Subsequently, the patient's underlying PUD should be evaluated and treated.

Patients with upper GI bleeding should be tested for HP at the time of endoscopy (see section on tests for HP). However, tests are associated with an increased rate of false-negatives when obtained during acute bleeding episodes.⁹³ If the initial results are negative, a confirmatory test should be performed following the acute bleeding episode. There is no rationale for using intravenous therapy to eradicate HP. Ulcer treatment, including HP eradication, if appropriate, should be initiated after the acute bleeding episode (see sections on treatment of HP-associated ulcers and treatment of NSAID-induced ulcers).

STRESS-RELATED MUCOSAL BLEEDING

More than 75% of critically ill patients develop SRMD within 24 hours of admission to an ICU, but the incidence of clinically significant SRMB is considered to be in the range of 2% to 6%.^{90,100,101} Clinically significant bleeding increases the length of ICU stay by approximately 4 to 8 days, results in excessive health care costs, and is associated with an increased mortality rate.¹⁰² Thus attempts to prevent SRMB are warranted in high-risk patients. Prophylactic therapy to prevent bleeding is most effective if initiated early in the patient's course.

Patients at risk for SRMB include those with respiratory failure (need for mechanical ventilation for >48 hours), coagulopathy, hypotension, sepsis, hepatic failure, acute renal failure, multiple trauma, severe burns (>35% of body surface area), head injury, traumatic spinal cord injury, major surgery, or history of GI bleeding.^{90,91,100}

Although the relative importance of the various risk factors remains controversial, most clinicians concur that patients with respiratory failure (mechanical ventilation for >48 hours) or coagulopathy should receive prophylaxis, as these two factors were shown to be independent risk factors in a large observational study.⁹¹ In the absence of these two risk factors, some clinicians only use prophylaxis in patients who have two of the aforementioned risk factors.⁹⁰ Although exactly who should receive prophylaxis remains controversial, not all patients in a hospital or ICU are at increased risk of SRMB. A cost-effective approach is to target prophylactic therapy at high-risk patients.

Prevention of SRMB includes resuscitative measures which restore mucosal blood.⁹⁰ Although the benefits of enteral nutrition to patient outcome (e.g., improved nutritional status enhances mucosal integrity) are of overall clinical importance, its precise role as a sole modality to prevent SRMB remains controversial.¹⁰³ Therapeutic options for the prevention of SRMB include antacids (which are of historical interest, as they are no longer used because of cumbersome dosage schedules and side effects), antisecretory drugs (H₂RAs and PPIs), and sucralfate, a mucosal protectant.^{90,104} Cimetidine, given as a continuous intravenous infusion, is the only regimen that is FDA-labeled for the prevention of SRMB. However, in clinical practice, intermittent intravenous H₂RAs are more commonly used.

H₂-receptor antagonists are preferred for prophylaxis of SRMB. A large landmark study demonstrated that intravenous ranitidine was superior to oral sucralfate in preventing SRMB.¹⁰¹ Moreover, ranitidine did not increase the risk for nosocomial pneumonia, as the incidence of pneumonia was no different between the two treatment groups. In itself, critical illness places the patient at risk for nosocomial pneumonia. Also there are potential problems associated with sucralfate therapy (e.g., constipation, clogging tubes, hypophosphatemia, and drug interactions).¹⁰⁴

Proton pump inhibitors should only be used as alternatives to H₂RAs or sucralfate for preventing SRMB, as their superiority has not been firmly established.¹⁰⁵ Only a limited number of studies have evaluated their effectiveness.^{95,105,106} Only one published randomized controlled trial has demonstrated that omeprazole (40 mg/day oral or nasogastric) is superior to ranitidine (150 mg/day intravenous) in preventing SRMB.¹⁰⁶ Although the superiority of omeprazole may be related to its greater antisecretory potency, the possibility of study bias exists, as the population that received ranitidine was at greater risk for SRMB. The optimal dosage of the various intravenous PPIs as well as the preferred route of administration for this indication remains to be defined.

Improvement in the patient's overall medical condition (discharge from the ICU, extubation, and oral intake) suggests that prophylactic therapy can be discontinued. If a patient develops clinically significant bleeding, endoscopic evaluation of the GI tract is indicated along with aggressive drug therapy.

CONCLUSIONS

The eradication of HP infection has dramatically changed the way in which chronic PUD is treated. Although substantial progress has been made, there is still no ideal treatment, and much of what has been learned has not yet been instilled into clinical practice. The widespread use of NSAIDs and their associated GI complications remains a major concern, especially in older adults. Cotherapy with misoprostol or a PPI, or switching to a selective COX-2 inhibitor reduces NSAID-related GI events, but studies are needed to determine their comparative cost effectiveness.

ABBREVIATIONS

BAO: basal acid output
 COX-1: cyclooxygenase-1
 COX-2: cyclooxygenase-2
 CYP450: cytochrome P450
 ECL: enterochromaffin-like
 HP: *Helicobacter pylori*
 H₂RA: histamine-2 receptor antagonist
 ICU: intensive care unit
 MALT: mucosa-associated lymphoid tissue
 MAO: maximal acid output
 NSAID: nonsteroidal antiinflammatory drug
 NUD: nonulcer dyspepsia
 PG: prostaglandin
 PPI: proton pump inhibitor
 PUD: peptic ulcer disease
 SRMB: stress-related mucosal bleeding
 SRMD: stress-related mucosal damage
 UBT: urea breath test
 ZES: Zollinger-Ellison syndrome

INFLAMMATORY BOWEL DISEASE

Joseph T. DiPiro and Robert R. Schade

Learning Objectives and other resources can be found at www.pharmacotherapyonline.com.

KEY CONCEPTS

- 1 The exact cause of inflammatory bowel disease (IBD) is unknown, although there are components that appear to be infectious and other components that suggest immune dysregulation. Genetic variations explain some of the increased risk of disease occurrence.
- 2 Ulcerative colitis is confined to the rectum and colon, causes continuous lesions, and affects primarily the mucosa and the submucosa. Crohn's disease can involve any part of the GI tract, often causes discontinuous (skip) lesions, and is a transmural process that can result in fistulas, perforations, or strictures.
- 3 Common complications of IBD include rectal fissures, fistulas (Crohn's disease), perirectal abscess (ulcerative colitis), and colon cancer, in addition to hepatobiliary complications, arthritis, uveitis, skin lesions (including erythema nodosum and pyoderma gangrenosum), and aphthous ulcerations of the mouth.
- 4 The severity of ulcerative colitis may be assessed by factors such as stool frequency, presence of blood in stool, fever, pulse, hemoglobin, erythrocyte sedimentation rate, C-reactive protein, abdominal tenderness, and radiologic or endoscopic findings. The severity of Crohn's disease can be assessed by the Crohn's disease activity index, which includes stool frequency, presence of blood in stool, endoscopic appearance, and physician's global assessment.
- 5 The goals of treatment of IBD are resolution of acute inflammation and complications, alleviation of systemic manifestations, maintenance of remission, and in some patients, surgical palliation or cure.
- 6 The first-line of treatment for mild to moderate ulcerative colitis or Crohn's colitis consists of oral sulfasalazine or mesalamine; mesalamine or steroid enemas may be used for rectosigmoid disease. Delayed-release oral formulations of mesalamine may be used for Crohn's ileitis.
- 7 Corticosteroids are often required for acute ulcerative colitis or Crohn's disease. The duration of steroid use should be minimized and the dose tapered gradually over 3 to 4 weeks.
- 8 Intravenous continuous infusion of cyclosporine is effective in treating severe colitis that is refractory to steroids.
- 9 Sulfasalazine and mesalamine derivatives can prevent recurrence of acute disease in many patients, while steroids are ineffective for this purpose.
- 10 Other drugs that are useful for treatment of Crohn's disease include metronidazole (for perineal disease), azathioprine or mercaptopurine (for inadequate response or to reduce steroid dosage), cyclosporine (for refractory disease), and infliximab for refractory or fistulizing disease.

There are two forms of idiopathic inflammatory bowel disease (IBD): (a) ulcerative colitis, a mucosal inflammatory condition confined to the rectum and colon; and (b) Crohn's disease, a transmural inflammation of the gastrointestinal tract that can affect any part, from the mouth to the anus. The etiologies of both conditions are unknown, but they may have some common pathogenetic mechanisms.

EPIDEMIOLOGY

At least 1 million Americans are believed to have IBD, with 15,000 to 30,000 new cases diagnosed annually.¹ Crohn's disease has a reported incidence of 3.6 to 8.8 per 100,000 persons in the United States and a prevalence of 20 to 40 per 100,000 people.² The rates of IBD are highest in Scandinavia, Great Britain, and North America.³ The incidence of Crohn's disease varies considerably among studies, but

has clearly increased dramatically over the last 3 or 4 decades.^{3,4} Ulcerative colitis incidence ranges from 3 to 15 cases per 100,000 persons per year among the white population with a prevalence of 80 to 120 per 100,000.² The incidence of ulcerative colitis has remained relatively constant over many years.^{3,4} Although most epidemiologic studies combine ulcerative proctitis with ulcerative colitis, from 17% to 49% of cases are proctitis.

Both sexes are affected equally with inflammatory bowel disease,^{1,2} although some studies show slightly greater numbers of women with Crohn's disease and males with ulcerative colitis.^{6,7} Ulcerative colitis and Crohn's disease have bimodal distributions in age of initial presentation. The peak incidence occurs in the second or third decades of life, with a second peak occurring between 50 and 80 years of age.⁴ A significantly increased incidence of ulcerative colitis (four to five times normal) has been observed in Ashkenazi Jews, while blacks and Asians have a relatively low incidence of occurrence.⁵

ETIOLOGY

Although the exact etiology of ulcerative colitis and Crohn's disease is unknown, similar factors are believed responsible for both conditions (Table 34–1). The major theories of the cause of IBD involve a combination of infectious, genetic, and immunologic factors.⁸ The inflammatory response with IBD may indicate abnormal regulation of the normal immune response or an autoimmune reaction to self-antigens. The microflora of the gastrointestinal tract may provide an environmental trigger to activate inflammation.⁹ Crohn's disease has been described as “a disorder mediated by T lymphocytes which arises in genetically susceptible individuals as a result of a breakdown in the regulatory constraints on mucosal immune responses to enteric bacteria.”¹⁰

INFECTIOUS FACTORS

Microorganisms are a likely factor in the initiation of inflammation in IBD.¹¹ However, no definitive infectious cause of IBD has been found, even though the presentation is similar to that caused by some invasive microbial pathogens. Patients with inflammatory bowel diseases have increased numbers of surface-adherent and intracellular bacteria.¹² IBD may involve a loss of tolerance toward normal bacterial flora.¹³

Suspect infectious agents include the measles virus, protozoans, mycobacteria, and other bacteria. Also, certain strains of bacteria produce toxins (necrotoxins, hemolysins, and enterotoxins) that cause mucosal damage. Bacteria elaborate peptides (e.g., formyl-methionyl-leucyl-phenylalanine) that have chemotactic properties and that cause an influx of inflammatory cells with subsequent release of inflammatory mediators and tissue destruction. Microbes may elaborate superantigens, which are capable of global T-lymphocyte stimulation and subsequent inflammatory response.¹¹ Through luminal exposure to potent nonspecific stimulatory bacterial products, the state of activation of the immune system pathways may be upregulated.¹⁴ As many as 70% of patients with Crohn's disease have circulating antibody to *Saccharomyces cerevisiae*, but this may not be a disease mechanism.¹⁵

GENETIC FACTORS

Genetic factors predispose patients to inflammatory bowel diseases, particularly Crohn's disease. In studies of monozygotic twins, there has been a high concordance rate, with both individuals of the pair having an IBD (particularly Crohn's disease). Also, first-degree relatives of patients with IBD had a 13-fold increase in the risk of disease.¹⁶ Other investigators have observed genetic markers that are found more frequently in those with IBD (particularly major histocompatibility complex, HLA-DR2 for ulcerative colitis and HLA-A2 for Crohn's disease).³ Multiple genes have been associated with IBDs; however, the nature of the gene products has not been established.

IMMUNOLOGIC MECHANISMS

The immunologic basis of IBD is supported by a number of observations.⁹ First is the pathology of the lesions. With Crohn's disease, the bowel wall is infiltrated with lymphocytes, plasma cells, mast cells, macrophages, and neutrophils. Similar infiltration has been observed in the mucosal layer of the colon in patients with ulcerative colitis. Inflammation in IBDs is maintained by an influx of leukocytes from the vascular system into sites of active disease. This influx is promoted by expression of adhesion molecules (such as alpha-4 integrins) on the surface of endothelial cells in the microvasculature in the area of inflammation.¹² Second, many of the systemic manifestations of IBD have an immunologic etiology (e.g., arthritis or uveitis). Finally, IBD is responsive to immunosuppressive drugs (e.g., corticosteroids and azathioprine).

The immune theory of IBD assumes that IBD is caused by an inappropriate reaction of the immune system. This may involve an immunodeficiency, such as a defect in cell-mediated immunity or of macrophages or neutrophils. Autoimmunity may be involved. Also, oxidant injury in colon epithelial crypt cells can be demonstrated from inflamed mucosa of patients with IBD.¹⁷

Potential immunologic mechanisms include both autoimmune and nonautoimmune phenomena.¹¹ Autoimmunity may be directed against mucosal epithelial cells or against neutrophil cytoplasmic elements. Some patients with IBD have abnormal structural features for colonic epithelial cells even in the absence of active disease. Autoantibodies to these structures have been reported. Also, antineutrophil cytoplasmic antibodies are found in a high percentage of patients with ulcerative colitis (70%) and much less frequently with Crohn's disease.¹² Presence of antineutrophil cytoplasmic antibodies in left-sided ulcerative colitis is associated with resistance to medical therapy.¹⁸ Dysregulation of cytokines is a component of IBD. Specifically, Th₁ cytokine activity (which enhances cell-mediated immunity and suppresses humoral immunity) is excessive with Crohn's disease, whereas Th₂ cytokine activity (which inhibits cell-mediated immunity and enhances humoral immunity) is excessive with ulcerative colitis.¹⁹ The result is that patients have inappropriate T-cell responses to antigens from their own intestinal microflora.¹⁹ Expression of interferon- γ (a Th₁ cytokine) in intestinal mucosa of diseased patients is increased, while interleukin-4 (a Th₂ cytokine) is reduced.^{20–22}

Tumor necrosis factor- α (TNF- α) is a pivotal proinflammatory cytokine in Crohn's disease. TNF- α can recruit inflammatory cells to inflamed tissues, activate coagulation, and promote the formation of granulomas. Production of TNF- α is increased in the mucosa and intestinal lumen of patients with Crohn's disease.²³ Eicosanoids such as leukotriene B₄ are increased in rectal dialysates and tissues of IBD patients and are related to disease activity. Leukotriene B₄ enhances neutrophil adherence to vascular endothelium and acts as a

neutrophil chemoattractant. These findings have led to the consideration of leukotriene inhibitor strategies for therapy.

PSYCHOLOGICAL FACTORS

Mental health changes appear to correlate with remissions and exacerbations, especially of ulcerative colitis, but psychological factors overall are not thought to be an etiologic factor. There is a weak association between the number of stressful events experienced and the time to relapse of ulcerative colitis.²⁴

DIET, SMOKING, AND NSAID USE

Changes in diet by people in industrialized countries where Crohn's disease is more common have not been consistently associated with the disease. Studies of increased intake of refined sugars or chemical food additives and reduced fiber intake have provided conflicting results regarding risk for Crohn's disease.

Smoking plays an important but contrasting role in ulcerative colitis and Crohn's disease. Smoking is protective for ulcerative colitis.¹² The risk of developing ulcerative colitis in smokers is about 40% of that in nonsmokers.²⁵ Clinical relapses are associated with smoking cessation, and nicotine transdermal administration has been effective in improving symptoms in patients with ulcerative colitis.^{26,27} In contrast, smoking is associated with a twofold increased frequency of Crohn's disease.³ Crohn's disease patients who stop smoking have a more benign course than patients who continue smoking.²⁸ The mechanisms of these differing effects have not been identified.

Use of nonsteroidal anti-inflammatory drugs (NSAIDs) can trigger disease occurrence or lead to disease flares.^{12,29} The effect of NSAIDs to inhibit prostaglandin production through cyclooxygenase inhibition may impair mucosal barrier protective mechanisms. The increased risk seems to be present for cyclooxygenase-2 inhibitors as well as cyclooxygenase-1 inhibitors.

PATHOPHYSIOLOGY

Ulcerative colitis and Crohn's disease differ in two general respects: anatomic sites and depth of involvement within the bowel wall. There is, however, overlap between the two conditions, with a small fraction of patients showing features of both diseases. Confusion can occur, particularly when the inflammatory process is limited to the colon. Table 34–2 compares pathologic and clinical findings of the two diseases.

ULCERATIVE COLITIS

2 Ulcerative colitis is confined to the rectum and colon, and affects the mucosa and the submucosa. In some instances, a short segment of terminal ileum may be inflamed; this is referred to as *backwash ileitis*. Unlike Crohn's disease, the deeper longitudinal muscular layers, serosa, and regional lymph nodes are not usually involved.⁶ Fistulas, perforation, or obstruction are uncommon because inflammation is usually confined to the mucosa and submucosa.

The primary lesion of ulcerative colitis occurs in the crypts of the mucosa (crypts of Lieberkuhn) in the form of a crypt abscess. Here, frank necrosis of the epithelium occurs; it is usually visible only with microscopy, but may be seen grossly when coalescence of ulcers occurs. Extension and coalescence ulcers may surround areas of uninvolved mucosa. These islands of mucosa are called *pseudopolyps*.

TABLE 34–2. Comparison of the Clinical and Pathologic Features of Crohn's Disease and Ulcerative Colitis

| Feature | Crohn's Disease | Ulcerative Colitis |
|--------------------------------------|-----------------|--------------------|
| Clinical | | |
| Malaise, fever | Common | Uncommon |
| Rectal bleeding | Common | Common |
| Abdominal tenderness | Common | May be present |
| Abdominal mass | Common | Absent |
| Abdominal pain | Common | Unusual |
| Abdominal wall and internal fistulas | Common | Absent |
| Distribution | Discontinuous | Continuous |
| Aphthous or linear ulcers | Common | Rare |
| Pathologic | | |
| Rectal involvement | Rare | Common |
| Ileal involvement | Very common | Rare |
| Strictures | Common | Rare |
| Fistulas | Common | Rare |
| Transmural involvement | Common | Rare |
| Crypt abscesses | Rare | Very common |
| Granulomas | Common | Rare |
| Linear clefts | Common | Rare |
| Cobblestone appearance | Common | Absent |

Other typical ulceration patterns include a "collar-button ulcer," which results from extensive submucosal undermining at the ulcer edge.⁶ The extensive mucosal damage seen in ulcerative colitis can result in significant diarrhea and bleeding, although a small percentage of patients experience constipation.

3 Ulcerative colitis can be accompanied by complications that may be local (involving the colon or rectum) or systemic (not directly associated with the colon). With either type the complications may be mild, serious, or even life threatening. Local complications occur in the majority of ulcerative colitis patients. Relatively minor complications include hemorrhoids, anal fissures, or perirectal abscesses, and are more likely to be present during active colitis. Enterointestinal fistulas are rare.

A major complication is toxic megacolon, which is a segmental or total colonic distension of >6 cm with acute colitis and signs of systemic toxicity.³⁰ It is a severe condition that occurs in up to 7.9% of ulcerative colitis patients admitted to hospitals and results in death rates up to 50%. With toxic megacolon, ulceration extends below the submucosa, sometimes even reaching the serosa. Vasculitis, swelling of the vascular endothelium, and thrombosis of small arteries occurs; involvement of the muscularis propria causes loss of colonic tone, which leads to dilatation and potential perforation.⁶ The patient with toxic megacolon usually has a high fever, tachycardia, distended abdomen, and elevated white blood cell count, and a dilated colon is observed on x-ray. Colonic perforation, however, may occur with or without toxic megacolon and is a greater risk with the first attack. Another infrequent major local complication is massive colonic hemorrhage. Colonic stricture, sometimes with clinical obstruction, may also complicate long-standing ulcerative colitis.

The risk of colonic carcinoma is much greater in patients with ulcerative colitis as compared to the general population. The risk of colon cancer begins to increase 10 to 15 years after the diagnosis of ulcerative colitis. The absolute risk may be as high as 30% 35 years after diagnosis, and as high as 49% for patients who have a long history of disease and who were less than 15 years of age at the time of diagnosis.

The inflammatory response seen in IBD has also been blamed for the systemic complications seen in both Crohn's disease and ulcerative colitis. The systemic extraintestinal complications of ulcerative colitis are summarized in the next section.

HEPATOBIILIARY COMPLICATIONS

Approximately 11% of patients with ulcerative colitis are reported to have hepatobiliary complications with frequencies ranging from 5% to 95% in IBD patients overall.^{31,32} Hepatic complications include fatty liver, pericholangitis, chronic active hepatitis, and cirrhosis. Biliary complications include sclerosing cholangitis, cholangiocarcinoma, and gallstones.

Fatty infiltration of the liver may be a result of malabsorption, protein-losing enteropathy, or concomitant steroid use. The most common hepatic complication is pericholangitis (acute inflammation surrounding the intrahepatic portal venules, bile ducts, and lymphatics), which occurs in up to one-third of ulcerative colitis patients. This is associated with progressive fibrosis of intrahepatic and extrahepatic bile ducts in a small percentage of ulcerative colitis patients, and is referred to as primary sclerosing cholangitis. Cirrhosis may be a sequela of cholangitis or of chronic active hepatitis. Often the severity of hepatic disease does not correlate with gastrointestinal disease activity.

Gallstones occur commonly in patients with Crohn's disease (particularly with terminal ileal disease) and may be related to bile salt malabsorption. Also, cholangiocarcinoma occurs 10 to 20 times more frequently in IBD patients as compared to the general population.³¹

JOINT COMPLICATIONS

Arthritis commonly occurs in IBD patients and is typically asymmetric (unlike rheumatoid arthritis) and migratory, involving one or a few usually large joints. The joints most often affected, in decreasing frequency, are the knees, hips, ankles, wrists, and elbows. Sacroiliitis also occurs commonly. Arthritis associated with ulcerative colitis is generally related to the severity of colonic disease, and resolution without recurrence is seen with proctocolectomy. Also, arthritis in this setting is different from rheumatoid arthritis in that rheumatoid factors are generally not detected. It is nondeforming and nondestructive, even after multiple episodes.

Another potential joint complication is ankylosing spondylitis, which is often unresponsive to treatment. The incidence of ankylosing spondylitis in patients with ulcerative colitis is 30 times that of the general population and occurs most commonly in patients with the HLA-B27 phenotype.

OCULAR COMPLICATIONS

Ocular complications including iritis, uveitis, episcleritis, and conjunctivitis occur in up to 10% of patients with IBD. The most commonly reported symptoms with iritis and uveitis include blurred vision, eye pain, and photophobia. Episcleritis is associated with scleral injection, burning, and increased secretions. These complications may parallel the severity of intestinal disease, and recurrence after colectomy with ulcerative colitis is uncommon.

DERMATOLOGIC AND MUCOSAL COMPLICATIONS

Skin and mucosal lesions associated with IBD include erythema nodosum, pyoderma gangrenosum, and aphthous ulceration. Five to

ten percent of IBD patients experience dermatologic or mucosal complications.³³

Raised, red, tender nodules that vary in size from 1 cm to several centimeters are manifestations of erythema nodosum. They are typically found on the tibial surfaces of the legs and arms. These lesions are more commonly observed in Crohn's disease patients and are noted to correlate with disease severity.

Pyoderma gangrenosum occurs more commonly in patients with ulcerative colitis (1% to 5% incidence) and is characterized by discrete skin ulcerations that have a necrotic center and a violaceous color of the surrounding skin.³³ They can be seen on any part of the body but are more commonly found on the lower extremities.

Oral lesions are found in 6% to 20% of patients with Crohn's disease and 8% of patients with ulcerative colitis.³³ The most common lesion is aphthous stomatitis, seen with Crohn's disease. The severity of these lesions tends to parallel GI disease.

CROHN'S DISEASE

2 Crohn's disease is best characterized as a transmural inflammatory process. The terminal ileum is the most common site of the disorder, but it may occur in any part of the GI tract from mouth to anus. About two-thirds of patients have some colonic involvement, and 15% to 25% of patients have only colonic disease.¹¹ Patients often have normal bowel separating segments of diseased bowel; that is, the disease is discontinuous.

Regardless of the site, bowel wall injury is extensive and the intestinal lumen is often narrowed. The mesentery first becomes thickened and edematous and then fibrotic. Ulcers tend to be deep and elongated and extend along the longitudinal axis of the bowel, at least into the submucosa. The "cobblestone" appearance of the bowel wall results from deep mucosal ulceration intermingled with nodular submucosal thickening.

3 Complications of Crohn's disease may involve the intestinal tract or organs unrelated to it. Small bowel stricture and subsequent obstruction is a complication that may require surgery. Fistula formation is common and occurs much more frequently than with ulcerative colitis.¹¹ Fistulae often occur in the areas of worst inflammation, where loops of bowel have become matted together by fibrous adhesions. Fistulae may connect a segment of the GI tract to skin (enterocutaneous fistula), two segments of the GI tract (enteroenteric fistula), or the intestinal tract with the bladder (enterovesicular fistula) or vagina. Crohn's disease fistulae or abscesses associated with them frequently require surgical treatment.

Bleeding with Crohn's disease is usually not as severe as with ulcerative colitis, although patients with Crohn's disease may have hypochromic anemia. Also, as with ulcerative colitis, the risk of carcinoma is increased but not as greatly as with ulcerative colitis.

Systemic complications of Crohn's disease are common, and similar to those found with ulcerative colitis. Arthritis, iritis, skin lesions, and liver disease often accompany Crohn's disease. Renal stones occur in up to 10% of patients with Crohn's disease (less frequently with ulcerative colitis) and are caused by fat malabsorption, which allows for greater oxalate absorption and formation of calcium oxalate stones. Gallstones also occur with greater frequency in patients with ileitis, possibly because of bile acid malabsorption at the terminal ileum.

Nutritional deficiencies are common with Crohn's disease.³⁴ Reported frequencies of various nutritional parameters are: weight loss, 40% to 80%; growth failure in children, 15% to 88%; iron deficiency anemia, 25% to 50%; vitamin B₁₂ deficiency, 20% to 37%; folate

deficiency, 13% to 37%; hypoalbuminemia, 25% to 76%; hypokalemia, 33%; and osteomalacia, 36%. There are usually decreased fat stores and lean tissue. Growth failure in children may be associated with hypozincemia.

CLINICAL PRESENTATION

The patterns of clinical presentation of IBD can vary widely. Patients may have a single acute episode that resolves and does not recur, but most patients experience acute exacerbations after periods of remission. With more severe disease, prolonged illness may occur.

ULCERATIVE COLITIS

Although a typical clinical picture of ulcerative colitis can be described, there is a wide range of presentation, from mild abdominal cramping with frequent small-volume bowel movements to profuse diarrhea (Table 34–3). Most patients with ulcerative colitis experience intermittent bouts of illness after varying intervals with no symptoms. Only a small percentage of patients have continuous unremitting symptoms or have a single acute attack with no subsequent symptoms.

4 Complex disease classifications are generally not used in clinical practice for ulcerative colitis. The arbitrarily determined distinctions of mild, moderate, and severe disease activity are generally used, and these are determined largely by clinical signs and symptoms.⁶

Mild—Fewer than four stools daily, with or without blood, with no systemic disturbance and a normal erythrocyte sedimentation rate (ESR).

Moderate—More than four stools per day but with minimal systemic disturbance.

Severe—More than six stools per day with blood, with evidence of systemic disturbance as shown by fever, tachycardia, anemia, or ESR of >30.

It is also important to determine disease extent; that is, which part of the colon is involved—rectum, descending colon only, or the entire colon.

TABLE 34–3. Clinical Presentation of Ulcerative Colitis

Signs and symptoms

- Abdominal cramping
- Frequent bowel movements, often with blood in the stool
- Weight loss
- Fever and tachycardia in severe disease
- Blurred vision, eye pain, and photophobia with ocular involvement
- Arthritis
- Raised, red, tender nodules that vary in size from 1 cm to several centimeters

Physical examination

- Hemorrhoids, anal fissures, or perirectal abscesses may be present
- Iritis, uveitis, episcleritis, and conjunctivitis with ocular involvement
- Dermatologic findings with erythema nodosum, pyoderma gangrenosum, or aphthous ulceration

Laboratory tests

- Decreased hematocrit/hemoglobin
- Increased erythrocyte sedimentation rate
- Leukocytosis and hypoalbuminemia with severe disease

Two-thirds of patients with ulcerative colitis have mild disease, which almost always starts in the rectum. Occasionally, the mild form may progress to severe disease, which may be called “fulminant” if it occurs acutely. Systemic signs and symptoms of the disease (e.g., arthritis, uveitis, or pyoderma gangrenosum) may be present in these patients, and in fact may be the reason the patient seeks medical attention. Patients with mild disease are believed to be at lower risk of colon cancer. Moderate disease is observed in one-fourth of patients.

With severe disease, the patient is usually found to be in acute distress, has profuse bloody diarrhea, and often has a high fever with leukocytosis and hypoalbuminemia. Often, the patient is dehydrated, and therefore may be tachycardic and hypotensive. This presentation may have a sudden onset with rapid progression.

The diagnosis of ulcerative colitis is made on clinical suspicion and confirmed by biopsy, stool examinations, sigmoidoscopy or colonoscopy, or barium radiographic contrast studies. The presence of extracolonic manifestations such as arthritis, uveitis, and pyoderma gangrenosum may also aid in establishing the diagnosis.

CROHN'S DISEASE

As with ulcerative colitis, the presentation of Crohn's disease is highly variable. A single episode may not be followed by further episodes, or the patient may experience continuous, unremitting disease. The time between the onset of complaints and the initial diagnosis may be as long as 3 years. The patient typically presents with diarrhea and abdominal pain. Hematochezia occurs in about one-half of the patients with colonic involvement and much less frequently when there is no colonic involvement. Commonly, a patient may first present with a perirectal or perianal lesion (Table 34–4). The diagnosis should also be suspected in children with growth retardation, especially with abdominal complaints.

The course of Crohn's disease is characterized by periods of remission and exacerbation. Some patients may be free of symptoms for years, while others experience chronic problems in spite of medical therapy. Nearly all patients have a recurrence of Crohn's disease within 10 years of the initial episode.¹⁷ As with ulcerative colitis, the diagnosis of Crohn's disease involves a thorough evaluation using laboratory, endoscopic, and radiologic testing to detect the extent and characteristic features of the disease. Because of similarities that may exist between ulcerative colitis and Crohn's disease confined to the colon, a definitive diagnosis cannot be made in up to 15% of cases, even with pathologic specimens in hand. Small bowel involvement and strictures detected on radiographs are characteristic of Crohn's disease.

TABLE 34–4. Clinical Presentation of Crohn's Disease

Signs and symptoms

- Malaise and fever
- Abdominal pain
- Frequent bowel movements
- Hematochezia
- Fistula
- Weight loss
- Arthritis

Physical examination

- Abdominal mass and tenderness
- Perianal fissure or fistula

Laboratory tests

- Increased white blood cell count and erythrocyte sedimentation rate

▶ TREATMENT: Inflammatory Bowel Disease

■ DESIRED OUTCOME

5 To treat IBD properly, the clinician must have a clear concept of realistic therapeutic goals for each patient. These goals may relate to resolution of acute inflammatory processes, resolution of attendant complications (e.g., fistulas and abscesses), alleviation of systemic manifestations (e.g., arthritis), maintenance of remission from acute inflammation, or surgical palliation or cure. The approach to the therapeutic regimen differs considerably with varying goals as well as with the two diseases, ulcerative colitis and Crohn's disease.

When determining goals of therapy and selecting therapeutic regimens it is important to understand the natural history of IBD.³⁵ Some cases of acute ulcerative colitis are self-limited. With mild to moderate acute colitis without systemic symptoms, 20% of patients may experience spontaneous improvement in their disease within a few weeks; however, a small percentage of patients may go on to experience more serious disease. With severe colitis, improvement without treatment cannot be expected. For instance, the response to medical management of toxic megacolon is variable and emergent colectomy may be required. When remission of ulcerative colitis is achieved, it is likely to last at least 1 year with medical therapy. In the absence of medical therapy, one-half to two-thirds of patients are likely to relapse within 9 months.³⁵ In some reports, remission rates with placebo have approached those found with active treatment.

A considerable number of patients with active Crohn's disease may achieve at least temporary remission without drug therapy. In two large trials, 26% and 42% of ambulatory patients on placebo achieved remission.^{36,37} Once remission is achieved, two-thirds to three-fourths of patients remain in remission up to 2 years without drug therapy.³⁵ The implication of these data is that up to 40% of patients with active Crohn's disease improve in 3 to 4 months with observation alone, and that most patients remain in remission for prolonged periods without medical intervention. These observations apply more to mild or moderate disease than to severe disease.

■ GENERAL APPROACH TO TREATMENT

6 Treatment of IBD centers on agents used to relieve the inflammatory process. Salicylates, corticosteroids, antimicrobials, and immunosuppressive agents such as azathioprine and mercaptopurine are commonly used to treat active disease, and for some agents, to lengthen the time of disease remission.

In addition to the use of drugs, surgical procedures are sometimes performed when active disease is inadequately controlled or when the required drug dosages pose an unacceptable risk of adverse effects. For most patients with IBD, nutritional considerations are also important, because these patients are often malnourished. Finally, a variety of therapies may be used to address complications or symptoms of IBD. For example, antidiarrheals may be used in some patients, although these are generally to be avoided in severe ulcerative colitis because they may contribute to the development of toxic colonic dilatation. Antimicrobial agents may be used in conjunction with drainage when abscesses are present. Iron may be required, particularly with ulcerative colitis, where blood loss from the colon can be significant.

■ NONPHARMACOLOGIC THERAPY

■ NUTRITIONAL SUPPORT

Proper nutritional support is an important aspect of the treatment of patients with IBD, not because specific types of diets are useful in alleviating the inflammatory conditions, but because patients with moderate to severe disease are often malnourished either because the inflammatory process results in significant malabsorption or maldigestion, or because of the catabolic effects of the disease process. Malabsorption may occur in the patient with Crohn's disease with inflammatory involvement of the small bowel, where many nutrients are absorbed, as well as in patients who have undergone multiple small bowel resections with subsequent reduction in absorptive surface ("short gut"). Maldigestion can occur if there is a bile salt deficiency in the gut.

Many specific diets have been tried to improve the condition of patients with IBD, but none has gained widespread acceptance. With each individual it is helpful to eliminate specific foods that exacerbate symptoms. This elimination process must be conducted cautiously, as patients have been known to exclude a wide range of nutritious products without adequate justification. Some patients with IBD, although not the majority, have lactase deficiency; therefore diarrhea may be associated with milk intake. In these patients, avoidance of milk or supplementation with lactase generally improves the patient's symptoms.

The nutritional needs of the majority of patients can be adequately addressed with enteral supplementation.³⁸ Patients who have severe disease may require a course of parenteral nutrition to attain a reasonable nutritional status or in preparation for surgery. In severe acute ulcerative colitis, enteral nutrition resulted in a significantly greater increase in serum albumin, fewer adverse effects related to the nutritional regimen, and fewer postoperative infections, as compared to isocaloric, isonitrogenous parenteral nutrition.³⁹ The regimens were similar with regard to remission rate and the need for colectomy.³⁹ Consideration should be given to lipid administration for its caloric value, as well as in recognition of depleted peripheral fat stores in many IBD patients and the greater potential for fatty acid deficiency.

Parenteral nutrition is an important component of the treatment of severe Crohn's disease or ulcerative colitis. The use of parenteral nutrition allows complete bowel rest in patients with severe ulcerative colitis, which may alter the need for proctocolectomy. Parenteral nutrition has also been valuable in Crohn's disease, because remission may be achieved with parenteral nutrition in about 50% of patients.⁴⁰ In some patients, the disease may worsen when parenteral nutrition is stopped. Patients with enterocutaneous fistulas of various etiologies benefit from parenteral nutrition.⁴⁰ Parenteral nutrition may also be valuable in children or adolescents with growth retardation associated with Crohn's disease, but surgery is often necessary with severe disease. Finally, when possible, home parenteral nutrition should be used for patients requiring long-term therapy, particularly those with "short gut" as a consequence of surgical resection.

There is a growing interest in using probiotic approaches for IBD. Probiotics involves the reestablishment of normal bacterial flora within the gut by oral administration of live bacteria such as non-pathogenic *Escherichia coli*, bifidobacteria, lactobacilli, or *Streptococcus thermophilus*. Probiotic formulations have been effective in maintaining remission in ulcerative colitis.⁴¹⁻⁴³

■ SURGERY

Surgical procedures have an established place in the treatment of IBD. Although surgery (proctocolectomy) is curative for ulcerative colitis, this is not the case for Crohn's disease. Surgical procedures involve resection of segments of intestine that are affected, as well as correction of complications (e.g., fistulas) or drainage of abscesses.

For ulcerative colitis, colectomy may be necessary when the patient has disease uncontrolled by maximum medical therapy or when there are complications of the disease such as colonic perforation, toxic dilatation (megacolon), uncontrolled colonic hemorrhage, or colonic strictures. Colectomy may be indicated in patients with long-standing disease (greater than 8 to 10 years), as a prophylactic measure against the development of cancer, and in patients with premalignant changes (severe dysplasia) on surveillance mucosal biopsies. The most common surgical procedures include proctocolectomy, after which the patient is left with a permanent ileostomy, and abdominal colectomy, with removal of the mucosa of the rectum and anastomosis of an ileal pouch to the anus (ileoanal pull-through). The risk from surgery in these patients is relatively low if the operations are performed on a nonemergent basis.

The indications for surgery with Crohn's disease are not as well established as for ulcerative colitis, and surgery is usually reserved for the complications of the disease. A recognized problem with intestinal resection for Crohn's disease is the high recurrence rate. Surgery may be appropriate in well-selected patients who have severe or incapacitating disease or obstruction in spite of aggressive medical management. The surgical procedures performed include resections of the major intestinal areas of involvement. In some patients with severe rectal or perineal disease, diversion of the fecal stream is performed with a colostomy. Other indications for surgery include the finding of colon cancer, an inflammatory mass, or intestinal perforations.

■ PHARMACOLOGIC THERAPY

Drug therapy plays an integral part in the overall treatment of IBD. None of the drugs used for IBD is curative; at best they serve to control the disease process. Therefore a reasonable goal of drug therapy is resolution of disease symptoms such that the patient can carry on normal daily functions. The major types of drug therapy used in IBD include aminosalicylates, corticosteroids, immunosuppressive agents (azathioprine, mercaptopurine, cyclosporine, and methotrexate), antimicrobials (metronidazole and ciprofloxacin), and agents to inhibit TNF- α (anti-TNF- α antibodies).

Sulfasalazine, an agent that combines a sulfonamide (sulfapyridine) antibiotic and mesalamine (5-aminosalicylic acid) in the same molecule, has been used for many years to treat IBD but was originally intended to treat arthritis. Sulfasalazine is cleaved by gut bacteria in the colon to sulfapyridine (which is mostly absorbed and excreted in the urine) and mesalamine (which mostly remains in the colon and is excreted in stool).⁴⁴

The active component of sulfasalazine is mesalamine.⁴⁴ The mechanism of action of mesalamine is not well understood. Cyclooxygenase or lipoxygenase inhibition alone do not account for the agent's effects. Aminosalicylates may block production of prostaglandins and leukotrienes, inhibit bacterial peptide-induced neutrophil chemotaxis and adenosine-induced secretion, scavenge reactive oxygen metabolites, and inhibit activation of the nuclear regulatory factor NF- κ B.¹²

Because the mechanism of action of sulfasalazine is not related to the sulfapyridine component, and since sulfapyridine is believed to be responsible for many of the adverse reactions to sulfasalazine, mesalamine alone can be used. Mesalamine can be used topically as an enema for the treatment of proctitis, or given orally in slow-release formulations that deliver mesalamine to the small intestine and colon (Table 34–5 and Fig. 34–1). Slow-release oral formulations of mesalamine such as Pentasa release mesalamine from the duodenum to the ileum, with about 75% of the drug passing into the colon.⁴⁵ Olsalazine is a dimer of two 5-aminosalicylate molecules linked by an azo bond. Mesalamine is released in the colon after colonic bacteria cleave olsalazine. Balsalazide is a mesalamine prodrug that is enzymatically cleaved in the colon to produce mesalamine. The recommended daily doses of the oral mesalamine derivatives are intended to approximate the molar equivalent of mesalamine present in 4 g of sulfasalazine. At present, sulfasalazine is used in preference to oral mesalamine derivatives, mainly because it costs much less. However, it is not tolerated as well as the mesalamine alternatives. Because the oral mesalamine formulations are coated tablets or granules, they should not be crushed or chewed.

Corticosteroids and adrenocorticotropic hormone have been widely used for the treatment of ulcerative colitis and Crohn's disease, given parenterally, orally, or rectally. Corticosteroids are believed to modulate the immune system and inhibit production of cytokines and mediators. It is not clear whether the most important steroid effects are systemic or local (mucosal). Budesonide is a corticosteroid that is administered orally in a controlled-release formulation. The drug undergoes extensive first-pass metabolism, so systemic exposure is thought to be minimized. Immunosuppressive agents such as azathioprine, mercaptopurine (a metabolite of azathioprine), methotrexate, or cyclosporine are sometimes used for the treatment of IBD.⁴⁶

TABLE 34–5. Mesalamine Derivatives for Treatment of Inflammatory Bowel Disease

| Product | Trade Name(s) | Formulation | Dose/Day | Site of Action |
|---------------|--------------------------------------|--|-----------|------------------------|
| Sulfasalazine | Azulfidine | Tablet | 4–6 g | Colon |
| Mesalamine | Rowasa, Salofalk, Claversal, Pentasa | Enema | 1–4 g | Rectum, terminal colon |
| | Asacol | Mesalamine tablet coated with Eudragit-S (delayed-release acrylic resin) | 2.4–4.8 g | Distal ileum and colon |
| | Pentasa | Mesalamine capsules encapsulated in ethylcellulose microgranules | 2–4 g | Small bowel and colon |
| Olsalazine | Dipentum | Dimer of 5-aminosalicylic acid oral capsule | 1.5–3 g | Colon |
| Balsalazide | Colazal | Capsule | 6.75 g | Colon |

FIGURE 34-1. Site of activity of various agents used to treat inflammatory bowel disease.

Azathioprine and mercaptopurine are effective for long-term treatment of Crohn’s disease and ulcerative colitis.⁴⁷ These agents are generally reserved for patients who are refractory to steroids, and they may be associated with serious adverse effects such as lymphomas, pancreatitis, or nephrotoxicity. They are usually used in conjunction with mesalamine derivatives and/or steroids, and must be used for long periods of time (from a few weeks up to 6 months) before benefits may be observed.⁴⁸ Remission can be prolonged by azathioprine in steroid-dependent patients with ulcerative colitis.⁴⁹ Cyclosporine

has also been of short-term benefit in treatment of acute, severe ulcerative colitis when used in a continuous intravenous infusion. Oral doses are ineffective. The agent poses a risk of nephrotoxicity and neurotoxicity. Methotrexate given 15 to 25 mg intramuscularly once weekly is useful for treatment and maintenance of Crohn’s disease but not ulcerative colitis.

Antimicrobial agents, particularly metronidazole, are frequently used in attempts to control Crohn’s disease but are not useful in ulcerative colitis. Metronidazole is of value in some patients with active Crohn’s disease, particularly involving the perineal area or fistulas.⁵⁰ The mechanism of metronidazole’s effect on Crohn’s disease has not been determined but is theorized to relate to interruption of a bacterial role in the inflammatory process. Ciprofloxacin has also been used for treatment of IBD.

Infliximab is an IgG₁ chimeric monoclonal antibody that binds TNF- α and inhibits its inflammatory effect in the gut. The agent is useful for steroid-dependent or fistulizing disease, but the cost far exceeds that of other regimens.

■ ULCERATIVE COLITIS

■ Mild to Moderate Disease

Most patients with active ulcerative colitis have mild to moderate disease and do not require parenteral medications (Fig. 34-2). The first line of drug therapy for these patients is oral sulfasalazine or an oral mesalamine derivative, or topical mesalamine or steroids for distal

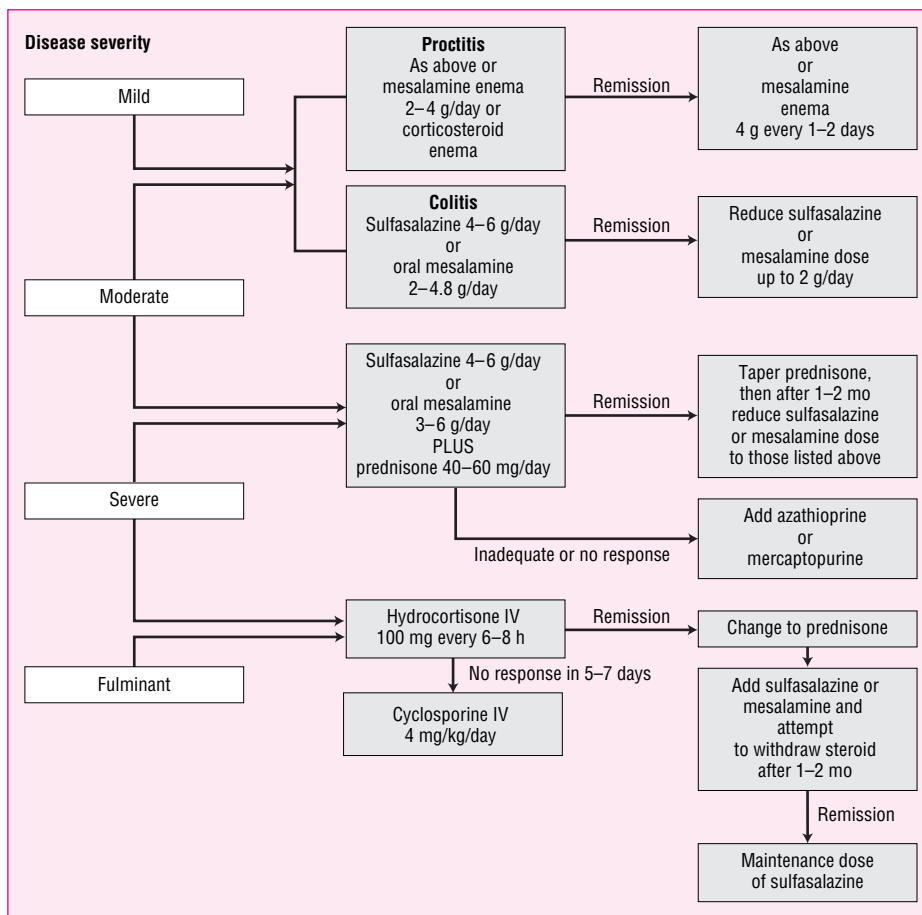

FIGURE 34-2. Treatment approaches for ulcerative colitis.

disease.⁵¹ When given orally, usually 4 g/day, and up to 8 g/day, of sulfasalazine is required to attain control of active inflammation. There does not appear to be an increased rate of response with increased dosage over 4 g/day, although side effects increase. Even with the use of adequate doses, patient improvement usually takes 2 to 3 weeks, and sometimes longer. The dosage of sulfasalazine that can be given is usually limited by the patient's tolerance of the agent; most adverse effects of sulfasalazine are dose related (GI disturbances, headache, and arthralgia).⁴⁸ Sulfasalazine therapy should be instituted at 500 mg/day and increased every few days up to 4 g/day or the maximum tolerated. It should not be used in patients with allergy to sulfa drugs.

Oral mesalamine derivatives (such as those listed in Table 34–5) are reasonable alternatives to sulfasalazine for treatment of ulcerative colitis. These agents are clearly more effective than placebo but no more effective than sulfasalazine. However, mesalamine preparations are better tolerated.⁵² For many patients the dose of mesalamine can be increased without an increase in adverse effects. The majority of patients intolerant to sulfasalazine should tolerate one of the other oral mesalamine derivatives. While the dosage range for Pentasa is 2 to 4 g/day, 4 g/day appears to be more effective.⁵³ Olsalazine (a dimer of 5-aminosalicylic acid that is given orally) is effective for treatment of mild to moderate ulcerative colitis. However, of patients taking olsalazine, 15% to 25% experience severe diarrhea, often necessitating discontinuation of the drug. This results from a direct osmotic effect of the drug to induce small bowel fluid secretion. For this reason it is not the drug of first choice. Balsalazide is another mesalamine derivative that is effective for treatment of mild to moderate ulcerative colitis.⁵⁴ For patients with distal disease, combination therapy of oral mesalamine derivatives and topical (enema) mesalamine therapy may be beneficial for induction of remission as well as for maintenance.^{12,55}

7 Steroids have a place in the treatment of moderate to severe ulcerative colitis that is unresponsive to maximal doses of oral and topical mesalamine derivatives. Oral steroids (usually up to 1 mg/kg per day of prednisone equivalent) may be used for patients who do not have an adequate response to sulfasalazine or mesalamine. Overall, steroids and sulfasalazine appear to be equally efficacious; however, the response to steroids may be evident sooner. Oral steroids should not be used as initial therapy for mild to moderate ulcerative colitis, mainly because of the known risks of steroid use. If steroids are used to attain remission, tapered drug withdrawal should be accomplished to minimize long-term steroid exposure.

Rectally administered steroids or mesalamine can be used as initial therapy for patients with ulcerative proctitis or distal colitis. Rectal agents are also beneficial for treatment of tenesmus. With these agents, local actions are believed to be responsible for drug effects. Rectal steroids are effective in the treatment of active, distal ulcerative colitis. However, rectal mesalamine is more effective than rectal steroids for inducing remission.^{56,57}

CLINICAL CONTROVERSY

The choice of rectally administered steroid is a subject of debate, as there is varying potential for systemic steroid absorption with different products. Although many steroids have been administered rectally, certain agents such as betamethasone-17-valerate, beclomethasone dipropionate, prednisolone metasulfobenzoate, prednisolone-21-phosphate, and budesonide have been used in attempts to reduce systemic steroid effects. Systemic side effects may be the least severe with beclomethasone dipropionate, because

the gut wall and liver rapidly metabolize this agent.⁵⁶ Most patients do not experience adrenal suppression from rectal steroids. The use of rectal steroids may often result in reduction of the required oral dose.

Nicotine has been proposed as a treatment for ulcerative colitis (but not as a treatment for Crohn's disease) based on the observation of the onset of a flare of ulcerative colitis after smoking cessation in some individuals. When used in the highest tolerated dose, transdermal nicotine improved symptoms of patients with mild to moderate active ulcerative colitis.⁵⁸

Severe or Intractable Disease

Patients with uncontrolled severe colitis or who have incapacitating symptoms require hospitalization for effective management. Under these conditions, patients generally receive nothing by mouth to put the bowel at rest. Most medication is given by the parenteral route. With severe colitis, there is a much greater reliance on parenteral steroids (intravenous hydrocortisone) and surgical procedures. Sulfasalazine or mesalamine derivatives are not beneficial for treatment of severe colitis because of rapid elimination of these agents from the colon with diarrhea, thereby not allowing sufficient time for gut bacteria to cleave the molecules. Overall it is difficult to evaluate drugs in this setting, because patients with severe disease almost always receive additional medications including steroids.

Steroids have been valuable in the treatment of severe disease because the use of these agents may allow some patients to avoid colectomy. A trial of steroids is warranted in most patients before proceeding to colectomy, unless the condition is grave or rapidly deteriorating. The dose of steroid generally used is 1 mg/kg of prednisone equivalent daily (up to 60 mg/day), although some patients may require much less or much more for satisfactory control. With higher doses, however, steroid side effects may limit drug benefits. The length of the medical trial before consideration of surgery is open to debate. Steroids increase surgical risk, particularly infectious risk, if an operation is required later. After a colectomy is performed, steroids should no longer be required for the disease; however, they must be withdrawn gradually (usually over 3 to 4 weeks) to avoid hypoadrenal crisis due to adrenal suppression.

8 Patients who are unresponsive to parenteral corticosteroids after 7 to 10 days should receive cyclosporine by intravenous infusion. Most hospitalized patients who are unresponsive to corticosteroids will respond to cyclosporine.^{59–61} Continuous intravenous infusion of cyclosporine (4 mg/kg per day) was rapidly effective in steroid-resistant acute severe ulcerative colitis and reduced the need for emergent colectomy.⁶² Intravenous cyclosporine has been recommended as an alternative to steroids in patients with severe attacks of ulcerative colitis (fulminant colitis).⁶³ Patients who are controlled on intravenous cyclosporine can then be switched to an oral cyclosporine taper regimen.

Maintenance of Remission

9 After remission from active disease is achieved, the goal of therapy is to maintain remission. The major agents used for maintenance of remission are sulfasalazine and the mesalamine derivatives; steroids do not have a role. The value of sulfasalazine in preventing recurrences has been documented in placebo-controlled trials.

One-fourth of patients taking sulfasalazine (2 g/day) had a relapse within 1 year, while three-fourths of patients taking placebo had a relapse.⁶⁴

Mesalamine preparations and olsalazine are effective for maintaining remission. A meta-analysis of trials concluded that mesalamine was more effective than placebo, but not as effective as sulfasalazine for maintaining remission.⁶⁵

CLINICAL CONTROVERSY

A major question about the use of sulfasalazine for maintenance of remission with ulcerative colitis is the duration of the preventive regimen. Maintenance of remission has been well documented up to 1 year and may last as long as 3 years. The efficacy of sulfasalazine appears to be related to the dose administered, up to a point. Although 4 g/day has a lower recurrence rate than 2 g or 1 g, a 4-g dose will result in intolerable side effects in about one-fourth of patients. Therefore 2 g/day is recommended.

Steroids do not have a role in the maintenance of remission with ulcerative colitis because they are ineffective.⁴⁸ Steroids should be gradually withdrawn after remission is induced (over 3 to 4 weeks). If they are continued, the patient will be exposed to steroid side effects without likelihood of benefits. For patients who require chronic steroid use (>20 mg/day), there is a strong justification for alternative therapies or colectomy. Azathioprine is effective in preventing relapse of ulcerative colitis for periods of up to 2 years.⁶⁶ However, 3 to 6 months may be required before beneficial effects are noted. Oral azathioprine also maintains long-term remission after IV cyclosporine induction.⁶⁷

■ CROHN'S DISEASE

Management of Crohn's disease often proves more difficult than management of ulcerative colitis, partly because of the greater complexity of presentation with Crohn's disease (Fig. 34-3). The disease may

involve any segment of the GI tract, from mouth to anus, and may involve other visceral structures and soft tissues through fistulization. There is a greater reliance on drug therapy with Crohn's disease, because resection of all involved intestine may not be possible and disease recurrence after surgery is common.

■ Active Crohn's Disease

The goal of treatment for active Crohn's disease is to achieve remission; however, in many patients, reduction of symptoms so the patient may carry out normal activities, or reduction of the steroid dose required for control, is a significant accomplishment. In the majority of patients, active Crohn's disease is treated with sulfasalazine, mesalamine derivatives, or steroids, although azathioprine, mercaptopurine, methotrexate, or metronidazole are frequently used.

The role of sulfasalazine in the treatment of active Crohn's disease is not as well established as its role in the treatment of ulcerative colitis. Sulfasalazine is more effective when Crohn's disease involves the colon.³⁶ In these circumstances, sulfasalazine is as effective as prednisone.^{36,68} A trial of sulfasalazine or an oral mesalamine derivative should be initiated in patients with mild to moderate Crohn's disease, particularly when the colon is involved.

Mesalamine products such as Pentasa or Asacol, that release mesalamine in the small bowel, are more effective than sulfasalazine for ileal involvement. In a trial of 310 patients with active Crohn's disease, Pentasa alone was more effective than placebo in achieving remission in a 16-week trial (43% vs. 18%, respectively).⁶⁹ This beneficial effect was dose dependent and greatest with a dose of 4 g/day. A course of steroids is appropriate in patients who cannot be controlled with mesalamine. However, when a patient is maintained on steroids, there appears to be no benefit from the addition of sulfasalazine.

7 Steroids are frequently used for the treatment of active Crohn's disease, particularly with more severe presentations. In the National Cooperative Crohn's Disease Study,³⁶ prednisone was more effective than placebo in achieving remission (60% remission rate after 17 weeks vs. a 30% remission rate for placebo). In this trial, the prednisone doses were 0.25 mg/kg per day for mild disease,

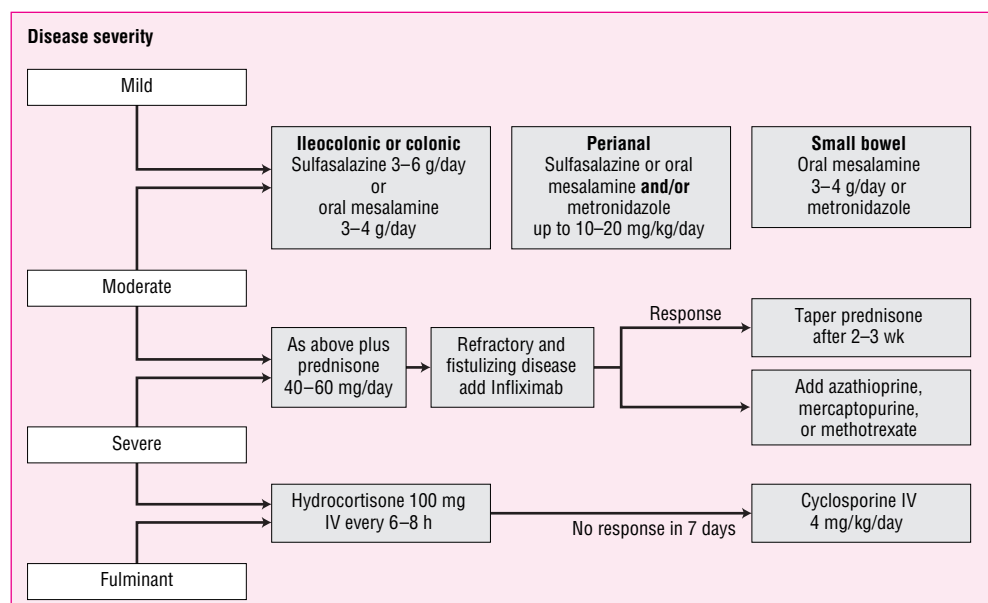

FIGURE 34-3. Treatment approaches for Crohn's disease.

0.5 mg/kg per day for moderate disease, and 0.75 mg/kg per day for severe disease. Prednisone was effective for disease limited to the small bowel. The major limitation of steroids is the risk of adverse effects with long-term use.

Steroids are preferred for treatment of severe Crohn's disease, mainly because these agents can be given parenterally and response to therapy may occur sooner than with other agents. However, once remission is achieved, it is difficult to reduce the steroid dosage without a flare of active disease.

◀10 Metronidazole (given orally up to 20 mg/kg per day in divided doses) may be useful in some patients with Crohn's disease, particularly in patients with colonic involvement, or in those patients with perineal disease.⁵⁰ For most patients, metronidazole would be added to a mesalamine product, or steroid therapy when those agents alone are not effective. The role for metronidazole is not fully defined. It may deserve a trial as adjunctive therapy for patients with colonic or perineal disease, where satisfactory control of Crohn's disease is not gained with first-line agents, or in attempts to reduce steroid dosage.⁷⁰ Ciprofloxacin has gained attention as an alternative to metronidazole and appears to be effective.⁷¹

The immunosuppressive agents (azathioprine and mercaptopurine) are generally limited to use in patients not achieving adequate response to standard medical therapy, or to reduce steroid doses when high steroid doses are required. Azathioprine and mercaptopurine demonstrated long-term benefits in patients with Crohn's disease.⁴⁷ The usual doses of azathioprine are 2 to 2.5 mg/kg per day, and for mercaptopurine 1 to 1.5 mg/kg per day. They are begun at 50 mg/day and increased at 2-week intervals while monitoring white blood cell and platelet counts. Treatment with azathioprine may need to be continued for up to 6 months to observe a response.⁴⁸ In one trial of patients already receiving sulfasalazine or prednisone, mercaptopurine decreased steroid requirement and healed fistulas. One problem noted with mercaptopurine was that more than 3 months was required to observe a response in 32% of patients. In a report of 20 years of experience with 148 patients, mercaptopurine (50 mg/day, mean 34 months) was judged effective for reduction of steroid dosage or elimination of the need for steroids, healing of fistulas and abscesses, and healing of Crohn's disease of the stomach and duodenum.⁷² Some investigators have suggested that azathioprine or mercaptopurine should be started earlier in the course of treatment than has been traditional.

Clinical response to mercaptopurine is related to whole-blood concentrations of the metabolite 6-thioguanine, and hepatotoxicity is correlated with another metabolite, 6-methylmercaptopurine.⁷³ Metabolic inactivation of azathioprine and mercaptopurine occurs by thiopurine S-methyltransferase, which exhibits genetic polymorphism. Enzyme-deficient patients are at greater risk of bone marrow suppression from these agents.^{74,75} Determination of enzyme activity may be necessary to determine which patients require lower doses of these agents.

Cyclosporine is not recommended for treatment of Crohn's disease except for patients with symptomatic and severe perianal or cutaneous fistulas.¹² Approximately 80% of patients with refractory fistulas responded to intravenous cyclosporine (4 mg/kg per day) within a mean of 7.9 days.⁷⁶ The dose of cyclosporine is important in determining efficacy. An oral dose of 5 mg/kg per day was ineffective,⁷⁷ whereas 7.9 mg/kg per day was effective.⁷⁸ However, toxic effects limit application of the higher dosage. At present, the therapeutic blood or plasma concentration range for cyclosporine has not been established for Crohn's disease, but whole-blood trough concentrations of 200 to 800 ng/mL (by monoclonal radioimmunoassay) or 200 to 400 ng/mL (by high-performance liquid chromatography) have been recommended.³ When using cyclosporine, however, clinicians should

recognize the accompanying long-term risk of renal toxicity as well as the potential for drug interactions.

Methotrexate given as a weekly injection of 5 to 25 mg has demonstrated efficacy for induction of remission in Crohn's disease as well as for maintenance therapy.^{79,80} It is also useful for corticosteroid-sparing effects.^{81,82} While there are risks of bone marrow suppression, hepatotoxicity, and pulmonary toxicity, low-dose methotrexate appears relatively safe.⁷⁹

Infliximab is approved for treating refractory or fistulizing Crohn's disease. A 5 mg/kg single infusion of infliximab resulted in clinical improvement in 80% of patients with chronic Crohn's disease who were receiving steroids.⁸³ The benefit lasted 8 to 12 weeks with reinfusion producing a sustained response. Infliximab also significantly reduced fistula drainage. Additional studies have demonstrated the effectiveness of long-term use (10 mg/kg every 8 weeks for 32 weeks).⁸⁴ Patients who receive infliximab often develop antibodies to infliximab, which can result in infusion reactions and loss of response to the drug. Administration of a second dose within 8 weeks of the first dose and concurrent administration of hydrocortisone (200 mg intravenously) significantly reduced antibody formation.^{85,86} Smoking reduces the response to infliximab, both the percentage of patients responding (73% in nonsmokers and 22% in smokers) and the duration of response.⁸⁷

■ Maintenance of Remission

◀9 Prevention of recurrence of disease is clearly more difficult with Crohn's disease than with ulcerative colitis. There is evidence that some agents, particularly sulfasalazine and oral mesalamine derivatives, are effective in preventing acute recurrences in quiescent Crohn's disease.⁸⁸ The support for sulfasalazine has been largely anecdotal;⁸⁸ however, a trial of 232 patients demonstrated a lower relapse rate compared with placebo for up to 2 years when given 3 g/day.⁸⁹

There is support for the use of oral mesalamine derivatives for maintenance of symptomatic remission. On average, oral mesalamine derivatives decrease recurrence rates by 40% as compared to placebo in long-term studies.⁷⁷ In one trial of 161 patients in remission, 2 g/day of mesalamine (Pentasa) for 2 years resulted in a significantly reduced relapse rate when begun within 3 months of achieving remission.⁹⁰ In another trial of mesalamine (Asacol), 125 patients received 2.4 g/day or placebo for 12 months, resulting in a significantly reduced relapse rate with Asacol.⁹¹ Steroids also have no place in the prevention of recurrence of Crohn's disease; these agents do not appear to alter the long-term course of the disease. However, a study of oral budesonide 6 mg/day demonstrated prolongation of time to relapse in ileal and ileocecal disease.⁹²

Azathioprine, mercaptopurine, and methotrexate are useful in some patients to maintain remission. Although the published data are inconsistent, there is evidence to suggest that azathioprine and mercaptopurine are effective in maintaining remission in Crohn's disease and are documented to increase quality-adjusted life expectancy.^{48,49,93} Low-dose methotrexate (15 mg intramuscularly once weekly) is also effective in maintaining remission.⁹⁴ These agents should be reserved for patients who cannot tolerate the dosages of steroids required to control their disease and who are not good surgical candidates.

Infliximab infusion given every 8 weeks is more effective than placebo in maintaining remission in patients who initially respond to infliximab for active Crohn's disease. It can be administered 5 or 20 mg/kg every 8 weeks.⁹⁵

SELECTED COMPLICATIONS

TOXIC MEGACOLON

The treatment required for toxic megacolon includes general supportive measures to maintain vital functions, consideration for early surgical intervention, and drugs (steroids, cyclosporine, and antimicrobials). Aggressive fluid and electrolyte management is required for dehydration. Fluids and electrolytes may be lost through vomiting, diarrhea, and nasogastric intubation, as well as through fluid accumulation in the bowel. When the patient has lost significant amounts of blood (through the rectum), blood replacement is also necessary. Opiates and anticholinergics should be discontinued because these agents enhance colonic dilatation, thereby increasing the risk of bowel perforation. Broad-spectrum antimicrobials that include coverage for gram-negative bacilli and intestinal anaerobes should be used.

Steroids in high dosages should be administered intravenously to reduce acute inflammation. Doses as high as 2 mg/kg per day of prednisone equivalent have been recommended (generally administered as hydrocortisone).⁶ The duration of steroid administration is not certain; however, most clinicians continue the high-dose steroids for up to 2 weeks after improvement is observed, and then reduce the dosage (approximately 0.5 to 1 mg/kg per day) for a few additional weeks. Antimicrobial regimens that are effective against enteric aerobes and anaerobes (e.g., an aminoglycoside with clindamycin or metronidazole, imipenem, or an extended-spectrum penicillin with β -lactamase inhibitor) should be administered from the time of diagnosis and continued until patient improvement is assured. The duration of the antimicrobial regimen (often 2 to 3 weeks) should be determined with consideration that there may be significant intra-abdominal contamination with signs and symptoms hidden by steroid effects.

Emergent surgical intervention, mainly an abdominal colectomy with formation of an ileostomy, is an important consideration in patients with toxic megacolon and prevents death in some patients. In most cases in which colectomy is performed in the face of toxic megacolon, there is a significant risk of operative complications, including postoperative infection.

SYSTEMIC MANIFESTATIONS

The common systemic manifestations of IBD include arthritis, anemia, skin manifestations such as erythema nodosum and pyoderma gangrenosum, uveitis, and liver disease. These problems may be related to the inflammatory process. For some of these manifestations specific therapies can be instituted, whereas for others the treatment that is used for the GI inflammatory process also addresses the systemic manifestations.

Anemia occurs when there is significant blood loss from the GI tract. If the patient can consume oral medication, ferrous sulfate should be administered. If the patient is unable to take oral medication and the patient's hematocrit is sufficiently low, blood transfusions or intravenous iron infusions may be required. Anemia may also be related to malabsorption of vitamin B₁₂ or folic acid, so these may also be required.

There are no consistently recommended therapies for liver disease, skin manifestations, or uveitis associated with IBD. Some reports suggest that these manifestations are worse during exacerbations of the intestinal disease and that measures improving intestinal disease will improve these systemic manifestations. Unfortunately, this association has not been demonstrated consistently. Liver transplantation

is being used more frequently for definitive treatment of primary sclerosing cholangitis. For arthritis associated with IBD, aspirin or another NSAID may be beneficial, as might be steroids.

SPECIAL CONSIDERATIONS

PREGNANCY

Either the occurrence or consideration of pregnancy may cause significant concerns in the patient with IBD. Patients with IBD do not appear to be less fertile than women in general.^{6,96} The rate of normal childbirth is similar to that for healthy populations. Some studies have noted a greater risk of spontaneous abortions in patients with IBD. Also, there is a greater incidence of low birth weight infants in mothers with chronic idiopathic ulcerative colitis.⁹⁷ Pregnancy does not affect the course of IBD. Patients who are pregnant experience recurrence rates similar to those of nonpregnant females. Also, there is no justification for therapeutic abortion with IBD because termination of the pregnancy has not been observed to improve the disease. There is also unfounded concern that the drugs required to treat IBD may be teratogenic.

Steroids and sulfasalazine should be administered during pregnancy with the same guidelines that would be applied to the nonpregnant patient.^{6,97} Steroids given systemically do not appear to be detrimental to the fetus. Sulfasalazine is generally well tolerated; however, there has been suggestion of increased frequency of congenital abnormalities when it is given during pregnancy.⁹⁸ Interestingly, sulfasalazine has also been reported to cause decreased sperm counts and reduced fertility in males.⁹⁹ This effect is reversible on discontinuation of the drug, and it is not reported with mesalamine. Immunosuppressive drugs (azathioprine and mercaptopurine) may be associated with fetal deformities in humans; however, they have been used without detriment in some patients.⁹⁶ Metronidazole should not be used in those contemplating pregnancy, as it may be teratogenic.

Overall, drug therapy for IBD is not a contraindication for pregnancy, and most pregnancies are well managed in patients with these diseases. The indications for medical and surgical treatment are similar to those in the nonpregnant patient. If a patient has an initial bout of IBD during pregnancy, a standard approach to treatment should be initiated.

Recommendations for the use of drugs in nursing mothers vary. Although prednisone and prednisolone can be detected in breast milk, breast-feeding is believed to be safe for the infant when low doses of prednisone are used.¹⁰⁰ Sulfasalazine does not pose a risk of kernicterus, as levels of sulfapyridine in breast milk are low or undetectable. Metronidazole should not be given to nursing mothers because it is excreted into breast milk.¹⁰⁰

ADVERSE DRUG EFFECTS

Drug intolerance often limits the usefulness of agents used to treat IBD. Many patients receiving sulfasalazine, mesalamine, corticosteroids, metronidazole, azathioprine, mercaptopurine, or infliximab experience some undesired effects. In some cases, these adverse effects can be significant and require discontinuation of the therapy. Knowledge of the common or important adverse reactions will assist in avoiding or minimizing their effects.

Sulfasalazine is often associated with adverse drug effects and these effects may be classified as either dose related or idiosyncratic. Dose-related side effects usually include GI disturbances such as nausea, vomiting, diarrhea, or anorexia, but may also include headache

and arthralgia. These adverse reactions tend to occur more commonly on initiation of therapy and decrease in frequency as therapy is continued. Patients may experience these adverse effects at the commonly used dosages. One approach to the management of these reactions is to discontinue the agent for a short period and then reinstitute therapy at a reduced dosage. The sulfapyridine portion of the sulfasalazine molecule is believed to be responsible for much of the sulfasalazine toxicity.¹⁰¹ Folic acid absorption is impaired by sulfasalazine, which may lead to anemia. Patients receiving sulfasalazine should receive oral folic acid supplementation.

Adverse effects that are not dose related most commonly include rash, fever, or hepatotoxicity, as well as relatively uncommon but serious reactions such as bone marrow suppression, thrombocytopenia, pancreatitis, and hepatitis. For most patients with idiosyncratic reactions, sulfasalazine must be discontinued. In some patients who have experienced allergic reactions to sulfasalazine, a desensitization procedure can be instituted. By gradually increasing sulfasalazine dosage over weeks to months, patient tolerance has been improved.¹⁰² Most of the idiosyncratic reactions observed with sulfasalazine are similar to those with the class of sulfonamides in general.

Oral mesalamine derivatives may impose a lower frequency of adverse effects as compared to sulfasalazine.⁵² Up to 80% to 90% of patients who are intolerant to sulfasalazine will tolerate oral mesalamine derivatives.¹⁰¹ Olsalazine, however, may frequently (in as many as 25% of patients) cause watery diarrhea, sometimes requiring drug discontinuation.¹⁰³

Adverse reactions to corticosteroids are well recognized and may occur when corticosteroids are used for any indication. However, there is a greater potential for adverse effects when corticosteroids are used for the treatment of IBD because high doses must often be used for extended periods. In the National Cooperative Crohn's Disease Study, half of patients receiving high-dose steroid therapy experienced side effects, as did one-third of the patients on the lower-dose regimens for maintenance.³⁶ The well-appreciated adverse effects of corticosteroids include hyperglycemia, hypertension, osteoporosis, acne, fluid retention, electrolyte disturbances, myopathies, muscle wasting, increased appetite, psychosis, and reduced resistance to infection. In addition, corticosteroid use may cause adrenocortical suppression. To minimize corticosteroid effects, clinicians have used alternate-day steroid therapy; however, some patients do not do well on the days when no steroid is given. For most patients a single daily corticosteroid dose suffices, and divided daily doses are unnecessary. Another problem with corticosteroids is adrenal insufficiency after abrupt steroid withdrawal. Patients sometimes discontinue prescribed medications when they feel better.

Immunosuppressants such as azathioprine and mercaptopurine have a significant potential for adverse reactions. Azathioprine causes bone marrow suppression and has been associated with lymphomas (in renal transplant patients), skin cancer, and pancreatitis (about 3% of patients). Some investigators believe that induction of leukopenia may be necessary for therapeutic effect.^{104,105} Mercaptopurine causes adverse reactions similarly to azathioprine; however, there are fewer reports of lymphomas with this agent. In one cohort of IBD patients, adverse effects from mercaptopurine were as follows: pancreatitis, 1.2%; allergic reactions, 3.9%; significant leukopenia, 11.5%; and infectious complications, 14%.¹⁰⁶ Ten percent of patients who received azathioprine or mercaptopurine required discontinuation of treatment because of adverse effects.¹⁰⁷ Allopurinol inhibits the metabolism of mercaptopurine, and a dosage reduction of the latter is required when the two are used in combination.

Myelosuppression resulting in leukopenia from azathioprine and mercaptopurine is related to a deficiency of thiopurine S-

methyltransferase (TPMT) due to excessive accumulation of toxic metabolites.¹⁰⁸ Approximately 0.1% of people are homozygous for a nonfunctional TPMT gene, which causes TPMT deficiency. These patients have a much greater risk of toxicity, and should not receive either drug. Heterozygous patients have an increased risk of toxicity and may receive either drug with careful monitoring of white blood cell counts.

Most patients receiving metronidazole for Crohn's disease tolerate the agent fairly well; however, mild adverse effects occur frequently. They commonly include paresthesias and reversible peripheral neuropathy, metallic taste, urticaria, and glossitis.⁵¹ Other effects include a disulfiram-like reaction if alcohol is ingested in conjunction.

Infliximab has been related to adverse effects such as infusion reactions, serum sickness, sepsis, and reactivation of tuberculosis. Infusion reactions and serum sickness relate to the immune response to foreign protein. Patients often develop anti-infliximab antibodies with multiple infusions. Serum sickness has occurred in patients who received infliximab doses separated by a long period of time. Sepsis and tuberculosis may occur because of the inhibition of TNF-protective mechanisms.

EVALUATION OF THERAPEUTIC OUTCOMES

The success of therapeutic regimens to treat IBD can be measured by patient-reported complaints, signs, and symptoms; by direct physician examination (including endoscopy); by history and physical examination; by selected laboratory tests; and by quality-of-life measures. Evaluation of IBD severity is difficult because much of the assessment is subjective. To create more objective measures, disease rating scales or indices have been created. The Crohn's Disease Activity Index is a commonly used scale, particularly for evaluation of patients during clinical trials.¹⁰⁹ The scale incorporates eight elements: (1) number of stools in the past 7 days; (2) sum of abdominal pain ratings from the past 7 days; (3) rating of general well-being in the past 7 days; (4) use of antidiarrheals; (5) body weight; (6) hematocrit; (7) finding of abdominal mass; and (8) a sum of symptoms present in the past week. Elements of this index provide a guide for those measures that may be useful in assessing the effectiveness of treatment regimens.

Standardized assessment tools have also been constructed for ulcerative colitis.¹¹⁰ Elements in these scales include (1) stool frequency; (2) presence of blood in the stool; (3) mucosal appearance (from endoscopy); and (4) physician's global assessment based on physical examination, endoscopy, and laboratory data.

Additional studies that are often useful include direct endoscopic examination of affected areas and/or radiocontrast studies. For patients with acute disease, assessment of fluid and electrolyte status is important, because these may be lost during diarrheal episodes. Other laboratory tests, such as serum albumin, transferrin, or other markers of visceral protein status, as well as markers of inflammation (erythrocyte sedimentation rate) may be used.

Assessment of the IBD patient must include consideration of adverse drug effects. Because many of the agents used have a relatively high probability of causing adverse effects, particularly corticosteroids and other immunosuppressive agents, patient assessment should include collection of history and physical and laboratory data that are necessary to prevent or recognize adverse drug effects.

Finally, a patient quality-of-life assessment should be performed regularly.¹¹¹ Agents that appear clinically equivalent may differ substantially in resulting quality of life. Inquiry should be made regarding general well-being, emotional function, and social function. Social function may include assessment of the ability to perform routine

daily functions, maintain occupational activities, sexual function, and recreation.

Quality-of-life studies have been conducted with infliximab. To balance the exceptionally high cost of this therapy, Crohn's disease patients who receive infliximab have improved quality of life, fewer emergency room visits, a reduced requirement for surgery, and are more likely to be employed.^{112,113}

ABBREVIATIONS

ESR: erythrocyte sedimentation rate
 IBD: inflammatory bowel disease
 NSAID: nonsteroidal anti-inflammatory drug
 TPMT: thiopurine S-methyltransferase
 TNF- α : tumor necrosis factor-alpha
